HANDBOOK OF SMALL ANIMAL PRACTICE, ISBN: 978-1-4160-3949-5
Fifth Edition

Library of Congress Control Number 2007925903

Vice President and Publisher: Linda Duncan
Publisher: Penny Rudolph
Developmental Editor: Shelly Stringer
Publishing Services Manager: Patricia Tannian
Project Manager: Jonathan M. Taylor
Designer: Amy Buxton

Printed in the United States of America

Last digit is the print number: 9 8 7 6 5 4 3 2 1

The fifth edition of the *Handbook of Small Animal Practice* is dedicated to

Scamp (1976-1990)
Corky (1991-2006)
Duma (1991-2007)

During the first 30 years of my career and the preparation of all five editions of the *Handbook of Small Animal Practice*, these three Pembroke Welsh corgis were my constant companions. They spent innumerable hours resting at my feet as I labored to edit the books and also frequently prompted me to take well-timed breaks for walks and other adventures. These intelligent, enthusiastic, and entertaining friends greatly enriched my life and continuously reminded me of how fortunate we are to share the world with animals.

Section Editors

SECTION **2** Cardiovascular System
Kristin MacDonald, DVM, PhD, DACVIM

SECTION **3** Respiratory System
J. David Fowler, DVM, MVSc, DACVS

SECTION **4** Neurologic System
Marc Kent, DVM, DACVIM

SECTION **5** Digestive System
Lisa E. Moore, DVM, DACVIM

SECTION **6** Endocrine and Metabolic System
Rita H. Miller, DVM, MS, DACVIM

SECTION **7** Urinary System
Cathy E. Langston, DVM, DACVIM

SECTION **8** Reproductive System
Ronald M. Bright, DVM, MS, DACVS

SECTION **9** Hemolymphatic System
A. Eric Schultze, DVM, PhD, DACVP

SECTION **11** Musculoskeletal System
Nicholas J. Trout, MA, VetMB, MRCVS, DACVS, DECVS

SECTION **12** Dermatologic System
Rosanna Marsella, DVM, DACVD

SECTION **13** Diseases of the Eye
Rachel D. Ring, DVM, DACVO

SECTION **14** Diseases of the Ear
Lynette K. Cole, DVM, MS, DACVD

SECTION **15** Infectious Diseases
Lynn Guptill, DVM, PhD, DACVIM

SECTION **18** Toxicology
Petra A. Volmer, DVM, MS, DABVT, DABT

SECTION **19** Environmental Injuries
Marie E. Kerl, DVM, DACVIM, DACVECC

Preface

Welcome to the fifth edition of the *Handbook of Small Animal Practice.* For those of you unfamiliar with *HSAP,* you will notice it is written entirely in an outline format. Every effort has been made to keep standardized prose to a minimum. This format provides the busy practitioner with the latest, most applicable information on a subject in a concise and easily retrievable manner.

Whenever applicable, each subject is explored under the headings of *Definition, Causes, Pathophysiology, Clinical Signs, Diagnosis, Differential Diagnosis, Treatment,* and *Monitoring of the Animal.* The book consists of nineteen different sections and four appendices. Many sections are subdivided into chapters based on the anatomic components of that body system. In turn, each chapter is organized in a chronological fashion, beginning with congenital and developmental disorders and followed by degenerative, infectious, inflammatory, idiopathic, parasitic, metabolic/toxic, immune-mediated, vascular, nutritional, neoplastic, and traumatic diseases. This chronology is maintained wherever possible so the reader can predict and find the location of a given subject within a chapter.

Although the goals, aspirations, organization, and format of the fifth edition remain similar to previous editions, the following noteworthy changes were made in this edition:

- The first chapter of the book now addresses preoperative evaluation and anesthetic protocols.
- The Cardiovascular, Neurologic, Digestive, Urinary, Musculoskeletal, Dermatologic, Behavioral Disorders, Nutrition, Toxicology, and Environmental Injuries sections were written primarily by new authors.
- Some large chapters were split into two separate chapters so the authors could be more thorough in addressing their respective subjects.
- The Dermatologic System section was reorganized using a problem-based approach. Readers are encouraged to use the index to help locate certain diseases within this section.
- The Toxicology section was also reorganized to better reflect the most common toxicants now encountered in small animal practice.
- The Drug Appendix was extensively revised and updated.

I am deeply indebted to the section editors who helped on this project and to all the contributors who provided up-to-date, concise information in their respective chapters. A special "thank you" is due Leah Ann Crussell for her work in producing the drug appendix. Compilation of the drug dosages from all 136 chapters is an enormous and tedious task, and Leah Ann did a great job.

I would also like to recognize the talented crew at Elsevier who helped me manage and produce this text, especially Ms. Shelly Stringer, Ms. Stacy Beane, and Mr. Jonathan Taylor. It takes tremendous coordination to complete a project of this size on time and to do it well. The Elsevier team was supportive, responsive, detail-oriented, and great to work with.

Although it might seem a bit crazy to spend almost three decades working on such monolithic projects as the five editions of *HSAP*, the process has been a rewarding experience. Working with so many expert authors on each edition has taught me many things, not the least of which is how lucky our profession is to attract so many dedicated and gifted people.

As always, I hope this edition will continue to be a useful *and* often-used guide for all the veterinarians who strive each day to make ill and injured animals well and whole again.

Rhea V. Morgan, DVM

CHAPTER 1

Preoperative Evaluation and Anesthetic Protocols

Andrea L. Looney

PREOPERATIVE EVALUATION

Identify Proper Signalment

I. Age
   A. Age is not a disease, but often affects many body system functions and reserves.
   B. Cardiac output depends on heart rate in neonatal and pediatric animals; therefore anticholinergic agents are often recommended for premedication (Pascoe and Moon, 2001).
   C. Geriatric animals often have reduced cardiac output and baroreceptor activity, reduced chest compliance, and decreased hepatic and renal function (Carpenter et al., 2005).

II. Reproductive status
   A. In the case of an intact female, has the owner observed any recent estrous cycle? Is pregnancy a possibility?
   B. Many anesthetic drugs have teratogenic or abortigenic effects if administered in early pregnancy (Papich, 1989).

III. Breed
   A. Beware of breed misconceptions and breed-related myths (Wagner et al., 2003; Cuvelliez and Rondenay, 2002).
      1. Many large-breed dogs are not sensitive to certain agents, but are more accurately dosed based on body surface area (vs weight).
      2. Many Persian cats may not metabolize ketamine as readily as other breeds (Shamir et al., 2004).
      3. Idiosyncratic hepatic disease has been reported in Labrador retrievers on carprofen; however, many Labradors and Labrador-mix dogs utilize this drug without hepatic problems (MacPhail et al., 1998).
   B. Anesthetic problems may be more common in certain breeds because of common congenital or hereditary issues.
      1. Standard poodles have a higher incidence of Addison's disease (Famula et al., 2003), and Addisonian crises may be precipitated by certain preanesthetic and anesthetic agents (e.g., acepromazine, medetomidine, isoflurane, sevoflurane).
      2. Brachycephalic dogs and cats are more likely to have respiratory difficulties during induction and recovery.
      3. Afghan hounds have a higher incidence of subclinical pulmonary disease (Neath et al., 2000), which may become clinical during positive pressure ventilation.
      4. Greyhounds may metabolize many drugs, including propofol, less effectively than other breeds, even other sighthounds.
      5. Greyhounds also have more perioperative coagulopathies than other breeds (Feeman, 2005; Robertson et al.; 1992; Cuoto, 2006).

Identify the Chief Complaint

I. Determine if the animal is stable for the intended procedure.
II. The first goal of the anesthetist is to devise an accurate and objective preanesthetic problem list.

TABLE 1-1

Blood Flow, Oxygen Consumption, and Cardiac Output That Organs Receive in a Resting Individual

ORGAN	BLOOD FLOW (mL/100g/min)	OXYGEN CONSUMPTION (mL/100g/min)	CARDIAC OUTPUT (%)
Liver	57	2	28
Kidneys	420	6	23
Brain	54	3.3	14
Heart	84	9.7	5
Muscle	2.7	0.2	16
Skin	13	0.3	8

A. Blood flow, cardiac output, and oxygen consumption determine which organ systems need to be addressed first on the problem list (Table 1-1).
   1. Based on the high blood flows and oxygen consumptions of both the kidneys and the heart, it is predictable that these organs would suffer most with even a mild to modest decrease in cardiac output, such as occurs with heavy sedation, general anesthesia, or both.
   2. Because the kidney also receives a high percentage of cardiac output, it is likely to have the most severe perfusion consequences of any organ system from reduced cardiac output.
   3. Hence, stabilize animals with renal or cardiac disease before heavy sedation and anesthesia, or postpone anesthesia until adequate function of both systems is ascertained.

B. Stabilize animals with renal and heart disease through appropriate medical therapy before deep sedation and general anesthesia.
   1. Renal disease: pressor therapy with fluid therapy
   2. Heart disease: pressor therapy and fluid restriction

C. Renal failure and heart failure are contraindications to general anesthesia.

D. Renal insufficiency and heart disease are not contraindications, but caution is indicated.
   1. Function of these organs must be optimal before initiation of general anesthesia.
   2. Warn owners of the increased chance of decompensation.
   3. Use drugs that aim to maintain cardiac output and improve perfusion and oxygenation (dopamine, ketamine infusions).
   4. Monitor blood pressure and treat abnormalities aggressively.

Review Medical History

I. Establishing a thorough checklist that is reviewed by the clinician for each animal is a key to success.

II. Medical clearance for anesthesia is defined as evaluation of the animal's current health against the history of prior illness and treatment, both of which help to predict reserve and outcome.

III. Recent travel to different geographical areas may predispose to certain diseases (vector transmitted, fungal disease) that worsen gastrointestinal (GI) (dogs) and respiratory diseases (many species).

IV. Determine and record history of vaccination, infectious diseases, parasite control, and heartworm status.
   A. Avoid nonspecific ("up-to-date") terminology to avoid medical errors.
   B. Establish the following:
      1. Is the animal protected within the hospital?
      2. Are other animals at risk from this pet entering the hospital?
      3. Are hospital staff members at risk from zoonotic diseases?
   C. Recommendations for reduced frequency and individualization of vaccinations may necessitate measurement of titers and flexible regulations concerning vaccination status before a procedure (Moore and Glickman, 2004).
   D. Heartworm disease is not a contraindication to anesthesia, but cardiac and pulmonary changes affect oxygenation and perfusion of other organ systems (see Table 1-1).

V. Elucidate any previous illnesses, procedures, surgeries, or anesthetic events.
   A. Prior masticatory myositis may preclude routine orotracheal intubation.
   B. Prior lumbosacral trauma may impact routine epidural placement.
   C. Repeated endotracheal intubation in smaller animals, especially cats, can predispose to tracheitis, tracheal rupture, or stenosis (Mitchell et al., 2000).
   D. Platelet aggregation abnormalities or thrombocytopenias may be aggravated by acepromazine, which can inhibit platelet adhesion and function (Barr et al., 1992).

VI. Record known or suspected allergies or adverse reactions to medications, foods, or nutritional supplements.
   A. Propofol contains egg phosphatide and soybean oil, and some formulations also contain sulfite stabilizers.
      1. Multiple reports of human anaphylactoid reactions have occurred with the use of propofol (Nishiyama and Hanaoka, 2001; Marik, 2004).
      2. Although no reports of anaphylaxis exist in animals, avoid use of propofol in animals with known (intradermal or serologic) allergies to eggs, soybeans, or sulfites.
   B. Morphine and meperidine readily cause histamine release, so dogs and cats with histamine-related fleabite dermatitis, endoparasitism, and allergic lung disease may experience severe hypotension and tachyphylaxis with these drugs.

Pursue Other Pertinent Questions

I. Environment and temperament
   A. Nordic breeds and working dogs (especially intact males) used for outdoor activity may experience hyperthermia with routine heat supplementation used during general anesthesia.
   B. Stressed animals are often difficult to sedate or anesthetize with any agent because of extreme neurohormonal fluctuation. The inability of acepromazine to work effectively in very anxious animals (also known as *epinephrine reversal of acepromazine*) epitomizes this phenomenon (Benson et al., 2000).

II. Current and recent medications
   A. Insecticides or insecticide-laden collars, powders, and sprays often contain anticholinesterases (organophosphates, carbamates), and some (amitraz) may potentiate the effects of anesthetics (Mealey and Matthews, 1999).
   B. Determine concurrent administration of over-the-counter medications, especially aspirin, antihistamines, or acetaminophen.

1. Washout periods are usually required for animals on aspirin therapy to avoid microvasculature platelet-related bleeding and to allow use of perioperative injectable nonsteroidal antiinflammatory drugs (NSAIDs) and corticosteroids (Lascelles et al., 2005).
2. Antihistamines have anticholinergic effects that may preclude the use of atropine or glycopyrrolate.

C. Glucosamine and chondroitin are synthetic heparinoids that may contribute to coagulopathies in animals undergoing anesthesia or surgical procedures (Goodman and Trepanier, 2005).
D. Topical flea and tick medications applied by an owner may inadvertently be carried through the epidermis with perioperative subcutaneous or IM injections and may cause deep, irritant chemical dermatopathies (Ackermann, 2005).
E. Herbal or homeopathic supplements may interact with perioperative medications.
   1. Ginkgo, garlic, ginger, and ginseng inhibit platelet aggregation (Glintborg et al., 2005).
   2. Herbs that contain salicylate, such as meadowsweet and willow, may also exacerbate the adverse effects of aspirin and other NSAIDs (Rubin, 2005).
F. Behavioral modification drugs, such as monoamine oxidase inhibitors, specific seratonin reuptake inhibitors, and tricyclic antidepressants, have caused pyrexia, hyperthermia, and even fatalities in humans treated with certain premedicants (morphine, ketamine) and general anesthetics (Mealey and Matthews, 1999).
G. Topical atropine commonly used in treating ophthalmic diseases can be absorbed systemically thereby precluding use of further anticholinergics and contributing to increased myocardial work and oxygen consumption.
H. Oral carbonic anhydrase inhibitors predispose to metabolic acidosis.
I. Prednisone use has certain effects.
   1. Catabolic state induced by chronic use is likely to weaken myocardial and respiratory musculature.
   2. Immunosuppression and weakened vasculature can predispose to skin infections near sites of venipuncture and regional nerve blocks.
J. Anticonvulsant usage must be determined.
   1. Phenobarbital is a potent enzyme inducer and may lead to rapid metabolism of other barbiturates.
   2. Liver enlargement caused by anticonvulsants may add to respiratory difficulties from compression of the diaphragm.
K. Many antibiotics given perioperatively reduce blood pressure intraoperatively (ampicillin, penicillin, cefazolin).
L. Some antibiotics (neomycin, vancomycin, amikacin) may act as neuromuscular blockers owing to acetylcholine inhibition.
M. Concurrent cardiac medications require attention.
   1. Angiotensin-converting enzyme inhibitors may predispose to hypotension.
   2. Beta blockers may reduce cardiac output and add to intraoperative or perioperative bronchospasm.

III. Recent illnesses

TABLE 1-2

Normal Physiologic Values for Conscious Small Animals Breathing Room Air

PHYSIOLOGIC PARAMETER	CANINE VALUES	FELINE VALUES
Temperature (° F)		
	99.5-102.5	100-102.5
Pulse Rate (beats per minute)		
Small (toy) breeds	120-160	120-200
Medium breeds	80-140	
Giant (large) breeds	60-100	100-150
Respiratory rate (breaths per minute)		
	10-35	10-50
Blood pressure (mm Hg)		
Systolic	120-150	150-170
Diastolic	70-90	90-120
Mean	100-120	110-140
Pulse oximetry (%)		
	93-95	93-95

Modified from Muir WW III, Hubbell JAE, Skarda RT: Handbook of Veterinary Anesthesia. Mosby, St. Louis, 2000.

A. Animals suffering from recent illness may be at increased anesthetic risk.
B. If possible, delay procedures until dehydration, fever, altered acid-base status, and abnormal electrolytes are corrected.

Perform a Thorough Physical Examination

I. Obtain weight and vital signs (Table 1-2) as soon as the animal enters the hospital to avoid stress-induced changes.
II. Body condition score is also noted (Figure 1-1).
   A. Obesity can cause multiple problems.
      1. Fat stores act as a depot of nonmetabolizing tissue that tends to release anesthetic agents back into the circulation slowly throughout the intraoperative or perianesthetic periods.
      2. Obese animals have decreased ventilatory capacity.
      3. Increased cardiac stroke work results in ventricular insufficiency and decreased myocardial perfusion.
      4. Drug dosages are calculated based on ideal body weight (Grimm, 2002).
   B. Excessive thinness may indicate underlying subclinical diseases, such as renal failure, heart disease, or chronic parasitism.
   C. Animals with little body fat are prone to hypothermia and heating pad injuries and may be unusually sensitive to highly fat-soluble drugs.
III. Pain and anxiety scoring can be performed with use of a relatively simple subjective scale and, ideally, is an average of the owner's and an impartial observer's (technician's) subjective rating (Figure 1-2).

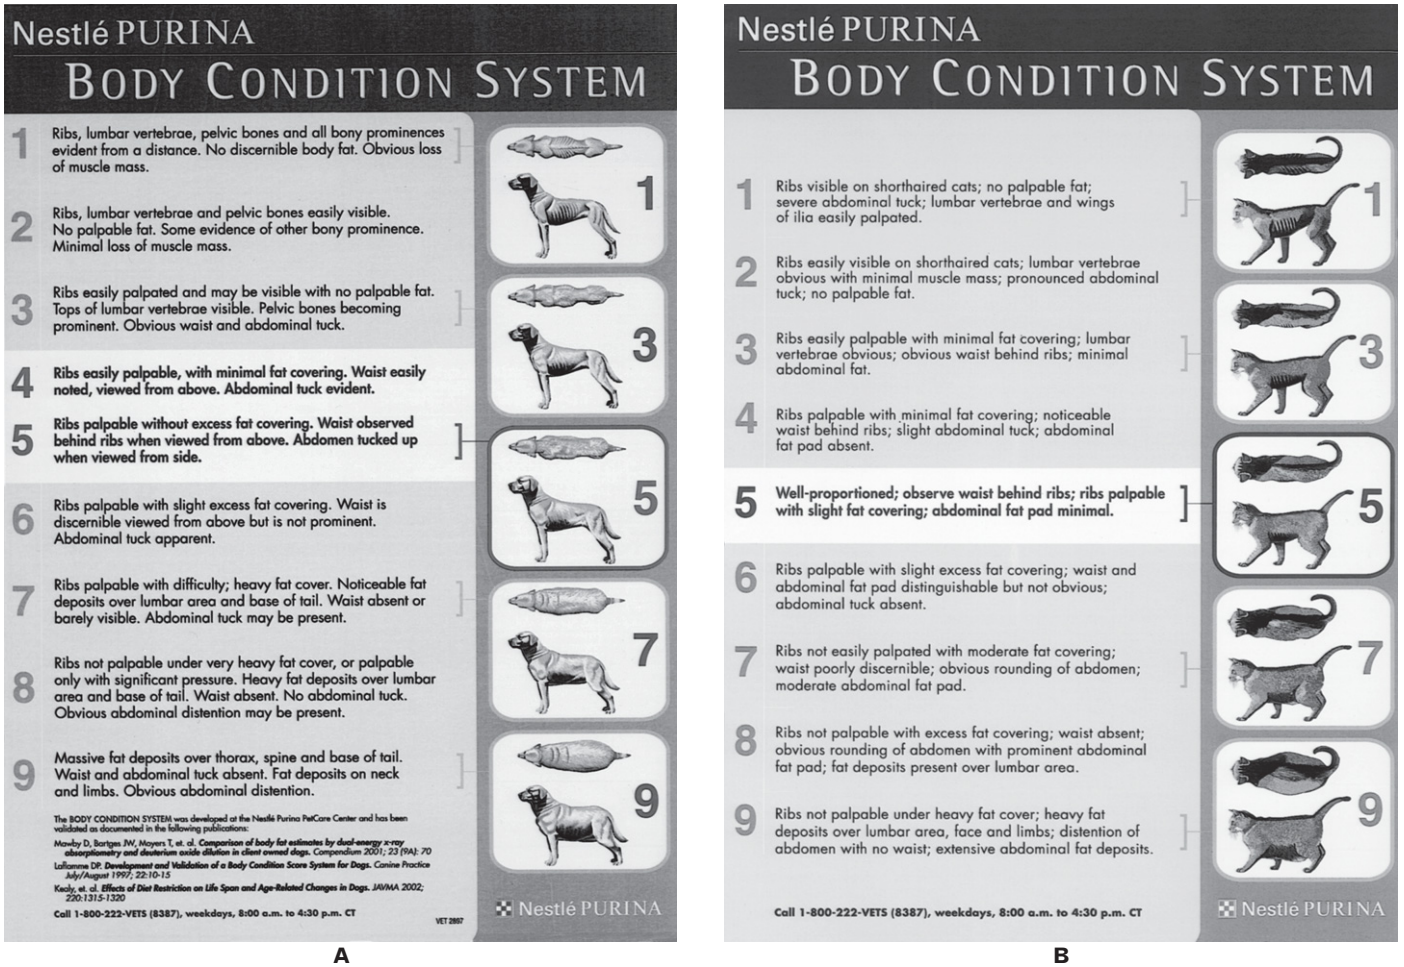

FIGURE 1-1 **A,** Body condition scoring system used in the dog. **B,** Body condition scoring system used in the cat. *From Laflamme DP, Kealy RD, Schmidt DA: Estimation of body fat by body condition score. J Vet Intern Med 8:154, 1994; with permission.*

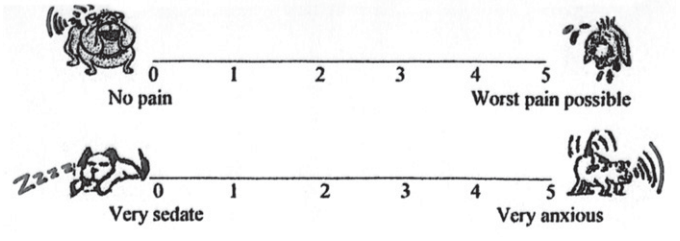

FIGURE 1-2 Simple pain and anxiety scales used in small animal medicine and surgery. The owner is asked to identify a point on each line. An impartial observer (technician or veterinarian) is also asked to identify a point on each line. Scores are then averaged and the final pain and anxiety scores are noted in the pet's record. *Courtesy P. Wantuch, with permission.*

IV. Preoperative blood pressure and pulse oximeter readings are obtained when warranted (e.g., presence of cardiac, renal, pulmonary diseases).
V. Ideally the preanesthetic examination includes determination of hydration status and examination of the oral cavity and pharynx.
VI. Examination of range of motion of the temporomandibular joint and documentation of cephalic conformation are useful in brachycephalic breeds or animals with neoplastic or inflammatory myositis.
VII. Auscultation of heart and lungs, palpation of pulses in several areas, abdominal palpation for the presence of fluid or a space-occupying mass, and assessment of neurologic and musculoskeletal systems are performed.

Classify Anesthetic Risk

I. The most widely accepted classification system for anesthesia risk is the American Society of Anesthesiologists (ASA) categorization (Hosgood and School, 2002; McKelvey and Hollingshead, 2000) (Table 1-3).
II. Inform owners of any increased risk and add an "E" status for emergency anesthesia.

Obtain Minimum Data Base

I. No universal guidelines for preanesthetic diagnostic tests exist.
II. In all but elective surgeries on young (<1 to 1.5 years), healthy animals, perform quick assessment tests (QATs).
III. Ideally, packed cell volume (PCV), albumin, total white blood cell (WBC) count, creatinine, serum alanine transferase, and urine specific gravity are measured to help

TABLE 1-3

Classification of Physical Status and Anesthesia Risk

CATEGORY—ASSOCIATED RISK	PHYSICAL CONDITION	CASE EXAMPLES
Class I—minimal risk	Normal, healthy animal No underlying disease	Ovariohysterectomy Castration Declawing Sedation for radiography, ear examination, nail trim
Class II—mild risk	Animal with slight to mild systemic disturbance Animal that is able to compensate without intervention	Neonatal or geriatric animals Mild obesity Skin mass removal Uncomplicated hernias Cystotomy Abscesses or minor wound debridement
Class III—moderate risk	Animal with moderate systemic disturbance Animal unable to compensate and showing clinical signs	Anemia Dehydration Low-grade fever Mild heart or pulmonary disease Renal insufficiency Controlled endocrinopathy
Class IV—high risk	Animal significantly and systemically ill with major organ compromise or failure	Severe dehydration Shock High fever Uremia Moderate heart or pulmonary disease Renal failure Trauma Uncontrolled endocrinopathy
Class V—grave risk	Animal moribund or comatose	Animal not expected to survive >24 hours, with or without surgery Advanced cases of multiple organ failure Major trauma Terminal neoplasia Shock Terminal endocrine disease

Modified from McKelvey D, Hollingshead KW: Small Animal Anesthesia and Analgesia. 2nd Ed. Mosby, St. Louis, 2000.

prioritize choice of drugs, monitoring, IV fluid types, and volumes.

A. Animals with albumin <2.0 mg/dL often require colloidal infusions perioperatively and use of low protein-binding, reversible preanesthetic and anesthetic agents, such as midazolam, fentanyl, thiopental, and etomidate.
B. Animals with low specific gravity and mildly elevated creatinine may require measures to preserve blood pressure.
   1. Benzodiazepines might replace acepromazine as premedication.
   2. Periods of hypotension are aggressively treated with fluid volume expansion (5 to 10 mL/kg crystalloid IV infusion over 5 to 10 minutes) and vasopressor therapy (dopamine 3 to 5 µg/kg/min IV).
   3. Animals with low PCVs (<20% to 24%, depending on acute or chronic state) may be transfused before removal or biopsy of a vascular organ, such as the spleen or kidney.
   4. Hyperkalemic (>6.0 to 6.5 mEq/L) animals require treatment before induction of general anesthesia to avoid cardiac disturbances (see Chapter 48).

IV. Additional testing (coagulation profile, electrolyte determination, blood gases, lactate levels, electrocardiography, and thoracic or abdominal radiographs) is performed based on body system abnormalities identified on physical examination.

SELECTION OF ANESTHETIC PROTOCOLS

Safe and Effective Sedation/Anesthesia

I. Stabilize the animal according to the triaged problem list before administering anesthesia.

II. The goal of anesthesia is to maintain, if not improve, oxygenation, perfusion, and waste removal of all tissues during a procedure.
III. The basic protocol followed for anesthesia of most animals is outlined below:
  A. Premedication is delivered either IM or IV, and consists of the following:
    1. A sedative or anxiolytic drug, such as a phenothiazine or benzodiazepine
    2. An analgesic drug, usually an opioid, alpha-2, agent, or both
    3. An anticholinergic drug, such as glycopyrrolate, if needed
      a. Glycopyrrolate is used in ophthalmic procedures, animals with GI disease, central nervous system (CNS) space-occupying lesions, and cervical or laryngeal diseases.
      b. Glycopyrrolate is not used in animals with cardiac disease, hyperthyroidism, pancreatic disease, overt nervousness or anxiety, or shock.
      c. Atropine is no longer used for routine premedication owing to its ability to induce potent tachycardias, potentiation of CNS disorders, and because of its profound potential for ileus.
  B. An induction agent is usually delivered IV.
    1. The induction agents may be delivered with premedications in protocols for elective surgery (e.g., ketamine, butorphanol, and medetomidine combined and delivered together IM).
    2. Common choices of induction agents include ketamine, ketamine/benzodiazepine combinations, thiopental, opioid/benzodiazepine combinations, propofol, and etomidate.
  C. A maintenance agent, usually isoflurane or sevoflurane, is typically delivered in oxygen or oxygen-nitrous oxide mixtures via agent-specific vaporizers.
  D. Local or regional nerve blockade is usually administered after induction.
  E. Nonsteroidal antiinflammatory agents are administered preoperatively, intraoperatively, or postoperatively.
  F. Infusions of certain agents (morphine, fentanyl, lidocaine, or ketamine) can be given pre-, intra-, or postoperatively to reduce administration of more potent induction and inhalant agents, aid in anxiolysis, promote muscle relaxation, and provide analgesia.
  G. Suggested doses of agents are listed in Table 1-4.

Drug Options for Problem Cases

I. Animals with pulmonary or thoracic diseases
  A. Intrathoracic effusion and/or accumulation of air are removed before inhalant administration.
  B. Arterial blood gases help to determine severity of respiratory dysfunction.
  C. Preoxygenation is essential to reduce hypoxemia of induction agent administration.
  D. Sedation usually improves oxygenation, but may worsen hypercarbia.
  E. Low-dose anticholinergics and ketamine are useful for bronchodilation.
  F. Pure mu agonists, such as hydromorphone and fentanyl, may cause marked respiratory depression.
    1. Their use is warranted for prevention and treatment of pain.
    2. Monitoring via capnography and pulse oximetry is recommended.
    3. Mechanical ventilation may be necessary with end-tidal carbon dioxide >50 mm Hg.
  G. Ventilation with high frequencies and low tidal volumes is useful in the presence of intrathoracic or large pulmonary mass lesions.
  H. Local or regional nerve blockade (intercostal, intrapleural, or epidural analgesia) is *highly recommended* to provide excellent comfort and avoid systemic opioid side effects.
II. Animals with upper respiratory disorders
  A. Minimize stress to improve oxygenation and decrease anxiety of dyspnea.
    1. Acepromazine relieves stress and improves blood flow.
    2. The combination of low-dose medetomidine coupled with mild opioids (butorphanol or buprenorphine) relieves anxiety, provides analgesia, is antitussive, and is reversible.
  B. Anticholinergics are usually necessary to combat increased vagal tone, but avoid high doses and repeat dosing.
    1. Bronchodilation potentially increases negative inspiratory pressure further.
    2. Increased viscosity of secretions worsens main airway obstruction.
  C. Preoxygenation is important but can be of limited help if obstruction (laryngeal paralysis, nasopharyngeal polyp) is severe.
    1. Masks must not be used in cases of upper airway obstruction unless the animal tolerates them.
    2. Masks worsen stress, hypoxia, and hypercapnia.
    3. Flow-by oxygenation is suggested instead.
      a. The end of rebreathing circuits held to an animal's nares or mouth.
      b. Oxygen line directly from an oxygen flowmeter is held similarly.
      c. Oxygen line is directed into an Elizabethan collar "chamber."
      d. Oxygen can be delivered via an oxygen cage.
  D. Assorted tracheal tubes (smaller than expected), suction apparatus, and tracheostomy kits are made readily available *before* induction.
  E. Ketamine and benzodiazepine combinations, as well as carefully titrated propofol, are suitable induction agents.
  F. In most cases, postoperative extubation is delayed as long as possible for animals with nasal disease.
  G. Ironically, many animals with pharyngeal or laryngeal inflammatory disease oxygenate better if extubated earlier, as long as attention is paid to their potential for aspiration.
III. Animals with cardiovascular instability

TABLE 1-4

Preanesthetic and Anesthetic Agents with Suggested Dose Ranges

DRUGS	CANINE DOSE	FELINE DOSE
Preanesthetic Agents		
Anticholinergics		
Glycopyrrolate	0.003-0.01 mg/kg SC, IM, IV	0.003-0.007 mg/kg SC, IM, IV
Sedatives and Tranquilizers		
Acepromazine	0.01-0.03 mg/kg SC, IM, IV	0.01-0.03 mg/kg SC, IM, IV
Diazepam	0.1-0.5 mg/kg IV	0.1-0.5 mg/kg IV
Midazolam	0.1-0.5 mg/kg SC, IM, IV	0.1-0.5 mg/kg SC, IM, IV
Sedative Analgesics		
Medetomidine	0.001-0.010 mg/kg SC, IM, IV	0.005-0.030 mg/kg SC, IM, IV
Dexmedetomidine	0.001-0.005 mg/kg SC, IM, IV	0.002-0.015 mg/kg SC, IM, IV
Opioid Analgesics		
Butorphanol	0.1-0.2 mg/kg SC, IM, IV	0.1-0.2 mg/kg SC, IM, IV
Buprenorphine	0.01-0.02 mg/kg SC, IM, IV	0.02 mg/kg mucosally, SC, IM, IV
Morphine	0.3-0.7 mg/kg SC, IM	0.2-0.5 mg/kg SC, IM
Hydromorphone	0.1-0.15 mg/kg SC, IM, IV	0.1 mg/kg SC, IM, IV
Oxymorphone	0.1-0.2 mg/kg SC, IM, IV	0.1 mg/kg SC, IM, IV
Fentanyl	0.003-0.005 mg/kg SC, IM, IV	0.003-0.005 mg/kg SC, IM, IV
Remifentanil	0.001-0.003 mg/kg IV	0.001-0.003 mg/kg/IV
Nonsteroidal Antiinflammatory Drugs (parenteral only)		
Meloxicam	0.2 mg/kg SC, IM, IV	0.2-0.3 mg/kg SC, IM, IV
Carprofen	2.2-4 mg/kg SC, slow IV	2.2 mg/kg SC
Ketoprofen	1-2 mg/kg SC, IM, IV*	1 mg/kg SC, IM, IV*
Single and Combination Induction Agents		
Thiopental	6-10 mg/kg IV to effect†	6-10 mg/kg IV to effect†
Propofol	3-6 mg/kg IV to effect†	3-6 mg/kg IV to effect†
Ketamine and diazepam or ketamine and midazolam	3-5 mg/kg ketamine with 0.3-0.5 mg/kg diazepam or midazolam IV‡	3 mg/kg ketamine with 0.3-0.5 mg/kg diazepam or midazolam IV‡
Fentanyl and etomidate	0.003-0.005 mg/kg fentanyl with 1 mg/kg etomidate IV§	0.005 mg/kg fentanyl with 1 mg/kg etomidate IV§
Midazolam and fentanyl	0.3 mg/kg midazolam with 0.02 mg/kg fentanyl IV§	0.3 mg/kg midazolam with 0.01 mg/kg fentanyl IV§
Midazolam or diazepam and oxymorphone or hydromorphone	0.3 mg/kg midazolam or diazepam with 0.1 mg/kg oxymorphone or hydromorphone IV§	0.3 mg/kg midazolam or diazepam with 0.1 mg/kg oxymorphone or hydromorphone IV§
Ketamine, medetomidine, and butorphanol	3 mg/kg ketamine, 0.005 mg/kg medetomidine, and 0.2 mg/kg butorphanol IM‖	5 mg/kg ketamine, 0.025 mg/kg medetomidine, and 0.2 mg/kg butorphanol IM‖

SC, Subcutaneous; *IM,* intramuscular; *IV,* intravenous.

*Hemorrhage has been seen with preoperative and intraoperative use of ketoprofen. If used perioperatively, administer it postoperatively and ensure adequate coagulation ability before administration.

†"To effect" implies administration of agents until adequate laryngeal relaxation and central nervous system depression are seen.

‡Drugs listed are mixed together before administration.

§Drugs listed are given in succession, with the second drug often given to effect.

‖Used for elective surgical procedures. In the dog, additional IV induction agents may be required to achieve adequate plane of anesthesia for intubation.

Continued

TABLE 1-4

Preanesthetic and Anesthetic Agents with Suggested Dose Ranges—*cont'd*

DRUGS	CANINE DOSE	FELINE DOSE
Local and Regional Blockade		
Perilesional or perineural infiltration with lidocaine	2-5 mg/kg SC	2-3 mg/kg SC
Perilesional or perineural infiltration with bupivacaine	0.5-2 mg/kg SC	0.2-0.5 mg/kg SC
Epidural	0.1 mg/kg morphine with 0.3 mg/kg bupivacaine or 0.1 mL/kg saline	0.05 mg/kg morphine with 0.1 mg/kg bupivacaine or 0.1 mL/kg saline
Continuous Rate Infusions		
Lidocaine	0.05 mg/kg/min IV	0.005 mg/kg/min IV
Ketamine	0.01-0.02 mg/kg/min IV	0.01 mg/kg/min IV
Morphine	0.002 mg/kg/min IV	0.002 mg/kg/min IV
Fentanyl	0.3-0.7 μg/kg/min IV	0.3 μg/kg/min IV
Remifentanil	0.1-0.3 μg/kg/min IV	0.1 μg/kg/min IV

A. Stabilization of fluid balance before induction of anesthesia is critical.
   1. Pulmonary, pleural, or abdominal fluid accumulations are drained (at least partially) with appropriate diuretics or centesis before any agent administration or procedures.
   2. Normovolemia to hypovolemia with adequate blood pressure (mean Doppler pressure of >60 to 70 mm Hg) is required.

B. Preoxygenation is essential.
   1. It avoids desaturation and hypoxemia that occurs with preanesthesia and induction agent use.
   2. It readily relieves anxiety and angina, especially in cats.
   3. Oxygen is a potent pulmonary and cardiac vasodilator that improves cardiac function.

C. Choice of premedication is carefully considered.
   1. Opioids and benzodiazepines are drugs of choice for premedication.
   2. Morphine is very beneficial for anxiolysis, anginal pain, and redistribution of vascular volume from the pulmonary circulation through peripheral vasodilation.
   3. Anticholinergics and acepromazine are avoided.
   4. When decreased myocardial perfusion is present (cardiomyopathies in cats), alpha-2 agents may be indicated (Lamont et al., 2001; Lamont et al., 2002).
   5. Alpha-2 agents are not used in dogs with valvular disease or any animal with a life-threatening bradyarrhythmia or dilated cardiomyopathy.

D. Induction agents are given to effect.
   1. Cats
      a. Ketamine and ketamine/benzodiazepine combinations are avoided.
      b. Appropriate options are fentanyl, fentanyl and midazolam, propofol in small doses, and etomidate.
   2. Dogs
      a. Ketamine with diazepam or midazolam combinations are useful for increasing cardiac output in mild to moderate cardiac deficient states (valvular disease or mild dilated cardiomyopathy).
      b. Other appropriate induction options are opioid/benzodiazepine and fentanyl/etomidate combinations.

E. Isoflurane is the preferred maintenance inhalant agent to improve myocardial blood flow.

F. Local and regional nerve blockade, such as epidural opioid administration, is useful to provide excellent analgesia and avoid respiratory depression associated with systemic opioid use.

G. Pericardial disease requires unique intervention before induction of anesthesia.
   1. Effusions are removed before induction with use of ultrasonography or electrocardiographic guidance.
   2. Maintenance of preload is essential, so fluids are given to maintain cardiac output (mean Doppler blood pressure >70 mm Hg) and to increase central venous pressure (5 to 10 cm H_2O) when it is low in this subset of cardiac patients.

IV. Animals with renal disease

A. Animals with acute renal failure *should not be sedated or anesthetized* until adequate hydration, volume, acid base and electrolyte status, as well as blood pressures are attained.

B. Animals with renal insufficiency *must be well hydrated* before sedation and anesthesia.

C. Minimal premedication is suggested with use of drugs that are least likely to diminish cardiac output (e.g., benzodiazepines, opioids).
   1. Hydromorphone or oxymorphone is the preferred opioid; metabolites of morphine may accumulate with renal disease.

2. Acepromazine may be beneficial to allow afferent vasodilatation and increased renal blood flow (Bostrom et al., 2003).

D. Most induction and inhalant agents reduce glomerular filtration rate through decreases in renal blood flow; therefore, maintenance of blood pressure becomes paramount to success.

E. Induction agent choices are limited.
1. Avoid highly protein-bound drugs, such as barbiturates, or drugs excreted primarily by the kidney (e.g., ketamine).
2. Opioid/benzodiazepine combinations and propofol are suggested induction agents.

F. Isotonic crystalloid solution is administered at a fairly high rate (10 to 15 mL/kg/hr IV) to promote diuresis, with the rate reduced over time if adequate blood pressure and urine output are maintained; if preexisting hypoalbuminemia is present, judicions use of both colloids and crystalloids is recommended.

G. Isoflurane and sevoflurane are used as inhalant agents.

H. A byproduct of sevoflurane's interaction with the carbon dioxide absorbent, Compound A, has been found to cause renal impairment in laboratory animals, but this phenomenon has not been documented in domestic species anesthetized with sevoflurane.

I. Colloids (hetastarch 2 to 4 mL/kg/hr IV) or vasoactive agents (dopamine 3 to 5 μg/kg/min IV) can be added to increase blood pressure or urine output.

V. Animals with neurologic disease

A. Limited evidence exists that acepromazine reduces the seizure threshold (Wagner et al., 2003; Blaze, 2005; Brock 1994).

B. Although some anesthetic agents (ketamine, methohexital, etomidate) appear to increase the potential for seizures, use of acepromazine is not likely to do so (McKelvey and Hollingshead, 2000; Tobias et al., 2006).

C. Anticholinergics are used sparingly; glycopyrrolate is preferred over atropine because of its modest effect at increasing heart rate and purported inability to cross an intact blood-brain barrier and aggravate delirium.

D. Avoid anesthetics known to increase intracranial pressure, such as ketamine, tiletamine, and halothane.

E. Direct effects of opioids on cerebral blood flow and intracranial pressure are negligible, so they are useful agents.

F. Benzodiazepines and ultra–short-acting barbiturates in low doses are useful, owing to their effect on maintaining intracranial pressure and reducing neuronal activity.

G. Thiopental, propofol, benzodiazepine, and fentanyl combinations are all useful induction agents that act to slow neuronal activity and decrease intracranial pressure.

H. Sevoflurane is the preferred inhalant for maintenance of cerebral perfusion pressure.

I. Controlled hyperventilation with monitoring by capnography counteracts the effects of inhaled agents (central vasodilatation) on intracranial pressure.

J. Fluid administration is restricted to maintaining euvolemia, normal to hyperosmolarity, and adequate arterial blood pressures.
1. Fluids are regularly restricted to 2 to 5 mL/kg/hr IV.
2. Mannitol (0.5 to 1 g/kg IV slowly over 20 minutes) is given when increased intracranial pressure or tentorial herniation is suspected (ventral eye rotation, papillary dilation, optic disc edema, bradycardia, bradypnea, apneustic breathing patterns).
3. Fluid therapy is stopped during mannitol administration.
4. Furosemide can be administered at 1 to 2 mg/kg IV for enhanced diuresis after mannitol therapy.

VI. Animals with liver disease

A. Premedications and induction agents that are highly protein bound to gamma aminobutyric acid (GABA) receptors (benzodiazepines and barbiturates) are avoided in animals with overt or suspected hepatic encephalopathy.

B. Opioids are useful, but hepatic clearance is usually impaired.
1. Lower doses and less frequent administration are often required.
2. Epidural administration is the preferred route for opioid analgesia.
3. Remifentanil is an ultrapotent, short-acting opioid metabolized by plasma esterases; in animals with severe liver dysfunction, it represents a suitable induction agent and analgesic infusion agent.

C. Hypotension is often severe in animals with end-stage chronic disease or hepatic encephalopathy, and is often resistant to treatment with vasoactive or vasopressor agents.

D. Because of the potential for severe hypotension, impaired coagulation, and hypoalbumenimia, avoid acepromazine.

E. Alpha-2 agonists may be useful as premedicants because their sedative and cardiovascular effects are short-lived, and effects of these agents are reversible.

F. Induction agent choice is very limited.
1. Thiopental is metabolized actively by the liver, so prolonged recovery is expected if liver impairment is significant.
2. Propofol is the agent of choice, owing to its short half-life and limited hepatic uptake.

G. Sevoflurane is metabolized by the liver slightly more than isoflurane, but both are acceptable choices for animals with liver disease.

H. Avoid lactate-containing fluids; Normosol-R, Plasmalyte, or saline are the preferred crystalloid solutions.

CHAPTER 2

Collection and Interpretation of Laboratory Data

Rhea V. Morgan

This chapter presents the techniques and procedures for collecting samples for certain laboratory tests (Tables 2-1 to 2-4). Normal values and interpretative guidelines are included. (For normal physiologic values, see Appendix I.)

ANION AND OSMOLAL GAPS

Anion Gap

Definition

I. By the law of electroneutrality, the concentration of circulating anions equals that of circulating cations.
II. Cations and anions are classified as measured or unmeasured.
  A. Measured
    1. Anions: Cl^-, HCO_3^-
    2. Cations: Na^+, K^+
  B. Unmeasured
    1. Anions (UA): albumin, α- and β-globulins, PO_4^{3-}, SO_4^{2-}, organic acids, certain toxins and drugs
    2. Cations (UC): gamma globulins, Ca^{2+}, Mg^{2+}, certain drugs
  C. In electroneutrality:

$$Na^+ + K^+ + UC = Cl^- + HCO_3^- + UA$$

III. Anion gap is the difference between measured cation and anion concentrations.
  A. Denotes an alteration in some unmeasured component of the equation
  B. Anion gap = $(Na^+ + K^+) - (Cl^- + HCO_3^-)$
    1. Normal: 12 mEq/L; range: 8 to 16 mEq/L
    2. May be increased by either a decrease in UC or an increase in UA
    3. Is decreased by either an increase in UC or a decrease in UA
    4. Potassium sometimes deleted from equation because of its low, constant concentration

Causes

I. Causes of increased anion gap
  A. Increase in UA
  B. Increase in serum lactate, ketoacids, and uremia
  C. Certain medications: carbenicillin, penicillin
  D. Dehydration: concentrated normal anions
  E. Alkalemia
  F. Decrease in UC concentrations: Ca^{2+}, Mg^{2+}
  G. Increase in serum albumin
  H. Toxins: ethylene glycol, methanol, salicylate, paraldehyde
II. Causes of decreased anion gap
  A. Increase in normal cations, especially Ca^{2+}, Mg^{2+}, and globulins
  B. Retention of abnormal cations (e.g., multiple myeloma)
  C. Loss of UA: hypoalbuminemia

Clinical Significance

I. Increases index of suspicion that unexpected (or unmeasured) cations or anions are present in serum
II. Allows further definition and classification of metabolic acidotic states
  A. Metabolic acidosis with normal or decreased anion gap is usually caused by renal or intestinal loss of bicarbonate (hyperchloremic acidosis).
  B. Metabolic acidosis associated with an increased anion gap may have various causes.
    1. Diabetic ketoacidosis
    2. Lactic acidosis
    3. Ethylene glycol or paraldehyde intoxication
    4. Acute renal failure

Osmolal Gap

Definition

I. Osmolal gap is the difference between measured serum osmolality and calculated osmolality.
II. Serum osmolality can be measured with an osmometer.
  A. The major osmotically active solutes are Na^+, K^+, glucose, and urea (measured as blood urea nitrogen [BUN]).
  B. Normal osmolality is 285 to 300 mOsm/kg.
III. Calculated serum osmolality is derived from the following equation:

$$2(Na^+ + K^+) + \frac{\text{Glucose}}{18} + \frac{\text{BUN}}{3}$$

IV. A difference of >10 mOsm between the measured and calculated values is significant.

Causes

I. If the calculated value exceeds the measured value, a mathematical or laboratory error exists.
II. If the measured value is normal but the calculated value is low, a decrease in serum water is the usual cause.

TABLE 2-1

Endocrine Assays

TEST	PROTOCOL	SAMPLE REQUIRED	NORMAL VALUES	INTERPRETATION OF ABNORMAL VALUES
Basal T_3, T_4		Serum	*Dog:* T_3 = 80-200 ng/dL = 0.8-2 ng/mL = 1.2-3.1 nmol/L T_4 = 1.3-4 µg/dL = 13-40 ng/mL = 20-52 nmol/L *Cat:* T_3 = 60-150 ng/dL = 0.6-1.5 ng/mL = 0.6-1.9 nmol/L T_4 = 1-4.5 µg/dL = 10-45 ng/mL = 15-58 nmol/L	Suggestive of hypothyroidism: *Dog:* T_3< 30 ng/dL T_4 < 1 µg/dL Hyperthyroidism: *Cat:* T_3 > 200 ng/dL T_4 > 5 µg/dL *Dog:* T_3 > 290 ng/dL T_4 > 4 µg/dL
Free T_4 (FT_4) by dialysis		Serum	*Dog:* 16-30 pmol/L *Cat:* 15-48 pmol/L	*Dog:* FT_4 < 16 pmol/L suggestive of hypothyroidism, but may accompany other diseases *Cat:* FT_4 > 48 pmol/L indicative of hyperthyroidism
TSH response test	*Dog:* 0.1 IU TSH/kg IV *(Thytropar);* TSH inconsistently available	Measure serum T_4 at 0 and 4 or 6 hr after TSH	Post-TSH $T_4 \geq 2 \times$ basal T_4 or >35 nmol/L	Post-TSH $T_4 < 2 \times$ basal T_4 or < 35 nmol/L diagnostic of hypothyroidism
Canine endogenous TSH		Serum	*Dog:* 2-30 µU/L 2.7-7.9 ng/mL	Primary hypothyroidism: T_4 decreased, TSH increased (20-30 ng/mL) Canine assay validated for cats
TRH stimulation test	*Dog:* 0.2 mg TRH IV *Cat:* 0.1 mg TRH IV	Measure serum T_4 at 0 and 4 hr after TRH	*Dog:* Post-T_4 > 2 µg/dL or > basal T_4 + 0.5 µg/dL *Cat:* Post-T_4 increased by > 60%	Hypothyroidism (dog): Post-T_4 < 0.5 µg/dL Hyperthyroidism (cat): Post-T_4 increased by < 50% Equivocal findings (cat): Post-T_4 elevation of 50%-60%
T_3 suppression test	*Cat:* 25 µg T_3 PO TID × 7 doses	Measure T_4, T_3 before and 2-4 hr after last dose of T_3	$T_4 \leq$ 15 ng/mL ≤ 20 nmol/L	Hyperthyroid cats: T_4 does not suppress High T_3: confirms administration of T_3
ACTH response test	A. Synthetic ACTH *(Cortrosyn)* *Dog:* 0.5 U/kg IV, IM (max = 20 U) *Cat:* 0.125-0.25 mg IV, IM B. *Dog or cat:* ACTH gel 2.2 U/kg IM	A. Measure serum cortisol at 0 and 1 hr after ACTH in dogs or at 0, 30, and 60 min in cats B. Measure serum cortisol at 0 and 2 hr after ACTH in dogs and at 0, 1, and 2 hr in cats	≤ 50% of pretreatment values *Dog:* Pre-ACTH = 1.1-5 µg/dL, 25-38 nmol/L Post-ACTH = 6.2-16.8 µg/dL, 200-500 nmol/L *Cat:* Pre-ACTH = 0.33-2.6 µg/dL, 15-72 nmol/L Post-ACTH = 4.8-7.6 µg/dL, 130-210 nmol/L	Hyperadrenocorticism: Pre-ACTH = 4-10.8 µg/dL Post-ACTH = 11.7-50 µg/dL Primary hypoadrenocorticism: Pre- and post-ACTH = ≤1 µg/dL, ≤30 nmol/L

T_3, Triiodothyronine; *T_4,* thyroxine; *TSH,* thyroid-stimulating hormone; *TRH,* thyroid-releasing hormone; *ACTH,* adrenocorticotropic hormone; *max,* maximum.

ACTH assay	Draw sample into chilled syringe and insert into chilled EDTA tube; transfer sample to plastic tube and cool for 20 min in ice water; centrifuge sample for short time, retrieve plasma into another plastic tube, and Trasylol; freeze sample immediately and transport on dry ice		*Dog:* 20-80 pg/mL (avg. 45) 2-8.8 pmol/L *Cat:* 20-61 pg/mL 1-20 pmol/L	Pituitary-dependent hyperadrenocorticism: ACTH ≥40-500 pg/mL >88 pmol/L Functional adrenal tumor: ACTH ≤20 pg/mL ≤4.4 pmol/L
Low-dose dexamethasone suppression test	0.01 mg/kg dexamethasone sodium phosphate IV	Measure serum cortisol at 0, 4, and 8 hr after dexamethasone	*Dog:* Pre = 1.1-5 µg/dL Post = <1 µg/dL (Normal dogs suppress)	Hyperadrenocorticism: no suppression 4 or 6 hr post: 30% of pituitary-dependent hyperadrenocorticism cases suppress
High-dose dexamethasone suppression test	0.1 mg/kg dexamethasone sodium phosphate IV	Measure serum cortisol at 0, 4, and/or 8 hr after dexamethasone	Pre values reflect hyperadrenocorticism (4-10.8 µg/dL)	8 hr post: >1 µg/dL, >30 nmol/L
Urine cortisol:creatine ratio		Fresh urine sample	Urine cortisol (nmol/L):urine creatinine (mmol/L) ratio ≤35 (dog), <28 (cat)	Ratio > normal is suggestive of hyperadrenocorticism
Insulin assay		Measure serum insulin after 24-hr fast or during episodes of hypoglycemia	6-22 µU/mL	Values < normal preclude diagnosis of insulinoma Values > normal are suggestive of insulinoma
GH assay		Serum; assay currently unavailable	*Dog:* 0-10 ng/mL (usually 2-3 ng/mL) *Cat:* 0-8.5 ng/mL (mean = 1.21 ± 1.0 ng/mL)	Values > 90 ng/mL have been associated with neoplasia causing diencephalic syndrome in the dog and acromegaly in the cat Low values are difficult to asses; stimulation tests should be performed
Clonidine stimulation test	10 µg clonidine kg IV *(Catapresan)*	Measure plasma GH at 0, 15, 30, 45, 60, and 120 min after clonidine; keep samples frozen until assayed; GH assay currently unavailable	Normal dogs show increase in GH between 15 and 45 min with a peak of 25-40 ng/mL	Clonidine is a GH stimulant; pituitary dwarfs demonstrate either no or little response to clonidine
Xylazine stimulation test	100 µg/kg IV *(Rompun)*	Measure plasma GH at 0, 15, 30, 45, 60, and 120 min after xylazine; keep samples frozen until assayed GH assay currently unavailable	Normal dogs show increase in GH between 15 and 45 min with a peak of 25-40 ng/mL	Pituitary dwarfs show no response to xylazine

EDTA, Ethylenediamine tetraacetic acid; *GH,* growth hormone.

Continued

TABLE 2-1

Endocrine Assays—*cont'd*

TEST	PROTOCOL	SAMPLE REQUIRED	NORMAL VALUES	INTERPRETATION OF ABNORMAL VALUES
Somatomedin-C; IGF-1		Serum	*Dog:* 280 ± 23 ng/mL (adults) 345 ± 50 ng/mL (immature dogs) 5-45 nmol/L	Pituitary dwarfs have low value (11 ± 2 ng/mL or <5 nmol/L) Acromegaly in cats: Values of 70-100 nmol/L are nondiagnostic; repeat in 3 mos Values > 100 nmol/L are diagnostic
Gastrin assay		Plasma after 12-hr fast	*Dog:* 45-125 pg/mL *Cat:* 28-135 pg/mL	Plasma gastrin levels are increased with primary gastrointestinal tract disease (e.g., functional gastrinomas) or secondary to other systematic diseases, especially chronic renal failure
Antidiuretic hormone response test	Perform water deprivation test first; give desmopressin acetate 2-4 drops intranasally or conjunctivally or 10-20 µg/kg SC (dogs); if available, aqueous vasopressin may be given at 2-5 UIM (dogs)	Empty bladder and collect urine at 60, 120, 180, and 240 min	Normal: sp. gr. >1.025	Central diabetes insipidus: sp. gr. >1.015 Nephrogenic diabetes insipidus or medullary washout: sp. gr. <1.015
PTH assay		Serum	*Dog:* 2-13 pmol/L, 16-136 pg/mL *Cat:* 0-4 pmol/L, 3.3-22.5 pg/mL	Hypoparathyroidism: PTH is low or undetectable, especially if ionized calcium is low Parathyroid adenoma: PTH as high as 45 pmol/L Secondary hyperparathyroidism (renal failure): PTH grossly elevated
Calcitonin assay		Plasma	*Dog:* ≤25 pg-Eq/mL	Values of plasma calcitonin are difficult to interpret at this time; extreme elevations may be caused by calcitonin-producing thyroid tumors
Erythropoietin		Serum	*Dog:* 5-15 mU/mL *Cat:* 5-22 mU/mL	Low: primary polycythemia, chronic renal failure Normal or high: secondary polycythemia Very elevated: asplastic anemia, certain renal tumors
Ionized calcium		Serum	1.12-1.42 nmol/L	Primary hyperparathyroidism: increased values Malignant hypercalcemia; increased values Renal failure: normal or increased values Hypoparathyroidism: decreased values Feline pancreatitis: decreased values

IGF-1, Insulin-like growth factor-I; *sp. gr.,* specific gravity; *PTH,* parathormone.

TABLE 2-2

Gastrointestinal Studies

TEST	PROTOCOL	SAMPLE REQUIRED	NORMAL VALUES	INTERPRETATION
Bile acid assays	1. Fast animal 12 hr 2. Feed a routine or high-protein meal	Serum samples are colleted after 12-hr fast and 2 hr after a meal	*Dog:* Fasting ≤5 µmol/L Postprandial ≤ 15.5 µmol/L *Cat:* Fasting ≤ 2 µmol/L Postprandial ≤ 10 µmol/L	Elevations indicate dysfunction of normal hepatobiliary physiology, with the degree of elevation providing limited quantitative information
Ammonium tolerance test	Give 100 mg/kg NH_4Cl PO (max dose = 3 g)	1. Draw blood sample into EDTA or heparinized saline before and 30 min after NH_4Cl 2. Cool blood on ice immediately	Fasting ≤ 120-150 µg/dL Post-NH_4Cl ≤ 200-250 µg/dL	Elevation of blood ammonia indicates either hepatic dysfunction or shunting of portal blood away from the liver (i.e., portocaval shunt)
Glucagon tolerance test	1. Fast animal 2 hr 2. Give glucagon 0.03 mg/kg IV	Measure serum glucose at 0, 15, 30, 60, and 90 min after glucagon administration	Serum glucose rises in response to glucagon, with peak at 15 min, and returns to normal by 90 min	Glucose curve remains flat with severe hepatic insufficiency, portocaval shunt, glycogen storage disease, and prolonged anorexia or starvation
BT-PABA test	1. Fast animal 18 hr 2. Give 5 mL 1% BT-PABA/kg PO followed by 25-100 mL water 3. Stomach tubing is preferred 4. Avoid concurrent use of chloramphenicol, sulfonamides, diuretics, and pancreatic extracts for 5 days before test	Heparinized plasma is obtained for measuring plasma PABA at 0, 30, 60, 90, and 120 min	*Dog:* >5-35 µg/mL *Cat:* >7.5 µg/mL (at 90 min)	Indirectly measures chymotrypsin activity Values <1.25 µg/mL are compatible with pancreatic exocrine insufficiency and also reflect small intestinal absorption capabilites Values of 1.25-4 µg/mL are compatible with malabsorption
TLI; canine (cTLI) and feline (fTLI) assays available	Fast animal 6-12 hr	Serum	*Dog:* 5-35 µg/L *Cat:* 17-49 µg/L	Maldigestion (exocrine pancreatic insufficiency): <2 µg/L (dog), <8 µg/L (cat) Malabsorption: >5 µg/L (dog) Pancreatitis: >50 µg/L (dog) >200 µg/L (cat)

BT-PABA, N-benzoyl-L-tyrosyl-p-aminobenzoic acid; *TLI,* trysin-like immunoreactivity.

Continued

TABLE 2-2

Gastrointestinal Studies—*cont'd*

TEST	PROTOCOL	SAMPLE REQUIRED	NORMAL VALUES	INTERPRETATION
PLI	Fast animal 6-12 hr	Serum	*Dog:* 0-200 µg/L *Cat:* 2-6.8 µg/L	Poor diagnostic accuracy for pancreatitis Pancreatitis: >400 µg/L (dog) >12 µg/L (cat)
Fecal alpha 1-protease inhibitor assay	Collect fresh fecal specimens	Feces	*Dog:* 0-32 µg/g	Increased with protein-losing enteropathies
Folate levels	Fast animal 6-12 hr	Serum	*Dog:* 6.7-17.4 µg/L *Cat:* 13-4-38 µg/L	Increased with gastrointestinal bacterial overgrowth, pancreatic exocrine insufficiency, folate supplementation, or hemolyzed blood samples Low with small intestine malabsortion
Cobalamin levels	Fast animal 6-12 hr	Serum	*Dog:* 225-660 ng/L *Cat:* 200-1680 ng/L	Low with cobalamin malabsorption (ileal disease), pancreatic exocrine insufficiency, or small intestinal bacterial overgrowth Increased with parenteral supplementation

PLI, Pancreatic lipase immunoreactivity.

TABLE 2–3

Renal Function Tests

TEST	PROTOCOL	SAMPLE REQUIRED	NORMAL VALUES	INTERPRETATION
PSP excretion in urine	A. 1. Empty bladder via catheterization 2. Give 6 mg PSP IV B. Give 1 mg PSP/kg IV	A. Catheterize bladder 20 min later and collect all urine B. Collect 4 mL heparinized plasma before and 60 min after PSP administration	A. Normal: >30% excretion of PSP B. Normal: 80 µg/dL Suspicious: 80-120 µg/dL Abnormal: ≥120 µg/dL	A. Assesses renal blood flow B. Assess renal tubular function; abnormal retention occurs with renal insufficiency
SS clearance	Give 0.2 mL of 10% solution/kg IV after a 12-hr fast	Obtain heparinized blood at 30, 60, and 90 min	Results are expressed as the time needed to clear 50% of dye from the blood ($t_{1/2}$) Normal $t_{1/2}$ = 32-84 min.	SS retention in plasma above normal reflects diminished GFR SS clearance is usually reduced before the development of either azotemia or urine concentration defects
Endogenous creatinine clearance	1. Acclimate animal to metabolism cage 2. Catheterize and empty bladder 3. Allow access to free-choice water 4. Collect all urine for 24 hr; empty bladder again at end of test 5. Avoid contamination of urine with feces 6. Store urine in closed, refrigerated container until test is concluded 7. Record total volume of urine	1. Submit serum sample obtained midway through test for creatinine assay (SC) 2. Submit urine sample from the pooled collection for creatinine measurement (UC) 3. Use equation to calculate clearance: $\text{GFR} = \frac{\text{UC (mg/dL)} \times \text{urine volume (mL)}}{\text{SC (mg/dL)} \times 1440 \text{ min} \times \text{weight (kg)}}$	Normal, dogs: 2-5 mL/min/kg Normal, cats: 1.6-4 mL/min/kg	Decreased GFR occurs with decreased renal blood flow (prerenal), obstruction of urine outflow (postrenal), and renal parenchymal disease Decreased GFR in an otherwise normal dog indicates renal insufficiency
Urine protein quantitation	Follow protocol outlined for endogenous creatinine clearance Most common assay is trichloroacetic acid–ponceau S method	1. Submit pooled urine sample 2. Protein excretion/24 hr = urine protein (mg/dL) × urine volume (dL) 3. Protein excretion/kg = total protein (mg)/weight (kg)	1. Protein/kg/day ≤30 mg/kg/day 2. Total protein: 333 ± 309 mg/day	Significant proteinuria occurs with glomerular disease Other causes include Bence Jones proteinuria, myoglobinuria, and severe urinary tract trauma
UP/C ratio	Random sample	*Dog:* urine	Normal ≤1.0	Significant proteinuria: UP/C >1.0 Results are affected by both pyuria and gross blood contamination

PSP, Phenolsulfonphthalein; *SS,* sodium sulfanilate; *GFR,* glomerular filtration rate; *UP/C,* urine protein:creatinine.

TABLE 2-4

Interpretation of Selected Serologic Tests

DISEASE	TEST	INTERPRETATION
Brucellosis	A. RSAT	A. Good screening test False positives occur, so perform further seologic assay to confirm the diagnosis; a modification of the test (ME-RSAT) using a less mucoid (M-) variant of *Brucella canis* has fewer false positives; it becomes positive within 3-4 wk, but false negatives can occur up to 8 wk
	B. Tube agglutination tests 1. TAT	B. Most common confirmatory test 1. Becomes positive by 3-6 wk Titer results: 1:50 = early or recovering infection 1:50-1:100 = suspicious ≥1:200 = active infection Occurrence of false positives similar to RSAT
	2. ME-TAT	2. Fewer false positives Becomes positive 1-2 wk after TAT or 5-8 wk post-infection ≥1:200 = active infection
	C. AGID	C. Becomes positive in 8-12 wk Very specific; used to confirm diagnosis, especially in chronic cases Both somatic and cytoplasmic (CPAg-AGID) tests available, but somatic rarely used Results reported as positive, suspicious, or negative Repeat in 4-6 wk if first results are suspicious May remain positive for 1 yr
	D. ELISA	D. Very specific, but less sensitive than TAT tests Becomes positive by 4 wk
	E. IFA	E. Sensitivity is uncertain, so some infected dogs may be missed
Leptospirosis	A. MAT	A. Titers <1:400 may be postvaccinal Titers >1:800 usually indicate infection Paired samples 2-4 wk apart are tested; a fourfold increase in titer is diagnostic Tests for serovar groups, not individual serovars
	B. ELISA	B. IgM titer: develops after 1 wk IgG titer: develops in 2-3 wk Vaccinates: high IgG titer with low or negative IgM titer
Feline infectious peritonitis (FIP)	A. IFA, ELISA	A. Titer >1: 1600 (most laboratories) or fourfold increase over 2-4 wk is compatible with a positive diagnosis Titer > 1: 240 is inconclusive NOTE: This titer cross-reacts with other feline coronaviruses, so is not specific for FIP
	B. PCR assay	B. May help confirm presence of coronavirus in seronegative cats, but false negatives can occur and is not specific for FIP
Canine parvovirus	A. Hemagglutination inhibition, ELISA	A. Positive diagnosis: Single high IgM titer Fourfold rise in IgG titer over 2-4 wk; also considered protective
	B. Fecal ELISA or hemagglutination	B. Sensitive and specific test Shedding of virus is brief and usually not detected by day 10-12 of infection (day 5-7 of clinical illness) Vaccination produces false positives 5-12 days after administration

RSAT, Rapid slide agglutination test; *TAT,* tube agglutination test; *ME-TAT,* 2-mercaptoethane TAT; *AGID,* agar-gel immunodiffusion; *ELISA,* enzyme-linked immunosorbent assay; *IFA,* indirect immunofluorescence antibody; *MAT,* microscopic agglutination test; *IgM,* immunoglobulin M; *IgG,* immuoglobulin G; *PCR,* polymerase chain reaction; *FIP,* feline infectious peritonitis.

TABLE 2-4

Interpretation of Selected Serologic Tests—*cont'd*

DISEASE	TEST	INTERPRETATION
Ehrlichiosis *(Ehrlichia canis)*	A. IFA	A. Becomes positive in 7-28 days Titer >1:80 is considered positive in endemic areas Any measurable titer (>1:10) is significant in dogs in nonendemic areas Submit a second sample 2-3 wk later if suspicious case is negative on first sample Titers persist for 6-9 mo after infection Cross-reactivity occurs with *Neorickettsia* spp., *Helminthoeca* spp., and other ehrlichial agents
	B. Western immunoblotting assay	B. Detects antibodies 2-8 days after exposure Can distinguish *E. canis* from *E. ewingii*
	C. PCR assay	C. Positive within 4-10 days In the future, it may be able to distinguish active infection from titers that persist following successful treatment of disease
Rocky Mountain spotted fever	A. Indirect immunofluorescence test (Micro-IF) or ELISA for IgG	A. Submit acute and convalescent titers 2-3 wk apart Titer ≤1:64 = normal Titer ≥1:1024 in East, ≥1:25 in West = infected Fourfold increase in titers is diagnostic False negatives occur early in disease Titers may stay elevated (1:128) for 5-10 mo
	B. Micro-IF or ELISA for IgM	B. Decreases within 4-8 wk Single high titer indicates active infection
	C. Latex agglutination	C. Sensitivity lower than Micro-IF tests Single high titer (≥132) is diagnostic
	D. PCR assay	D. Can be run on both whole blood and tissues Nested PCR more sensitive in treated dogs
Borreliosis (Lyme disease)	A. IFA, ELISA	A. Titers are difficult to interpret and may indicate exposure rather than active infection Can cross-react with other bacteria, especially other *Borrelia* spp. and *Leptospira* spp. Symptomatic dogs usually have titers >1:128 Measure IgG and IgM titers simultaneously Fourfold increase in paired samples submitted 2-4 wk apart is supportive IgG titers become positive in 4-6 wk and persist for ≥2 yr IgM titers may persist for several months Titers do not distinguish postvaccinal responses from actual infection
	B. Western immunoblotting assay	B. Can distinguish postvaccinal responses from actual exposure/infection and identify false negatives
	C. ELISA for specific outer surface proteins (Osp)	C. Antibodies to OspA and OspB indicate post-vaccinal response Antibodies to OspC indicate active infection C_6 assay way indicate active infection and help assess response to treatment
Toxoplasmosis	A. IHA	A. Becomes positive in 2 wk; detects IgG Relatively insensitive, not species specific Fourfold rise in titer over 2-3 wk supportive
	B. LAT, MAT	B. Become positive in 2 wk, detects IgG MAT more sensitive Positive results: LAT > 1:64 MAT > 1:100 Fourfold rise in titer over 2-3 wk supportive Test may be applied to aqueous humor or CSF

IHA, Indirect hemagglutination; *LAT,* latex agglutination test; *CSF,* cerebrospinal fluid.

Continued

TABLE 2-4

Interpretation of Selected Serologic Tests—*cont'd*

DISEASE	TEST	INTERPRETATION
	C. IFA for IgM, IgG	C. False positives occur IgM elevated within 1-2 wk and IgG detectable after 2 wk Single high IgM titer (1:64), with negative IgG titer, implies active infection Fourfold increase in titers over 2-5 wk supportive Test may be applied to aqueous humor or CSF
	D. ELISA for IgM, IgG	D. More sensitive than IHA or LAT IgM titer >1.256, with negative IgG titer, implies active infection IgM is detected within 1-2 wk IgG is detectable in approximately 2-4 wk Fourfold increase in titers over 2-3 wk supportive Test may be applied to aqueous humor or CSF
	E. All tests	E. NOTE: Use caution when interpreting results; antibodies can occur in the sera of both healthy and diseased cats; therefore serologic tests alone do not confirm the presence of disease; titers may persist for months to years following infection
Blastomycosis	A. AGID	A. If positive, dog has 91% chance of having active disease but test may be negative in acute stages
	B. ELISA	B. May be more sensitive than AGID in cats Accuracy and sensitivity poorly defined
Cryptococcosis	A. LAT	A. *Cat:* Titer >1:12 indicative of active infection *Dog:* Any positive result indicative of infection False negatives can occur with localized disease False positives possible with contamination of assay; test cross-reacts with *Trichosporon* spp. Titers correlate well with extent and course of disease, and response to therapy May be assayed in serum, urine, CSF
	B. PCR	B. May be performed on tissues May be assayed in serum, urine, CSF
Coccidioidomycosis	A. TP test	A. Becomes positive in 2-6 wk Detects IgM; is a qualitative test and fades quickly (within 4-6 wk)
	B. CF test	B. Detects IgG and appears in 8-10 wk Titer ≤1:4 = negative Titer ≥1:16 = suspicious, chronic, or localized disease Titer ≥1:32 = active disease Rise or drop in titer corresponds well with clinical course, but titers remain elevated for months after treatment or disease arrest
	C. LAT	C. Measures IgM, so detects acute infection Some false positives in dogs
	D. AGID-TP, AGID-CF	D. More sensitive assays AGID-TP detects IgM; AGID-CF detects IgG
	E. ELISA	E. Available for detection of both IgM and IgG Some false positives in dogs; cross-reacts with blastomycosis
Histoplasmosis	A. CF titer B. Skin histoplasmin test	Neither test is considered reliable in dogs and cats for definitive diagnosis
Aspergillosis	A. AGDD	A. False positive rate of 6%; cross-reacts with *Penicillum* spp.
	B. CIE	B. Up to 15% false-positive results
	C. ELISA	C. Less reliable than AGDD or CIE
	D. PCR assay	D. Used experimentally; clinical availability limited NOTE: Some infected dogs never seroconvert; false negative rate is higher when only one antigen tested

TP, Tube precipitin; *CF,* complement fixation; *AGDD,* agar gel double diffusion; *CIE,* counterimmunoelectrophoresis.

III. An unmeasured osmole is suggested when both values are elevated and a significant gap exists.
   A. Mannitol, glycerin
   B. Sorbitol, acetone
   C. Ethylene glycol, alcohol
   D. Myeloma protein, hyperlipidemia
   E. Infused hyperosmotic solutions
   F. Activated charcoal containing propylene glycol and glycerol (Burkitt et al., 2005)

Clinical Significance

I. Directs attention to laboratory errors
II. Detects presence of unmeasured osmoles (e.g., ethylene glycol)
III. Can be used to confirm hyperproteinemia and hyperlipidemia

CHAPTER 3

Selected Diagnostic and Therapeutic Procedures

Rhea V. Morgan

CENTRAL VENOUS PRESSURE MEASUREMENT

Definition

I. Central venous pressure (CVP) is the measurement of fluid pressure in the anterior vena cava or right atrium.
II. It is a dynamic function of both cardiac output and venous return to the heart.
III. CVP does not correlate with pulmonary venous pressure in left-sided congestive heart failure.

Indications

I. Assessment of intravenous (IV) fluid therapy
II. Monitoring circulation hemodynamics during shock
III. As a diagnostic aid in cases of heart failure and pericardial effusion with tamponade

Restraint

I. The animal may be placed in either sternal or lateral recumbency.
II. Sedation is neither indicated nor desirable.

Technique

I. Insert an indwelling IV catheter into the external jugular vein, bringing the tip of the catheter to rest in the cranial vena cava.
   A. The length of catheter to use can be estimated by measuring the distance from the entrance site in the neck to a point near the 4th rib.
   B. Positioning can be confirmed via a lateral radiograph if an IV catheter with a radiopaque marker is used.
II. Connect the catheter to the male end of a three-way stopcock via extension tubing.
III. Attach a manometer calibrated in centimeters to the stopcock, perpendicular to the catheter line (Box 3-1).
IV. Attach an IV infusion solution to the third portal of the stopcock.
V. Fill the tubing and manometer with heparinized saline or IV solution, ensuring no air bubbles are present.
VI. Hold the manometer so the zero mark is level with the right atrium.
   A. Sternal recumbency: 4th intercostal space, 2 to 3 inches above the sternum
   B. Lateral recumbency: parallel to the sternum near the 4th sternebra
VII. Turn the stopcock so that the infusion set is off and the manometer connection to the catheter is open.
VIII. Allow liquid in the manometer to equilibrate.
IX. Note the pressure at the point where the meniscus stops descending.
X. If the meniscus falls below zero, refill the manometer and lower it so that the zero point is now at the 5-cm mark, with values between 0 and 5 cm denoting negative measurements.
XI. In cats, caudal vena cava CVP measurements can be used as an alternative (Machon et al., 1995).

Sources of Error

I. Incorrect positioning of the manometer
II. Rapid or labored breathing
III. Kinking of catheter or extension tubing
IV. Clots within the catheter
V. Malfunctioning of stopcock
VI. Pleural effusion: falsely elevates CVP in absence of right-sided congestive heart failure (Gookin and Atkins, 1999)

Interpretation

I. CVP is an insensitive test, but the sensitivity can be increased by using minimal lengths of connective tubing and removing all extraneous catheter adapters.
II. The trends that develop with sequential CVP recordings are more significant than isolated or individual measurements.
III. Values above 10 cm H_2O reflect hypervolemia/venous congestion.
IV. CVP measurement can be used to judge the endpoint of diuresis (unacceptably low values) or a large fluid infusion (high values).
V. See Appendix I for normal CVP values.

PERICARDIOCENTESIS

Definition

Pericardiocentesis is the transthoracic insertion of a needle or cannula into the pericardial space for the collection of fluid for diagnostic or therapeutic purposes.

Indications

I. Collection of pericardial fluid for gross, cytologic, and bacterial analysis

Box 3-1

Diagnostic and Therapeutic Instruments

Manometer

Pharmaseal Manometer Tray (Baxter Healthcare Corp., Pharmaseal Division, Glendale, Calif.)

Blood Pressure Monitors

Dinamap monitor Model 8100 (Critikon, Inc., Tampa, Fla.)
Parks (ultrasonic Doppler) flow detector model 811-B (Parks Medical Electronics, Inc., Aloha, Ore.)
Cardell monitors, various models (CAS Medical Systems, Branford, Conn.)
Trax (manufactured by Colin for DRE, Louisville, Ky.)
Memoprint (S+B medVET, Babenhausen, Germany)
Colin 8800c (Colin Medical Instruments, San Antonio, Tex.)

Indwelling Chest Tube

Argyle trocar catheter with Sentinel Eye (Argyle Division of Sherwood Medical, St. Louis, Mo.)

One-way Air Valve

Heimlich Chest Drain Valve (Bard-Parker/Becton, Dickinson Acute Care, Franklin Lakes, N.J.)

Continuous Evacuation Pump

Pleur-Evac (Deknatel, Division of Pfizer, Queens Village, N.Y.)
Closed chest suction (Argyle Division of Sherwood Medical Products, St. Louis, Mo.)

Nasal Oxygen Tubes and Nasal Feeding Tubes

Kaofeed II polyurethane feeding tube (Jorensen Laboratories, Loveland, Colo.)
Sterile single-use feeding tube and urethral catheter (Jorensen Laboratories, Loveland, Colo.)
Argyle nasogastric feeding tube (Argyle Division of Sherwood Medical, St. Louis, Mo.)

Nasal Oxygen Humidification

Hudson Humidifier (USA Hudson Respiratory Care, Research Triangle Park, N.C.)

Tracheostomy Tube

Portex (Portex, Wilmington, Mass.)

Transtracheal Fluid Trap

Lukens specimen container (Sherwood Medical Company/Tyco Kendall Healthcare, Deland, Fla.)

Percutaneous Gastrostomy Tubes

Medicut intravenous cannula (Sherwood Medical Industries, Inc., St. Louis, Mo.)
Bard urologic catheter (Bard Urologic Division of C.R. Bard, Covington, Ga.)
Silicone percutaneous endoscopic gastrostomy kit (Ballard Medical of Kimberly Clark, Roswell, Ga.)
EndoVine low-profile percutaneous endoscopic gastrostomy kit (Boston Scientific, Natick, Mass.)

Gastrostomy Tube Placement Device

Eld Gastrostomy Tube Applicator (Jorgensen Laboratories, Loveland, Colo.)

Bone Marrow Biopsy Needles

Osgood needle (Becton, Dickinson and Co., San Jose, Calif.)
Rosenthal needle (Becton, Dickinson and Co., San Jose, Calif.)
Jamshidi needle (Baxter Healthcare, Pharmaseal Division, Glendale, Calif.)

Bone Biopsy Instrument

Michel trephine (Jorgensen Laboratories, Loveland, Colo.)

II. Removal of pericardial fluid that is restricting diastolic filling of the ventricles during cardiac tamponade
III. Performing radiographic contrast studies, with administration of intrapericardial positive or negative contrast media to enhance radiographic visualization of intrapericardial structures

Restraint

I. Restrain the animal in lateral or sternal recumbency, or in a standing position.
II. Many dogs undergo this procedure with local anesthesia only.
III. If needed, mild chemical sedation (opioids, benzodiazepines) may be used, but must be used cautiously in animals with cardiovascular compromise (see Chapter 1).

Technique

I. A rectangular area of the right lateral thoracic skin is clipped and prepared aseptically from the sternum to the midthorax and from the 2nd to the 8th rib.
II. Thoracic ultrasonography can be used for needle placement.
III. Electrocardiography (ECG) is performed throughout the procedure.
IV. If ultrasound is unavailable, the site for needle insertion is selected based on review of the dorsoventral and lateral thoracic radiographs to assess the location of the pericardial silhouette.
    A. Usually the 4th, 5th, or 6th intercostal space is best.
    B. The right side is preferable for minimizing trauma to the lungs (because of the cardiac notch) and the major coronary arteries (located mostly on the left).
    C. A point one fourth of the distance from the sternebrae to the costochondral junction at the strongest palpable cardiac impulse (usually between the 4th and 6th ribs) is selected.
        1. The ventral location reduces the risk of coronary artery laceration by the needle.
        2. Also avoid the internal thoracic artery, which lies just dorsal to the sternebrae.

D. The skin and subcutaneous and intercostal tissues may be infiltrated with a local anesthetic before needle insertion. Note that the intercostal vessels and nerves course along the caudal edge of the ribs.
E. A variety of equipment can be used.
   1. Over-the-needle catheters (12 to 20 gauge) are used based on the size of the animal.
   2. A 19-gauge through-the-needle catheter is also appropriate.
   3. The needle is passed through the skin, subcutis, and intercostal muscles until it is in the pericardial space.
   4. The catheter is advanced, and the needle is withdrawn from the chest wall.
   5. The stylet is removed, and a three-way stopcock and sterile syringe (12 or 20 mL) are attached.
   6. If the beating heart can be felt against the tip of the catheter, withdraw it for a short distance and monitor the ECG for arrhythmias.
F. Fluid is aspirated.
   1. If no fluid is obtained, the catheter is slowly withdrawn while applying intermittent suction.
   2. As the volume of fluid decreases in the pericardial sac, the catheter may need to be repositioned.
   3. After completion of fluid collection, the catheter is withdrawn.
G. The fluid is transferred to ethylenediamene tetraacetic acid (EDTA) tubes for cytologic study and to transport medium for bacteriologic analysis.

Complications

I. Cardiac arrhythmias may be induced by the needle contacting or penetrating the myocardium.
II. Laceration of a coronary artery can lead to hemorrhage and tamponade.
   A. Collection of bloody fluid that clots soon after collection may indicate coronary artery laceration.
   B. Insertion of the needle in a ventral location (near cardiac apex) or under guidance with fluoroscopy or ultrasonography reduces the likelihood of this complication.

THORACENTESIS

Definition

Thoracentesis is the surgical puncturing of the chest wall for drainage of fluid or air from the pleural cavity.

Indications

I. Alleviation of pneumothorax
II. Obtaining fluid samples for analysis
III. Removal of fluid to relieve dyspnea

Restraint

I. Sternal recumbency is preferred so that gravity causes intrathoracic fluid to be positioned ventrally in the chest and air to be trapped dorsally.
II. Compromised animals are restrained manually.
III. Fractious or anxious animals may be mildly tranquilized.

Technique

I. Shave the hair and aseptically prepare the skin at the site of puncture.
   A. To remove air, aspirate dorsally at the 7th to 9th intercostal spaces.
   B. To retrieve fluid, aspirate ventrally at the 7th or 8th intercostal space, avoiding the apex beat of the heart.
   C. Avoid inserting the needle close to the caudal edge of the ribs because the intercostal vessels and nerves lie in this area.
   D. Also avoid inserting the needle in the area just dorsal to the sternebrae, or the internal thoracic artery may be punctured.
II. Aspirate either air or fluid using appropriate equipment.
   A. Air and most fluids can be retrieved using a 21-gauge butterfly catheter, a three-way stopcock, and a 20- to 60-mL syringe.
   B. In large dogs and in cases with viscous fluids, 14- to 16-gauge IV over-the-needle catheters are used, with extension tubing, a three-way stopcock, and syringe attached after the stylet is removed.
III. Pass the needle through the skin, intercostal muscles, and parietal pleura into the pleural cavity.
IV. If an IV catheter is used, thread the catheter into the chest for several inches and withdraw the needle.
V. Apply negative pressure to the syringe with the three-way stopcock in the open position.

Complications

I. Accidental puncture of the internal thoracic artery, intercostal or coronary vessels, and myocardium
II. Accidental pneumothorax if the three-way stopcock is left open, connections in the aspiration line become loose, or if the visceral pleura is lacerated

CHEST TUBE PLACEMENT

Definition

Chest tube placement refers to insertion of an indwelling chest tube for treatment of pleural cavity disease.

Indications

I. Providing access to the pleural space for repeated, intermittent aspiration of free pleural fluid or air
II. Providing continuous evacuation of air in cases of severe and/or tension pneumothorax
III. Providing a means for installation and subsequent drainage of intrathoracic antibiotics, lavage solutions, and chemotherapeutic agents

Restraint

I. For insertion of the chest tube, the animal is placed in lateral recumbency.
II. Manual restraint is preferred but sedation may be considered.
III. Once the chest tube is inserted and positioned, actual aspiration of the chest may be attempted in any position that facilitates removal of the fluid or air.

Technique

I. The hair is shaved and the skin is aseptically prepared.
II. If time allows, the skin and musculature are infiltrated with a local anesthetic, one to two ribs caudal to the insertion site.
III. The sites chosen for insertion are similar to those for thoracentesis.
   A. Air: dorsal 7th or 8th intercostal spaces
   B. Fluid: ventral 6th to 8th intercostal spaces
   C. One or more tubes inserted unilaterally or bilaterally
IV. A stab incision with a scalpel blade is made through the skin over the infiltrated site.
V. The chest tube with trocar is inserted through the incision and advanced cranially under the skin to the desired site.
VI. With a quick, forceful movement, the tube is pushed through the intercostal muscles and into the thorax (Figure 3-1).
VII. As the trocar is removed, the tube is cross-clamped, and the free end is attached to a three-way stopcock, one-way valve, or continuous evacuation pump (see Box 3-1).
VIII. The clamp is released, the patency of the tube ensured, and a purse-string suture placed in the skin where the tube exits.
   A. The tube is marked at the level where it enters the skin, so that migration of the tube can be detected.
   B. A non–water-soluble ointment is applied at the exit site.
IX. The tube is fixed to the chest by placing stay sutures through a tape butterfly surrounding the free end of the tube, and a light chest wrap is applied to protect the tube from dislodgment.
X. Postprocedural thoracic radiographs are recommended to verify correct placement of the chest tube.

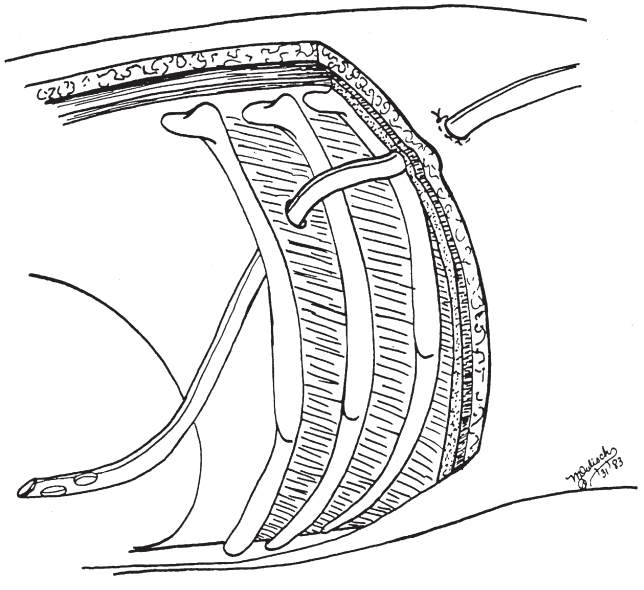

FIGURE 3-1 Technique for inserting an indwelling chest tube. *From Morgan RV: Manual of Small Animal Emergencies. Churchill Livingstone, New York, 1985; with permission.*

Complications

I. Inadvertent laceration of intercostal, internal thoracic, or cardiac vessels (see Thoracentesis for vessel location) is a potential complication.
II. Accidental pneumothorax can occur during removal of the trocar.
III. In the days after insertion of the chest tube, close monitoring is necessary to ensure the following:
   A. The chest tube remains patent, and all moving parts remain free of viscous discharges.
   B. The position of the tube is correct within the chest, and it does not back out.
   C. All connections are tight, with no leakage of air into the chest.
   D. All portals are protected from bacterial contamination.

NASAL OXYGEN ADMINISTRATION

Definition

Nasal cannulation allows the administration of oxygen from a tube placed through the nares into the ventral nasal meatus to increase arterial blood oxygen concentration.

Indications

I. Any cause of hypoxia
   A. Cardiopulmonary disease
   B. Hematologic abnormalities
   C. Metabolic disease
   D. Shock
II. Useful in animals too mobile for an oxygen mask or too large for an oxygen cage
III. May be more effective than some oxygen cages

Restraint and Technique

I. Topical anesthesia is usually all that is required.
   A. With the head extended, 0.1 to 0.5 mL of 2% lidocaine is dripped into the nares.
   B. Lidocaine gel is also applied to the junction of the skin and the nares laterally, allowing several minutes for the region to become anesthetized.
II. A fenestrated polyurethane or soft rubber catheter of appropriate size (usually a 4, 6, or 8 French) is selected.
III. Infant feeding tubes also work well.
IV. The tube is measured from the nares to approximately the level of the fourth premolar tooth and marked.
V. The tube is then passed through the nares into the ventral nasal meatus until the predetermined mark is reached.
VI. It is sutured to the skin lateral to the nares using 3-0 or 2-0 nylon.
   A. It is important to place this first suture as close to the nasal mucosa as possible to ensure good tube stability.
   B. Once the first knot is placed, the suture material is passed several times around the tube in a "bootlace" pattern.
VII. A second suture is placed on the midline of the forehead, fixing the skin to an adhesive tape butterfly placed around the tube.

VIII. Humidified oxygen is delivered to the animal.
  A. Commercially available humidifiers may be used (see Box 3-1).
  B. A homemade humidifier can be made (Fitzpatrick and Crowe, 1985).
    1. An IV extension tube is attached to the nasal oxygen tube (see Box 3-1) and run into the administration port of a half-full bottle of warm saline.
    2. The tube carrying the oxygen source is attached to the vent hole of the bottle, and the oxygen is bubbled through the water.
  C. The oxygen flow rate is set at 50 to 150 mL/min/kg body weight initially and then adjusted as needed.
IX. Mostly commonly, a unilateral tube is placed; bilateral tubes increase the risk of oxygen toxicity with prolonged administration (Dunphy et al., 2000).

Complications

I. If the oxygen flow rate is too high, nasal mucosal erosions ("jet lesions") and nasal irritation may occur.
II. Gastric dilatation can occur if the tube is placed too far caudally toward the pharynx or if the oxygen flow rate is too high.
III. Unhumidified oxygen causes dryness of the respiratory passages.
IV. Traumatic tube placement may result in mild epistaxis.

TRACHEOSTOMY TUBE INSERTION

Definition

A tracheostomy is the surgical creation of an opening into the trachea for insertion of a tracheostomy tube.

Indications

I. Providing a means for delivering air or oxygen past an upper airway obstruction
II. Allowing a means to evacuate secretions from the airway
III. Facilitating passage of air or oxygen to the lungs under positive pressure

Restraint

I. General anesthesia is preferred.
II. In an emergency, physical restraint with or without local anesthesia may be all that is required.

Technique

I. Shave the hair and aseptically prepare the skin from the angular process of the jaw to the thoracic inlet, with the animal in dorsal recumbency.
II. Make a longitudinal incision over the trachea immediately caudal to the larynx or caudal to the obstruction.
III. Separate the two sternohyoid muscles with blunt dissection (Figure 3-2, *A*).
IV. Incise the trachea between the cartilaginous rings. For high obstructions, make the incision between rings 2 and 3 or 3 and 4.
V. Enlarge the incision with a scalpel blade, being careful not to lacerate the endotracheal tube (Figure 3-2, *B*).
VI. A loop of 2-0 silk suture is placed around the ventral aspect of the tracheal ring cranial and caudal to the tracheostoma to facilitate intubation and reintubation.
VII. Withdraw the endotracheal tube and insert a tracheostomy tube (Figure 3-2, *C,* and see Box 3-1).
VIII. If the tracheostomy tube is supplied with an obturator, remove it.
IX. Tie the tracheostomy tube in place with umbilical tape or suture the tube to the skin of the neck.
X. Sterile endotracheal tubes may be used in giant-breed or thick-necked dogs in which ordinary tubes cannot be adequately secured.

Complications

I. Patency of the airway may be compromised during the tracheostomy procedure by blood and secretions, so suction the airway immediately after inserting the tube.
II. The normal warming and humidification of air by the nasal passages is bypassed with a tracheostomy tube.
  A. Thick, dry mucus may accumulate as a result and diminish the tube's patency.
  B. Measures can be taken to prevent accumulation of mucus.
    1. Suction the tube every 2 to 4 hours using aseptic technique.
    2. Liquefy secretions.
      a. Nebulize with saline every 4 to 8 hours.
      b. Instill 1 mL saline into the tracheal tube every 2 to 8 hours.

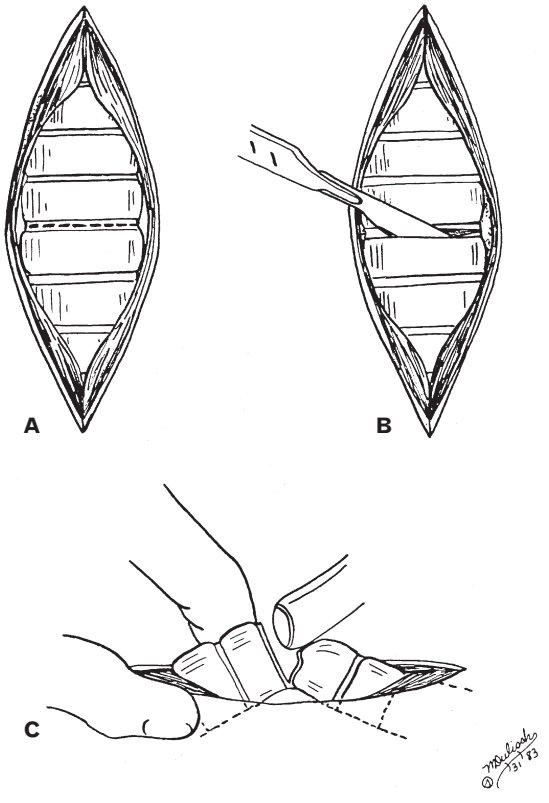

FIGURE 3-2 Technique for insertion of a tracheostomy tube. *From Morgan RV: Manual of Small Animal Emergencies. Churchill Livingstone, New York, 1985; with permission.*

3. Maintain normal body hydration with SC or IV fluids.

III. Overzealous aspiration may cause rupture of the airway and secondary pneumothorax or mediastinum.
IV. Forceful insertion of an overly large tracheostomy tube may result in pressure necrosis of the tracheal mucosa and possible damage to the dorsal tracheal membrane and cartilaginous rings.
V. When the tracheostomy tube is removed, the site is left open to heal by second intention.
   A. The open site is cleaned several times daily.
   B. Surgical closure of the tracheostomy site may result in subcutaneous emphysema or pneumomediastinum.

TRANSTRACHEAL/ENDOTRACHEAL ASPIRATION

Definition

I. Transtracheal aspiration (TTA) is the placement of a cannula from the rostral trachea into the lower respiratory tract for the collection of uncontaminated bronchial secretions.
II. Endotracheal aspiration is the passage of sterile tubing through a sterile endotracheal tube into the lower respiratory tract for the collection of uncontaminated bronchial secretions.

Indications

I. To determine the cause of inflammatory conditions of the respiratory tract
   A. Bacterial infections
   B. Viral infections
   C. Fungal infections
   D. Allergic disease
   E. Parasitic infestation
   F. Neoplastic disease: high number of false negative results
II. As a prognostic aid after smoke inhalation or exposure to fire and toxic fumes

Restraint

I. Dogs
   A. Mild sedation (butorphanol 0.2 to 0.4 mg/kg IV and diazepam 0.2 mg/kg IV) may be indicated, depending on the temperament and physical status of the animal.
   B. Hold the conscious dog in sternal recumbency, with the neck outstretched and the head pointing towards the ceiling.
II. Cats
   A. IV induction of general anesthesia with an ultra–short-acting thiobarbiturate or propofol
   B. Heavy sedation with ketamine 2 to 4 mg/kg IV and diazepam 0.1 to 0.2 mg/kg IV
   C. Sternal or lateral recumbency

Technique

I. Dogs
   A. Aseptically clip and prepare the ventral cervical skin.
   B. Palpate the site for catheter insertion, and either the cricothyroid membrane or the space between any of the first three tracheal rings may be used.
   C. Infuse the skin and subcutaneous tissues with a local anesthetic.
   D. Advance a 16- to 19-gauge IV through-the-needle catheter through the skin and subcutis and into the tracheal lumen at the selected site (Figure 3-3).
   E. Once the needle is within the tracheal lumen, direct the needle distally toward the carina, and the catheter is advanced. A transient cough reflex usually occurs during this step.
   F. Retract the needle from the site.
   G. Attach a sterile syringe containing a multiple-electrolyte solution (1 mL/5 lb body weight).
   H. Aspiration on the syringe yields air if the catheter is placed correctly.
   I. If central suction is available, inject the entire calculated dose of fluid.
      1. Disconnect the syringe from the catheter, and attach a Lukens specimen container (14 French with 20-mL trap and male adapter plug) to the catheter (see Box 3-1).
      2. Apply central suction to the trap, and collect fluid.
      3. When a sufficient specimen has been collected, turn off suction and withdraw the catheter.
   J. If central suction is not available, the fluid is injected at 2-mL increments with intermittent aspiration until fluid, not air, is retrieved.

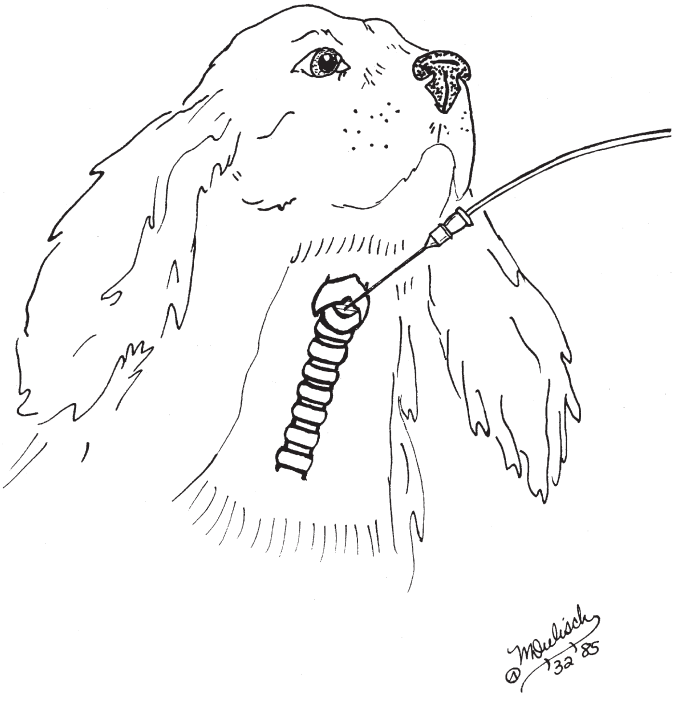

FIGURE 3-3 Transtracheal aspiration is accomplished by inserting an intravenous catheter through the cricothyroid membrane of the larynx into the trachea. The catheter is then advanced into the lower airway.

1. The volume of fluid necessary may vary from 2 to 25 mL.
2. The actual specimen collected is usually 0.5 to 2 mL.

II. Cats
   A. The technique is basically the same as for the dog except that it is performed under sedation through a sterile endotracheal tube.
      1. Carefully place a sterile endotracheal tube in the trachea by intubation.
      2. Advance the catheter through the endotracheal tube; administer and collect fluid in the same manner as described for the dog.
   B. An alternative method is to perform the technique outlined for the dog.

III. Specimen handling
   A. Place a portion of the fluid in transport medium for microbiologic analysis.
   B. Spin the remaining fluid in a centrifuge, and examine the cellular fraction microscopically.

Complications

I. Most complications are mild and transient.
   A. Coughing
   B. Subcutaneous or mediastinal emphysema
   C. Hemoptysis
   D. Subcutaneous hematoma

II. Inadvertent collection of pharyngeal (squamous epithelium present in sample) or upper tracheal secretions may yield inappropriate results.

III. The use of collection fluids containing bacteriostatic agents may cause false-negative culture results.

IV. Although neoplastic cells from bronchial or pulmonary tumors may be identified microscopically in TTA specimens, there is a high incidence of false-negative results with pulmonary tumors.

CEREBROSPINAL FLUID COLLECTION

Definition

A cerebrospinal fluid (CSF) tap is used to collect CSF by percutaneous needle aspiration of the subarachnoid space.

Indications

I. Retrieval of CSF for analysis when organic dysfunction of the central nervous system (CNS) is suggested
   A. Recent history of neurologic symptoms
   B. Neurologic deficits present on examination

II. Insertion of contrast medium into the subarachnoid space to localize spinal cord lesions (see Chapter 4)

Restraint

I. General anesthesia is always indicated for CSF taps in dogs and cats.

II. Proper positioning is critical to accomplish accurate needle placement.
   A. Cisternal tap
      1. Place the animal in lateral recumbency, with the head flexed ventrally to open the atlanto-occipital interspace.
      2. Pull the ears forward to tense the skin.
      3. Elevate the nose slightly so that it is parallel to the surface of the table.
      4. A towel or sandbag may be positioned under the head to maintain the entire spine a consistent distance from the table surface.
   B. Lumbar tap
      1. Place the animal in sternal recumbency, with an assistant pulling the hind legs in a cranial and dorsal direction to open the interarcual space between the caudal lumbar vertebrae.
      2. The entire spine must be kept straight.

Technique

I. Cisternal tap
   A. Clip the hair and aseptically prepare the skin on the dorsal cervical region from 2 cm rostral to the occipital protuberance to the level of the 3rd cervical vertebra.
   B. With one hand, the operator digitally palpates the external occipital protuberance and the rostral wings of the atlas.
      1. The index finger can be used to palpate a depression between these three structures.
      2. This depression marks the site for needle placement (Figure 3-4).
   C. A spinal needle with stylet is slowly inserted through the skin, subcutaneous tissues, and muscles.
      1. Large dogs: 20-gauge, 1- to 3-inch needle
      2. Small dogs and cats: 22-gauge, 1- to 2-inch needle

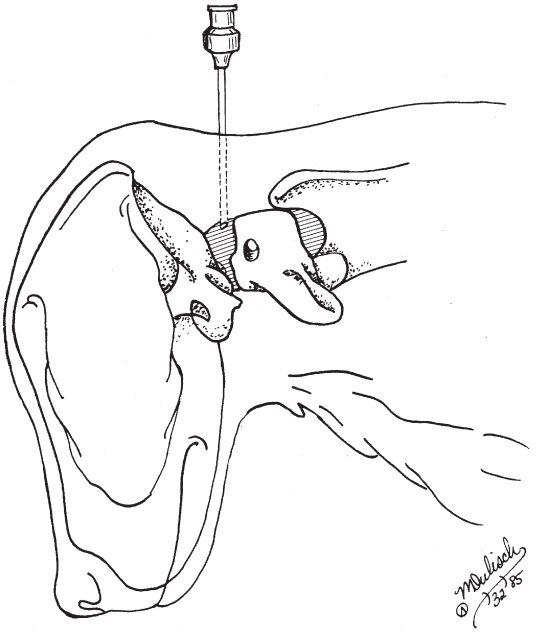

FIGURE 3-4 Cisternal puncture for spinal fluid collection and/or insertion of contrast medium for myelographic study.

D. The combined dura mater and arachnoid membranes are penetrated.
   1. Withdraw the stylet with each incremental advancement of the needle through the membranes to check for the presence of fluid.
   2. Always replace the stylet before advancing the needle.
E. When fluid is observed, attach a spinal manometer with three-way stopcock if measurement of CSF pressure is desired.
F. Allow the CSF to drip directly from the needle into a collection tube.
   1. It is important not to move the needle during pressure measurement and fluid collection.
   2. The quantity of fluid recovered varies.
      a. Large dogs: 1.0 to 3.5 mL
      b. Small dogs, cats: 0.5 to 1.5 mL
   3. Jugular vein compression may increase the flow of CSF.
G. If indicated, contrast material may be administered for myelography (see Chapter 4).
H. The needle is carefully and smoothly withdrawn.
I. Place fluid in a sterile tube for microscopic, chemical, and microbiologic analysis.

II. Lumbar tap
A. Clip the hair and aseptically prepare the skin over the dorsal lumbar spine.
B. Palpate the dorsal spinous processes of the lumbar (L) vertebrae.
C. Optimal sites for the collection of CSF are at the L4-5 or L5-6 interspace (Figure 3-5).
D. Insert a 20- or 22-gauge, 3.5-inch spinal needle immediately cranial to the dorsal spinous process of the vertebra at the caudal aspect of the planned puncture site.
   1. Advance the needle toward the spinal canal until it contacts a dorsal laminar surface.
   2. The needle must be maintained parallel to the dorsal spinous processes.
   3. The needle is "walked" cranially or caudally along the laminar surface until it drops into the interarcual space.
   4. A twitch in the rear legs or tail may indicate proper needle placement (see Figure 3-5).
E. Withdraw the stylet, attach a syringe to the needle, and apply gentle aspiration until fluid is recovered.
   1. The depth of needle insertion may be adjusted slightly during aspiration.
   2. The subarachnoid space is small in the region of the lumbar cord, and only a small quantity of fluid may be recovered (0.5 to 2.5 mL).
F. At this point, contrast medium can be injected if myelographic study is indicated (see Chapter 4).
G. Remove the needle and place fluid into a sterile tube for microscopic, chemical, and microbiologic analysis.

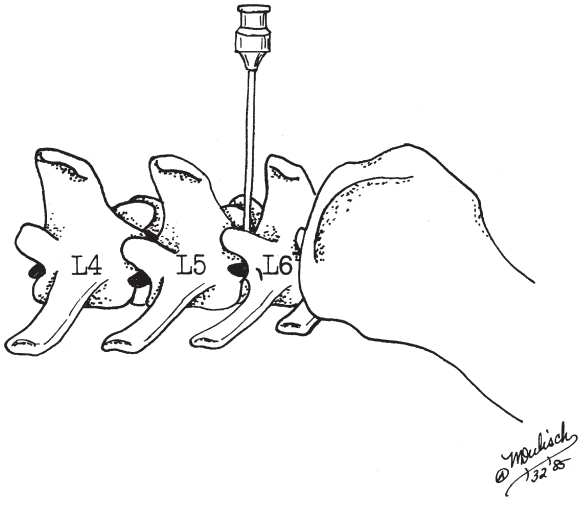

FIGURE 3-5 A lumbar spinal tap is demonstrated at the interarcual space between lumbar vertebrae 5 and 6.

Complications

I. Direct needle trauma to the parenchyma of the brain or spinal cord can occur if careful, controlled advancement of the needle is not performed.
II. Iatrogenic hemorrhage may make interpretation of laboratory results difficult; if contamination with blood occurs, consider the following correction factors:
   A. One white blood cell (WBC) is expected for every 500 red blood cells (RBCs).
   B. One thousand RBCs will increase CSF protein by approximately 1 mg/dL.

NASAL FEEDING TUBE PLACEMENT

Definition

I. A nasal feeding tube is a tube placed from the external nares into the stomach (nasogastric) or distal esophagus (nasoesophageal) for administration of fluids and nutrients or to allow decompression of a dilated or distended stomach.
II. For feeding purposes, if the esophagus is functional, a nasoesophageal tube is inserted; if the esophagus is nonfunctional (e.g., megaesophagus or esophageal stricture), a nasogastric tube is inserted.

Indications

I. Provide short-term (≤10 days) nutritional support to animals unwilling or unable to eat for various reasons
   A. Facial, maxillary, and mandibular fractures
   B. Oral and esophageal disease
   C. Prolonged anorexia from a systemic disorder
II. For temporary decompression of the stomach before or after corrective surgery for gastric dilatation volvulus
III. For evacuation of gastric fluid in cases of ileus

Restraint

I. Usually, local anesthesia is all that is required.
II. Occasionally, mild sedation is useful.
   A. Dog: butorphanol 0.2 to 0.4 mg/kg IV
   B. Cat: diazepam 0.1 to 0.5 mg/kg IV, with or without ketamine 2.0 mg/kg IV

Technique

I. Based on the animal's size, a 3.5 to 8 French polyurethane or polyvinyl chloride tube is selected (see Box 3-1).
II. The distance from the tip of the nares to the last rib (for nasogastric tube) or to the 7th rib (for nasoesophageal tube) is measured and the tube is marked accordingly.
III. Instill 2% lidocaine into the nostril (several drops for cats; 0.5 to 1 mL for dogs), and keep the head slightly elevated for 1 to 2 minutes as the lidocaine takes effect.
IV. The tube, nares, and skin where the sutures are to be applied are lubricated with 2% lidocaine jelly (Figure 3-6).
V. The tube is then advanced through the nostril and into the ventral nasal meatus.
    A. In dogs the tube is inserted dorsomedially for the first centimeter to avoid the alar fold and nasal vestibule, and then advanced ventrally. Alternatively, the external naris is pushed dorsally as the tube is advanced in a caudal-ventral-medial direction (Abood and Buffington, 1991).
    B. In cats the tube may initially be directed ventromedially, because there is no well-developed alar fold.
VI. As the tube enters the pharynx, the animal is encouraged to swallow, allowing for easy passage into the esophagus.
VII. Advance the tube until the premarked spot reaches the tip of the nares.
VIII. Inject a small quantity of air and then saline into the tube to check for correct placement.
    A. Abdominal auscultation indicates air bubbling in the stomach.
    B. The injection should be well tolerated by the animal without struggling or coughing.
    C. A lateral caudal thoracic radiograph is taken if there is any uncertainty as to the final location of the tube.
IX. Secure the tube in place using 3-0 nonabsorbable sutures.
    A. Place the first suture in the skin as close to the lateral margin of the external nares as possible to ensure tube stability.
    B. Once the first ligature is made, pass the suture around the tube several times in a bootlace pattern and then tie the suture in place.
    C. Pass the second suture through an adhesive butterfly tape around the tube and into the skin along the dorsal midline of the head.
X. Attach an IV extension tube to the exposed end of the nasal tube to allow for appropriate connections and free movement of the animal.
XI. An Elizabethan collar is usually required to prevent tube removal by the animal.
XII. The tube may be left open to allow constant decompression of gas, or it may be capped with an IV catheter cap and opened intermittently for infusion of nutrients and intermittent evacuations.
XIII. A variety of canine and feline liquid diets are available for use with this type of feeding tube (Table 3-1) (Wortinger, 2006).
XIV. Flush the tube periodically to maintain lumen patency.

FIGURE 3-6 Correct placement of a nasal feeding tube.

Complications

I. Mild discomfort and rhinitis can occur, although animal compliance is usually good.
II. Nasogastric tubes may predispose to gastroesophageal reflux or produce gastric irritation and vomition, which can be decreased by placing the tube in the distal esophagus.
III. Vomiting or regurgitation from other causes can alter tube location, which can be verified with radiography and/or capnography (Johnson et al., 2000).
IV. If the liquid diet is too thick, the tube may become plugged.
    A. Flushing the tube before and after feedings helps keep it from clogging.
    B. Use of a syringe pump also decreases clogging of the tube.
V. Feeding of cold liquids or too rapid administration may result in vomiting.
VI. Feeding of hot foods may cause damage to the esophageal or gastric mucosa.
VII. If hyperosmolar solutions are used, diarrhea may occur, which can be minimized by diluting the formulation to an osmolarity between 200 and 300 mOsm/kg.

ESOPHAGOSTOMY TUBE PLACEMENT

Definition

I. An esophagostomy tube is placed directly through the skin into the lumen of the rostral esophagus.
II. Vomiting may make it difficult to maintain the tube, but such tubes can be kept in place for weeks to months.

Indications

I. It is indicated in animals that have a functional esophagus, stomach, and intestines.
II. It is designed to provide nutritional support to animals unwilling or unable to eat for various reasons.
    A. Facial or head trauma

TABLE 3-1

Liquid Diets for Use in Tube Feeding

BRAND	MANUFACTURER	INDICATIONS
CliniCare, Renal Care	Abbott CliniCare	Various formulations available; designed to meet protein caloric requirements of dogs and cats but require functional GI integrity
Concentration Instant Diet	Waltham/Pedigree Waltham/Whiskas	Designed to meet protein caloric requirements of dogs and cats but require functional GI integrity
Nutritional Recovery	Iams/Eukanuba	Specifically formulated for critically ill dogs and cats
Formula V Enteral Care	Pet Ag, Inc.	Various formulas of supplemental products available; not designed as a complete diet
Osmolite HN	Ross Nutritional	High in both protein content and quality but difficult to balance both protein and caloric requirements
Peptamen	Nestlé Clinical Nutrition	Complete elemental diet for use in animals with impaired GI function

GI, Gastrointestinal.

B. Oral or esophageal disease or after surgery
C. Anorexia secondary to systemic disease

III. Because esophagostomy tubes are larger than nasoesophageal tubes, different types of gruel may usually be delivered through the tube.

Restraint

I. General anesthesia is usually required.
II. The animal is placed in right lateral recumbency.
III. A mouth gag is used to facilitate placement.

Technique

I. Use a soft latex or rubber catheter (12 to 22 French).
II. Mark the tube so that, when placed, the tip of the catheter will sit in the distal esophagus (approximately at the level of the 7th rib).
III. Advance a long, right-angle hemostat through the cricopharyngeal sphincter.
IV. Force the tip of the hemostat upward to show the position of the incision.
V. Make an incision through the skin, and use blunt dissection to the level of the esophagus.
VI. Open the hemostat slightly, allowing a stab incision to be made through to its tips.
VII. Advance the tip of the hemostat through the wall of the esophagus and out through the skin incision.
VIII. Grasp the end of the feeding tube and pull it into the esophagus and out the mouth until the female end of the tube is left protruding from the neck.
IX. Redirect the distal end of the catheter down the esophagus.
X. Secure the tube with a bootlace suture and place a light bandage.
XI. To remove the tube, cut the sutures and pull the tube, leaving the stoma to heal by second intention.

Complications

I. Proper care when dissecting down to the esophagus will prevent disruption of vessels or nerves.
II. Vomiting may cause displacement of the tube, which may be verified with radiography.
III. Feeding of cold liquids or too-rapid administration may result in vomiting.
IV. Feeding of hot foods may cause damage to the esophageal mucosa.
V. Other complications include premature removal by the animal and secondary infection of the skin at the entrance site.

PERCUTANEOUS TUBE GASTROSTOMY

Definition

This procedure involves the placement of a feeding tube directly through the skin and into the gastric lumen with the use of an endoscope.

Indications

I. Percutaneous endoscopic gastrostomy (PEG) tubes provide long-term (>10 days) nutritional support to animals unwilling or unable to eat for various reasons.
A. Facial and head trauma
B. Oral and esophageal disease or after surgery
C. Anorexia secondary to a systemic disorder (e.g., hepatic lipidosis in cats)
II. The larger diameter of the gastrotomy tube allows for more routine feeding (e.g., a mixture of blended canned food and water).
III. Nutrition is easily administered while the animal is cared for at home.

Restraint

I. General anesthesia with either injectable or inhalation anesthetics is required.
II. The animal is placed in right lateral recumbency, and a mouth gag is used to facilitate the passage of the endoscope.

Technique

I. Clip the hair and aseptically prepare the skin of the left paracostal region.
II. Advance the endoscope through the mouth and esophagus into the gastric lumen; insufflate the stomach with air until the gastric wall is under tension and in contact with the abdominal wall.
III. Select a gastrostomy tube and cannula.
  A. Silicone percutaneous endoscopic gastrostomy kit (see Box 3-1)
  B. A 14 to 20 French mushroom-tipped catheter with a 16-gauge Medicut IV cannula and stylet (see Box 3-1)
IV. Make an appropriate site for tube insertion by endoscopic observation or digital palpation.
V. Advance the cannula (with stylet in place) through the skin, abdominal wall, and gastric wall and into the gastric lumen.
VI. Remove the stylet and place a No. 1 or 2 nonabsorbable suture through the catheter into the stomach.
VII. The suture is grasped in the stomach by a snare from the endoscope; together they are pulled cranially toward the oral cavity.
VIII. The cannula is removed from the abdominal wall and passed tapered end first over the suture exiting the mouth.
IX. Cut the funneled end of the gastrostomy tube to fit inside the catheter, and suture the two together using 3-0 nylon on a straight needle that passes transversely through the catheter sheath and tube.
X. Apply a water-soluble lubricant to the cannula and tube, and pass both through the oral cavity and esophagus and into the stomach, using gentle traction from the transabdominal suture.
XI. Using an endoscope, check for correct positioning (against the left body wall) of the gastrostomy tube.
XII. Using the transabdominal suture exiting the abdomen, pull the cannula and gastrostomy tube through the gastric and abdominal walls (by pushing down on the skin with one hand and placing gentle traction on the suture/cannula with the other) until the mushroom end of the tube comes to rest against the stomach wall.
XIII. Secure the gastrostomy tube to the skin using traction sutures, and mark the tube at the skin margin so it can be monitored for signs of migration.
XIV. Place an adapter and three-way stopcock at the end of the tube to allow for intermittent feedings, and apply a light abdominal bandage over the tube.
XV. The tube should remain in place for a minimum of 10 to 14 days to decrease the incidence of peritonitis after tube removal.
XVI. To remove the tube, cut the sutures using one of the two following methods.
  A. Apply steady outward traction to the tube until the mushroom tip collapses and the tube can be pulled out through the abdominal wall.
  B. Pull the tube up against the body wall and then cut it flush at the skin, allowing the mushroom tip to fall back into the stomach and pass out the gastrointestinal tract (medium to large dogs) or be retrieved endoscopically (small dogs and cats).
XVII. An alternative method is blind percutaneous gastrostomy tube placement.
  A. Positioning and preparation is the same as for endoscopic placement.
  B. The device (see Box 3-1) is blindly and carefully advanced into the stomach lumen, until the tip can be seen pushing on the skin behind the last rib.
  C. The plunger on the handle is depressed until the trocar penetrates the skin.
  D. Pass a suture through a hole in the tip of the trocar, and withdraw the device from the animal.
  E. Placement of the tube from this point is identical to the endoscopic placement.
XVIII. For prolonged tube feedings (>12 to 16 weeks), the original PEG tube can be replaced by a low-profile silicone or Foley-type gastrostomy tube, which is less likely to be dislodged or removed by the animal.
  A. Manually insert the tube through the existing stoma.
  B. Sedation or anesthesia may be needed for the insertion.
  C. Silicone tubes may be used as long as 1 year, without requiring replacement.

Complications

I. Bloody or purulent peristomal discharge, peristomal swelling and inflammation (dermatitis)
II. Discomfort and chewing at the device
III. Premature removal of the tube, leakage around the tube, peritonitis
IV. Migration of the mushroom catheter tip into the pyloric antrum, causing vomiting
V. Splenic or intestinal laceration if either organ slips between the stomach and body wall during cannulation (higher incidence with the blind placement method)
VI. Pneumoperitoneum
VII. Vomiting from feeding of cold liquids or too rapid administration
VIII. Damage to the gastric mucosa from feeding of hot foods

BLOOD PRESSURE MEASUREMENT

Definition

I. Direct methods of measuring blood pressure involve insertion of a saline-filled catheter into an artery and using a pressure transducer.
II. Indirect methods of measuring blood pressure involve using an inflatable cuff and measuring arterial wall motion or blood flow after arterial occlusion.
III. The following discussion is limited to indirect blood pressure measurement.

Indications

I. Monitoring of surgical and critically ill animals
II. Shock assessment
III. Detection of hypertensive states

A. Cardiovascular and renal disease
B. Endocrine disorders
C. Neurologic and ocular disease
D. Hypercalcemia
E. Anemia and polycythemia
F. Obesity and aging

IV. Monitoring of animals on antihypertensive therapy
V. Monitoring of animals on drugs that may be hyper- or hypotensive

Restraint

I. Animals must be relaxed and minimally restrained
II. Measurements are performed in lateral or sternal recumbency or on some animals while they are standing.
III. Chemical restraint is not used, because blood pressure may be affected.

Technique

I. Oscillometric
   A. Place an inflatable cuff between the elbow and carpus on the foreleg or just below the hock on the hind leg.
   B. The width of the cuff is approximately 40% of limb circumference.
   C. The cuff is automatically inflated and deflated at a predetermined rate.
   D. The machine automatically displays pulse rate and systolic, diastolic, and mean arterial blood pressure.
   E. Five consecutive readings are obtained.
      1. The highest and lowest measurements are discarded, and the remaining three are averaged.
      2. Alternatively, three measurements can be used if the results are fairly consistent.
   F. This method is most accurate in animals >15 lb.
II. Doppler
   A. Place an inflatable cuff in one of the following locations:
      1. Mid-foreleg
      2. Just distal to the hock
      3. Around the tail base
      4. Below the stifle (cats)
   B. The width of the cuff is approximately 40% of limb circumference.
   C. A patch of hair is clipped distal to the cuff over the palpable artery on the palmar or plantar surface.
   D. The ultrasound transducer with coupling gel is placed over the clipped skin and positioned so that arterial flow is audible, and the transducer is taped or held in place.
   E. The cuff is inflated by a sphygmomanometer until arterial flow ceases and audible flow has disappeared.
   F. Cuff pressure is slowly reduced until flow is reestablished and flow sounds can be heard, which indicates the systolic blood pressure.
   G. Continued reduction of cuff pressure results in a change in sound quality that corresponds to diastolic pressure.
   H. Several readings are taken for accuracy.
   I. Diastolic blood pressure measurements may not be accurate or obtainable in many animals.

Complications

I. Stress may cause a falsely elevated blood pressure.
II. Inappropriate cuff size or placement may give erroneous results.
III. Doppler readings are somewhat subjective in relying on auditory signals for measurements.
IV. Oscillometric measurements may be difficult to determine in low-flow states.

FINE-NEEDLE ASPIRATION

Definition

Fine-needle aspiration involves the introduction of a small-gauge needle into a tissue or organ and removal of a small amount of tissue by suction.

Indications

I. Differentiate causes of organomegaly involving lymph nodes, spleen, liver, and other organs
II. Differentiate between inflammation, hyperplasia, and neoplasia
III. Differentiate benign from malignant neoplasia
IV. Differentiate carcinomas, sarcomas, and round (discrete) cell tumors

Restraint and Technique

I. Manual restraint alone is sufficient in most animals.
II. Attach a small-gauge needle (23 to 25 gauge) to a 12- to 20-mL sterile syringe.
III. A needle alone (not attached to a syringe) can be used in some tissues to minimize damage to the cells and peripheral blood contamination.
   A. Lymph nodes
   B. Cutaneous masses
   C. Subcutaneous masses
IV. If the mass is superficial, sterile preparation is not mandatory.
V. Aseptic technique is required when aspirating masses or organs within body cavities.
VI. Advance the needle into the tissue; apply 6 to 8 mL of suction if using a syringe.
VII. Redirect the needle is redirected two to three times, release suction , and withdraw the needle.
VIII. Detach the needle, aspirate air into the syringe, reattach the needle, and express the sample onto a slide, making a smear.
IX. Several samples may be needed to obtain a diagnostic smear.

Complications

I. Minor hemorrhage
II. Tissue damage

BONE MARROW ASPIRATE/BIOPSY

Definition

Bone marrow samples may be obtained by aspiration through a bone marrow needle or by punch-type biopsy through a trephine instrument (core biopsy).

Indications

I. Aspirate or core biopsy
   A. Nonregenerative anemias
   B. Suspected bone marrow disease: myeloid or erythroid suppression, neoplasia
   C. Certain clotting disorders, especially involving platelets
II. Core biopsy
   A. To study the structural architecture of the bone marrow
   B. When aspiration biopsies have been unsuccessful
   C. When searching for metastatic or occult neoplasia
   D. Certain metabolic disorders of bone

Restraint

I. Most biopsies may be performed using local anesthesia, with or without mild sedation.
II. The position of restraint is determined by the site to be biopsied.
   A. Wing of ilium (Figure 3-7)
      1. Large dog: standing or sternal recumbency
      2. Small dog or cat: sternal recumbency with hind legs drawn up alongside the abdomen
   B. Proximal femur: lateral recumbency (Figure 3-8)
   C. Rib: sternal or lateral recumbency (Figure 3-9)
   D. Proximal humerus: lateral recumbency (Figure 3-10)
   E. Other less commonly used sites: ischial tuberosity, sternum

Technique

I. Shave the hair over the biopsy site, which is then prepared aseptically and infiltrated with local anesthesia down to periosteum.
II. Make a small stab incision in the skin with a scalpel blade.
III. Aspirate bone marrow.
   A. Select a 16- or 18-gauge, 1.5-inch Osgood or Rosenthal (see Box 3-1) biopsy needle.
   B. With the stylet in place, advance the needle through the soft tissues until it meets resistance at bone.
   C. Push the needle through the bone by applying pressure with a simultaneous rotating motion.

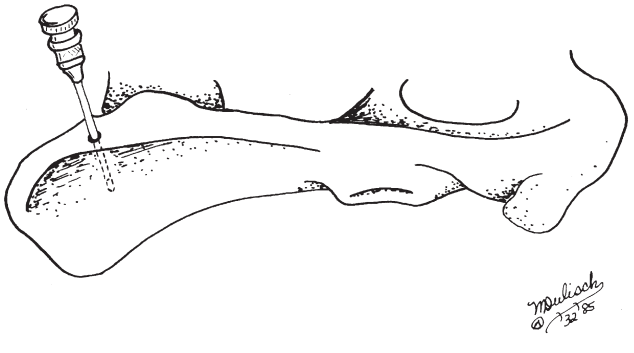

FIGURE 3-7 Insertion of bone marrow needle through the dorsal iliac spine into the marrow cavity of the wing of the ilium. The medial and lateral aspects of the spine are localized with the thumb and forefinger of one hand. With the other hand, the needle is directed ventrally and slightly laterally into the central portion of the wing of the ilium.

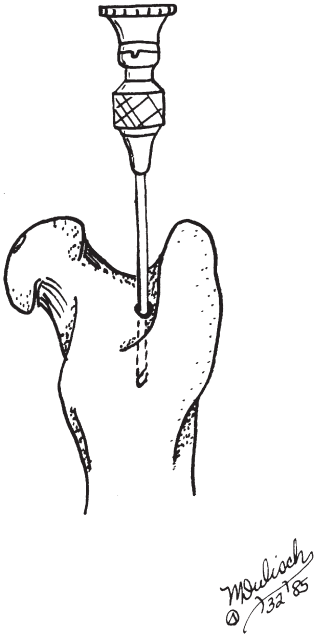

FIGURE 3-8 To retrieve a sample from the marrow cavity of the proximal femur, a bone marrow needle is advanced through the trochanteric fossa caudal and medial to the greater trochanter and directed laterally in a line parallel to the shaft of the femur.

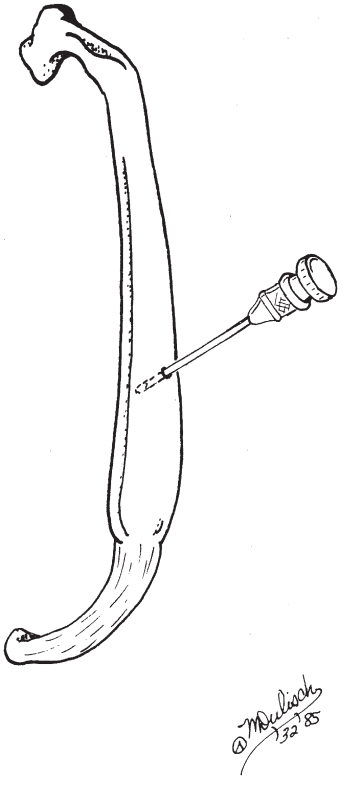

FIGURE 3-9 Bone marrow aspiration from a rib. Usually the 7th, 8th, or 9th rib is chosen. The biopsy needle is inserted at a slightly ventral angle at a point midway from the neck of the rib to the costal cartilage.

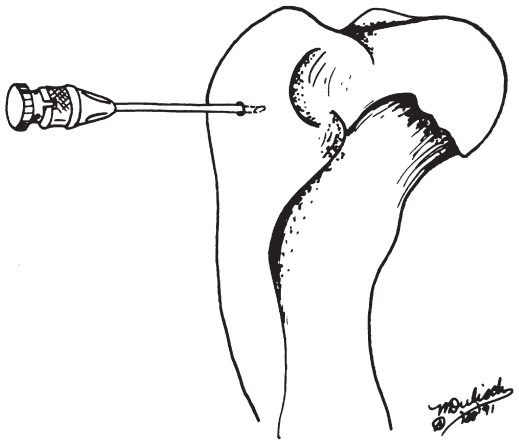

FIGURE 3-10 Bone marrow from the humerus is obtained by palpating the bony prominence of the greater tubercle lateral to the biceps tendon. The needle is inserted at a spot perpendicular to the long axis of the bone.

D. Decreased resistance indicates that the needle has passed through the cortex into the marrow cavity.
E. After advancing the needle into the marrow, remove the stylet, attach a 12-mL syringe, and exert negative pressure on the syringe.
   1. Evidence of pain with aspiration usually indicates that the needle is located within the marrow cavity.
   2. When marrow appears in the syringe, aspiration is halted and the syringe disconnected.
   3. Overzealous aspiration may lead to contamination of the sample with peripheral blood.
   4. Smears are quickly made on glass slides, and any clot is saved in formalin for histologic examination.
   5. A sample may also be submitted for culture.
F. If adequate marrow is retrieved, withdraw the needle.
G. The skin incision may be sutured or left to heal by second intention.

IV. Core biopsy
   A. Using a core biopsy instrument (e.g., Jamshidi bone marrow needle), advance the needle, with the stylet in place, through the soft tissues and then into bone, with steady pressure and a back-and-forth rotating motion.
   B. Once through the cortex, remove the stylet and push the trephine instrument into the marrow, advanced for 1 to 2 cm and then rotated around its long axis several times.
   C. Remove the needle, retrieve the core sample using the extending probe, and place the sample in formalin.

Complications

I. Complications are rare.
II. Damage to adjacent structures may occur.
   A. Poor positioning of the needle in the trochanteric fossa may damage the sciatic nerve.
   B. Accidental pneumothorax or laceration of intercostal vessels may accompany rib biopsies.
III. Infiltration of the trochanteric fossa with local anesthetic may result in transient paresis of the sciatic nerve.

ARTHROCENTESIS

Definition

Arthrocentesis is the percutaneous placement of a needle into a synovial cavity for the collection of synovial fluid for laboratory analysis.

Indications

I. As a diagnostic aid in suspected cases of inflammatory joint disease
   A. Septic or infectious arthritis
   B. Immune-mediated arthritis
   C. Hemarthrosis and traumatic synovial effusion
II. Insertion of contrast medium for radiographic evaluation (see Chapter 4)
III. Administration of therapeutic agents intrasynovially

Restraint

I. Local anesthesia and mild chemical sedation may be necessary depending on the temperament of the animal.
II. Lateral recumbency is used for centesis of the stifle, hock, elbow, and shoulder joints.
III. Centesis of the carpal joint may be performed in either lateral or sternal recumbency.

Technique

I. Clip the hair and aseptically prepare the skin over the affected joint.
II. Palpation of the distended joint capsule or the joint space must be precise before placing the needle.
III. A thorough knowledge of the joint and periarticular anatomy is essential for accurate needle placement (Figures 3-11 to 3-13).
IV. Attach a 22-gauge needle to a 3- or 6-mL syringe and advance it slowly through the skin, subcutaneous, periarticular, and synovial tissues to enter the synovial cavity.
V. Aspiration of the syringe results in collection of synovial fluid.
VI. Release suction is released and withdraw the needle when sufficient fluid (0.1 to 0.5 mL) has been collected.
VII. Place the fluid in EDTA tubes for cytologic study and in transport medium or thioglycolate broth for microbiologic analysis.
   A. Thin smears also are prepared and air-dried.
   B. Observe the viscosity of the fluid while preparing slides.
VIII. In suggested cases of polyarthritis, multiple joints are aspirated.

Complications

I. Inadequate preparation of the skin may result in bacterial inoculation of the joint or contamination of the specimen.
II. Intrasynovial trauma from the needle or repeated centesis may result in hemarthrosis or abrasion of the articular cartilage if technique is suboptimal.
III. Direct needle-induced damage to the periarticular blood vessels or nerves may occur if anatomical considerations are overlooked.

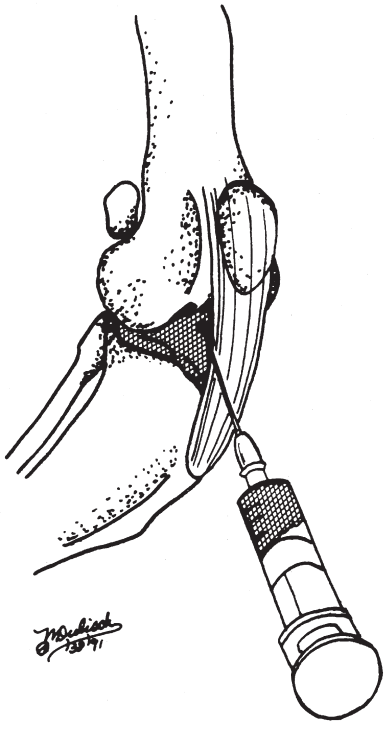

FIGURE 3-11 With the stifle joint partially flexed, the distal edge of the patella and proximal edge of the tibial tuberosity are palpated. The joint is entered at a spot approximately one third of the way between these two structures. Insert the needle into the joint just lateral to the straight patellar ligament and direct it slightly medially into the area between the two femoral condyles.

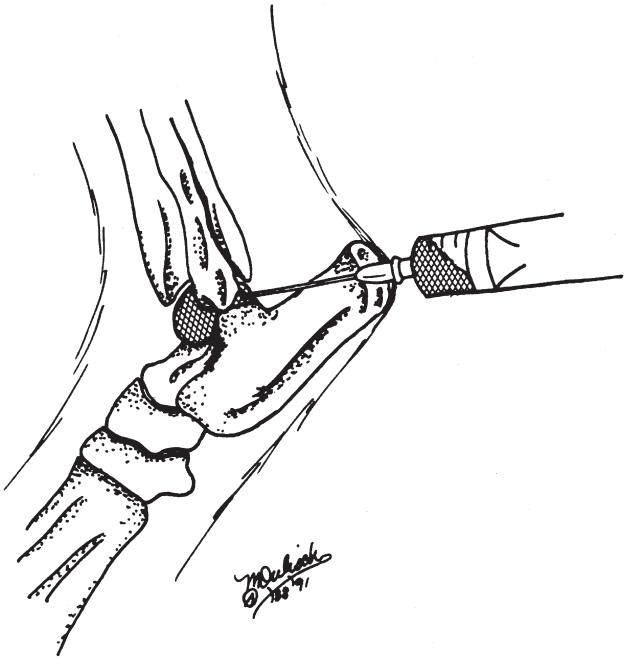

FIGURE 3-12 With the hock partially flexed, the tibiotarsal joint is entered laterally by inserting the needle under the malleolus from the plantar side. Care is taken to avoid the caudal branch of the lateral saphenous vein.

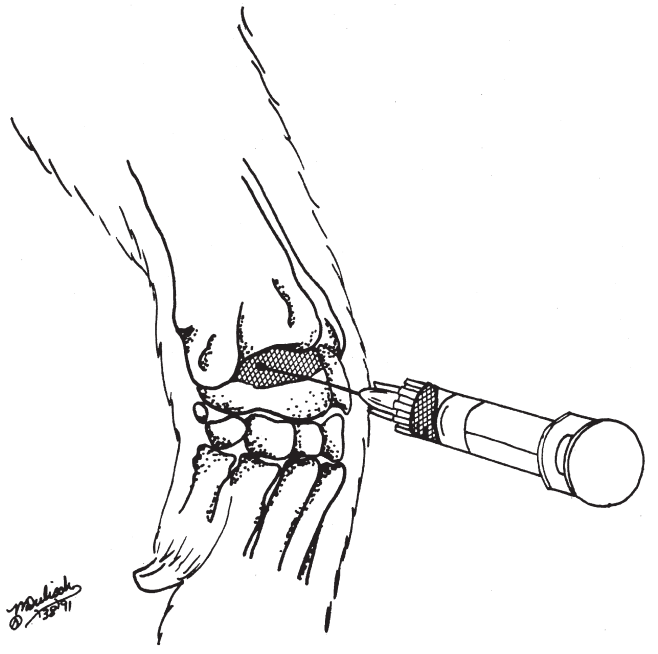

FIGURE 3-13 With the carpus partially flexed, the carpal joint is aspirated by inserting a needle into the medial radiocarpal space or between any of the palpable intercarpal spaces.

IV. Contamination of the sample with iatrogenic hemorrhage may necessitate centesis of another joint or repeated centesis of the same joint 48 hours later.

BONE BIOPSY

Definition

A trephine bone biopsy is the collection of a full-thickness specimen of bone for histopathologic and microbiologic analysis.

Indications

I. Obtaining a specimen for histological examination after radiographic evidence of a lesion involving bone, in certain suspected cases
   A. Primary or secondary neoplasia
   B. Bacterial, mycotic, or parasitic infection
   C. Developmental (idiopathic) or degenerative diseases of bone: panosteitis, hypertrophic osteodystrophy, hypertrophic pulmonary osteoarthropathy, and others.

II. Obtaining material for culture

Restraint and Technique

I. General anesthesia is required.
II. A wide area of skin around the affected site is clipped and prepared for aseptic surgery.
III. Radiographs are used to select an appropriate site to insert and direct the biopsy instrument.
IV. Make a 1-cm incision over the selected site.
V. Retract the subcutaneous, muscle, tendon, and deep fascial tissues to gain access to the periosteal surface.

VI. Using an appropriately sized Michel trephine biopsy instrument without stylet (see Box 3-1), use an oscillating, twisting motion to advance the instrument through the cortical bone, across the medullary cavity, and through the opposite cortex.
VII. Palpation of the trephine in the subcutaneous tissues indicates complete full-thickness biopsy.
VIII. Withdraw the trephine and insert the stylet to eject the core into bacteriologic transport medium or 10% formalin solution for microbiologic or histopathologic examination, respectively.
IX. Bleeding from the biopsy site is controlled with direct pressure and closure of the deep tissues.
X. Additional specimens may be collected until the surgeon is comfortable that a diagnostic sample has been obtained.

Complications

I. False-negative results may be obtained if inadequate or inappropriate tissues are collected.
   A. Careful radiographic analysis and collection of multiple samples minimize this complication.
   B. When samples are obtained for histopathology, avoid soft, necrotic bone and locate the biopsy site close to the junction with radiographically normal tissue.
II. Pathologic fractures may result from weakening of the bone.
   A. Such problems may be avoided by selecting smaller trephines and limiting the number of samples taken.
   B. External coaptation is used postoperatively if a secondary pathologic fracture is feared.

CHAPTER 4

Contrast Radiography

Lance Rozear

GENERAL CONSIDERATIONS

Purpose

I. To identify and characterize anatomical and pathologic findings that are not adequately evaluated on survey radiographs
II. To provide qualitative information on the function of selected systems

Contrast Agents

I. Positive and negative contrast agents
  A. Positive contrast agents contain atoms of high atomic number (barium and iodine) that attenuate x-rays with great efficiency, increasing their radiographic opacity.
  B. Negative contrast agents are gases with low physical density (carbon dioxide, room air, nitrous oxide) and low x-ray attenuation, therefore decreasing radiographic opacity.
  C. Double-contrast studies use a small amount of positive contrast medium to coat mucosal surfaces in combination with a larger volume of negative contrast medium to inflate the structure and enhance surface visualization.
II. Barium sulfate (Table 4-1)
  A. High atomic number and density that attenuates the majority of incident x-rays and appears opaque (white) on radiographs
  B. Insoluble compound that passes unchanged and unabsorbed as a suspension through the gastrointestinal (GI) tract with a predictable transit time
  C. Nonirritating to mucosal surfaces; provides good mucosal coating
  D. Used in routine imaging of the GI tract
  E. Available formulations
    1. Barium sulfate powder (USP)
      a. Mixed on site for reconstitution at desired volume and concentration
      b. Inexpensive
      c. Tends to precipitate and flocculate, confusing mucosal detail
    2. Commercially prepared barium sulfate suspension
      a. Most commonly used, inexpensive
      b. Provided in 100% weight/volume (w/v) colloidal suspension; diluted to desired concentration
      c. For GI studies
      d. Provides good mucosal detail
    3. Barium sulfate paste
      a. Viscous
      b. Good for evaluation of the esophagus, because the paste coats the mucosa for longer periods
      c. Not useful for stomach or intestinal studies
    4. Solid radiopaque markers or barium-impregnated polyethylene spheres (BIPS; Med ID, Grand Rapids, Mich.)
      a. Spheres available in differing sizes in gelatin capsules
      b. Uniformly sized spheres or a combination of sizes in capsules
      c. Used to evaluate GI transit time and for the diagnosis of GI obstruction
  F. Potential adverse effects and complications
    1. Aspiration
      a. If the amount is small and confined to the major airways, it is removed via the mucociliary apparatus and swallowed.
      b. If a small amount reaches the alveoli, it may cause a local granulomatous reaction or be sequestered in regional lymph nodes.
      c. Inadvertent passage of orogastric tube into the trachea or aspiration of a large volume may cause a severe inflammatory reaction and possibly death.
    2. Leakage
      a. If barium leaks into the peritoneal, pleural, or mediastinal space, it can cause a severe granulomatous inflammation.
      b. It is *not* recommended in cases of suspected GI perforation.
    3. May cause constipation (rare)
III. Ionic water-soluble contrast media (ICM) (see Table 4-1)
  A. Characteristics
    1. ICM are monomeric or dimeric derivatives of benzoic acid containing iodine that have a high atomic number and appear opaque (white) on radiographs.
    2. They include sodium or methylglucamine (meglumine) salts.
    3. They have variable osmolality (580 to 2100 mOsm/kg H_2O) and generally higher osmolality than nonionic compounds.

TABLE 4-1

Examples of Contrast Agents, Including Some Basic Chemical Properties

CONTRAST CLASS	GENERIC NAME	BRAND NAME	MANUFACTURER	CONCENTRATION*	OSMOLALITY (mOsm/kg H_2O)
Nonionic contrast media (NICM)	Iohexol	Omnipaque	GE Healthcare	140	322
				180	408
				240	520
				300	672
				350	844
	Iopamidol	Isovue	Bracco Diagnostics	200	413
				250	524
				300	616
				370	796
	Ioversol (not labeled for intrathecal use)	Optiray	Mallinckrodt	160	355
				240	502
				300	651
				320	702
				350	792
Ionic contrast media (ICM)	Diatrizoate meglumine (Meg)/sodium (Na)	Renograffin-60	Bracco Diagnostics	292.5	1450
		Renocal-76	Bracco Diagnostics	370	1870
		MD-76R	Mallinckrodt	370	1551
	Diatrizoate Meg	Hypaque Meglumine-60	GE Healthcare	282	1415
		Reno-dip	Bracco Diagnostics	141	588
		Reno-30	Bracco Diagnostics	141	673
		Reno-60	Bracco Diagnostics	282	1404
	Diatrizoate Na	Hypaque Na-20	GE Healthcare	120	
	Iothalamate Meg	Cysto-conray	Mallinckrodt	81	N/A
		Cysto-conray II		282	1400
		Conray		141	600
		Conray30		202	1000
		Conray43			
Barium	Iothalamate Na	Conray400	Mallinckrodt	400	2300
	BaSO4 suspension	Liquid Polibar	E-Z-EM	100	N/A
	BaSO4 paste	Intropaste	Lafayette	70	N/A
	Barium-impregnated polyethylene spheres (BIPS)	BIPS	Med ID	N/A	N/A

*For aqueous iodine solutions (NICM and ICM), concentrations are given in milligrams of iodine/milliliter solution (mg I/mL). For barium products, concentration is given in percent weight in grams of barium/100 mL final solution (% w/v).

   a. Monomeric agents have high osmolality (1200 to 2100 mOsm/kg H_2O).
   b. Dimeric agents are lower in osmolality, and are therefore less toxic (≈600 mOsm/kg H_2O).
4. Most agents are excreted predominantly by the kidneys because of low protein binding.
5. An alternate route of excretion through the GI tract and liver occurs in cases of renal dysfunction (vicarious excretion).
6. Higher protein-binding agents (e.g., ioxaglate) are excreted by the liver in the bile.
7. They are relatively inexpensive.

B. Uses
1. IV contrast studies: angiography, IV urography
2. Retrograde lower urinary tract imaging: cystography, urethrography
3. Fistulography, pleuro/peritoneography, lymphangiography, arthrography
4. *Not for intrathecal use*

C. Formulations
1. Provided in sterilized single- or multiple-dose vials
2. Sodium or meglumine salts, or a combination of both
   a. Sodium salts are lower in viscosity and easier to inject; however, they are more toxic.
   b. Meglumine salts are higher in viscosity and more difficult to inject rapidly, but they are less toxic.

c. Combinations with varying proportions of each salt are commonly used to compromise between viscosity and toxicity.

D. Adverse effects/complications (rare)
1. Primarily related to hypertonicity
a. Irritating to tissues if extravasated
(1) Possible soft tissue slough
(2) Treated with cold compresses ± local infiltration of physiological saline as a diluent
b. Pain at injection site
c. Salivation, nausea, vomiting: IV or oral administration
d. Sequestration of fluid in GI tract (if orally administered), creating fluid/electrolyte imbalances; *not* recommended for GI studies
e. Transient increase in blood volume from increased plasma osmotic pressure: danger for animals with cardiac disease
f. Peripheral vasodilation: danger for animals with cardiac disease
g. Osmotic diuresis: danger for animals with cardiac or renal disease
h. Increased capillary permeability: can alter blood-brain barrier
i. Crenates red blood cells (RBCs) that can then obstruct capillaries: most serious for myocardium, brain, and kidneys
j. Pulmonary edema as a result of hypertonicity if aspirated
2. Contrast-induced renal failure
a. Varies from clinically insignificant to anuric renal failure
b. Generally reversible with IV fluid therapy
3. Chemotoxicity
a. Sodium salts more toxic than meglumine salts
b. Damage to blood-brain barrier, heart, and kidneys
c. Electrolyte imbalances
4. Idiopathic, anaphylactoid, or pseudoallergic reactions
a. Unpredictable, variable in severity
b. Do not require previous exposure to contrast media
c. Signs: urticaria, sneezing, decrease in blood pressure, tachycardia, facial swelling, laryngeal edema, pulmonary and cerebral edema, bronchospasm, and cardiovascular collapse
5. Potential risk factors: multiple myeloma; diabetes mellitus; advanced age; chronic renal, hepatic, or cardiac disease

IV. Nonionic water-soluble contrast media (NICM) (see Table 4-1)
A. Characteristics
1. Monomeric (most common) and dimeric derivatives of benzoic acid
2. Generally lower osmolality than ionic compounds (300 to 1000 mOsm/kg H_2O)
3. Excreted almost exclusively by the kidneys
4. Relatively expensive
5. Safest of the positive contrast media; associated with the fewest adverse effects

B. Uses
1. Same as ICM
2. Labeled for intrathecal injection (except for Ioversol)
3. Safest media to use near nervous system (myelography, epidurography, discography)
4. Do not cause fluid sequestration in GI tract as do ICM; safer for oral use

C. Adverse effects
1. Idiopathic reactions are similar to those of high-osmolar ionic media, but with much lower incidence.
2. Dimeric agents are viscous, and difficult to use in veterinary myelography (Widmer and Blevins, 1991).
3. In neurologic imaging procedures, rare adverse reactions include seizures, convulsions, radicular pain, and transient exacerbation of neurologic signs.
4. If extravasated or aspirated, NICM cause a less severe reaction than do ICM.

V. Negative contrast agents
A. Characteristics
1. Gases: room air, carbon dioxide (CO_2), nitrous oxide (rarely used)
2. Low physical density and relatively low atomic number
3. Attenuate few incident x-rays; appear radiolucent (black) on radiographs

B. Uses
1. Can be instilled into the lower urinary or GI tract for single-contrast studies
2. Most often used in double-contrast studies to inflate the lower urinary or GI tract precoated with positive contrast for visualization of mucosal detail

C. Adverse effects
1. Venous gas embolization can occur.
a. CO_2 is more soluble than room air and is therefore safer.
b. With animal in left lateral recumbency, small amounts of gas are trapped in the right side of the heart and do not travel into the pulmonary artery.
2. Pneumoabdomen/pneumomediastinum may develop if the gas extravasates.

ESOPHAGOGRAPHY

Definition

I. Dynamic or static contrast study of the pharynx and esophagus
II. Dynamic study performed with fluoroscopy; static study performed with radiographs
III. Evaluates swallowing reflex, motility, and structural aspects of the pharynx and esophagus

Indications

I. Dysphagia, regurgitation, gagging or retching, recurrent aspiration pneumonia
II. Suspected esophageal rupture or bronchoesophageal fistula
III. Stricture, ulceration, foreign body, mass, or diverticulum
IV. Localizing esophagus in relation to normal or abnormal mediastinal structures
V. Evaluation of possible esophageal lesion seen in survey radiographs
VI. Evaluation of motility, sphincter function, and swallowing reflex

Contraindications

I. Increased risk of aspiration (altered mental state, intractable vomiting)
II. With suspected rupture or fistulation, risk of barium entering the mediastinum or lung
III. Probable transient hypomotility/dilation from aerophagia, dyspnea, pain, or sedation

Alternative Imaging Procedures

I. Mediastinal/cervical ultrasonography: can evaluate paraesophageal structures in the neck and ventral mediastinum
II. Endoscopy: cannot assess motility, but can evaluate lumen and mucosa and obtain biopsy
III. Computed tomography: cannot assess motility

Preparation of Animal

I. Fasted 12 to 24 hours to encourage voluntary consumption of contrast agents
II. Survey thoracic and cervical/pharyngeal radiographs
III. May require sedation; however, this is undesirable because of effects on motility

Technique

I. Place animal in lateral recumbency.
II. Administer contrast medium per os into the buccal pouch.
  A. Barium sulfate liquid suspension (30% w/v)
  B. Barium sulfate paste
  C. Moist food mixed with barium paste
  D. Kibble mixed with barium paste
III. Begin with liquid, followed by paste, then soft food, and finally contrast-coated kibble.
IV. For each administration of contrast medium, monitor swallowing and transport of contrast to the stomach with fluoroscopy or with orthogonal radiographs made post-swallowing.

Normal Findings

I. Oropharyngeal phase
  A. Formation of bolus at base of tongue
  B. Rapid propulsion of bolus from base of tongue to cricopharyngeal sphincter over a closed glottis via peristaltic contraction of the pharynx
  C. Simultaneous opening of the cricopharyngeal sphincter to accept bolus
II. Esophageal phase
  A. Primary peristaltic waves begin upon acceptance of a bolus from the oropharynx, and may continue to the stomach. Primary waves are stimulated by the oropharyngeal phase.
  B. Secondary peristaltic waves are initiated to carry incompletely delivered boluses to the stomach. These waves are independent of the oropharyngeal phase.
III. Gastroesophageal phase
  A. Opening of the lower esophageal sphincter and passage of bolus into the stomach
  B. May see transient reflux of small amount in normal animals, but clears quickly
IV. Mucosal appearance
  A. Smooth and intact
  B. Mucosal folds: linear striations
    1. Dogs: longitudinally oriented throughout the length of the esophagus
    2. Cats: oblique or "herringbone" striations in the distal one third of the esophagus

Abnormal Findings

I. Diverticula: congenital or acquired
II. Abnormalities of oropharyngeal phase
  A. Incoordination of bolus propulsion and glottis closing, or opening of cricopharyngeal sphincter (dyssynergia)
  B. Mass in pharynx, preventing bolus formation or passage (neoplasia, abscess, granuloma, cyst)
  C. Stricture or spasm at cricopharyngeal sphincter, preventing opening (achalasia)
  D. Neuromuscular disorder or anesthesia-induced failure of the cricopharyngeal sphincter to contract (chalasia)
III. Abnormalities of peristalsis
  A. Delayed primary or secondary peristalsis
  B. Aperistalsis (diffuse vs focal)
    1. May be accompanied by esophageal dilatation (megaesophagus)
    2. Mechanical: vascular ring anomaly, gastroesophageal achalasia, foreign body, or mass
    3. Neuromuscular: idiopathic megaesophagus, myasthenia gravis, lead toxicity, thymoma, others
  C. Gastroesophageal reflux: possibly increased with sedation
IV. Mass effects
  A. Intraluminal: foreign body, gastroesophageal intussusception, polypoid mass
  B. Mural: stricture, mass (abscess, neoplasm, granuloma)
  C. Extramural
    1. Mediastinal, pulmonary or heart base mass: abscess, granuloma, neoplasm, lymphadenopathy
    2. Hiatal hernia: sliding, permanent
V. Extravasation: perforation, fistulation
VI. Mucosal abnormalities
  A. Ulceration
    1. Retention of barium; may see a crater ± increased wall thickness
    2. May be benign or associated with neoplasia

B. Esophagitis
   1. Irregular mucosal pattern
   2. Secondary to vomiting, reflux, or mechanical or chemical irritation

Complications

I. Aspiration is the major concern. Discontinue the procedure and obtain thoracic radiographs to determine the location and amount of aspirated material.
II. Leakage of barium into mediastinum through an unanticipated perforation is also possible.

GASTROGRAPHY

Definition

I. Gastric contrast procedure using negative (pneumogastrography) or both positive and negative contrast media (double-contrast gastrography)
II. Allows detailed examination of gastric mucosa, lumen, and wall
III. Does not evaluate motility

Indications

I. Chronic vomiting
II. Suspected gastric wall lesion (ulcer, mass)
III. Suspected gastric foreign body
IV. Abnormal appearance on survey radiographs

Contraindications

I. Increased risk of positive contrast media aspiration (altered mental state, intractable vomiting)
II. High suspicion of gastric rupture, perforation, or wall necrosis
III. Unable to pass gastric tube because of pharyngeal or esophageal disease

Alternative Imaging Procedures

I. Upper GI series
II. Ultrasonography
III. Endoscopy
IV. Nuclear scintigraphy: evaluation of motility, localization of GI bleeding
V. Computed tomography

Preparation of Animal

I. Fasted for 12 to 24 hours and cleansing enemas to empty GI tract
II. Sedation or anesthesia (for double-contrast study)
III. Administration of glucagon to decrease gastric motility, allowing visualization of structure without peristalsis (optional for pneumogastrography)
   A. Dogs: 0.1 to 0.35 mg/kg IV (lower doses in smaller animals); cats: 0.1 mg IV
   B. Maximum dose: 1 mg
   C. Lasts approximately 15 minutes; may be repeated
   D. Contraindications to glucagon: pheochromocytoma, uncontrolled diabetes mellitus

Technique

I. Double-contrast gastrography
   A. Via orogastric tube, administer barium sulfate suspension (30% w/v) at 1.5 to 3 mL/kg in dogs (higher dose for smaller dogs), and 3 mL/kg in cats.
   B. Inflate stomach with approximately 20 mL/kg gas (dogs) until stomach is distended.
   C. Withdraw the tube and rotate animal 360° about the longitudinal axis of the body.
   D. Obtain ventrodorsal (VD), dorsoventral (DV), and right and left lateral views.
II. Pneumogastrography
   A. Via orogastric tube, inflate stomach with approximately 20 mL/kg gas (dogs) until stomach is distended.
   B. Alternatively, administer 60 mL of a carbonated beverage.
   C. Kink and quickly withdraw tube.
   D. Obtain VD and left lateral abdominal radiographs immediately, with additional views as needed.

Normal Findings

I. Rugal folds: linear striations running parallel to the axis of the stomach
II. Lower esophageal sphincter: "star" pattern of rugae on lesser curvature (may not see with pneumogastrography)
III. Smooth, uninterrupted mucosal surface
IV. Normal shape and orientation

Abnormal Findings

I. Double-contrast gastrography
   A. Ulceration: craters of barium retention in the mucosa ± wall thickening; may be benign or neoplastic
   B. Wall masses, circumferential or eccentric: neoplasia, polypoid gastritis, granuloma
   C. Thickened wall: gastritis or neoplasia
II. Pneumogastrography
   A. Luminal foreign bodies
   B. Wall masses, circumferential or eccentric: neoplasia, polypoid gastritis, granuloma

Complications

I. Regurgitation/aspiration
II. Iatrogenic damage from intubation or overdistention of diseased organ
III. Discomfort from dilation of stomach (reintubate to decompress)

UPPER GASTROINTESTINAL SERIES

Definition

I. Contrast procedure designed to opacify stomach and small intestine (upper GI tract)
II. Allows evaluation of the lumen, mucosal surfaces, motility, and contents

Indications

I. Signs of gastric or small intestinal disease: acute or chronic vomiting, small bowel diarrhea, anorexia, weight loss, abdominal pain

II. Suspected intestinal obstruction
III. Evaluation of GI transit time
IV. Abdominal mass localization
V. Abnormal appearance of stomach or small intestine on survey radiographs

Contraindications

I. Increased risk of aspiration (altered mental state, intractable vomiting)
II. Suspected perforation (use NICM)
III. Obvious surgical condition on survey radiographs
IV. Unmanageable animal (many radiographs required, sedation undesirable)

Alternative Imaging Procedures

I. Ultrasonography
II. Endoscopy
III. Scintigraphy: motility study, localization of GI bleeding

Preparation of Animal

I. Fasted for 12 to 24 hours and cleansing enemas to empty GI tract
II. Survey orthogonal abdominal radiographs
III. Sedation (if needed) using agents with minimal impact on motility
   A. Dogs: acepromazine 0.025 to 0.05 mg/kg IV, SC, or IM
   B. Cats: ketamine 2 to 4 mg/kg IV with acepromazine 0.05 mg/kg IV or diazepam 0.44 mg/kg IV

Technique

I. Orogastric intubation: preferred over PO administration
II. Barium sulfate suspension (20% to 30% w/v)
   A. Dogs: 6 to 12 mL/kg (larger dose for smaller dogs)
   B. Cats: 12 to 16 mL/kg
III. Questionable GI integrity: NICM used
   A. Use 10 mL/kg to total dose of 240 to 300 mg iodine/mL NICM diluted 1:2 or 1:3 in water.
   B. ICM is *not* recommended because of hypertonic effects on fluid/electrolyte status.
IV. Radiographic views to be obtained
   A. Increase kVp by 5% to 10%
   B. Typical timing of radiographic exposures
      1. Dogs
         a. Immediate VD, DV, and right and left lateral
         b. Lateral and VD views at 30 minutes, 1, 2, 3, and 4 hours
      2. Cats
         a. Immediate VD, DV, and right and left lateral
         b. Lateral and VD at 15 and 30 minutes, then 1, 1.5, and 2 hours
      3. Normal exam: complete when barium clears stomach and reaches colon
      4. Exam with abnormalities: continue as needed to obtain diagnosis

Normal Findings

I. Generalized smooth or finely fimbriated mucosal surfaces
II. Normal focal mucosal irregularities

TABLE 4-2

Typical Times of GI Events for Dogs and Cats With Barium Sulfate Suspension and NICM

EVENT	TIME OF OCCURRENCE	
	DOG	CAT
Contrast Begins To Leave Stomach		
Barium	Immediately to 15 min, maximum 30 min (Moon and Meyer, 1986)	Immediately to 15 min (Morgan, 1981)
NICM	Immediately (Augt et al., 1993)	Immediately (Moon and Meyer, 1986)
Gastric Contents Cleared		
Barium	30-20 min, maximum 4 hr (Miyabayashi et al., 1986; Miyabayashi and Morgan, 1991)	15-60 min, maximum 2 hr (Morgan, 1977, 1981)
NICM	30-120 min (Augut et al., 1993)	30-90 min (Williams et al., 1993)
Contrast Reaches Colon		
Barium	30-120 min (Miyabayashi et al., 1986)	30-60 min, maximum 2 hr (Hogan and Aronson, 1988; Morgan, 1977, 1981)
NICM	60-90 min (Augt et al., 1993)	15-75 min (Williams et al., 1993)
Contrast Clears Small Intestine		
Barium	3-5 hr (Miyabayashi et al., 1986)	Not reported

GI, Gastrointestinal; *NICM,* nonionic water-soluble contrast media.

A. Gastric rugal folds: parallel folds in mucosa running parallel to the greater curvature
B. Lower esophageal sphincter: "star" pattern of rugae on lesser curvature of stomach
C. Peyer's patches: focal outpouchings of contrast into the mucosa of the antimesenteric border of the descending duodenum (dogs only)

III. Transit times (Table 4-2)
IV. Contrast column
A. Peristaltic waves should propel the contrast through the small intestine, showing a contrast column of varying diameters. This can be dramatic in the normal cat duodenum, causing a "string-of-pearls" appearance.
B. Areas of peristaltic activity are transient. Repeatable focal narrowing of the contrast column is an indicator of focal disease.

Abnormal Findings

I. Increased gastric emptying time (motility decreased or transit slowed)
A. Emptying time >4 hours in dogs and >2 hours in cats
B. Mechanical pyloric outflow obstruction
1. Pyloric hypertrophy or stenosis
2. Pyloric mass: neoplasia, granuloma, polyp
3. Foreign body
C. Functional obstruction: pyloric spasm, inflammation, or ulceration
D. Hypomotility from stress, pain, anticholinergic medication, neurological damage, or ischemia or other motility disorder
E. Insufficient dose of barium to initiate peristalsis

II. Increased small intestinal transit time (motility decreased or transit slowed)
A. Generalized
1. Functional ileus from stress, pain, anticholinergic medication, neurologic damage, ischemia, or inflammation
2. Mechanical ileus from obstruction in distal small intestine: foreign body, intussusception, neoplasm, extra-GI masses, entrapment, others
3. Mesenteric volvulus or infarction
B. Focal
1. Mechanical ileus (complete or partial obstruction): focal dilatation of intestine proximal to obstruction
2. "Gravel sign": accumulation of debris and barium immediately proximal to a partially obstructive lesion

III. Decreased small intestinal transit time (faster transit)
A. Enteritis
B. Maldigestion/malabsorption syndrome

IV. Increased contrast column diameter (GI distention)
A. Generalized
1. Functional ileus
2. Distal small intestinal obstruction (chronic)
B. Focal
1. Stomach only: pyloric outflow obstruction (acute or chronic)
2. Small intestine: proximal to obstruction (acute, chronic, partial, or complete)

V. Irregular contrast border
A. Infiltration and rigidity of mucosa
B. Potential causes
1. Inflammation
a. Inflammatory bowel disease
b. Granulomatous enteritis
c. Focal inflammation: irritation from foreign body, parasites
2. Neoplastic infiltration
3. Scarring

VI. Contrast column filling defects
A. Intraluminal
1. Foreign body
2. Parasites
3. Mucosal mass: polyp, neoplasia
B. Mural
1. Circumferential
a. Stricture
b. Neoplasia, most common: lymphoma and adenocarcinoma
2. Eccentric
a. Neoplasia: as lymphoma, adenocarcinoma leiomyoma, leiomyosarcoma, etc.
b. Abscess, granuloma, hematoma
C. Extramural
1. Mass or adjacent structure: lipoma, lymphadenopathy, prostatomegaly, full bladder, etc.
2. Internal hernia

VII. Eccentric outpouching of contrast column and wall defects
A. Ulceration
1. "Crater" of retained barium ± increased surrounding intestinal wall thickness
2. May be benign or associated with neoplasia
B. Diverticulum

Complications

I. Vomiting and aspiration
II. Leakage of contrast at perforation site
III. Barium-induced constipation (rare)
IV. Drooling or emesis with oral NICM
V. Iatrogenic damage
A. Trauma to oral cavity, pharynx, esophagus, or stomach from intubation
B. Rupture of diseased stomach from overdistention
C. Inadvertent deposition of barium into lungs

Solid Radiopaque Marker (BIPS) Study

I. Used when full upper GI study is not necessary or is contraindicated
II. Specific considerations
A. Can be used when obstruction is the primary differential diagnosis
1. Administer BIPS, and obtain radiographs 4 to 12 hours later.
2. BIPS will accumulate proximal to obstruction.
B. Good for uncooperative animals (can hide BIPS in food or administer as pill)
C. Can be used to evaluate GI transit time

1. Variably sized spheres proceed through the GI tract at different rates depending on method of administration (pill form or mixed in soft or dry food).
2. The manufacturer includes information describing normal transit patterns.

COLONOGRAPHY

Definition and Indications

I. Positive, negative, and double-contrast studies of the colon
II. Used in identification and localization of the colon in relation to other abdominal structures
III. Used to evaluate colonic structure, including the wall, lumen, and mucosal surface

Contraindications

I. Inability or unwillingness to sedate or anesthetize the animal
II. Suspected perforation: use NICM *only;* not barium or gas
III. Risk of iatrogenic perforation: severe colitis, known ulceration, or post-biopsy

Alternative Imaging Procedures

I. Ultrasonography
II. Colonoscopy
III. Computed tomography

Preparation of Animal

I. Cleansing enemas, then a 2-hour wait to clear introduced gas and fluid
II. Survey radiographs of abdomen and pelvis

Technique

I. Pneumocolon (for identification/localization purposes only)
   A. Sedation is often unnecessary.
   B. Via a red rubber or tomcat catheter, inject room air or other negative contrast agent at 1 to 3 mL/kg body weight into the rectum.
   C. Obtain VD and lateral abdominal radiographs; both lateral views may be beneficial.
II. Positive and double-contrast colonography (for thorough evaluation of structure)
   A. Anesthesia is required.
   B. A balloon catheter is placed in the rectum and inflated to occlude the anal sphincter.
   C. With the animal in left lateral recumbency, infuse barium sulfate suspension until colon is full (5 to 15 mL/kg body weight).
   D. Use NICM if colonic integrity is questionable.
   E. Obtain VD and lateral radiographs (increase kVp by 5% to 10%).
   F. Remove barium and administer sufficient negative contrast to distend the colon.
      1. Dose is approximately 10 mL/kg.
      2. *Do not overdistend;* monitor with fluoroscopy or radiographs.
   G. Obtain VD, DV, and both lateral radiographs.

Interpretation of Pneumocolon

I. Identifies location of the colon in relation to other abdominal structures
II. Differentiates colon from small intestine

Interpretation of Double-Contrast Colonography

I. Normal findings
   A. Mucosa smooth and intact
   B. Wall thin and regular
   C. Cecum sometimes inflated, without retrograde flow of contrast into distal small intestine (unless overdistended)
II. Abnormal findings
   A. Mucosal defects: ulceration
   B. Filling defects
      1. Intraluminal: unevacuated feces, mucosal mass (e.g., polyp), intussusception
      2. Mural: neoplasia, stricture, abscess, granuloma, hematoma
      3. Extramural: mass or adjacent structure (e.g., bladder, prostate, uterus, lumbar lymph nodes, neoplasm, granuloma, abscess)
   C. Diverticula
   D. Herniation

Complications

I. Intraperitoneal leakage of barium from loss of colon wall integrity
II. Iatrogenic perforation

EXCRETORY UROGRAPHY

Definition

I. Contrast procedure designed to enhance visualization of the kidneys, renal pelvis, and ureters
II. Gives qualitative information on renal function
III. Also known as *intravenous urography* and *intravenous pyelography* (IVP)

Indications

I. To evaluate morphology and location of the kidneys, ureters, and bladder
II. To identify and localize urinary tract disease or dysfunction
III. To assess the effect of masses or trauma on the urinary tract
IV. As a crude assessment of renal function and urinary tract patency

Contraindications

I. Dehydration: associated with contrast-induced renal failure
II. Renal disease
   A. As renal function decreases, the quality of the study decreases.
   B. With blood urea nitrogen >50 to 75 mg/dL, the contrast agent dose may be doubled to increase quality of imaging.
   C. With severe azotemia, the study may be poor regardless of contrast agent dosage.

D. Increasing the dose in the face of decreased renal function leads to increased risk of renal toxic effects and systemic reactions.

III. Known sensitivity to contrast agents

Alternative Imaging Procedures

I. Ultrasonography
II. Nuclear scintigraphy: evaluation of glomerular filtration rate
III. Computed tomography

Preparation of Animal

I. Fasted for 12 to 24 hours, and cleansing enemas to empty GI tract
II. Peripheral venous indwelling catheter
III. Urinary catheter if trigone morphology to be investigated or cystography performed
IV. Anesthesia or sedation if necessary (recommended for evaluation of trigone)
V. Well-hydrated circulatory status
VI. Survey abdominal radiographs

Technique

I. Intravenous bolus of ICM or NICM (800 mg iodine/kg body weight)
II. Radiographic views to be obtained
  A. Ventrodorsal and lateral views immediately and at 5, 20, and 40 minutes
  B. Oblique views at 10 minutes to visualize trigone, if needed
III. Modifications if ureteral ectopia suspected
  A. Anesthesia is required.
  B. Perform a negative contrast cystogram with a retention cuff catheter prior to excretory urography to increase contrast at the trigone.
  C. Fluoroscopy or multiple radiographs are often necessary to visualize contrast in the ureters at the trigone.

Normal Findings

I. Nephrogram (renal opacification)
  A. Opacity peaks at 10 to 20 seconds post-injection and gradually fades over 1 to 3 hours.
  B. Less than 25% of normal dogs have opacification remaining at 2 hours (Feeney et al., 1979).
  C. The nephrogram is best visualized on immediate and 5-minute radiographs.
  D. There are two components of the nephrogram:
    1. Vascular nephrogram: contrast in the renal vasculature
      a. Cortex more opaque than medulla (5 to 10 seconds post-injection)
      b. Occurs immediately and then quickly obscured by tubular phase
    2. Tubular nephrogram: contrast within Bowman's capsules and renal tubules
      a. Kidney uniformly opaque
      b. Most typically seen phase of the nephrogram
  E. Degree of renal opacification depends on hydration, contrast dose, renal blood flow, and relative renal function.

II. Pyelogram (renal pelvis, pelvic diverticula, and ureter opacification)
  A. Opacification begins at 1 to 3 minutes and persists for several hours.
  B. It is best visualized within the first hour.
  C. The pyelogram is more opaque than nephrogram because of contrast media concentration.
  D. Normal pelvic diverticula are often not visible without abdominal compression.
  E. Normal peristalsis causes transient filling defects in the ureteral contrast column.

Abnormal Findings

I. Nephrogram
  A. Morphological changes: size, shape, location, number, margination (Table 4-3)
  B. Opacification sequence changes: onset, degree of opacification, and fading (Box 4-1)
II. Pyelogram (Table 4-4)
  A. Changes in onset or degree of opacification
    1. Onset of opacification is dependent on renal excretion and ureteral patency.
    2. An absent or delayed pyelogram can result from reduced renal blood flow (e.g., shock, hypovolemia, renal infarction), renal disease (decreased excretion, ± decreased concentration), or ureteral outflow obstruction.
  B. Decreased peristalsis: obstruction, infection, or ectopia
  C. Ureteral obstruction: calculi, hematoma, neoplasia, abscess/granuloma, or stricture
  D. Changes in size, shape, location, lumenal contents (filling defects)
  E. Ectopic ureters
    1. The ureter may be dilated.
    2. Unilateral or bilateral ectopia may be found.

Box 4-1

Nephrographic Opacification Sequence Changes and Associated Disorders

Poor Initial Opacification	Fair to Good Initial Opacification
Gradual increase in opacity	Increasing opacity
Acute extrarenal obstruction	Systemic hypotension
Systemic hypotension	Acute renal obstruction
Renal ischemia	Contrast-induced renal failure
Persistent poor opacity	Persistent opacity
Primary glomerular dysfunction (chronic)	Acute tubular necrosis
Severe generalized renal disease	Contrast-induced renal failure
Gradual decrease in opacity	Systemic hypotension
Primary polyuric renal failure	Ethylene glycol toxicosis
Acute pyelonephritis	Decreasing opacity
Inadequate dose	Normal

Modified from Feeney et al: Advances in canine excretory urography. Gaines Vet Symp 30:8, 1981; with permission.

TABLE 4-3

Nephrographic Findings During Excretory Urography, Including Limited Differential Diagnosis

FINDING	SMOOTH MARGIN		IRREGULAR MARGIN	
	UNIFORM OPACITY	NONUNIFORM OPACITY	UNIFORM OPACITY	NONUNIFORM OPACITY
Kidney size increased	Compensatory hypertrophy Infiltration by inflammatory or neoplastic cells	Renal cyst Perirenal pseudocyst Polycystic disease Neoplasia Hydronephrosis Other non–capsule-deforming mass effects	Neoplasia Other	Neoplasia Renal cyst Polycystic disease Granuloma Abscess Hematoma
Kidney size normal	Normal Acute glomerular disease	Neoplasm Hydronephrosis Infarction Pyelonephritis Intrarenal hemorrhage Polycystic disease Renal cyst	Pericapsular hematoma Neoplasia	Neoplasia Intrarenal hemorrhage Renal cyst Polycystic disease Infarction
Kidney size decreased	Hypoplasia Dysplasia	Glomerular disorders Dysplasia	Hypoplastic kidneys with superimposed disease Chronic renal failure	Chronic generalized and/or tubulointerstitial disease Multiple infarcts
Nephrogram absent Renal aplasia Infarction or avulsion of renal artery Nephrectomy Inadequate dose (if bilateral)				

Modified from Feeney DA, Barber DL, Osborne CA: Advances in canine excretory urography. Gaines Vet Symp 30:8, 1981; with permission.

TABLE 4-4

Pyelographic Opacification Sequence and Structural Changes and Associated Disorders

DELAYED ONSET/ DECREASED OPACITY	STRUCTURAL CHANGES		
	FILLING DEFECTS	SIZE/SHAPE CHANGES	LOCATION
Obstruction Renal failure/insufficiency Inadequate dose	Calculi Hemorrhage	Hydronephrosis Obstructive Functional (ectopic ureter) Pyelonephritis Compression/distortion from renal parenchymal mass Ureteral ectopia Ureteral stricture Ureterocele	Ectopia Deviation by retroperitoneal mass

3. The ureter may enter the urethra, vagina, uterus, or vas deferens.
4. The ureter may enter the bladder wall and have one orifice into the bladder, then "tunnel" through the wall to have a second orifice into the urethra.

F. Extravasation of contrast material into the retroperitoneal space: rupture

Complications

I. Contrast reaction (rare)
II. Risk reduced by ensuring adequate hydration of the animal

CYSTOGRAPHY/URETHROGRAPHY

Definition

I. Contrast study designed to enhance visualization of the urinary bladder and urethra
II. Single- or double-contrast studies
  A. Positive or negative contrast study for evaluating location, shape, patency, wall thickness, and integrity
  B. Double-contrast cystogram for mucosal detail and to visualize lumenal contents

Indications

I. Stranguria/dysuria
II. Recurrent cystitis
III. Suspected radiolucent calculi
IV. Suspected anatomic malformation
V. Suspected rupture of the lower urinary tract

Contraindications

I. Inability to safely sedate or anesthetize animal
II. Emphysematous cystitis
III. Hematuria: negative contrast agents avoided because of risk of venous embolization
IV. Suspected small perforation: negative contrast study less sensitive than positive contrast study
V. Known sensitivity to contrast agents

Alternative Imaging Procedures

I. Ultrasonography
II. Computed tomography
III. Cystoscopy

Preparation of Animal

I. Fasted for 12 to 24 hours and warm water enemas to empty GI tract
II. Survey abdominal and pelvic radiographs

Technique

I. Place animal in left lateral recumbency.
II. Insert urinary catheter and drain urine.
III. Perform a single-contrast cystogram.
  A. Inject ICM, NICM, or negative contrast media until bladder is palpably turgid (approximately 5 mL/kg).
  B. Obtain VD and lateral radiographs.
IV. Alternatively, perform a double-contrast cystogram.
  A. Distend the bladder with negative contrast, then inject low-volume ICM or NICM (0.5 to 1 mL for cats, 1 to 4 mL for dogs).
  B. Gently roll animal about its long axis to coat all mucosal surfaces.
  C. Obtain lateral radiographs and oblique radiographs, ± VD view.
V. Perform a urethrogram.
  A. Retrograde urethrogram (preferred)
    1. Ensure the bladder is full to provide adequate pressure (use saline or contrast media to fill if necessary).
    2. Advance a balloon catheter to the proximal (pelvic) urethra and inflate cuff.
    3. Obtain lateral and VD radiographs during injection of ICM or NICM (dose to effect).
    4. Withdraw catheter to distal urethra and repeat.
  B. Antegrade urethrogram
    1. Perform IVP and allow contrast to accumulate in bladder, or inject ICM or NICM into the bladder.
    2. Obtain VD and lateral radiographs while applying pressure to the bladder, forcing urine to flow antegrade through the urethra.

Normal Findings

I. The bladder mucosal surface is smooth and the wall is thin (≈1 to 2 mm).
II. Positive contrast forms a small, uniform, opaque pool in the dependent central bladder; small air bubbles may be seen at the periphery of this pool.
III. Normal ureteral reflux may be seen in normal young animals, with anesthesia, or with excessive distention.
IV. A normal urethrogram has the following characteristics:
  A. Males
    1. With a full bladder under sufficient pressure, the prostatic urethra is the widest section; however, with an empty bladder the prostatic urethra will be the narrowest.
    2. Mild prostatic reflux may be seen if the bladder is distended.
    3. The small longitudinal dorsal filling defect at the neck of the bladder and in the prostate is the normal colliculis seminalis.
  B. Females
    1. Uniform diameter of contrast column
    2. Smooth mucosal borders

Abnormal Findings

I. Abnormal shape/location: urachal diverticulum, pelvic bladder, herniation
II. Filling defects
  A. Air bubbles: round lucencies at the periphery of the contrast pool in the bladder or transient round filling defects in the urethra.
  B. Calculi or blood clots: repeatable filling defects, usually in the central contrast pool or urethra
    1. Blood clots: amorphous; can change shape with manipulation

2. Calculi: may change position with manipulation, but shape is typically consistent

C. Mural mass protruding into the lumen: neoplasm, abscess, granuloma, hematoma

D. Circumferential narrowing of urethra

1. Physiologic spasm: may be relieved by flushing 1 to 3 mL lidocaine through catheter
2. Stricture

III. Extravasation: rupture or avulsion

IV. Wall thickening/irregularity

A. General: cystitis/urethritis (± cobblestone appearance to mucosa)

B. Focal: cystitis (possibly polypoid) or neoplasia

1. Cranioventral: more likely cystitis
2. Dorsal trigone region: more likely neoplasia

V. Prostatic/ureteral reflux

A. Can be seen in a small percentage of normal animals

B. May indicate prostatic or ureteral disease/dysfunction

Complications

I. Air embolization: rare; risk reduced by placing animal in left lateral recumbency and using CO_2

II. Iatrogenic bladder or urethra damage

A. Do not force catheter (may damage or penetrate the wall).

B. Distend bladder only until palpably turgid; *do not overdistend.*

III. Iatrogenic infection introduced with catheterization

IV. Changes in urinalysis results: artifactually increased urine specific gravity and protein for 24 to 72 hours, which altered culture/sensitivity results

V. Contrast reaction (rare)

MYELOGRAPHY

Definition and Indications

I. The introduction of a positive contrast agent into the subarachnoid space (SAS) for delineation of the SAS and, indirectly, the spinal cord

II. Indicated when neurological signs are present referable to the spinal cord

III. Allows evaluation of the location and extent of spinal cord compressive lesions

IV. Allows evaluation of the effect of vertebral disease on the neural canal

Contraindications

I. Inability to anesthetize animal safely

II. High intracranial pressure: cisternal puncture possibly leading to brain herniation

III. Meningitis: possible exacerbation of inflammation or spread of infection

IV. Dehydration: increased contrast clearance time, thereby increasing complications

V. Known sensitivity to contrast agents

Alternative Imaging Procedures

I. Magnetic resonance imaging

II. Computed tomography

Preparation of Animal

I. General anesthesia is required.

II. Do not premedicate with phenothiazine derivatives because they may lower the seizure threshold.

III. Obtain survey lateral and VD radiographs of the spine with oblique views of suspicious regions.

Technique

I. Injection site: chosen based on neurologic localization of suspected lesion

A. Cervicothoracic spinal cord segments: cerebellomedullary cistern injection

B. Thoracolumbar and sacral spinal cord segments: lumbar injection (between the 5th and 6th, or 4th and 5th lumbar vertebrae)

II. *With NICM only*

A. Cervical study: dose = 0.3 mL/kg

B. Thoracolumbar study: dose = 0.3 to 0.4 mL/kg

C. Whole-spine study: dose = 0.45 mL/kg

III. Injection method

A. Aseptically prepare injection site.

B. Perform dural puncture and collect cerebrospinal fluid (CSF), if appropriate.

C. Administer injection slowly in the dorsal SAS for cisternal puncture, and ventral SAS for lumbar puncture.

D. CSF may not flow into the needle hub with lumbar puncture.

IV. Views to be obtained

A. Cervical study

1. Lateral and DV views (both lateral views possibly useful)
2. VD ± DV oblique views of lesions
3. Traction, extension, and flexion views if dynamic lesion (cervical vertebral instability) suspected

B. Thoracolumbar study

1. Lateral and VD views
2. Oblique views of lesions

Normal Findings

I. Uniform contrast medium columns (Figure 4-1, *A*)

II. May see slight undulation of ventral column in lumbar region of small dogs

III. May see asymmetrical columns (dorsal column wider than ventral or vice versa), but no complete attenuation of both columns on one view in any region

IV. Slight attenuation of contrast columns with circumferential widening of the spinal cord at the cervical and lumbosacral (L-S) intumescences

V. Occasional central canal filling: thin linear opacity parallel to and in the center of the cord

Abnormal Findings

I. Extradural compressive lesion (see Figure 4-1, *B*)

A. Eccentric deviation and attenuation of SAS

B. Type I or II intervertebral disk disease (IVDD), spinal ligament hypertrophy, stenotic myelopathy

C. Hemorrhage

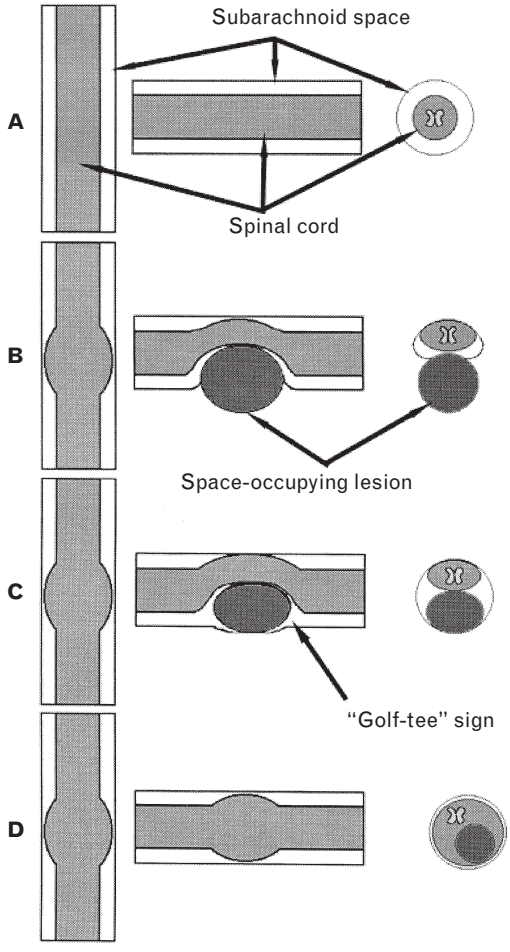

FIGURE 4-1 Myelographic findings associated with various space-occupying lesions. Orthogonal myelographic views and a cross-sectional view are shown. **A,** Normal. **B,** Extradural compressive lesion. **C,** Intradural-extramedullary lesion. **D,** Intramedullary lesion.

D. Neoplasia, cyst, abscess, granuloma
E. Displaced vertebral fracture or fracture fragment

II. Intradural/extramedullary space-occupying lesion (see Figure 4-1, *C*)
A. Characteristic "golf tee" sign to one contrast column as contrast medium flows around space occupying lesion, with attenuation of the other columns
B. Hemorrhage
C. Neoplasia, arachnoid cyst, abscess, granuloma

III. Intramedullary space-occupying lesion (see Figure 4-1, *D*)
A. Widening of the cord with circumferential SAS deviation and attenuation
B. Spinal cord swelling (edema or inflammation)
C. Hemorrhage
D. Neoplasia, abscess, granuloma

IV. Epidural injection
A. Wide, undulating ventral column with circular opacities at intervertebral foramina
B. Injection repeated after 30 minutes if needed (allows contrast medium to clear)

V. Contrast within cord
A. Wide central canal (>1 mm)
1. Hydromyelia: naturally occurring or iatrogenic from direct injection into central canal
2. Myelomalacia: poor to grave prognosis
B. Injection into cord parenchyma: no effect to worsening of signs; usually transient

Complications

I. Temporary worsening of clinical signs
II. Seizures
III. Apnea or changes in anesthetic plane during injection
IV. Radicular pain
V. Contrast reaction (rare)
VI. Injection into cord parenchyma
VII. Introduction of infection: rare, minimized by aseptic technique
VIII. Brain herniation through foramen magnum after cervical puncture in presence of high intracranial pressure

EPIDUROGRAPHY

Definition and Indications

I. Introduction of positive contrast agent into the caudal epidural space for opacification and delineation of the epidural space
II. Indicated for clinical signs referable to the cauda equina or L-S region

Contraindications

I. Inability to safely anesthetize animal
II. Infection (e.g., discospondylitis) and risk of iatrogenic dissemination
III. Known sensitivity to contrast agents

Alternative Imaging Procedures

I. Magnetic resonance imaging
II. Computed tomography
III. Myelography
IV. Discography

Preparation of Animal

I. General anesthesia: required
II. Survey VD and lateral radiographs

Technique

I. Injection site
A. L-S junction: palpable space between last lumbar and sacral spinous processes
B. Caudal vertebrae
1. Sagittal plane between vertebral arches anywhere between the 3rd sacral and 5th caudal vertebrae
2. Sacrocaudal junction easiest

II. Injection technique
A. Aseptically prepare the injection site.
B. Insert a 22-gauge spinal needle (length variable depending on size of animal) into interarcuate space, advancing to the floor of the canal.
C. Inject NICM 0.15 mL/kg initially, then 0.1 mL/kg if needed between subsequent exposures.

III. Radiographic views to be obtained
  A. Increased kVp by 5% to 10% over that used for survey radiographs
  B. Neutrally positioned lateral radiographs
  C. Lateral radiographs with hips extended and flexed
  D. DV radiographs for lateralization, if necessary

Normal Findings

I. Contrast columns are symmetrical with no filling defects.
II. The ventral column is immediately adjacent to the dorsal aspect of the vertebral bodies at the L-S junction.

Abnormal Findings

I. Elevation or deviation of the epidural contrast medium column with compression of >50% of the vertebral canal diameter or complete obstruction to contrast medium flow
  A. Lumbosacral IVDD
  B. Lumbosacral stenosis
  C. Ventral longitudinal ligament hypertrophy resulting from L-S instability
  D. May differentiate static versus dynamic lesion with flexion/extension views
II. Filling defects: neoplasia, hemorrhage, granuloma/abscess, cyst

Complications

I. Introduction or dissemination of infection
II. Contrast reaction (rare)

ARTHROGRAPHY

Definition

I. Contrast procedure for evaluation of joint space, capsule, and articular cartilage
II. Performed in many joints, but most often done in the shoulder joint

Indications

I. Lameness localized to joint, without specific survey radiographic findings
II. Osteochondritis desiccans (OCD): used to diagnose and determine number and location of cartilage flaps/fragments in the joint and/or tendon sheath
III. Wound near joint: used to determine communication of joint with the wound

Contraindications

I. Inability to safely anesthetize animal
II. Known sensitivity to contrast agents

Alternative Imaging Procedures

I. Ultrasonography
II. Computed tomography
III. Magnetic resonance imaging

Preparation of Animal

I. General anesthesia is required.
II. Obtain survey orthogonal radiographs of affected joint(s).

Technique

I. Perform aseptic arthrocentesis using 22-gauge spinal needle (see Chapter 3).
II. Aspirate joint fluid for culture and cytology.
III. Inject NICM or ICM, diluted 1:3 with sterile saline (NICM recommended).
  A. Shoulder: 2 to 4 mL, or until resistance (Muhumuza et al., 1988)
  B. Stifle: 0.3 to 0.4 mL/cm width of stifle joint (Hay et al., 1996)
  C. Elbow: 2 mL (Lowry et al., 1993)
IV. Hypertonic ICM may draw fluid into joint, thereby diluting contrast media quickly.
V. Gently flex and extend joint to evenly distribute contrast.
VI. Obtain orthogonal views with stress and oblique views as needed, thereby increasing kVp by 5% to 10% over survey radiographs.

Normal Findings

I. Smooth capsular and cartilage surfaces
II. Intraarticular tendons (e.g., bicipital tendon) visualized as linear filling defects

Abnormal Findings

I. Irregularity to cartilaginous surface: OCD or erosion
II. Intraarticular filling defects
  A. Cartilage flap secondary to OCD
  B. Joint bodies
  C. Osteochondroma/osteochondromatosis
  D. Adhesions
III. Irregularity to internal joint capsule surface
  A. Synovial hyperplasia/proliferative synovitis
  B. Osteochondroma/osteochondromatosis
  C. Adhesions

Complications

I. Infectious arthritis
II. Synovial irritation and influx of fluid by high-osmolar monomeric ICM; NICM safer
III. Synovial rupture if excessive pressure used
IV. Contrast reaction (rare)

PORTOGRAPHY

Definition and Indications

I. Contrast study used to visualize the portal vascular system
II. Used to identify portosystemic shunting
III. Practical methods: splenoportography and jejunal vein portography

Contraindications

I. Inability to safely anesthetize animal and possibly perform laparotomy
II. Known sensitivity to contrast agents
III. Coagulopathy

Alternative Imaging Procedures

I. Ultrasonography
II. Nuclear scintigraphy: transrectal portal scintigraphy, transsplenic portal scintigraphy

Preparation of Animal

I. Fasted 12 to 24 hours ± cleansing enemas to empty GI tract
II. Survey VD and lateral abdominal radiographs
III. General anesthesia required

Technique

I. Splenoportography
   A. Place the animal in right lateral recumbency and aseptically prepare site of injection.
      1. Evaluate location of spleen by palpation or with ultrasonography.
      2. Prepare area from hypaxial musculature to midline, parallel to the last rib—a region approximately 6 to 7 cm wide.
   B. Insert an over-the-needle catheter into splenic parenchyma (guided with ultrasonography, if possible), aiming toward hilus. Venous backflow will indicate proper needle placement.
   C. If ultrasonography is not available and palpation of the spleen is not possible, perform laparotomy to visualize the spleen for catheter placement, or perform jejunal venography.
   D. Perform a 1- to 2-mL test injection and record results with either fluoroscopy or radiography; if needle is in the proper location, proceed.
   E. Inject 5 to 15 mL of ICM or NICM.
   F. Obtain two to four radiographs in rapid succession 2 to 4 seconds post-injection.
   G. Repeat, if necessary; orthogonal studies may improve visualization.
II. Jejunal vein portography
   A. Perform a ventral midline laparotomy and isolate a loop of jejunum.
   B. Insert an over-the-needle catheter into a jejunal vein and secure with ligatures.
   C. Temporarily close the abdominal incision for transport and positioning, if needed.
   D. With the animal in dorsal recumbency, rapidly inject 1 to 2 mL/kg body weight ICM or NICM.
   E. Monitor flow with fluoroscopy or obtain radiograph at middle to end of injection.
   F. Reposition the animal in lateral recumbency and repeat injection and radiograph.

Normal Findings

I. Opacification of the portal branches associated with injection
   A. Splenoportography: splenic and cranial portal veins
   B. Jejunal vein: jejunal, cranial mesenteric, and portal veins
II. Arborization of portal vein as it enters the hepatic parenchyma

Abnormal Findings

I. Portosystemic shunt
   A. Single or multiple vessels connecting portal system to caudal vena cava or azygous vein
   B. May have decreased or complete lack of hepatic arborization
II. Shunt caudal to the 13th thoracic vertebra: high likelihood of extrahepatic shunt (Birchard et al., 1989)
III. Shunt cranial to the 13th thoracic vertebra: high likelihood of intrahepatic shunt (Birchard et al., 1989)
IV. Misdiagnosis
   A. With splenoportography, only the portal vein and its branches at and cranial to the splenic vein entrance can be evaluated. A shunt caudal to this point may be missed if hepatofugal flow is not present.
   B. With jejunal vein portography, a shunt arising from the caudal mesenteric vein or its branches may be missed if hepatofugal flow is not present.

Complications

I. Splenic laceration
II. Hemoabdomen
III. Contrast reaction (rare)

CHAPTER 5

Introduction

Kristin MacDonald

HEART DISEASE

Heart Failure

I. In moderate to severe cardiac disease, normal cardiovascular functions cannot be maintained.
II. The first change is elevation in capillary and venous pressures, leading to tissue edema (pulmonary edema, peripheral edema, ascites), which is termed *congestive heart failure (CHF)*.
   A. CHF occurs in the setting of moderate or severe cardiac disease.
   B. Often, cardiac disease is present without CHF.
   C. Increased preload (increased filling pressures) occurs when there is hypotension that activates the renin-angiotensin-aldosterone system.
   D. Increased aldosterone and antidiuretic hormone levels lead to increased fluid retention and increased preload.
III. Cardiac output is then reduced, which leads to exercise intolerance weakness, slow capillary refill time, hypothermia, and reduced pulmonary venous oxygen content.
   A. Initially the sympathetic nervous system is activated by reduced blood pressure.
      1. This activation leads to beta receptor stimulation, increased heart rate, and contractility.
      2. Alpha adrenergic stimulation leads to arteriolar vasoconstriction and maintenance of blood pressure.
   B. After 1 to 3 days, the beta receptors downregulate, and the short-term benefit of increased cardiac output is blunted.
IV. Maintenance of blood pressure is the last cardiovascular priority to fail in heart failure.
V. Cardiogenic shock occurs when the cardiovascular system cannot maintain adequate blood pressure, most often in acute heart failure.

Pathophysiology of Cardiac Diseases

I. Volume overload
   A. Many cardiac diseases lead to volume overload (e.g., atrioventricular valve disease, left-to-right shunting congenital heart defects).
   B. Increased preload occurs when there is increased blood volume and venous return to the ventricle, which leads to diastolic stretching of the cardiomyocytes.
   C. The initial response is Starling's law, with increased contractility to eject the excess volume.
   D. Chronic increased preload leads to eccentric hypertrophy and increased left ventricular chamber size, which help to normalize stroke volume and cardiac output.
   E. Eccentric hypertrophy is identified as increased end-diastolic diameter or volume on the echocardiogram.
   F. Sequelae to volume overload are increased diastolic filling pressure and development of CHF.
II. Pressure overload
   A. It occurs secondary to many cardiac diseases (e.g., pulmonic stenosis, aortic stenosis, systemic hypertension, pulmonary hypertension).
   B. Concentric hypertrophy (increased wall thickness) develops to normalize the increased systolic wall stress.
   C. Severe overload may lead to myocardial ischemia and fibrosis, which results in life-threatening ventricular arrhythmias.
   D. Systolic or diastolic failure may ensue.
   E. Concentric hypertrophy is identified on the echocardiogram as increased diastolic ventricular wall thickness.
III. Systolic myocardial failure
   A. Primary myocardial failure arises from idiopathic dilated cardiomyopathy.
   B. There are many secondary causes of systolic myocardial failure.

C. The primary abnormality of systolic myocardial failure is a reduction in contractility, which is seen as an increased end-systolic diameter or volume, reduced fractional shortening, and increased E point to septal separation on the echocardiogram.
D. The chronic compensatory mechanism of systolic myocardial failure is development of eccentric hypertrophy, which helps improve stroke volume and cardiac output.

IV. Diastolic dysfunction
A. Relaxation is the early phase of diastole.
1. Early, rapid filling is influenced by relaxation and by left atrial pressure.
2. Delayed early relaxation is the first abnormality in diastolic dysfunction.
B. Passive diastolic filling occurs in middle to late diastole, is influenced by compliance of the ventricle, which can be reduced by concentric hypertrophy, myocardial fibrosis, and myofiber disarray.
C. Diastolic dysfunction may lead to an elevated ventricular filling pressure and may cause CHF.
D. Systolic function usually remains normal.
E. Hypertrophic cardiomyopathy, unclassified cardiomyopathy, and restrictive cardiomyopathy are cardiac diseases that cause diastolic dysfunction.
F. Echocardiography (pulsed wave Doppler, tissue Doppler technique) is useful to identify diastolic dysfunction.

V. Arrhythmias
A. Sustained tachyarrhythmias (supraventricular or ventricular) may reduce cardiac output and lead to weakness, syncope, or collapse.
B. Bradyarrhythmias may also lead to reduced cardiac output and clinical signs as a result of severely reduced heart rate.

Clinical Assessment

I. Signalment
A. Useful to evaluate diseases with known breed, age, and sex predilections
B. Useful for diseases with known heritability patterns

II. Cardiovascular physical examination
A. Auscultation
1. Murmurs are classified based on location, timing, and grade of intensity.
2. Often the location of a murmur and its timing may be pathognomonic for a defect or may refine the differential list of possible defects.
3. The rhythm may be too slow, too fast, or irregular.
4. Lung sounds (rales, crackles) may be heard if there is pulmonary edema; dampened lung sounds occur with pleural effusion.
B. Precordial pulse palpation
C. Femoral arterial pulse palpation
1. Dampened, hypokinetic pulses: subaortic stenosis, cardiogenic shock, cardiac tamponade
2. Bounding pulses: patent ductus arteriosus, aortic insufficiency
D. Jugular venous distension or pulsation: tricuspid regurgitation, pulmonic stenosis, cardiac tamponade
E. Mucous membrane color and capillary refill time

III. Thoracic radiography
A. Assessment of overall heart size and quantification of heart size by vertebral heart scale
B. Assessment of great vessels: aorta, pulmonary artery, caudal vena cava
C. Assessment of pulmonary vasculature
D. Assessment of pulmonary parenchyma

IV. Echocardiography
A. It is the cornerstone for establishing a definitive diagnosis of a specific heart disease.
B. It is essential to evaluate cardiac function, chamber size, anatomical abnormalities, and valvular competence.
C. Noninvasive estimation of pressures between two chambers is possible using continuous wave Doppler and the modified Bernoulli's principle.

V. Electrocardiography (ECG)
A. It is used when an arrhythmia has been ausculted and is necessary for diagnosis of the specific arrhythmia.
B. Holter monitors are ambulatory, 24-hour ECG recorders that are useful for diagnosis of arrhythmias and monitoring antiarrhythmic therapy.
C. Event monitors are continuous loop recorders used in syncopal animals to determine whether an arrhythmia is causative.

VI. Cardiac catheterization is rarely necessary for diagnosis of a cardiac defect, but it is used before interventional catheter-based therapies.

CHAPTER 6

Cardiac Arrhythmias

Marc S. Kraus | Anna R.M. Gelzer

GENERAL CONSIDERATIONS

Cardiac Arrhythmias

Definition and Causes

I. Cardiac arrhythmias are defined as variations of rhythm from the normal sinus rhythm.
II. Some arrhythmias are clinically insignificant and require no specific therapy, whereas others may cause severe clinical signs or degenerate into serious arrhythmias (e.g., ventricular fibrillation [VF]) that lead to cardiac arrest and sudden death.

Pathophysiology

I. Mechanisms for cardiac arrhythmias can be grouped into abnormalities of impulse formation and impulse propagation.
II. Automaticity refers to the ability of cardiac cells to spontaneously and repetitively depolarize in the absence of external stimulation.
    A. Normal automaticity is dictated by the rate of phase 4 depolarization (balance of calcium, potassium, and sodium ions that cause spontaneous depolarization).
    B. Abnormal automaticity occurs when acceleration of phase 4 activity develops at some location or a region of the heart that normally is not capable of spontaneous depolarization (e.g., atrioventricular [AV] node) and gives rise to spontaneous depolarizations.
III. Reentry represents a potential circular path in which membrane potentials may be conducted.
    A. It is a phenomenon of recurring and self-perpetuating depolarization around a circuit.
    B. It accounts for many clinically significant tachyarrhythmias, such as atrial flutter and fibrillation; intraatrial sinoatrial (SA) and AV nodal tachycardias; tachycardia via accessory pathways; and some ventricular tachycardias.
IV. Triggered activity has some features of automaticity and reentry.
    A. Abnormal potentials, called *after-depolarizations,* follow closely on a previous normal action potential.
    B. The repolarization of a cardiac action potential may be interrupted or followed by another depolarization or after-depolarization.
    C. After-depolarizations that interrupt repolarizations are called *early after-depolarizations,* and those that follow repolarizations are called *delayed after-depolarizations.*

Clinical Signs

I. The end result of severe arrhythmias is inadequate cardiac output and subsequent hypotension with decreased brain perfusion, syncope, or organ damage (especially kidney and liver).
II. Common clinical signs are as follows:
    A. Weakness and/or collapse (syncope)
    B. Exercise intolerance
    C. Sudden death
III. Heart failure can develop from severe bradyarrhythmias or tachyarrhythmias.
    A. Long-standing ventricular tachycardia (VT) and supraventricular tachycardia (SVT) can produce a reversible, left ventricular dysfunction.
    B. The onset of cardiomyopathy and the severity of post-tachycardic changes depend on at least three parameters (type, rate, duration) of the tachycardia.

Diagnosis

I. Although a specific diagnosis may be suggested by auscultation and physical examination, electrocardiography (ECG) is required for a definitive diagnosis.
II. A systematic approach is also required for rhythm diagnosis (Figures 6-1, 6-2, and 6-3).
    A. Criteria used in assessing arrhythmias include the following:
        1. Whether the rate is fast or slow (tachycardia or bradycardia)
        2. Whether the rhythm is regular or irregular
        3. If irregular, whether the rate is slow or fast, or whether premature beats are present
        4. Whether P waves are present and normal (upright in lead II, suggestive of SA nodal origin)
        5. Whether there is a P wave for every QRS complex, and a QRS complex for every P wave
        6. Whether the QRS complexes are normal or abnormal in appearance
    B. Supraventricular arrhythmias must be differentiated from ventricular arrhythmias (Table 6-1).

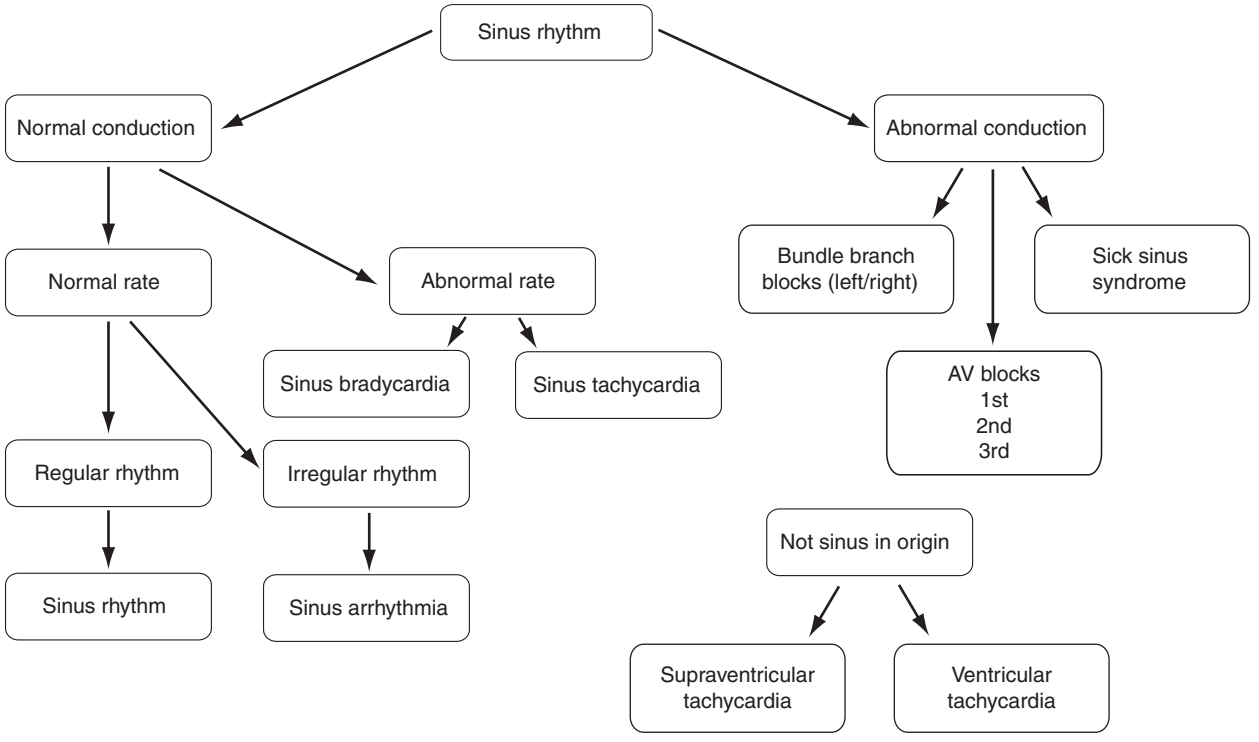

FIGURE 6-1 An algorithm for rhythm analysis if P waves are present on the ECG. If no P waves can be identified, the rhythm probably does not originate in the sinus node, unless it is a rapid supraventricular tachycardia (P wave may be hiding in preceding T waves). *AV,* atrioventricular.

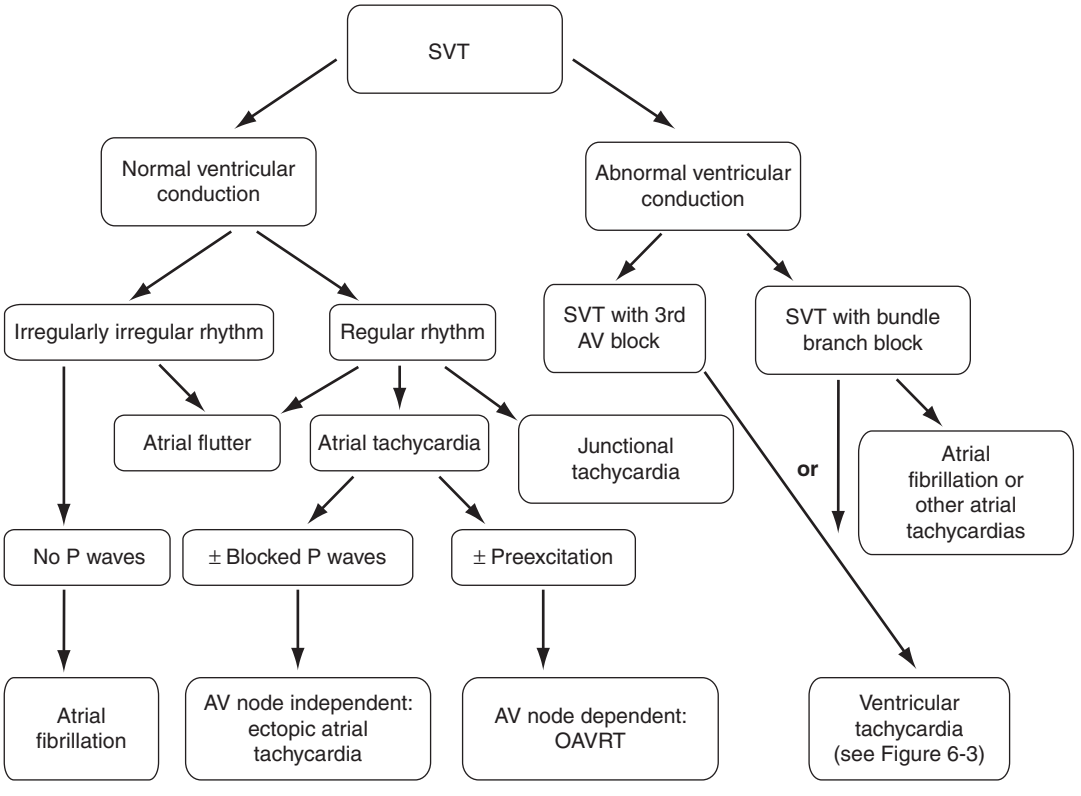

FIGURE 6-2 An algorithm for rhythm analysis of supraventricular tachycardia (SVT). SVT with narrow, upright QRS complexes implies normal ventricular conduction. *AV,* Atrioventricular; *OAVRT,* orthodromoc atrioventricular reciprocating tachycardia.

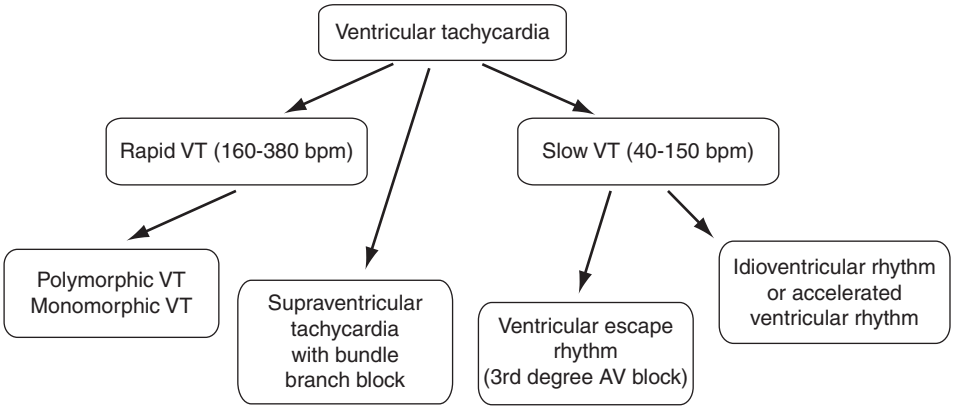

FIGURE 6-3 An algorithm for analysis of ventricular tachycardia (VT). *AV,* Atrioventricular; *bpm,* beats per minute.

TABLE 6-1

Features That Differentiate Supraventricular from Ventricular Arrhythmias

ELECTROCARDIOGRAPHIC FEATURE	SUPRAVENTRICULAR ARRHYTHMIA	VENTRICULAR ARRHYTHMIA
Size of QRS complex	Narrow	Wide
Premature complex has similar appearance to a sinus beat	Yes	No
P waves are associated with the QRS complex	Yes	No
Fusion beats are present	No	Yes

Sinus Arrhythmia

Definition

I. Sinus arrhythmia is a physiological, autonomically mediated cyclical change in sinus rate.
II. The P-P intervals are irregular from fluctuations in autonomic tone that result in phasic changes in the rate of SA node discharge.
III. Sinus arrhythmia is normal in the dog and abnormal in the cat.

Causes

I. Respiratory sinus arrhythmia: fluctuation associated with respiration
II. Nonrespiratory sinus arrhythmia
  A. Cyclic change in P-P interval is independent of respiration and arises from increased vagal tone.
  B. Causes include respiratory, central nervous system (CNS), increased intracranial pressure, ocular, and gastrointestinal (GI) diseases.

Pathophysiology

I. Respiratory sinus arrhythmia
  A. SA node discharge rate is regulated by the autonomic nervous system.
  B. Inspiration decreases vagal tone and increases sympathetic tone, resulting in an increased heart rate.
  C. On expiration, vagal tone increases and sympathetic tone decreases, resulting in a decreased heart rate.
II. Nonrespiratory sinus arrhythmia
  A. Autonomic influences can also cause sinus arrhythmia independent of respiration.
  B. Diseases most commonly associated with high vagal tone include respiratory, CNS, and GI disorders.

Clinical Signs

I. Respiratory sinus arrhythmia does not cause clinical signs.
II. In nonrespiratory sinus arrhythmia, clinical signs are usually related to the underlying disease.

Diagnosis

I. Physical examination findings
  A. Slow to normal heart rate
  B. Irregular heart rhythm that varies with respiration
  C. Normal pulse strength; may vary in intensity (based on R-R interval)
II. ECG characteristics (Figure 6-4)
  A. Heart rate is normal to slow (usually <140 beats per minute [bpm] in the dog).
  B. Variability in P-P interval is >10%.
  C. P wave morphology is normal, and every P wave is followed by a QRS complex.
  D. A wandering pacemaker is often seen (see Figure 6-4).
  E. QRS complexes are normal in appearance.

Differential Diagnosis

I. Slow AF: no P waves, irregularly irregular rhythm
II. Sick sinus syndrome: longer pauses between sinus beats
III. Atrial premature contractions: may interrupt a sinus rhythm

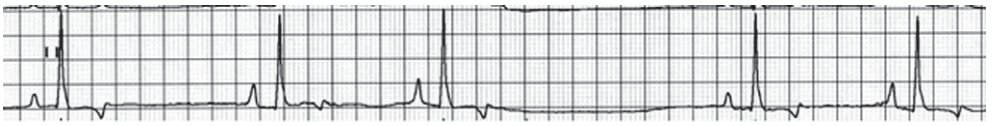

FIGURE 6-4 Electrocardiogram (Lead II, 50 mm/sec, 10 mm/mV) example of sinus arrhythmia. A wandering pacemaker is demonstrated by the variable amplitude of the P wave.

Treatment

I. Sinus arrhythmia does not warrant specific therapy.
II. Specific treatment is directed toward the underlying etiology.

SUPRAVENTRICULAR ARRHYTHMIAS

Atrial Premature Contractions

Definition and Causes

I. Atrial premature contractions (APCs) originate in the atria in a location other than the SA node.
II. They often indicate underlying cardiac pathology, particularly atrial enlargement (chronic valvular disease, cardiomyopathy, congenital heart disease).
III. Noncardiac causes include electrolyte abnormalities, sepsis, and organ failure (e.g., liver, kidney, pancreatitis).

Pathophysiology

I. The prematurity of the APC leads to an instantaneous decrease in stroke volume and ventricular filling.
II. A single APC is not hemodynamically significant.

Clinical Signs

I. Clinical signs are not observed with single APCs.
II. Clinical signs are observed (syncope, lethargy) if APCs progress to SVT.

Diagnosis

I. Physical examination findings
   A. Auscultation often reveals an irregular heart beat.
   B. A pulse deficit may be detected.
II. ECG characteristics
   A. QRS morphology looks similar to a normal sinus impulse.
   B. The QRS complex of the APC occurs earlier than expected, compared with the normal sinus rhythm.
   C. P wave morphology often appears different from the normal sinus P wave.
   D. Echocardiography and thoracic radiography are needed to evaluate underlying structural heart diseases and for presence of heart failure.

Differential Diagnosis

I. Ventricular, premature contraction with a narrow QRS morphology (originating near the bundle of His)
II. Multiple APCs: atrial tachycardia, atrial fibrillation

Treatment and Monitoring

I. No treatment is necessary for occasional APCs.
II. Appropriate therapy is indicated for underlying heart disease or failure.
III. Periodic ECGs or Holter monitoring is needed to assess the frequency of APCs and the presence of more severe arrhythmias (e.g., SVT).

Atrial Fibrillation

Definition

I. Atrial fibrillation (AF) is the bombardment of the AV node with multiple, disorganized atrial impulses.
II. Rapid atrial activation occurs, and the atrial rate can exceed 500 depolarizations per minute.
III. Abnormal automaticity and reentry are possible electrophysiological mechanisms that initiate and maintain AF.

Causes and Pathophysiology

I. AF is usually a chronic, permanent arrhythmia associated with underlying heart disease.
II. It is associated with advanced stages of atrial enlargement secondary to dilated or hypertrophic cardiomyopathy, or to volume overload (e.g., chronic AV valve regurgitation, uncorrected patent ductus arteriosus).
III. Idiopathic AF is diagnosed when no overt cardiovascular disease or other precipitating illnesses are present.
   A. It has low mortality initially.
   B. It may be a sign of occult heart disease and can become clinically significant over time.
   C. Occasionally the administration of narcotics has been associated with the induction of AF in large dogs (Moise et al., 2005).

Clinical Signs

I. Clinical signs are associated with rapid heart rates, usually >200 bpm.
II. Signs include exercise intolerance, coughing, weakness, and syncope.

Diagnosis

I. Physical examination findings
   A. Rapid irregular heart rate and heart sounds of variable intensity
   B. Weak pulses of variable intensity and pulse deficits
   C. Signs of congestive heart failure (CHF): murmur, gallop rhythm, harsh lung sounds
II. ECG characteristics (Figure 6-5)
   A. QRS complexes are usually narrow and upright in leads II, III, and aVF.

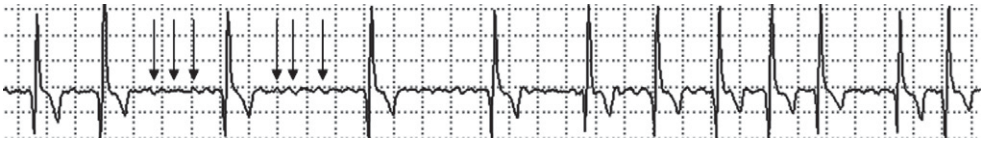

FIGURE 6-5 Electrocardiogram (Lead II, 25 mm/sec, 10 mm/mV) of atrial fibrillation showing a supraventricular rhythm with variable R-R intervals (irregularly irregular) and absence of identifiable P waves. An undulating baseline is present between QRS complexes, with small fibrillatory (f) waves *(arrows)*.

B. The QRS complex can be wide if a bundle branch block is present.
C. P waves are absent.
D. Atrial activity is represented by fibrillatory (f) waves of varying amplitudes.
E. Ventricular rhythm is irregular.
F. At very rapid rates, the rhythm can appear regular.

Differential Diagnosis

I. Rapid supraventricular arrhythmias with variable AV node conduction
II. Frequent APCs

Treatment

I. Management depends on the average heart rate.
II. Acquiring a baseline 24-hour Holter recording is ideal for establishing an accurate average heart rate before initiating treatment.
III. Medical conversion to a sinus rhythm is very difficult and rarely achieved in dogs.
IV. Ventricular rate is controlled via slowing of AV node conduction with diltiazem ± digoxin (Table 6-2).
   A. Although atenolol has been proposed as a treatment, it is avoided if significant myocardial failure (e.g., severe, dilated cardiomyopathy) is present.
   B. Diltiazem XR is well-tolerated in dogs with severe, systolic myocardial dysfunction.
   C. Digoxin as a monotherapy rarely controls the ventricular response rate adequately, especially during times of stress, exercise, or excitement.
V. Electrical cardioversion may be performed under anesthesia.
   A. Best results are seen in dogs with mild structural heart disease or idiopathic AF.
   B. The goal of cardioversion is to avoid structural or functional remodeling of the atria from chronic AF.
   C. The rate of recurrence is high, and related morbidity from transthoracic cardioversion (requires general anesthesia) makes this approach impractical in animals with significant structural heart disease.
   D. Pretreatment with sotalol, amiodarone, and/or angiotensin-converting enzyme inhibitors may improve the chance of cardioversion.

Monitoring of Animal

I. Evaluate heart rate 1 week after initiating treatment.
   A. Ideally this includes 24-hour Holter monitoring.
   B. Target heart rate is 90 to 120 bpm in dogs and 130 to 150 bpm in cats.
   C. If mean heart rate is >140 bpm in dogs, increase the dose of diltiazem/digoxin by 25% and repeat ECG 5 to 7 days later.
   D. Check for bradyarrhythmias (pauses >4 seconds) and, if present, decrease the dosage of the diltiazem/digoxin by 25%.
II. Measure serum digoxin levels (6 to 8 hours post-pill) 5 to 7 days after starting therapy.
   A. Ideal level is 1 to 2 ng/mL.
   B. Lower serum levels (0.6 to 0.8 ng/mL) may successfully control heart rate in some dogs.

Atrial Flutter

Definition and Causes

I. Atrial flutter is a form of reentry tachycardia that utilizes the anatomy of the right atrium to sustain a loop of continuous depolarization.
II. The causes are the same as for AF.
   A. Anything that causes atrial enlargement can predispose to this arrhythmia.
   B. It is uncommon in dogs and cats.
III. Atrial flutter can predispose to AF owing to the electric remodeling that occurs with continuous, rapid activation of the atrial myocardium.
IV. It is unknown if animals undergo a phase of atrial flutter before developing permanent, chronic AF.

Clinical Signs

I. Clinical signs are those associated with rapid heart rates.
II. Signs include exercise intolerance, coughing, weakness, and syncope.

Diagnosis

I. Physical examination findings: similar to AF
II. ECG characteristics (Figure 6-6)
   A. Rapid rhythm, which may be regular or irregular
   B. Sawtooth undulation of the baseline (flutter waves)
   C. Atrial rate usually >300 bpm
   D. Supraventricular appearance of QRS complexes

Differential Diagnosis

I. Rapid ectopic atrial tachycardia with 1:1 conduction is indistinguishable from atrial flutter.
   A. One-to-one conduction may be lethal.
   B. Ectopic atrial tachycardia with variable AV conduction appears similar, but the atrial rate is slower (200 to 250 bpm).
II. AF with course fibrillatory waves may appear similar.

TABLE 6-2

Drugs Used for Supraventricular Arrhythmias

DRUG *(BRAND NAME)*	PER OS ADMINISTRATION	INTRAVENOUS ADMINISTRATION	INDICATION
Diltiazem XR *(Dilacor-XR)*	*Dog:* 3-4 mg/kg BID *Cat:* 30-60 mg SID-BID (start with 30 mg SID)	NA	Atrial fibrillation, flutter, tachycardia OAVRT
Diltiazem *(Cardizem, Cardazem-CD)*	*Dog:* 0.5 mg/kg TID titrated to maximum dose of 1.5-2 mg/kg TID *Cat:* 10 mg/kg SID *(Cardazem-CD)*	*Dog:* 0.1-0.2 mg/kg bolus, then CRI at 2-6 µg/kg/min	Acute atrial fibrillation or flutter OAVRT
Atenolol *(Tenormin)*	*Dog:* 0.25-1 mg/kg SID-BID *Cat:* 6.25-12.5 mg SID-BID	NA	Atrial flutter or tachycardia OAVRT
Esmolol *(Brevibloc)*	NA	*Dog, cat:* 50-100 µg/kg bolus, repeated up to maximum 500 µg/kg or CRI of 50-200 µg/kg/min	Acute atrial fibrillation, flutter or tachycardia OAVRT
Sotalol *(Betapace)*	*Dog:* 1-2.5 mg/kg BID *Cat:* 10 mg BID	NA	Atrial fibrillation, flutter or tachycardia
Digoxin *(Lanoxin)*	*Dog:* 0.005 mg/kg BID Maximum dose for Doberman pinschers is 0.25 mg BID *Cat:* 0.31 mg q 3 days	NA	Atrial fibrillation
Procainamide *(Procain)*	*Dog:* 10-20 mg/kg TID-QID *Cat:* 2-5 mg/kg BID-TID	*Dog:* 10-15 mg/kg IV bolus slowly over 2 minutes or CRI of 25-50 µg/kg/min	Atrial tachycardia Tachycardia via accessory pathway
Amiodarone *(Cordarone)*	*Dog:* 10 mg/kg BID for 1 week (anecdotal loading dose) and 5 mg/kg SID (anecdotal maintenance dose)	*Dog:* 5-10 mg/kg IV bolus (anecdotal dose)	Atrial fibrillation and tachycardia
Lidocaine	NA	*Dog:* 2 mg/kg IV bolus, repeated if needed *Cat:* 0.25-1 mg/kg IV bolus (use with *extreme* caution)	Atrial fibrillation secondary to narcotics

NA, Not available; *OAVRT,* orthodromic atrial reciprocating tachycardia; *CRI,* constant rate infusion.

FIGURE 6-6 Electrocardiogram (Lead II, 25 mm/sec, 10 mm/mV) of atrial flutter demonstrating a sawtooth pattern of atrial flutter waves *(arrows)*. Atrial flutter waves are characterized by the absence of isoelectric diastolic intervals (no return to a smooth baseline) between atrial activations.

Treatment

I. A baseline 24-hour Holter tracing is recommended to determine if the arrhythmia is paroxysmal or chronic.
   A. If the arrythmia is chronic, drug therapy is indicated (see Table 6-2).
   B. If it is paroxysmal and infrequent, treatment may be postponed with reevaluation 3 to 6 months later.

II. Therapy is aimed at suppressing the atrial reentry circuit by using sotalol, amiodarone, or procainamide.

III. Attempts to abolish atrial flutter with drugs are often unsuccessful.

IV. Control of ventricular rates by slowing conduction through the AV node with calcium channel or beta blockers is often effective in dogs.
   A. Diltiazem XR is initially given at 3 mg/kg PO BID then titrated based on the ventricular rate.
   B. If the heart rate is consistently >150 bpm, increase the diltiazem to 4 mg/kg PO BID.

C. Alternatively, atenolol is started at 1 mg/kg PO BID, but must be used with caution if systolic function is impaired.
D. Digoxin monotherapy is usually ineffective in controlling the fast heart rate.

Monitoring of Animal

I. Evaluate the heart rate 1 week after initiating treatment, preferably via Holter monitoring or ECG.
II. Goal of therapy is to maintain the ventricular rate at <150 bpm.

Atrial Tachycardia

Definition

I. Atrial tachycardia (AT) occurs when localized regions in the atria (other than the sinus or AV node) develop the ability to fire rapidly (abnormal automaticity).
II. Clinically significant arrhythmia occurs with heart rates >180 bpm in the dog and >240 bpm in the cat.
III. AT differs from APCs primarily in that AT is sustained.

Causes and Pathophysiology

I. Causes can be the same as for AF.
II. AT may also occur in animals with no obvious cardiac or systemic abnormalities.
III. Untreated, chronic AT can lead to myocardial dysfunction (tachycardia-induced cardiomyopathy).

Clinical Signs

I. Clinical signs (exercise intolerance, panting, coughing, weakness, syncope) depend on the heart rate, duration of arrhythmia, and cardiac function.
   A. Chronically sustained heart rates >180 bpm (dogs) or >240 bpm (cats) often cause clinical signs and deterioration of myocardial function.
   B. With lower rates or sporadic AT, no clinical signs may be noted.
II. Signs of CHF may be present, including exercise intolerance, coughing, weakness, dyspnea, and syncope.

Diagnosis

I. Physical examination findings
   A. A rapid heart rate is ausculted and may be regular or irregular, depending on AV node conduction.
   B. Signs of CHF may be present.
II. ECG characteristics (Figure 6-7)
   A. Ectopic P waves are different in morphology from sinus P waves.
   B. Arrhythmias caused by abnormal automaticity usually show gradual acceleration and deceleration (warm-up and cool-down phenomena).
   C. Atrial rate is usually >180 bpm in dogs.
   D. Usually, QRS complexes are narrow and upright.
      1. Tachycardia may cause a functional bundle branch block, whereas the QRS complexes are wide but are associated with a P wave.
      2. In rapid tachycardia, a P wave may be buried in the preceding T wave and not visible.
      3. The ventricular rhythm is irregular when there is physiological second-degree AV block (the atrial rate is so rapid that not every atrial beat is conducted to the ventricles).

Differential Diagnosis

I. Atrial flutter, AF
II. AV junctional tachycardia
III. Sinus tachycardia
IV. Ventricular tachycardia
   A. AT with bundle branch block appears similar to VT.
   B. Visualization of a P wave associated with a wide QRS complex confirms a bundle branch block.
   C. VT is often suppressed by IV lidocaine, but AT with bundle branch block is not.

Treatment

I. Suppression of the rapidly firing atrial focus is attempted with sotalol, amiodarone, or procainamide (see Table 6-2).
II. Amiodarone must be used with caution because of its side effects, which include hepatic toxicity, GI disturbances, and blood dyscrasias in dogs.
III. If AT cannot be terminated with these drugs, a secondary goal is to control the ventricular rate with calcium channel blockers, beta blockers, or digoxin (see Table 6-2).
IV. The goal of therapy is to maintain a ventricular rate <150 bpm.

Monitoring of Animal

I. Evaluate heart rate 1 week after initiating treatment, with Holter monitoring or ECG.
II. If amiodarone is used, periodic complete blood counts and serum biochemistries are performed to monitor for blood dyscrasias and elevated hepatic enzymes.
III. Measure serum digoxin levels (6 to 8 hours post-pill) 1 week after starting digoxin.
   A. Target range is 0.7 to 2 ng/mL.
   B. Decrease the digoxin dose by 50% if amiodarone is given concurrently.

FIGURE 6-7 Electrocardiogram (Lead II, 50 mm/sec, 10 mm/mV) of atrial tachycardia displaying a rapid supraventricular rhythm, with P waves (P) superimposed on the ST segment of the preceding QRS complex. *R,* R wave; *T,* T wave.

C. High digoxin levels (>2 ng/mL) may cause inappetence, lethargy, GI signs, and may potentiate arrhythmias.

IV. Repeat an echocardiogram in 2 to 3 months to assess cardiac function in animals with myocardial failure.

V. Tachycardia-induced cardiomyopathy may improve with control of the heart rate, and systolic function may normalize over several weeks.

Atrioventricular Reentrant Tachycardia

Definition and Causes

I. Atrioventricular reciprocating tachycardia travels a circuit through the AV node and an accessory pathway (that can conduct impulses from the atria to the ventricles directly), and bypasses the AV node and the His Purkinje system.

II. During typical orthodromic AV reciprocating tachycardia (OAVRT), electrical activity proceeds from the atria to the ventricles through the AV node and then moves back up to the atria in a retrograde direction via the accessory pathway (bypass tract).

III. An accessory pathway can behave like a two-way street for electrical conduction.

IV. During early activation of the ventricle via the accessory pathway (if it conducts in an antegrade direction), a delta wave may be seen on the ECG.

A. Antegrade conduction is uncommon in the dog.

B. Accessory pathways are embryonic, muscular remnants that allow conduction from the atria to the ventricles and bypass the normal pathway of activation.

C. Labrador retrievers with tricuspid valve dysplasia occasionally have accessory pathways and OAVRT.

Clinical Signs

I. Clinical signs depend on the heart rate and duration of the abnormal rhythm.

II. Clinical signs are associated with rapid heart rates and include exercise intolerance, coughing, weakness, and syncope (rarely).

III. AV reciprocating tachycardia can be paroxysmal, and the animal may be asymptomatic.

IV. Signs of CHF may be present, such as cough, exercise intolerance, weak and rapid pulses, harsh lung sounds from pulmonary edema, and syncope (potentially).

Diagnosis

I. Physical examination findings

A. Rapid heart rate may be ausculted.

B. Signs of CHF may be present.

C. A right apical holosystolic murmur may be detected in Labrador retrievers with tricuspid valve dysplasia and OAVRT.

II. ECG characteristics

A. A short PR interval may be seen if antegrade conduction occurs (Figure 6-8).

B. A delta wave, with slurring and notching of the QRS complex, may be detected (ventricular pre-excitation).

C. In OAVRT, QRS complexes are narrow and the retrograde P wave (negative P wave) may be embedded into the early portion of the T wave.

D. One-to-one AV association is a requisite of atrioventricular reciprocating tachycardia because the atria and ventricles are both integral parts of the arrhythmia circuit.

Differential Diagnosis

I. Wide QRS tachycardia

A. QRS complexes are wide and bizarre, but the arrhythmia originates in the atria.

B. This term is used when differentiation between ST with aberrancy and VT cannot be made.

II. VT

Treatment

I. Treatments of choice are oral diltiazem or atenolol (see Table 6-2).

II. For acute management, IV diltiazem or esmolol is often effective.

III. For refractory cases, sotalol, procainamide, or amiodarone may be added; however, do not combine sotalol with atenolol.

IV. For dogs that do not adequately respond to medications (persistent tachycardia), transvenous catheter ablation of the accessory pathway using radiofrequency energy can be attempted.

V. Ventricular preexcitation without accompanying SVT requires no therapy.

Monitoring of Animal

I. Heart rate and presence of SVT are periodically assessed by Holter monitoring or ECG.

II. If ventricular response rate is >150 bpm, do the following:

A. If using monotherapy, increase drug dosage to the maximum tolerated dose.

B. Consider switching to another antiarrhythmic drug.

C. Combination therapy may be needed (e.g., sotalol, procainamide).

FIGURE 6-8 Electrocardiogram (Leads I and II, 50 mm/sec, 10 mm/mV) of ventricular preexcitation showing a sinus rhythm, with a short PR interval and wide QRS complexes that have a distinct notch in the upstroke of the R wave (delta wave, *arrows*). The delta wave is evidence of early activation of the ventricle via an accessory pathway.

III. Control of the arrhythmia usually eliminates the clinical signs.
IV. Ventricular preexcitation is permanent but does not appear to be progressive.

BRADYARRHYTHMIAS/ CONDUCTION DISTURBANCES

Sinus Bradycardia

Definition

I. Sinus bradycardia is a sinus rhythm in which the SA node discharge rate is low (≤60 bpm in an awake dog, ≤120 bpm in cats).
II. Sinus bradycardia of 45 to 60 bpm during sleep is normal.
III. Pathologic bradycardia often persists during excitement or exercise.
IV. Sinus bradycardia may occur as a pronounced sinus arrhythmia or a regular sinus bradycardia.

Causes and Pathophysiology

I. Sinus bradycardia may occur as a primary disorder.
II. It may arise secondarily.
  A. Drug toxicity: narcotics, overdose of beta blockers, calcium channel blockers or digoxin
  B. Excessive vagal tone from a systemic disease: CNS, ocular, respiratory, or GI diseases, head trauma
  C. Metabolic disorders: hyperkalemia, hypothyroidism, hypothermia
III. Chronic, severe bradycardia may lead to left-sided volume overload and subsequent CHF.
IV. It may exacerbate ventricular volume overload of other cardiac diseases (e.g., myxomatous AV valvular disease).

Clinical Signs

I. Clinical signs may be absent, or dogs may display weakness, exercise intolerance, or syncope.
II. Mild exercise intolerance is often underrecognized by owners.
III. Concurrent signs of CHF (coughing, lethargy, inappetence) may be present if heart rate has been slow for several months.

Diagnosis

I. Physical examination findings
  A. Findings may be unremarkable, except for a slow heart rate.
  B. A soft, left apical holosystolic murmur may be present if there is functional (secondary) mitral regurgitation from left ventricular enlargement.
II. ECG characteristics (Figure 6-9)
  A. Sinus rhythm with upright P waves in leads II, III and aVF
  B. Normal, upright, narrow QRS complexes, unless concurrent conduction disorder present
  C. Slow sinus discharge rate: ≤60 bpm in dogs; ≤120 bpm in cats
  D. ± Escape beats from AV node or ventricular Purkinje fibers

Differential Diagnosis

I. Marked sinus arrhythmia
II. Sick sinus syndrome

Treatment

I. The decision to treat a sinus bradycardia is based on clinical signs and the degree of bradycardia present.
II. Sinus bradycardia often requires no therapy.
III. In animals with syncope or episodic weakness, pacemaker insertion is indicated, even if the underlying disease may be curable.
IV. If pacemaker therapy is not an option, medical therapy is aimed at abolishing the increased vagal tone.
  A. An atropine response test helps identify animals that may benefit from medical management.
  B. Following injection of atropine (0.01 to 0.04 mg/kg IM, IV), the heart rate should increase by 50% to 100% within 5 to 10 minutes (initial transient AV block is normal).
  C. Animals experiencing at least a partial response to atropine may be candidates for medical management.
  D. Treatment options include the following:
    1. Vagolytic drugs: propantheline bromide 0.25 to 0.5 mg/kg PO BID
    2. Sympathomimetics: albuterol 0.02 to 0.05 mg/kg PO BID to TID or terbutaline 0.2 mg/kg PO BID to TID
    3. Phosphodiesterase inhibitors: theophylline 20 mg/kg PO BID
    4. Disadvantages: erratic or poor efficacy, adverse effects (anxiety, excessive panting, anorexia, GI signs)
  E. Other agents may be tried in emergency situations, but they may initiate other arrhythmias.
    1. Dogs, cats: epinephrine 0.05 to 0.2 mg IV

FIGURE 6-9 Electrocardiogram (Lead II, 50 mm/sec, 10 mm/mV) of sinus bradycardia showing a regular, slow sinus rhythm.

2. Dogs, cats: dopamine 1 to 3 μg/kg/min IV as a constant rate infusion (CRI)
3. Dogs: dobutamine 5 to 20 μg/kg/min IV CRI
4. Cats: dobutamine 2 to 5 μg/kg/min IV CRI
5. Dogs, cats: isoproterenol 0.01 to 0.2 μg/kg/min IV CRI

Monitoring of Animal

I. With medical therapy, 24-hour Holter monitoring is done to determine whether the heart rate has increased to an acceptable level (>70 bpm) and whether it increases during exercise.
II. Alternatively, an ECG is used to monitor response to therapy.
III. Pacemaker implantation usually requires long-term monitoring of battery life and function.
   A. The pacemaker is usually set at a fixed rate for 1 month, which allows the owner to easily assess the heart rate at home; it is then changed to a rate-responsive mode.
   B. Reevaluations are done at 3, 6, and 12 months for the first year, and then once or twice yearly.
IV. Prognosis after pacemaker implantation is excellent, with most animals living years after implantation; however, ventricular function may worsen with time (after long periods of ventricular pacing).

Sick Sinus Syndrome

Definition and Causes

I. Sick sinus syndrome (SSS) is a disease in which spontaneous SA node discharge is either slower than normal (primary sinus bradycardia) or intermittently absent (sinus arrest).
II. Subsidiary pacemaker tissue (AV node, Purkinje fibers) is usually also abnormal, resulting in inadequate escape beats so that asystole (pauses) can be >6 seconds.
III. SSS occurs primarily in small-breed dogs, such as the miniature schnauzer, American cocker spaniel, West Highland white terrier, and dachshund.
IV. Doberman pinschers and boxers may have syncope associated with long sinus pauses, suggestive of SSS.
V. The underlying cause is unknown, but it may be associated with fibrous replacement of the SA node.

Clinical Signs

I. Clinical signs include exercise intolerance, lethargy, and syncope.
II. Dogs with primary sinus bradycardia may show only mild exercise intolerance, which is often unrecognized by owners.

Diagnosis

I. Because of the intermittent nature of the sinus pause, Holter monitoring or use of an event monitor may be necessary to definitively identify SSS.
II. Definitive diagnosis requires documentation of SA node dysfunction with clinical signs of SSS.
III. Periods of bradycardia or asystole followed by paroxysms of SVT are typical (Figure 6-10).

Differential Diagnosis

I. Sinus bradycardia
II. Sinus arrest

Treatment

I. Pacemaker insertion is the treatment of choice for syncopal or lethargic animals, because medical management is rarely a long-term solution.
II. Some cases have supraventricular tachyarrhythmias (atrial tachycardia, flutter, or fibrillation) in addition to the sinus pauses, so antiarrhythmic therapy also may be needed.
III. Insert a pacemaker before initiation of antiarrhythmic therapy (diltiazem, atenolol, or sotalol) for SVT.

Monitoring of Animal

I. Monitoring is similar to that for sinus bradycardia.
II. If a pacemaker is implanted, periodic examinations are necessary.
III. Most animals respond well to pacing with the resolution of clinical signs and improved energy.

Atrial Standstill (Asystole)

Definition and Causes

I. Atrial standstill is a lack of ECG evidence of atrial depolarization (no P waves are visible on the ECG).
II. Two main reasons exist for atrial standstill.
   A. Hyperkalemia: urethral obstruction, hypoaldosteronism, reperfusion syndrome in arterial thromboembolic disease
   B. Primary atrial muscle disease: neoplasia, atrial myopathy, scapulohumeral muscular dystrophy of English springer spaniels (Miller et al., 1992; Smith, 1997; Buchanan, 2005).

Clinical Signs

I. Weakness, lethargy, and/or syncope
II. Signs relating to low cardiac output and CHF
   A. Lethargy, coughing, syncope, possible abdominal distension from ascites

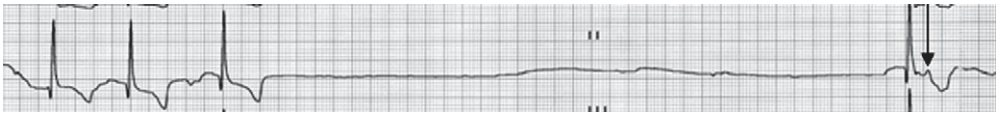

FIGURE 6-10 Electrocardiogram (Lead II, 50 mm/sec, 10 mm/mV) of sick sinus syndrome illustrating an abrupt pause in electrical activity (sinus arrest). A junctional escape beat (narrow QRS) has a P wave *(arrow)* appearing in the ST segment.

B. Occur with significant bradycardia (<50 bpm)

III. Signs related to neuromuscular disease in English springer spaniels with scapulohumeral muscular dystrophy (Miller et al., 1992)

Diagnosis

I. Physical examination findings: slow, irregular heart rate

II. ECG abnormalities (Figure 6-11)
   A. P waves are absent.
   B. The escape rhythm may be junctional (60 to 80 bpm, narrow QRS) or ventricular (20 to 40 bpm, wide QRS) in origin.
   C. If associated with hyperkalemia, tall T waves and wide, bizarre QRS complexes may occur.

Treatment

I. If hyperkalemia is documented, IV fluids are required to lower potassium via dilution and increased excretion.
   A. Acceptable fluids include 0.9% saline, 0.45% saline with 2.5% dextrose, or 5% dextrose in water.
   B. Dextrose increases insulin secretion, which drives potassium into the cells.

II. Regular insulin (0.5 U/kg) may be given with 50% dextrose (2 g/U insulin) by slow IV infusion, followed by monitoring for hypoglycemia.

III. Calcium gluconate 10% (0.5 mL/kg IV very slowly) may be given to make more cardiac sodium channels available for activation.

IV. Correction of the underlying disease process is also important.

V. Pacemaker implantation is required for atrial muscle diseases.

Monitoring of Animal

I. Hyperkalemia-induced atrial standstill requires repeated monitoring of potassium levels.

II. If atrial muscle disease is present, the prognosis is guarded as the myopathy may progress to CHF, and despite pacemaker therapy the underlying disease often worsens within several months.

Atrioventricular Conduction Abnormalities

Definition

I. These abnormalities arise from prolonged or complete failure of conduction between the atria and ventricles via the AV node.

II. First-degree AV block is prolongation of conduction through the AV node that results in a PR interval of ≥ 0.13 seconds in the dog and ≥ 0.1 seconds in the cat.

III. Second-degree AV block has morphologically normal P waves and QRS complexes, and a constant PR interval, but intermittently a P wave is not followed by a QRS complex.
   A. Mobitz type I (Wenckebach): PR interval gradually increases until a dropped ventricular beat occurs.
   B. Mobitz type II
      1. A fixed PR interval is present until a nonconducted P wave occurs.
      2. It is a more advanced degree of block that often occurs in the AV junction or His bundle.
   C. High-grade, second-degree AV block
      1. There are more than two P waves for each QRS complex.
      2. There is a fixed PR interval of the conducted P waves.
      3. This type of block indicates severe AV disease.

IV. In third-degree (complete) AV block, none of the P waves conduct through the AV node.
   A. Atrial and ventricular activities are independent of each other.
   B. There is no consistent PR interval.

Causes and Pathophysiology

I. The exact cause of AV block is undetermined in most cases.
   A. Neoplastic and infectious causes have been implicated.
   B. Lyme myocarditis has been reported as a cause in a dog (Levy and Duray, 1988).
   C. Systemic diseases that cause hyperkalemia (e.g., hypoadrenocorticism, urethral obstruction) may induce AV block that is reversible with normalization of potassium levels.
   D. Drugs, such as beta-blockers, calcium channel blockers, and digoxin, may depress AV conduction.

II. Complete AV block is often a primary abnormality of the AV node.

III. Prolonged bradycardia can lead to volume overload and subsequent CHF.

Clinical Signs

I. Clinical signs depend on the type and severity of AV block.

II. First-degree AV block is an incidental finding on the ECG and does not cause symptoms.

III. With second-degree AV block, animals are usually asymptomatic; however, syncope and lethargy can occur with slow heart rates (<40 to 50 bpm).

FIGURE 6-11 Electrocardiogram (Lead II, 50 mm/sec, 10 mm/mV) of atrial standstill, with the characteristic absence of P waves and a slow ventricular escape rhythm.

IV. With high-grade, second-degree, or third-degree AV block, lethargy, exercise intolerance, collapse, and syncope are common.

Diagnosis

I. ECG is required for definitive diagnosis.
II. First-degree AV block is characterized by a PR interval ≥0.13 second, and normal P waves and QRS complexes that occur at a 1:1 ratio (Figure 6-12).
III. With second-degree AV block P waves and QRS complexes are normal, but P waves are not always followed by QRS complexes (Figure 6-13).
IV. Complete AV block is characterized by the following (Figure 6-14):
   A. The atrial and ventricular rates are unrelated to each other, with P waves dissociated from the QRS complexes.
   B. The atrial rate is faster than the ventricular rate.
   C. If the ventricular rate is faster than the atrial rate, AV dissociation is present (not AV block).
   D. The rhythm is usually regular.
   E. Escape beats may arise from subsidiary pacemakers (AV node, bundle of His below the site of AV block, Purkinje fibers, etc.).
      1. AV nodal escape beats have a narrow, upright QRS morphology (supraventricular), and their rate is usually 40 to 60 bpm in dogs, and 80 to 120 bpm in cats.
      2. Ventricular escape beats have wide, bizarre QRS complexes and are usually slower (30 to 50 bpm) in the dog.

Differential Diagnosis

I. Third-degree AV block must be differentiated from AV dissociation (frequency of the ventricular rhythm exceeds that of the atrial rhythm).
II. Ventricular premature complexes or idioventricular rhythms must be differentiated from third-degree AV block with ventricular escape beats, as suppression of any ventricular escape rhythm could be lethal.

Treatment

I. First-degree AV block requires no treatment.
II. Second-degree AV block may or may not require treatment.
   A. An atropine challenge test is performed (see Sinus Bradycardia) to assess whether vagal tone is contributing to the AV block and to identify animals that may be candidates for medical therapy.
   B. High-grade, second-degree AV block usually requires a pacemaker.
   C. Pacemaker therapy is indicated if clinical signs are observed.
   D. Medical management can be attempted similar to sinus bradycardia, but the efficacy of medical therapy is often erratic and short-lived.
III. Complete AV block requires pacemaker implantation.

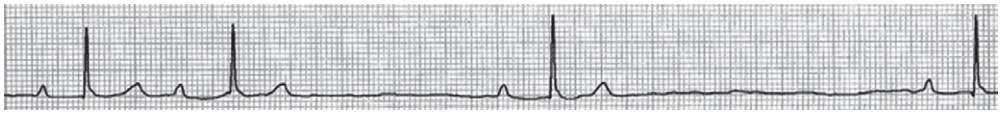

FIGURE 6-12 Electrocardiogram (Lead II, 50 mm/sec, 10 mm/mV) of first-degree atrioventricular (AV) block showing a prolonged PR interval (0.18 to 0.22 sec), which indicates slowed conduction through the AV node.

FIGURE 6-13 Electrocardiogram (Lead II, 25 mm/sec, 10 mm/mV) of second-degree atrioventricular (AV) block, which is intermittent conduction through the AV node. P waves *(arrows)* may or may not (*) be conducted.

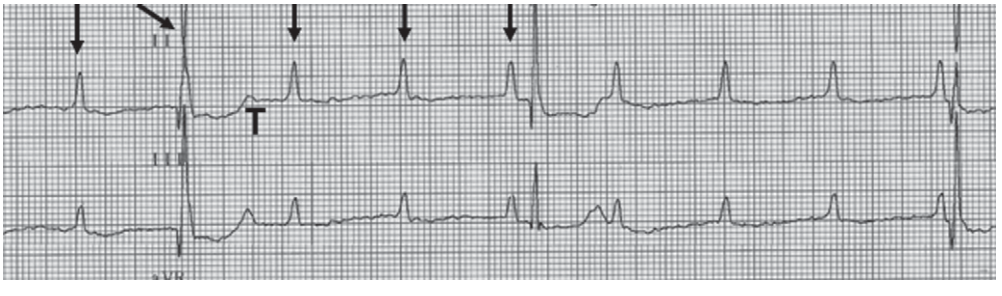

FIGURE 6-14 Electrocardiogram (Leads II and III, 50 mm/sec, 10 mm/mV) of third-degree atrioventricular (AV) block depicting a regular sinus node discharge rate, and no association between P waves *(straight arrows)* and the QRS complexes. An AV nodal escape beat results in a narrow QRS complex *(angled arrow)*. *T,* T wave.

IV. Ventricular antiarrhythmic therapy (lidocaine) or negative chronotropic antiarrhythmic drugs (beta blockers, calcium channel blockers, and digoxin) are contraindicated in third-degree AV block before pacemaker implantation, as they may be lethal.

Monitoring of Animal

I. Monitoring is similar to that for sinus bradycardia.
II. First- or second-degree AV block may progress to third-degree block.
III. Sudden death may occur in dogs with third-degree block.
IV. Third-degree block in cats does not appear to be as life-threatening, and cats with collapsing episodes may live for >1 year without pacemaker implantation (Kellum and Stepien, 2006).

VENTRICULAR ARRHYTHMIAS

Ventricular Premature Contractions/ Tachycardia

Definition

I. Ventricular arrhythmias are abnormal depolarizations that originate from any location in the ventricle.
II. Three or more ventricular premature contractions (VPC) in succession is termed *VT*.
III. Accelerated idioventricular arrhythmia is a VT of slower rates (60 to 160 bpm) and does not cause significant hemodynamic abnormalities.
IV. Breed-specific ventricular arrhythmias occur in the boxer, Doberman pinscher, and German shepherd dog.
   A. Boxers with cardiomyopathy may develop ventricular arrhythmias at 4 to 6 years of age that often increase in frequency and severity over time.
   B. Doberman pinschers with dilated cardiomyopathy typically develop arrhythmias at 3 to 6 years of life, and their frequency and severity usually increase with time.
   C. The German shepherd dog may develop ventricular arrhythmias at 12 to 16 weeks of age.
      1. Frequency and severity often increase until 24 to 30 weeks of age.
      2. Some dogs remain severely affected, whereas others have a progressive decline in the frequency of the arrhythmias.

Causes

I. Cardiomyopathies are a common cause.
   A. Cardiomyopathy in the boxer and Doberman pinscher are inherited as autosomal dominant traits.
   B. The disease in German shepherd dogs has a polygenic mode of inheritance.
II. Dogs with congenital heart diseases (severe subaortic or pulmonic stenosis) are predisposed to develop ventricular arrhythmias, possibly from abnormal myocardial perfusion and fibrosis.
III. Other causes include the following:
   A. Chronic valvular disease
   B. Trauma: traumatic myocarditis
   C. Gastric dilatation-volvulus, certain surgeries (e.g., splenectomy)
   D. Pancreatitis, hyperthyroidism (cats), sepsis and other systemic diseases
   E. Severe electrolyte abnormalities: hypokalemia, hyperkalemia, hypercalcemia, hypomagnesemia
   F. Drugs: digoxin, tricyclic antidepressants, opioids, antiarrhythmic agents
   G. Neoplasia: cardiac and other
IV. In many cases, the cause is not identified (idiopathic).

Pathophysiology

I. Rapid VT (>180 bpm in the dog, >250 bpm in the cat) reduces cardiac output and blood pressure.
II. VT is potentially life-threatening because it may degenerate into ventricular fibrillation, resulting in sudden death.

Clinical Signs

I. Clinical signs vary depending on the number of VPCs, and the rate and duration of VT.
   A. Single VPCs cause no clinical signs.
   B. Rapid VT is associated with syncope, weakness, or sudden death.
   C. The animal may be asymptomatic if VT is not sustained (<30 seconds).
   D. Intermittent rapid breathing may coincide with rapid VT.
II. Clinical signs of CHF may be present.
III. In boxers syncope is often the first sign observed, especially during exercise, stress, or excitement.
   A. The boxer may tolerate multiple collapsing episodes before sudden death, whereas the Doberman pinscher may die suddenly during the first syncopal event.
   B. The incidence of sudden death in the Doberman pinscher before onset of CHF is between 30% to 50% (Calvert et al., 2000; Calvert and Wall, 2001).

Diagnosis

I. Physical examination findings
   A. Irregular cardiac rhythm, with variable intensity of heart sounds
   B. Variable pulse intensity with pulse deficits
   C. ± Signs of CHF or underlying systemic diseases
II. ECG characteristics (Figures 6-15, 6-16, and 6-17)
   A. QRS complexes are wide and abnormal in shape.
   B. No P wave is associated with the QRS complex.
   C. AV dissociation is common.
   D. Fusion beats are common and are characterized by a short PR interval and an intermediate QRS morphology (similar in shape to ectopic ventricular complex and the normal QRS).
   E. Normal, upright QRS complexes may occur if the arrhythmia originates near the septum, but the QRS duration is prolonged.
   F. Initial direction of the QRS complex is different from a normal QRS.

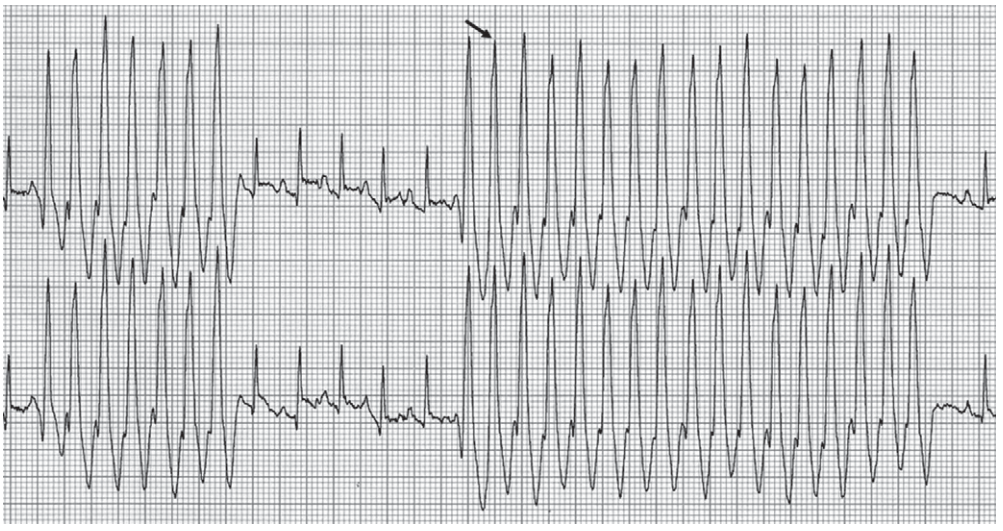

FIGURE 6-15 Electrocardiogram (Leads II and III, 25 mm/sec 10 mm/mV) of ventricular tachycardia showing rapid runs of ventricular complexes separated by five normal sinus beats. The *arrow* points to an occurrence of R on T phenomenon.

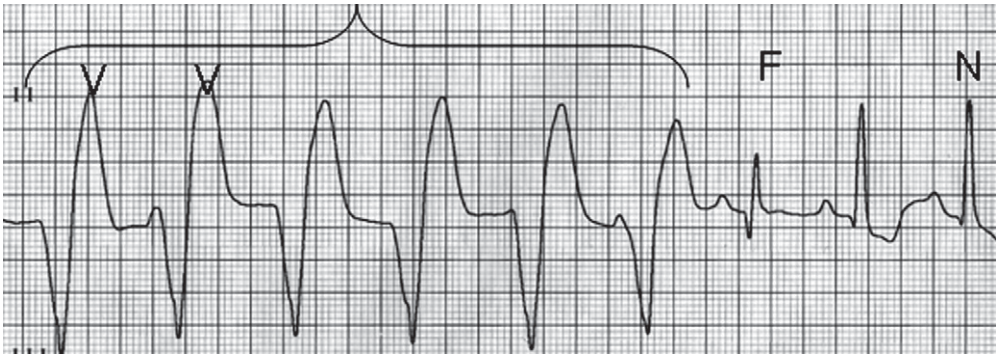

FIGURE 6-16 Electrocardiogram (Lead II, 50 mm/sec, 10 mm/mV) displaying multiple, consecutive ventricular premature beats (V, under bracket) that convert to a sinus rhythm (N) after a fusion beat (F).

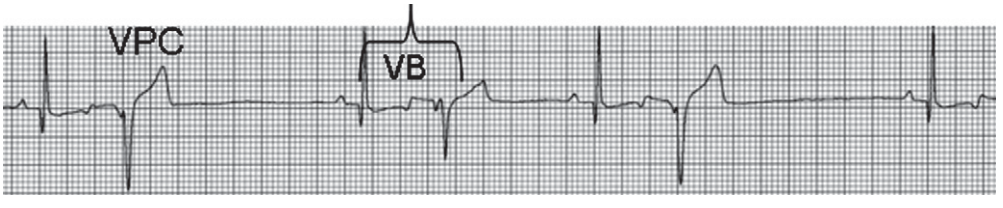

FIGURE 6-17 Electrocardiogram (Lead II, 50 mm/sec, 10 mm/mV) of single ventricular premature contractions (VPCs) that appear immediately after a normal sinus beat, which is termed *ventricular bigeminy* (VB).

G. Affected boxers have QRS complexes that are positive in leads II, III, and aVF (Kraus et al., 2002; see Figure 6-15).
H. Affected Doberman pinschers have QRS complexes with monomorphic and polymorphic characteristics.
I. Wide, bizarre T waves often have opposite polarity to QRS complexes.
J. Ventricular couplets, polymorphic complexes, R on T phenomenon (T wave embedded in R wave and not visible; see Figure 6-15), and VT are considered high-grade, more severe arrhythmias.

Differential Diagnosis

I. Supraventricular tachycardias (e.g., AF) with bundle branch block
II. APCs with aberrant conduction
III. Ventricular or AV nodal escape beats

Treatment

I. Treatment of VPCs
   A. Deciding when to treat VPCs is difficult because not all affected animals are at risk for sudden death.

TABLE 6-3

Drugs Used for Ventricular Arrhythmias

DRUG *(BRAND NAME)*	PER OS ADMINISTRATION	INTRAVENOUS ADMINISTRATION	INDICATION
Sotalol *(Betapace)*	*Dog, cat:* 0.5-2 mg/kg BID	NA	VT
Mexiletine *(Mexitil)*	*Dog:* 4-8 mg/kg TID	NA	VT, but not effective alone
Amiodarone *(Cordarone)*	*Dog:* 10 mg/kg BID for 1 week (anecdotal loading dose) and 5 mg/kg SID (anecdotal maintenance dose)	*Dog:* 5-10 mg/kg (anecdotal dose)	Refractory VT
Lidocaine	NA	*Dog:* 2 mg/kg IV bolus, repeated up to 3 times, followed by CRI of 30-90 µg/kg/min *Cat:* 0.25-1 mg/kg IV bolus (used with *extreme* caution)	Life-threatening VT
Procainamide	*Dog:* 10-20 mg/kg TID-QID *Cat:* 2-5 mg/kg BID-TID	*Dog:* 10-15 mg/kg IV bolus slowly over 2 minutes or CRI of 25-50 µg/kg/min *Cat:* 1-2 mg/kg IV bolus slowly or CRI of 10-20 µg/kg/min	Life-threatening VT
Atenolol *(Tenormin)*	*Dog:* 0.25-1 mg/kg SID-BID *Cat:* 6.25-12.5 mg SID-BID	NA	VT; effective only in combination with mexiletine
Esmolol *(Brevibloc)*	NA	*Dog, cat:* 50-100 µg/kg bolus, repeated to maximum dose of 500 µg/kg or CRI of 50-200 µg/kg/min	Life-threatening VT

NA, Not available; *VT,* ventricular tachycardia; *CRI,* constant rate infusion.

B. Considerations include the frequency and degree of prematurity and the presence of concurrent underlying diseases.
C. The following are suggested guidelines:
1. Unifocal, single VPCs (<30 to 50/hour) probably require no treatment, even if structural heart disease is present.
2. More frequent, unifocal, single VPCs (>50/hour) may require antiarrhythmic treatment, especially if an underlying heart disease (dilated cardiomyopathy) is present.
3. Unifocal, numerous VPCs (>100/hour) are usually treated with antiarrhythmic drugs.
4. Multiform VPCs and ventricular couplets in the presence of structural heart disease are usually treated.
5. R on T phenomenon is usually treated.
6. If normal blood pressure is not maintained, treatment is initiated.
D. For specific antiarrhythmic therapy, see Table 6-3 and Treatment of VT.

II. Acute, life-threatening ventricular arrhythmias in dogs (Table 6-3)
A. Administer lidocaine slowly in boluses of 2 mg/kg IV (up to 8 mg/kg total) until VT converts to sinus rhythm, then follow with CRI of 30 to 80 µg/kg/min IV.
B. If lidocaine therapy fails, administer procainamide slowly in boluses of 2 mg/kg IV (up to 20 mg/kg total) until VT resolves, then follow with CRI of 20 to 50 µg/kg/min IV or 8 to 20 mg/kg IM QID.
C. If no response occurs to either lidocaine or procainamide, CRIs of both drugs can be combined.
D. If no response occurs to combined therapy, administer boluses of esmolol (0.05 to 0.1 mg/kg IV slowly every 5 minutes) to a cumulative dose of 0.5 mg/kg, or as a CRI of 50 to 200 µg/kg/min IV.
E. Combination therapy with esmolol and procainamide/lidocaine may cause significant hypotension.

III. Life-threatening ventricular arrhythmias in cats (see Table 6-3)
A. They are less common than in dogs.
B. Use extreme caution when administering lidocaine.

IV. Chronic oral antiarrhythmic therapy in dogs
A. Baseline 24-hour Holter monitoring may be done before therapy (if not life threatening) to determine the number of VPCs, their duration and rate, the presence of episodes of VT, and the presence and length of pauses.
B. The preferred oral antiarrhythmic drug for VT in most dogs is sotalol, with the exception of German shepherd dogs (arrhythmogenic in this breed).
1. In German shepherd dogs, the combination of mexiletine and sotalol is usually the most effective.
2. If advanced myocardial systolic dysfunction (fractional shortening <15%) is present, sotalol may not be tolerated because of its beta-blocker effect.

FIGURE 6-18 Electrocardiogram (Lead II, 50 mm/sec, 10 mm/mV) of a slow idioventricular rhythm (V) that is temporarily interrupted by normal sinus beats (N).

C. Mexiletine in combination with atenolol is also very effective in boxers (Meurs et al., 2002).
D. For refractory VT, a combination of sotalol and mexiletine may be given, with sotalol started first, and mexiletine added after 2 to 3 days to avoid side effects (AV block, inappetence).
E. Amiodarone is used as a last resort for refractory VT.
1. In large-breed dogs, 200 mg PO SID is usually well-tolerated, but 400 mg PO SID consistently causes toxicity (Kraus et al., 2005).
2. Monitoring of biochemistry panels is recommended because elevated liver enzymes usually precede the onset of clinical signs associated with drug toxicity.
3. Amiodarone hepatopathy is reversible with reduction or discontinuation of the drug (usually within 3 months).
4. Other toxicities include neutropenia, hypothyroidism, and hyperthyroidism.

V. Chronic, oral, antiarrhythmic therapy in cats (see Table 6-3)

Monitoring of Animal

I. Holter recordings are used to evaluate treatment.
A. Adequate treatment involves an 80% reduction in VPCs and suppression of VT.
B. Presence of couplets, triplets, or multiform VPCs suggests inadequate therapy.

II. If a Holter monitor is not available, ECG is used to evaluate response to therapy.

III. Measurement of plasma drug levels (sotalol, mexiletine, amiodarone) is indicated if the arrhythmia is not controlled with standard dosages of these drugs.

Idioventricular Rhythm

Definition and Causes

I. Idioventricular rhythm is characterized by a ventricular rate that is slow or comparable to a normal sinus rate (60 to 150 bpm in the dog, >100 bpm in cats).

II. It has many causes.
A. Systemic diseases: anemia, septicemia, splenic hemangiosarcoma
B. Drug toxicity: digoxin, anesthetic agents (opioids) that can slow the SA node discharge rate
C. Electrolyte abnormalities: hypokalemia

III. Enhanced automaticity may be the electrophysiologic mechanism that causes the arrhythmia.

Clinical Signs

I. Generally, no clinical signs occur.

II. If clinical signs are present, they are often associated with the underlying illness.

Diagnosis

I. Physical examination findings: irregular cardiac rhythm, occasional pulse deficits

II. ECG characteristics (Figure 6-18)
A. The ventricular rate usually remains within 10 to 15 bpm of the sinus rate.
B. The cardiac rhythm switches back and forth between two competing pacemaker sites.
C. The QRS complexes are wide and bizarre.

Differential Diagnosis

I. Supraventricular rhythm with bundle branch block

II. VT with a relatively slow rate

Treatment

I. Idioventricular rhythms usually do not require treatment.

II. Management of the underlying cardiac disease or metabolic abnormality is needed.

III. If the animal is symptomatic or hemodynamically compromised (low blood pressure), increasing the sinus rate with an anticholinergic drug abolishes the idioventricular rhythm.

Ventricular Fibrillation

Definition

I. Ventricular fibrillation (VF) is an irregular, chaotic rhythm of the ventricles in which there is no effective ventricular contraction.

II. VF is a terminal rhythm if the animal is not successfully defibrillated.

Causes and Pathophysiology

I. Ventricular tachycardia can degenerate to VF.

II. VF can occur primarily from heart disease or secondary to systemic disorders, such as shock, hypoxemia, drug reactions, trauma, and electrolyte disturbances.

III. Dogs with congenital heart diseases that are predisposed to ventricular arrhythmias (e.g., subaortic and pulmonic stenosis) may develop VF during exercise.

IV. Electrocution may induce VF.

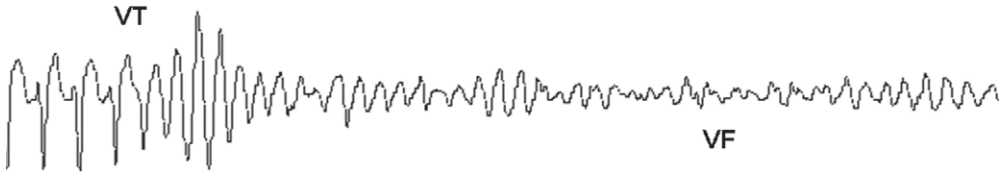

FIGURE 6-19 In this electrocardiogram (Lead II, 50 mm/sec, 10 mm/mV) ventricular tachycardia (VT) degenerates into ventricular fibrillation (VF), which is characterized by a low-amplitude, chaotic baseline, and contains no distinct waveforms.

Clinical Signs

I. Within seconds of onset, severe hypotension leads to collapse.
II. VF often occurs without forewarning.
III. Dyspnea or labored breathing may immediately precede VF.
IV. Sudden death is common.

Diagnosis

I. Physical examination findings
   A. No auscultable heart beat
   B. No palpable pulse
   C. Pale mucous membranes, slow or nonexistent capillary refill time
II. ECG characteristics (Figure 6-19)
   A. Chaotic and irregular deflections of varying amplitudes
   B. No P waves, QRS complexes, or T waves

Differential Diagnosis

I. ECG artifact
II. Rapid, polymorphic VT

Treatment and Monitoring

I. Immediate electrical defibrillation is the only viable treatment option (see Chapter 7).
II. VF has a grave prognosis if not corrected within 3 minutes of onset.

CHAPTER 7

Cardiopulmonary Arrest

Sean Smarick

CARDIOPULMONARY ARREST

Definition

I. Cardiopulmonary arrest (CPA) is a lack of spontaneous respiration and circulation.
II. In most instances, it is the common pathway preceding death.

Causes

I. The possible causes are numerous and many of these causes are potentially reversible.
II. A memory aid suggested by the American Heart Association for reversible causes includes the following list of "H"s and "T"s, and can be adapted to small animals.
   A. Hypovolemia
   B. Hypoxia
   C. Hypoglycemia
   D. H^+ (acidosis)
   E. Hyperkalemia
   F. Hypothermia
   G. Tablets (drugs)
   H. Trauma (brain)
   I. Tamponade
   J. Tension pneumothorax
   K. Thromboembolism

Pathophysiology

I. An underlying disease or insult causes hypoxia or decreases perfusion and notably affects the coronary and cerebral circulations.
II. Decreased perfusion results in cell dysfunction or death, leading to cardiac arrest, neurological impairment, and whole-body ischemia.

Clinical Signs

I. Collapse
II. Unresponsiveness
III. Lack of chest wall movement or agonal respirations

Diagnosis

I. If any of the clinical signs are noted, confirmation of CPA is pursued without hesitation, simultaneous to initiating specific treatment.
II. Physical examination findings of an unconscious and unresponsive animal require ruling out CPA.
   A. Lack of respiratory effort indicates respiratory arrest.
   B. Auscultation reveals no or only intermittent agonal breath sounds and no heart sounds during cardiac arrest.
   C. In cardiac arrest, palpation does not yield an apex heart beat or a peripheral pulse.
III. Cardiac arrest is characterized by electrocardiographic (ECG) evidence of asystole, pulseless electrical activity, or ventricular fibrillation.
   A. Animals in respiratory arrest or early CPA may have other arrhythmias (Rush and Wingfield, 1992).
   B. Electrical activity on the ECG does not ensure mechanical activity, and bradycardic waveforms are interpreted as CPA.
   C. A lack of a discernible ECG rhythm also warrants the consideration of technical difficulties, such as poor electrode-patient coupling, machine malfunction, among others.
IV. Changes in anesthetic or critical-care parameters help support the presence of CPA.
   A. Arterial blood pressure or Doppler blood flow intensity drops precipitously.
   B. Capnometry shows acute downward trends of end-tidal carbon dioxide ($_{ET}CO_2$) or apnea.
   C. Pulse oximetry waveforms or light-emitting diode indicators decrease abruptly; however, a decrease in oxygen saturation (S_pO_2) is not a reliable indicator of CPA.

Differential Diagnosis

I. Coma or neurological event
II. Syncope
III. Technical difficulties with monitoring devices

Treatment

I. Treatment is based on the owner's informed consent or, in the absence of a documented "do-not-resuscitate" request, dependent on any obvious signs of irreversible death (rigor).
   A. People's expectations are often unrealistic because of emotional involvement or unrealistic impressions (Diem et al., 1996).
   B. In dogs, survival rates range from 4% for cardiac arrest to 28% for respiratory arrest (Kass and Haskins, 1992; Wingfield and Van Pelt, 1992).

C. In cats, survival rates range from 2% for cardiac arrest and 58% for respiratory arrest (Kass and Haskins, 1992; Wingfield and Van Pelt, 1992).
D. Most successful resuscitations are related to anesthetic complications (Gilroy et al., 1987; Kass and Haskins, 1992; Waldrop et al., 2004).

II. Resuscitation is aimed at restoring spontaneous circulation while mitigating cerebral ischemia.
A. Cardiopulmonary cerebral resuscitation (CPCR) has been suggested as the treatment for CPA, because it reflects the goal of survival with intact neurological function.
B. Return of spontaneous circulation has been correlated with maximizing coronary perfusion pressure.

III. Duration of treatment is determined for each case, but most successful resuscitations last <15 minutes (Gilroy et al., 1987; Kass and Haskins, 1992; Waldrop et al., 2004).

IV. A dedicated area, cart, or tackle box for CPCR supplies, and regular staff training increases the likelihood of successfully reversing CPA.

V. The letters *A* through *G* provide a mnemonic guide to treatment (Figure 7-1).

Access Airway

I. Extend the neck (in a nontraumatized animal); pull the tongue rostrally.

II. Place and secure an appropriately sized endotracheal tube, confirming initial and continued placement with capnometry, visualization, or palpation.

III. If an airway obstruction is suspected or the endotracheal tube cannot be passed, relieve the obstruction.
A. Suction any vomitus or secretions from the laryngeal/pharyngeal area.
B. Physically remove any foreign body or use a polypropylene urinary catheter as a stylet to guide the endotracheal tube around the obstruction.
C. For foreign bodies not visible, perform a Heimlich maneuver by sharply compressing the abdomen in a ventrodorsal direction, just cranial to the umbilicus.
D. A tracheostomy is performed if an upper airway obstruction cannot be relieved.

Breathing

I. If only respiratory arrest is present, provide positive-pressure ventilation with 100% oxygen at a rate of 20 breaths per minute.

II. If cardiac arrest is present, ventilate 8 to 10 times per minute.

III. Use Ambu-bags, Baines, or other nonbreathing circuits, anesthesia machines, and even mouth-to-nose breathing to ventilate the animal.

IV. Experimentally, dogs maintain an oxygen saturation >90% without positive-pressure ventilation for up to 4 minutes and maintain a partial pressure of arterial oxygen (P_aO_2) of 80 mm Hg during CPCR on room air; however, ventilation with 100% oxygen is still recommended.

Circulation

I. Generate forward blood flow to perfuse the heart and brain.

II. Begin external chest compressions.
A. Compression dynamics are as follows:
1. Compress the chest by about 30% of its diameter.
2. Maintain a 1:1 compression:relaxation ratio.
3. Perform at a rate of 100 beats per minute (bpm) and minimize interruptions.
B. Thoracic conformation and size determine the best position for external compressions.
1. Cats and small dogs are circumferentially compressed at the level of the 5th intercostal space while in lateral recumbency.
2. Medium-size dogs (<15 kg) with greater dorsal-ventral versus lateral dimensions are placed in lateral recumbency, with the hands placed one over the other at the 5th intercostal space.
3. In large dogs, hand placement is over the widest portion of the thorax with the dog in lateral recumbency, or just cranial to the xiphoid process with the dog in dorsal recumbency.
C. Changing compressors, placement of hands, varying the rate and depth may offer some benefit if unsatisfactory results are obtained (e.g., increased $_{ET}CO_2$, perfusion pressure, or return of spontaneous circulation.
D. Procedures to augment external compressions may be considered.
1. Interposed abdominal compressions are performed midway between the umbilicus and xiphoid to generate a pressure of 100 mm Hg.
2. Active compression-decompression ± inspiratory threshold impedance valves require specialized equipment.
3. Simultaneous ventilation-compression CPCR and the application of military antishock trousers or caudal abdominal binding are no longer recommended.

III. Internal cardiac compressions may be considered.
A. Despite on-going debate, it is universally accepted that internal cardiac compressions must be used within 2 to 5 minutes to have any benefit.
B. Indications include a chest wall defect, penetrating trauma, cardiac tamponade, ineffective external compressions (especially in large or barrel-chested dogs) loss of chest wall compliance, or pleural space disease.
C. The technique for internal compressions is described in Box 7-1.

Differential Diagnosis and Drugs

I. While instituting the "ABCs," also start appropriate therapy for reversible causes of CPA.

II. Vascular access is obtained to administer fluids and drugs.
A. Central IV catheters are best for administering drugs, but placement is technically difficult during CPCR, and their long length is not ideal for administering fluid boluses.
B. Intraosseous (IO) access of the humerus or femur is technically feasible, especially in young or small animals, and provides central access.

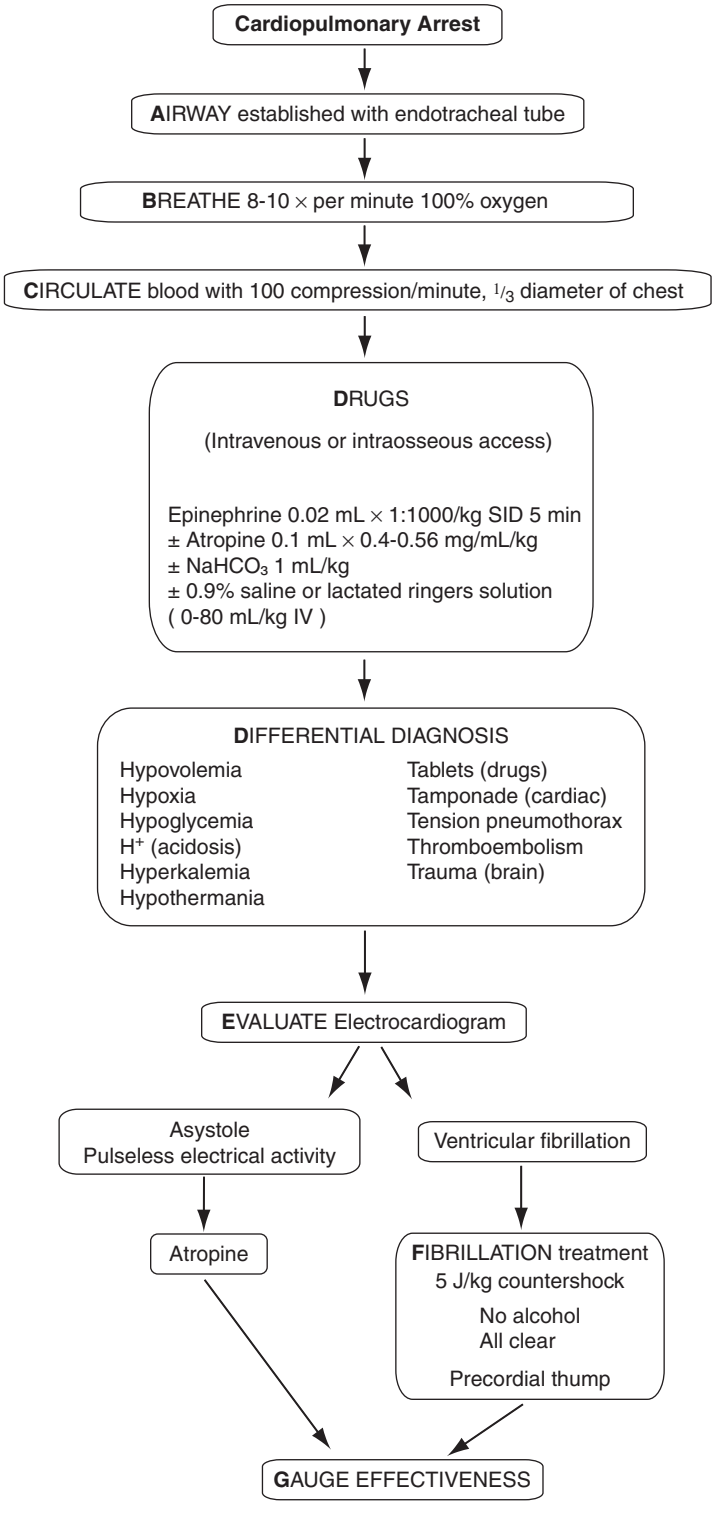

FIGURE 7-1 Algorithm for cardiopulmonary cerebral resuscitation for cardiopulmonary arrest.

C. Peripheral IV catheters are most often used but should be placed within the cephalic vein to minimize time to reach the heart during CPCR.
   1. Follow all drugs with a 20 mL bolus of IV fluids.
   2. Elevate the extremity afterward for 20 seconds.

III. Dosages of drugs administered intratracheally are at least doubled, except for epinephrine.

A. Drugs are dissolved in 5 to 10 mL of sterile water for injection or 0.9% saline, injected via a red rubber catheter at the level of the carina, and followed by two ventilated breaths.

B. *NAVEL* is the mnemonic for drugs that can be administered intratracheally (IT).
   1. **N**aloxone 0.04 mg/kg IT

Box 7-1

Technique for Performing Internal Cardiac Compressions

1. Animal is placed in right lateral recumbency.
2. Minimal to no surgical preparation is required over the left 6th intercostal space.
3. Incise the skin with a scalpel blade.
4. Make a controlled stab incision into the pleural space cranial to the rib with the tips of curved Mayo scissors.
5. Extend the incision by advancing the partially open Mayo scissors dorsally and ventrally, stopping short of the internal thoracic and vertebral arteries.
6. Insert Balfour or other self-retaining retractors.
7. Alternatively, incise the diaphragm during a celiotomy.
8. Incise the pericardial sac with the Mayo scissors to expose the heart.
9. Compression dynamics are as follows:
   a. Use the palmar surfaces of the fingers and hand(s).
   b. Compress the heart from apex to base.
   c. Compress at a rate of 100 to 150 beats/min.
10. Occlude the descending aorta by digital compression or by blunt dissection and occlusion with a red-rubber catheter, Penrose drain, or Rumel tourniquet.
11. If resuscitation is successful, release the aortic occlusion over 5 to 10 minutes while administering sodium bicarbonate empirically or as determined by blood gas analysis, and close the chest routinely after pleural lavage.

2. **A**tropine 0.08 mg/kg IT
3. **V**asopressin 1.6 U/kg IT
4. **E**pinephrine 0.2 mg/kg IT
5. **L**idocaine 4 mg/kg IT

IV. Sublingual administration of medications has been recommended only anecdotally.

V. Fluid administration in CPCR has been associated with worse outcomes in euvolemic animals, but if hypovolemia caused or contributed to CPA, appropriate boluses of isotonic crystalloids (0.9% saline, lactated Ringer's solution) are indicated.

VI. The administration of some drugs warrant ECG evaluation (see following section); however, others are immediately indicated.
   A. Antagonists for anesthetic agents during an anesthetic arrest (e.g., naloxone for a narcotic)
   B. Calcium gluconate 10% (0.6 mL/kg IV), insulin (0.2 U/kg IV), and dextrose (1 g/kg IV), and sodium bicarbonate (1 mEq/kg IV) for known hyperkalemia
      1. Calcium gluconate is only indicated for CPA associated with hyperkalemia, hypocalcemia, or calcium channel blocker intoxication.
      2. In other causes of CPA, calcium gluconate may worsen outcome.
   C. Epinephrine as a vasopressor
      1. Give 0.01 to 0.02 mg/kg IV every 3 to 5 minutes.
      2. High doses (0.1 to 0.2 mg/kg) have not been shown to be superior.
      3. Other alpha-2 agonists, such as phenylephrine or norepinephrine, have shown no increased benefit.
   D. Vasopressin 0.8 U/kg IV once: alternative to epinephrine (Schmittinger et al., 2005)
   E. Empirical vagolytic therapy
      1. Atropine may be given at 0.01 to 0.04 mg/kg IV.
      2. Empirical use is justified, as approximately 80% of the arrhythmias seen in CPA require atropine.
   F. Sodium bicarbonate ($NaHCO_3$)
      1. Dose: 1 mEq/kg IV initially, then 0.5 mEq/kg every 10 minutes
      2. Contraindicated in hypercarbia and requires adequate ventilation to avoid intracellular acidosis
      3. Indicated in animals with known metabolic acidosis or prolonged (>10 minutes) CPA

Evaluation of Electrocardiogram

I. Asystole (flat line) and pulseless electrical activity (wide, often bizarre bradyarrhythmia with no or ineffective mechanical cardiac activity) are most often observed.
   A. Administer atropine 0.04 mg/kg and repeat in 5 minutes.
   B. Transthoracic or transesophageal electrical pacing (available on many defibrillators) may be beneficial.
   C. Defibrillation is not indicated and can cause further myocardial insult.

II. Severe sinus bradycardia is often seen early in a vagal-induced arrest.
   A. Atropine is given at 0.004 to 0.01 mg/kg IV.
   B. Transthoracic or transesophageal pacing is indicated if bradycardia deteriorates or atrioventricular block occurs

III. Ventricular fibrillation (sawtooth waveform) accounts for approximately 20% of initial CPA rhythms and can occur during resuscitation efforts.

Fibrillation Treatment

I. Immediate defibrillation therapy is indicated, as survival is inversely proportional to the amount of time from onset to the first countershock.

II. Electrical defibrillation is the only effective therapy.
   A. Quickly clip area for electrodes to decrease impedance and potential for arcing.
   B. Electrode options include the following:
      1. Manually hold both standard paddles on opposite sides of the chest with the one marked "sternum" over the animal's right cranial thorax.
      2. Flat paddle marked "apex" is slid under the animal (in left lateral recumbency) while on a nonconducting table surface and the paddle marked "sternum" is placed on the animal's right cranial, lateral thorax.
      3. Self-adhesive electrodes are applied to the skin in the same areas as with hand-held paddles.
      4. Internal paddles are applied directly to either side of the heart (after thoracotomy).
      5. Select energy settings.
         a. Set at 5 to 10 J/kg for monophasic (older) defibrillators.

b. Newer biphasic defibrillators use approximately 40% less energy as the current flows from electrode to electrode and back again.
c. Internal defibrillation is done at approximately 10% of external settings.

6. Apply firm pressure to hand-held paddles to decrease transthoracic impedance.
7. Do not use alcohol; use coupling gel or saline-soaked gauzes.
8. Just before delivering a countershock, make sure everyone is clear of direct and indirect animal contact.
9. Administer one shock and then perform compressions, ventilation, and drug therapy for 1 minute before repeated attempts.

C. Pharmacological attempts at defibrillation have been very disappointing and are no longer recommended.
1. After unsuccessful countershocks, CPCR and vasopressor therapy, pharmacological intervention may be helpful in electroconversion before additional counter shocks.
2. Amiodarone 5 mg/kg IV is the drug of choice, and half of the initial dose may be repeated once.
3. Lidocaine may be used alternatively at 1 mg/kg IV and then 0.5mg/kg every 5 minutes to a maximum of 3 mg/kg.
4. Magnesium is only indicated in hypomagnesemic states or Torsades de pointes and is given at 20 mg/kg diluted in dextrose 5% in water (D_5W) over 5 minutes IV.

D. In the absence of a defibrillator, a precordial thump can be attempted but is not recommended for routine use.

Gauge Resuscitative Efforts

I. Monitor for return of spontaneous circulation.
II. $_{ET}CO_2$ values >10 mm Hg are evidence of effective oxygenation and circulation.
III. Diastolic arterial pressures >30 mm Hg correlate with coronary perfusion pressure of >15 to 20 mm Hg, which is adequate; however, indirect measurements (oscillometric, Doppler) are unreliable in CPCR.
IV. No other clinical indicators (pulse strength, pulse oximetry) have proven reliable for real-time evaluation of CPCR effectiveness.
V. If efficacy of CPCR is in question, do the following:
A. Confirm endotracheal tube placement.
B. Augment compressions.
C. Consider buffer therapy, such as $NaHCO_3$.
D. Reevaluate the ECG.
E. Revisit the differential diagnosis list to address any reversible causes.
F. Evaluate electrolytes, pH, and attempt to correct imbalances
VI. Consider discontinuing CPCR if there has been no return of spontaneous circulation and CPCR has lasted for 15 to 30 minutes, the animal was presented in CPA, or the underlying disease was already receiving maximal therapy.

Hypothermia

I. In successfully resuscitated animals, lowering the body temperature to approximately 91.5° F (33° C) by permissive means (not providing heat support), cooling blankets, or ice packs may improve neurological recovery in hemodynamically stable animals.
II. Intensive care and monitoring are usually required for successful recovery once spontaneous circulation is established.

Monitoring of Animal

I. Maintain oxygenation at P_aO_2 >80 mm Hg or S_pO_2 >95%, with supplemental oxygen or intermittent positive-pressure ventilation (IPPV).
II. Ventilation is assessed by measurement of arterial blood gas carbon dioxide (P_aCO_2), venous blood gas (P_vCO_2), or $_{ET}CO_2$ to maintain normocapnia (≈35 mm Hg).
III. Blood pressure is supported with vasopressors (norepinephrine 0.05 to 0.5 μg/kg/min, phenylephrine 1 to 10 μg/kg/min, or dopamine 10 to 40 μg/kg/min constant rate IV infusion) to maintain a mean arterial pressure >100 mm Hg or a Doppler systolic pressure >125 mm Hg for the first 12 hours, and then to maintain normotension.
IV. Monitor the ECG for arrhythmias that can affect cardiac output, blood pressure, and lead to rearrest.
V. Central venous pH is normalized by maximizing perfusion, maintaining normocapnia, and correcting acidosis with $NaHCO_3$ (0.3 mEq/kg/mmol × base deficit IV).
VI. Blood glucose is monitored to maintain euglycemia.
VII. Additional monitoring is warranted to identify the onset of coagulopathy, pneumonia, sepsis, renal failure, and seizures, with appropriate treatment instituted as needed.
VIII. Assess the animal for complications of external chest compression, such as rib or sternum separations or fractures, hemothorax, pneumothorax, pulmonary contusions, and hepatic and splenic lacerations.
IX. Prognostic factors for poor neurological outcome or death 24 hours post-resuscitation include the following:
A. Corneal reflex absent
B. Pupillary light response absent
C. Withdrawal response to pain absent
D. Motor response absent

CHAPTER 8

Congenital Heart Disease

John D. Bonagura

OVERVIEW OF CONGENITAL HEART DISEASE

Definition

I. Congenital heart disease (CHD) is a developmental lesion of the heart or great vessels present at birth.
II. Malformations are the most common cause of cardiovascular disease in dogs and cats <1 year of age.

Causes

I. CHD can be caused by genetic, environmental, chromosomal, infective, toxicologic, or nutritional factors, or it may develop from teratogenic effects of drugs.
II. Most cases have a genetic basis, but the precise mode of inheritance is often unknown.
III. There are numerous examples of breed-related predispositions to specific cardiac malformations (Table 8-1).
IV. Penetrance of a lesion can be incomplete, making clinical recognition difficult or impossible.

Pathophysiology

I. CHD can be classified as left-to-right shunts, right-to-left shunts, outflow tract stenosis, atrioventricular (AV) valve malformations, and complex malformations.
II. Outcomes can include congestive heart failure (CHF), arrhythmias, syncope, or sudden death.
III. Right-to-left shunts and complex malformations create hypoxemia and secondary polycythemia, with clinical complications related to tissue hypoxia and blood hyperviscosity (e.g., hypertrophic osteopathy).
IV. Pulmonary hypertension (PH) can develop with large cardiac shunts or with mitral valvular stenosis.
   A. Pulmonary arterial injury creates a high-resistance vascular system, increased right ventricular (RV) pressures, and reduced venous return to the left atrium.
   B. Severe PH can lead to limited cardiac output, exercise intolerance, and syncope.
   C. A left-to-right shunt may become right-to-left with severe PH (Eisenmenger's physiology).
   D. Severe pulmonary vascular disease is generally irreversible, and surgical closure of a shunt that decompresses the right circulatory side can be fatal.
   E. Clinical evidence of PH includes RV hypertrophy, main pulmonary artery dilation, right atrial enlargement, and reduced size of the left heart chambers.

Clinical Signs

I. In most cases, the pet owner does not recognize overt clinical signs of heart disease.
II. Stunted growth is common with severe CHD.
III. CHD often leads to exercise-induced problems, such as tiring, collapse, and syncope.
IV. Signs of CHF can be observed, including tachypnea, orthopnea, coughing, respiratory distress, or abdominal distension (from ascites).
V. Cyanosis is common with right-to-left shunts and when severe pulmonary dysfunction accompanies left-sided or biventricular CHF.
VI. Death from CHD may occur from unmanaged CHF, severe hypoxemia, or a cardiac arrhythmia (ventricular fibrillation, asystole).

Diagnosis

I. The diagnosis is suspected from identification of a cardiac murmur in a young animal, particularly in a breed at risk for CHD.
   A. The pet may appear normal, even with serious CHD.
   B. When clinical signs of CHD are present, suspect a severe cardiovascular malformation.
   C. Once clinical signs have developed, the prognosis is generally poor unless definitive or palliative treatments are initiated.
   D. Noncardiac causes of the clinical signs (e.g., anemia, parasitism, or pneumonia) must be ruled out.
II. Physical examination findings can be suggestive of CHD.
   A. Precordial palpation may identify cardiomegaly via caudal displacement of the left ventricular (LV) apical impulse or as a prominent RV impulse (heave).
   B. A palpable vibration or thrill indicates the presence of a loud cardiac murmur (grade V or VI) and identifies the point of maximum murmur intensity.
   C. Cardiac murmurs are typical of CHD.
      1. Most murmurs associated with CHD are systolic.
      2. A continuous murmur occurs with patent ductus arteriosus (PDA) or, rarely, from an aorticopulmonary window.
      3. A diastolic murmur usually indicates aortic regurgitation and, rarely, AV valvular (or supravalvular) stenosis.
      4. Distinguishing an innocent (functional) murmur from one caused by CHD can be difficult, if not

TABLE 8-1

Common Breed Predispositions to Congenital Heart Disease

BREED	MALFORMATION
Airedale terrier	Pulmonic stenosis
Beagle	Pulmonic stenosis, pulmonary insufficiency
Bichon frise	Patent ductus arteriosus
Boykin spaniel	Pulmonic stenosis
Boxer	Subaortic stenosis, pulmonic stenosis, atrial septal defect
Bull terrier	Mitral valve dysplasia, aortic stenosis
Chihuahua	Patent ductus arteriosus, pulmonic stenosis
Cocker spaniel	Patent ductus arteriosus, pulmonic stenosis
Collie	Patent ductus arteriosus
Doberman pinscher	Atrial septal defect
English bulldog	Pulmonic stenosis, tetralogy of Fallot, ventricular septal defect, subaortic stenosis
English springer spaniel	Patent ductus arteriosus, ventricular septal defect
German shepherd dog	Patent ductus arteriosus, subaortic stenosis, mitral valve dysplasia, tricuspid valve dysplasia, persistent right aortic arch
German shorthair pointer	Subaortic stenosis
Golden retriever	Subaortic stenosis, mitral valve dysplasia, tricuspid valve dysplasia
Great Dane	Mitral valve dysplasia, tricuspid valve dysplasia, aortic stenosis, persistent right aortic arch
Irish setter	Persistent right aortic arch, patent ductus arteriosus
Kerry blue terrier	Patent ductus arteriosus
Keeshond	Tetralogy of Fallot, ventricular septal defect, patent ductus arteriosus
Labrador retriever	Tricuspid valve dysplasia, patent ductus arteriosus
Maltese	Patent ductus arteriosus
Mastiff	Mitral valve dysplasia, pulmonic stenosis, subaortic stenosis
Newfoundland	Subaortic stenosis, mitral dysplasia, patent ductus arteriosus
Old English sheepdog	Tricuspid valve dysplasia
Poodle breeds	Patent ductus arteriosus
Poodle (standard)	Atrial septal defect
Pomeranian	Patent ductus arteriosus
Rottweiler	Aortic stenosis, mitral dysplasia
Samoyed	Pulmonic stenosis, aortic stenosis
Schnauzer breeds	Pulmonic stenosis
Shetland sheepdog	Patent ductus arteriosus
Weimaraner	Tricuspid valve dysplasia, peritoneopericardial diaphragmatic hernia
West Highland white terrier	Pulmonic stenosis
Yorkshire terrier	Patent ductus arteriosus

impossible; however, murmurs caused by clinically significant CHD are typically louder and of longer duration.

5. A particularly difficult issue for breeders is the persistence of a soft ejection murmur in the absence of an echocardiographic lesion, which makes it impossible to determine the presence of CHD.
6. With the exception of ventricular outlet obstruction (aortic or pulmonic stenosis [PS]), murmur grade (intensity) and duration do not correlate well with the severity of the cardiac lesion.
7. A murmur can be soft or absent even in serious situations, such as right-to-left shunting defects with polycythemia; pulmonary or aortic atresia; large unrestrictive ventricular septal defect (VSD); tricuspid dysplasia; or severe PH.

D. Jugular venous distension or pulsations suggest right heart disease (e.g., PS, tricuspid regurgitation, right-sided CHF).
E. A hypokinetic or late-rising femoral arterial pulse suggests outflow obstruction, LV dysfunction, or heart failure.
F. A bounding (hyperkinetic or waterhammer) pulse is typical of PDA and aortic regurgitation.
G. Cyanosis can be a sign of CHD and is caused by either right-to-left shunting or pulmonary dysfunction from lung edema or pleural effusion.
   1. Concurrent bronchopneumonia may be the most common cause of cyanosis in CHD.

2. The term *differential cyanosis* generally refers to the condition of pink oral membranes and cyanotic caudal membranes (best seen in the vulva or prepuce) and is most typical of reversal of a left-to-right PDA.

III. Thoracic radiographs can identify cardiomegaly, dilation of the great vessels, alterations in pulmonary circulation, and findings compatible with CHF.
   A. Young puppies have a relatively prominent RV shadow until 6 to 8 weeks of age.
   B. Radiographs also provide objective proof of the presence of CHF and can help guide initial treatment plans.
   C. Routine 6-lead electrocardiography (ECG) may identify atrial or ventricular enlargement, but can be negative and is rarely definitive.

IV. Definitive diagnosis and appropriate staging of CHD requires advanced echocardiography with Doppler studies.
   A. Two-dimensional (2D) and motion-mode (M-mode) echocardiography precisely define lesions, cardiac and great vessel enlargement, and ventricular function.
   B. Doppler studies identify the direction and velocity of blood flow and can be used to estimate intracardiac pressures.
   C. Turbulence algorithms can delineate abnormal patterns of blood flow, such as shunting or valvular regurgitation.

V. Cardiac catheterization and angiocardiography are needed to diagnose ambiguous cases of serious CHD, particularly if significant coronary, systemic, or pulmonary vascular malformations are present.

VI. Cases of trivial CHD can escape detection or defy clear definition, even with advanced echocardiographic methods and expert examination.
   A. For many dogs with soft ejection murmurs, distinguishing a functional (innocent) murmur from definitive disease can be difficult.
   B. These situations are unimportant relative to the health of the affected dog, but they do cause consternation regarding breeding soundness.

Differential Diagnosis

I. The most important considerations and most common problems are as follows:
   A. Stunted growth: malformations of other organ systems, metabolic diseases, chronic infection, malnutrition, or severe parasitism
   B. Respiratory signs: infectious respiratory diseases (viral infections, respiratory parasites, bordetellosis, bacterial bronchopneumonia), developmental diseases of the respiratory tract
   C. Abdominal distension with fluid: right-sided CHF, obstruction of caudal vena caval entry (cor triatriatum dexter), noncardiac diseases
   D. Syncope: acquired cardiac rhythm disturbance, myocarditis in puppies

II. In a young animal, the differential diagnosis of a murmur includes functional or innocent murmurs in puppies and kittens as well as cardiomyopathy in cats.
   A. Soft ejection-type murmurs (<III and/or VI) in otherwise healthy puppies or kittens are often innocent and disappear over time.
   B. Increasing murmur intensity, other physical abnormalities (stunted growth, cyanosis), or any clinical signs (exercise intolerance, respiratory distress) should prompt immediate evaluation by a specialist in CHD.
   C. A loud systolic murmur, a diastolic murmur, or a continuous murmur is very unlikely to be innocent and needs prompt evaluation.
   D. A persistent, soft-ejection murmur is common in many breeds at risk for aortic stenosis (e.g., boxer, Bouvier de Flanders, golden retriever), but it can be difficult or impossible to distinguish trivial CHD from a normal physiologic variation.
   E. In young cats (<2 years) with a systolic murmur and echocardiographic evidence of a concentrically hypertrophied LV, the differential diagnosis includes genetic hypertrophic cardiomyopathy, mitral valve malformation with dynamic obstruction of the ventricular outflow tract, or (rarely) fixed aortic stenosis.

Treatment

I. Definitive or palliative therapy for CHD often requires surgery or catheter-based intervention.
   A. Before such treatments begin, a definitive diagnosis *must* be established.
   B. Specific treatments are described under individual malformations.
   C. Unfortunately, many cases of CHD require surgery during cardiopulmonary bypass, so definitive repair is rarely accomplished, except for PDAs.
   D. Medical therapy may be needed for complications of CHD (e.g., CHF, cardiac arrhythmias, PH, secondary polycythemia).

II. CHF is a consequence of progressive volume or pressure overload of the affected ventricle.
   A. Initial management of left-sided CHF involves furosemide (2 to 4 mg/kg IV, IM, SC), oxygen supplementation, possibly 2% nitroglycerin ointment, and sedation with butorphanol (0.25 mg/kg IM, SC) as needed.
   B. If CHF persists and the cause is a left-to-right shunt, nitroprusside (0.5 to 2.5 μg/kg/min IV infusion) can be used to reduce arterial blood pressure and the magnitude of shunting.
      1. Chronic therapy with enalapril (0.5 mg/kg PO BID), amlodipine (0.05 to 0.2 mg/kg PO SID), or hydralazine (0.5 to 2 mg/kg PO BID) may reduce blood pressure and left-to-right shunting.
      2. Amlodipine or hydralazine may be needed in addition to an angiotensin-converting enzyme (ACE) inhibitor.
      3. Maintain systolic blood pressure at 80 to 120 mm Hg, particularly in cases of aortic stenosis (hypotension reduces coronary perfusion).
   C. Long-term medical therapy of CHF in dogs and cats with CHD is identical to that described in Chapter 9.

D. The use of beta-blockers in treatment of dogs with CHF from CHD is unresolved, and care must be used to avoid bradycardia, especially in dogs with fixed obstructions, such as subaortic stenosis and PS.
E. In some cases (e.g., PDA), medical therapy for CHF can be discontinued if definitive repair of the defect is performed successfully.

III. Controlling arrhythmias in animals with severe CHD helps to maintain a compensated state and can prevent sudden death (see Chapter 6).
IV. Management of PH is difficult, as the vascular changes responsible often are irreversible.
A. PH usually develops rapidly in dogs with large left-to-right shunts (<6 months of age), but in cats it may develop more gradually and may be arrested by closure of the defect or management of a stenotic mitral valve.
B. When reactive vasoconstriction is identified, drugs that reduce pulmonary vascular resistance, such as sildenafil *(Viagra)* at initial doses of 0.5 to 2 mg/kg PO BID can be beneficial (although very expensive).
C. Arterial blood pressure must be monitored, as reduced systemic resistance leads to greater right-to-left shunting.
D. Controlling exercise is important to prevent exertional collapse or dyspnea.
V. Management of polycythemia may be required.
A. Balloon valvuloplasty or surgery decreases right-sided pressures and reduces shunting from anatomic obstruction (PS).
1. Drugs can be tried to reduce pulmonary vascular resistance (see above).
2. Care must be exercised with large VSDs, as florid left-to-right shunting can develop if RV pressures approach normal.
B. Phlebotomy may be required in animals with right-to-left shunting and secondary polycythemia (see Chapter 64).
1. While a packed cell volume (PCV) of 62% to 65% is often well tolerated, values >68% to 70% are likely to cause exercise difficulties or predispose to thrombotic stroke or sudden death.
2. Amount of blood removed (mL) = (body weight [kg] × 0.08) × 1000 mL/kg × (actual PCV – desired PVC ÷ actual PCV).
3. Simultaneously administer IV fluids at one to two times the volume removed.
4. Alternatively, remove 10% of blood volume in the morning and 2% to 10% in the afternoon without fluid replacement.
C. When the need for phlebotomy becomes too frequent, reversible bone marrow suppression with hydroxyurea (10 to 20 mg/kg PO SID) may be tried.

Monitoring and Prevention

I. Follow-up care is individualized and based on the specific defect, the severity of disease, prior treatments, and supervening complications.
II. No genetic tests are available to detect carriers of CHD, so genetic counseling for breeding dogs can be difficult.
A. Animals with even mild CHDs should not be bred.
B. Dogs with normal cardiac phenotype that produce CHD-affected puppies in more than one litter are removed from breeding programs.
C. Breeding dogs with equivocal cardiac status based on echocardiographic and Doppler studies are bred only if other important characteristics are considered normal or outstanding.

PATENT DUCTUS ARTERIOSUS

Definition

I. PDA is a persistent patency of the fetal ductus arteriosus, which connects the descending aorta and the main or adjacent left pulmonary artery.
II. This defect is present in approximately 2.5 of 1000 live canine births; it is rare in cats.

Causes

I. PDA is a genetic disorder in many breeds (see Table 8-1); the exact mode of inheritance is undetermined but may be related to multiple genes or modifying genes.
II. Females are predisposed, but both sexes are affected.

Pathophysiology

I. Left-to-right shunting leads to pulmonary overcirculation, volume overload of the left side of the heart, progressive LV dysfunction, and ultimately left-sided CHF.
II. Cardiomyopathy of chronic volume overload (myocardial failure, systolic dysfunction) and atrial fibrillation are common in large-breed dogs with untreated PDA.
III. In a small percentage of cases, reversed shunting is caused by pulmonary vascular injury (Eisenmenger's physiology).

Clinical Signs

I. Most puppies are asymptomatic.
II. Once tachypnea and exercise intolerance develop, left-sided CHF is likely.
III. Exertional rear limb weakness is typical of "reversed" PDA.

Diagnosis

I. A key finding is a continuous cardiac murmur that is loudest over the left craniodorsal cardiac base.
II. The diastolic component of the murmur is less prominent or absent in very young puppies, cats, or cases of progressive PH.
III. Arterial pulses are typically hyperkinetic.
IV. The LV can be enlarged, with palpable caudoventral apical displacement.
V. Pelvic limb weakness that improves with rest, differential cyanosis, loss of the continuous murmur, and a loud second heart sound are typical of reversed PDA.
VI. Radiographs identify pulmonary overcirculation with a left-to-right shunting PDA.
VII. Radiographs and 2D echocardiograms demonstrate dilation of the left atrium, LV, ascending aorta, descending aorta ("ductus bump"), and main pulmonary artery.

VIII. M-mode echocardiography demonstrates eccentric hypertrophy (increased diastolic diameter) and, possibly, reduced LV systolic function (decreased shortening fraction).
IX. Doppler studies demonstrate continuous blood flow in the main pulmonary artery, and mitral regurgitation and pulmonic insufficiency from chamber dilatation.
X. The echocardiogram typically shows enlargement of the LV and possibly the left atrium.
XI. In reversed PDA, diagnostic studies reveal mainly right heart enlargement, dilation of the main pulmonary artery, and reduced pulmonary blood flow, whereas contrast echocardiography (after cephalic vein injection) demonstrates contrast medium in the descending aorta.

Differential Diagnosis

I. Aortopulmonary communication (window) is a congenital connection between the ascending aorta and pulmonary artery, and it may produce a continuous murmur.
II. VSDs with aortic regurgitation, or aortic stenosis with aortic regurgitation can produce both systolic and diastolic murmurs that can be confused with a PDA murmur.
III. Multiple (bronchial artery) systemic to pulmonary fistulas can create a PDA-like situation; however, a continuous murmur is not evident, mandating angiography for diagnosis operation when performed by an experienced surgeon.
IV. Signs of reversed PDA can mimic neuromuscular diseases, particularly myasthenia gravis.

Treatment

I. Early closure is strongly recommended for left-to-right shunting defects, as the 1-year mortality for untreated dogs probably exceeds 60%.
II. For a reversed (right-to-left) shunting PDA, closure of the defect is contraindicated.
III. Thoracotomy and surgical ligation of the ductus is a successful operation when performed by an experienced surgeon.
   A. Closure generally results in complete resolution of signs.
   B. A postoperative murmur of mitral regurgitation is common, but generally subsides by the time of suture removal.
IV. Less-invasive transcatheter techniques for closure of PDAs include insertion of embolization coils and use of various Amplatzer occluding devices.
V. When CHF complicates PDA, medical management is needed (see Treatment under Overview of Congenital Heart Disease).
VI. Reversed PDA has a poor prognosis, although some animals live beyond 5 years of age.
   A. They are affected mainly by pelvic limb weakness during exercise.
   B. They require management of PH and polycythemia.

Monitoring of Animal

I. Early therapeutic intervention can slow or eliminate irreversible myocardial damage and prevent CHF.
II. The prognosis following closure of a PDA is excellent.
   A. A normal lifespan can be anticipated, and most cases do not require any cardiac follow-up.
   B. Exceptions include dogs with marked LV systolic dysfunction, prior CHF, or atrial fibrillation.
III. Monitor clinical signs and PCV in reversed PDA cases.

VENTRICULAR SEPTAL DEFECT

Definition

I. A VSD is a communication between the left and right ventricles, and shunting usually proceeds from the LV to RV.
II. Based on location, a VSD can be classified as para(peri)-membranous, inlet, muscular (trabecular), or subarterial (subpulmonic, supracristal, doubly committed).
III. Large defects are sometimes associated with malalignment of the aorta and are likely to cause aortic root prolapse and valvular regurgitation.
IV. A large VSD is also a component of the tetralogy of Fallot.

Causes

I. VSD is probably caused by genetic factors in some breeds (see Table 8-1).
II. Experimentally, VSD (various species) has been associated with a number of drugs, infections, or environmental factors.

Pathophysiology

I. Most cases of uncomplicated VSD in dogs are well tolerated, as long as the defect is "restrictive."
   A. Most defects that are <50% of the aortic root area are restrictive in nature.
   B. Very large defects are likely to cause CHF and death at approximately 1 to 2 months of age as pulmonary vascular resistance drops (before presentation to a veterinarian).
   C. The shunting physiology of VSD is similar to that of PDA, in that a left-to-right shunt causes pulmonary overcirculation and volume overload of the left atrium and LV.
   D. Large defects complicated by aortic regurgitation are likely to cause CHF.
II. The degree of RV overload depends on the size of the defect, presence of RV outflow tract obstruction, location of the defect, and development of PH.
III. Concurrent PS, a double-chambered RV (a midventricular obstruction), or development of Eisenmenger's physiology can lead to reversed shunting.

Clinical Signs

I. Most dogs and cats are asymptomatic, with occasional cases showing signs of CHF or PH.
II. Cyanosis indicates a complicated VSD.

Diagnosis

I. A systolic murmur, generally loudest over the cranial right sternal edge, is typical of the paramembranous VSD.

II. If the defect is located elsewhere in the septum, or if fibrous tissue partially occludes the defect, a systolic murmur that is apical or loudest over the left sternal edge may occur.
III. Results of radiography are variable, but overcirculation of the lungs is common.
  A. Various combinations of left and right heart enlargement are typical.
  B. The main pulmonary artery can be dilated from increased flow or PH.
IV. The ECG can be normal, or LV enlargement and wide or splintered Q-wave in leads I, II, and aVF may be detected.
V. Echocardiography (2D imaging) demonstrates the defect and Doppler studies delineate the direction and velocity of shunting.
  A. Restrictive defects are characterized by high velocity (>4.5 m/sec) shunting, indicating maintenance of the left-to-right ventricular pressure gradient.
  B. Hemodynamically important defects create significant left-sided volume overload.
  C. It is important to scrutinize the RV for obstructive lesions and the aortic root for malalignment or regurgitation.

Differential Diagnosis

I. Other defects can lead to systolic murmurs on the right side of the thorax, especially tricuspid valve dysplasia and aortic stenosis.
II. Mitral regurgitation can create a similar murmur (in terms of timing).
III. Subpulmonic VSDs create left basilar murmurs that can be confused with PS, aortic stenosis, or mitral regurgitation.

Treatment

I. Most dogs and cats with an isolated, uncomplicated VSD (without severe aortic regurgitation or other lesions) that survive to 4 months of age do not require treatment.
II. Surgical closure of septal defects is the definitive treatment but requires cardiopulmonary by-pass and open heart surgery.
III. Palliative pulmonary arterial banding creates a supravalvular PS and reduces the magnitude of left-to-right shunting; banding is recommended only for those animals with rapidly progressive cardiomegaly and overt or impending CHF.
IV. Transcatheter occlusion devices have been developed for closure of VSDs.
V. If CHF develops, medical management is indicated (see Treatment under Overview of Congenital Heart Disease).
VI. Right-to-left shunting can develop in dogs or cats with VSD from PH (Eisenmenger's complex); valvular or subvalvular PS; or progressive, midventricular fibromuscular obstruction (double-chambered RV).
  A. Exercise intolerance and polycythemia can develop.
  B. Treatment is as described previously for polycythemia.

Monitoring of Animal

I. A small restrictive VSD carries an excellent prognosis for longevity.
II. CHF associated with VSD is uncommon in most small animals.
III. CHF is anticipated in dogs with a VSD, aortic root prolapse, and audible aortic regurgitation.
  A. CHF can develop during middle age from LV volume overload.
  B. Empirical treatment with ACE-inhibitors may be considered.
IV. CHF also develops in some cats with VSD, especially when the defect is nonrestrictive.
V. Infrequently, a VSD closes from fibrous tissue proliferation or adherence of the septal leaflet of the tricuspid valve.
  A. This can lead to a septal aneurysm but without significant shunting.
  B. These lesions are functionally closed.
VI. Yearly cardiology examinations with echocardiography are recommended.

ATRIAL SEPTAL DEFECT

Definition

I. An atrial septal defect (ASD) is a communication between the left and right atria, and shunting usually proceeds from left to right.
II. The location of an ASD determines the classification of the defect.
  A. They are defined as a secundum, primum, or sinus venosus defects.
  B. If the two membranes of the foramen ovale do not close, the functional result is an ASD.
III. A defect in the ventrally located AV septum or the embryonic endocardial cushions can lead to a primum (ventral) ASD, VSD, and malformation of the septal leaflets of the AV valves with regurgitation.

Causes

I. ASD is probably caused by genetic factors in some breeds (see Table 8-1).
II. A patent foramen ovale is created when the two atrial septal membranes are either pulled or pushed apart.
  A. Patency can be maintained by either severe left atrial stretching or from higher-than-normal right atrial pressures that push the membranes apart.
  B. The latter is caused by some other form of right-sided disease (e.g., PS, tricuspid valve malformation).

Pathophysiology

I. A left-to-right shunt with volume overload of the right atrium and RV occurs.
II. Pulmonary overcirculation is also present, but the left atrium typically is normal in size (except with an endocardial cushion defect).
III. A large ASD can cause right-sided CHF or lead to pulmonary vascular injury with PH.
IV. An endocardial cushion defect can cause left-sided or biventricular CHF.

V. Right-to-left shunting can occur across an ASD in the presence of PH or from obstructive lesions on the right side of the heart.
VI. Severe tricuspid regurgitation also can cause cyanosis by raising right atrial pressure and causing right-to-left shunting.

Clinical Signs

I. Most dogs and cats with an isolated ASD are asymptomatic or have nonspecific signs.
II. Pressure differences across an ASD are relatively small; therefore the defect does not cause a murmur other than that of increased flow across the pulmonary valve ("relative" PS).
III. Classically the second heart sound is split, owing to a relatively longer duration of RV ejection.
IV. Occasionally, affected animals have signs of CHF (pleural effusion, ascites) or PH.
V. Cyanosis indicates a complicated ASD.

Diagnosis

I. A systolic murmur is suspicious for CHD.
II. Radiography of an animal with a secundum ASD demonstrates right heart enlargement, dilation of the pulmonary artery, and overcirculation of the lungs; however, left atrial size is variable.
III. With an endocardial cushion defect, significant mitral regurgitation can occur, leading to left heart enlargement or evidence of left-sided CHF on radiography.
IV. ECG shows RV and usually right atrial enlargement with right axis deviation; however, a left cranial frontal axis is more typical of a primum ASD or an endocardial cushion defect.
V. Echocardiography is the diagnostic study of choice.
   A. The septal defect can be observed with 2D imaging, and Doppler studies delineate the direction of shunting, which is often bidirectional.
   B. It is important to scrutinize the RV for obstructive lesions and the AV valves for malformation and regurgitation.
   C. Overreliance on color Doppler imaging for the diagnosis is discouraged, because even normal right atrium (RA) flow patterns can be confusing.

Differential Diagnosis

I. Rule out other causes of systolic murmurs in young dogs, including pulmonic and aortic stenosis.
II. Anomalous pulmonary venous drainage can create a similar physiology and may be associated with a sinus venosus ASD.

Treatment

I. Little experience exists in the management of ASD in dogs and cats, as this defect is relatively uncommon.
   A. With a patent foramen ovale, treatment of the related lesion can cause the defect to functionally close.
   B. Transcatheter atrial septal occlusion devices have been applied to dogs.
   C. Open-heart surgery has been used for successful closure of ASDs, but is not readily available.
II. If CHF develops, medical management is indicated.
III. Right-to-left shunting ASDs may cause exercise intolerance and polycythemia that require treatment.

Monitoring of Animal

I. Yearly cardiology examinations with an echocardiogram are recommended.
II. Radiographs are obtained to monitor endocardial cushion defect cases.
III. Late-onset pulmonary vascular disease with PH or reversed shunting can occur.

TETRALOGY OF FALLOT

Definition and Cause

I. Tetralogy of Fallot is defined as a combination of PS, large (unrestrictive) VSD, dextropositioned aorta, and RV hypertrophy.
II. It is one of the most common causes of cyanotic CHD and has a genetic basis in some breeds (see Table 8-1).

Pathophysiology

I. The presence of PS increases RV systolic pressure and allows shunting of blood from right to left.
II. Depending on the severity of RV outflow obstruction and systemic vascular resistance, blood will shunt from right to left, left to right, or (most commonly) in a bidirectional manner.
III. Right-to-left shunting leads to hypoxemia, cyanosis, and secondary polycythemia.

Clinical Signs

I. The history can include exercise intolerance, syncope, or tachypnea.
II. When the PS is not severe, the condition is well tolerated and shunting is predominately left to right ("pink tetralogy").

Diagnosis

I. A systolic murmur of PS is typically detected over the left heart base.
II. Cyanosis is typical.
   A. Pulse oximetry usually identifies clinically significant desaturation ($SpaO_2$ <90%).
   B. Blood gas analysis reveals hypoxemia, often with Po_2 <65 mm Hg.
III. RV hypertrophy is evident on ECG and imaging studies.
IV. Radiographs demonstrate the following:
   A. RV rounding, a small and straight left heart border on the ventrodorsal projection, and pulmonary undercirculation
   B. The ascending aorta, which can be widened ventrally on the lateral projection (overriding aorta)
V. Echocardiography (2D) is diagnostic and demonstrates the four components of the malformation.

A. Doppler studies show low-velocity shunting across the VSD and high-velocity flow (typically 4 to 5 m/sec) across the proximal pulmonary artery.
B. Contrast echocardiography reveals right-to-left ventricular shunting below the aortic root.

VI. PCV may indicate polycythemia in animals with persistent oxygen desaturation.
VII. Cardiac catheterization is rarely needed to establish the diagnosis.

Differential Diagnosis

I. Tricuspid atresia, pulmonary atresia (pseudotruncus arteriosus), PS with an ASD (or patent foramen ovale), and VSD are other causes of cyanotic CHD.
II. Complex malformations, such as double-outlet RV, can also lead to cyanotic CHD.

Treatment

I. Animals with a sedentary lifestyle often tolerate this disease well, especially if the PS is not too severe.
A. Some animals live for 5 years or longer.
B. Exercise creates vasodilation in skeletal muscle and increases tissue oxygen demands, and may lead to worsening of cyanosis, tachypnea, and exercise intolerance.
II. Sudden death is common from progressive hypoxemia, polycythemia, and cardiac arrhythmias.
III. Drugs that cause systemic vasodilation are avoided, as right-to-left shunting can be exacerbated.
IV. Vasopressors may be needed during anesthesia to avoid systemic hypotension that enhances right-to-left shunting.
V. Beta-blockade with propranolol (starting at 0.25 mg/kg PO TID and increased over 4 weeks to 1 mg/kg PO TID) can be beneficial by reducing exercise-induced RV hypercontractility.
VI. Definitive surgery is rarely done and involves cardiopulmonary by-pass.
VII. Palliative surgery involves the creation of an extracardiac shunt between the systemic and pulmonary circulations (e.g., Blalock-Taussig shunt).
A. Such shunts increase pulmonary flow, improve arterial saturation, and can produce significant clinical improvement.
B. The major limitation is the extent to which these shunts remain patent.
C. Aspirin or other drugs that inhibit platelet activation (e.g., clopidogrel) are indicated.
VIII. Balloon valvuloplasty of a stenotic pulmonary valve can reduce RV pressure, but complete resolution of the PS is contraindicated because it allows for marked left-to-right shunting.
IX. Polycythemia is managed as described previously.

Monitoring of Animal

I. Monitor clinical signs, PCV, and arterial oxygen saturation.
II. Yearly reevaluation is indicated for stable cases.
III. If a palliative shunt has been created, Doppler examination is done to evaluate patency of the shunt.

PULMONIC STENOSIS

Definition and Cause

I. Pulmonic stenosis (PS) is a congenital narrowing of the pulmonic valve, subpulmonic region, or immediate supravalvular tissues.
II. The components of valvular PS include valve thickening, fusion along the valvular commissures, and varying degrees of hypoplasia of the valve.
III. Subvalvular obstruction can be fixed (fibrous) or related to dynamic obstruction from infundibular muscular hypertrophy.
IV. An unusual type of subvalvular PS is associated with a single origin (R2A type) of the coronary arteries from the right sinus of Valsalva.
A. It is most common in English bulldogs.
B. The left coronary artery causes an extramural, subvalvular obstruction.
V. PS is rare in cats.
VI. A genetic basis is responsible for most cases in dogs (see Table 8-1).

Pathophysiology

I. Increased resistance to ejection creates a pressure overload of the RV, with compensatory concentric RV hypertrophy.
II. High-velocity ejection of blood across the stenosis is associated with turbulent flow and poststenotic dilatation of the pulmonary artery.
III. If there is a concurrent patent foramen ovale, ASD, or VSD, then right-to-left shunting can develop.
IV. Cardiac output is limited, and right-sided CHF can occur from diastolic and systolic RV dysfunction, tricuspid regurgitation, and, possibly, atrial fibrillation.

Clinical Signs

I. Most affected dogs are asymptomatic, but fatigue, exercise intolerance, and syncope can be observed in severe cases.
II. If right-sided CHF occurs, abdominal distension develops from ascites.
III. Approximately 30% of dogs with severe PS die suddenly.

Diagnosis

I. The typical ejection murmur of PS is systolic and loudest over the pulmonary valve and craniodorsal left heart base.
A. The more severe the defect, the louder and later the murmur peak.
B. An ejection sound can be detected in valvular PS.
C. A loud holosystolic murmur on the right side is suggestive of tricuspid regurgitation from either RV hypertrophy or concurrent tricuspid valve malformation.
II. Mucous membranes are pink, unless there is right-to-left shunting.
III. A prominent jugular pulse can usually be identified.
IV. Right-sided CHF with hepatomegaly and ascites is found in a small percentage of cases.

V. Rarely, pleural effusion or chylothorax is identified in dogs with CHF.
VI. ECG, thoracic radiography, and 2D echocardiography demonstrate RV enlargement and, often, dilation of the RA.
  A. Imaging reveals poststenotic dilation of the pulmonary artery in severe cases.
  B. The pulmonary circulation is normal to reduced.
VII. Doppler echocardiography shows high-velocity, turbulent flow in the RV outflow tract and the pulmonary artery along with pulmonary insufficiency.
VIII. If RV systolic function is normal (and the animal is not heavily sedated or anesthetized), the peak velocity of ejection correlates with the severity of obstruction.
  A. Velocities <3.5 m/sec (peak gradient <50 mm Hg) indicate a relatively mild stenosis and good prognosis.
  B. Peak velocities >5 m/sec are considered severe (100 mm Hg peak pressure gradient), and carry a guarded to poor prognosis.
IX. Careful examination of the atrial and ventricular septa with color Doppler is needed to exclude a right-to-left shunt, and contrast echocardiography is an efficient way to screen for a defect.
X. Concurrent tricuspid regurgitation is a common finding and can develop from RV overload or from tricuspid valve dysplasia.
XI. Cardiac catheterization is performed mainly in preparation for catheter-based intervention.
XII. Angiography may be required for the identification of a single-origin coronary artery or other vascular anomalies.

Differential Diagnosis

I. Another cause of CHD that creates a systolic murmur or right-sided enlargement
II. Tetralogy of Fallot
III. Functional ejection murmur

Treatment

I. Mild to moderate PS (peak pressure gradients <50 and 100 mm Hg, respectively) generally carry a good prognosis (survival of ≥ 8 years).
  A. Some dogs (75 to 100 mm Hg range) benefit from valvuloplasty.
  B. Severe disease (gradient > 100 mmHg) increases the likelihood of sudden death or CHF.
II. Transcatheter balloon valvuloplasty is the treatment of choice for moderate to severe PS when the lesion is characterized by valvular thickening with commissural fusion.
  A. The procedural mortality is low when performed by experienced operators, and the dilation usually results in a ≥50% reduction of RV systolic pressures.
  B. Successful valvuloplasty of severe stenosis reduces by 50% the risk of sudden death.
  C. Therapy should not be delayed as gradients and muscular hypertrophy can progress with time and growth.
  D. Valvuloplasty is contraindicated in dogs with a single origin of the coronary artery.
III. When PS is complicated by severe RV hypertrophy or subvalvular fibromuscular obstruction, balloon valvuloplasty is combined with propranolol or atenolol (1 mg/kg PO BID), sometimes for life.
IV. Surgical techniques include patch grafting, pulmonary valve repair or resection, or surgical dilation.
  A. They are indicated for cases of severe fibromuscular RV obstruction, broad subvalvular fibrous ring, or in dogs in which PS is complicated by marked pulmonary valvular hypoplasia.
  B. An RV to pulmonary artery conduit can be used to bypass a hypoplastic valve or stenosis related to an anomalous coronary artery.
V. In cases that cannot be treated more definitively, atenolol provides empirical cardiac protection.
VI. PS with patent foramen ovale, ASD, or VSD can progress to right-to-left shunting with polycythemia, which requires treatment.

Monitoring of Animal

I. In cases of mild, stable PS, reevaluation may not be necessary in dogs > 1 year of age.
II. Dogs with moderate to severe PS are examined yearly with Doppler echocardiography so that the pressure gradient, competency of the tricuspid valve, and RV systolic and diastolic function can be monitored.

SUBAORTIC STENOSIS

Definition and Cause

I. Aortic stenosis (AS) is a congenital narrowing of the LV outflow tract.
  A. The condition is common in dogs and rare in cats.
  B. The most common location for obstruction is the subvalvular portion of the outflow tract SAS.
II. Valvular AS occurs in some dogs and is characterized by thick or fused aortic valve leaflets or by the presence of fused bicuspid leaflets.
III. Subvalvular obstruction is typically fixed (fibrous).
  A. Dynamic obstruction of the outflow tract can be caused by a malformation of the mitral valve leading to systolic anterior motion of the mitral valve.
  B. This form of SAS is labile and worsens with elevated sympathetic tone.
IV. Intramural coronary arteries are abnormal in SAS and reduce the blood supply to the myocardium.
V. Dogs with AS are at a higher risk for infective endocarditis.
VI. SAS is a genetic disorder in many dogs (see Table 8-1).

Pathophysiology

I. Pressure overload of the LV is created, with increased systolic pressure needed to eject blood across the stenotic zone.
II. This pressure is generated by concentric hypertrophy of the LV.
III. High-velocity ejection is associated with poststenotic turbulence and dilation in the ascending aorta.

IV. Coronary arterial insufficiency can lead to subendocardial ischemia, which predisposes to exercise intolerance and cardiac arrhythmias.
V. Cardiac output is limited, and left-sided CHF can develop from diastolic and systolic LV dysfunction, mitral regurgitation, and, possibly, atrial fibrillation.
VI. Syncope or sudden death can be triggered by exertion, especially from ventricular arrhythmias or from stimulation of ventricular mechanoreceptors (cardiac baroreceptor reflex).

Clinical Signs

I. Most affected dogs are asymptomatic, but fatigue, exercise intolerance, and syncope can be observed in severe cases.
II. If CHF occurs, tachypnea and other respiratory signs arise from pulmonary edema.

Diagnosis

I. The typical ejection murmur of AS is systolic and loudest over the aortic valve and subaortic areas.
   A. In SAS, the more severe the defect, the louder and later peaking of the murmur, and the more likely a prominent right-sided component (along with radiation into the carotid arteries) will be evident.
   B. The murmur of a true valvular AS is often loudest over the right dorsal heart base.
   C. A loud, holosystolic murmur over the apex may be indicative of concurrent mitral regurgitation.
II. The femoral pulse is late-rising and weak with moderate to severe AS.
III. Overt left-sided CHF occurs in a small percentage of cases.
IV. ECG, thoracic radiography, and 2D echocardiography may demonstrate LV enlargement in moderate to severe cases and, less often, dilation of the LA.
   A. Cardiac size may appear normal on thoracic radiographs.
   B. Concentric LV hypertrophy and subendocardial hyperechogenicity consistent with fibrosis is identified by 2D imaging with severe and sometimes moderate SAS.
   C. Imaging often reveals poststenotic dilation of the ascending aorta (on the right of the midline) in severe cases.
   D. The pulmonary circulation is normal to prominent.
   E. The finding of left atrial dilation is a poor prognostic sign and indicates either LV failure, mitral valve disease, or a left-to-right shunt.
V. Doppler echocardiography shows high-velocity, turbulent flow in the LV outflow tract and the ascending aorta, with the most accurate velocities obtained from a subcostal transducer position.
   A. If LV systolic function is normal (and the animal is not heavily sedated or anesthetized), the peak velocity of ejection correlates with the severity of obstruction.
   B. Peak velocities >4.5 to 5 m/sec are considered severe (>80 to 100 mm Hg peak pressure gradient), and carry a guarded to poor prognosis.
   C. Color and spectral Doppler examination reveal aortic regurgitation (generally silent on auscultation).
   D. The diagnosis of trivial AS by Doppler methods only is controversial.

Differential Diagnosis

I. Other causes of CHD that create a systolic murmur or left-sided enlargement: VSD, mitral valve malformation
II. Other causes of a left-sided murmur: PS, ASD
III. Functional ejection murmur

Treatment

I. Transcatheter balloon dilation of the stenotic orifice reduces LV pressure gradients by 40% to 50%, but does not appear to provide any survival benefit over beta-blockade with atenolol.
II. Open surgical resection of the stenotic lesion provides the best long-term reduction of pressure gradients, but clinical results have been disappointing.
III. With atenolol (1 to 2 mg/kg PO BID) a median survival of >4 years has been observed in some dogs, even with severe SAS (gradients >120 mm Hg).
   A. Atenolol is recommended for all dogs with peak gradients >50 mm Hg.
   B. Beta-blockade of a dynamic SAS caused by mitral valve malformation alleviates the obstruction and allows regression of LV hypertrophy.
IV. Dogs with even mild disease are at higher risk for development of infective endocarditis; therefore, prophylactic antibiotics are administered during elective surgical procedures or whenever wound contamination occurs.

Monitoring of Animal

I. In mild, stable SAS, reevaluation may not be necessary.
II. Dogs with moderate to severe SAS are examined annually with Doppler echocardiography, so the pressure gradients, competency of the aortic and mitral valves, and LV systolic and diastolic functions can be monitored.
III. Giant-breed dogs are evaluated just before full maturity, as the severity of the obstruction can increase dramatically during the first year of life.
IV. Severe SAS carries a poor prognosis, owing to premature death.
   A. Sudden death from cardiac arrhythmias and progressive LV dysfunction are typical outcomes.
   B. Mature dogs with mild SAS are more likely to live normal lives, although some still experience sudden death.

ATRIOVENTRICULAR VALVULAR DYSPLASIA

Definition

I. Dysplasia or malformation of the mitral or tricuspid valves includes a number of morphologic abnormalities of the AV valve apparatus, such as malformed papillary muscles; excessively short or long chordae tendineae; abnormal valve leaflets and cusps; and fusion along valve commissures.

II. The functional outcome is valvular regurgitation (most common), valvular stenosis with obstruction to ventricular filling, or both.
   A. Severity can range from trivial to life threatening.
   B. Concurrent defects, such as an ASD or patent foramen ovale, may occur.
   C. Tricuspid dysplasia in Labrador retrievers can be associated with anomalous conduction that predisposes to reentrant supraventricular tachycardias.

Causes

I. AV valve dysplasia is most likely a genetic disorder in dogs (see Table 8-1).
II. The mode of inheritance is likely autosomal dominant with incomplete penetrance in Labrador retrievers with tricuspid dysplasia.

Pathophysiology

I. AV valve regurgitation causes volume overload of the affected side of the heart.
   A. Chronic, severe regurgitation leads to CHF.
   B. Atrial dilatation predisposes to atrial arrhythmias, including atrial fibrillation.
II. The pathophysiology of AV valve stenosis is more complicated.
   A. The outcome of severe dysplasia may include CHF of the affected side.
      1. Atrial arrhythmias are also very common.
      2. If the stenotic valve is competent, ventricular function is relatively normal.
   B. Acute pulmonary capillary hypertension can lead to acute edema and hemoptysis.
   C. In cases of mitral stenosis, reactive changes in the pulmonary vasculature can lead to significant PH with RV hypertrophy and limited exercise capacity (most common in cats).
   D. In tricuspid stenosis (or severe regurgitation) there is a high potential for continued patency of the foramen ovale, which can lead to right-to-left shunting, arterial hypoxemia, and cyanotic heart disease.

Clinical Signs

I. Clinical signs can be absent until the onset of CHF or atrial fibrillation.
II. Astute clients generally recognize some exercise intolerance.
III. With trivial or mild malformations, the dog is normal.
IV. With tricuspid dysplasia and a patent foramen ovale, fatigue and obvious cyanosis may be noted.

Diagnosis

I. The most common finding is a systolic murmur of AV valvular regurgitation over the affected valve area; however, a mild AV valve malformation may not cause an obvious murmur.
II. Diastolic murmurs of AV valve stenosis are usually very soft and easily missed.
III. Mucous membranes are pink, unless there is right-to-left shunting.
IV. Definitive diagnosis requires careful 2D echocardiographic imaging of the affected valve, combined with Doppler studies.
   A. Diagnosis of subtle AV valvular malformations is often difficult and controversial.
   B. Characteristic Doppler flow patterns can be identified for valvular stenosis and regurgitation.
   C. The severity of the disease can be gauged with noninvasive ultrasound studies.
V. With mitral valve dysplasias changes are most evident on the left side of the heart.
   A. With mitral regurgitation, radiography, ECG, and 2D echocardiography demonstrate LV and LA dilatation.
   B. With mitral stenosis, marked left atrial dilation and possibly PH with secondary RV hypertrophy are evident.
   C. Atrial fibrillation is common and can precipitate clinical signs.
   D. CHF with pulmonary edema is a common finding.
VI. With tricuspid valve dysplasia, right-sided atrial and ventricular enlargement is typical.
   A. Right-sided CHF with hepatomegaly and ascites is found in advanced cases.
      1. Atrial fibrillation is common.
      2. Rarely, pleural effusion or chylothorax is identified in dogs.
   B. A prominent jugular pulse can usually be identified.
   C. Notched or "splintered" R-waves are observed on ECG in dogs, along with occasional reentrant supraventricular tachycardias or ventricular preexcitation.
   D. Cyanosis, arterial hypoxemia, and polycythemia are common when severe dysplasia is complicated by an ASD.
VII. Cardiac catheterization is rarely needed to establish the diagnosis.

Differential Diagnosis

I. Dogs can survive for many years with AV valvular malformation, so acquired disorders, such as myxomatous valvular degeneration (endocardiosis), dilated cardiomyopathy, and infective endocarditis, may also develop.
II. Endocardiosis, PH, and right-sided cardiomyopathies can lead to tricuspid regurgitation and must be distinguished from tricuspid dysplasia.
III. For cyanotic animals, the differential diagnosis is similar to that for tetralogy of Fallot.
IV. AV stenosis can also arise from an obstructive fibrous or fibromuscular ring situated above the mitral or tricuspid valve (called *supravalvular mitral/tricuspid ring*).
V. Tricuspid stenosis can be confused (or occur along) with an obstructive partitioning of the RA, termed *cor triatriatum dexter.*
   A. In this malformation, the caudal RA is separated from the tricuspid orifice by a persistent membrane with a small orifice.
   B. Vena caval blood flow is obstructed and leads to hepatomegaly and ascites.

C. A similar condition can rarely occur in the LA (cor triatriatum sinister), leading to pulmonary venous obstruction.

Treatment

I. Balloon valvuloplasty has been variably successful in dogs with tricuspid and mitral valvular or supravalvular stenosis.
II. Surgical repair or annular support of affected valves can be attempted.
III. Replacement or repair of dysplastic valves has been performed successfully with cardiopulmonary by-pass.
IV. Most cases are treated medically when signs of CHF or atrial fibrillation develop.
   A. Use of an ACE-inhibitor (enalapril) and a beta-blocker (carvedilol, metoprolol) may be considered for dogs with severe mitral regurgitation and associated cardiomegaly.
   B. Heart rate control and avoidance of tachycardia is important to improve ventricular filling in animals with stenotic AV valves.
      1. Beta-blockers may be beneficial in preventing sinus tachycardia.
      2. Diltiazem may be useful for atrial fibrillation.
   C. Animals with stenotic AV valves may be sensitive to diuretic therapy, as ventricular filling depends on higher atrial pressures; however, such therapy may be life saving for peracute pulmonary edema with hemoptysis.
V. Tricuspid malformation associated with an ASD can lead to right-to-left shunting, so manage any secondary polycythemia (discussed previously).
VI. Mild mitral or tricuspid valvular dysplasia is often well tolerated; however, severe lesions lead to CHF and arrhythmias.
   A. Dogs with severe mitral disease usually develop CHF in early to middle age, particularly when the valve is both stenotic and incompetent.
   B. Many dogs with relatively severe tricuspid regurgitation survive for 7 to 8 years before CHF ensues.

Monitoring of Animal

I. The course of disease can be relatively long, especially with tricuspid dysplasia.
II. Severe AV valvular stenosis often causes signs within the first 1 to 2 years of life.
III. For asymptomatic dogs and cats with moderate to severe disease, a cardiology evaluation and echocardiography are preformed at least yearly.

CHAPTER 9

Acquired Atrioventricular Valvular Disease

Jens Häggström | Kristin MacDonald

DEGENERATIVE DISORDERS

Jens Häggström

Atrioventricular Valvular Degeneration

Definition

I. Pathologic degeneration of the atrioventricular (AV) valves is characterized by the accumulation of glycosaminoglycans (myxomatous proliferation) and fibrosis of the valve leaflets and tendinous chordae.
II. Valvular degeneration leads to insufficient coaptation of the valve leaflet, valvular regurgitation, and eventually congestive heart failure (CHF) in some animals.
III. The degeneration most commonly involves the mitral valve, with or without involvement of the tricuspid valve.
IV. Isolated tricuspid degeneration occurs but is less common.
V. It has been given many names, including endocardiosis, chronic degenerative valvular disease, chronic valvular disease, chronic valvular fibrosis, and acquired mitral or tricuspid regurgitation or insufficiency.

Causes

I. The primary (inciting) cause of myxomatous degeneration is currently unknown.
II. The primary factor may be a defect in the quality of connective tissue (ground substance) within the valve.
III. There is no scientific evidence of any association between the disease and vaccination routines or hematological spread of bacteria from the oral cavity.
IV. AV valvular disease is the most common cardiac disease in dogs, and accounts for the highest cardiac-related mortality (Egenvall et al., 2006).
    A. The disease occurs in all breeds, but is most common in small- to medium-sized dogs, such as the papillon, poodle, Chihuahua, dachshund, and Cavalier King Charles spaniel (Egenvall et al., 2006).
    B. The condition is common in older dogs.
        1. Age of onset is inherited as a polygenetic trait (Swenson et al., 1996; Olsen et al., 1999).
        2. Males have an earlier onset and progress more rapidly than females (Häggström et al., 2004; Egenvall et al., 2006).
    C. The major role played by genetic factors suggests that other factors (level of exercise, degree of obesity, diet) play only a small role.
    D. The prevalence of acquired mitral valve disease in cats without primary myocardial disease is unknown, but it is low and rarely clinically important.

Pathophysiology

I. Myxomatous degeneration
    A. The primary defect leads to abnormal valve motion with prolapse of the leaflets, which in turn increases the shear stress imposed on the leaflets, both directly (abnormal leaflet apposition) and indirectly (increased regurgitant flow).
    B. Regurgitation and valve stress leads to endothelial damage and subsequent activation of fibroblasts in the valve (Black et al., 2005).
    C. This activation causes subendothelial deposition of glycosaminoglycans and fibrosis, leading to further distortion of valve morphology and regurgitation (Black et al., 2005).
II. Valve regurgitation and heart failure
    A. With progression, the valvular lesions cause insufficient coaptation of the leaflets, leading to regurgitation into the atrium.
    B. Severity and progression of AV valve regurgitation depends on the severity and progression of the valvular lesions (Olsen et al., 1999; Pedersen et al., 1999b).
    C. Ventricular dilatation further increases the regurgitation by causing secondary valvular insufficiency.
    D. Compensatory mechanisms include cardiac dilatation, eccentric hypertrophy, increased force and rate of contraction, increased heart rate, increased pulmonary lymphatic drainage (left-sided AV valve regurgitation), fluid retention, and neurohormonal modulation of cardiovascular function (Häggström et al., 2005).
    E. With progression, compensation is no longer possible and leads to reduced cardiac output and increased venous pressures with subsequent pulmonary edema (left-sided CHF) or ascites (right-sided CHF).

Clinical Signs

I. Chief complaints
   A. A murmur may be an incidental finding, with no clinical signs of disease caused by the valvular regurgitation.
   B. Valvular regurgitation may cause cardiac compression of the main stem bronchi.
      1. Cough
      2. Tachypnea, dyspnea
      3. Syncope in conjunction with paroxysms of coughing, often triggered by excitement or exercise
   C. Syncope may occur as a consequence of intermittent supraventricular tachycardia.
   D. Valvular regurgitation may cause clinical signs of CHF (most commonly left-sided).
      1. Cough: often worse in the morning or evening hours
      2. Tachypnea, dyspnea, orthopnea
      3. Lethargy, anorexia
      4. Reduced exercise tolerance
      5. Syncope
      6. Weight loss
      7. Ascites (right-sided CHF)
   E. Sudden death may occur as a consequence of an acute complication (see Monitoring of Animal), but is uncommon, especially in the absence of clinical signs of CHF.

II. Physical examination findings in asymptomatic animals
   A. A systolic click (early stage) is a high-pitched, sharp sound between S1 and S2 heart sounds.
   B. An apical systolic heart murmur is present with mitral or tricuspid regurgitation.
   C. A soft early, late, or holosystolic murmur (grade I-II/VI) is consistent with mild regurgitation.
   D. A loud murmur (grade IV-VI/VI) is consistent with moderate to severe regurgitation (Häggström et al., 1994).

III. Physical examination findings in symptomatic animals
   A. Loud heart murmur (grade IV-VI/VI) and loud first heart sound, unless there is significant myocardial failure
   B. Tachycardia and loss of respiratory sinus arrhythmia
   C. ± Arrhythmia, most commonly supraventricular, premature beats or atrial fibrillation
   D. Weak femoral pulses, pulse deficits
   E. Prolonged capillary refill time, pale mucous membranes
   F. Tachypnea, dyspnea, orthopnea
   G. ± Respiratory crackles (rales) from pulmonary edema
   H. Pink froth in the nostrils and oropharynx from pulmonary edema (fulminant CHF)
   I. Ascites and jugular venous distension with right-sided CHF

Diagnosis

I. Auscultatory findings of a systolic click and/or a left apical systolic murmur compatible with mitral regurgitation (MR) in a geriatric dog of a typical breed are highly suggestive of myxomatous valve disease.
   A. A low-intensity murmur (grade I-II), with or without a systolic click in an otherwise healthy dog, usually indicates low disease severity.
   B. A high-intensity murmur (grade IV-VI) and increased intensity of S1 indicates a more advanced stage of disease.

II. Echocardiographic findings include thickening or prolapse of the AV valve and identification of a regurgitant jet on spectral or color flow Doppler (Box 9-1).
   A. Determination of severity of MR involves assessment of the magnitude of left atrial (LA) dilation and left ventricular (LV) eccentric hypertrophy.
   B. Size of the regurgitant jet on color Doppler may be used to semiquantify the severity of MR (Kittleson et al., 1998; Kittleson et al., 2003).
   C. Unlike small breed dogs, large breed dogs less commonly have severe valve prolapse and thickening.

III. Presence of tachyarrhythmias, such as atrial fibrillation or ventricular ectopy on electrocardiography usually indicates severe disease, presence of complications (acute chordal rupture or myocardial infarction), or other concurrent cardiac disease.

IV. Supraventricular premature complexes are the most common arrhythmia.

V. Radiographic findings include left-sided cardiomegaly and LA dilation in dogs, with moderate or severe MR.

Box 9-1

Echocardiographic Findings in Dogs with Myxomatous Mitral Valvular Disease

Abnormality	Echocardiographic Finding
Severe valvular disease (poor prognosis)	Severe prolapse (>2 mm), valvular thickening, ruptured chordae tendineae, valve flailing
Size and velocity of regurgitant jet	Color Doppler semiquantitative Jet size <30% of LA size = mild MR Jet size >50% of LA size = severe MR Large jet with velocity <5-6 m/sec indicative of increased LA pressure
Left atrial dilation in mild MR	LA:Ao >1.5 = mild LA dilation
Severe LA dilation, high likelihood of CHF	LA:Ao >2 = severe LA dilation
LV volume overload in moderate or severe MR	↑ LV internal diastolic diameter ↑ Fractional shortening (>40%) Hyperdynamic contractions
LV systolic failure in large dogs with mild MR or in small dogs with chronic severe MR	↑ End systolic diameter Normalized or ↓ fractional shortening ↑ EPSS (>6 mm)
Pulmonary hypertension (uncommon)	Right atrial and ventricular enlargement, tricuspid regurgitation TR velocity >2.8 m/sec PI velocity >2.2 m/sec (Johnson et al., 1999)

LA, Left atrium; *MR,* mitral regurgitation; *CHF,* congestive heart failure; *LA:Ao,* left atrial to aortic root diameter; *LV,* left ventricle; *EPSS,* E point to septal separation; *TR,* tricuspid regurgitation; *PI,* pulmonic insufficiency

A. Vertebral heart score of >10.5 is indicative of cardiac enlargement (Buchanan and Bücheler, 1995).
B. Left-sided CHF causes perihilar to caudodorsal pulmonary infiltrates (interstitial, mixed, or alveolar pattern) and pulmonary venous distention.
C. Compression of the left mainstem bronchus causes widening of the left bronchial angle at the body of the LA on dorsoventral and ventrodorsal views and splitting of the bronchi on the lateral view.

VI. Blood pressure (BP) is measured to identify dogs with hypertension (>160 mmHg), because MR is worsened by increased afterload.
VII. Hematology and biochemistry panels are usually unremarkable in mild cases, but more serious cases may have mildly increased liver enzymes and evidence of prerenal azotemia.
VIII. Serum troponin I levels are normal (usually <0.07 ng/mL) in mild cases.
A. Levels are mildly to moderately increased with moderate to severe disease.
B. Severe elevations indicate myocardial ischemia, myocarditis, or infarction (Oyama et al., 2004).
IX. Measurement of natriuretic peptides is often unremarkable in mild cases.
A. Moderate to severe disease is associated with increased levels (Häggström et al., 2000).
B. Plasma concentration of brain natriuretic peptide may be useful to differentiate dogs with CHF-related dyspnea from other causes.

Differential Diagnosis

I. Other causes of systolic heart murmurs
A. Secondary MR from dilated or hypertrophic cardiomyopathy
B. Congenital heart diseases, especially mitral valve dysplasia
C. Infective endocarditis of the AV valve
D. Anemia
E. Physiological flow (innocent) murmur
1. Soft (grade I-II/VI) early systolic murmur
2. Localized to the basilar region or poorly localized to the left side

II. Other causes of respiratory distress
A. Primary respiratory diseases: bronchitis, pneumonia, tracheal/bronchial collapse, neoplasia, others
B. Pleural effusion
C. Noncardiogenic pulmonary edema
D. Anemia

III. Other causes of reduced exercise capacity, lethargy, and muscle wasting
A. Musculoskeletal diseases: chronic degenerative joint disease, intervertebral disc disease, neuromuscular disease, others
B. Other systemic diseases: renal or hepatic failure, neoplasia, anemia

IV. Other causes of episodic weakness and/or syncopal-like signs
A. Seizures
B. Primary arrhythmias

Treatment

I. Asymptomatic disease
A. Treatment is not indicated in the absence of clinical signs.
B. Surgical repair or valve replacement is usually not technically or economically feasible.
C. No treatment has been shown to slow or halt disease progression (Kvart et al., 2002; Häggström et al., 2004).

II. Symptomatic disease
A. Goal is to alleviate clinical signs and improve quality of life and life expectancy.
B. Treatment involves eliminating pulmonary edema and/or ascites, improving hemodynamic flow, controlling heart rate, reducing aortic impedance, providing inotropic support, and protecting the heart from detrimental exposure to neurohormones.

III. Treatment of dogs with compression of mainstem bronchus and no evidence of CHF on radiographs
A. Cough suppressants
1. Hydrocodone bitartrate 2.5 to 10 mg/dog PO BID to QID
2. Butorphanol 0.55 to 1.1 mg/kg PO BID to QID
B. Arterial vasodilators to reduce afterload, regurgitant fraction, and LA size
1. The goal is to reduce the systolic blood pressure by 10 to 20 mm Hg compared with baseline in normotensive dogs.
2. Goal in hypertensive dogs is to reduce the systolic blood pressure to <140 mm Hg (Kittleson MD et al., 1983).
3. Hydralazine is given at 1 to 2 mg/kg PO BID; gastrointestinal side effects are common.
4. Amlodipine is given at 0.1 to 0.3 mg/kg PO SID to BID.

IV. Treatment of acute heart failure
A. Diuresis with furosemide
1. Dose for moderate CHF: 2 to 4 mg/kg IV, IM, SC, PO BID to TID
2. Dose for severe or fulminant CHF: 4 to 8 mg/kg IV, IM, SC every 2 to 6 hours
B. Oxygen supplementation and cage rest with 60% oxygen, then decreased to <50% after 12 hours
C. Nitroglycerine ointment 4 to 12 mg topically BID to TID
1. Apply inside the pinna while wearing gloves.
2. Whether it actually causes venodilation in dogs is controversial (Parameswaran et al., 1999).
D. Arterial vasodilators
1. In animals with severe CHF that do not respond to aggressive diuresis with furosemide, an arterial vasodilator is used to reduce afterload.
2. Hydralazine (1 to 3 mg/kg PO BID) causes acute vasodilation within 30 minutes.
a. Monitor BP every 1 hour initially.

b. Repeat dose if BP has not decreased by 15 to 20 mm Hg.
c. If no change in BP occurs, increase to maximum cumulative dose of 3 mg/kg.
d. Total cumulative dose is then given BID.
e. Reduce dose by 50% in dogs on angiotensin converting enzyme (ACE) inhibitors (Kittleson, 1985).

3. Amlodipine (0.1 to 0.3 mg/kg PO SID to BID) causes vasodilation in 4 to 6 hours, so is not used for fulminant CHF.
4. Sodium nitroprusside (1 to 5 μg/kg/min IV as a constant rate infusion; maximum 10 μg/kg/min IV) is a potent vasodilator that acts within minutes and must be carefully monitored with BP measurements (preferably direct arterial BP).

E. Pimobendan 0.3 to 0.5 mg/kg PO BID
F. Abdominal paracentesis for moderate or severe ascites

V. Treatment of chronic heart failure
A. Choice of drug(s) depends on disease severity and clinical signs.
B. Diuretics are used when there is evidence of CHF on thoracic radiographs or as a preventative in dogs with previous episodes of CHF.
1. Furosemide
a. Dose for mild to moderate CHF: 1 to 3 mg/kg PO SID to BID
b. Dose for moderate to severe CHF: 2 to 4 mg/kg PO BID to TID
c. Doses incrementally increased as needed
d. Maximum effective dose: 4 mg/kg PO TID
2. Spironolactone 2 mg/kg PO SID to BID
a. It is a weak diuretic and is used as adjunctive therapy with furosemide.
b. It may reduce potassium loss in animals receiving furosemide.
3. Hydrochlorothiazide (2 to 4 mg/kg PO BID) for animals with refractory CHF already receiving high furosemide doses

C. ACE inhibitors are indicated once CHF develops.
1. They may improve quality of life, cause minimal to mild reductions in BP, and are not used primarily as vasodilators.
2. They exert modest, positive effects over weeks to months and are not used in acute CHF.
3. They may cause significant azotemia if given to a dehydrated animal that has been treated aggressively with diuretics.
4. Functional azotemia may be seen in a small percentage of dogs and is reversible once the ACE inhibitor is stopped.
5. A renal panel is indicated prior to starting ACE inhibitors, and repeated in 1 to 2 weeks, with discontinuation if moderate or severe azotemia is detected.
6. Doses are as follows:
a. Enalapril 0.5 mg/kg PO BID
b. Benazepril 0.25 to 0.5 mg/kg PO SID
c. Ramipril 0.25 to 0.5 mg/kg PO SID

D. Pimobendan is a phosphodiesterase III inhibitor that acts as a vasodilator and a positive inotrope.
1. Pimobendan is approved in Canada and most European countries, but not in the United States.
a. It may be imported on a compassionate use basis, with permission from the Food and Drug Administration.
b. The approval process takes at least 4 weeks.
2. Hemodynamic effects include reduction in systemic and pulmonary vascular resistance, positive lusitropic (improves diastolic function) and inotropic activity, reduction in LV filling and LA pressure, and improvement in myocardial contractile efficiency without increasing oxygen consumption.
3. It significantly reduces mortality and improves the quality of life in dogs with CHF (Smith et al., 2005; Lombard et al., 2006).
4. Dosage is 0.3 to 0.5 mg/kg PO BID; the presence of food reduces absorption.
5. Side effects include tachycardia and gastrointestinal upset, which are dose related.
6. Contraindications are hypertrophic cardiomyopathy or conditions in which increased stroke volume is not possible owing to functional or anatomical obstructions (e.g., aortic stenosis).
7. It should not be combined with a calcium-channel blocker.

E. Digoxin (0.005 to 0.01 mg/kg or 0.22 mg/m^2 PO BID) is administered to control heart rate if a tachyarrhythmia, such as atrial fibrillation, is present, and may be used in dogs with moderate or severe myocardial failure and MR.
F. Tachyarrhythmias, such as atrial fibrillation, may require therapy with beta blockers or calcium channel blockers, but these drugs must be used with caution because they are negative inotropes (see Chapter 6).
G. Avoid food with high sodium content, such as salty table foods, cured meats and cheeses, and salty dog treats (sausage or bacon flavor).
H. Low-salt, cardiovascular diets (0.15 to 0.2 g Na/1000 kcal) can be used in animals receiving high diuretic doses for refractory, chronic CHF.
1. Such diets help limit sodium and water retention and are used in conjunction with standard medical therapy.
2. Some dogs find these diets less palatable (Rush et al., 2000).

I. Affected dogs are allowed walks, but strenuous exercise is avoided.

Monitoring of Animal

I. Frequency of recheck examinations depends on the severity of valvular insufficiency and clinical signs.
II. Asymptomatic dogs with slight to moderate regurgitation are rechecked every 6 to 12 months, and those with

moderate to severe regurgitation are rechecked every 3 months.

III. After control of acute CHF and discharge from the hospital, reexamination is scheduled in 1 to 2 weeks.
   A. Monitor for resolution of clinical signs, level of hydration, electrolytes, renal function, thoracic radiographic evidence of CHF, and the presence of complications.
   B. If the dog is stable, rechecks are scheduled every 3 to 6 months thereafter, with more severe cases requiring more frequent monitoring.

IV. Complications to monitor for include the following:
   A. Asymptomatic dogs may develop CHF.
   B. Dogs stabilized by medical therapy often develop recurrent CHF.
   C. Dogs with initially left-sided CHF may develop biventricular CHF, with pulmonary hypertension and ascites.
   D. Arrhythmias, especially atrial fibrillation, may occur and may worsen CHF.
   E. Rupture of the chordae tendinae may cause life-threatening pulmonary edema or sudden death.
   F. An atrial tear may lead to an acquired atrial septal defect or pericardial effusion and cardiac tamponade.
   G. Formation of an intracardiac thrombus or large myocardial infarction are rare events.
   H. Small infarcts caused by arteriosclerotic changes are common, but their clinical significance is currently unknown (Häggström et al., 2005).

V. Prognosis and outcome are highly variable.
   A. Dogs without signs of CHF may remain asymptomatic for several years.
      1. Risk factors for progression from mild to severe disease include the severity of valvular lesions, increasing age, and male gender.
      2. Risk factors for the onset of CHF include regurgitation severity, LA size, and elevations of natriuretic peptides (Häggström et al., 2000).
   B. The prognosis for dogs with CHF (acute or stabilized) is dependent on age, severity of failure, and presence of other diseases (e.g., renal failure).
   C. Clinical trials have shown a mean survival time after onset of CHF of 8 to 10 months, but survival time may vary from days to years (Ettinger et al., 1998; BENCH Study Group, 1999).

INFECTIOUS DISORDERS

Kristin MacDonald

Endocarditis

Definition

I. Infective endocarditis is caused by invasion of a microbe into the endothelium of the valves of the heart, resulting in proliferative or erosive lesions, and, consequently, valvular insufficiency.

II. Endocarditis has a low incidence in dogs, and is extremely rare in cats.

III. The mitral and aortic valves are almost exclusively infected.

Causes

I. Predisposing factors
   A. Bacteremia from diskospondylitis, prostatitis, pneumonia, urinary tract infections, pyoderma, periodontal disease, and long-term, indwelling central venous catheters
   B. Subaortic stenosis (SAS) (Sisson and Thomas, 1984)
   C. Possible increased risk associated with corticosteroid use (Calvert, 1982)

II. Etiologic agents
   A. The most common bacterial isolates are *Staphylococcal* spp. (*S. aureus, S. intermedius,* coagulase positive, and coagulase negative), *Streptococcus* spp. (*S. canis, S. bovis*, and beta-hemolytic), and *Escherichia coli*.
   B. Other less common bacteria include *Pseudomonas* spp., *Erysipelothrix rhusiopathiae, Enterobacter* spp., *Pasteurella* spp., *Corynebacterium* spp., and *Proteus* spp.
   C. Since many dogs are currently receiving antibiotics at the time of blood culture, most cases (60% to 70%) are culture negative (MacDonald et al., 2004; Sisson and Thomas, 1984).
   D. *Bartonella* spp. is a fastidious, intracellular bacteria that has emerged as an important cause of endocarditis in dogs.
      1. *Bartonella* spp. were identified in 28% of affected dogs and 45% of dogs with negative blood cultures (MacDonald et al., 2004).
      2. *Bartonella vinsonii berkhoffii* is the most common species isolated, followed by *B. henselae, B. clarridgeiae, B. clarridgeiae*-like, and *B. washoensis* (MacDonald et al., 2004).

Pathophysiology

I. The inciting event is bacterial adherence to the valve.
   A. Disruption of the endothelial surface may occur secondary to inflammatory or mechanical (SAS) causes.
   B. A coagulum of fibrinogen, fibrin, platelet proteins, and fibronectin forms and avidly binds bacteria, and shields them from host defense and antibiotics.
   C. Bacteria may secrete destructive enzymes that erode the valve.

II. Severe mitral or aortic valvular insufficiency leads to elevated LV end-diastolic pressure, LA pressure, and pulmonary capillary wedge pressure, with subsequent left heart failure.

III. Affected animals may develop high titers of antibodies against the offending bacteria.
   A. Immune complexes form, and consist of immunoglobulin (Ig) M, IgG, and complement.
   B. Rheumatoid factor may also be increased, which impairs the ability to solubilize immune complexes.
   C. Immune complexes are deposited in the basement membrane and cause further complement activation and tissue destruction.

D. Immune-mediated glomerulonephritis, polyarthritis, and skin diseases are common sequelae.

IV. Septic or aseptic thromboembolism frequently occurs to the kidney, spleen, heart, brain, systemic arteries, and other organs.

Clinical Signs

I. Medium to large breed, middle-aged to older male dogs are most commonly affected.

II. The most common clinical sign is lameness (44%), followed by lethargy, anorexia, respiratory abnormalities, weakness, and collapse (MacDonald et al., 2004).

III. Cardiovascular abnormalities are commonly found.
   A. A murmur is present in most (89% to 96%) dogs (MacDonald et al., 2004; Calvert, 1982).
      1. A left apical holosystolic murmur occurs with MR.
      2. A left basilar diastolic murmur and bounding femoral arterial pulses are highly suggestive of aortic valve involvement.
   B. Many dogs (4% to 70%) have arrhythmias, including (in order of incidence) ventricular arrhythmias, supraventricular tachycardia, third-degree AV block, and atrial fibrillation (MacDonald et al., 2004; Sisson and Thomas, 1984; Calvert, 1982).
   C. Dyspnea, cough, or rales may be present in animals with CHF.

IV. Fever is present in 70% of dogs, and joint effusion and lameness are also common (MacDonald et al., 2004).

Diagnosis

I. The criteria for diagnosis are presented in Table 9-1.

II. Positive blood cultures help confirm the disease.
   A. Blood samples (three or four) are aseptically collected from different venous sites, 30 to 60 minutes apart, and submitted for aerobic and anaerobic bacterial culture.
   B. Lysis centrifugation tubes (Isolator, Isostat microbial system, Wampole Laboratories, Cranbury, NJ) may increase yield of bacteria.

III. Serum is submitted for measurement of antibody titers to *Bartonella vinsonii berkhoffii*, *Bartonella clarridgeiae*, and *Bartonella henselae*.
   A. A titer ≥1:1024 is strongly suggestive of Bartonellosis.
   B. There is strong cross reactivity among the *Bartonella* spp.
   C. *Bartonella* spp. are rarely cultured despite long-term incubation in enriched medium, so culture is not recommended.

IV. Echocardiographic identification of a hyperechoic, oscillating, vegetative lesion on the valve is the principal method of diagnosing endocarditis.
   A. Erosive lesions may be more difficult to identify.
   B. Color flow Doppler is used to assess the presence and severity of valvular insufficiency.
   C. LA enlargement may be present in chronic endocarditis of the mitral valve, but LA size is most often normal in acute disease.
   D. LV eccentric hypertrophy (increased LV diastolic diameter) occurs in response to chronic aortic and mitral endocarditis.
   E. End-systolic diameter and E-point to septal separation may be increased and fractional shortening decreased in animals with systolic failure secondary to chronic aortic insufficiency.
   F. Transesophageal echocardiography may be needed if visualization of the valves is poor with transthoracic echocardiography and a high clinical suspicion of endocarditis exists.

TABLE 9-1

Criteria for Diagnosis of Infective Endocarditis in Small Animals

MAJOR CRITERIA	MINOR CRITERIA	DIAGNOSIS
Positive echocardiogram: vegetative or erosive lesion, or abscess	Fever Medium to large dog (>15 kg) Subaortic stenosis	Definite Histopathology of valve 2 major criteria present 1 major and 2 minor criteria present
New valvular insufficiency: mild aortic insufficiency without subaortic stenosis or annuloaortic ectasia	Thromboembolic disease Immune mediated disease: polyarthritis, glomerulonephritis	Possible 1 major and 1 minor criteria present 3 minor criteria present
Positive blood culture: ≥2 positive blood cultures ≥3 if isolate is common skin contaminant	Positive blood culture not meeting major criteria *Bartonella* spp. serology ≥ 1:1024*	Rejected Other disease diagnosed Resolution of regurgitation or valvular abnormality within 4 days of treatment No pathologic evidence of endocarditis on postmortem examination

Criteria are modified from Baddour LM, Wilson WR, Bayer AS et al: Infective endocarditis: diagnosis, antimicrobial therapy, and management complications. Circulation. 111:e394, 2005.

*Not officially accepted yet as a criterion in dogs.

V. Thoracic radiographs are obtained to evaluate for CHF, which is seen in approximately 50% of affected dogs (MacDonald et al., 2004).
   A. Perihilar to caudodorsal interstitial to alveolar pulmonary infiltrates and pulmonary venous distension are characteristics of left-sided CHF.
   B. Often there is no evidence of LA enlargement because of the acute nature.

VI. Other diagnostic tests include a complete blood count, serum biochemistry panel, urinalysis, urine protein:creatinine ratio (if proteinuria is present), and urine culture.
   A. Most animals (78%) have leukocytosis, with mature neutrophilia and monocytosis (MacDonald et al., 2004).
   B. A mild, nonregenerative anemia is also common.
   C. Serum biochemistries often reveal azotemia (prerenal or renal), metabolic acidosis, hypoalbuminemia, and elevated liver enzymes.
   D. Hemoglobinuria, hematuria, cystitis, and proteinuria may also be seen.

Differential Diagnosis

I. MR from myxomatous mitral valve degeneration or mitral valve dysplasia
II. Aortic insufficiency secondary to aortic valve degeneration or a large ventricular septal defect
III. Lameness from immune-mediated polyarthritis, septic arthritis, tick-borne diseases, or degenerative arthritis
IV. Fever from other systemic diseases, such as sepsis, pneumonia, neoplasia, or immune-mediated diseases

Treatment

I. Long-term, bactericidal antibiotic treatment is necessary for 3 to 4 months.
   A. Selection of the appropriate antibiotic is based upon culture and sensitivity.
   B. While the culture results are pending, or if there is no microbe cultured, empirical treatment with broad-spectrum antibiotics (aminoglycosides, beta-lactams) is recommended.
   C. Initially, antibiotics are administered for 1 to 2 weeks IV, followed by PO forms.
   D. IV fluids are necessary for animals treated with aminoglycosides, and concurrent furosemide is avoided because it worsens aminoglycoside-induced nephrotoxicity.
   E. Aminoglycosides are contraindicated in CHF for these reasons.

II. Specific antibiotic combinations include the following:
   A. Acute endocarditis
      1. Amikacin 20 mg/kg IV SID and *Timentin* 50 mg/kg IV QID *or*
      2. Amikacin and imipenem 10 mg/kg IV TID for 1 to 2 weeks
   B. Chronic endocarditis
      1. Imipenem 10 mg/kg SC TID *or*
      2. Amoxicillin-clavulanate 20 mg/kg PO TID *or*
      3. Enrofloxacin 5 to 10 mg/kg PO BID for 8 weeks (dogs)
   C. For treatment of Bartonellosis
      1. Acute endocarditis: amikacin (20 mg/kg IV SID) and *Timentin* 50 mg/kg IV QID for 1 to 2 weeks
      2. Chronic endocarditis
         a. Amoxicillin-clavulanate 20 mg/kg PO TID *or*
         b. Doxycycline 5 mg/kg PO SID for 6 to 8 weeks *or*
         c. Azithromycin 5 mg/kg PO SID for 7 days, then QOD for 6 to 8 weeks

III. Treatment of CHF involves the following:
   A. Diuresis with furosemide
      1. Stable mild to moderate CHF: 1 to 4 mg/kg PO BID-TID
      2. Acute fulminant CHF: 5 to 8 mg/kg IV every 2 to 4 hours initially, then reduced
   B. ACE inhibitors
      1. Enalapril 0.5 mg/kg PO BID
      2. Lisinopril 0.5 mg/kg PO SID
      3. Benazepril 0.25 to 0.5 mg/kg SID
      4. Ramipril 0.25 to 0.5 mg/kg PO SID
   C. Positive inotropes if there is myocardial failure: digoxin, pimobendan
   D. Afterload reducers for severe aortic insufficiency: hydralazine, nitroprusside, amlodipine

Monitoring of Animal

I. In animals with positive blood or urine cultures, repeat the culture 1 to 2 weeks after starting antibiotics, and 2 weeks after termination of the antibiotics.
II. An echocardiogram is repeated 1 to 2 weeks after starting therapy, at 4 weeks, and at 2 weeks after stopping therapy to assess vegetative size, chamber sizes, severity of valvular insufficiency, and ventricular function.
III. Repeat antibody titers for *Bartonella* spp. after 1 month of treatment; if they have not decreased, change the antibiotic.
IV. Prophylactic treatment may be considered in animals with increased risk for endocarditis (SAS).
   A. A beta-lactam or cephalosporin is given 1 hour before and 6 hours after surgery or any dental procedure.
   B. No evidence exists that dogs with myxomatous valve degeneration are at increased risk of endocarditis.
V. Prognosis is grave for aortic endocarditis (median survival of 3 days) (MacDonald et al., 2004).
   A. Median survival of mitral endocarditis is 476 days (MacDonald et al., 2004).
   B. CHF or sudden death are the most common causes of death.

CHAPTER 10

Acquired Myocardial Diseases

Alan Spier | Kristin MacDonald

CANINE CARDIOMYOPATHY

Alan Spier

Definition

I. Idiopathic cardiomyopathy is an intrinsic disorder of cardiac muscle (myocardium) resulting in altered structure/function.
II. Secondary cardiomyopathy includes myocardial abnormalities resulting from other disease processes or etiologies.

Causes

I. By definition, cardiomyopathy implies an idiopathic cause, but genetic and other factors (myocarditis) may be involved.
II. Secondary cardiomyopathies result from other disease processes or conditions.
   A. Chronic volume overload: primary valvular disease, left-to-right shunts
   B. Nutritional deficiencies: carnitine, taurine
   C. Systemic inflammation
   D. Chemotherapy: especially doxorubicin
   E. Tachycardias
   F. Endocrinopathy: hypothyroidism, hypoadrenocorticism, hyperthyroidism

Pathophysiology

I. Cardiomyopathy can affect both mechanical and electrical functioning of the heart.
   A. Mechanical dysfunction
      1. Systolic dysfunction is common in dogs, especially with dilated cardiomyopathy (DCM).
      2. Diastolic dysfunction is rare in dogs but occurs with feline cardiomyopathy.
   B. Electrical dysfunction
      1. Arrhythmogenic right ventricular cardiomyopathy (ARVC) in boxers (boxer cardiomyopathy) is caused by fatty or fibrofatty replacement of the cardiomyocytes of the right and left ventricles (lesser extent).
      2. It can occur as an initial manifestation of DCM.
   C. Both mechanical and electrical dysfunction
      1. DCM in Doberman pinschers
      2. Uncommon manifestation of boxer cardiomyopathy
II. Cardiomyopathy affecting mechanical function ultimately causes decreased stroke volume (SV) and activation of the neuroendocrine system.
   A. Decreased SV causes a decrease in cardiac output (CO).
   B. Decreased CO triggers neurohormonal activation with increased sympathetic tone and activation of the renin-angiotensin-aldosterone system (RAAS).
   C. Sympathetic activation increases heart rate and contractility.
      1. Short-term improvement in hemodynamics and maintenance of blood pressure (BP) occurs, but beta receptor down-regulation begins within 2 days.
      2. Long-term increase in catecholamines exacerbates myocardial fibrosis and dysfunction, thereby worsening cardiac performance.
   D. Neuroendocrine activation is largely responsible for the progression of the heart disease.
      1. Volume overload from RAAS activation increases preload and results in left ventricular (LV) eccentric hypertrophy.
      2. Ventricular filling pressures increase, leading to congestive heart failure (CHF).

Clinical Signs

I. Signs depend on whether a mechanical dysfunction (manifesting as heart failure) or electrical dysfunction (manifesting as syncope or sudden death) is present.
II. With mechanical dysfunction, neuroendocrine activation enables the body to maintain BP and CO, but mechanical dysfunction occurs at the cost of venous pressures.
   A. Increased venous (diastolic) pressure on the left side results in pulmonary edema.
   B. Increased venous (diastolic) pressure on the right side results in ascites and/or pleural effusion.
   C. Retention and extravasation of fluid is usually the first stage of CHF and causes respiratory signs (coughing, tachypnea, dyspnea) and abdominal distension (ascites).
   D. Nonspecific signs, such as loss of energy, appetite, and normal exercise capacity, are often seen at this stage.
III. As heart failure progresses, progressive inability to maintain CO and BP occurs.
   A. Dogs show signs of low output failure, such as exercise intolerance, weakness, and cold extremities.

B. End-stage disease manifests as cardiogenic shock with hypotension and multiple organ dysfunction.

IV. Arrhythmias are a common complication in dogs with mechanical dysfunction (DCM) and exacerbate signs of CHF.
   A. Atrial fibrillation is the most common arrhythmia seen.
   B. Ventricular arrhythmias also are common.

V. For dogs with primarily electrical dysfunction (arrhythmogenic cardiomyopathy), clinical signs are related to episodes of syncope or weakness.
   A. Sudden death may result during syncope.
   B. Syncope in many cases can be considered an aborted sudden death.
   C. Ventricular tachycardia typically causes clinical signs, whereas frequent ventricular premature complexes (VPCs) that occur singly or in pairs are unlikely to cause signs.
   D. Most dogs with arrhythmogenic forms of cardiomyopathy are otherwise normal and show signs only when the arrhythmia is severe, which explains the episodic nature of their signs.

Diagnosis

I. The diagnosis of cardiomyopathy depends on the form of disease.

II. Consider the following in dogs with DCM.
   A. Diagnosis is largely based on signalment, history, and physical examination findings.
      1. Breed disposition is important, with an autosomal dominant mode of inheritance in boxers and Doberman pinschers.
      2. Signs of coughing, exercise intolerance, or overt respiratory difficulty are typical.
      3. Identification of a soft, left apical, systolic murmur indicates mitral regurgitation (MR).
      4. An arrhythmia, especially atrial fibrillation or premature beats, may be present.
   B. Thoracic radiographs are used to identify cardiac enlargement and pulmonary edema or pleural effusion.
   C. Abdominal radiographs and ultrasonography may be used to document ascites.
   D. Electrocardiography (ECG) may identify patterns compatible with chamber enlargement (tall or wide P waves, tall R waves) and confirm the presence of arrhythmias.
   E. Echocardiography is the best method to confirm DCM.
      1. Decreased systolic function and ventricular enlargement are the hallmark findings.
      2. Increased end-systolic ventricular dimension, increased E-point to septal separation, and reduced fractional shortening (FS) are usually detected.
      3. CHF may occur once FS is severely reduced (<15%).
      4. Left atrial (LA) dilation is usually present but is not severe unless there is concurrent myxomatous mitral valvular degeneration.
      5. Annular dilation results in secondary MR.
      6. Implied in the diagnosis is the absence of other conditions that can cause chamber dilation and systolic dysfunction.
      7. Identification of echocardiographic evidence of DCM in an asymptomatic dog is termed *occult dilated cardiomyopathy,* which may be prolonged (4 to 5 years).
   F. Plasma and whole blood taurine are measured in atypical breeds with systolic dysfunction to evaluate for taurine deficiency-induced cardiomyopathy.
      1. Plasma taurine <40 nmol/mL and whole blood taurine <150 nmol/mL are consistent with taurine deficiency.
      2. American cocker spaniels, golden retrievers, and Newfoundlands are overrepresented.
      3. Systolic dysfunction may be reversible with taurine supplementation for several months.
      4. Dose is 500 mg PO BID in small dogs and 1 g PO BID in large dogs.

III. Dogs with arrhythmogenic cardiomyopathy are diagnosed as follows:
   A. Base diagnosis on identification of ventricular arrhythmias via ECG and ambulatory Holter or event monitoring.
   B. Evaluate character of arrhythmia (number, grade, or complexity); however, no criteria for diagnosis of ARVC have been established.
      1. Dogs with VPCs in excess of 500 per day are likely to be affected, but dogs with as few as 50 per day may also be affected.
      2. Dogs with high-grade arrhythmias (couplets, triplets, runs of ventricular tachycardia) are more likely to be affected and may be at increased risk for adverse events.
   C. Other tests are often normal, including thoracic radiography, ECG, and BP.
   D. Boxers may have both mechanical and electrical abnormalities (Harpster, 1983).
   E. Implied in the diagnosis is the exclusion of other causes of ventricular arrhythmias.

Differential Diagnosis

I. For DCM, rule out causes of systolic dysfunction and chamber enlargement.
   A. Chronic volume overload: primary AV valve disease, congenital heart disease
   B. Tachycardia-induced systolic dysfunction: reversible upon resolution of the tachycardia
   C. Myocarditis
   D. Myocardial toxicity: doxorubicin
   E. Systemic illness, metabolic disease

II. For electrical dysfunction, exclude other causes of arrhythmias.
   A. Other forms of heart disease: congenital disease (e.g., subaortic or pulmonic stenosis)
   B. Metabolic, systemic diseases

C. Altered autonomic balance: increased sympathetic tone, pheochromocytoma
D. Drugs and toxicities
E. Associated with surgery and other events: splenic disease and splenectomy, gastric dilatation-volvulus, trauma

Treatment

I. DCM associated with systolic dysfunction and heart failure
  A. Chronic heart failure therapy (see Chapter 9)
    1. Triple therapy with furosemide, angiotensin converting enzyme (ACE) inhibitors, and digoxin
    2. Additional diuretics including spironolactone or thiazides for refractory heart failure
    3. Inodilator therapy with pimobendan 0.25 to 0.3 mg/kg PO BID
    4. Antiarrhythmics for associated arrhythmias (see Chapter 6)
      a. Atrial fibrillation: beta blockers (use with caution in CHF), calcium channel blockers, digoxin
      b. VPCs, ventricular tachycardia: mexiletine, beta blockers, procainamide, amiodarone
    5. Nutritional supplements
      a. Often used, but no evidence to support efficacy
      b. Carnitine 50 mg/kg PO BID to TID
      c. Taurine in dogs 500 mg PO BID and in cats 250 mg PO SID to BID
      d. Coenzyme Q 30 mg PO BID, up to 90 mg PO BID in large dogs
  B. Acute heart failure therapy (see Chapter 9)
    1. Furosemide 1 to 4 mg/kg IV, IM, SC
    2. Supplemental oxygen
    3. Vasodilation
      a. Nitroglycerin $^1/_8$ to $^1/_2$ inch QID topically on pinna of ear or to inguinal area
      b. Sodium nitroprusside starting at 1 µg/kg/min IV as a constant rate infusion (CRI), titrated to desired effect
      c. Hydralazine 1 to 2 mg/kg PO, repeated hourly until BP decreases
    4. Inotropic support
      a. Dobutamine 1 to 5 µg/kg/min IV CRI
      b. Digoxin 0.003 to 0.005 mg/kg PO, IV; increased risk for acute toxicity and exacerbation of arrhythmias with IV use
      c. Pimobendan 0.25 to 0.3 mg/kg PO BID
II. Treatment for occult cardiomyopathy
  A. Systolic dysfunction and/or ventricular dilation with no clinical signs
  B. Therapy not proven to prevent progression
  C. Cardioprotective efforts (possible adverse effects, questionable efficacy)
    1. ACE inhibitors: block adverse effects of angiotensin II on left ventricular hypertrophy and myocardial fibrosis experimentally
    2. Beta blockers: block adverse effects of increased sympathetic tone
    3. Spironolactone: blocks adverse effects of aldosterone on myocardial fibrosis and possibly cardiac hypertrophy experimentally
  D. Digoxin: weak inotrope, not considered cardioprotective, may exacerbate arrhythmias
  E. Beta blockers
    1. Their use in dogs is controversial.
    2. There is no evidence of improved survival in dogs with DCM (Oyama, 2006).
    3. They must be used with caution, because they can make dogs in CHF feel worse.
    4. They must be titrated over 1 to 2 months from a low starting dose.
III. Treatment for arrhythmogenic cardiomyopathy (see Chapter 6)
  A. Adequate studies are lacking to identify if antiarrhythmics reduce the risk of sudden death in dogs; however, arrhythmogenic effects can be seen.
  B. Therapy is more commonly used in animals that are syncopal.
    1. To reduce frequency or severity of episodes
    2. Do not necessarily reduce risk of sudden death
  C. Therapy for asymptomatic animals is very controversial.
  D. Common medications include mexiletine, beta blockers, sotalol, procainamide, and amiodarone.

Monitoring of Animal

I. Screening tests for normal dogs or monitoring the asymptomatic dog for disease progression
  A. Mechanical disease is diagnosed primarily by echocardiography.
  B. ECG (ideally by Holter monitoring) identifies presence of arrhythmogenic disease.
  C. Holter monitor results may have value for predicting onset of overt disease.
II. Monitoring the asymptomatic dog on medication
  A. Echocardiography and ECG/Holter monitoring are useful to evaluate progression of disease.
  B. Echocardiography can be used to monitor for adverse effects of beta-blocker therapy (worsened systolic dysfunction).
  C. ECG identifies exacerbation of arrhythmias with digoxin.
  D. Thoracic radiographs are important to evaluate presence of CHF from disease progression or as an adverse effect of beta-blocker therapy.
  E. BP measurement is important in dogs receiving ACE inhibitors, spironolactone, or beta blockers.
  F. Kidney function and electrolytes are monitored in dogs receiving ACE inhibitors, spironolactone, or digoxin.
  G. For dogs on digoxin, serum levels are measured 7 to 10 days after starting the drug (6 to 8 hours post-pill), with an ideal range of 0.7 to 2 ng/mL.
  H. For dogs receiving antiarrhythmic therapy, monitor ECG for reductions in frequency and severity of arrhythmias (see Chapter 6), and for proarrhythmic effects of antiarrhythmic drugs.

III. Monitoring the dog on therapy for CHF
  A. Monitor for reaccumulation of fluid via thoracic radiography and abdominal ultrasonography.
  B. Echocardiography is generally not as useful once a diagnosis has been made and CHF therapy has been initiated.
  C. Monitor for adverse effects of therapy by evaluating BP, kidney function, electrolytes, and ECG.
IV. Prognosis variable
  A. Dogs with occult DCM may remain asymptomatic for years.
  B. Dogs with DCM and CHF usually succumb in 6 to 12 months.
  C. DCM warrants a worse prognosis (weeks to months) in Doberman pinschers.
  D. Some dogs with arrhythmogenic cardiomyopathy may remain asymptomatic for years and die of unrelated disease.
    1. Dogs are always at risk for sudden death, usually during exercise or excitement.
    2. ARVC and DCM (type III) boxer cardiomyopathy carry a poor prognosis (weeks to months).

FELINE MYOCARDIAL DISEASES

Kristin MacDonald

Hypertrophic Cardiomyopathy

Definition and Causes

I. Concentric hypertrophy (increased muscle thickness) of the LV occurs in the absence of other causes, such as systemic hypertension, aortic stenosis, or hyperthyroidism.
II. Idiopathic forms usually occur in domestic shorthair cats.
III. Autosomal dominant mode of transmission occurs in Maine coon cats from a missense mutation of the sarcomeric protein, myosin-binding protein C.
IV. An autosomal dominant form also occurs in American shorthair cats.
V. There is often a familial basis in other purebred cats.

Pathophysiology

I. A sarcomeric defect of a myocardial muscle protein causes dysfunction of the affected sarcomeres (contractile unit of the muscle cell), which leads to increased myocyte stress, and subsequent development of myocyte hypertrophy, collagen synthesis, and myocyte disarray (malalignment of myofibrils).
II. The end result is abnormal diastolic function consisting of delayed relaxation and increased myocardial stiffness.
III. As diastolic function worsens, the LV diastolic pressure increases, which leads to elevated LA and pulmonary venous pressures.
IV. Left-sided CHF (pulmonary edema ± pleural effusion) occurs when LA pressure exceeds 20 to 25 mm Hg.
V. LA dilation may lead to thrombus formation within the LA or auricle.
VI. Sudden death may occur secondary to a severe ventricular arrhythmia.

Clinical Signs

I. Males are more often diagnosed than females, and the mean age is 6.5 years (range 4 months to elderly (Rush et al., 2002; Atkins et al., 1992).
II. Other predisposed breeds are the ragdoll, British shorthair, Norwegian forest cat, Turkish van, Scottish fold, and Devon rex.
III. A dynamic systolic murmur is ausculted in 80% of cats with hypertrophic cardiomyopathy (HCM).
IV. Other auscultation abnormalities may include a gallop heart sound (S3 or S4) or an arrhythmia (Atkins et al., 1992: Rush et al., 2002).
V. Respiratory abnormalities are often present in cats with CHF, such as tachypnea, dyspnea, rales or crackles, or dampened lung sounds ventrally.
VI. Lameness and absence of arterial pulses are found if arterial thromboembolism has occurred.
VII. Some nonspecific signs (lethargy and anorexia) may occur.
VIII. Many cats have no clinical signs.
IX. Sudden death may be the only abnormality.

Diagnosis

I. Echocardiography
  A. Using two-dimensional (2D) echocardiography, measurement of LV wall or interventricular septal thickness at end-diastole is ≥6mm.
    1. Papillary hypertrophy may be the first abnormality detected.
    2. End-systolic cavity obliteration is also common.
  B. Systolic anterior motion of the mitral valve may be seen using the right parasternal, long-axis, LV outflow tract view.
    1. Color flow Doppler reveals a double jet of turbulent blood flow in the LV outflow tract and MR.
    2. Severity of systolic anterior motion is determined by continuous wave Doppler measurement of the peak systolic aortic blood flow velocity from the left apical 5-chamber view and reveals a dynamic, late-systolic, peaking jet.
  C. LA dilation is assessed by measurement of the LA and aortic (Ao) diameters using 2D echocardiography from the right parasternal, cross-sectional view, with LA defined as LA:Ao ≥ 1.5.
  D. Tissue Doppler imaging is useful to detect diastolic dysfunction, which is reflected by reduced early diastolic myocardial velocity and may be abnormal prior to development of concentric hypertrophy.
  E. Mitral inflow velocity measurements may show a delayed relaxation pattern or a restrictive pattern in more severe diastolic dysfunction.
II. Thoracic radiography
  A. Pulmonary venous distension and interstitial to alveolar pulmonary infiltrates may be seen with left-sided CHF.

B. Although any pattern of edema distribution is possible, infiltrates often occur in the perihilar region and caudal-ventral lung lobes.
C. Pleural effusion may be seen secondary to left- or right-sided CHF.

III. Electrocardiography
A. The most common arrhythmias are VPCs, atrial premature complexes, or atrial fibrillation (in severe cases).
B. Other abnormalities indicating LV hypertrophy include left axis deviation (mean electrical axis 0 to 90 degrees) and QRS amplitudes >1 mv.

Differential Diagnosis

I. Diseases causing compensatory concentric hypertrophy
A. Systemic hypertension
B. Hyperthyroidism
C. Subaortic or valvular aortic stenosis

II. Other cardiac diseases including unclassified cardiomyopathy, restrictive cardiomyopathy, DCM, or acquired AV valvular degeneration

III. Noncardiac causes of pleural effusion (see Chapter 19)

IV. Innocent heart murmurs
A. They may be caused by dynamic, right ventricular outflow tract stenosis.
B. In cats, differentiation of innocent murmurs from murmurs caused by structural heart disease requires echocardiography.

Treatment

I. Treatment of asymptomatic cats with echocardiographic evidence of HCM but no radiographic evidence of CHF is debatable.
A. Antihypertrophic treatment is recommended if there is moderate or severe concentric hypertrophy.
B. No studies have evaluated the effects of diltiazem or beta blockers on survival or time to development of CHF in cats with compensated HCM and no thromboembolism.
C. Ramipril does not reduce LV mass or improve diastolic function in Maine coon cats with mild to severe compensated HCM (MacDonald et al., 2006).
D. Atenolol is used to reduce systolic anterior motion and possibly reduce hypertrophy, and is given at 6.25 to 12.5 mg PO SID to BID.
1. Target heart rate is <160 beats per minute.
2. Atenolel is a selective beta-1 blocker, but may aggravate bronchoconstriction in asthmatic cats.
E. Diltiazem may reduce concentric hypertrophy (Bright et al., 1991).
1. Diltiazem 7.5 mg PO TID
2. *Dilacor XR* 30 mg PO SID to BID (sustained-release formulation)
3. *Cardizem CD* 45 mg or 10 mg/kg PO SID (sustained-release formulation)

II. Reduction of moderate to severe systolic anterior motion of the mitral valve is done with beta blockers to reduce LV pressure overload, which may reduce the concentric hypertrophy.

III. Acute decompensated CHF requires the following:
A. Furosemide 1 to 2 mg/kg SC, IM, IV every 2 to 8 hours
B. Oxygen supplementation
C. ± Nitroglycerin 2% 1/8 to 1/4 inch every 4 to 6 hours topically for 24 hours
D. Therapeutic thoracocentesis for significant pleural effusion

IV. Chronic CHF is treated with the following:
A. Furosemide
1. Mild CHF: 1 mg/kg PO SID to BID
2. Moderate CHF: 2 to 3 mg/kg PO BID
3. Severe CHF: 3 to 4 mg/kg IV, IM, SC, PO BID to TID
B. ACE inhibitors
1. Enalapril 0.5 mg/kg PO BID
2. Ramipril, lisinopril, or benazepril 0.5 mg/kg PO SID
3. After obtaining baseline renal blood work
4. Questionable efficacy (Fox, 2003)

V. For chronic, refractory CHF, add hydrochlorothiazide 1 to 4 mg/kg PO BID and introduce a low-salt diet.

VI. Antiarrhythmic therapy is indicated for significant arrhythmias (see Chapter 6).

Monitoring of Animal

I. In acute CHF, monitor resting respiratory rate and effort.
A. Thoracic radiographs are repeated in 24 hours to assess improvement in pulmonary edema.
B. In stable animals with CHF, repeat thoracic radiographs 1 week after starting therapy.

II. Repeat renal panel and electrolytes 1 week after starting ACE inhibitors and furosemide.
A. If significant azotemia develops after starting ACE inhibitors, discontinue them and reduce the furosemide dose temporarily.
B. Mild azotemia is expected when using ACE inhibitors and diuretics.
C. Moderate hypokalemia may need correction with potassium gluconate PO.

III. In cats with HCM and no LA dilation, repeat an echocardiogram every 4 to 6 months initially, and if stable for >12 months, consider an annual echocardiogram.

IV. Repeat an echocardiogram 1 to 2 weeks after initiating treatment for systolic anterior motion, and measure aortic blood flow velocity.
A. Additionally, monitor murmur intensity and heart rate.
B. Ideally, cats given beta blockers should have heart rates ≤160 beat per minute and murmur intensity should lessen.

V. For cats with LA dilation, repeat an echocardiogram and thoracic radiographs every 3 to 6 months.

VI. In cats with hyperthyroidism or systemic hypertension, echocardiography is repeated 4 months after adequate treatment.
A. Hypertrophy regresses if it is secondary to hyperthyroidism or hypertension.
B. HCM is a concurrent disease if hypertrophy persists despite normal BP and thyroxine levels.

VII. In cats with HCM without CHF or arterial thromboembolism, the prognosis is variable.
  A. Prognosis ranges from good to fair (median survival >5 years) (Atkins et al., 1992).
  B. Young, male purebred cats may develop severe disease by 2 to 4 years of age.
VIII. In cats with CHF or thromboembolism, survival is variable (mean survival of 2 months and 3 months, respectively) (Laste and Harpster, 1995).

Dilated Cardiomyopathy

Definition and Causes

I. DCM is a primary myocardial disease resulting in systolic myocardial failure (decreased contractility).
II. Most cases are idiopathic in origin.
III. Taurine deficiency can induce myocardial failure that is reversible.
  A. Taurine is an essential amino acid in cats, with the highest concentrations occurring in the myocardium, retina, central nervous system, leukocytes, and platelets.
  B. Taurine may help maintain intracellular osmolality, calcium concentration, and ion fluxes in the heart.
  C. Prior to 1988, feline diets were deficient in taurine (Pion et al., 1992a).
  D. Commercial diets are now supplemented with taurine, but cats fed vegetarian diets or exclusively one kind of canned food may develop taurine deficiency (Pion et al., 1992a).

Pathophysiology

I. Decreased contractility results in an increased end-systolic volume and reduced CO, leading to hypotension and activation of the β-adrenergic nervous system and RAAS.
II. The increased end-systolic volume results in increased LV diastolic filling pressure.
III. Increased preload leads to a compensatory, eccentric LV hypertrophy (increased end-diastolic diameter).
IV. Left-sided CHF develops when LV end-diastolic pressure exceeds 20 to 25 mmHg.
V. When there is also right ventricular myocardial failure, right-sided CHF (ascites, hepatomegaly, pleural effusion, jugular venous distension) develops with right ventricular end-diastolic pressures ≥15 mm Hg.

Clinical Signs

I. Respiratory signs may include tachypnea, dyspnea, and, rarely, coughing.
II. Ascites may occur with right-sided CHF.
III. Other nonspecific signs include lethargy or inappetence.
IV. Signs of arterial thromboembolism or syncope may occur.

Diagnosis

I. Thoracic radiography
  A. Pleural effusion is common and may obscure the cardiac silhouette.
  B. Left- and right-sided cardiomegaly, LA dilation, pulmonary venous distension, and pulmonary edema are common findings.
  C. The caudal vena cava may be dilated if there is right-sided CHF.
II. Echocardiography
  A. Systolic myocardial failure is present if increased end-systolic diameter (>10 mm), reduced FS (<28% or <20% with severe DCM), and increased E point to septal separation (>4 mm) are found.
  B. A compensatory increased end-diastolic diameter (>18 mm) may be detected.
  C. LA dilation is commonly present (La:Ao ≤ 1.5).
  D. Right ventricular eccentric hypertrophy and right atrial dilation are common.
  E. Mild secondary MR and tricuspid valve regurgitation may develop from annular dilation.
  F. Tissue Doppler imaging may show reduced systolic myocardial velocity.
III. Plasma and whole blood taurine
  A. They are indicated to rule out taurine deficiency.
  B. Plasma taurine <50 nmol/mL and whole blood taurine <250 nmol/mL are diagnostic.
IV. Systolic BP is often normal unless there is severe DCM and low-output heart failure.

Differential Diagnosis

I. Myocardial failure and eccentric hypertrophy may be caused by other cardiac diseases, such as severe MR, patent ductus arteriosus, or ventricular septal defect.
II. Congestive heart failure may be caused by HCM, unclassified cardiomyopathy, restrictive cardiomyopathy, acquired AV valve disease, or congenital heart diseases.
III. Pleural effusion may be caused by noncardiac diseases (see Chapter 19).
IV. Ascites may be caused by peritonitis, liver disease, neoplasia, or hypoproteinemia.

Treatment

I. Positive inotropic therapy is indicated when there is moderate or severe myocardial failure.
  A. Digoxin 0.031 mg PO QOD in cats <4 kg or SID in cats >4 kg
  B. Pimobendan 0.3 mg/kg PO BID
II. Administer taurine (250 mg PO BID) if the cat is taurine deficient or until results of taurine assays are available.
  A. Myocardial function improves over 2 to 4 months with taurine supplementation.
  B. After recovery of myocardial function, all other medications except taurine may be discontinued.
III. If CHF is present, begin furosemide and an ACE inhibitor, as described for HCM.
IV. Begin anticoagulant therapy if there is moderate or severe LA dilation (see Arterial Thromboembolism).
V. Avoid negative inotropes (beta blockers) in cats with moderate or severe myocardial failure.

Monitoring of Animal

I. Repeat thoracic radiographs following the onset of diuretic therapy and intermittently throughout treatment.
II. Repeat renal panel and electrolytes 1 to 2 weeks after starting an ACE inhibitor.
III. Measure serum digoxin level in 7 to 14 days (6 to 8 hours post-pill), with the ideal level being 0.7 to 2 ng/mL.
IV. Repeat echocardiography 2 months after starting medical therapy to assess myocardial function.
V. The prognosis for idiopathic DCM is grave, and cats with CHF may survive weeks to several months.
VI. Taurine deficiency-induced cardiomyopathy has a good prognosis for cats that survive the first several weeks (Pion et al., 1992b).

Miscellaneous Feline Cardiomyopathies

See Table 10-1.

Arterial Thromboembolism

Definition

I. Embolism of a thrombus (blood clot) occurs to a distal arterial site.
II. The origin of the thrombus in cats with severe cardiac disease is almost always the LA or auricle.

Causes

I. Thromboembolism occurs with severe heart diseases that cause LA dilation.
II. Most cats with arterial thromboembolism (75%) have moderate or severe LA dilation (Smith et al., 2003).

Pathophysiology

I. LA dilation leads to stasis of blood, and a thrombus forms within the dilated LA or auricle.
II. Other contributing factors may include red blood cell and platelet hyperaggregability.
III. Systemic arterial thromboembolism occurs most frequently to the terminal aorta and occasionally to the right brachiocephalic trunk.
IV. Vasogenic amines (serotonin and thromboxane) are released from the thrombus and cause collateral vasoconstriction.
V. Reperfusion injury may occur when the thrombus is lysed and often results in acute, life-threatening acidosis and hyperkalemia.

Clinical Signs

I. Acute paresis, often of the hind limbs
II. Pain with recent (<24 hours) thromboembolism
III. Absent or markedly reduced arterial pulse
IV. Cyanotic nail beds and foot pads
V. Possible muscle contracture in the affected limbs
VI. Murmurs common

Diagnosis

I. Detection of suspicious clinical signs on physical examination
II. Absence of bleeding or oozing of dark blood with trimming of a toenail artery
III. No blood flow detected by Doppler placed over the femoral artery

TABLE 10-1

Miscellaneous Feline Cardiomyopathies

DISORDER	CLINICAL SIGNS	ECHOCARDIOGRAPHIC DIAGNOSIS	TREATMENT/PROGNOSIS
Unclassified cardiomyopathy	Similar to HCM Tachypnea, dyspnea, gallop rhythm, ± murmur	Left atrial ± right atrial dilation ± Mild left ventricular hypertrophy ± Mild ↓ contractility Mild AV insufficiency ± Diastolic dysfunction	Furosemide and ACE inhibitor for CHF Anticoagulant for moderate to severe atrial dilation ± Antiarrhythmic
Restrictive cardiomyopathy*	Similar to HCM Tachypnea, dyspnea, gallop rhythm, ± murmur	Severely hyperechogenic endocardium Severe fibrotic band bridging the left ventricular free wall and septum Severe diastolic dysfunction	Furosemide and ACE inhibitor for CHF High risk (45%) of thromboembolism
Arrhythmogenic right ventricular cardiomyopathy†	Right-sided CHF Ascites, pleural effusion, hepatomegaly Ventricular arrhythmia (75%), gallop rhythm	Severe right atrial and right ventricular dilation Mild tricuspid regurgitation ± Right ventricular aneurysm ± Mild left atrial dilation	Grave prognosis Median survival 30 days Ventricular antiarrhythmic drugs Anticoagulant for moderate to severe atrial dilation

HCM, Hypertrophic cardiomyopathy; *ACE,* angiotensin converting enzyme; *CHF,* congestive heart failure; *AV,* atrioventricular valve.

*Fox PR: Endomyocardial fibrosis and restrictive cardiomyopathy: pathologic and clinical features. J Vet Cardiol 6:25, 2004.

†Fox PR, Maron BJ, Basso C et al: Spontaneously occurring arrythmiogenic right ventricular cardiomyopathy in the domestic cat: a new animal model similar to the human disease. Circulation 102:1863, 2000.

IV. Identification of the thrombus and obstructed flow distal to the thrombus on abdominal ultrasonography
V. Thoracic radiographic findings compatible with CHF
VI. Detection of underlying cardiac disease on echocardiography

Differential Diagnosis

I. Intervertebral disc disease with acute disc herniation
II. Cranial cruciate rupture or other orthopedic diseases

Treatment

I. Supportive care is indicated for all cases.
   A. Many cats autolyse their thromboemboli within 1 to 14 days.
   B. Provide pain medications.
      1. Hydromorphone 0.05 to 0.2 mg/kg SC, IM QID
      2. Butorphanol 0.1 to 0.4 mg/kg SC, IV, IM QID
      3. Buprenorphine 0.01 mg/kg SC, IV, IM TID
   C. Consider low-dose acepromazine (0.05 to 0.1 mg/kg SC, IV, IM) as a sedative and vasodilator.
   D. Assess bladder size and express distended bladders (rarely necessary).
   E. Turn laterally recumbent cats.
   F. Institute range-of-motion exercises after the initial 24 hours.
   G. Consider IV fluids at low rates (half maintenance) if no CHF is detected.
II. Anticoagulation is necessary to prevent further thrombus formation.
   A. Aspirin 6 mg/kg PO every 72 hours has had variable efficacy (Pion, 1988; Smith et al., 2003).
   B. Heparin is given at 50 to 100 units/kg SC QID, with the therapeutic goal of prolonging the activated partial thromboplastin time (APTT) to 1.5 × baseline.
   C. Low–molecular-weight heparins (enoxaparin or dalteparin) may be substituted at 1 mg/kg SC BID to TID, but no controlled studies have evaluated their efficacy in cats.
   D. Warfarin may eventually be started at 0.25 mg PO SID.
      1. Use heparin initially and continue it for a 48-hour overlap period.
      2. Dosage adjustments are needed to maintain international normalized ratio or APTT at 1.5 to 2 × baseline.
   E. Clopidogrel is a platelet inhibitor that has been used in cats at 18.75 mg PO SID (Hogan et al., 2004).
III. Thrombolytic therapy is rarely performed.
   A. Only 40% of cats survived to be discharged from the hospital (Pion, 1988).
   B. The dose of streptokinase is 90,000 units IV over 30 minutes, then 45,000 U/hr for 3 hours.
   C. Tissue plasminogen activator is given at 0.25 to 1 mg/kg/hr IV, with total dose of 1 to 10 mg/kg IV.

Monitoring of Animal

I. Assess the presence and severity of pain, and titrate opioids as needed.
II. Palpate femoral arterial pulses, and inspect the nail beds and foot pads to assess return of blood flow.
III. Inspect the skin of the affected limbs for discoloration, lichenification, or other evidence of impending necrosis.
IV. Monitor renal function and electrolytes.
V. Monitor respiratory rate and effort, and repeat thoracic radiographs in cats treated with furosemide for CHF.
VI. Repeat APTT in cats receiving heparin ± warfarin to achieve a target of 1.5 × baseline.
VII. Prognosis is poor in cats that show no return of blood flow within several days.

CHAPTER 11

Pericardial Disorders

Anthony H. Tobias

CONGENITAL/DEVELOPMENTAL DISORDERS

Peritoneopericardial Diaphragmatic Hernia

Definition

I. A peritoneopericardial diaphragmatic hernia (PPDH) is a defect in the ventral diaphragm and pericardium that allows abdominal contents to enter the pericardial space.
II. Herniated structures include liver, gall bladder, spleen, stomach, small intestines, omentum, and falciform ligament.
III. PPDH is an uncommon defect.
  A. Incidence in cats is 0.05%.
  B. Incidence in dogs is 0.02%.
  C. Data are from the Veterinary Medical Database at Purdue University from January 1992 to April 2003.
IV. Persian cats and Weimaraners may be predisposed (Evans and Biery, 1980; Neiger, 1996).

Causes and Pathophysiology

I. During embryonic development, the diaphragm forms from the ventrally located septum transversum, the mesoesophagus, a pair of pleuroperitoneal folds, and tissue from the body wall.
II. The liver arises as a large ventral outgrowth from the foregut ectoderm and grows cranioventral to penetrate the septum transversum, and eventually distracts from the septum transversum, to form the ventral mesentery (falciform ligament).
III. If separation between the developing liver and septum transversum is defective, an opening in the ventral part of the diaphragm may occur, allowing the peritoneal and pericardial cavities to communicate.
IV. Abdominal organs may then pass through the defect into the pericardial space resulting in a PPDH (King, 1999; Noden and de Lahunta, 1985).
V. The diaphragm does not form part of the pericardium in small animals, and traumatic PPDH has not been reported in either the dog or cat (Neiger, 1996; Hay et al., 1989).

Clinical Signs

I. Clinical signs vary depending on the herniated organs or tissue.
II. Some affected animals show no clinical signs, and PPDH is an incidental finding.
III. In symptomatic animals, signs referable to the respiratory and gastrointestinal system predominate.
  A. Tachypnea, respiratory distress, vomiting, and anorexia are common.
  B. Other signs include lethargy, weight loss, diarrhea, and coughing.

Diagnosis

I. The following physical examination findings support a diagnosis of PPDH:
  A. The apex beat may be absent or displaced; heart sounds are frequently muffled.
  B. Some animals have a fever.
  C. Commonly associated abnormalities in dogs include sternal malformations (incomplete xiphoid; pectus excavatum; and absent, deformed, and fused sternebrae), cranioventral abdominal hernias, and other congenital heart defects (pulmonic stenosis, ventricular septal defect).
  D. Associated abnormalities in cats are less common and are usually limited to sternal malformations and cranioventral abdominal hernias.
II. Radiographic findings that support a diagnosis of PPDH include the following:
  A. Enlargement of the cardiac silhouette with dorsal displacement of trachea, overlapping of the diaphragmatic and caudal cardiac silhouette borders, and sternal malformations may be seen.
  B. The cardiac silhouette often contains gas-filled bowel loops and structures of differing radiolucencies (Figure 11-1, *A*).
  C. The hepatic silhouette may be small or absent in the anterior abdomen.
  D. Various other organs (e.g., small intestines, spleen) may be absent from the abdomen (Figure 11-1, *B*).
  E. In cats, a dorsal peritoneopericardial mesothelial remnant, which represents the dorsal border of the hernia, may be recognized in the lateral view as a curvilinear opacity between the cardiac silhouette and the diaphragm, either ventral to or superimposed over, the caudal vena cava (Berry et al., 1990).
  F. Positive and negative contrast peritoneography and gastrointestinal contrast studies are occasionally necessary to confirm the diagnosis.

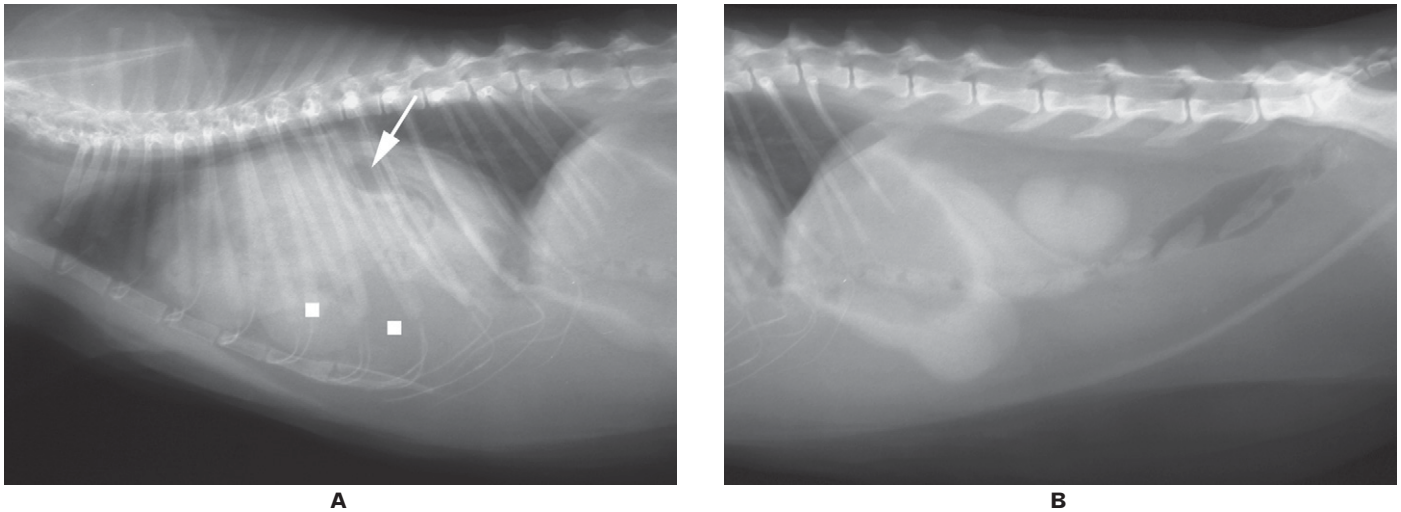

FIGURE 11-1 Lateral thoracic (**A**) and abdominal radiographs (**B**) from a cat with a peritoneopericardial diaphragmatic hernia. **A,** A markedly enlarged cardiac silhouette contains gas-filled bowel loops *(arrow)* and structures of differing radiolucencies *(squares)*. **B,** Most of the abdominal contents are displaced into the pericardial space, leaving the abdomen fairly empty. *Modified from Tobias AH: Pericardial disorders. p. 1104. In Ettinger SJ, Feldman EC (eds): Textbook of Veterinary Internal Medicine. 6th ed. Elsevier, St. Louis, 2005; with permission.*

III. Electrocardiograms (ECGs) may be normal or show low-voltage complexes and abnormal orientation of the mean electrical axis.
IV. Echocardiography reveals abdominal viscera within the pericardial space.
    A. Pericardial effusion is present in some cases.
    B. In cats the liver is the most commonly herniated organ, and focal hyperechoic areas (myelolipomas) are frequently seen within the herniated lobe(s) (Tobias, 2005).

Differential Diagnosis

I. Pericardial effusion
II. Primary cardiac disease
III. Diaphragmatic hernia

Treatment and Monitoring

I. Surgical PPDH reduction and repair are necessary for all cases that have clinical signs ascribable to the defect and are strongly recommended for all young animals with PPDH (symptomatic or not).
II. Prognosis with surgery is excellent.
III. In older animals, adhesions between herniated organs and the pericardium may complicate or preclude PPDH reduction.
IV. Consequently, in an asymptomatic older animal where PPDH is an incidental finding, it may be prudent to recommend continued observation rather than surgical repair.

Benign Intrapericardial Cysts

Definition and Causes

I. Benign intrapericardial cysts are large, fluid-filled masses within the pericardial space that occur occasionally in small animals.
II. In virtually all cases, histopathology discloses that the cysts are encapsulated adipose tissue, with extensive hemorrhage and necrosis, or organizing cystic hematomas.
III. In some cases, the benign intrapericardial cyst is associated with a small PPDH.
IV. In other cases, the cyst is attached by a pedicle to the apex of the pericardium as a result of prenatal herniation of omentum or falciform fat from the peritoneum into the pericardium and subsequent closure of a PPDH.
V. Cyst formation probably results from vascular obstruction of the herniated tissue, or repeated trauma from the beating heart (Simpson et al., 1999; Sisson et al., 1993).
VI. Intrapericardial hepatic cysts have been described in cats with PPDH as a result of incarceration of portions of the liver (Less et al., 2000; Liptak et al., 2002).
VII. True congenital intrapericardial cysts in humans are endothelium-, epithelium-, or mesothelium-lined (depending on their origin) and are rare in small animals (Labadie, 1993; Sisson et al., 1993).

Clinical Signs and Diagnosis

I. Intrapericardial cysts cause cardiac tamponade (significant compression of the heart from accumulating pericardial contents) by direct cardiac compression and associated pericardial effusion.
II. The pathophysiology, clinical signs, and diagnosis for pericardial effusion and cardiac tamponade are discussed later in this chapter.

Treatment

Surgical removal of the cyst and its associated pedicle, pericardectomy, and repair of the PPDH.

Pericardial Defects

I. Pericardial defects are communications between the pericardial and pleural space that may be single or multiple

and range in size from small, round or oval holes to total absence of one side of the pericardium.

II. They are rare in dogs and are usually found incidentally on postmortem examination.

III. Some are thought to be congenital (Gagg and Luer, 1977).

IV. Herniation with incarceration of cardiac chambers through pericardial defects has been reported in dogs (Gagg and Luer, 1977; Sisson and Thomas, 1999; Van den Ingh, 1977).

ACQUIRED DISORDERS

Pericardial Effusion

Definition

I. Accumulation of an abnormal amount of pericardial fluid within the pericardial space

II. Data from the University of Minnesota Veterinary Medical Center (UMVMC) from January 1999 to December 2001
   A. The incidence in dogs was 0.43%.
   B. Average age was 9.7 ± 2.2 years.
   C. Average weight was 31.2 ± 12.6 kg.
   D. There was no sex predisposition, and golden retrievers were overrepresented (Tobias, 2005).

Causes

I. Infections
   A. Bacterial
      1. Bacterial infections are uncommon causes.
      2. Most bacterial infections are thought to arise from intrapericardial foreign body penetration, especially by migrating grass awns (foxtails or *Hordeum* spp.) (Aronson and Gregory, 1995).
   B. Fungal
      1. Systemic *Coccidioides immitis* is an occasional cause in dogs (Heinritz et al., 2005; Shubitz et al., 2001; Thomas et al., 1984).
      2. *Aspergillus niger* has also been reported in a dog (Carpenter et al., 2001).
      3. In most cases, fungal infections result in effusive-constrictive or constrictive pericarditis.
   C. Viral: occasionally feline infectious peritonitis
   D. Protozoal: rarely visceral leishmaniasis in dogs (Font et al., 1993)

II. Idiopathic forms
   A. Pericardial effusions are idiopathic in origin in 19% to 23% of affected dogs (Berg and Wingfield, 1983; Tobias, 2005).
   B. Signalment is typical of pericardial effusion in general.

III. Metabolic and/or toxic forms (uncommon)
   A. Secondary to uremia (Berg and Wingfield, 1983; Rush et al., 1990)
   B. Cholesterol-based effusion with hypothyroidism (MacGregor et al., 2004)
   C. Coagulation disorders
      1. Dogs: anticoagulant rodenticide toxicity (Petrus and Henik, 1999)
      2. Cats: secondary to disseminated intravascular coagulation, warfarin toxicity, other coagulopathies (Rush et al., 1990)

IV. Cardiovascular disorders
   A. Pericardial effusion is frequently detected in dogs and cats with congestive heart failure (CHF), but seldom in sufficient quantity to cause significant hemodynamic compromise.
   B. Left atrial perforation is an uncommon cause in small-breed dogs with severe mitral regurgitation from chronic degenerative valvular disease.

V. Neoplasia
   A. Cardiac hemangiosarcoma
      1. It is a highly malignant neoplasm of vascular endothelium that usually involves the wall of the right atrium (RA) or auricle.
      2. It is the most common cause of pericardial effusion in dogs (61% of dogs in UMVMC data) (Tobias, 2005).
      3. Signalment is typical of pericardial effusion in general.
      4. Primary cardiac hemangiosarcoma of the RA has been reported in a cat (Merlo et al., 2002).
   B. Heart base tumors
      1. The term is used to designate any mass located at the base of the heart in association with the ascending aorta and main pulmonary artery.
      2. Most are aortic body tumors in dogs, although 5% to 10% are ectopic thyroid tumors (Capen, 1978).
      3. Despite being the second most common cardiac tumor in dogs (7% of dogs in UMVMC data), incidence is approximately tenfold lower than cardiac hemangiosarcoma (Ware and Hopper, 1999).
      4. English bulldogs, boxers, and Boston terriers are predisposed.
         a. These tumors also occur in nonbrachycephalic breeds.
         b. Chronic hypoxia-induced hyperplasia and neoplasia of chemoreceptors may explain the predisposition of brachycephalic dogs to aortic body tumors (Hayes and Sass, 1988).
      5. Age range at time of diagnosis is 6 to 15 years (average 10 years) (Owen et al., 1996).
      6. Both male and no gender predispositions have been reported.
      7. They occasionally occur in cats.
   C. Mesothelioma
      1. Mesothelioma, a diffuse neoplasm of the pericardium and other serosal surfaces, was confirmed in 5% of dogs in UMVMC data (Tobias, 2005).
      2. No sex or breed predisposition has been reported.
      3. It has rarely been described in cats.
   D. Other uncommon cardiac tumors: lymphosarcoma, rhabdomyosarcoma, fibrosarcoma

VI. Trauma
   A. Pericardial effusions associated with intrapericardial foreign bodies occur occasionally.
   B. In UMVMC data, one dog (1%) had pericardial effusion associated with an intrapericardial pellet.

Pathophysiology

I. Pericardial effusion increases intrapericardial pressure and causes cardiac tamponade.
II. Cardiac tamponade results in depressed cardiac output (CO), elevation and equilibration of right and left ventricular diastolic pressure and pericardial pressure, and pulsus paradoxus.
III. Increased intrapericardial pressure impairs ventricular filling in diastole, which results in diminished stroke volume.
IV. Pericardial effusion also causes decreased systolic function because the compressed and underfilled cardiac chambers operate at the lower ends of their respective Frank-Starling curves (Spodick, 2001).
V. Acute accumulations of relatively small amounts of pericardial effusion can cause profound hemodynamic compromise and clinical signs of low CO.
VI. With more chronic accumulations, the volume of the pericardial sac expands (Kardon et al., 2000).
    A. Compensatory mechanisms (increased sympathetic tone, activation of the rennin-angiotensin-aldosterone system) increase heart rate and preload or filling pressure in an effort to restore CO.
    B. Atrial natriuretic peptide does not increase, because atrial distention (the primary stimulus for atrial natriuretic peptide secretion) does not occur owing to external compression of the heart (Koller et al., 1987, Spodick, 1989).
    C. Signs of increased systemic venous pressure predominate and manifest as right-sided CHF (hepatomegaly, ascites, jugular distention, pleural effusion).
VII. Pulsus paradoxus is defined as ≥10 mmHg decrease in systolic arterial blood pressure (BP) with inspiration during normal breathing (Spodick, 2001).
    A. Left ventricular stroke volume and systemic arterial BP normally decrease slightly with inspiration.
    B. This phenomenon is accentuated with cardiac tamponade and may be recognized clinically as phasic variations in pulse quality associated with respiration.

Clinical Signs

I. Clinical complaints and histories are most commonly acute and nonspecific.
II. Presenting signs from UMVMC data are as follows:
    A. Lethargy (53%)
    B. Respiratory difficulty (44%)
    C. Collapse (40%)
    D. Reduced appetite (38%)
    E. Vomiting (30%)
    F. Abdominal distention (23%)
    G. Less common: polydipsia, weakness, coughing

Diagnosis

I. Physical examination findings range from vague and subtle to hemodynamic collapse.
    A. Muffled heart sounds are most common.
    B. Other findings include depression, weak pulses, and abdominal distention with a fluid wave (ascites).
    C. Jugular distention and pulsus paradoxus may be identified.
II. Thoracic radiographic features that support a diagnosis of pericardial effusion are as follows:
    A. An enlarged and globoid cardiac silhouette, with tracheal elevation and widening of the caudal vena cava
    B. Overlap of the cardiac silhouette and diaphragm and bilateral contact between the pericardium and the chest wall
    C. A sharply delineated edge to the cardiac silhouette, because the distended pericardium has little or no motion during systole and diastole
    D. Lung fields that show no evidence of left-sided CHF (no cardiogenic pulmonary edema)
    E. Typical radiographic findings with chronic, large-volume effusions
        1. With smaller effusions, the cardiac silhouette is variably enlarged and it is not necessarily globoid.
        2. Pleural effusion may obscure the cardiac silhouette.
    F. Other possible abnormalities: pulmonary metastases, radiopaque intrapericardial foreign bodies
III. Electrocardiographic findings may include the following:
    A. Most dogs with pericardial effusions have either a normal sinus rhythm or a sinus tachycardia.
    B. Ventricular arrhythmias are fairly common, and supraventricular arrhythmias occasionally occur.
    C. Low-voltage QRS complexes (R waves <1 mV in all limb leads) are present in approximately half the cases.
    D. Electrical alternans (beat-to-beat variations in the contour and amplitude of the QRS complex, ST segment, and T wave) strongly suggests the presence of pericardial effusion (Bonagura, 1981) (Figure 11-2).
IV. Hematology and biochemistry tests may reveal the following:
    A. Dogs with hemangiosarcoma are frequently anemic and may have nucleated red blood cells (RBCs), schistocytes, acanthocytes, and thrombocytopenia.
    B. Mild-to-moderate liver enzyme elevations often occur from hepatic congestion.
    C. Mild prerenal azotemia may be present.
    D. Cats with feline infectious peritonitis may have neutrophilia, lymphocytopenia, and hyperglobulinemia.
    E. Ascitic fluid analysis discloses a modified or high-protein transudate.
    F. *C. immitis* serology is indicated in dogs from endemic areas.
    G. Assessment of coagulation is recommended prior to pericardiocentesis if a coagulopathy is suspected clinically.
    H. Serum cardiac troponin I assays may be useful in dogs to distinguish between cardiac hemangiosarcoma and idiopathic pericardial effusion, with higher concentrations usually present with cardiac hemangiosarcoma (Shaw et al., 2004).
V. Pericardial effusions in dogs, irrespective of cause, are almost always sanguinous or serosanguineous, sterile in-

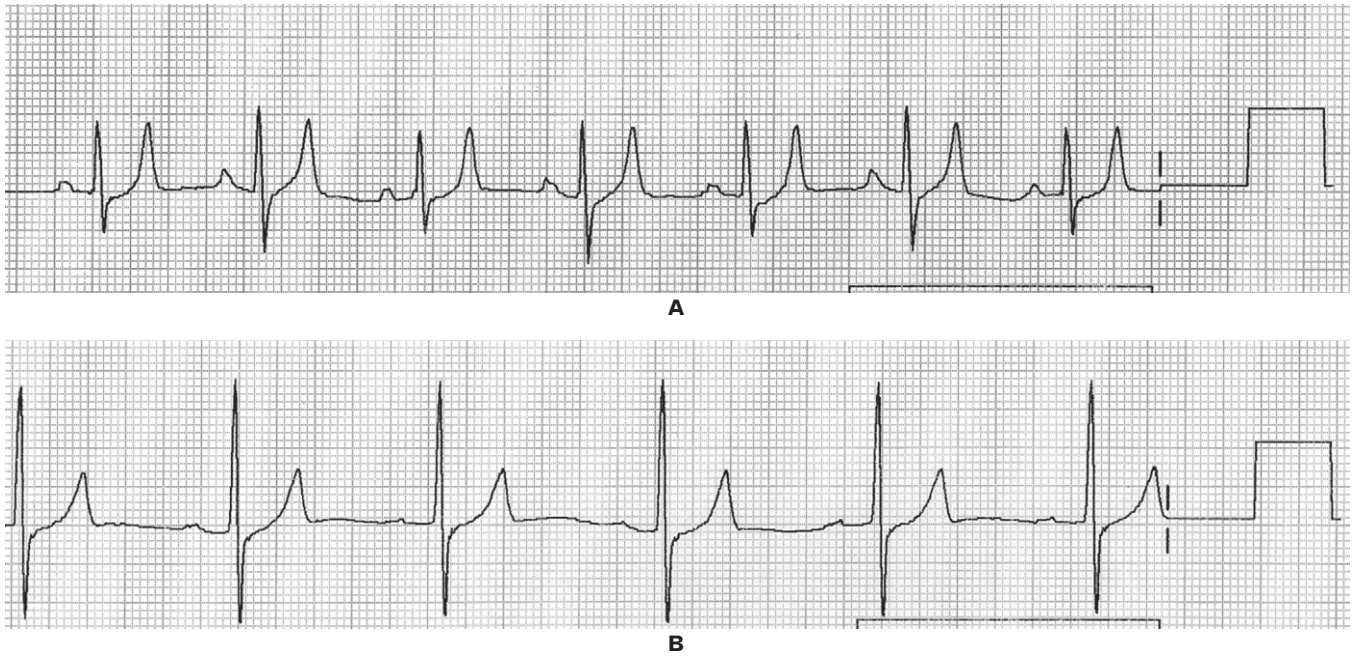

FIGURE 11-2 Lead II electrocardiograms from a dog with pericardial effusion. **A,** Before pericardiocentesis, the complexes are low-voltage (R wave amplitude approximately 1 mV), the QRS complexes show beat-to-beat variations in contour and amplitude (electrical alternans), and heart rate is 140 beats per minute (bpm). **B,** After pericardiocentesis, R wave amplitude is almost 2 mV, electrical alternans is no longer present, and heart rate is 110 bpm. Calibration square is 1 mV in amplitude.

flammatory exudates and similar in gross appearance to blood, but they do not clot.

A. Cytologic evaluation does not differentiate between neoplastic and nonneoplastic causes in most cases.
B. Total nucleated cell counts, RBC counts, protein concentrations, pericardial fluid pH, and other biochemistries overlap extensively between causes (de Laforcade et al., 2005; Fine et al., 2003; Sisson et al., 1984).
C. Hemangiosarcoma and aortic body tumors are rarely identified on cytological evaluation.
D. Pericardial diseases that lead to effusion result in dramatic mesothelial proliferation; exfoliated mesothelial cells often have characteristics that mimic malignancy (Alleman, 2003).
E. Despite its generally low diagnostic yield, pericardial fluid cytology (and culture when appropriate) is crucial for the diagnosis of some of the less common causes of pericardial effusion, such as bacterial and protozoal pericarditis, and lymphoma.

VI. Echocardiography is the most sensitive and specific noninvasive method to confirm the presence of pericardial effusion.
   A. With two-dimensional (2D) echocardiography, pericardial effusion appears as an echolucent zone surrounding the heart.
   B. In cases with concurrent pleural effusion, the pericardium is well visualized with fluid on either side.
   C. The heart may show swinging motions within the pericardial fluid.
   D. Cardiac chambers may appear small, and the walls may show thickening or pseudohypertrophy from external compression.
   E. The right atrial free wall is normally rounded throughout the cardiac cycle, reflecting positive right atrial transmural pressure.
      1. Any inversion or collapse of the right atrial free wall provides indirect evidence of elevated intrapericardial pressure and transient reversal of transmural pressure.
      2. Right atrial inversion occurs in late diastole and continues into ventricular systole (Figure 11-3, *A*).
   F. Right ventricular diastolic collapse is characterized by inward motion of the right ventricular free wall that may range from a transient and localized concavity to virtual complete right ventricular chamber obliteration throughout diastole.

VII. Echocardiography also detects intrapericardial masses.
   A. Findings consistent with cardiac hemangiosarcoma
      1. Hemangiosarcoma most commonly arises from the wall of the RA or auricle, protrudes into the pericardial space, and moves with the RA or auricle.
      2. It may also protrude into the right atrial chamber, and involve other areas of the heart base, pericardium, and right atrioventricular groove.
      3. Typically small hypoechoic spaces (mottled or cavitary appearance) and occasionally cystic lesions are seen.
      4. It is usually demonstrated in the right parasternal long- and short-axis views.

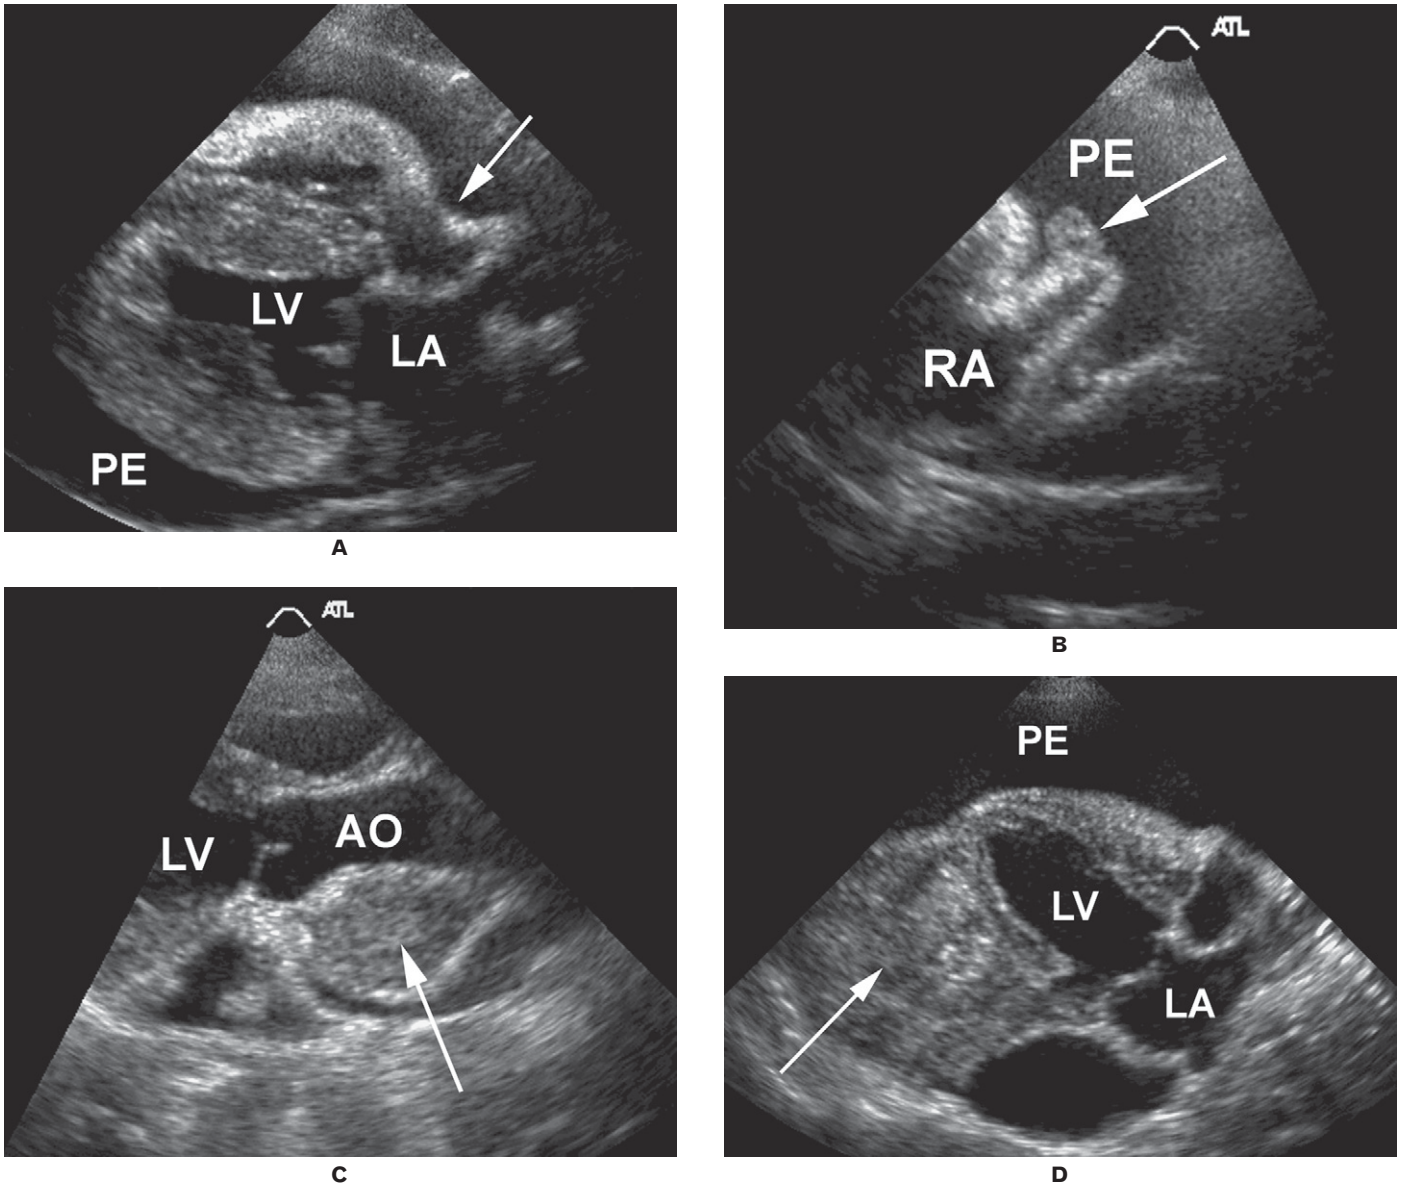

FIGURE 11-3 Echocardiograms from dogs with pericardial effusion. **A,** The effusion forms an echolucent zone around the heart. Inversion of the right atrial free wall *(arrow)* indicates cardiac tamponade. **B,** Imaging from the left cranial location demonstrates a small cavitated hemangiosarcoma *(arrow)* protruding from the wall of the right auricle. **C,** A large tumor *(arrow)* associated with the ascending aorta is characteristic of a heart base tumor. **D,** A large tumor *(arrow)* is arising from the wall of the left ventricle and was a confirmed fibrosarcoma. *LV,* Left ventricle; *LA,* left atrium; *PE,* pericardial effusion; *RA,* right atrium; *AO,* aorta.

5. Occasionally the mass is identified best in left parasternal views (see Figure 11-3, *B*).

B. Features characteristic for heart base tumors
   1. Heart base tumors are associated with the ascending aorta (see Figure 11-3, *C*).
   2. They vary from small, oval structures to extensive masses that surround the aorta and main pulmonary artery.
   3. Indentation or invasion of the atria and major blood vessels may be seen.
   4. They tend to have a more homogenous echogenicity than hemangiosarcoma.

C. Other echocardiographic findings
   1. Other cardiac tumors (see Figure 11-3, *D*)
   2. Abdominal viscera within the pericardial space with PPDH
   3. Benign intrapericardial cysts
   4. Intrapericardial thrombi associated with left atrial perforation

VIII. Whenever the clinical condition permits, pericardiocentesis is deferred until a thorough echocardiographic examination has been completed.
   A. Pericardial fluid forms an echolucent zone around the right atrium and auricle, and the ascending aorta.
   B. Consequently, the presence of pericardial fluid greatly facilitates the detection of intrapericardial masses,

especially cardiac hemangiosarcoma and heart base tumors.

IX. Idiopathic pericardial effusion is a diagnosis of exclusion that is made when no intrapericardial masses are identified and ancillary tests do not disclose a cause.

X. Mesothelioma rarely forms discrete masses detectable by echocardiography.
   A. It is extremely difficult to distinguish from idiopathic effusion, even with pericardial histopathology and immunohistochemistry (Churg et al., 2000; Stepien et al., 2000).
   B. In many cases, the diagnosis is only confirmed on postmortem examination.
   C. A clinical course that includes accumulation of significant amounts of pleural effusion within 4 to 6 months of pericardectomy suggests mesothelioma.
   D. The chronic inflammatory process of idiopathic effusion may predispose golden retrievers to pericardial mesothelioma (Machida et al., 2004).

Differential Diagnosis

I. Other causes of right-sided CHF (e.g., dilated cardiomyopathy, tricuspid dysplasia) and ascites (e.g., hepatic disease, abdominal neoplasia)

II. Other causes of muffled heart sounds: pleural effusion, thoracic masses, diaphragmatic hernia

III. Other causes of low-voltage complexes on ECG: pleural effusion, obesity, hypothyroidism

IV. Other causes of prominent enlargement of the cardiac silhouette on thoracic radiography: dilated cardiomyopathy, tricuspid dysplasia, PPDH

Treatment and Monitoring

I. Pericardiocentesis for removal of fluid is necessary for any animal with significant hemodynamic compromise.

II. Following pericardiocentesis and appropriate supportive care, treatment is directed towards the specific cause.

III. Dogs with bacterial pericarditis are treated with pericardectomy, removal of any foreign bodies, chest drainage, and antibiotics for up to 6 months.
   A. Many recover without complications.
   B. Prognosis is good when treated aggressively with a combination of surgical and medical therapy (Aronson and Gregory, 1995).

IV. Treatment and prognosis for *C. immitis*–related pericardial disease is discussed under Constrictive/Effusive-Constrictive Pericarditis.

V. There is no effective treatment for feline infectious peritonitis and the disease is invariably fatal, but pericardiocentesis may provide temporary palliation with clinically significant pericardial effusion.

VI. First episodes of idiopathic pericardial effusion may sometimes be treated by pericardiocentesis alone, followed by pericardectomy in recurrent cases.
   A. Cardiac tamponade often recurs within 1 to 2 months of pericardiocentesis and is often fatal.
   B. Recurrent tamponade with effusive-constrictive pericarditis may also develop (Tobias, 2005).
   C. Complete cure is uncommon, but long-term survival has been reported with repeated pericardiocentesis (Mellanby and Herrtage, 2005).
   D. Surgical or minimally invasive thoracoscopic pericardectomy is recommended with the initial episode of idiopathic pericardial effusion to avoid the risk of recurrent, potentially fatal cardiac tamponade.
   E. Surgical pericardectomy also permits examination of thoracic and intrapericardial structures for causes of pericardial effusion.
   F. Pericardectomy is usually curative for idiopathic pericardial effusion.

VII. Left atrial perforation may require only medical therapy for CHF.
   A. Episodes of weakness or collapse may be transient.
   B. Relatively little pericardial fluid and only mild echocardiographic evidence of cardiac tamponade may be present.
   C. Echocardiograms repeated 7 to 10 days later may demonstrate resolution of both the pericardial effusion and intrapericardial thrombi.
   D. These cases have severe underlying heart disease and survival beyond 6 months after the acute episode is uncommon.
   E. Pericardiocentesis is required for cases that are hemodynamically compromised from cardiac tamponade.
      1. Continued hemorrhaging may necessitate blood transfusion, and thoracotomy to remove large clots from the pericardial space and repair the left atrial perforation.
      2. The prognosis in such cases is grave (Prosek et al., 2003; Sadanaga et al., 1990).

VIII. Treatment for cardiac hemangiosarcoma is challenging, and the prognosis is extremely poor.
   A. By the time of diagnosis, it usually has metastasized and should be considered a systemic disease.
   B. Palliative pericardiocentesis is usually associated with marked clinical improvement, but cardiac tamponade typically recurs within a few days, often resulting in death or euthanasia (median survival time of 11 days, range 0 to 208 days from UMVMC data) (Tobias, 2005).
   C. More aggressive treatment of cardiac hemangiosarcoma includes various combinations of tumor resection, pericardectomy, chemotherapy, and splenectomy (for splenic metastases).
      1. Despite these therapies, median survival time is short (56 days, range 0 to 229 days).
      2. Chemotherapy, especially with doxorubicin, after tumor resection may prolong survival, but the benefit appears to be small (Weisse et al., 2005).

IX. Most aortic body tumors are benign and expansive, although they may be locally invasive and/or metastasize in dogs and cats.
   A. The biological behavior of ectopic thyroid tumors at the heart base is not well described, although both

adenomas and adenocarcinomas with metastases have been reported.
B. Complete surgical resection of heart base tumors is seldom possible because they are highly vascular, associated with major blood vessels, and usually extensive by the time of diagnosis.
C. In a retrospective study of dogs with aortic body tumors, palliative pericardectomy often prolonged survival, with excellent quality of life.
1. Median survival time following pericardectomy was 730 days.
2. Median survival time without pericardectomy was 42 days (Ehrhart et al., 2002).

X. Pericardial mesothelioma is difficult to treat.
A. Long-term survival has been reported in a dog treated with pericardectomy, intracavitary cisplatin and intravenous doxorubicin (Closa et al., 1999).
B. Following a presumptive diagnosis (accumulation of significant amounts of pleural effusion within 4 to 6 months of pericardectomy), repeated thoracocentesis is necessary and adjunctive chemotherapy (intracavitary cisplatin, intravenous doxorubicin) should be considered.

XI. Cardiac lymphosarcoma is classified as stage V, substage b.
A. Dogs with stage III lymphosarcoma or higher and clinical signs (substage b) have a poor prognosis for remission and survival.
B. In a retrospective study of 12 dogs treated with various combinations of pericardiocentesis, pericardectomy, and chemotherapy, median survival time was 41 days.
C. Three dogs were alive 328 days after initial diagnosis, suggesting that cardiac lymphosarcoma may not always warrant a poor prognosis (MacGregor et al., 2005).

Constrictive/Effusive-Constrictive Pericarditis

Definition

I. Constrictive pericarditis is fusion of the visceral and parietal layers, with the heart encased within a stiff, fibrotic pericardium.
II. Effusive-constrictive pericarditis may be defined as a combination of a relatively small amount of a tense pericardial effusion enclosed within an unyielding, fibrous, parietal pericardium (Spodick, 2001).

Causes and Pathophysiology

I. Effusive-constrictive pericarditis occurs occasionally in dogs.
A. Many causes are idiopathic, or develop months or years after an episode of idiopathic pericardial effusion.
B. Other causes include metallic foreign bodies, *C. immitis*, *Aspergillus niger*, actinomycosis, and osseus metaplasia of the pericardium.

II. Constrictive pericarditis in dogs is uncommon.
A. It may develop as a consequence of any form of chronic pericarditis.
B. It may be a severe complication of systemic *C. immitis*.

III. Pathophysiology is similar to other causes of cardiac tamponade, except that the nondistensible, thickened, fibrotic pericardium contributes substantially (effusive-constrictive pericarditis) or entirely (constrictive pericarditis) to compression of the heart.

Clinical Signs and Diagnosis

I. Effusive-constrictive pericarditis
A. Dogs typically have signs of right-sided CHF.
B. Common complaints are abdominal distention and muscle wasting.
C. Findings on physical examination include abdominal distention with a fluid wave (ascites), jugular distention, and muffled heart sounds.
D. On ECG, a normal sinus rhythm or sinus tachycardia and low-voltage QRS complexes are commonly found.
E. The cardiac silhouette on thoracic radiography ranges from normal to moderately enlarged and rounded, and the caudal vena cava may appear wide.
1. The presence of pleural effusion may complicate evaluation of the size and shape of the cardiac silhouette.
2. Radiopaque intrapericardial foreign bodies may be detected.
F. Echocardiography shows pericardial effusion that separates the myocardium and pericardium by just a few millimeters.
1. Echocardiographic signs of cardiac tamponade (late diastolic to systolic inversion of the right atrium, and diastolic collapse of the right ventricle) are usually present.
2. Pericardial thickness cannot be accurately assessed except in extreme cases.
G. *C. immitis* serology is indicated in dogs from endemic areas.

II. Constrictive pericarditis
A. Clinical signs, thoracic radiographs, and electrocardiographic findings are similar to other causes of chronic cardiac tamponade and effusive-constrictive pericarditis.
B. In contrast to most other forms of pericardial disease, echocardiography demonstrates neither pericardial effusion nor right atrial and ventricular collapse, but may include the following:
1. Abrupt flattening of the left ventricular posterior wall on M-mode echocardiography in mid to late diastole
2. Rapid early closure of the mitral valve, as well as premature pulmonary valve opening
3. A diastolic septal bounce, mild atrial enlargement, vena cava and hepatic vein dilation, and ascites
4. Alterations in the flow characteristics in pulmonary veins, vena cava, hepatic vein, and across the mitral valve
5. Thickened pericardium in severe cases (Myers and Spodick, 1999)
C. Cardiac catheterization is generally necessary to establish the diagnosis, and hemodynamic findings include the following:

1. Elevation and equilibration or near equilibration of the diastolic pressures of all cardiac chambers
2. A right atrial pressure trace with an M or W pattern
3. A ventricular pressure trace that shows a dip-and-plateau pattern or "square-root" sign in diastole
4. Rapid IV fluid infusion possibly necessary to fully reveal characteristic hemodynamic features (Myers and Spodick, 1999; Sisson and Thomas, 1999; Thomas et al, 1984)

D. *C. immitis* serology is indicated in dogs from endemic areas.

Differential Diagnosis

Similar to pericardial effusion

Treatment and Monitoring

I. Treatment for idiopathic effusive-constrictive pericarditis involves pericardectomy, and the prognosis is excellent.
   A. Slight epicardial fibrosis and roughness that does not require epicardial excision is present in most cases.
   B. Adhesions between the visceral and parietal pericardium are uncommon.

II. Severe involvement of the epicardium and adhesions between the parietal and visceral pericardium confer a less favorable prognosis.
   A. Dogs with fungal pericarditis from *C. immitis* are particularly prone to extensive involvement of both the visceral and parietal pericardium.
   B. In such cases, pericardectomy and excision of the constricting epicardium from the underlying myocardium are necessary, along with long-term antifungal therapy and monitoring.
      1. In a retrospective study of 17 dogs with effusive-constrictive pericarditis from *C. immitis*, perioperative mortality was high (23.5%).
      2. Surgery was successful in relieving right-sided CHF in some dogs, with longevity >2 years (Heinritz et al., 2005).

III. The treatment, monitoring, and prognosis for cases of constrictive pericarditis are similar to effusive-constrictive pericarditis with severe involvement of the epicardium and adhesions between the parietal and visceral pericardium.

CHAPTER 12

Heartworm Disease

Ray Dillon

CANINE HEARTWORM DISEASE

Definition

I. Heartworm disease (HWD): inflammatory disease of pulmonary vasculature and lung parenchyma
II. Distribution
  A. It occurs in temperate and tropical climates where suitable mosquito vectors and reservoir animals exist.
  B. It is endemic in most parts of the world, including southern Canada, Central America, South America, Australia, Japan, western and southern Africa, and southern Europe.
  C. In the United States, canine HWD has been detected in every state.
III. Primary hosts and principal reservoirs of infection
  A. Domestic dogs: almost 100% of dogs infected with third-stage larvae develop adult heartworm (HW) infections
  B. Wild canines, wolves, foxes, and coyotes
IV. Other susceptible hosts
  A. Domestic and captive wild cats (e.g., African lion)
  B. Ferret: more susceptible than cats
  C. California sea lion
V. Aberrant hosts
  A. Other mammals, including humans
  B. May be infected but do not become microfilaremic, so do not serve as reservoirs of infection

Causes

I. *Dirofilaria immitis* with mosquitoes as an obligatory intermediate host
II. Lifecycle of *D. immitis* (Figure 12-1)
  A. Microfilaria (MF)/embryo stage (L1)
    1. MF may circulate in the blood of an infected canine host for >2 years after being released by a gravid female.
    2. Live MF actively navigate capillaries.
    3. MF are ingested by a suitable mosquito vector.
  B. Third stage (L3)
    1. MF molt twice (L1→L2, L2→L3) in the mosquito to reach the infective L3, with maturation occurring in the midgut region.
    2. MF migrate (only mature L3) to the proboscis of the infected mosquito within 12 to 40 days, depending on ambient temperature.
    3. Requirements for the mosquito to develop infective larvae are 130 heat units (1 heat unit is a mosquito environment of 1° C of temperature >14° C each day).
    4. MF are deposited on the skin and enter the definitive host through a mosquito bite wound.
  C. Tissue migratory stages
    1. L3 infective larvae molt (within 2 weeks) to the fourth stage (L4) and migrate toward the heart.
    2. Maturation to the fifth stage (juvenile to adult, L5) occurs about 50 to 70 days after infection.
  D. Adult stage
    1. Fifth-stage larvae penetrate systemic veins between 70 and 85 days and arrive in the right ventricle as immature L5.

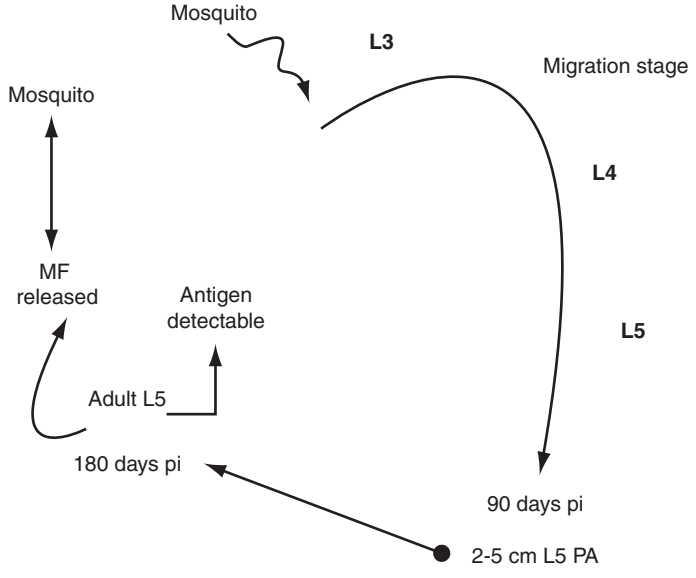

FIGURE 12-1 Life cycle of *Dirofilaria immitis*. Third-stage larvae (L3) are deposited on the skin and enter the host during mosquito feeding. After molting into fourth stage (L4) and migration, fifth stage (L5) arrive in the pulmonary arteries (PAs) 75 to 90 days postinfection (pi). Immature L5 stages are in distal pulmonary arteries for 3 months before antigen or microfilaria can be detected. Worms grow to full size and patency occurs by 180 days after infection. If males and females are present, microfilaria (MF) are eventually released into the circulation making L1 stages available for ingestion by feeding mosquitoes.

2. L5 locate in the distal pulmonary arteries as 1.5-cm worms, usually in left and right caudal pulmonary arteries.
3. L5 mature over the next 90 days and become adults by 180 days postinfection.
4. Adult worms may survive up to 5 years.

III. Pathogenic lifecycle stages
- A. The L5 (immature and mature) HW is responsible for most pathologic changes.
- B. Renal glomerular changes have been attributed to deposition and immunological destruction of MF but are of limited clinical significance.
- C. Death of MF cause significant inflammation in any tissue that can persist months after death.
- D. Cardiopulmonary changes are associated with the following:
  1. Arrival of immature L5 (90 days postinfection) in the lungs
  2. Physical presence of live adult HWs
  3. Death of immature L5 and adult HWs
  4. Release of substances from adult HWs, with local and systemic effects

IV. Variability of host responses to parasite infection
- A. *Wolbachia* spp. role in *D. immitis*
  1. It is an intracellular endosymbiotic bacteria with vertical transmission that is present in all stages of the HW life cycle (L1 to L5)
  2. Highest concentrations are in the reproductive tract of female HWs.
  3. Absence of bacteria results in infertility and decreased MF production.
  4. Association of bacteria and inflammation secondary to HWD is unclear.
- B. Killing bacteria with tetracyclines before adulticides may be associated with less pathology, but clinical significance is unknown.

Pathophysiology

I. Pulmonary vascular disease
- A. Vascular lesions are related to severity of inflammation and shear stress on endothelium associated with high cardiac output.
- B. Endothelial injury and myointimal proliferation is associated with local trauma and platelet activation by live and dead (especially) HWs.
- C. Cor pulmonale is a consequence of the activity pattern of the dog and not HW numbers (e.g., active dogs with low worm burden may have severe cardiovascular disease).
- D. Myointimal proliferation may be reversible after removal of HWs, but capillary bed fibrosis and increased pulmonary vascular resistance associated with small vessel disease may be irreversible.
- E. Embolization and obstruction of flow are rarely the cause of pulmonary hypertension.
- F. Acute lung injury is the most life-threatening aspect of HWD.

II. Cardiac disease
- A. High cardiac outputs with exercise, together with lung pathology in active dogs cause the following:
  1. Right ventricular hypertrophy (RVH): classic cor pulmonale
  2. Right-sided congestive heart failure (CHF) and ascites
  3. Pulmonary hypertension
- B. Tricuspid valve regurgitation may develop.
  1. Dilatation of tricuspid annulus from right ventricular enlargement
  2. Mechanical interference by HWs (caval syndrome)

III. Pulmonary parenchymal disease
- A. Diffuse interstitial infiltration
  1. Initial arrival of immature L5s at 70 to 90 days postinfection results in intense eosinophilic inflammation.
  2. Parenchymal lesions and loss of type I alveolar cells are especially significant during death of HWs.
  3. Pulmonary fibrosis of capillary beds occurs in active dogs.
- B. Pulmonary granulomas
  1. Develop after HW death and thrombosis
  2. Associated with immunological destruction of MF and most severe in occult HWD (no circulating MF)

IV. Caval syndrome
- A. Heavy adult worm infections (typically >75 HWs)
- B. Displacement of worms to the right atrium, caudal vena cava, and hepatic veins
- C. Presence of the worms within the tricuspid valve annulus causing tricuspid insufficiency
- D. Tricuspid insufficiency and hepatic congestion resulting in red blood cell fragility and lysis

V. Glomerulonephritis
- A. Deposition of immune complexes containing worm antigen in the glomerular basement membrane
- B. Physical damage to glomerulus by viable MF
- C. Rarely significant proteinuria

Clinical Signs

I. General trends
- A. Although HW infection can cause devastating disease, dogs often remain asymptomatic indefinitely.
- B. Signs may develop as early as 3 to 6 months after infection from the pulmonary reaction to arriving L5s.
- C. Pulmonary hypertension and significant cardiac changes may never occur or may be delayed in the inactive dog.
- D. Significant disease may develop in the athletic dog regardless of worm numbers.
- E. Death of HWs is associated with acute clinical signs.

II. Signs associated with chronic cardiopulmonary disease
- A. Nonproductive cough
- B. Respiratory distress
- C. Exercise intolerance, lethargy
- D. Syncope triggered by sudden exercise
- E. Weight loss: cardiac cachexia
- F. Ascites
- G. Hemoptysis: uncommon except with HW death

III. Acute signs associated with caval syndrome

A. Anorexia, lethargy, weakness, fever
B. Hemolytic crisis: icterus, hemoglobinuria, bilirubinuria, pale mucous membranes
C. Tachycardia, bounding pulses
D. Acute, intermittent, or chronic (weeks) duration

Diagnosis

I. Physical examination findings
   A. Heart murmur (inconsistent finding)
      1. Systolic murmur of tricuspid regurgitation may develop secondary to tricuspid insufficiency.
      2. A murmur of tricuspid regurgitation is common in dogs with caval syndrome.
      3. A diastolic murmur of pulmonary valve insufficiency is uncommon.
      4. Splitting of the second heart sound from asynchrony of closure of the aortic and pulmonic valve is associated with pulmonary hypertension and severe HWD.
   B. Lung sounds: harsh rales possible
   C. Evidence of right-sided CHF
      1. Jugular venous pulsation, distention
      2. Hepatomegaly, ascites
      3. Chronic weight loss
      4. Gallop rhythm: accentuated third heart sound
   D. Normal examination in most dogs with HWD
II. Thoracic radiography
   A. Diffuse interstitial pattern initially develops in caudal lung lobes 90 days after infection (HW haze).
   B. The earliest vascular changes are linear opacification of peripheral pulmonary arteries in the caudal lung lobes on the ventrodorsal (VD) view.
   C. Pulmonary artery tortuosity, loss of uniform tapering, and truncation develop over time.
   D. If the dog is active and increased cardiac output is generated over time, the result is right heart hypertrophy, with increased sternal contact on the lateral view and a "reverse D-shaped" heart on the VD view.
   E. Diffuse interstitial patterns and loss of detail can be associated with eosinophilic pneumonitis and acute lung injury.
   F. Nodular pulmonary parenchymal densities are indicative of focal granulomas and major arterial thrombosis.
   G. Large eosinophilic granulomas with clearly defined borders are uncommon.
   H. Minimal changes may occur even with significant worm burdens.
III. Electrocardiography (ECG)
   A. ECG evidence of RVH may occur and result in right axis deviation and deep S waves.
   B. Arrhythmias are very uncommon, even with severe disease.
IV. Echocardiography
   A. Hypertrophy of the right ventricular wall
   B. Right atrial enlargement and tricuspid insufficiency in severe HWD
   C. Paradoxical motion of the interventricular septum in some cases of pulmonary hypertension
   D. Pulmonary artery dilation with pulmonary hypertension
   E. HWs in cross-section: short parallel, echodense lines in the pulmonary artery (right peristernal view) and right heart
   F. Pulmonary hypertension: tricuspid regurgitation velocity >3 m/sec, pulmonic insufficiency velocity >2.7 m/sec
V. Clinical laboratory findings
   A. Hematology: possible eosinophilia and basophilia early in the infection
   B. Serum biochemical profile
      1. Hypergammaglobulinemia
      2. ± Elevation of hepatic enzymes
      3. Elevated serum creatinine and blood urea nitrogen (BUN) with coexisting disease or caval syndrome
   C. Urinalysis
      1. Albuminuria: rarely associated with HWD
      2. Hemoglobinuria, hyperbilirubinuria: post-caval syndrome
VI. Definitive diagnostic tests
   A. Species identification of circulating MF
      1. MF of *D. immitis* and *D. reconditum* must be differentiated.
      2. Rarely, other MF are identified in dogs from Europe.
      3. Although routine tests for MF have become less common, they are still important.
         a. MF are reservoirs of infection.
         b. Some microfilaremic dogs do not have detectable amounts of circulating HW antigen (Ag).
         c. MF-positive dogs with large numbers of MF may have adverse reactions to microfilaricidal medications.
      4. Concentration techniques (Knott test and filter method) are far superior to fresh blood smears as screening tests because MF numbers vary with temperature and activity of the dog.
      5. MF detection is negative in 40% to 50% of spontaneous HW cases and higher in dogs on preventative medications.
      6. False-positive results can occur with poor laboratory technique, failure to kill MF after adulticidal therapy, and in puppies from transplacental transfer of MF before birth if the bitch was MF positive.
      7. Only 1% to 3% of dogs with circulating MF do not have adult HWs in the heart.
   B. Serological testing
      1. Some infected dogs do not have circulating MF for one of the following reasons:
         a. Prepatent infection, with L5s in heart and lungs that are not mature enough to produce MF
         b. Host hypersensitivity to MF (immune occult)
         c. Unisex infection: >30% of MF-negative dogs
         d. Microfilaricide (chemoprophylaxis) suppression of MF
         e. Infertile HWs
      2. Regardless of testing method, all commercially available Ag assays test for the same glycoprotein.

a. The Ag measured is released in quantities high enough to be detected only from fully mature female HWs.
b. Microwell titer methods detect the lowest Ag loads (higher sensitivity).
c. There is a general relationship between the number of fully mature, female HWs and the amount of Ag.
d. False-negative results are caused by low antigenemia.
(1) Immature infections
(2) Low numbers of females
(3) Unisex (male) infections
(4) Test method with low sensitivity (whole blood tests)
e. False-positive results are rare.
(1) Technical errors: inadequate wash techniques in microwell titer methods
(2) Nonspecific binding to sample debris

C. Application of MF and HWAg testing
1. A positive MF test does not assure the presence of adult HWs.
2. A positive HWAg test indicates a current or recent infection with adult HWs.
3. A negative HWAg test does not indicate the dog is HW negative.
4. A dog can have immature adult HWs (3 to 6 months postinfection) in the heart and be negative on both MF and HWAg testing.
5. After initial testing of any dog >6 months of age, retest 3 months later to ensure HW status.
6. When screening in areas where prevalence of infection is low, the predictive value of a positive test result depends more on the specificity of the test than its sensitivity.

D. Direct visualization of adult HWs via two-dimensional echocardiography
1. The right cardiac chambers, main pulmonary artery, and caudal vena cava can be adequately imaged for adult HWs.
2. Findings can be negative in large dogs when worms reside in distal pulmonary vessels that cannot be imaged.
3. Negative results do not rule out the disease.
4. A cluster of worms surging back and forth through the tricuspid valve is a classic feature of caval syndrome.

Differential Diagnosis

I. Pulmonary thromboses
A. Hyperadrenocorticism
B. Glomerulonephritis with low antithrombin III levels
C. Idiopathic pulmonary thrombosis
D. Autoimmune hemolytic anemia
E. Primary pulmonary hypertension
F. Previously resolved HWD

II. Pulmonary neoplasia

III. Primary chronic respiratory disease
A. Chronic bronchitis
B. Bacterial and fungal pneumonia
C. Tracheal collapse

IV. Heart failure
A. Dilated cardiomyopathy
B. Pericardial disease
C. Valvular heart disease

V. Pleural cavity diseases

Treatment

I. Pretreatment evaluation
A. Perform a thorough physical examination with particular attention to coexisting diseases that might complicate therapy.
B. Counsel the owner of working dogs that exercise intolerance may continue postadulticidal therapy.
C. Thoracic radiography assesses the degree of cardiac and pulmonary arterial changes but cannot predict postadulticidal complications.
D. Initial laboratory tests include a complete blood count, serum biochemical profile, urinalysis, and semiquantitative HWAg assay.
E. Additional studies include ECG and echocardiography.

II. General sequence of therapy
A. Confirm positive results and determine Ag load with microwell testing methods.
B. Perform pretherapy screening for subclinical disease.
C. Initiate an HW preventative medication that has no acute microfilaricidal activity (NOTE: Milbemycin is microfilaricidal at the preventative dose.)
D. Administer melarsomine in split doses (see following discussion).
E. Restrict exercise during and for 6 weeks after last administration of adulticide.
F. Check for MF and treat (if present) with microfilaricide 4 weeks after melarsomine.
G. Recheck HWAg 3 to 4 months after melarsomine.

III. Patient classification (Table 12-1)
A. Classification of dogs can be useful in considering the reversibility of the disease and ability of the dog to regain activity.
B. It is not useful in predicting complications of adulticidal therapy.
C. There is a strong relationship between the number of worms killed (which cannot be predicted) and postherapeutic complications.

IV. Elimination of adult HWs
A. Melarsomine HCl (Immiticide)
1. Treat dogs with class 1 and class 2 disease with two injections of 2.5 mg/kg IM, 24 hours apart.
a. This standard dose may be used in areas where the HW burden is consistently low.
b. Regardless of classification, in endemic areas all dogs should be treated with the split-dosing regimen (see following discussion).
2. Give dogs with class 3 disease in endemic areas one injection of 2.5 mg/kg IM; wait at least 30 days, then give two injections of 2.5 mg/kg IM, 24 hours apart (split-dosing regimen).

TABLE 12-1

Classification of Heartworm Disease in Dogs

CLASS	CRITERIA
Class 1: subclinical disease	1. Weakly positive HWAg test (low worm burden) 2. No clinical signs 3. Normal physical examination 4. Thoracic radiographs normal or mild evidence of pulmonary arterial or parenchymal changes 5. Laboratory tests normal
Class 2: moderate disease	1. Moderately positive HWAg test (moderate worm burden) 2. Moderate exercise intolerance and/or an occasional cough 3. Good to fair general condition 4. Moderate right ventricular and/or main pulmonary artery enlargement, moderate enlargement of the pulmonary arteries with truncation, diffuse perivascular pulmonary parenchymal infiltrates on radiography 5. Possibly mild anemia, circulating eosinophilia
Class 3: severe disease	1. Strongly positive HWAg test (high worm burden) 2. Obvious clinical signs: significant exercise intolerance, respiratory distress, persistent cough, ascites, anorexia, weight loss 3. Poor to fair general condition, increased respiratory sounds, easily elicited cough, jugular venous distention, ascites, prolonged capillary refill time, pale mucous membranes 4. Right ventricular and atrial enlargement, enlarged pulmonary arteries with pruning, truncation and loss of arterial arborization, diffuse pulmonary parenchymal infiltrates with evidence of pulmonary thromboembolism 5. Elevated levels of blood urea nitrogen, creatinine, and hepatic enzymes

HW, Heartworm; *Ag,* Antigen

3. Even with careful attention to needle handling and injection techniques (medication must be given by deep-lumbar IM injection), local inflammation occurs.
4. Reactions to one injection may not consistently be followed by reactions to subsequent injections.
5. Efficacy against adult HWs is significantly higher than that of thiacetarsamide, and incidence of acute hepatic and renal toxicities is rare.
6. Minimize physical activity during and for 4 to 6 weeks after treatment.
7. Death of HWs (typically 2 to 3 weeks after injections) is associated with acute lung injury and platelet activation.
8. Efficacy is related to the age and sex of the worm, and a single injection can result in significant, acute lung injury if older worms are present.

B. Slow-kill methods
1. Ivermectin (Heartgard Plus) administered at the preventative dose (6 μg/kg PO once monthly) for >18 months has been associated with an incomplete, slow kill of adult HWs.
2. Monthly dosing with selamectin *(Revolution)* has less adulticidal effect than with ivermectin *(Heartgard Plus)*.
3. Moxidectin and milbemycin have very limited adulticidal effects at the preventative doses.
4. The killing of HWs (regardless of cause) is associated with acute lung injury and increased lung pathology.
5. Dogs not confined and treated with slow-kill methods have increased risk of thromboembolic disease and acute respiratory distress.
6. Slow-kill methods are not considered an effective alternative to adulticidal therapy unless other significant medical problems exist.

C. Surgical extraction of adult HWs
1. Straight alligator forceps are used for worms in the right atrium or caudal vena cava.
2. Venotomy is indicated only in caval syndrome.
3. Pulmonary arteriotomy can be performed but is usually confined to heavy worm burdens where adulticides are considered too risky.
4. Flexible grasping forceps can be introduced with fluoroscopy into the pulmonary artery via a venotomy for worm removal.

V. Elimination of MF

A. Ivermectin
1. Dose is 50 μg/kg PO, repeated in 2 weeks if MF persist.
2. The cattle parasiticide may be diluted 1:9 with propylene glycol and given at 0.5 mL/10 kg PO.
3. Dosage in collies and other ivermectin-sensitive dogs must be precise, because adverse reactions may occur at the 200 μg/kg dose.
4. Microfilaricidal reactions may occur within 2 hours in dogs with high MF numbers, so hospitalization and monitoring are prudent.
5. Prophylactic dosing of avermectins also eliminates MF by embryostasis and results in the elimination of circulating MF within 6 to 12 months, even when adults are present.

B. Milbemycin oxime
1. The prophylactic dose (500 μg/kg PO) is microfilaricidal and eliminates MF quickly.
2. Microfilaricidal reactions may occur within 2 hours in dogs with high MF numbers, so hospitalization and monitoring are prudent.

3. Inadvertent administration to dogs of unknown MF status should be avoided.

VI. Chemoprophylaxis of HW infection
   A. Ivermectin
      1. Dosage is 6 to 12 μg/kg PO once monthly.
      2. Protection is provided for an exposure period of at least 45 days preceding administration.
      3. If administered for 12 consecutive months, it kills all stages up to 4 months postinfection.
      4. At 4 months postinfection, the HWs are already in the pulmonary arteries and death of the worms is associated with lung injury, thus the terms *reach-back effect* and *prevention of infection* when administered to dogs with immature HW infections.
      5. Long-term administration to dogs with prepatent or patent infections results in suppression of MF.
      6. This dose is safe in all breeds of dogs.
   B. Milbemycin oxime
      1. Dose is 500 μg/kg PO once monthly.
      2. It also controls roundworm, hookworm, and whipworm infections.
      3. If administered for 12 consecutive months, it kills all stages up to 3 months postinfection.
      4. At 3 months postinfection, the HWs are already in the pulmonary arteries and death of the worms is associated with lung injury, thus the terms *reach-back effect* and *prevention of infection* when administered to dogs with immature HW infections.
      5. Long-term administration to dogs with prepatent or patent infections results in suppression of MF.
      6. This dose is safe in all breeds of dogs.
   C. Selamectin
      1. Dosage is 6 mg/kg applied topically every 30 days.
      2. It kills adult fleas and prevents flea eggs from hatching.
      3. This dose is safe in all breeds tested.
   D. Moxidectin
      1. Dose is 0.17 mg/kg SC every 6 months.
      2. It reduces circulating MF numbers and is not associated with adverse effects.
      3. Currently, the repositol injection formula is not commercially available.
   E. Diethylcarbamazine citrate (DEC)
      1. Dosage is 6.6 mg/kg PO SID preceding infection and for 60 days following last exposure to mosquitos.
      2. In dogs with MF, acute reactions can occur.
      3. It may be continued in dogs that subsequently become microfilaremic, as long as daily administration is not interrupted for >3 days.
      4. It may be used immediately in occult (MF-negative) infections.
   F. Reports of lack of efficacy of chemoprophylaxis
      1. Lack of client compliance is the most common cause of poor efficacy.
      2. An initial HWAg test will be negative when immature HWs are present, and if preventatives are dispensed, the dog may become positive on assay repeated 6 to 12 months later.

VII. Ancillary treatments
   A. Prednisolone
      1. Dosage is 1 to 2 mg/kg PO BID for acute lung injury associated with adulticidal therapy.
      2. It can be administered in decreasing doses over 2 weeks for suspected eosinophilic pneumonitis and pulmonary granulomas.
      3. Routine administration is not recommended with adulticidal therapy.
   B. Supplemental oxygen: induces pulmonary vasodilation and oxygenation during postadulticidal complications
   C. Therapy for right-sided CHF
      1. Strict exercise limitation
      2. Diuretics in modest doses
      3. Dietary sodium restriction
      4. Supplemental oxygen

Monitoring of Animal

I. Complications of therapy are numerous (Table 12-2).
II. Assess the efficiency of adulticide treatment by the following:
   A. Clinical signs of efficacy
      1. Development or worsening of respiratory signs 5 to 10 days after treatment from death of HW
      2. Eventual improvement in respiratory signs
      3. Nonprogression of postadulticidal signs after 8 weeks
   B. HW antigenemia
      1. Persistence beyond 12 to 20 weeks after treatment is indicative of a residual or new infection.
      2. Disappearance within 12 to 20 weeks indicates complete eradication or survival of very few worms.
   C. Microfilaremia: disappearance of MF does not guarantee all adults have been killed, because preventatives suppress MF production.
III. Assessing efficacy of microfilaricides requires timing of reexaminations.
   A. Ivermectin usually eliminates MF within 2 weeks (often within 72 hours).
   B. MF may persist in some cases.
      1. Occasionally postadulticide MF-negative status is not achieved.
         a. Persistent, dual-sex infection
         b. Inadequate dose of microfilaricide
      2. A postadulticide return of MF may occur within weeks of an initially successful microfilaricide treatment.
         a. Persistent, dual-sex infection
         b. Unisex infection with female continuing to release MF
      3. A postadulticide return of MF may occur 2 to 3 months after successful microfilaricide treatment because of reinfection with a new generation of HWs.
         a. Inadequate dose or duration of chemoprophylactic agent
         b. Noncompliance with chemoprophylactic administration

TABLE 12-2

Complications of Heartworm Therapy

THERAPIES	COMPLICATIONS AND TREATMENT
Adulticide	
Melarsomine	Deep muscle pain and swelling at injection site Use separate needle for injection Deeply inject in the muscle with digital pressure afterward Consider antiinflammatory drugs for muscle pain Subsequent injections may not follow same reaction Systemic effects Minimal complications compared to thiacetarsamide Efficacy is highly dose related, and accurate dosing by weight is critical to efficacy Pulmonary thromboembolism Fever, tachypnea, cough, and sometimes hemoptysis are evident Clinical signs usually manifest as the worms die (5 to 14 days after treatment) Disseminated intravascular coagulation may develop owing to rapidity and number of worms dying Prednisolone and oxygen are useful Bacterial pneumonia is a very rare complication of heartworm therapy Exercise restriction is essential
Microfilaricides	
Ivermectin	Overdosing in a sensitive dog may produce dose-dependent side effects Minor signs (within 10 to 12 hours) include salivation, vomiting, mydriasis, tachypnea, disorientation, stupor, mild ataxia, and tremors Severe signs (may begin within 4 to 6 hours) are marked ataxia, tremors, seizures, recumbency, coma, and death Therapy for toxicosis involves supportive care with fluid therapy Rapid reduction in MF may be confused with toxicosis Onset within 2 to 8 hours: listlessness, fever, anorexia, vomiting, diarrhea, cough, shock Therapy: supportive care with fluid therapy and corticosteroids
Milbemycin oxime	No adverse reactions attributed when administered at preventative doses Rapid reduction in MF may cause clinical signs Onset within 2 to 8 hours: listlessness, fever, anorexia, vomiting, diarrhea, cough, shock Therapy: supportive care with fluid therapy and corticosteroids
Chemoprophylactic Agents	
Ivermectin	There are no confirmed reports of adverse reactions at the prophylactic dose It is safe in all breeds at this dose
Milbemycin oxime	There are no confirmed adverse reactions to date In dogs with high MF numbers, acute reactions are related to microfilaricidal activity
Selamectin	There are no confirmed reports of adverse reactions at the prophylactic dose It is safe in all breeds
Moxidectin	Localized reactions at injection sites Repositol formula is not currently available No adverse reactions are reported from oral administration
Diethylcarbamazine	Systemic reactions occur in *Dirofilaria immitis* MF-positive dogs within 20 minutes of receiving the drug: Emesis, diarrhea, salivation Depression, lethargy, incoordination, collapse Hypovolemic shock Disseminated intravascular coagulation Reaction peaks within 1 to 2 hours, with recovery in most dogs by 6 hours Supportive therapy consists primarily of fluid therapy and administration of corticosteroids

MF, Microfilaria.

FELINE HEARTWORM DISEASE

Definition

I. An inflammatory disease of pulmonary vasculature and lung parenchyma
II. Distribution
  A. In temperate and tropical climates in which suitable mosquito vectors and reservoir animals exist
  B. Endemic in most parts of the world and in every location where dog HWD reported
III. Primary hosts and principal reservoirs: canine species
  A. Domestic and captive wild cats (e.g., African lion) are susceptible.
  B. Ferrets are more susceptible than cats.
  C. Because the infected cat rarely produces MF, a mosquito must feed on a dog and then after L3s develop, the mosquito must feed on a cat in order for the cat to get HWD.
  D. The different feeding preferences of mosquito species for cats and dogs influence the transmission of HWD from dogs to cats.

Causes

I. Caused by parasite *D. immitis,* with the mosquito as an obligatory intermediate host
II. Lifecycle of *D. immitis* (see Figure 12-1)
  A. The mortality rate of immature L5s is higher in cats than dogs, which results in more lung inflammation associated with some early worm death (80 to 160 days after infection).
  B. Adult worms may survive 1 to 3 years in cats.
III. Pathogenic lifecycle stages
  A. The L5 (immature and mature) HW is responsible for nearly all pathologic changes.
  B. The arrival and death of some immature L5 stages as early as 70 days after infection account for the early, acute respiratory disease that occurs in cats.
  C. No renal glomerular changes have been attributed to HWD in cats.
  D. Death of MF causes significant inflammation in any tissue.
  E. Cardiopulmonary changes are associated with the following:
    1. Arrival of immature L5s: intense eosinophilic reaction in cats
    2. Physical presence of live, adult HWs
    3. Death of immature L5 and adult HWs causing acute lung injury as early as 3 months after infection
    4. Release of substances from adult HWs with local and systemic effects
    5. Continued inflammatory lung disease after HW death

Clinical Signs

I. Clinical signs are respiratory, not cardiac in nature.
II. Signs can include the following:
  A. Coughing
  B. Intermittent dyspnea
  C. Sporadic vomiting: rarely associated with eating but not always associated with respiratory signs
  D. Lethargy, weight loss
  E. Hemoptysis: uncommon
  F. Nonspecific neurological signs: aberrant migration or location
III. Sudden death may result.

Diagnosis

I. Physical examination findings
  A. Heart murmurs: rare
  B. Lung sounds: harsh rales, increased bronchovesicular sounds
  C. Rarely signs associated with right-sided CHF
    1. Jugular venous pulsation, distention
    2. Pleural effusion: muffled heart and lung sounds
II. Thoracic radiography
  A. Pulmonary radiographic features are first recognizable in the caudal lung lobes and best appreciated in the VD projection.
  B. The first radiographic signs are bronchointerstitial and associated with arrival of immature L5s.
  C. Indistinct widening of the caudal pulmonary arteries may occur and can be obscured by lung parenchymal densities.
  D. Peribronchial and interstitial pulmonary lesions are often independent of tortuosity and truncation of peripheral pulmonary arteries, and the caudal lung lobes are typically the most affected.
  E. Enlargement of the caudal pulmonary arteries (ratio >1.6:1 when compared with the 9th rib in the dorsoventral or VD projection) is a transient lesion that may abate even with persistent HWD.
  F. Pleural effusion has been documented but is uncommon.
III. ECG
  A. ECG evidence of RVH is rare in cats, because pulmonary hypertension is uncommon.
  B. Hemodynamically significant arrhythmias are rare.
IV. Echocardiography
  A. The RV is typically normal.
  B. Dilatation of the main pulmonary artery and visualization of adult worms may be detected in the right parasternal view.
V. Clinical laboratory findings
  A. Eosinophilia and basophilia are highly suggestive.
  B. Biochemistry profiles and urinalysis are typically normal.
VI. Definitive diagnosis of infection
  A. Serological and MF testing
    1. Cats with HWD typically do not have circulating MF because of the following:
      a. Prepatent infections
      b. Host hypersensitivity to MF (immune occult)
      c. Unisex infection
      d. Infertility of female HW
    2. When present, MF are very transient.

3. Commercially available HWAg detection kits are applicable for all host species, with the exception of the bifunctional antibody/hemagglutination test.
   a. False-negative results are caused by low antigenemia.
      (1) Prepatent (immature) infections
      (2) Light infections with <3 worms
      (3) Unisex (male) infections
   b. False-positive results are uncommon.
      (1) Technical errors: related to inadequate wash cycles
      (2) Nonspecific binding to sample debris
4. Feline HW antibody (Ab) tests are sensitive and specific for Ab response to developing larvae and adults.
   a. Most commercial HWAb tests become positive 2 to 3 months after the infection.
   b. Cats with adult HWs may be HWAb negative.
   c. Because each commercial test evaluates different Ab responses to different Ags, discordant results between testing methods are common when examining the same cat at different times during the HW lifecycle.

B. Interpretation of results
   1. A positive HWAg test is indicative of a current or recent infection with adult female HWs.
   2. A negative HWAg test does not eliminate the disease.
   3. A negative HWAb test does not eliminate HWD.
   4. A positive HWAb test documents that the cat has been successfully infected and the L3 stage has molted and lived at least 2 to 3 months.
      a. Results may or may not reflect immature HWs in the pulmonary arteries.
      b. Results do not establish a diagnosis of an adult infestation.
      c. Ab titers or concentrations indicate a recent infection but are also frequently associated with death of immature and adult HWs.

C. Direct visualization of adult HWs with two-dimensional echocardiography
   1. The right cardiac chambers, the main pulmonary artery and right branch, and the caudal vena cava can be adequately imaged to identify adult HWs.
   2. Findings may be positive even when all other tests are negative.
   3. Failure to visualize HWs does not rule out the disease as immature worms may reside in distal pulmonary arteries.

Differential Diagnosis

I. Feline bronchial disease (asthma)
II. Pulmonary neoplasia
III. Inflammatory respiratory disease: feline infectious peritonitis, pneumonia, lung worms, lung flukes
IV. Heart failure: cardiomyopathy, pericardial disease, valvular heart disease

Treatment

I. Because of the severity of postadulticide complications in cats, adulticides are rarely administered.
II. Clinical evaluation involves the following:
   A. Thorough physical examination
   B. Thoracic radiography
      1. Assesses degree of cardiac and pulmonary arterial and parenchymal changes
      2. May help differentiate feline HWD from other potential diagnoses
   C. Selective laboratory tests
      1. Complete blood count, serum biochemical profile, urinalysis
      2. Semiquantitative HWAg assessment using a microwell technique to determine low antigenemia
      3. HWAb assay
   D. Additional special studies depending on the clinical circumstances
      1. ECG: seldom diagnostic
      2. Echocardiography
         a. Sensitivity is much greater in cats than in dogs.
         b. The bifurcation of the pulmonary artery must be imaged.
         c. Worms appear as short, hyperechoic, parallel lines.
      3. Nonselective pulmonary angiography
         a. Allows for critical evaluation of pulmonary vascular size and tortuosity, even in the presence of pulmonary parenchymal infiltrate
         b. May detect intraluminal filling defects
         c. May help rule out important differential diagnoses
III. Most investigators recommend *against* the use of adulticide therapy in cats.
   A. Melarsomine HCl (Immiticide)
      1. Limited safety or efficacy studies in cats.
      2. Single dose of 2.5 mg/kg IM resulted in 35% worm kill with no significant adverse effects, but adulticide efficacy was not significantly different from placebo (McCall, 2005).
   B. Surgical extraction of adult HWs
      1. Horsehair brush or endoscopic basket retrieval device via venotomy or pulmonary arteriotomy
      2. Indicated only in symptomatic cats in which HWs can be visualized with echocardiography or that are Ag positive
IV. Elimination of MF is rarely needed in cats.
   A. Ivermectin
      1. The prophylactic dose (24 μg/kg PO) is almost microfilaricidal.
      2. MF often disappear spontaneously.
   B. Milbemycin oxime
      1. Prophylactic dose (500 μg/kg PO) is also microfilaricidal.
      2. Microfilaricidal reactions may occur within 8 hours in cats with high MF numbers (very uncommon).

V. Chemoprophylaxis for HWD is as follows:
   A. Ivermectin
      1. Dosage is 24 µg/kg PO once monthly (4 × the canine dose).
      2. Protection is provided for an exposure period of at least 45 days preceding administration.
   B. Milbemycin oxime
      1. Dosage is 500 µg/kg PO once monthly (same as the canine dose).
      2. Provides protection for the prior 45 days, if administered at 60 and 90 days after exposure.
   C. Selamectin
      1. Dosage is 6 mg/kg applied topically every 30 days.
      2. It kills adult fleas and prevents flea eggs from hatching.
      3. It also controls internal parasites.

VI. Supportive therapy for chronic disease includes the following:
   A. Prednisolone
      1. Dosage is 1 to 2 mg/kg PO BID, then tapered over 7 to 14 days.
      2. It decreases pulmonary parenchymal inflammation caused by immature L5 stages and acute lung injury.
   B. Bronchodilators
      1. They are used to control bronchoconstriction associated with eosinophilic parenchymal inflammation.
      2. Theophylline 25 mg/kg PO has had mixed results.
   C. Antileukotrienes
      1. Empirically decrease the life-threatening respiratory crisis
      2. Montelukast sodium *(Singular)* 5 mg PO SID

Monitoring of Animal

I. Complications of therapy
   A. Adulticide administration or spontaneous death of HWs can be fatal.
      1. Acute lung injury
      2. Pulmonary thromboembolism with severe lung injury
         a. Prednisolone is useful, as for dogs (see earlier).
         b. Antibiotics are not necessary because pneumonia is rare.
         c. Exercise restriction for 4 weeks is essential.
   B. Complications associated with the use of microfilaricides are uncommon because these drugs are infrequently used in cats.
   C. All prophylactic HW prevention can be administered to HW-positive cats.
      1. Ivermectin
         a. No confirmed reports of adverse reactions at prophylactic doses
         b. Safe in all breeds at this dose
      2. Milbemycin oxime
         a. No confirmed adverse reactions to date
         b. Has unlikely but potential side effects in cats, with high MF numbers related to its microfilaricidal activity
      3. Selamectin: no confirmed adverse reactions to date

II. Long-term prognosis of HW-positive cats
   A. Cats with respiratory and cardiac disease
      1. They are radiographed every 3 months after a positive diagnosis.
      2. Clinical signs often do not correlate with radiographic lesions.
      3. Medication is continued to decrease parenchymal inflammation, even in asymptomatic cats.
      4. Cats rarely develop cardiac changes, and CHF is uncommon.
      5. Death of HWs is unpredictable and typically associated with exacerbation of respiratory signs.
   B. Prognosis in cats with HWD
      1. HW-positive cats are placed on preventatives to avoid additional infections.
      2. HWAb titers do not reflect status of adult HWs.
      3. Conversion of a cat from HWAg positive to negative does not consistently reflect status of adult HWs.
      4. Most cats with HWs eventually survive the infection but may continue to have chronic respiratory disease.
      5. Lifelong treatment for chronic bronchial disease may be necessary, even after death of all HWs in cats.

CHAPTER 13

Introduction

J. David Fowler

FUNCTIONAL ANATOMY OF THE RESPIRATORY SYSTEM

I. Nasal cavity and sinuses
   A. They extend from external nares to nasopharynx.
   B. Nasal turbinates are lined by ciliated columnar epithelium and mucus-producing goblet cells.
      1. Larger particles (≥6 μm) in inspired air are trapped via turbulent precipitation.
      2. Inspired air is warmed and humidified.
      3. Mucus contains factors responsible for local immunity, such as interferon, lysozyme, and protease inhibitors.
      4. A reflex sneeze follows stimulation.

II. Nasopharynx and pharynx
   A. Coordinated pharyngeal muscle contractions are necessary for normal swallowing.
   B. A reflex induced by irritation stimulates reverse sneezing.
   C. Lymphocytic aggregates are involved in immunological response to inhaled antigens.

III. Larynx
   A. Complex of articulated cartilages: arytenoids, thyroid, cricoid, and epiglottis
   B. Intrinsic musculature of larynx
      1. Abduction during inspiration reduces airway resistance.
      2. Adduction during swallowing prevents aspiration.
      3. Cough reflex is induced by laryngeal stimulation.

IV. Trachea
   A. It is lined by ciliated columnar epithelium.
      1. Mucociliary action moves sedimented particulate matter toward the pharynx, where the matter is coughed and swallowed.
      2. Local factors in mucus are responsible for mucosal immunity.
   B. Stimulation results in cough.

V. Small airways: bronchi and bronchioles
   A. Distribution of inspired air into lungs
   B. Immunoglobulin A: predominant immunoglobulin
   C. Smooth muscle within bronchioles involved in bronchial constriction

VI. Pulmonary parenchyma
   A. Alveoli
   B. Pulmonary interstitium
   C. Pulmonary capillaries
   D. Area of diffusion of gases

VII. Pleural space and mediastinum
   A. Mediastinum contains major vasculature, trachea, esophagus, thymus, and heart.
   B. Pleural space is defined as a potential space between the lungs and chest wall.
   C. Pleural space is lined by mesothelium and normally contains a small volume of fluid.

VIII. Chest wall
   A. Protects intrathoracic structures
   B. Actively contributes to inspiration via external intercostal muscles

RESPIRATORY PHYSIOLOGY

I. Ventilation
   A. Inspiration is an active process.
      1. Contraction of diaphragm
      2. Contraction of external intercostal muscles
   B. Expiration is normally passive.
      1. Elastic recoil of diaphragm, chest wall, and lung
      2. Active expiration by abdominal contraction during exertion
   C. Work of breathing is determined by three factors:
      1. Compliance work is determined by lung and chest wall elastic forces.
      2. Tissue resistance work is determined by the viscosity of the lung and chest wall structures.

3. Airway resistance work is determined by the integrity and dynamics of the nares, larynx, trachea, bronchi, and bronchioles.
   a. Compliance and tissue resistance are affected by pulmonary parenchymal diseases.
   b. Airway resistance is affected by airway disease.

D. Alveolar ventilation is defined as the rate at which new air reaches the alveoli.
1. Normal tidal volume is a small percentage of total lung capacity.
   a. Insufficient volume to reach alveoli
   b. Gases exchanged via diffusion from small airways to alveoli
2. Dead space is defined as air volume within the airways where gas exchange does not occur.
   a. Anatomical dead space is normal.
   b. Physiologic dead space consists of alveoli that are nonfunctional owing to decreased blood flow.

II. Perfusion

A. Efficient gas exchange depends on physiological distribution of pulmonary blood flow.

B. Distribution is affected by alveolar oxygen concentration.
1. Decreased alveolar oxygen concentration (<70% of normal) causes vascular constriction.
2. Vascular constriction results in increases in vascular resistance up to five times normal.
3. Increased vascular resistance shunts blood away from hypoxic alveoli.
   a. Opposite effect from that in systemic vasculature
   b. Termed *physiologic shunt*

C. Pulmonary vasculature accommodates increased flow during exercise.
1. There is an increase in the number of open capillaries.
2. Existing capillaries distend to accommodate greater flow.
3. Pulmonary artery pressure increases.

III. Gas exchange

A. Gas exchange occurs in the respiratory unit.
1. Respiratory bronchioles
2. Alveolar ducts
3. Atria
4. Alveoli

B. Respiratory units are lined by a membrane.
1. Thin layer of fluid and surfactant
2. Alveolar epithelium
3. Basement membrane of alveolar epithelium
4. Interstitial space
5. Capillary basement membrane
6. Capillary endothelium

C. Rate of gas exchange through the respiratory membrane is a function of several factors.
1. Thickness of the respiratory membrane
   a. Average: 0.6 μm
   b. Increased with edema, pulmonary fibrosis
2. Surface area: decreased with emphysema
3. Diffusion coefficient of gases
   a. CO_2 is 20 times greater than O_2.
   b. O_2 is two times greater than nitrogen.
4. Differences in partial pressure of gases across the respiratory membrane

D. Ventilation/perfusion (V_A/Q) ratio determines the efficiency of gas exchange.
1. Abnormal ratio of ventilation to perfusion leads to inefficient gas exchange.
   a. Ventilation approaches zero, blood flow normal ($V_A/Q = 0$): no gas exchange
   b. Ventilation normal, blood flow approaches zero (V_A/Q = infinity): no gas exchange
2. Decreased V_A/Q arises with inadequate ventilation relative to perfusion and results in shunted blood that does not become oxygenated.
3. Increased V_A/Q occurs with poor perfusion of normally ventilated alveoli and is termed *physiologic dead space*.
4. Both increased V_A/Q and decreased V_A/Q occur simultaneously in many respiratory disease processes.
   a. Bronchial obstruction: decreased V_A/Q
   b. Alveolar disruption: increased V_A/Q

LOCALIZING RESPIRATORY DISEASE

I. History and signalment

A. Signalment can be helpful because many respiratory diseases are breed associated.
1. Tracheal collapse in small-breed dogs
2. Idiopathic laryngeal paralysis in large-breed dogs

B. Dyspnea is defined as pathologically increased respiratory effort.

C. Excessive respiratory reflexes are common presenting complaints.
1. Reverse sneezing is consistent with nasal or nasopharyngeal disease.
2. Cough indicates irritation of the trachea or airways.
   a. Dry cough is consistent with tracheobronchial irritation.
   b. Moist cough is seen with exudative processes, such as pneumonia.
3. Sneezing localizes a disease to the nasal passages.

II. Observation of respiratory pattern

A. Increased inspiratory effort and duration are typical of extrathoracic obstructive disease.
1. Laryngeal paralysis
2. Laryngeal stenosis
3. Tracheal stenosis or collapse

B. Increased expiratory effort and duration are typical of intrathoracic obstructive diseases, such as chronic bronchitis.

C. Marked inspiratory intercostal effort with rapid effortless expiration is consistent with pleural space-occupying disease.

D. Noise associated with respiration can be helpful in identifying the site of disease.

1. Whistling or raspy with nasal obstruction
2. Stertor with pharyngeal obstruction
3. Stridor with dynamic laryngeal obstruction
4. Expiratory wheezes with bronchial obstruction

III. Auscultation and percussion
   A. Normal lung sounds
      1. Bronchial sounds are heard best on expiration and over the trachea, and are quieter in peripheral lung fields.
      2. Vesicular sounds are normally very quiet and are best heard in peripheral lung fields during deep inspiration.
   B. Abnormal lung sounds
      1. Wheezes are usually heard on expiration and indicate obstruction or narrowing of small airways.
      2. Crackles are caused by the opening of small airways during inspiration and are heard with bronchial inflammation and pneumonia.
      3. Bronchial sounds referred to the peripheral lung fields may indicate lung consolidation.
      4. Loss of normal vesicular sounds ventrally in a standing animal is consistent with pleural effusion.
      5. Bowel sounds on thoracic auscultation are consistent with possible diaphragmatic hernia.
   C. Percussion
      1. Thorax is normally resonant on percussion.
      2. Areas of decreased resonance indicate lung consolidation or pleural fluid accumulation.
      3. Increased resonance is difficult to appreciate, but may be heard with emphysema or pneumothorax.

IV. Palpation
   A. Chest wall
      1. Intrathoracic extension of chest wall tumors is typically greater than extrathoracic expansion.
      2. Flail chest is caused by multiple fractures of adjacent ribs and causes paradoxical chest wall motion.
   B. Cervical region
      1. Flattening of tracheal rings is noted with tracheal collapse.
      2. Cervical tumors can cause compression of the trachea, larynx, or recurrent laryngeal nerves.

CHAPTER 14

Diseases of the Nasal Cavity and Paranasal Sinuses

Stacey Nicoll Madden

INFECTIOUS/INFLAMMATORY DISEASES

Rhinitis/Sinusitis

Definition

I. Rhinitis is inflammation of the nasal cavity, and sinusitis is inflammation of the nasal sinuses.
II. Rhinitis and sinusitis often occur together and can be acute or chronic.

Causes

I. Bacterial infections
  A. Primary bacterial infections are rare, although secondary infections are common.
  B. They are most often a secondary complication of viral, parasitic, or fungal rhinitis; nasal foreign bodies; trauma; dental disease; or neoplasia (Van Pelt and McKiernan, 1994).
  C. Anaerobic bacteria and mycoplasma species were detected in nasal biopsy samples more commonly in cats with chronic rhinosinusitis (Johnson et al., 2005).
II. Viral infections
  A. In the dog, canine distemper virus is the most common cause of rhinitis.
    1. The incidence is low in vaccinated dogs, but it does occur in puppies 3 to 6 months of age as maternal antibodies are decreasing (Van Pelt and McKiernan, 1994).
    2. In unvaccinated and/or overcrowded populations, the virus may affect animals of any age.
  B. Other causes include parainfluenza virus, herpesvirus, and adenovirus (Clark and Carothers, 1992).
  C. Most infections in cats arise from feline herpesvirsus (rhinotracheitis) or calicivirus, especially in kittens 6 to 12 weeks of age (Morse, 1985).
  D. Recurrent rhinitis is common with feline leukemia virus or feline immunodeficiency virus (Beck et al., 1986).
III. Fungal infections
  A. The most common organism in the dog is *Aspergillus* spp.
  B. Also seen are *Penicillium*, *Cryptococcus*, and *Rhinosporidium* spp. (Gartrell et al., 1995).
  C. The most common organism in the cat is *Cryptococcus* spp., whereas *Aspergillus* spp. occurs rarely.
  D. Dogs with cryptococcosis have a greater propensity to develop secondary central nervous system (CNS) involvement and disseminated disease than do cats (O'Brien et al., 2004).
IV. Parasitic infections
  A. Although uncommon, examples in the dog include the nasal mite, *Pneumonyssoides caninum*, and a nasal nematode, *Capillaria aerophila* (King et al., 1990).
  B. In the cat, parasitic infections include *C. aerophila* and the gapeworm, *Mammomonogamus iere* (Cape, 1992).
V. Allergic conditions
  A. Allergic (immune-mediated) rhinitis is an uncommon condition in dogs (Burgener et al., 1987).
  B. There is little evidence that feline allergic rhinitis exists.
VI. Dental disease
  A. Both periodontal disease and endodontic disease can lead to a chronic rhinitis (Marreta, 1992).
  B. Oronasal fistula is also a cause of rhinitis.
VII. Foreign bodies
  A. Although an uncommon cause, foreign bodies may enter the nasal cavity by inhalation or be thrust into the nasopharynx and choanae as an animal chews (Van Pelt and McKiernan, 1994).
  B. Common foreign bodies include grass awns, twigs, and rocks.
VIII. Trauma
  A. Blunt trauma can give rise to epistaxis.
  B. Depressed facial bone fracture fragments may develop into sequestra with secondary rhinitis.
IX. Idiopathic cases (Sharp, 1990; Cape 1992)
  A. Rhinitis is idiopathic when clinical signs persist without a definitive cause.
  B. Chronic inflammatory rhinitis is commonly found in dogs with chronic nasal disease and is characterized by lymphoplasmacytic infiltrates in the nasal mucosa in the absence of an obvious etiologic process (Windsor and Johnson, 2006).
  C. Detection of high levels of fungal DNA in nasal biopsies of dogs with lymphoplasmacytic rhinitis suggests that fungal organisms may be causally associated with the inflammation (Windsor et al., 2006).

D. Some cases may actually be allergic in nature (McCarthy and McDermaid, 1990).

Pathophysiology

I. The nasal cavity responds initially to most insults by increasing glandular activity, giving rise to a serous nasal discharge.
II. Mucoid or mucopurulent discharge is seen as the disease becomes chronic or if secondary bacterial infection develops (Van Pelt and McKiernan, 1994).
III. As the disease progresses, mucosal erosion and ulceration can develop.
IV. Lysis of bone and loss of normal turbinate structure are common with more aggressive etiologies.

Clinical Signs

I. Signalment
  A. Dolichocephalic and mesocephalic breeds are more susceptible to fungal infection, whereas brachycephalics are rarely affected (Sharp, 1990).
  B. Neoplasia is more common in older dogs and is relatively rare in cats.
II. Sneezing
  A. Acute onset of paroxysmal sneezing may indicate inhalation of a foreign body.
  B. Chronic, intermittent sneezing is associated with many different causes.
  C. Gagging may also be observed as discharge pools in the nasopharynx.
III. Nasal discharge
  A. It is the primary clinical sign with nasal disease.
    1. Note whether discharge is acute or chronic, uni- or bilateral.
    2. Note character (mucoid vs hemorrhagic) of discharge.
  B. Serous nasal discharge is common early in the course of many diseases.
  C. Mucoid or mucopurulent discharge occurs with viral, bacterial, and fungal infections, as well as chronic allergy.
  D. Hemorrhagic discharge occurs with trauma, coagulation abnormalities, and fungal disease, particularly aspergillosis.
  E. Unilateral discharge is usually found with foreign bodies, dental disease, and fungal disease.
  F. Unilateral nasal discharge may be seen in animals with bilateral disease.
  G. Bilateral discharge is consistent with infectious diseases, allergy, and coagulopathies.
IV. Ulceration of the nares
  A. Occurs with many causes of rhinitis
  B. Most consistently seen with mycotic infections (Sharp, 1990)
V. Facial asymmetry
  A. Facial symmetry may be lost owing to bony or soft tissue changes.
  B. It is associated with fungal disease, trauma, or secondary inflammation.
VI. Ocular discharge
  A. It may indicate blockage of the nasolacrimal duct.
  B. Exophthalmia or inability to retropulse the eye suggests extension of disease behind the globe.
VII. Loss of airway patency
  A. Indicates severe airway compromise
  B. May be bilateral or unilateral

Diagnosis

I. Physical examination techniques and findings
  A. Palpate nasal region carefully for pain or soft-tissue swelling.
  B. Focal swelling with or without drainage may indicate a tooth root abscess.
  C. Facial deformity often reflects a destructive process, such as neoplasia or fungal infection (Rudd and Richardson, 1985).
  D. Ulceration at the external nares is consistent with fungal infection.
  E. Evaluate patency of the nasal passages.
  F. Evaluate eyes for epiphora, exophthalmos, or inability to retropulse the globes (Rudd and Richardson, 1985).
  G. Perform a complete oral examination.
    1. This may require heavy sedation or general anesthesia.
    2. Evaluate and palpate the hard and soft palates, tonsils, and oral mucosa.
      a. Nasopharyngeal masses may produce a ventral bulge in the soft palate.
      b. Tumors of the nasal cavity may cause a palpable deviation of the hard palate.
II. Clinical pathology
  A. Obtain a routine database to evaluate general health status and as a preliminary assessment for general anesthesia.
  B. Assess a coagulation panel if epistaxis is present.
III. Cytology
  A. Nasal cytology is often nonspecific; however, it occasionally provides or confirms the diagnosis.
  B. Cytological specimens are obtained after radiographs.
  C. Cytology does not appear to be a reliable means for detection of chronic rhinitis in cats (Michiels et al., 2003).
  D. Cytology of tissue samples obtained and collected under direct endoscopic visualization in dogs with aspergillosis has high diagnostic accuracy (DeLorenzi et al., 2006).
  E. Specimens are obtained via nasal swab, flush, or biopsy.
    1. Nasal swabs: poor diagnostic value
    2. Nasal flushing: rigid catheter is inserted aggressively into the nasal cavity with intermittent flushing and suction to obtain fluid and tissue.
    3. Biopsy samples: evaluation of impression smears, histopathology
IV. Culture and sensitivity testing

A. Nasal swab cultures are of little diagnostic value because of the diversity of normal flora present.
B. Tissue samples are cultured for both bacteriological and fungal analysis.
C. Positive fungal cultures are reliable if they are consistent with radiographic and rhinoscopic findings, or with serological testing (Harvey, 1984).

V. Fungal serology
A. Use agar gel double diffusion (AGDD), counterimmunoelectrophoresis (CIE), and enzyme-linked immunosorbent assay techniques to detect serum antibodies against *Aspergillus* spp. (Sharp et al., 1991b).
B. Use some caution when interpreting positive results because false-positive rates for AGDD and CIE are between 5% and 15% (Sharp et al., 1991b).
C. Serological tests must be interpreted in light of the clinical findings and diagnostic test results.
D. The latex cryptococcal antigen test (LCAT) is considered diagnostically accurate.

VI. Plain radiography
A. The dorsoventral, intraoral view of the nasal cavity and the rostrocaudal view of the frontal sinus are most useful.
B. Other useful projections are the lateral and ventral 20-degree rostral-dorsocaudal oblique views (Russo et al., 2000).
C. The signs with the highest predictive value for rhinitis in dogs are lack of ipsilateral sinus lesions, lucent foci, focal or multifocal loss of turbinate detail, and focal soft-tissue opacification (Gibbs et al., 1979).
D. Changes in cats include opacification of one or both nasal passages and frontal sinuses, nasal septum erosion, loss of turbinate structure, soft-tissue opacification, and erosion of the lateral bones (O'Brien et al., 1996).
E. Signs of fungal infection are nasal turbinate destruction, punctate lysis of the frontal and vomer bones, and increased density in the caudal nasal cavity and frontal sinuses (Sullivan et al., 1986).

VII. Computed tomography (CT) and magnetic resonance imaging (MRI)
A. Both CT and MRI are considered superior to radiography in defining the extent of the disease process and in differentiating infectious rhinitis from neoplasia (Codner et al., 1993).
B. CT is the best technique for detection of cortical bone lesions associated with nasal disease (Saunders et al., 2004).
C. CT and MRI are also useful in determining the degree of CNS involvement (Park et al., 1992).
D. Diagnostic imaging is best performed before biopsy or surgery.

VIII. Rhinoscopy
A. Rhinoscopy allows gross visualization of intranasal contents and identification of intranasal parasites, foreign bodies, oronasal fistulas, mass lesions, inflammatory or erosive processes, and mycotic plaques (Lent and Hawkins, 1992).
B. The diagnostic success of rhinoscopy alone is 8% and of rhinoscopy-assisted biopsy is 83% (Lent and Hawkins, 1992).
C. There is poor correlation between rhinoscopic appearance and inflammation severity in nasal biopsy specimens in cats with upper respiratory tract disease (Johnson et al., 2004).
D. Rhinoscopy is performed with an otoscope, flexible endoscope, or rigid arthroscope (Gartrell, 1995).
E. Anterograde rhinoscopy and retroflexed endoscopy have higher specificity and sensitivity than radiology for the diagnosis of neoplasia, inflammatory rhinitis, aspergillosis, and foreign bodies (Tasker et al., 1999).
F. Rhinoscopy is not as useful as CT and MRI for defining the extent of lesions and cannot assess bone involvement (Saunders et al., 2004).

IX. Tissue sampling methods
A. Obtain biopsy samples for histopathologic analysis in a blind fashion with rhinoscopic guidance or via rhinotomy.
B. Use radiography, CT, and MRI to help guide the biopsy.
C. Rhinoscopy-assisted biopsy provides a definitive diagnosis in 83% of cases (Lent and Hawkins, 1992).
D. Perform rhinotomy if previous nonsurgical methods fail or if it may have therapeutic potential or diagnostic benefits.

Treatment

I. Bacterial infections
A. Treatment of the underlying cause is vital in achieving resolution; otherwise, antimicrobial therapy provides only temporary resolution of clinical signs.
B. Antimicrobial selection is based on culture results.
1. Heavy growth of a single organism is clinically important.
2. If culture results are not available, or if a mixed flora is cultured, administer broad-spectrum antibiotics for a minimum of 4 to 6 weeks.
C. Medical management of cats with chronic, recurrent bacterial rhinitis/sinusitis offers temporary improvement, but clinical signs often return once treatment is completed.
1. Extension of the bacterial infection into the frontal sinus establishes a nidus not amenable to medical therapy (O'Brien and Harvey, 1976).
2. Such cases may be helped by surgical ablation of the frontal sinuses, followed by implantation of autogenous fat grafts and curettage of the ethmoid conchae (Anderson, 1987).
D. Supportive therapy is also important in the treatment of secondary bacterial rhinitis.
1. Adequate hydration and nutrition must be maintained.
2. The external nares are cleaned of debris, as needed.
3. Nebulization may aid in the movement of secretions and help relieve obstructed nasal passages.

4. Topical administration of decongestants may improve airflow, increase drainage, and decrease secretions (Ford, 1983).
   a. Phenylephrine (1.25%) applied as nose drops BID to TID
   b. Pseudoephedrine 15 to 50 mg PO BID to TID (dogs) and 2 to 4 mg/kg PO BID to TID (cats)
   c. Diphenhydramine 2 to 4 mg/kg PO TID

II. Viral infections
   A. Treatment is mainly supportive.
   B. Maintain adequate nutrition and hydration.
   C. Because secondary bacterial infections are common, treatment with broad-spectrum antibiotics is indicated.

III. Aspergillosis
   A. Rhinotomy followed by a 1-hour infusion of 2% enilconazole and oral itraconazole resulted in a satisfactory outcome in dogs with severe or recurrent aspergillosis (Clayes et al., 2006).
   B. Frontal sinus trephination, followed by a 5-minute flushing of 1% topical clotrimazole solution and installation of 1% clotrimazole cream resulted in an 86% positive response rate (Sissener et al., 2006).
   C. Topical 1% to 2% enilconazole can be administered through endoscopically or blindly placed tubes (Zonderland et al., 2002; Schuller and Clercx, 2007).
      1. Administer 120 to 200 mL and provide total drug contact time of 45 to 60 minutes.
      2. Two to three treatments are usually necessary, but good clinical results have been observed with 5% enilconazole within days of the initial treatment (McCullough et al., 1998).
   D. Topical administration of 1% clotrimazole is done through blindly placed tubes (Davidson and Pappagianis, 1985).
      1. Use 50 mL per nasal cavity and provide a contact time of 60 minutes.
      2. Multiple treatments may be necessary.
      3. Complete resolution of clinical signs may occur in dogs within 28 months of initiating therapy (Davidson et al., 1992).
      4. Adverse drug reactions have been reported, including pharyngitis, pharyngeal edema, and prolongation of anesthetic recovery (Caulkett et al.,1997).
   E. Ketoconazole at 5 mg/kg PO BID or thiabendazole at 10 mg/kg PO BID, administered for 6 to 8 weeks, can eliminate the disease in up to 50% of dogs (Sharp and Sullivan, 1989).
   F. Fluconazole at 1.25 to 2.5 mg/kg PO BID may provide resolution of clinical signs in 60% of dogs (Sharp et al., 1991a).
   G. Itraconazole at 5 mg/kg PO BID for 2 to 3 months is approximately 70% successful and induces less side effects than ketoconazole (McKiernan, 1997).
   H. Rhinotomy alone is rarely therapeutic in cases of nasal aspergillosis.
   I. Turbinectomy may be of benefit where removal of dense fungal plaque formation aids in topical drug exposure.

IV. Cryptococcosis
   A. The preferred treatment for feline cryptococcosis is fluconazole 2.5 to 5.0 mg/kg PO SID to BID (Malik et al., 1992).
      1. Fluconazole can penetrate the CNS.
      2. It is the treatment of choice for cats with CNS involvement (Perfect et al., 1986).
   B. Other agents include ketoconazole 10 mg/kg PO BID and itraconazole 10 mg/kg PO SID (Van Pelt and Lappin, 1994).
   C. The combination of amphotericin B and flucytosine has also been recommended.
      1. Amphotericin B 0.25 to 0.50 mg/kg IV every 48 to 72 hours, with total cumulative dose of 5.0 mg/kg
      2. Flucytosine 100 mg PO QID until 2 months after the resolution of signs (Ford, 1983)

V. Parasitic infections
   A. Treatments for *P. caninum* include ivermectin 0.2 to 0.4 mg/kg SC (except for ivermectin-sensitive breeds) and milbemycin oxime 0.5 to 1.0 mg/kg PO once a week for 3 weeks (Gunnarson et al., 1999).
   B. Nasal capillariasis in the dog can be treated with ivermectin 0.2 mg/kg PO once(except for ivermectin-sensitive breeds); levamisole 10 mg/kg PO SID for 5 days and repeated in 9 days; and fenbendazole 25 mg/kg PO BID for 10 days (Gartrell, 1995).
   C. In cats, nasal capillariasis is treated with ivermectin 0.2 mg/kg SC, PO once, and repeated in 3 weeks.

VI. Allergic disease: see treatment of allergies in Section 12.

VII. Dental disease
   A. Periodontal pockets and oronasal fistulas are treated by tooth extraction, closure of the defect with a mucoperiosteal flap, and appropriate antimicrobial therapy (Marreta, 1992).
   B. Fractured teeth and associated endodontic disease are treated with either root canal or extraction procedures (Van Pelt and McKiernan, 1994).

VIII. Foreign bodies
   A. If found under endoscopic guidance, attempt removal.
   B. Remove small foreign bodies rostrally with forceps.
   C. Push larger ones into the nasopharynx or pharynx for removal (McCarthy and McDermaid, 1990).
   D. If numerous small foreign bodies are present, or if a single one is tightly lodged in the nasal cavity, rhinotomy is indicated.
   E. Removal is followed by appropriate antimicrobial therapy.

IX. Trauma
   A. If acute, attempt to control epistaxis with sedation and packing the nose with gauze.
   B. If a depressed bone fragment is retained as a sequestrum, it is managed as a foreign body and removed.

X. Idiopathic disease
   A. Medical management of feline idiopathic chronic rhinosinusitis consists of antibiotic therapy, decongestants, supportive care, and, possibly, oral corticosteroids.

B. For dogs with chronic lymphoplasmacytic rhinitis, treatment options include antihistamines, oral and inhalant steroids, nonsteroidal antiinflammatories, antifungal medications and various antibiotics, such as doxycycline and azithromycin (Windsor and Johnson, 2006).
C. Surgical options include sinus trephination and irrigation, rhinotomy and turbinectomy, or ethmoid curettage and frontal sinus ablation with autogenous fat grafts (Cape, 1992).

Monitoring of Animal

I. In most cases, clinical signs resolve within 10 to 14 days of treatment.
II. If chronic destructive rhinitis is present, some degree of nasal discharge may persist.
III. Multiple treatments may be needed in dogs with aspergillosis.
A. Serial CT or MRI examinations can be used to assess response to treatment.
B. Long-term outcome following enilconazole therapy appears to be good (Schuller and Clercx, 2007).
IV. Monitor liver enzymes on a regular basis in animals receiving fluconazole or ketoconazole.
V. LCAT titers can be used to monitor response to therapy in cases of cryptococcosis (McKiernan, 1997).

Nasopharyngeal Stenosis

Definition and Cause

I. Nasopharyngeal stenosis is an unusual form of upper airway obstruction secondary to scar tissue formation across the nasopharynx (Griffon and Tasker, 2000).
II. It is thought to occur in cats following severe upper respiratory infections, particularly those that involve mucosal ulceration, such as that seen with herpesvirus (Novo and Kramek, 1999).
III. Choanal atresia and secondary nasopharyngeal stenosis occurs rarely in the dog (Richardson and Osguthorpe, 1988).
IV. Choanal atresia is failure of the posterior nasal cavity to communicate with the nasopharynx (Richardson and Osguthorpe, 1988).
V. A form of choanal atresia, called *nasopharyngeal dysgenesis,* has been reported in the dachshund (Kirberger et al., 2006).

Clinical Signs

I. Chronic history of nonprogressive upper airway stertor unresponsive to medical management.
II. Signs exacerbated by eating or swallowing
III. Minimal nasal discharge or history of sneezing
IV. Dachshunds with nasopharyngeal dysgenesis
A. Usually young: 1 to 5 years of age
B. Dyspnea, expiratory cheek puff
C. Salivation, dysphagia

Diagnosis

I. Physical examination findings
A. Upper airway stertor is ameliorated by open-mouthed breathing.
B. Lack of airflow through either nostril is noticed.
C. Macroglossia occurs in affected dachshunds.
II. Plain radiography
A. It does not aid in the diagnosis of secondary stenosis, but usually reveals lack of communication between the naso- and laryngopharynx in dachshunds with dysgenesis.
B. Increased soft-tissue opacity in one or both nasal passages may be seen with choanal atresia (Richardson and Osguthorpe, 1988).
III. Rhinoscopy
A. Retroflex the endoscope above the soft palate to view the caudal nasal passage.
B. With stenosis, the caudal opening is markedly reduced by the presence of a web of tissue across the nasopharynx.
C. Evaluate further the degree of stenosis via cannulation of the external nares with a small catheter.
D. Typically, the catheter cannot be advanced into the oropharynx.
E. With choanal atresia, the choanal openings are severely restricted or blocked completely.
IV. Oral examination of dogs with dysgenesis
A. Slitlike intrapharyngeal ostium visible
B. Confirms macroglossia

Differential Diagnosis

I. Other causes of chronic upper respiratory tract disease, including rhinitis, nasopharyngeal polyps, sinusitis, and neoplasia.
II. Pharyngeal or laryngeal disorders

Treatment

I. Secondary stenosis requires surgery.
A. Incise the soft palate to expose the nasopharynx, then resect the stenotic web of tissue.
B. To prevent recurrence, the resultant defect in the dorsal nasopharynx is reconstructed using an advancement flap from mucosa at the nasopharynx and laryngopharynx (Griffon and Tasker, 2000).
C. The use of a Wallstent wire-braided endoprosthesis may also help prevent recurrence (Novo and Kramek, 1999).
D. Bougienage of the stricture has had limited success (Novo and Kramek, 1999).
II. Choanal atresia is managed using a ventral rhinotomy for excision of the choanal membranes.
A. As with acquired stenosis, recurrence is high.
B. Permanent tracheostomy to relieve clinical signs may also be considered (Richardson and Osguthorpe, 1988).
III. Surgery to enlarge the nasopharyngeal opening in dogs with dysgenesis has not been very successful (Kirberger et al., 2006).

Monitoring of Animal

I. Recurrence of clinical signs from stricture recurrence is common.
II. Repeat the rhinoscopy 6 to 8 weeks following surgery to assess patency of the nasopharynx and choanae.

III. Although the inspiratory noise usually resolves following surgery, nasal discharge and congestion may remain.

NEOPLASIA

Nasal and Nasopharyngeal Polyps

Definition

I. Polyps are rare in dogs and relatively uncommon in cats.
II. They are the most common nasopharyngeal disease found in young cats.
III. They are small, benign masses that eventually lead to nasal or nasopharyngeal obstruction.
  A. Nasopharyngeal polyps are believed to grow from the mucosa of either the auditory tube or middle ear (Landsborough, 1994).
  B. Nasal polyps are thought to arise from the ethmoturbinates (Galloway et al., 1997).

Causes and Pathophysiology

I. Nasopharyngeal polyps are often associated with otitis media.
  A. Whether otitis media is a primary or secondary factor in the etiopathogenesis of polyp formation is unknown (Kapatkin et al., 1990).
  B. The proliferative tissue caused by otitis media may grow down the auditory tube to the nasopharynx or out through the tympanum to the external ear canal (Kapatkin et al., 1990).
II. Bacterial and viral infections and congenital lesions may play a role in the development of nasopharyngeal polyps (O'Brien and Harvey, 1976; Parker and Binnington, 1985).
III. It is thought that nasal polyps develop as a sequela to chronic upper respiratory inflammation (Galloway et al., 1997).

Clinical Signs

I. With nasopharyngeal polyps, signs of upper airway obstruction predominate and include stertorous breathing, dyspnea, sneezing, and nasal discharge.
II. Some cats with nasopharyngeal polyps present with Horner's syndrome (see Chapters 105 and 108).
III. Animals with nasal polyps present with sneezing, stertorous breathing, and inspiratory dyspnea.

Diagnosis

I. Physical assessment
  A. Evaluate for signs of upper airway obstruction, Horner's syndrome, and otic disease.
  B. Under heavy sedation or general anesthesia, perform an oropharyngeal examination, including palpation of the soft palate.
II. Skull radiography
  A. Evaluate lateral, oblique, open-mouth, and ventrodorsal views.
  B. Pay special attention to the osseous and tympanic bullae, petrous-temporal bones, nasal cavities, and nasopharynx (Kapatkin et al., 1990).
  C. Radiographs may reveal a soft-tissue density within the nasopharynx and thickening of the bulla.
  D. Soft-tissue density with loss of normal turbinate structure may be seen with nasal polyps (Galloway et al., 1997).
III. Rhinoscopy
  A. Generally not required in the diagnosis of nasopharyngeal polyps
  B. Can be helpful in the diagnosis of nasal polyps

Differential Diagnosis

I. Nasal and/or nasopharyngeal mass or foreign body
II. Nasopharyngeal stenosis
III. Pharyngeal and laryngeal disorders

Treatment

I. In animals with radiographic evidence of middle ear thickening, a ventral bulla osteotomy is recommended (see Chapter 108).
II. Polyp removal is achieved by gentle traction placed at the base of its stalk.
III. Treatment of choice for nasal polyps is ventral or dorsal rhinotomy and curettage of the nasal cavity to remove all polypoid material.
  A. Postoperative antiinflammatory medications may be helpful (Galloway et al., 1997).
  B. The efficacy of surgery alone is approximately 85% (Mortellaro, 1989).

Monitoring of Animal

I. Complications associated with ventral bulla osteotomy include facial nerve paresis, Horner's syndrome, and vestibular abnormalities, all of which usually resolve over 3 to 6 weeks (see Chapter 108).
II. Recurrence of polyps is common when bulla osteotomy is not performed (Kapatkin et al., 1990).
III. Resolution of clinical signs after bulla osteotomy and polyp removal is >90% (Kapatkin et al., 1990).

Malignant Tumors

Definition

I. Nasal tumors account for 1% to 2% of all neoplasms in the dog and 1% to 5% of all neoplasms in the cat (Madewell et al., 1976).
II. Nasal tumors are more common in middle-aged and older dogs (8 to 10 years) of the dolichocephalic and mesocephalic breeds (Theisen et al., 1996).

Causes

I. Eighty percent of canine tumors are malignant; 60% to 75% are of epithelial origin (Legendre, 1983).
  A. Most common tumors: adenocarcinoma, squamous cell carcinoma, and undifferentiated carcinoma
  B. Others: osteosarcoma, fibrosarcoma, chondrosarcoma, lymphosarcoma, melanoma, transmissible venereal tumor

II. The most common tumors in the cat are adenocarcinoma, undifferentiated carcinoma, and lymphoma (O'Brien et al., 1996).
III. Less common in the cat are fibrosarcomas, lymphohistiocytic sarcomas, chondrosarcomas, and chondromas (O'Brien et al., 1996).

Pathophysiology

I. Tumor mass within the nasal cavity can cause upper airway obstruction.
II. Invasion of adjacent structures leads to facial asymmetry and possible neurological abnormalities (Smith et al., 1989).
III. Nasal tumors are locally aggressive and destructive; metastasis occurs very late in the course of disease, if at all.

Clinical Signs

I. Intranasal tumors in dogs and cats tend to follow a slow and insidious clinical course, with signs being present for months.
II. The most common signs in dogs include nasal discharge, sneezing, and epistaxis.
    A. The discharge may initially be unilateral and later become bilateral when the tumor erodes through the nasal septum.
    B. The discharge often starts as serous and later becomes serosanguineous.
    C. Epistaxis is rarely seen early in the course of the disease.
III. Other signs in dogs include epiphora, facial asymmetry, and neurological abnormalities from extension of the tumor through the cribriform plate.
IV. Clinical signs in cats include nasal discharge, sneezing, facial and/or nasal masses, epiphora, epistaxis, stertor, and CNS signs (Theon et al., 1994).

Diagnosis

I. Suspicious history and physical findings
    A. Most animals present with a chronic history of nasal discharge and sneezing.
    B. Cats may exhibit loss of teeth associated with bone erosion (O'Brien et al., 1996).
II. Plain radiography
    A. The most useful views are the dorsoventral intraoral view of the nasal cavity and the rostrocaudal view of the frontal sinuses.
    B. Other useful projections are the lateral and the ventral 20-degree rostral-dorsocaudal oblique (Russo et al., 2000).
    C. Abnormal findings with high predictive values for the diagnosis of neoplasia include the following in the dog (Russo et al., 2000).
        1. Lytic bone lesions compatible with bony invasion
        2. Lesions affecting the entire nasal cavity
        3. Soft-tissue or fluid opacity in the ipsilateral frontal sinus
        4. Loss of turbinate detail
        5. Generalized increased opacity
    D. Certain features assist in the diagnosis of intranasal neoplasia in cats.
        1. Unilateral aggressive lesions may be seen, including lysis of the lateral bones, nasal turbinate destruction, and loss of teeth.
        2. Severity of radiographic findings is not always a good indicator of neoplasia, as similar radiographic signs can be seen with chronic rhinitis.
III. CT and MRI
    A. CT and MRI are more sensitive for detecting bone destruction and extension into adjacent soft-tissue structures (Park et al., 1992).
    B. Both techniques provide higher contrast resolution, which increases visualization of soft-tissue structures.
    C. When compared with plain radiography, CT was less sensitive at detecting the presence of nasal cavity neoplasia in cats, but more sensitive at localizing changes and determining the extent of disease (Schoenborn et al., 2003).
IV. Nasal cytology
    A. Nasal flushing for cytological samples provides a diagnosis in only 50% of animals with neoplasia (MacEwan et al., 1977).
    B. Aspiration biopsies, using a large-bore tube (7-mm diameter) improve the diagnostic success rate to 97% in dogs (Withrow et al., 1977).
V. Rhinoscopy and histopathology
    A. Rhinoscopy-assisted biopsy provides a diagnosis in approximately 83% of cases (Lent and Hawkins, 1992).
    B. Endoscopic evaluation of the choanae in dogs and cats is very helpful in the diagnosis of neoplasia (Willard and Radlinsky, 1999).
VI. Rhinotomy
    A. It is performed if less-invasive methods fail to provide a diagnosis.
    B. It provides reliable samples for cytological and histopathologic analysis.

Differential Diagnosis

I. Nasal aspergillosis
II. Coagulopathies
III. Chronic, severe bacterial rhinitis

Treatment

I. Radiation therapy
    A. When orthovoltage radiation therapy is preceded by surgical curettage, reported median survival times are 17.5 months (Adams et al., 1987) and 7.4 months (Northrup et al., 2001).
    B. Megavoltage radiation has superior penetrating ability relative to orthovoltage radiation.
        1. Average survival time is 10.1 months (Adams et al., 1987).
        2. Pretreatment cytoreductive surgery is not needed before therapy.
        3. Dogs undergoing surgical exenteration of the nasal cavity following radiation had 2-year survival rates of 69% versus 44% for those dogs undergoing only radiation (Adams et al., 2005).

4. Chronic complications of rhinitis, osteomyelitis and osteonecrosis were higher in dogs treated with surgery and radiation compared to radiation alone (Adams et al., 2005).

C. Brachytherapy using iridium-192 for intranasal neoplasms in dogs after cytoreductive surgery had a mean survival time of 7.1 months (Thompson et al., 1992).

D. Extensive disease does not preclude radiation therapy for nasal tumors.

E. Radiation therapy is also efficacious for the treatment of feline nasal tumors, with median survival times of 20.8 (Evans and Hendrick, 1989) and 13 months (Straw et al., 1986).

F. Variables associated with decreased survival in dogs undergoing radiation include an age of >10 years, regional lymph node metastasis, advanced tumor stage, and total dose >55 Gy delivered (LaDue et al., 1999).

II. Surgery

A. Rhinotomy for surgical debulking is only efficacious if followed by radiation therapy.

B. Surgery alone does not improve survival, although it may improve quality of life for a short time.

III. Chemotherapy

A. With the exception of lymphosarcoma, chemotherapy has demonstrated little efficacy in the treatment of nasal tumors.

B. The use of cisplatin in dogs with nasal adenocarcinoma did not improve survival when compared with surgery alone or no treatment.

1. A combination of radiation and a slow-release cisplatin chemotherapy in dogs resulted in mean and median survival times of 570 and 474 days, respectively (Lana et al., 2004).
2. Cisplatin may have a palliative effect in decreasing nasal discharge, sneezing, and epistaxis (Hahn et al., 1992).

C. A clinical response to therapy has been demonstrated in dogs with nasal tumors using alternating doses of doxorubicin and carboplatin, in conjunction with oral piroxicam (Langova et al., 2004).

Monitoring of Animal

I. Acute complications associated with radiation include rhinitis, oral mucositis, dermatitis, and keratoconjunctivitis (Ogilvie and LaRue, 1992).

II. Chronic complications of radiotherapy include retinal damage, cataracts, bone necrosis, skin ulceration, and brain damage.

III. Metastasis is rare with nasal neoplasia, but, as the efficacy of radiation treatment improves and survival times increase, metastatic disease may become an issue.

CHAPTER 15

Diseases of the Larynx and Pharynx

J. David Fowler | Ronald M. Bright

DEVELOPMENTAL DISORDERS

Ronald M. Bright

Brachycephalic Syndrome

Definition

I. Multiple abnormalities of the upper airway (anatomical and acquired) result in partial to severe obstruction.
II. One or several of the following conditions contribute to this syndrome:
  A. Stenotic nares
  B. Elongated soft palate extending 2 to 4 mm caudal to the tip of the epiglottis
  C. Redundant pharyngeal mucosa
  D. Tracheal hypoplasia (primarily English bulldog)
  E. Everted laryngeal saccules
  F. Laryngeal collapse

Causes

I. The syndrome occurs primarily in brachycephalic breeds, such as the English bulldog, Boston terrier, pug, Pekingese, shih tzu, French bulldog, and boxer.
II. Sometimes, brachycephalic cats (Himalayan, Persian breeds) have similar problems.
III. The genetic influence related to this syndrome has not been well defined.
IV. Additional factors can contribute to the severity of signs.
  A. Excitement
  B. Strange environment
  C. Enclosed area (cage)
  D. Hyperthermia
  E. Obesity
  F. Anesthetic episode

Pathophysiology

I. The skull of the brachycephalic breeds is shortened rostrally from an inherited developmental defect in the bones of the skull.
  A. Compression of the nasal passages occurs, and cartilage plates of the external nares are shortened, thickened, and medially displaced.
  B. There is distortion of the pharyngeal tissues.
  C. There is an increased resistance to airflow.
  D. The work of breathing is increased.
  E. The degree of obstruction varies among animals but increases with age.
II. Greatly increased negative pressures are generated during inspiration through the obstructed nares, pharynx, or both.
  A. Inflammatory changes are often seen in the oropharynx.
  B. Secondary changes, such as everted laryngeal saccules, laryngeal edema, edematous soft palate, and redundant pharyngeal mucosa, develop in most dogs to some degree.
  C. Persistent negative pressures during inspiration can cause inflammation, stretching, and, finally, collapse of the laryngeal tissues.
  D. Some upper gastrointestinal (GI) problems may occur secondary to the airway problem(s) (Poncet et al., 2006).
III. Over time the obstructed airway can result in an increased inspiratory effort, excessive muscle activity, hyperthermia, dyspnea, cyanosis, and collapse.

Clinical Signs

I. Stertorous breathing
  A. Increased efforts are required to overcome the obstruction.
  B. The soft palate flutters and vibrates.
  C. Turbulence further traumatizes the soft palate.
  D. Inflammation, edema, and swelling develop.
II. Gagging, coughing up phlegm
III. Regurgitation and/or vomiting (occasionally)
IV. Severe snoring when animal is in a state of relaxation or sleep
V. Excessive panting
VI. Dyspnea, cyanosis
VII. Exercise intolerance, collapse

Diagnosis

I. Signalment: brachycephalic breed
II. History of inspiratory-related signs of distress, stertorous breathing
III. Physical examination findings
  A. Stenotic nares
  B. Difficult auscultation of lungs owing to referred sounds
  C. Exacerbation of signs with stress
  D. Obesity common
  E. Hyperthermia

IV. Oropharyngeal examination under light anesthesia
  A. Elongated soft palate
  B. Thickened and inflamed soft palate and laryngeal mucosa
  C. Everted, edematous lateral (laryngeal) saccules
  D. Laryngeal collapse that worsens on inspiration
V. Radiography of the thorax and cervical region
  A. Evaluate trachea for hypoplasia.
  B. Look for lower airway disease and cardiac changes.
  C. Assess concurrent upper airway problems.
  D. Look for evidence of concurrent megaesophagus or hiatal hernia (English bulldog, shar-pei).

Differential Diagnosis

I. Nasopharyngeal polyps (cats) or tumor involving oropharynx or larynx
II. Laryngeal paralysis, stenosis
III. Pharyngeal (salivary) mucocele
IV. Tracheal mass, foreign body, granuloma, stenosis

Treatment

I. Resolution of brachycephalic syndrome requires surgical corrective procedures.
II. Upper GI disorders are evaluated endoscopically to rule out inflammatory diseases that may require treatment before surgical correction of the brachycephalic syndrome (Poncet et al., 2006).
III. Anesthetic induction and recovery are critical in these animals.
  A. Give oxygen preoperatively via oxygen mask or cage.
  B. Tracheostomy is an optional procedure.
    1. It allows the administration of maintenance gas anesthesia after induction, thereby enhancing visualization of the pharynx and larynx.
    2. It helps ameliorate any problems related to postoperative dyspnea secondary to airway edema and inflammation.
  C. The animal is intubated rapidly after induction.
    1. Have a small-diameter endotracheal tube ready for dogs with possible tracheal hypoplasia.
    2. Leave the endotracheal tube in place as long as possible postoperatively.
    3. Remove the endotracheal tube gently with the cuff partially inflated.
IV. Take steps to avoid aspiration pneumonia or reflux esophagitis postoperatively.
  A. Preoperatively, fast the dog for a longer period (18 to 24 hours).
  B. Administer metoclopramide 0.2 to 0.4 mg/kg SC 30 minutes before anesthetic induction to decrease gastroesophageal reflux during surgery and the immediate postoperative period.
  C. Increase the pH of gastric contents to diminish injury to esophagus or respiratory tract if reflux occurs.
    1. Ranitidine 0.1 to 0.2 mg/kg IV
    2. Famotidine 0.5 mg/kg IV
    3. Pantoprazole 1.0 mg/kg IV (Bersenas et al., 2005)
    4. Given 30 minutes before induction of anesthesia
  D. Repeat metoclopramide and an injectable antacid TID for a total of 4 to 5 doses.
V. Use antiinflammatories preoperatively to decrease postoperative swelling.
  A. Dexamethasone 0.5 to 2.2 mg/kg IV, SC, IM
  B. Prednisolone 1.5 to 2.0 mg/kg SC, IM
  C. Repeated 4 to 6 hours after surgery
VI. Surgical options include the following:
  A. Stenotic nares surgery (rhinoplasty) is ideally performed early in life (4 to 6 months of age).
    1. Remove a vertically oriented wedge of tissue from the wing of the nostril to include the alar cartilage.
    2. The edges of the wound are sutured together with 4-0 or 5-0 synthetic multifilament suture.
    3. An alternative technique has recently been described (Ellison, 2004).
  B. Soft palate resection (staphylectomy) may be performed as follows:
    1. The soft palate is surgically incised at a point between the caudal edges and midpoint of the tonsillar crypts.
    2. A "cut-and-sew" technique is recommended (Bright and Wheaton, 1983).
    3. Laser surgery may also be performed (Clark and Sinabaldi, 1994).
  C. Everted saccules are amputated via a transoral approach.
  D. Laryngeal collapse is difficult to correct (see under Laryngeal Collapse).
    1. Laryngeal collapse is thought to be an end-stage airway obstruction secondary to the brachycephalic syndrome.
    2. Correcting the brachycephalic syndrome may be sufficient in some dogs with varying degrees of laryngeal collapse (Torrez and Hunt, 2006).
      a. Laryngeal collapse was present in 53% of the brachycephalic dogs.
      b. Correction of the brachycephalic-related problems improved 56.5% of the dogs; 10.9% did not improve.
      c. Laryngeal collapse can occur in puppies <6 months of age, so assess for brachycephalic syndrome when early signs are apparent.

Monitoring of Animal

I. Closely monitor for signs of aspiration pneumonia and reflux esophagitis postoperatively.
II. Place the animal in an oxygen-rich and humidified environment 6 to 8 hours postoperatively.
III. Prognosis is better when surgery is performed in a younger animal.
IV. Postoperative complications (primarily aspiration pneumonia) are greatest in the English bulldog (Lorinson et al., 1997).
  A. Concurrent esophageal motility problems may be present.
  B. Hiatal hernia is often a complicating factor, possibly from abnormalities of the thoracic bellows that result

from severe respiratory effort over time (Hardie et al., 1998).

DEGENERATIVE DISORDERS

J. David Fowler

Laryngeal Paralysis

Definition and Causes

I. Laryngeal paralysis is a dynamic inspiratory airway obstruction caused by paralysis of the cricoarytenoideus dorsalis (CAD) muscle.
II. Laryngeal paralysis may occur as a congenital defect in the Siberian husky, the Bouvier des Flandres, and bull terrier.
III. Laryngeal paralysis develops as part of a polyneuropathy complex in young Dalmatians and rottweilers (Braund et al., 1994: Mahony et al., 1998).
IV. Laryngeal paralysis occurs spontaneously in white-coated German shepherd dogs (Ridyard et al., 2000).
V. Juvenile laryngeal paralysis has been reported in Siberian husky and Alaskan malamute puppies (Polizopoulou et al., 2003).
VI. Acquired laryngeal paralysis occurs more frequently than congenital laryngeal paralysis.
    A. Idiopathic laryngeal paralysis
        1. Most common form of laryngeal paralysis
        2. Occurs in older large-breed dogs, especially Labrador retrievers
    B. Iatrogenic laryngeal paralysis
        1. Direct injury to the recurrent laryngeal nerve
        2. Surgery of the neck, especially following tracheal manipulation
        3. Surgical dissection of the cranial mediastinum
    C. Traumatic laryngeal paralysis following cervical trauma
        1. Bite wounds
        2. Strangulation
    D. As a component of any polyneuropathy syndrome (e.g., myasthenia gravis, hypothyroidism) (Braund et al., 1989)

Pathophysiology

I. Arytenoid cartilages
    A. Paired cartilages forming the rima glottis
    B. Lie within the thyroid cartilage and cranial to the cricoid cartilage
    C. Articulate with the cricoid cartilage
    D. Muscle process where CAD attaches
II. CAD muscle
    A. It originates on the dorsolateral margin of the cricoid cartilage, and inserts on the muscular process of the arytenoid cartilage.
    B. Contraction pulls the arytenoid cartilage into an abducted position.
    C. It is innervated by the recurrent laryngeal nerve.
III. Pathogenesis of laryngeal paralysis
    A. Traumatic disruption of recurrent laryngeal nerves
    B. Idiopathic demyelination of recurrent laryngeal nerves
    C. As a component of systemic neuromuscular disease (myasthenia gravis)
    D. As a component of a polyneuropathy

Clinical Signs

I. The hallmark of dynamic laryngeal obstruction is inspiratory stridor.
    A. High-pitched or raspy inspiratory noise
    B. Exacerbated during times of increased inspiratory effort (exercise or heat stress)
II. Voice change is often reported.
III. Gagging, coughing, and nasal discharge may also be seen.
IV. Cyanosis, hyperthermia, and collapse are often consequences of severe laryngeal obstruction.

Diagnosis

I. Diagnosis is based on direct visualization of laryngeal motion.
    A. Opioid sedation is sometimes adequate to allow laryngeal examination.
    B. Light general anesthesia is required in most cases.
        1. Minimal dose of thiobarbiturate IV is preferred (Jackson et al., 2004).
        2. Acepromazine with isoflurane mask induction is also effective (Jackson et al., 2004).
        3. Minimal dose of propofol IV can be used.
        4. Doxapram IV is helpful to stimulate respiration and aid in diagnosis (Tobias et al., 2004).
    C. A deeper plane of anesthesia obliterates normal laryngeal reflexes, resulting in a possible false-positive diagnosis of laryngeal paralysis.
    D. The hallmark feature of laryngeal paralysis is failure of the laryngeal walls to abduct during the inspiratory phase.
        1. Paralysis can be unilateral or bilateral.
        2. A paradoxical motion of laryngeal adduction during inspiration may be noted and is caused by negative airway pressure.
    E. Secondary hyperemia and edema of laryngeal mucosa are common.
II. Ultrasound assessment of laryngeal motion correlates closely with direct laryngoscopy and may provide a noninvasive means of diagnosis (Rudorf et al., 2001).
III. Cervical and thoracic radiographs are required for a complete assessment.
    A. To rule out cervical and cranial mediastinal neoplasia or masses
    B. To assess for megaesophagus, which is common with myasthenia gravis
IV. Complete blood count and biochemistry tests are recommended to rule out systemic diseases in older animals.

Differential Diagnosis

I. Laryngeal collapse
    A. Collapse may be secondary to brachycephalic airway syndrome.
    B. Signalment is helpful to differentiate collapse from paralysis.
    C. Rarely, they can occur concomitantly.

II. Fixed laryngeal obstruction
  A. Laryngeal neoplasia
  B. Laryngeal granuloma
III. Cervical tracheal collapse presenting with dynamic inspiratory dyspnea
  A. Tracheal collapse is most often seen in small-breed dogs.
  B. Tracheal collapse is usually associated with chronic cough.
IV. Tracheal or laryngeal foreign body

Treatment

I. Initial treatment is aimed at stabilization of the animal.
II. Reduce body temperature if hyperthermic (see Chapter 135).
III. Sedation is indicated to help relieve anxiety.
  A. Increased respiratory effort increases negative airway pressure and worsens dynamic adduction of arytenoid cartilages.
  B. Narcotic sedation is recommended for most dogs.
    1. Butorphanol 0.1 to 0.2 mg/kg IV
    2. Oxymorphone 0.05 to 0.1 mg/kg IV
    3. Hydromorphone 0.05 mg/kg IV
  C. Acepromazine 0.02 to 0.05 mg/kg IV can be used if the animal is normotensive.
IV. Administer oxygen if the animal is in respiratory distress (see Chapter 3).
V. Intravenous fluid therapy is usually indicated and allows rapid IV drug administration.
VI. Administration of rapid IV anesthetics allows intubation if the animal is not responsive to the previous measures.
VII. Insertion of a tracheostomy tube is indicated for temporary management of continued dynamic obstruction (see Chapter 3).
VIII. Surgery is required for definitive correction of the problem.
  A. Cricoarytenoid lateralization
    1. Using a lateral approach to the larynx, the cricothyroid and cricoarytenoid articulations are dissected.
    2. The CAD is transected and elevated from the cricoid cartilage, and two monofilament nonabsorbable sutures are placed from the dorsolateral cricoid cartilage to the muscular process of the arytenoid cartilage (LaHue, 1989).
    3. The suture is tied under moderate tension to abduct the arytenoid cartilage but not overly deform the rima glottides (Bureau and Monnet, 2002).
    4. The procedure is performed unilaterally.
      a. Left approach is best for the right-handed surgeon and vice versa.
      b. Avoid bilateral procedures because of risk of aspiration pneumonia.
  B. Thyroarytenoid lateralization
    1. Perform a lateral approach to the larynx, as described previously.
    2. Monofilament nonabsorbable suture is placed from the muscular process of the arytenoid cartilage through the opposing surface of the thyroid cartilage (White, 1989).
    3. It does not actively abduct the arytenoid cartilage, but prevents dynamic adduction of the arytenoid during inspiration (Griffiths et al., 2001).
    4. It is sometimes combined with a single cricoarytenoid lateralization suture, with results similar to cricoarytenoid lateralization (Demetriou and Kirby, 2003).
  C. Contraindications to lateralization procedures (MacPhail and Monnet, 2001)
    1. Dysphagia
    2. Esophageal dysfunction
    3. Increased risk of aspiration pneumonia
  D. Partial arytenoidectomy or ventriculocordectomy
    1. Combinations of unilateral or bilateral partial resection of the arytenoid cartilage, aryepiglottic fold, and vocal folds may be considered (Holt, 1994; Trout et al., 1994).
    2. Techniques increase the glottic opening but do not preclude dynamic adduction of the arytenoid cartilage.
    3. There is an increased risk of postoperative aspiration pneumonia compared with lateralization procedures (Ross et al., 1991).
IX. Check for adequate arytenoid abduction immediately after surgery by temporarily extubating while the animal is still under general anesthesia.
X. Consider administering an antiinflammatory dose of corticosteroids if laryngeal mucosal edema is extensive.
  A. Dexamethasone 0.5 to 1.0 mg/kg IV, SC
  B. Prednisolone 0.5 to 2 mg/kg IM, PO

Monitoring of Animal

I. Allow access to water PO after full recovery from anesthesia, and observe for evidence of aspiration.
  A. A soft cough is common after drinking and may occur for days to weeks after surgery.
  B. Excessive or persistent coughing suggests excessive aspiration.
    1. Reevaluate the degree of arytenoid abduction and glottic deformation.
    2. Consider a second surgery to correct an enlarged or deformed glottic opening.
    3. Reassess for worsening of myasthenia gravis or megaesophagus following anesthesia and surgery.
II. Allow access to food 12 to 24 hours after surgery.
  A. Do not offer food if there is evidence of aspiration after drinking water.
  B. Observe dog while eating and withdraw food if aspiration occurs.
  C. Hand-feeding small balls of canned dog food for 1 to 2 weeks after surgery controls the rate of ingestion and may decrease the risk of aspiration.
III. Warn the owners of a voice change because fixed unilateral abduction of the arytenoid cartilage and vocal fold results in a soft, hoarse bark.
IV. Prognosis varies depending on the cause of the paralysis.

A. Good to excellent with unilateral arytenoid lateralization techniques in dogs with idiopathic or congenital forms of laryngeal paralysis
   1. Approximately 85% of owners report improved quality of life following surgical correction (Snelling and Edwards, 2003).
   2. Results are poorer in dogs weighing <10 kg, with 55% of owners reporting improved quality of life (Snelling and Edwards, 2003).
B. Variable to poor with other acquired forms

Laryngeal Collapse

Definition

I. Laryngeal collapse arises secondary to loss of structural integrity of the laryngeal cartilages.
II. The severity of collapse is classified into three types.
   A. Stage 1 laryngeal collapse occurs with eversion of the laryngeal saccules.
   B. Stage 2 laryngeal collapse occurs with medial deviation of the cuneiform process of the arytenoid cartilage and aryepiglottic fold.
   C. Stage 3 laryngeal collapse denotes medial deviation or collapse of the corniculate process of the arytenoid cartilage.

Causes

I. May arise subsequent to direct laryngeal trauma and disruption of laryngeal cartilages
II. Most commonly occurs secondary to chronic upper airway obstruction, particularly as a consequence of brachycephalic airway syndrome

Pathophysiology

I. Upper airway obstruction causes increased airway resistance, increased negative intraluminal pressure, and increased flow velocity.
II. Changes in airflow dynamics cause edema of laryngeal mucosa, with eventual eversion of laryngeal saccules into the laryngeal lumen.
III. Laryngeal saccule eversion worsens airway obstruction and exacerbates abnormal airflow.
IV. Negative intraluminal pressure eventually fatigues laryngeal cartilage and causes medial deviation and eventual collapse of the arytenoid cartilages.

Clinical Signs

I. Typically presents as a worsening of chronic clinical signs associated with upper airway obstruction.
II. Often associated with stridor, but can be masked by stertor from an overlong soft palate
III. Most cases seen in brachycephalic animals >2 years of age
   A. Younger age does not preclude a diagnosis of laryngeal collapse.
   B. All animals presenting with clinical signs of brachycephalic airway syndrome or other forms of upper airway obstruction must be evaluated for laryngeal collapse.

Diagnosis

I. Definitive diagnosis is made on laryngoscopic examination under general anesthesia.
II. Everted laryngeal saccules appear as bilaterally symmetrical mucosal masses located immediately cranial to, and obliterating visualization of, the vocal cords.
III. Aryepiglottic collapse appears as medial deviation of the aryepiglottic folds and the cuneiform processes of the arytenoid cartilages.
IV. Corniculate collapse appears as medial deviation and deformation of the corniculate processes of the arytenoid cartilages.

Differential Diagnosis

I. Laryngeal collapse must be differentiated from laryngeal paralysis, and the two may occur concomitantly.
   A. Younger brachycephalic breeds are predisposed to laryngeal collapse.
   B. Older large breeds are predisposed to idiopathic laryngeal paralysis.
II. Other causes of laryngeal or pharyngeal obstruction can mimic laryngeal collapse.
   A. Laryngeal or pharyngeal neoplasia
   B. Granulomatous laryngitis
   C. Pharyngeal or laryngeal foreign body
   D. Pharyngeal mucocele or abscess

Treatment

I. Concurrent causes of upper airway obstruction must be alleviated (see Brachycephalic Syndrome).
   A. Correct congenital stenotic nares.
   B. Resect overlong soft palate.
   C. Everted laryngeal saccules are amputated using a transoral approach.
   D. Correction of stenotic nares and elongated soft palate can improve clinical function in many dogs with laryngeal collapse (Torrez and Hunt, 2006).
II. Mild to moderate stage 2 laryngeal collapse can be managed by unilateral aryepiglottic fold resection.
   A. Grasp the aryepiglottic fold and cuneiform process using an Allis tissue forceps.
   B. Resect the fold and cuneiform process using Mayo scissors.
   C. Allow healing by second intention.
   D. Avoid bilateral aryepiglottic fold resection because of risk of aspiration pneumonia.
III. Severe stage 2 or stage 3 laryngeal collapse requires permanent tracheostomy.
IV. Lateralization procedures, as described for laryngeal paralysis, are not effective for laryngeal collapse owing to the loss of structural integrity of the laryngeal cartilages.

Monitoring of Animal

I. Endotracheal tubes are maintained as long as possible during anesthetic recovery.
II. Observe carefully for respiratory obstruction following removal of the endotracheal tube.

A. If severe respiratory embarrassment occurs, the animal must be reevaluated for severity of collapse or the presence of laryngeal mucosal edema.
B. Administer an antiinflammatory dose of corticosteroids if mucosal edema is present.
C. Temporary tracheostomy is performed if needed and the tracheostomy tube maintained until edema is resolved, usually in 24 to 72 hours.
D. Permanent tracheostomy is performed if severe laryngeal collapse is noted on reevaluation.

III. The prognosis associated with laryngeal collapse varies with the stage of disease.
A. Stage 1 collapse has a favorable prognosis with correction of predisposing causes of upper airway obstruction.
B. Stage 2 collapse has a guarded prognosis because it often progresses to stage 3 collapse.
C. Stage 3 collapse has a poor prognosis for preservation of laryngeal function and requires a permanent tracheostomy.

INFLAMMATORY DISORDERS

Laryngitis

J. David Fowler

Definition and Causes

I. Laryngitis denotes inflammation of the larynx.
II. Laryngitis may be either primary or secondary.
A. Primary causes
1. Canine distemper virus infection
2. Infectious canine tracheobronchitis (kennel cough)
a. Adenovirus type 2
b. *Bordetella bronchiseptica*
c. Parainfluenza virus
3. Feline rhinotracheitis and calicivirus infections
B. Secondary causes
1. Upper respiratory irritation: smoke inhalation, regurgitation and aspiration
2. Granulomatous inflammation: etiology poorly understood
3. Iatrogenic injury during intubation and anesthesia
4. Trauma

Clinical Signs

I. Primary causes of laryngitis also result in inflammation of other upper respiratory organs (e.g., nasal cavity, trachea, bronchi).
II. Clinical signs are usually referable to organs other than the larynx (e.g., nasal discharge, cough).
III. Smoke inhalation and regurgitation and aspiration are usually associated with inflammation beyond the larynx (see Chapter 18).
IV. Inflammation restricted to the larynx is seen following laryngeal trauma or with granulomatous laryngitis.
V. Clinical signs of laryngitis include the following:
A. Cough
B. Dysphagia
C. Laryngeal obstruction: inspiratory stridor, exercise intolerance
D. Voice change

Diagnosis

I. Signalment, history, and clinical signs referable to organs other than the larynx are seen with kennel cough, feline upper respiratory viral infections, and aspiration.
II. Direct laryngeal trauma may cause fractures of laryngeal cartilages and disruption of the airway.
A. Unstable laryngeal cartilage on palpation
B. Crepitus, if subcutaneous emphysema present
C. Cartilage fractures or subcutaneous emphysema on cervical radiographs
III. Laryngoscopy under general anesthesia is required for definitive diagnosis of granulomatous laryngitis and to differentiate granulomas from other mass lesions of the larynx.
A. Partial resection and histopathologic examination are performed if lesions are extensive.
B. Total excisional biopsy may be done if lesions are focal.

Differential Diagnosis

I. Tracheitis or tracheobronchitis
II. Other causes of coughing
III. Other causes of dysphagia
IV. Neoplasia, especially for granulomatous laryngitis

Treatment

I. Acute laryngitis is usually self-limiting and may be treated symptomatically if coughing is a persistent problem.
A. Butorphanol 0.05 to 0.1 mg/kg PO BID to TID (dogs)
B. Hydrocodone bitartrate 0.22 mg/kg PO SID to TID (dogs)
II. Granulomatous laryngitis is treated by excision of granulomatous masses and use of antiinflammatory doses of prednisone at 1 to 2 mg/kg PO SID.
III. Most cases of laryngeal trauma respond to conservative management.
A. A temporary tracheostomy is required if laryngeal inflammation and edema cause obstruction.
B. Systemic antibiotics are indicated with extensive local edema or subcutaneous emphysema.
C. Antiinflammatory medications, such as corticosteroids or nonsteroidal antiinflammatory drugs, may help reduce inflammation and speed resolution of edema.
D. Surgical reconstruction of the larynx is required if trauma causes loss of the structural integrity of the airway.
E. Occasionally a permanent tracheostomy is needed following severe laryngeal trauma.
IV. Animals with laryngeal edema, loss of structural integrity, or granulomatous masses are subject to airway obstruction, and their condition may become critical.
A. Supplemental oxygen delivered via a nasopharyngeal tube or oxygen cage is beneficial if airway obstruction is suspected.
B. Consider sedation if increased respiratory effort and signs of obstruction worsen.

Monitoring of Animal

I. Keep animals with laryngitis cool and in a calm and quiet environment.
II. Avoid excitement during handling.
III. Monitor body temperature, because obstruction to airflow limits the ability to cool through panting.
IV. Combat any hyperthermia because it causes increased respiratory effort with a relative worsening of airway obstruction (see Chapter 135).

Acquired Laryngeal Stenosis

J. David Fowler

Definition

Acquired laryngeal stenosis occurs secondary to restrictive laryngeal intraluminal scar formation.

Causes and Pathophysiology

I. Bilateral ventriculocordectomy (debarking)
  A. Excessive removal of vocal folds ventrally disrupts laryngeal mucosa across the midline.
  B. Denuded areas of mucosa heal by formation of granulation tissue and wound contraction.
  C. The glottic area is reduced in size as scar tissue forms and as arytenoid cartilages are pulled into the adducted position.
II. Laryngeal trauma with loss of structural integrity
III. Extensive inflammatory disease such as granulomatous laryngitis

Clinical Signs

I. Laryngeal stenosis causes a fixed laryngeal obstruction.
  A. Both inspiratory and expiratory dyspnea are present.
  B. Inspiratory effort is usually more severe.
  C. Inspiratory stridor is usually present.
  D. Expiratory noises are sometimes present.
II. Severity of dyspnea worsens as respiratory effort increases during exercise or heat stress.

Diagnosis

I. Laryngoscopy under general anesthesia is required for definitive diagnosis.
  A. Various sizes of endotracheal tubes should be available because intubation is often difficult and requires a relatively small-diameter tube.
  B. Be prepared for insertion of a temporary tracheostomy if intubation is unsuccessful (see Chapter 3).
  C. Preoxygenation via mask delivery of 100% oxygen for 5 minutes before anesthesia reduces the risk of hypoxia during induction.
II. Laryngoscopy reveals narrowing of the airway in the presence of fibrotic scar tissue.

Differential Diagnosis

I. Laryngeal paralysis
II. Laryngeal collapse
III. Laryngeal neoplasia
IV. Laryngeal foreign body

Treatment

I. Goals of treatment
  A. Resect proliferative granulation or fibrous tissue within the lumen of larynx.
  B. Establish an intact mucosal surface, especially across the midline.
    1. Elevate mucosal advancement flaps.
    2. Reappose mucosa using 4-0 or 5-0 synthetic absorbable suture material.
  C. Reconstruct or stabilize laryngeal cartilage if necessary.
II. Ventral laryngotomy: preferred approach for most cases
III. Transoral approach appropriate in some cases
  A. Recurrence rate is higher.
  B. Unsuccessful mucosal reconstruction is the reason for recurrence.

Monitoring of Animal

I. Systemic antibiotics are administered for 5 to 10 days after surgery, because the surgical field is contaminated.
II. Acute postoperative respiratory distress may occur with severe laryngeal mucosal edema.
  A. Administer prednisone 1 to 2 mg/kg PO SID to BID or dexamethasone 0.2 to 1.0 mg/kg SC BID to TID to reduce postoperative inflammation.
  B. Delicate tissue handling and hemostasis also help to reduce the risk of significant postoperative edema.
III. Recurrence of stenosis may arise from postoperative scar formation 6 to 12 weeks after surgery.
IV. Prognosis is good with precise reconstruction.

Nasopharyngeal Polyps

Ronald M. Bright

Definition

I. Inflammatory soft-tissue growth originating in the auditory tube or middle ear
II. May cause obstruction of nasopharynx and contribute to chronic otitis externa and media

Causes

I. Chronic inflammation of nasopharynx
II. Ascending infection of nasopharynx
III. Feline calicivirus
IV. Chronic otitis media or externa
V. Branchial arch remnant

Pathophysiology

I. Polyps may be single or multiple.
II. They can involve one or both auditory tubes.
III. They may grow to be 1 to 2 cm in diameter and develop on a stalk.
IV. They sometimes involve the nasopharynx and lie under the edge of the soft palate.

V. The opening of the larynx may become partially obstructed.
VI. The ear canal, middle ear (bulla), and nasopharynx can be involved singly or in combination (see Chapter 108).

Clinical Signs

I. Sneezing, inspiratory stridor
II. Serous or purulent nasal discharge: unilateral or bilateral
III. Otic discharge: usually unilateral
IV. Occasionally, dysphagia with large nasopharyngeal masses
V. Rarely, vestibular signs: head tilt, nystagmus

Diagnosis

I. History and clinical signs are often suspicious.
II. Physical examination findings include the following:
  A. Otic examination
    1. Otic discharge, ulceration
    2. Pedunculated smooth or nodular pink masses
    3. Possibly ruptured tympanic membrane
  B. Oral examination
    1. Distorted soft palate from presence of a mass
    2. Often requires retraction of soft palate to demonstrate mass(es)
  C. Radiography
    1. Increase in radiodensity of the bulla(e)
    2. Possible soft-tissue mass in pharyngeal region
    3. Possibly soft-tissue density within the horizontal ear canal

Differential Diagnosis

I. Laryngeal neoplasia
II. Foreign body
III. Tumor involving tissue of oro- or nasopharynx
IV. Chronic rhinitis or sinusitis
V. Otitis externa (see Chapter 107)

Treatment and Monitoring

I. Gentle traction is applied to the polyp until it is pulled free.
II. Incise soft palate to help access the polyp.
III. Regardless of whether there is radiographic evidence of a polyp in the bulla, a ventral bulla osteotomy is recommended on the side(s) involved.
  A. The surgery allows easier access to a mass located in the horizontal ear canal that has grown through the tympanic membrane.
  B. The mass can be pulled from the ear canal more easily after the surgeon releases it from its attachment in the bulla.
IV. Topical otic antibiotics are given for 5 to 7 days after a single dose of preoperative antibiotics.
V. Recurrence is less common if a ventral bulla osteotomy is done (Kapatkin et al., 1990).
VI. An antiinflammatory dose of dexamethasone 0.5 to 2.0 mg/kg IV, SC, or IM or prednisolone 1.5 to 2.0 mg/kg SC, IM is given postoperatively to decrease inflammation and edema secondary to surgery.

LARYNGEAL NEOPLASIA

J. David Fowler

Definition and Causes

I. All forms of laryngeal neoplasia are relatively uncommon in the dog and cat.
II. Canine tumors include the following (Carlisle et al., 1991):
  A. Laryngeal rhabdomyoma (oncocytoma)
    1. Benign tumor arising from striated muscle
    2. Most common in younger dogs; no apparent sex predilection
  B. Locally invasive malignant tumors with significant metastatic potential
    1. Squamous cell carcinoma
    2. Adenocarcinoma
    3. Fibrosarcoma
    4. Mast cell tumor
    5. Osteosarcoma and chondrosarcoma
III. Lymphoma is the most commonly reported feline laryngeal tumor, followed by squamous cell carcinoma.

Clinical Signs

I. Voice change, stridor
II. Dysphagia
III. Coughing
IV. Dyspnea

Diagnosis

I. Most laryngeal tumors are not palpable.
II. Radiography often reveals a mass lesion encroaching on the laryngeal lumen.
III. Definitive diagnosis requires laryngoscopy and histopathologic and/or cytological examination of biopsy specimens.
IV. Staging includes assessment of regional lymph nodes and lungs for possible metastasis and is indicated for suspected malignant disease.

Differential Diagnosis

I. Laryngeal paralysis
II. Laryngeal collapse
III. Granulomatous laryngitis
IV. Pharyngeal mucocele

Treatment

I. Local resection with preservation of laryngeal function is indicated for the treatment of rhabdomyoma.
II. Treatment of malignant laryngeal neoplasia varies with the tumor type.
  A. Radiation therapy is effective for local tumor control, particularly with lymphoma, squamous cell carcinoma, and mast cell tumor.
  B. Chemotherapy is indicated for the management of lymphoma, but its use and results for other tumor types are not well documented.
  C. Total laryngectomy with permanent tracheostomy can be considered, but is rarely performed in animals.

Monitoring of Animal

I. Respiratory function must be monitored closely after biopsy or surgical removal or during the course of chemotherapy or radiation therapy.
   A. Antiinflammatory doses of corticosteroids may help alleviate mucosal edema.
   B. Temporary or permanent tracheostomy is considered if respiratory embarrassment is severe.
II. Animals are monitored for local recurrence and metastatic disease every 2 to 3 months.
III. The prognosis associated with rhabdomyoma is favorable.
IV. Prognosis associated with malignant neoplasms is often guarded to poor, although outcome is poorly documented.

CHAPTER 16

Diseases of the Trachea

Lynelle R. Johnson

CONGENITAL DISORDERS

Hypoplastic Trachea

Definition

I. Tracheal hypoplasia is a congenital malformation that results in fixed narrowing of the tracheal lumen.
II. It can be segmental or may involve the entire tracheal length.
III. The ends of the tracheal rings meet or overlap rather than being C-shaped, and the dorsal tracheal membrane is typically short or absent.
IV. In some cases, the tracheal cartilages are V-shaped or triangulated.

Causes

I. A congenital or inherited lesion is proposed.
II. An increased incidence has been reported in the bulldog, Boston terrier, and boxer (Coyne and Fingland, 1992).
III. The disorder has also been reported in the Labrador retriever, German shepherd dog, Weimaraner, basset hound, and a litter of husky-mix dogs (Van Pelt, 1988).
IV. Males (2:1) are affected more often than females (Coyne and Fingland, 1992).

Pathophysiology

I. Narrowing of the tracheal lumen results in primarily inspiratory respiratory difficulty and a failure to clear respiratory secretions.
II. Although retained secretions can potentially predispose to recurrent respiratory infections, this has not been documented in retrospective studies.
III. Hypoplastic trachea is associated with an increased incidence of other congenital anomalies, including elongated soft palate, stenotic nares, cardiac defects (pulmonic or aortic stenosis), and megaesophagus.

Clinical Signs

I. Inspiratory difficulty
II. Stridorous sounds on inspiration
III. Coughing or gagging frequently noted
IV. Exercise intolerance from hypoventilation
V. Syncope related to hypoxia or cardiac defects
VI. Regurgitation, if megaesophagus also present
VII. Worsening of signs with excitement.

Diagnosis

I. History, signalment, and the presence of typical, clinical signs in a breed commonly affected by tracheal hypoplasia are suggestive of the diagnosis.
II. Physical examination can reveal some or all of the following findings.
  A. The trachea can feel narrow on palpation.
  B. High-pitched inspiratory sounds may be ausculted over the trachea related to turbulent airflow through the narrowed lumen.
  C. The opening of the nares must be compared to breed standards to detect stenosis.
  D. Thorough cardiac auscultation is necessary to detect concurrent congenital anomalies.
III. Radiographs of the chest establish the diagnosis.
  A. The cardinal finding is decreased tracheal diameter.
  B. Two methods may be used to evaluate tracheal diameter.
    1. The ratio of the tracheal lumen diameter (TD) at the thoracic inlet to the diameter of the thoracic inlet (TI) is calculated (Harvey and Fink, 1982).
      a. Tracheal hypoplasia is present if TD:TI is less than the normal value.
      b. The normal value for the bulldog is 0.127, for non-bulldog brachycephalic breeds is 0.160, and for nonbrachycephalic dogs is 0.204.
    2. The ratio of the TD halfway between the thoracic inlet and the carina to the width of the third rib (3R) is calculated (Suter, 1984).
      a. Normal is >3.0.
      b. Tracheal hypoplasia is present if TT:3R is <3.0.
  C. Radiographs are closely evaluated for evidence of pulmonic or aortic stenosis (see Chapter 8) and for megaesophagus (see Chapter 30), although echocardiography is needed to rule out the former conditions in a dog with a heart murmur.

Differential Diagnosis

I. Brachycephalic upper airway syndrome
II. Tracheal obstruction or neoplasia
III. Tracheal collapse
IV. Primary ciliary dyskinesia

Treatment

I. The severity of clinical signs is related to the presence of other disorders rather than the degree of reduction in tracheal diameter.
II. Concurrent respiratory or cardiac abnormalities associated with tracheal hypoplasia must be identified and managed.
   A. Upper airway abnormalities that can be surgically corrected (e.g., elongated soft palate, everted laryngeal saccules, stenotic nares) are managed early in life to reduce clinical signs.
   B. Respiratory infections must be controlled early in the course of disease.
   C. Management of obesity is strongly recommended.
   D. Judicious use of diuretics and vasodilators is indicated for treatment of congestive heart failure (see Chapter 9).

Monitoring of Animal

I. Many dogs with tracheal hypoplasia enjoy a good quality of life and can be maintained relatively free of clinical signs or respiratory distress; however, other animals are severely debilitated by disease.
II. No specific therapy is available to widen the tracheal lumen.
III. Hot and humid conditions adversely affect dogs with tracheal hypoplasia and should be avoided.
IV. Recheck examinations are advised at least yearly for early detection of complicating diseases.

DEGENERATIVE DISORDERS

Tracheal Collapse

Definition

I. Tracheal collapse is characterized by reduction in the luminal diameter of the cervical and/or intrathoracic trachea.
II. Flattening of the tracheal rings typically occurs dorsoventrally and leads to lengthening of the dorsal tracheal membrane.
III. Prolapse of the dorsal membrane into the tracheal lumen results in dynamic collapse.

Cause

I. The etiology is unknown; however, hypocellular cartilage has been detected histologically in some affected dogs.
II. Abnormal chondrocyte function with deficient production of the matrix components may result in altered integrity of the cartilage ring structure and a predisposition to collapse.
III. An increased incidence of disease is seen in small-breed dogs, such as the poodle, Yorkshire terrier, Pomeranian, and Chihuahua.
   A. Clinical signs are often seen at an early age, and it is possible that this disorder is congenital.
   B. Poor nutrition or metabolic influences may contribute to a failure of chondrogenesis and the development of abnormal cartilage metabolism in these breeds.

Pathophysiology

I. In normal animals, the trachea is a rigid but flexible structure and exhibits only minor changes in intraluminal diameter in response to pressure changes that occur during respiration.
   A. As the chest wall expands during inspiration, intrapleural pressure becomes increasingly negative.
   B. This pressure is translated across the airways and results in airflow from the glottis toward the alveolar region.
   C. On passive expiration, intrapleural pressure becomes less negative and air flows down the pressure gradient toward an equal pressure point near the thoracic inlet, where the transmural pressure difference is zero.
   D. In the normal dog, rigid cartilage within the airway walls prevents airway collapse within the thorax on expiration.
II. In some dogs with tracheal collapse, there is a deficiency in chondroitin sulfate and glycosaminoglycan in the cartilage ring structure of the trachea, which results in decreased water binding within the cartilage matrix and weakening of the tracheal cartilage (Dallman et al., 1988).
   A. Decreased rigidity in the cartilage matrix allows the cervical tracheal rings to flatten when negative pressure develops in the airway during inspiration.
   B. During forced expiration or coughing, intrathoracic pressures rise and exert positive pressure on airway walls, with collapse of the intrathoracic trachea on expiration.
III. Chronic intermittent airway obstruction results in respiratory distress and coughing, which perpetuate laryngeal, tracheal, and bronchial irritation (Done et al., 1976).
   A. Affected animals may suffer frequent, repeated episodes of respiratory distress or coughing before veterinary attention is sought.
   B. The presence of concurrent disorders, such as upper airway obstruction, chronic bronchitis, or cardiac failure, may produce serious clinical signs in a previously asymptomatic dog.
   C. Other trigger events include endotracheal intubation and respiratory infections.
   D. Obesity results in poor thoracic compliance and decreased diaphragmatic excursion, and the ability of the lung to expand on inspiration is diminished, which result in relative pulmonary atelectasis, abnormal pressure gradients along the airways, and an increased tendency toward airway collapse.
IV. Two sites of tracheal collapse have been described.
   A. Cervical (extrathoracic) tracheal collapse is characterized by signs of coughing or distress on inspiration, and upper airway obstruction from laryngeal paralysis, everted laryngeal saccules, or an elongated soft palate as the pressure drops across the upper airway.
   B. Intrathoracic tracheal collapse causes clinical signs on expiration when intrapleural pressure exceeds intraluminal airway pressure and results in airway collapse.
      1. Signs are generally more severe during forced expiration or coughing, and are enhanced by bronchitis or infection.

2. Collapse of the mainstem bronchi can occur with or without tracheal collapse.

C. Cervical and intrathoracic tracheal collapse can occur alone but are found concurrently in many dogs.

Clinical Signs

I. Long history of respiratory abnormalities
   A. Inspiratory difficulty with cervical collapse
   B. Worsened clinical signs on expiration with intrathoracic tracheal collapse or collapse of the mainstem bronchi
II. Paroxysms of coughing, classically described as a "goose honk" cough
III. Signs elicited by excitement, pressure exerted on the trachea, high heat or humidity, and eating or drinking
IV. Coughing followed by retching
V. Respiratory distress, exercise intolerance, cyanosis, and syncope in severe cases

Diagnosis

I. Signalment and clinical signs are often very suggestive of the diagnosis.
II. The following may be noted on physical examination:
   A. Affected dogs are often obese, and hepatomegaly of undetermined etiology may be present.
   B. The animal may appear normal at rest; however, excitement often induces a honking cough, airway obstruction, or respiratory distress.
   C. Marked tracheal sensitivity is typical, and even gentle palpation can precipitate a medical crisis.
   D. When the cervical trachea is severely flattened, the free edges of the cartilage rings can be palpated along their lateral aspect.
   E. Tracheal auscultation reveals musical inspiratory noises with cervical collapse.
      1. Specific attention must be paid to laryngeal auscultation.
      2. Stridor on inspiration is suggestive of concurrent laryngeal paralysis, which has been reported in 14% to 30% of dogs with tracheal collapse (Buback et al., 1996; Tangner and Hobson, 1982).
   F. Intrathoracic tracheal collapse is characterized by respiratory difficulties on expiration, with an end-expiratory snap sometimes heard over the thoracic cage.
   G. Wheezes or harsh crackles suggest the presence of concurrent bronchitis.
   H. Cardiac auscultation often reveals the presence of coexisting mitral valve insufficiency.
      1. Congestive heart failure may or may not be present.
      2. The presence of a right-sided heart murmur, gallop rhythm, or a split-second heart sound indicates that pulmonary hypertension may have developed as a complicating factor.
III. Lateral thoracic radiographs are taken on full inspiration and on expiration to detect the dynamic nature of cervical and intrathoracic tracheal collapse.
   A. The cervical trachea may be collapsed on inspiration or "balloon" open on expiration.
   B. The intrathoracic trachea collapses on expiration and may "balloon" open at the carina on inspiration.
   C. Normal static films do *not* rule out the diagnosis of tracheal collapse.
   D. Fluoroscopy is useful in suspected cases of tracheal collapse that have normal chest radiographs.
   E. When fluoroscopy is unavailable, obtaining radiographs during a cough can aid in the detection of collapsing airways.
   F. Cervical tracheal collapse also can be detected with ultrasonography; however, a high level of expertise is required because of the difficulty in delineating structures at the air-tissue interface (Rudorf et al., 1997).
IV. Both lateral and ventrodorsal thoracic radiographs are closely evaluated to identify concurrent pulmonary disease or cardiac failure.
   A. Obesity confuses interpretation of pulmonary infiltrates and can lead to artifactual enlargement of the cardiac silhouette.
   B. The degree of obesity can be demonstrated by measuring the thickness of the fat pad between the ribs and the skin on the ventrodorsal radiograph.
V. Confirmation of tracheal collapse and identification of underlying infectious or inflammatory airway disease are best achieved through bronchoscopy.
   A. Bronchoscopy can be used to obtain respiratory samples and to visualize dynamic airway changes.
   B. The grade, extent, and severity of tracheobronchial collapse can be definitively documented.
   C. Airway sampling is recommended to identify underlying pulmonary infection or inflammation.
   D. If a tracheal wash is performed, a transoral approach using a small-diameter endotracheal tube is recommended rather than a transtracheal technique in order to diminish tracheal trauma.
VI. Perform cytologic analysis and cultures for bacteria and *Mycoplasma* spp.
   A. Oropharyngeal contamination is indicated by the presence of squamous cells or *Simonsiella* spp. bacteria.
   B. The trachea is not a sterile environment (McKiernan and Smith, 1982).
   C. Positive qualitative cultures may be found in most dogs with tracheal collapse and must be interpreted in light of clinical and cytologic findings.
   D. True bacterial infection is supported by septic, suppurative inflammation on cytology and positive bacterial cultures.
   E. Quantitative bacterial cultures may be required for definitive diagnosis of lower respiratory tract infection.
VII. When either a tracheal wash or bronchoscopy is performed, upper airway structure and function should be evaluated at the beginning of the procedure to rule out laryngeal paresis or paralysis.

Differential Diagnosis

I. Infectious tracheobronchitis
II. Tracheal obstruction

III. Chronic bronchitis
IV. Congestive heart failure

Treatment

I. Treatment of coexisting medical and respiratory problems is essential.
II. Dogs that have upper airway abnormalities, such as laryngeal paralysis or everted laryngeal saccules, may become less symptomatic for tracheal collapse when these obstructive disorders are corrected surgically.
III. Dogs with bronchitis require treatment of their primary airway disease, generally with corticosteroids (see Chapter 17).
IV. Dogs with marked epithelial injury from tracheal irritation may require a short course of corticosteroids (5 to 7 days of a tapering dose) to reduce inflammation.
V. Inhaled steroids can be used to reduce tracheal or bronchial inflammation and are associated with fewer side effects.
   A. Administer fluticasone propionate (110 μg/puff) at a dose of 1 puff BID to QID, ensuring that the dog takes 8 to 10 breaths and does not pant.
   B. Administer via a spacing chamber and face mask.
VI. Bronchodilators can result in some reduction in clinical signs in dogs with intrathoracic airway collapse by dilating small airways and reducing the pressure gradient within intrathoracic airways.
   A. Extended-release theophylline 10 mg/kg PO BID
   B. Terbutaline 1.25 to 2.5 mg PO BID to TID
   C. Albuterol 50 μg/kg PO BID to TID
VII. Antibiotics are warranted when infection is documented by cytology and culture results.
VIII. Cough suppressants are used to reduce mechanical irritation of the tracheal epithelium when infectious or inflammatory processes have been adequately treated.
   A. The severity of cough in dogs with tracheal collapse may require the use of narcotic agents.
   B. Give butorphanol 0.5 to 1.0 mg/kg PO BID to QID or hydrocodone 0.22 mg/kg PO every 4 to 8 hours, as needed.
IX. Obese animals are started on a gradual weight loss program of regular exercise combined with a low-fat diet.
X. During leash walking, the use of a harness is encouraged to avoid mechanical irritation to the trachea.
XI. Dogs with tracheal collapse are susceptible to worsening of clinical signs when exposed to heat and humidity, so avoid these elements.
XII. Excessive excitement and stress must also be avoided; judicious use of tranquilizers may be considered.
XIII. Use of intratracheal stents has shown promise in the short-term management of dogs with life-threatening tracheal collapse (Moritz et al., 2004).
   A. Migration of the stent may worsen coughing, and the development of granulomatous lesions can limit their use.
   B. Dorsoventral collapse of stents has also been reported (Radlinsky et al., 1997).
XIV. Surgical placement of external ring prostheses can be used in animals with cervical tracheal collapse that fail to respond to medical management, although controversy exists on the role of surgery in the management of tracheal collapse (White and Williams, 1994).
   A. Placement of tracheal ring prostheses is technically demanding.
   B. In one study, laryngeal paralysis occurred postoperatively in 19% and necessitated a permanent tracheostomy or arytenoid lateralization (Buback et al., 1996; White 1995).
   C. Although a relatively high rate of both immediate and long-term complications such as continued coughing and respiratory distress occur after surgery, these conditions are usually manageable and acceptable to owners.
   D. Most animals that have undergone surgical intervention have an improved quality of life and reduction in clinical signs.
   E. Young dogs that undergo surgery may have a better prognosis than older dogs.

Monitoring of Animal

I. Dogs with tracheal collapse have variable clinical signs throughout their entire life, and some coughing will always be present.
II. It is likely that collapse of the lower airways can progress in severity.
III. For dogs that are managed surgically, inform owners that the duration of benefit from surgery varies.
IV. Counsel owners regarding risk factors that exacerbate disease and the need for follow-up examinations.
V. Concurrent diseases and/or obesity require rigorous monitoring.

INFLAMMATORY DISORDERS

Infectious Tracheobronchitis

Definition and Causes

I. Tracheitis is characterized by inflammation of the epithelial lining of the trachea and is typically associated with erosion of the mucosal surface, goblet cell hyperplasia, mucus accumulation, and disruption of the mucociliary clearance apparatus.
II. Viral agents (e.g., parainfluenza virus, canine adenovirus, canine distemper virus) infect respiratory epithelial cells.
III. Viral damage to the epithelium predisposes the animal to secondary infection with bacteria, primarily *Bordetella* spp. or *Mycoplasma* spp. (see also Chapter 114).
IV. The highly contagious nature of the disease leads to rapid spread among susceptible animals, with clinical signs seen 2 to 10 days postexposure.
V. Neonates and immune-compromised animals are susceptible to *Bordetella* spp. or *Mycoplasma pneumoniae.*

Clinical Signs

I. Sudden development of a dry, paroxysmal, "seal bark" cough
II. Absence of systemic signs of illness
III. Coughing easily elicited by tracheal manipulation

Diagnosis

I. Diagnosis is often based on the history of exposure to a potential carrier and on detection of the typical clinical signs in an otherwise healthy animal.
II. The primary physical examination finding is marked tracheal sensitivity.
  A. Lung sounds are normal in uncomplicated cases.
  B. Fever, anorexia, lethargy, or nasoocular discharge are indicators of systemic disease.
III. A complete diagnostic work-up is reserved for animals with systemic illness.
IV. A complete blood count may reveal the following:
  A. Lymphopenia suggests a viral etiology but is only present early in the course of disease.
  B. Neutrophilia can indicate the presence of concurrent bacterial infection, especially bronchopneumonia.
V. Thoracic radiographs are often normal.
  A. A generalized interstitial pattern is compatible with viral pneumonia.
  B. The presence of an alveolar infiltrate is suggestive of secondary bacterial pneumonia.
VI. In complicated cases, a transoral tracheal wash is performed for cytological analysis, bacterial and *Mycoplasma* spp. cultures, and antibiotic sensitivity testing.

Differential Diagnosis

I. Tracheal collapse
II. Tracheal obstruction
III. Pneumonia
IV. Acute bronchitis
V. Parasitic bronchitis or pneumonia
VI. Tracheal irritation

Treatment

I. Supportive care measures such as maintaining a warm, draft-free environment, ensuring adequate systemic hydration, and providing good nutritional support are implemented.
II. Antibiotics are indicated for treatment of secondary infection.
  A. Local antimicrobial therapy with an aminoglycosides is most likely to reduce bacterial numbers.
  B. Nebulization or intratracheal injection of gentamicin (3 to 5 mg/kg SID for 5 days) can reduce the number of bacteria present in the trachea and enhance clearance of the organism from the airway surface (Bemis and Appel, 1977).
  C. Systemic antibiotics may have limited efficacy against *Bordetella* spp. infection because this organism resides on the surface of airway epithelial cells and does not penetrate cells.
  D. Antibiotics with in vitro efficacy against *Bordetella* spp. and *Mycoplasma* spp. are possibly indicated for 7 to 10 days to reduce the spread of bacteria.
    1. Doxycycline 3 to 5 mg/kg PO BID; may stain teeth of young animals
    2. Amoxicillin-clavulanic acid 10 to 15 mg/kg PO BID; no efficacy against *Mycoplasma* spp.
    3. Enrofloxacin 2.5 to 5.0 mg/kg PO SID; possible cartilage deformation in young animals (Speakman et al., 2000)
III. Judicious use of antitussives is indicated after infection is cleared.
  A. Narcotic antitussives are often required.
  B. If antitussives are used too early, they can encourage development of pneumonia from trapping of bacteria in the lower airways.
IV. Owners are instructed to avoid use of a collar to reduce direct tracheal irritation.
V. Isolation of infected animals is recommended, humidity in the environment is reduced, and adequate ventilation is ensured.

Monitoring of Animal

I. Infectious tracheobronchitis is generally a self-limiting disease, with signs resolving within 7 to 10 days.
II. Contact with other dogs must be discouraged given the highly infectious nature of the disease.
III. Bleach can be used to disinfect the area contaminated by an infected dog (see Chapter 114).
IV. Use of a parenteral or intranasal vaccine against *Bordetella bronchiseptica* reduces the severity of infection in susceptible animals, and sequential administration of both types of vaccines may provide the highest level of protection (Ellis et al., 2001).

Parasitic Tracheitis

Definition and Causes

I. *Oslerus osleri* is a nematode parasite that resides beneath the epithelium of the carina and major bronchi in dogs.
II. The parasite has a worldwide distribution, is responsible for disease in both wild and domestic canids, and more commonly infects younger animals.

Pathophysiology

I. Transmission from bitch to offspring is believed to occur primarily through grooming activity or possibly regurgitant feeding.
II. Direct, horizontal transmission has been demonstrated experimentally (Lappin and Prestwood, 1988) but is unlikely to occur in the natural setting.
III. Infection occurs through ingestion of first-stage (L1) larvae that migrate from the intestine to the right heart and then to the tracheal wall during a 10- to 21-week prepatent period.
IV. Adult parasites live in nodules within the larger airways, often at the carina, which irritates the trachea and causes coughing.
V. Eggs and infective L1 larval stages are coughed up, swallowed, and shed intermittently in the feces.

Clinical Signs

I. Chronic, dry cough unresponsive to antibiotic therapy
II. Inspiratory respiratory distress, anorexia, and exercise intolerance

Diagnosis

I. Physical examination findings are often nonspecific, and increased tracheal sensitivity is usually present.
II. Fecal examination using the Baermann technique or zinc sulfate flotation is performed to detect first stage larvae; however, samples are often falsely negative owing to intermittent shedding.
III. Tracheal nodules associated with *O. osleri* are occasionally visible on radiographs.
IV. Bronchoscopy allows visualization of nodules at the carina, and biopsy can be performed for definitive diagnosis.
V. Transtracheal wash or bronchoalveolar lavage cytology or tracheal swabs may reveal larvae or eggs.
VI. Eosinophilia is variably present on a complete blood count or on cytology of airway washes.

Differential Diagnosis

I. Chronic bronchitis
II. Parasitic pneumonia or lungworm infection
III. Infectious or irritant tracheobronchitis
IV. Tracheal collapse

Treatment

I. No single therapy has proven efficacious for eradication of *O. osleri*, and combinations of drugs may be required for resolution of disease.
   A. Ivermectin 200 to 400 µg/kg PO or SC once weekly in breeds not susceptible to ivermectin toxicity (Outerbridge and Taylor, 1998)
   B. Fenbendazole 50 mg/kg/day PO for 10 to 30 days
   C. Thiabendazole 32 to 140 mg/kg/day PO for 10 to 23 days
II. Horizontal transmission in a kennel situation is unlikely; however, routine cleaning and hygienic maintenance are recommended.
III. Removal of infected bitches from a breeding colony reduces the incidence of disease in the offspring.

Monitoring of Animal

I. Resolution of clinical signs is the easiest method for following response to therapy, although it does not confirm the efficacy of treatment.
II. Fecal examinations are unreliable given the intermittent shedding of larvae.
III. Use radiographs to follow resolution of tracheal nodules if they were visualized on initial films.
IV. Use bronchoscopy to follow regression of intraluminal nodules with therapy.

Irritant Tracheitis

Definition and Causes

I. Tracheal irritation results from direct trauma to the cervical region, inhalation of noxious fumes, use of an overly large endotracheal tube, overdistension of an endotracheal tube cuff, or as a chronic sequela to bronchial or pulmonary disease.
II. Direct epithelial injury increases mucus production and stimulates a cough.
III. Chronic cough then results in a cycle of epithelial erosion and desquamation, increased mucus production, and trapping of secretions that perpetuate tracheal inflammation.

Clinical Signs

I. Chronic, nonproductive cough and increased tracheal sensitivity
II. Facial burns associated with smoke inhalation or cervical swelling related to choke chain trauma (see Chapter 133)

Diagnosis

I. History of smoke inhalation, recent endotracheal intubation, or recent pulmonary disease increases the suspicion of this disorder.
II. Other causes of cough must be dismissed.
III. Bronchoscopic evaluation of the airway shows irritations, hypervascularity of mucosa, increased mucus, and hemorrhage in the trachea.

Differential Diagnosis

I. Infectious tracheobronchitis
II. Tracheal collapse
III. Parasitic tracheobronchitis

Treatment

I. Eliminate environmental features, such as excessive smoke or noxious fumes.
II. Antitussives are used to decrease chronic irritation associated with coughing, but infectious diseases must be ruled out first.
III. Prednisone 0.5 mg/kg/day PO for 2 to 5 days can help alleviate tracheitis.
IV. Alternately, inhaled steroids can be used (see Tracheal Collapse).

Monitoring of Animal

I. Use of a harness may facilitate resolution of clinical signs by decreasing pressure on the trachea.
II. Cases with severe inflammation may be monitored with repeated bronchoscopy.
III. Severely affected cases are at risk for developing tracheal stenosis.
IV. Tracheal necrosis can also occur resulting in air leakage into the subcutaneous space.

TRACHEAL OBSTRUCTION

Definition and Causes

I. Tracheal obstruction results from narrowing of the tracheal lumen by internal obstruction, stenosis, or by external compression.
II. Foreign bodies that may cause airway obstruction include grass awns, tree needles, teeth, or dental tartar.
III. Intratracheal mass lesions can be caused by neoplasia, abscess formation, and parasitic or fungal granulomas.

IV. Tracheal stenosis can result from a congenital deformation, but more commonly occurs secondary to trauma (e.g., endotracheal intubation, automobile crash, tracheostomy, penetrating injury).
V. Extraluminal obstruction of the trachea can result from an esophageal mass or diverticulum, megaesophagus, thyroid cyst, lymphadenopathy, or from a mediastinal mass, abscess, or hemorrhage.
VI. Tracheal narrowing results in increased resistance to airflow, mechanical irritation of the trachea, stimulation of cough receptors, and increased susceptibility to airway infection.

Clinical Signs

I. Acute or chronic cough, with or without hemoptysis
II. Acute or progressive respiratory distress, panting
III. Anxiety, pawing at the face
IV. Dysphagia, halitosis
V. Exercise intolerance

Diagnosis

I. History of vomiting, intubation, or trauma raises the suspicion of a tracheal foreign body or obstruction.
II. Physical examination often reveals increased tracheal sensitivity.
   A. High-pitched, musical sounds can be heard over the trachea when the lumen is narrowed by an obstruction or increased secretions.
   B. Stridor may be detected in animals with high cervical tracheal obstruction.
   C. A cervical mass or esophageal enlargement may result in palpable thickening of the neck region.
III. Radiographs may reveal a radiodense foreign body or soft-tissue mass within the tracheal lumen, a focal narrowing of the tracheal air column (stenotic lesion), or an external mass impinging on the tracheal lumen.
IV. Use bronchoscopy to confirm the diagnosis of an intraluminal mass or foreign body, stenotic lesion, or extraluminal obstruction.

Differential Diagnosis

I. Tracheal collapse
II. Infectious tracheobronchitis
III. Tracheal hypoplasia
IV. Parasitic tracheitis
V. Feline bronchial disease

Treatment

I. Tracheal foreign bodies are best removed via bronchoscopy when possible.
   A. Infection with *Nocardia* spp. may be associated with foreign bodies (Lotti and Niebauer, 1992).
   B. Both aerobic and anaerobic bacterial cultures are performed, as *Actinomyces* spp. or anaerobes can be found.
II. Bougienage, balloon dilatation, or laser resection can be attempted for tracheal stenosis.
   A. The inflammatory response generated by the procedure can lead to rapid reformation of the stricture.
   B. The risk of tracheal laceration leading to pneumomediastinum or subcutaneous emphysema must be considered.
III. Tracheal stenosis usually requires surgical resection and anastomosis, with lesions involving <8 to 10 tracheal rings being resected without excessive stress on the incision site.
IV. Extraluminal compressive lesions are best evaluated by computed tomography, followed by surgical exploration of the region.

Monitoring of Animal

I. Recurrent hemoptysis, pneumonia, and chronic coughing are indications that either a foreign body or infection persists.
II. After tracheal resection and anastomosis, cough suppressants are used to reduce irritation of the tracheal mucosa.
III. Harness-style restraints can also be used to restrict excessive neck motion and reduce tension at the anastomotic site.

NEOPLASIA

Definition and Causes

I. Neoplasia results from uncontrolled overgrowth of abnormal epithelial or mesenchymal cells within the airways.
II. Adenocarcinoma, lymphosarcoma, squamous cell carcinoma, melanoma, plasmacytoma, and chondrosarcoma occur in the dog and cat (Carlisle et al., 1991).
III. Osteochondroma is the most common tracheal tumor and is usually found in young dogs (Carlisle et al., 1991).
IV. Mass lesions within the trachea cause upper airway obstruction or respiratory distress from narrowing of the tracheal lumen and increased resistance to air flow.

Clinical Signs

I. Inspiratory difficulty or respiratory distress, panting, or abnormal respiratory movements
II. Exercise intolerance
III. Coughing
IV. Increased inspiratory noises
V. Cyanosis, syncope
VI. Systemic signs often absent

Diagnosis

I. Physical examination often reveals abnormal respiratory sounds.
   A. Musical or wheezing noises can be heard over the trachea.
   B. Increased tracheal sensitivity may also be present.
II. Radiographs may show an intraluminal mass lesion.
III. Bronchoscopy often allows visualization and biopsy of the mass; occasionally, resection or debulking can be performed.

Differential Diagnosis

I. Tracheal collapse
II. Tracheal obstruction: foreign body, granuloma, *O. osleri*
III. Laryngeal paralysis

IV. Congestive heart failure
V. Chronic bronchitis
VI. Pulmonary hypertension

Treatment

I. Prepare for an emergency tracheotomy in any case in which neoplasia of the cervical trachea is suspected.
II. Mass removal via bronchoscopy may be possible when the mass is attached to the mucosa by a pedunculated stalk.
III. Tracheal resection and anastomosis can be curative in some cases with only local disease.
IV. Involvement of >8 to 10 tracheal rings may prohibit surgical treatment because of the risk of excessive tension on the suture line after anastomosis.
V. Aggressive neoplasms often require subsequent chemotherapy or radiation therapy.
   A. Lymphoma involving the trachea often responds to standard chemotherapy regimens.
   B. Palliation of clinical signs may be achieved through a permanent tracheostomy distal to the tumor, with radiation therapy and/or chemotherapy.

Monitoring of Animal

I. Closely monitor the animal for signs of metastasis and local recurrence through bimonthly radiographs.
II. Osteochondromas are associated with an excellent prognosis when the tumor can be fully resected.
III. Response to therapy is variable for malignant neoplasms affecting the trachea.

TRAUMA

Definition and Causes

I. Tracheal trauma usually results from penetrating neck injuries, bite wounds, gun shot wounds, or from an automobile accident.
II. Iatrogenic trauma most commonly occurs with overinflation of an endotracheal tube cuff.
III. In cats, 1.6 ± 0.7 mL of air sufficiently inflates the cuff of most endotracheal tubes (Hardy et al., 1999).
IV. Use of excessive force during endotracheal intubation or application of high intrapulmonary pressures during anesthesia or ventilator therapy can lead to tracheal injury or rupture.
V. Breakdown of a tracheotomy or tracheostomy site results in clinical signs similar to those found with penetrating injuries to the trachea.

Pathophysiology

I. Damage to the tracheal cartilage or annular ligament allows leakage of air into the fascial planes of the cervical region with each inspiration.
II. In cats the most common lesion is a linear tear in the dorsal trachealis muscle near the thoracic inlet or in the thoracic trachea (Hardy et al., 1999).
III. Excessive air accumulation within the neck region may compress the trachea.
IV. Decreased flow of oxygen into the lung results in alveolar hypoventilation and respiratory embarrassment.

Clinical Signs

I. May be delayed with tracheal necrosis
II. Subcutaneous emphysema
III. Inspiratory dyspnea, tachypnea, and occasionally cyanosis

Diagnosis

I. History of a predisposing event increases the probability of tracheal trauma, even if the onset of signs is delayed.
II. In cats, tracheal injury occurs most commonly after dental procedures (Hardy et al., 1999).
III. Physical examination may reveal the following:
   A. Subcutaneous emphysema usually originates in the neck region but may extend across the entire body.
   B. Bite wounds, lacerations, or other evidence of trauma may be found in the cervical region.
IV. Radiographs may show subcutaneous air accumulation in the cervical region, pneumomediastinum, or potentially, pneumothorax.
V. Tracheoscopy can locate tracheal lacerations in some cases.

Differential Diagnosis

I. Infection with gas producing bacteria
II. Other causes of tracheal stenosis and obstruction

Treatment

I. Conservative management is usually successful when signs are mild, such as in cases of blunt trauma without tracheal or airway penetration.
   A. Bandage the wound securely to prevent additional air leakage without restricting respiratory effort or venous return.
   B. Provide an oxygen-enriched environment to reduce respiratory distress and alleviate hypoxemia.
   C. Forced cage rest is important.
II. If significant respiratory distress develops because of severe subcutaneous emphysema, place 18- to 20-gauge needles under the skin to expel air from the subcutaneous space and relieve external compression of the airway.
III. Surgical treatment is required in severely affected cases to prevent further leakage of air into the subcutaneous space and to stabilize respiration.
   A. Surgical debridement and meticulous closure of tracheal rents are indicated in cases refractory to conservative therapy.
   B. Tracheal resection and anastomosis may be required in cases with substantial tracheal damage.

Monitoring of Animal

I. Subcutaneous air accumulation resolves within 7 to 10 days in uncomplicated cases, although it may persist for up to 6 weeks.
II. Closely monitor for complications related to laryngeal damage or paralysis, as well as esophageal injury.
III. Tracheal stenosis or stricture can occur weeks to months later.

CHAPTER 17

Diseases of the Lower Airway

Astrid Nielssen | Susan M. Taylor

CONGENITAL DISORDERS

Primary Ciliary Dyskinesia

Definition

I. Primary ciliary dyskinesia is a heterogenous group of disorders causing congenital ciliary dysmotility or immotility associated with ultrastructural defect in ciliary axonemes.
II. The absence of normally functioning cilia can result in rhinitis, sinusitis, bronchitis, bronchiectasis, otitis media, hydrocephalus, dilatation of renal tubules, and infertility.
III. Kartagener's syndrome is a subsidiary disorder defined by the presence of partial or complete situs inversus, rhinosinusitis, and bronchiectasis.

Causes

I. Primary ciliary dyskinesia has an autosomal recessive inheritance pattern in dogs.
   A. It has been identified in the English springer spaniel, English pointer, Old English sheepdog, golden retriever, bichon frisé, border collie, bull mastiff, Chihuahua, chow chow, cocker spaniels, Dalmatians, Doberman pinscher, English setter, Irish wolfhound, miniature poodle, Newfoundland, rottweiler, Staffordshire terrier, and Chinese shar-pei.
   B. It is rarely reported in cats.
II. Acquired structural and functional disorders of cilia may also arise secondary to respiratory disorders, such as viral, bacterial, and mycoplasmal infections; inflammatory conditions; and exposure to inhaled toxins (e.g., smoke).
III. Acquired abnormalities are distinguished from primary inherited ciliary dyskinesia by ciliogenesis and the type of ultrastructural defects identified (Clercx et al., 2000).

Pathophysiology

I. Defects in the respiratory cilia of dogs with primary disease include dynein arm deficiency, abnormal microtubular patterns, absent radial spokes, and absence of central tubules.
   A. Defects with secondary disorders include peripheral microtubular abnormalities, partial dynein arm deficiency, and shortening of the dynein arms.
   B. With secondary disease, a much lower percentage of cells (<20%) are affected compared to primary dyskinesia.
II. Normal mucociliary transport in the airways requires coordinated beating of respiratory cilia and, without this normal defense mechanism, the upper and lower respiratory tracts become congested with mucus and are highly susceptible to infection.
III. Ciliary defects also result in signs of disease outside of the respiratory tract.
   A. In the auditory tube, impaired mucociliary clearance results in the accumulation of secretions and fluid within the middle ear, potentially resulting in a sterile, serous otitis media.
   B. Defective spermatozoal flagellum in the male and oviductal cilia in the female often causes impaired fertility.
   C. Hydrocephalus may arise from impaired cerebrospinal fluid circulation owing to dysfunctional ependymal cilia or early mycoplasmal infection (Daniel et al., 1995).
   D. Other abnormalities of uncertain origin also may be noted in dogs with primary disorders.
      1. Situs inversus (Edwards et al., 1992; Supp et al., 1997)
      2. Malformations of the axial skeleton, renal cortical fibrosis, cystic distal renal tubules, cleft palate, elongated soft palate, and corneal opacities
      3. Cardiac defects (Reichler et al., 2001)

Clinical Signs

I. Signs may develop any time from the neonatal period to the geriatric years, depending on the severity of the dyskinesia.
II. Initial signs include chronic mucoid or mucopurulent nasal discharge, sneezing, and coughing.
   A. The cough is typically productive and is easily elicited with tracheal palpation.
   B. Auscultation may reveal increased lung sounds over all lung fields.
   C. Respiratory distress (tachypnea, dyspnea, cyanosis) can occur in severely affected animals.

Diagnosis

I. A complete blood count often reveals a mature neutrophilia and lymphocytosis.
   A. Lymphocytosis is helpful in differentiating primary ciliary dyskinesia from canine distemper.
   B. Canine distemper typically causes lymphopenia.

II. Chronically ill animals may be hyperglobulinemic.
III. Arterial blood gas analysis may reveal hypoxemia and normo- or hypocapnia.
IV. Thoracic radiography may reveal bronchitis, bronchiectasis, consolidating pneumonia, and situs inversus.
V. Fluid from airway washes commonly grows one or more organisms, so aerobic, anaerobic, and mycoplasmal cultures are indicated.
VI. Nuclear scintigraphy reveals impaired nasal or tracheal mucociliary clearance (Edwards et al., 1992).
   A. Normal beagles have a tracheal clearance velocity of 8.83 + 3.3 mm/min (Whaley et al., 1987).
   B. With primary dyskinesia, tracheal clearance velocity is often 0 mm/min.
VII. Definitive diagnosis of primary ciliary dyskinesia requires electron microscopic analysis of nasal or other respiratory epithelium, or spermatozoa, to assess for the presence and extent of ciliary structural abnormalities (Edwards et al., 1992).
VIII. Functional ultrastructural analysis of ciliary beat frequency and synchrony are also helpful.
IX. Ciliogenesis identifies persistent primary defects and confirms the resolution of secondary defects.

Differential Diagnosis

I. Acquired respiratory tract diseases: bronchopneumonia, chronic bronchitis
II. Immunodeficiency syndromes: immunoglobulin A deficiency

Treatment

I. Treatment is directed at controlling infection through long-term, and sometimes lifelong, administration of broad-spectrum antibiotics (ideally chosen from culture of appropriate samples).
II. Improved clearance of respiratory secretions is promoted via airway humidification and chest coupage.
III. Cough suppressants are contraindicated.
IV. Do not breed close relatives of affected dogs in order to prevent genetic transmission of the disorder.

Monitoring of Animal

I. Evaluate response to therapy by periodically assessing clinical signs and thoracic radiography.
II. Mildly affected animals may do well with appropriate therapy.

DEGENERATIVE DISORDERS

Bronchiectasis

Definition

I. Irreversible dilatation of distal airways caused by chronic inflammation and damage to bronchial walls
II. Associated with pooling and poor clearance of airway secretions
III. Focal or diffuse disorder

Causes

I. Bronchiectasis arises secondary to a variety of congenital or acquired diseases.
II. Congenital conditions include primary ciliary dyskinesia or immotile cilia syndrome (most common) and bronchial dysgenesis (Edwards et al., 1992; Hoover et al., 1989; Killingsworth et al., 1987; LaRue et al., 1990).
III. Acquired conditions include chronic bronchitis and bronchopneumonia, obstructive airway disease, and neoplasia.

Pathophysiology

I. Primary airway disease results in the destruction of respiratory epithelium and cilia within the bronchioles.
II. Pooling of airway secretions and impaired mucociliary clearance predisposes to infection.
III. Inflammation leads to further bronchial wall destruction.
IV. Destruction of tissues supporting the airways allows for the distracting forces from the surrounding lung tissue to be unopposed, resulting in irreversible airway dilatation.

Clinical Signs

I. Dogs are more frequently affected than cats.
II. Older male cats may have a higher incidence of this disorder in comparison to the general feline population.
III. The American cocker spaniel, West Highland white terrier, miniature poodle, Siberian husky, English springer spaniel, and dogs >10 years of age have an increased risk for the disorder.
IV. Animals suffering from congenital disorders develop bronchiectasis at a young age.
V. Animals developing bronchiectasis secondary to chronic acquired airway disease are usually middle-aged or older.
VI. The most common clinical sign in dogs is a chronic productive cough, with or without increased respiratory effort.
VII. Hemoptysis may occur.
VIII. As many as 50% of affected cats may be asymptomatic, while others exhibit signs of lower respiratory tract disease (Norris and Samii, 2000).
IX. Auscultation reveals the presence of moist crackles and expiratory wheezes associated with increased effort.

Diagnosis

I. Symptoms and physical findings localize the disease to the lower respiratory tract.
II. The hemogram may be normal or may reveal a mature neutrophilia and monocytosis.
III. Hyperglobulinemia is common from chronic immune stimulation.
IV. Proteinuria may occur in association with reactive amyloidosis.
V. Thoracic radiography is considered an insensitive test, but classic findings may be present.
   A. Large bronchial lumen
   B. Visualization of large airway into the lung periphery
   C. Thickened bronchial walls
   D. Localized pulmonary consolidation, associated with an alveolar pattern

E. Possibly mixed bronchiolar, interstitial, and alveolar patterns

VI. Blood gas analysis reveals hypoxemia and an increased alveolar-arterial oxygen gradient.

VII. The most clinically useful tool for identifying bronchiectasis in affected dogs and cats is bronchoscopy.
   A. Bronchoscopy often reveals dilatation of small airways, increased airway secretions, and hyperemia of the respiratory mucosa.
   B. Bronchoalveolar wash samples often show suppurative inflammation.
   C. Aerobic and anaerobic cultures are indicated and frequently identify the presence of opportunistic infections.

VIII. Specialized tests may be needed to confirm the diagnosis of primary ciliary dyskinesia.

Differential Diagnosis

I. Chronic bronchitis without bronchiectasis
II. Bronchopneumonia without bronchiectasis
III. Emphysema
IV. Cystic or bullous lung disease

Treatment

I. Hospitalize and aggressively treat severely affected animals.
   A. Intravenous fluid therapy
   B. Parenteral broad-spectrum antibiotics
      1. Base antibiotic choice on results of culture and sensitivity testing.
      2. Long-term antibiotic therapy is indicated, even if culture results are negative, for at least 6 to 12 weeks, and permanently in some cases.
      3. If no culture and sensitivity results are available, use an antibiotic with good pulmonary tissue penetration, such as the following:
         a. Doxycycline 5 to 10 mg/kg PO SID
         b. Clindamycin 10 mg/kg PO BID
         c. Chloramphenicol 25 to 50 mg/kg PO TID (dogs)
   C. Bronchodilators
      1. Aminophylline 11 mg/kg IV, PO TID in dogs and 6.6 mg/kg PO BID in cats
      2. Theophylline
         a. Theo-Dur tablets: 20 mg/kg PO BID in dogs and 20 mg/kg PO SID in the evening in cats
         b. Slo-Bid Gyrocaps: 25 mg/kg PO BID in dogs and 25 mg/kg PO SID in the evening in cats

II. Nebulization and coupage therapy help with removal of the abnormal airway secretions buildup.

III. Lung lobectomy is indicated in dogs with very localized disease.

IV. Cough suppressants are contraindicated.

Monitoring of Animal

I. Affected animals are very prone to recurrent respiratory tract infections.

II. Assess therapy through historical clinical signs and regular rechecks, including follow-up thoracic radiography and airway washes if indicated.

III. Possible sequelae include amyloidosis, cor pulmonale, and sepsis.

IV. Bronchiectasis is not curable, requires lifelong therapy, and warrants a poor prognosis.

Emphysema

Definition and Causes

I. Emphysema occurs when there is overdistension of the alveolus with air secondary to destructive changes in the alveolar walls, and it is typically associated with decreased alveolar gas exchange.

II. In small animals, emphysema occurs infrequently, but may be a sequela to other respiratory tract disorders, such as chronic bronchitis or bronchiectasis.

III. Congenital lobar emphysema arises secondary to congential respiratory tract lesions, such as bronchial dysplasia.

Pathophysiology

I. Hyperinflation of the lung results in poor perfusion and partial ischemia, but does not (in the absence of other enzymatic damage) cause emphysema.

II. Inflammatory cell enzymes, such as collagenase and elastase, result in alveolar septal destruction.

III. Abnormal enzymatic control mechanisms (i.e., α_1-antitrypsin deficiency) may play a role in the development of emphysema.

IV. With destruction of alveolar septae, alveoli become confluent and form thin-walled cysts.

V. Bullae may develop when there is partial airway obstruction.

Clinical Signs

I. In acquired disease, signs are usually attributable to the primary condition.

II. In puppies with congenital lobar emphysema, the main signs are progressive dyspnea and cyanosis.
   A. Exercise-associated respiratory distress and tachypnea may be noted.
   B. Age of onset is dependent on the severity of the anatomical abnormalities present.
   C. Wheezes and crackles may be heard on auscultation.

Diagnosis

I. Thoracic radiography reveals pulmonary hyperlucencies or hyperinflation.
   A. A caudally flattened or displaced diaphragm
   B. Attenuation of the peripheral pulmonary vasculature
   C. Focal pulmonary hyperlucencies consistent with bullae

II. Ventilation-perfusion scans may identify abnormalities in ventilation and blood flow.

III. Sometimes bullae are not identified until thoracoscopic examination or thoracotomy.

IV. Definitive diagnosis requires histopathologic analysis of affected lung tissue.

Differential Diagnosis

I. For pulmonary hyperinflation
   A. Gas trapping secondary to obstructive lower airway disease

B. Compensatory hyperventilation from volume loss elsewhere in the lungs
C. Pulmonary hypoperfusion secondary to shock, pulmonary hypertension, or pulmonary artery thrombosis

II. For focal pulmonary hyperlucencies
A. Pulmonary cysts
B. Pulmonary abscesses
C. Cavitating neoplasms

Treatment

I. In acquired disorders, direct treatment toward managing the underlying disease.
II. In congential lobar emphysema, consider pulmonary lobectomy.

Monitoring of Animal

I. With acquired diseases, monitoring of the primary respiratory disease is imperative.
II. With congenital emphysema, assess respiratory function frequently, including monitoring of respiratory effort and rate, exercise tolerance, and blood gas analysis.
III. A decline in overall respiratory function necessitates prompt consideration of further medical and/or surgical therapies.

INFLAMMATORY/IMMUNOLOGICAL DISORDERS

Acute Bronchitis

Definition

I. Acute bronchitis is defined as a short-lived cough attributable to lower airway inflammation or irritation.
II. Acute bronchitis is not associated with irreversible airway damage.

Causes

I. Bacterial or viral infections: infectious tracheobronchitis, feline viral upper respiratory tract infection
II. *Mycoplasma* spp. infection
III. Parasites
IV. Inhaled foreign bodies
V. Airway irritation: smoke, dust
VI. Airway compression by a pulmonary neoplasm, enlarged hilar lymph nodes, or cardiomegaly
VII. Tracheal collapse
VIII. Allergic tracheobronchitis
IX. Tracheobronchitis secondary to material exuded into airways from lung disease

Pathophysiology

I. Reversible airway inflammation is induced by an infectious or irritant agent.
II. Stimulation of cough receptors occurs, with resultant coughing and increased production of mucus in the airway.

Clinical Signs

I. Acute bronchitis is associated with a productive or nonproductive cough of short (<2 months) duration.
A. Viral infection: typically dry cough
B. Bacterial infection: commonly productive cough
C. Tracheal collapse: nonproductive "goose-honking" cough

II. Systemic signs of illness (fever, malaise) may accompany tracheobronchitis if there is concurrent pulmonary inflammation.
III. Thoracic auscultation reveals increased bronchovesicular sounds, wheezes, and crackles.

Diagnosis

I. Suspected based on compatible clinical signs and physical examination
II. Identification of the underlying cause
A. Hemogram: often unremarkable, neutrophilic leukocytosis possible with bacterial disease
B. Thoracic radiography
1. Usually normal
2. Pulmonary parenchymal infiltrates with concurrent pneumonia
3. Possibly cardiomegaly, lymphadenopathy, or pulmonary masses
4. Inspiratory-expiratory views useful in diagnosing tracheal collapse
5. Fluoroscopy for dynamic assessment of tracheal collapse

C. Analysis of airway secretions
1. Secretions are collected by transtracheal aspiration, by endotracheal suction, or during bronchoscopy.
2. Increased eosinophils suggest allergic or parasitic disease.
3. Mild neutrophilic inflammation is common with tracheal collapse, cardiomegaly, solid lung masses, and inhaled irritants.
4. Neutrophilic inflammation with intracellular bacteria is typical of bacterial tracheobronchitis.
5. Culture is recommended to identify the organism(s) involved, especially for *Mycoplasma* spp.

D. Possible bronchoscopy findings
1. Foreign body within the airways
2. Parasitic tracheobronchitis: *Oslerus osleri*
3. Collapsing trachea
4. Tracheal or airway neoplasia

Differential Diagnosis

I. Cardiac enlargement, heart failure
II. Allergic bronchitis (see later discussion)
III. Parasitic tracheobronchitis, including heartworm disease
IV. Bronchopneumonia
V. Neoplasia
VI. Primary ciliary dyskinesia

Treatment

I. Some disorders resolve spontaneously once the inciting cause has been eliminated.

II. If an infectious cause of acute bronchitis is identified, it is treated with appropriate antibiotics based on culture and sensitivity testing.
III. If a tracheal foreign body is suspected, endoscopic retrieval is attempted.
  A. Retrieval under fluoroscopy has been reported in cats (Tivers and Moore, 2006).
  B. If unsuccessful, thoracotomy may be necessary.
IV. Eliminate inhaled irritants (e.g., passive smoke, dust, fumes).
V. Maintain airway hydration through nebulization to help mobilize secretions and soothe the inflamed tracheal mucosa.
VI. Cough suppressants may be indicated.
  A. They are not used if the cough is productive or if a transtracheal wash suggests infection.
  B. They help break the cycle of cough-induced inflammation that leads to further coughing.
  C. They are useful for severe paroxysmal cough.
  D. Several choices are available.
    1. Butorphanol 0.5 to 1 mg/kg PO BID to QID
    2. Hydrocodone 0.22 mg/kg PO BID to QID
    3. Codeine 1 to 2 mg/kg PO BID to TID
VII. Bronchodilators help to control signs in dogs with concurrent small airway obstruction and expiratory wheeze.
  A. Methylxanthines
    1. Theophylline
      a. Theo-Dur tablets: 20 mg/kg PO BID
      b. Slo-Bid Gyrocaps: 25 mg/kg PO BID
    2. Adverse effects: gastrointestinal upset, tachycardia, hyperactivity
    3. Caution warranted in dogs with heart disease
    4. Dose reductions necessary with drugs that inhibit metabolism, such as enrofloxacin
  B. β_2-Adrenergic agonists
    1. Terbutaline 1.25 to 5 mg PO TID (dogs)
    2. Albuterol 20 to 50 µg/kg PO BID to TID
    3. Adverse effects: hyperexcitability, tremors
    4. Use cautiously in dogs with heart disease
VIII. Short-term use of corticosteroids may be warranted to decrease airway inflammation in severe cases.
  A. It is important to wait to initiate treatment until all diagnostic tests are complete.
  B. Use these drugs for a 3-day course to resolve airway inflammation.
    1. Prednisone 0.25 to 0.5 mg/kg PO BID
    2. Dexamethasone 0.10 to 0.2 mg/kg IV, IM, SC, PO BID

Monitoring of Animal

I. Monitor animals carefully to ensure that the inciting cause and all clinical signs resolve.
II. Failure to eliminate the inciting cause can lead to chronic bronchitis.

Chronic Bronchitis

Definition

I. The presence of a chronic, unrelenting cough for >2 consecutive months
II. Associated with irreversible changes in the airways
III. Original inciting or underlying cause not identified

Causes

I. The underlying cause of the lower airway disease is usually no longer identifiable.
II. Chronic infections, allergies, or inhaled irritants are all possible causes.

Pathophysiology

I. Chronic mucosal inflammation and injury cause several changes.
  A. Hypertrophy and hyperplasia of goblet cells and mucous glands
  B. Hypertrophy of airway smooth muscle
  C. Fibrosis of the lamina propria
  D. Epithelial erosion with squamous metaplasia
  E. Excessive mucus accumulation in airways
    1. Contributes to small airway obstruction and collapse
    2. Possibly results in bronchiectasis
II. Chronic airway changes result in an increased risk for infection.

Clinical Signs

I. Signs are typically seen in middle-aged to geriatric small-breed dogs.
II. The presence of a persistent productive or nonproductive cough is the hallmark feature.
III. Systemic signs of illness are usually absent.
IV. Severely affected animals may have a history of exercise intolerance, intractable coughing fits, and respiratory distress.
V. Acute exacerbations of signs may arise in the presence of complicating infections, exposure to inhaled irritants, or excessive stress, and excitement.
VI. Auscultation reveals increased bronchovesicular sounds, wheezes, and crackles.
VII. Animals with pulmonary hypertension resulting from long-standing airway disease may have a loud or split second heart sound (see Chapter 18).

Diagnosis

I. The diagnosis of chronic bronchitis is one of exclusion and made only after an extensive evaluation of the respiratory system.
II. The hemogram is often unremarkable.
III. Thoracic radiography may be normal or reveal the following:
  A. Bronchial thickening with peribronchiolar cuffing
  B. Bronchiectasis, atelectasis, and pneumonia in severe cases
IV. Airway secretions are collected by transtracheal aspiration, endotracheal suction, or bronchoscopy.
  A. Allergic and parasitic diseases commonly produce eosinophilic inflammation.
  B. Tracheal collapse, cardiomegaly, solid lung masses, and inhaled irritants cause mild neutrophilic inflammation.

C. Bacterial infections cause neutrophilic inflammation with intracellular bacteria.
D. More than two intracellular bacteria per high power field on a Gram stain of bronchial lavage fluid is suggestive of significant lower tract infection (Peeters et al., 2000).
E. Culture and sensitivity of airway fluids is recommended, with special media used for culturing *Mycoplasma* spp.

V. Bronchoscopy can be useful to rule out the following:
A. Foreign bodies within the airways
B. Parasitic tracheobronchitis: *O. osleri*
C. Collapsing trachea
D. Tracheal or airway neoplasia

Differential Diagnosis

I. Cardiac enlargement, heart failure
II. Allergic bronchitis
III. Parasitic tracheobronchitis, including heartworm disease
IV. Bronchopneumonia
V. Neoplasia
VI. Primary ciliary dyskinesia

Treatment

I. Symptomatic treatment is indicated.
II. Avoidance of airway irritants and excitement is helpful.
III. Nebulization to humidify the airway helps to decrease the viscosity of airway secretions and soothes inflamed tracheal mucosa.
IV. Antibiotics are used to treat secondary infections.
A. Ideally based on culture and sensitivity testing
B. Empirical use of an antibiotic with good pulmonary tissue penetration (e.g., doxycycline, clindamycin, chloramphenicol)

V. Cough suppressants are not used if the cough is productive, or if the transtracheal wash suggests infection.
A. May be useful for paroxysmal cough in dogs
B. Butorphanol 0.5 to 1 mg/kg PO BID to TID
C. Hydrocodone 0.22 mg/kg PO BID to QID
D. Codeine 1 to 2 mg/kg PO BID to QID

VI. Bronchodilators are useful in dogs with small airway obstruction and expiratory wheeze.
A. Theo-Dur tablets: 20 mg/kg PO BID
B. Slo-Bid Gyrocaps: 25 mg/kg PO BID

VII. Short-term administration of corticosteroids may be warranted to decrease airway inflammation in severe cases.
A. Delay initiation of these drugs until all diagnostic testing is complete.
B. Options include prednisone 0.25 to 0.5 mg/kg PO BID and dexamethasone 0.10 to 0.2 mg/kg IV, IM, SC, PO BID.
C. Fluticasone propionate 110 µg BID may be delivered via aerosol in dogs <20 kg and 220 µg BID may be given to dogs >20 kg.

VIII. Weight control to eliminate obesity is also helpful.

Monitoring of Animal

I. Lifelong therapy is often required, because the disease is rarely cured.
II. The therapeutic goal is to control airway inflammation and prevent progression of disease.
III. Control of clinical signs is the best method to assess therapeutic efficacy.
IV. Inadequate control of clinical signs requires reassessment for new concurrent diseases (especially infections) and appropriate changes in therapy.
V. Reevaluate affected animals every 3 to 6 months, even if signs are stable.

Feline Allergic Bronchitis

Definition

I. It is a syndrome of reversible airway inflammation and narrowing that causes coughing, wheezing, and/or dyspnea.
II. Signs result from bronchial smooth muscle constriction (bronchoconstriction), bronchial wall edema, and excessive mucus secretion.
III. A classification scheme has been proposed (Moise and Dietze, 1989).
A. Bronchial asthma is reversible airway obstruction that results primarily from bronchoconstriction.
B. Acute bronchitis is reversible airway inflammation of short duration (<3 months).
C. Chronic bronchitis is irreversible airway damage resulting from chronic airway inflammation (>2 to 3 months).
D. Emphysema is overexpansion of alveolar airspaces caused by bronchiolar and alveolar wall destruction.

Causes

I. The acute (early) response in allergic feline bronchitis (asthma) represents a type I allergic reaction potentially triggered by inhaled allergens such as smoke, dust, and molds.
II. In most cases, the allergen is not identified.
III. Mycoplasma infection may trigger the bronchitis in some cats (Foster et al., 2004).
IV. Chronically, antigen-specific T lymphocytes in the airways secrete cytokines and leukotrienes.

Pathophysiology

I. The airways respond in a variety of ways to irritants or immunological stimuli.
A. The airway epithelium hypertrophies and undergoes metaplasia, resulting in airway narrowing.
B. Goblet cells and submucosal glands enlarge and increase production of mucus.
C. Bronchial smooth muscle constricts.
D. Cellular infiltration of the bronchial mucosa and submucosa results in airway edema.

II. Eosinophils play an important role in airway inflammation in some cats with asthma.
A. Eosinophils release chemical mediators.
B. These result in increased airway damage, fibrosis, and eosinophil chemotaxis.

Clinical Signs

I. Young and middle-aged cats are affected most often.
II. Presenting signs include cough, wheeze, and respiratory distress.
III. Systemic signs of illness (e.g., weight loss, anorexia, lethargy) rarely occur.
IV. Physical examination is often unremarkable between episodes of bronchoconstriction.
V. Physical examination during a symptomatic episode may reveal respiratory distress with increased expiratory effort, expiratory wheezes, and a barrel chest from prolonged air trapping.

Diagnosis

I. Clinical history and physical examination findings are used to make a tentative diagnosis.
II. Peripheral eosinophilia is an inconsistent finding on the hemogram.
III. Thoracic radiographic findings vary.
  A. Normal radiographs are common.
  B. Interstitial, bronchial, or alveolar patterns predominate.
  C. Atelectasis of the right middle lung lobe may occur as a result of bronchial obstruction.
  D. Lung parenchymal hyperlucency and expansion reflects air trapping, even in mildly symptomatic cats.
IV. Transtracheal wash or bronchoalveolar cytology typically reveals increased inflammatory cell and mucus content.
  A. The inflammatory cell content can be either neutrophilic or eosinophilic.
  B. Alveolar macrophages may be seen in some samples.
  C. The presence of oropharyngeal squamous cells and *Simonsiella* spp. indicates oropharyngeal contamination and the need to use caution in interpretation of the results.
V. Bronchoscopy reveals mild hyperemia and increased airway mucus secretions.
VI. Bacterial culture and antibiotic sensitivity testing of tracheal wash samples is recommended, because infection may contribute to airway inflammation and hypersensitivity.
  A. Gram staining of airway wash samples is a useful tool while culture results are pending.
  B. Remember that 77% of normal cats have positive culture results, and bacterial infection is rarely significant in affected cats (Dye et al., 1996).
  C. Bacteria isolated from normal cats include *Pasteurella, Pseudomonas, Staphylococcus, Streptococcus,* and *Micrococcus* spp., as well as *Eschericia coli* and *Bordetella bronchiseptica*.
  D. Growth of large numbers ($>10^3/\mu L$) of bacteria indicates infection requiring antibiotic treatment.
  E. Retrieval of *Mycoplasma* species from a cat with symptomatic bronchitis is considered significant and requires treatment.
    1. Use culture media specific for *Mycoplasma* spp.
    2. Avoid the use of wooden or cotton-tipped swabs for sample collection, as they may inhibit mycoplasmal growth.
VII. Heartworm testing is performed in endemic areas.
VIII. Fecal examinations are performed for airway and pulmonary parasites where prevalent.

Differential Diagnosis

I. Nonallergic airway inflammation or irritation
  A. Environmental irritants: smoke, dust
  B. Bacterial or mycoplasmal infections
  C. Lung parasitism (see Chapter 18)
  D. Neoplasia
  E. Bronchial foreign body
II. Pneumonia
III. Pharyngeal disease, obstruction (see Chapter 15)
IV. Pleural space disease

Treatment

I. Acute stabilization of the cat in respiratory distress
  A. Oxygen supplementation
  B. Rapid-acting corticosteroids
    1. Prednisolone sodium succinate 10 to 20 mg/kg IV
    2. Dexamethasone sodium phosphate 0.2 to 2.2 mg/kg IV, IM
  C. Bronchodilators
    1. Terbutaline 0.01 mg/kg IM, SC
    2. Aminophylline 5 mg/kg IV
    3. Albuterol 90 μg q 30 minutes for up to 4 hours, delivered with a metered dose inhaler, rebreathing spacer, and mask
II. Long-term management of cats with chronic disease
  A. Eliminate or reduce exposure to inhaled irritants and potential allergens.
    1. Replace clay litter with shredded newspaper; wood chips; or low-dust, clumping litter.
    2. Reduce passive smoke inhalation.
    3. Replace or clean dirty furnace air filters.
    4. Minimize exposure to aerosols, powders, perfumes, and fragrances.
  B. Corticosteroids are an important component of long-term management.
    1. It is preferable to administer steroids continuously rather than intermittently to control ongoing inflammation and prevent the development of chronic bronchitis.
    2. Fluticasone propionate is given at 110 to 220 μg BID via a metered dose inhaler (Kirschvink et al., 2005; Reinero et al., 2005; Schulman et al., 2004).
      a. Fluticasone propionote is preferred because of its potency, prolonged half-life, and minimal systemic absorption.
      b. For proper administration, shake the metered inhaler to open the valve, attach it to the spacer and mask, fit the mask to the cat, and watch for the animal to take 7 to 10 breaths after delivery of the drug.
      c. Correct placement of the mask minimizes the risk of conjunctivitis from the drug.
    3. Prednisone 0.5 to 1.0 mg/kg PO BID can also be used initially in cats with moderate to severe signs.
      a. Onset of effects of fluticasone is delayed, and some cats do not tolerate inhalant therapy.

b. After 7 to 10 days, decrease the dose if the cat is stable.
c. Eventually switch to alternate-day therapy.
d. Rapid dose tapering or drug withdrawal can result in worsening of symptoms.
e. Long-term therapy may be needed in refractory cases.

4. Treat cats that do not tolerate pilling or inhalant therapy with injectable methylprednisolone acetate at 10 to 20 mg IM every 2 to 8 weeks.
a. Possible increased risk for developing refractory disease
b. Increased risk of complications of chronic glucocorticoid administration, including urinary tract infection and diabetes mellitus
c. Anecdotal reports of injection-associated sarcomas with repeated administration
d. Not recommended for routine use

C. Bronchodilators help reduce signs of airway obstruction and bronchoconstriction.
1. Albuterol
a. Administered via metered dose inhaler at 90 µg per inhalation
b. Used as needed or up to QID
2. Terbutaline
a. Oral administration of 0.625 mg BID
b. Severe distress: 0.01 mg/kg IM, SC
c. Injectable terbutaline for at-home emergency use
3. Theophylline
a. Theo-Dur tablets: 25 mg/kg PO SID in the evening
b. Slo-Bid Gyrocaps: 25 mg/kg PO SID in the evening

D. Cyproheptadine may block allergen-induced bronchoconstriction and is given at 2 mg PO BID.

E. Cyclosporine is a possible adjunctive treatment for the small subpopulation of affected cats that are steroid resistant or require extremely large dosages of steroids.
1. Dose is 10 mg/kg PO BID.
2. Cyclosporine blood levels are checked weekly until trough blood levels of 500 to 1000 ng/mL are achieved.
3. Cats are relatively resistant to the side effects reported in other species.

F. The use of antileukotriene agents has not been justified because the role of leukotrienes in feline allergic bronchitis has been questioned.

Monitoring of Animal

I. The prognosis for control of clinical sings is good in most cats.
II. Ongoing therapy is usually required, and relapses are possible.
III. Lack of resolution of clinical signs with appropriate medical management warrants reassessment to ensure an appropriate diagnosis was made and complicating factors are not present.
IV. Inadequate control of airway inflammation may result in progression to chronic irreversible airway disease.
V. Exhaled breath condensate and barometric whole body plethysmography techniques for evaluating markers of airway inflammation and airflow restriction may provide more objective means of evaluating the response to treatment in the future.

Canine Allergic Bronchitis

Definition

I. Canine allergic bronchitis is an inflammatory condition of the airways that occurs in response to an inhaled allergen or a hematogenously carried antigen.
II. Unlike feline allergic bronchitis, acute bronchospasm is not a common component of the disease.

Causes

I. A variety of antigens may elicit a hypersensitivity reaction within the airways.
A. Dusts and molds
B. Cigarette smoke
C. Aerosol sprays
II. Parasitic infections *(Dirofilaria immitis)* and fungal infections, in particular *Aspergillus* spp., can cause a hypersensitivity response in the airways and result in allergic bronchitis.

Pathophysiology

I. Humoral and cell-mediated immune responses occur and involve the production of both immunoglobulins E and G.
II. Mediators such as histamine, serotonin, kinins, and eosinophil chemotactic factor are released, causing several reactions.
A. Airway inflammation and edema
B. Bronchoconstriction
C. Increased mucus production
III. Long-standing airway inflammation associated with the hypersensitivity reaction may cause permanent airway changes and result in chronic bronchitis.

Clinical Signs

I. Typically young to middle-aged dogs
II. Cough a consistent feature
A. The cough is usually unproductive.
B. Coughing is exacerbated by exercise, cold air, and chest or tracheal compression.
III. Respiratory distress associated with wheezing and increased expiratory effort (rare)

Diagnosis

I. A cough is easily elicited on tracheal palpation.
II. Occasionally, increased expiratory effort is noted.
III. Thoracic radiography may reveal bronchial wall thickening and peribronchial cuffing, or is occasionally normal.
IV. Airway washes typically reveal marked eosinophilia.
V. Heartworm testing and fecal examinations are performed to rule out parasitic disease in all dogs with an eosinophilic tracheal wash.
VI. Bronchoscopy may be considered, especially to evaluate for *O. osleri* infection.

Differential Diagnosis

I. Acute tracheitis or bronchitis syndromes
II. Chronic bronchitis
III. Bronchopneumonia
IV. Pulmonary edema
V. Pulmonary neoplasia

Treatment

I. If an infectious cause of the hypersensitivity reaction can be identified, treat it appropriately.
II. Institute environmental changes when inhalant allergens are identified.
III. Immunosuppressive doses of corticosteroids are recommended.
   A. Prednisone 1 to 2 mg/kg PO BID is initiated.
   B. Administer this dose for 14 days, then taper to the lowest effective dose.
IV. Bronchodilators are administered for signs of bronchoconstriction (e.g., increased expiratory effort, wheezing).
V. Inhalant medications (fluticasone propionate, albuterol) may also be considered.
VI. Humidification of airways decreases inflammation and improves mucociliary clearance.

Monitoring of Animal

I. Closely monitor, through repeated examinations, clinical response to treatment.
II. Resolution of airway inflammation and prevention of progression to chronic bronchitis is the goal.
III. Acute relapses require immediate reevaluation and adjustment of medications.

CHAPTER 18

Pulmonary Parenchymal Diseases

O. Lynne Nelson

PULMONARY EDEMA

Definition

I. Pulmonary edema is fluid accumulation in the interstitium of the lung.
II. Cardiogenic pulmonary edema occurs when left-sided congestive heart failure (CHF) and increased pulmonary venous hydrostatic pressure are responsible for the edema.
III. Noncardiogenic edema is edema from any other cause.

Causes

I. The causes are typically divided into three or four major mechanisms.
   A. Decreased plasma oncotic pressure
   B. Increased vascular hydrostatic pressure
   C. Increased vascular permeability
   D. Miscellaneous
II. Causes are listed in Box 18-1.

Pathophysiology

I. Fluid translocates into the interstitial space from one of the major mechanisms above.
II. The lymphatic drainage systems cannot match the rate of fluid influx.
III. The interstitial space is eventually overwhelmed, and fluid accumulates in the alveoli.
IV. Gas exchange is impaired when airways become flooded.
V. Atelectasis, decreased lung compliance, and airway compression all increase pulmonary vascular resistance.
VI. Hypoxemia results from ventilation-perfusion mismatch.
VII. Hypoxemia contributes to increased pulmonary vascular resistance from hypoxemia-mediated pulmonary arterial vasoconstriction.

Clinical Signs

I. Most animals present with tachypnea, cough, or respiratory distress (severe hypoxia).
II. Symptoms are directly related to the cause and severity of the edema.
III. The respiratory character is usually that of increased effort (both inspiration and expiration).
IV. Severe edema may cause coughing with expectoration of blood-tinged fluid.
V. Auscultation may reveal several abnormalities.
   A. Crackles may be absent in early or mild edema, but subtle crackles at the end-inspiration to early expiration phase are common.
   B. Crackles may be heard on both inspiration and expiration in advanced pulmonary edema.
   C. Lung sounds may seem exceptionally quiet with very severe edema.
   D. Abnormal cardiac auscultation (murmurs, transient sounds, arrhythmias) indicates the presence of heart disease.
      1. Identification of a heart murmur does not always indicate the presence of cardiogenic edema.
      2. Some animals with CHF lack abnormal heart sounds (cardiomyopathies).

Diagnosis

I. Thoracic radiography, combined with historical and physical findings, is often diagnostic (Box 18-2).
II. Cardiogenic edema is characterized by "fluffy" interstitial opacities that rapidly progress to an alveolar pattern.
   A. In the dog, the opacities are most often located in the hilar lung regions.
   B. In the cat, the opacities are patchy and may be diffuse or focal.
   C. Pulmonary venous enlargement suggests pulmonary venous and left atrial hypertension consistent with CHF.
   D. Enlargement of the cardiac silhouette (particularly left sided) is commonly present.
III. Edema caused by increased vascular permeability is typically most severe in the caudodorsal lung lobes.
   A. Vascular permeability edema is caused by numerous disorders (see Box 18-1).
   B. History and laboratory parameters are helpful in identifying underlying causes (e.g., electrocution, smoke inhalation, pancreatitis).
   C. In many cases (e.g., sepsis, uremia), the edema is mild and not a part of the primary clinical complaint.
   D. Acute respiratory distress syndrome (ARDS) is a unique syndrome of increased pulmonary vascular permeability secondary to critical illness states (see under Idiopathic Disorders).
IV. Pulmonary edema from decreased plasma oncotic pressure usually has a generalized interstitial or mixed interstitial-alveolar pattern.

Box 18-1

Possible Causes of Pulmonary Edema

Decreased Plasma Oncotic Pressure

Hypoalbuminemia
- Gastrointestinal loss
- Glomerulopathy
- Liver disease
- Iatrogenic overhydration
- Starvation

Vascular Overload

Cardiogenic
- Left heart failure
- Left-to-right shunts
- Overhydration

Lymphatic Obstruction (Rare)

Neoplasia

Increased Vascular Permeability (Acute or Adult Respiratory Distress Syndrome)

Inhaled toxins
- Smoke inhalation
- Gastric acid aspiration
- Oxygen toxicity

Drug or toxins
- Snake venom
- Cisplatin in cats

Electrocution
Trauma
- Pulmonary
- Multisystemic

Sepsis
Pancreatitis
Uremia
Disseminated intravascular coagulation
Inflammation (infectious or noninfectious)*

Miscellaneous Causes

Thromboembolism
Severe upper airway obstruction
Near drowning
Neurogenic edema
- Seizures
- Head trauma

From Hawkins EC: Disorders of the pulmonary parenchyma. p. 311. In Nelson RW, Conto CG (eds): Small Animal Internal Medicine. 2nd Ed. Mosby, St. Louis, 1998.
*Inflammation is usually the prominent clinical abnormality, not edema.

Box 18-2

Radiographic Changes with Parenchymal Disease

Disease	Radiographic Signs
Pneumonia	
Bronchopneumonia	Alveolar or mixed alveolar–bronchial pattern Air bronchograms present Changes present in multiple lobes and throughout the lobes
Aspiration	Most commonly affects ventral portions of middle lobes May be unilateral or bilateral Mixed alveolar–interstitial pattern Air bronchograms present unless consolidated
Inhalation	Early changes confined to interstitial pattern with peribrochial infiltrates Late changes show mixed alveolar–interstitial pattern with air bronchograms present Early changes are widespread and diffuse Later changes may affect dependent portions of lungs, mirnicleing aspiration
Pulmonary contusion	Irregular, patchy areas of mixed alveolar–interstitial patterns or consolidation Often contain air bronchograms May be associated with rib fractures, pneumothorax, or atelectasis
Pulmonary edema	
Cardiogenic	
Dog	Hilar, mixed alveolar–interstitial densities
Cat	Diffuse, peripheral alveolar or mixed pattern
Electric shock, snakebite, inhalation	Generalized, severe mixed pattern Often most pronounced in diaphragmatic lobes Bilateral, symmetrical Air bronchograms present
Hypoproteinemia	Mixed pattern with air bronchograms late Often accompanied by hydrothorax
Feline asthma	Increased interstitial densities and peribronchial markings Increased thoracic size Straightening of diaphragm Hyperlucency of lungs ± Aerophagia Emphysematous bullae with chronic asthma

From Morgan RV: Manual of Small Animal Emergencies. p. 198. Churchill Livingstone, New York, 1985.

A. Pleural effusion may also be present.
B. Vascular congestion is absent.

V. Blood gas analysis often detects hypoxemia, hypocapnia, and widened A-a gradient (difference in oxygen tension between alveolar [A] and arteriolar [a] blood) (Lagutchik, 1997).
VI. Laboratory abnormalities are helpful in determining the cause, particularly in noncardiogenic edema.

Differential Diagnosis

I. Bronchopneumonia
II. Pulmonary contusions
III. Parenchymal neoplasia
IV. Pulmonary thromboembolic disease

Treatment

I. Improve oxygenation
   A. Minimize stressful handling.
   B. Administer oxygen through nasal cannula, face mask, or oxygen cage.
   C. Intubate and begin positive-pressure ventilation if necessary.
II. Diuretic therapy is particularly effective for vascular overload disorders, especially CHF.
   A. Administer furosemide 2 to 4 mg/kg IV every 4 to 12 hours for clinical pulmonary edema.
   B. Diuretics are less beneficial for increased vascular permeability disorders (e.g., ARDS).
   C. Caution is advised in hypovolemic animals.
III. Xanthine-derivative bronchodilators may be beneficial to combat bronchospasm, enhance mucociliary function, and diminish diaphragmatic fatigue.
   A. Aminophylline 6 to 11 mg/kg PO TID (dogs) and 4 to 6 mg/kg PO BID (cats)
   B. Theophylline 4 to 5 mg/kg PO TID
IV. Institute specific therapies for each cause.
   A. Hypoproteinemia
   B. Cardiac disease (see Chapter 9)
   C. Smoke inhalation (see Chapter 133)

Monitoring of Animal

I. Monitor pulmonary function and cardiac disease parameters every 1 to 8 hours.
   A. Evaluate mucous membrane color, respiratory rate, and character for progressive trends.
   B. Monitor oxygenation with arterial blood gases and/or pulse oximetry.
   C. Monitor heart rate, rhythm, and QRS morphology on electrocardiography.
   D. The appearance of ventricular ectopic beats, increasing heart rate, or ST segment depression may indicate worsening of a hypoxic state.
II. Thoracic radiographs are reevaluated every 24 to 48 hours, remembering that radiographic changes often lag behind clinical response.
III. Monitor hydration status and cardiac output using serial measures, including packed cell volume (PCV), total protein (TP), central venous pressure, daily body weight, arterial blood pressure, urine output, and pulmonary capillary wedge pressures.

INFECTIOUS DISEASES

Bacterial Pneumonia

Definition

I. Pneumonia is inflammation of the lung.
II. Pneumonia is considered bacterial when bacterial organisms are identified as the cause or a part of the inflammatory process.
III. Bacterial bronchitis is bacterial infection of the airways.
IV. Bronchopneumonia occurs from bacterial colonization of the airways and parenchymal tissues (alveoli, interstitium).
V. Interstitial pneumonia is infection or inflammation of the pulmonary interstitium.
VI. Lobar pneumonia is inflammation affecting a single lung lobe.

Causes

I. Primary bacterial pneumonia is uncommon, and typically a predisposing condition exists.
   A. Chronic bronchitis ± bronchiectasis
   B. Ciliary dyskinesia
   C. Viral and fungal diseases
   D. Diseases associated with aspiration: regurgitation, dysphagia
   E. Foreign body penetration
   F. Immunosuppressive drug therapy, severe metabolic compromise
   G. Endocrinopathies: diabetes mellitus, hyperadrenocorticism
   H. Prolonged recumbency: atelectasis and hypostatic congestion
   I. Trauma
   J. Neoplasia
II. *Staphylococcus* spp., *Streptococcus* spp., *Escherichia coli,* and *Mycoplasma* spp. are common organisms.

Pathophysiology

I. Bacteria may be inhaled (most common route).
   A. Organisms may extend from upper airway disease.
   B. Organisms may be opportunistic invaders in diseases with impaired clearance mechanisms, such as chronic bronchitis, ciliary dyskinesia, and immunosuppressive drugs or disease states.
II. Bacteria may enter the lung hematogenously.
   A. Pneumonia may be a consequence of sepsis from any cause (immunosuppressive drugs).
   B. Intravenous catheter use in critical patients can be associated with pneumonia.
III. Bacteria may enter the lung through direct extension.
   A. Wound penetrating the thoracic cavity
   B. Inhaled foreign objects: grass awns
   C. Perforating esophageal lesions
   D. Iatrogenic: diagnostic or surgical procedures

Clinical Signs

I. History
  A. A thorough history provides an important insight into potential underlying causes.
    1. Vaccine status and animal exposure
    2. Geographic area traveled
    3. Prior illness
      a. Medications administered
      b. Signs related to other underlying causes
  B. A history of chronic airway disease is common.
  C. A history of vomiting or regurgitation may be present.
  D. A history of anesthesia and prolonged recumbency may suggest aspiration.
II. Respiratory signs
  A. Cough, usually productive
  B. Tachypnea, respiratory distress
  C. Bilateral mucopurulent nasal discharge
  D. Exercise intolerance
  E. Expiratory wheeze
III. Systemic signs
  A. Lethargy, anorexia
  B. Fever (not a consistent finding)
  C. Weight loss
  D. Signs related to predisposing causes

Diagnosis

I. Auscultation on physical examination
  A. Inspiratory (if bronchial component) and expiratory (most common) crackles may be ausculted.
  B. Expiratory wheeze is an occasional finding.
  C. Abnormal sounds may be most prominent over the ventral lung fields.
  D. Diminished sounds are often noted over areas of consolidation.
  E. Auscultation is sometimes insensitive for detecting early pulmonary changes.
II. Laboratory tests
  A. Complete blood count (CBC)
    1. A neutrophilic leukocytosis with a left shift (60% of cases) may be present (Greene, 2006).
    2. A neutropenia with a degenerative left shift can sometimes be seen.
    3. A normal CBC does not rule out bacterial pneumonia.
  B. Biochemistry panel: abnormalities related to underlying diseases
III. Thoracic radiography (see Box 18-2).
  A. Bacterial bronchitis is characterized by a prominent bronchial pattern with peribronchial cuffing ("doughnuts").
  B. Bronchopneumonia can affect multiple pulmonary regions and is characterized by bronchial, interstitial, and especially alveolar changes (air bronchograms).
  C. Bronchopneumonia lesions are typically found in the cranioventral lung fields.
  D. Interstitial pneumonia often appears as a diffuse reticular increase in parenchymal opacity.
  E. Interstitial lesions that assume a more caudal pattern are seen with hematogenous pneumonia.
  F. Lobar pneumonia is usually localized to one region or lung lobe.
    1. Consolidation with air bronchograms is commonly observed.
    2. Lesions associated with foreign bodies are focal.
IV. Pulmonary specimens
  A. Bronchoalveolar lavage
    1. Specimens are collected before antibiotics are administered.
    2. Septic neutrophilic inflammation is typical on cytology.
    3. Intracellular bacteria are usually present.
  B. Transthoracic aspirates
    1. They are particularly helpful in consolidated lung lesions or prominent interstitial disease.
    2. Septic neutrophilic inflammation and intracellular bacteria are noted.
  C. Lung biopsy
    1. Allows histopathologic examination
    2. Important if surgery is planned, such as with focal lesions
V. Culture of pulmonary specimens
  A. Isolation of the organisms is essential to support the diagnosis and provide specific treatment.
  B. Aerobic and anaerobic cultures are submitted.
  C. *Bordetella* spp. and *Mycoplasma* spp. require special culture media.
  D. Culture results must be interpreted in light of the source and collection method.

Differential Diagnosis

I. Other forms of infectious pneumonia: viral, protozoal, mycotic
II. Aspiration pneumonia
III. Pulmonary edema
IV. Pulmonary contusion
V. Infiltrative neoplasia
VI. Chronic bronchial disease
VII. Parasitic and eosinophilic pulmonary disease

Treatment

I. Antibiotics are the mainstay of therapy for bacterial pneumonia.
  A. Infections with more than one organism are common.
  B. Antibacterial chosen depends on culture and sensitivity.
  C. Broad-spectrum antibiotics are given empirically pending the results of culture and sensitivity.
    1. Cephalexin 20 to 40 mg/kg PO TID
    2. Trimethoprim-sulfadiazine 15 to 30 mg/kg PO BID
    3. Doxycycline 5 to 10 mg/kg PO BID (dogs) and 5 mg/kg PO BID (cats)
    4. Amoxicillin-clavulanate 20 to 25 mg/kg PO TID

II. Airway hydration is recommended to help prevent drying with increased viscosity of airway secretions and to enhance clearance of bacterial organisms.
   A. Fluid therapy is warranted with evidence of dehydration or systemic hypotension.
   B. Humidification of air provides additional moisture to the airways.
      1. Humidification is recommended for animals with lung consolidation or chronic airway disease (chronic bronchitis).
      2. Place pet in a steamy bathroom three to four times per day.
      3. Commercially available air-humidifying units can be purchased.
      4. Nebulizers deliver moisture deeper into airways than humidifiers.
         a. Disposable units are attached to bottled oxygen.
         b. Antibiotics are sometimes added to the nebulizing fluid.
III. Bronchodilators may be beneficial with suggested bronchospasm.
   A. Expiratory wheeze may be noted on physical examination.
   B. Cats are especially prone to bronchospasm secondary to airway inflammation.
   C. Methylxanthines help to relax bronchioles, enhance mucociliary clearance, and decrease respiratory muscle fatigue.
      1. Aminophylline 6 to 11 mg/kg PO TID (dogs) and 4 to 6 mg/kg PO BID (cats)
      2. Theophylline 4 to 5 mg/kg PO TID
   D. Other bronchodilators may be empirically used.
      1. Terbutaline 1.25 to 5.0 mg PO BID (dogs) and 0.625 mg to 1.25 mg PO BID (cats)
      2. Albuterol 50 μg/kg PO TID or aerosolized and inhaled
      3. Ipratropium bromide aerosol
IV. Physiotherapy promotes deeper respirations and coughing, with clearance of mucous debris.
   A. Light activity is encouraged if the animal is capable of ambulation without discomfort or distress.
   B. If the animal is recumbent for long periods, rotate it every 2 hours to decrease the potential for lung consolidation.
   C. Coupage is performed by bluntly striking the chest wall with cupped hands.
      1. Coupage enhances coughing and clearance of mucus and airway debris.
      2. It is particularly useful after nebulization.
V. Oxygen supplementation is indicated if cyanosis, distress, or severe hypoxemia (partial pressure of alveolar oxygen <60 to 65) is documented.
VI. Oxygen therapy helps minimize hypoxic-induced pulmonary arterial vasoconstriction.
VII. Identify and treat predisposing causes.
VIII. Surgical intervention may be required in those cases of lung lobe consolidation that are not responsive to medical therapy, or in rare cases in which secondary pneumothorax occurs.
IX. In general, corticosteroids, diuretics, and cough suppressants are avoided.

Monitoring of Animal

I. Pulmonary function is monitored 2 to 10 times per day for signs of deterioration, depending upon clinical severity.
   A. Respiratory rate, effort, and coughing
   B. Mucous membrane color
   C. Arterial oxygenation: serial blood gases, pulse oximetry
II. Thoracic radiographs are evaluated every 24 to 72 hours initially.
   A. Radiographic changes frequently lag 24 to 48 hours behind clinical findings.
   B. Radiographs may be repeated every 7 to 10 days after animal is stable.
III. A CBC is assessed every 24 to 48 hours initially.
IV. If there is a poor response to therapy, consider the following:
   A. Inappropriate antibiotic choice or administration
   B. Development of complications: sepsis, abscessation, consolidation, thrombosis
   C. Superinfection with resistant organisms
   D. Poor owner compliance with medications
   E. Inappropriate treatment of underlying condition
   F. Incorrect diagnosis

Viral Lung Disease

See Chapters 112 and 114.

Mycotic Lung Disease

Definition

I. Mycotic lung disease is a pulmonary infection caused by fungal (mycotic) organisms.
II. Mycotic diseases are often part of systemic infections.

Causes

I. *Coccidioides immitis*
II. *Blastomyces dermatitidis*
III. *Histoplasma capsulatum*
IV. *Cryptococcus neoformans:* most common systemic fungal disease of the cat
V. *Aspergillus flavus*

Clinical Signs

I. Clinical signs depend on route of entry, localization, or dissemination.
II. Pulmonary signs are similar to other forms of pneumonia (see Bacterial Pneumonia).
   A. Pulmonary signs are common in dogs with blastomycosis and coccidioidomycosis.
   B. Pulmonary signs may also be seen in cats with histoplasmosis and coccidioidomycosis.
III. Nasal signs are the predominant complaint with cryptococcosis and aspergillosis, although pulmonary disease may be present with severe disseminated infection or with

immunosuppression from steroid administration or a concurrent disease.
IV. Central nervous system and ocular disease (chorioretinitis and uveitis) occur with many fungal organisms.
V. Bony involvement resulting in pain and lameness may be noted, particularly with blastomycosis and coccidioidomycosis.
VI. Systemic signs are also common (weight loss, fever, lymphadenopathy).

Diagnosis

I. Thoracic radiographs are often characteristic.
   A. Diffuse, nodular interstitial pattern
   B. Miliary nodular pattern
   C. Hilar lymphadenopathy (particularly histoplasmosis and coccidioidomycosis)
   D. Sometimes bronchointerstitial patterns and lung lobe consolidation
II. Cytological evaluation of bronchoalveolar lavage samples or transthoracic aspirations may identify the organisms.
III. Fungal cultures may be performed, but the organisms can be difficult to grow.
IV. Serology is diagnostic with certain types of fungal infection (see Chapter 111).

Differential Diagnosis

I. Neoplastic lung disease
II. Bacterial pneumonia
III. Parasitic pneumonia
IV. Eosinophilic lung disease
V. Complicated chronic airway diseases

Treatment and Monitoring

I. Long-term therapy is essential for most cases of mycotic pneumonia (see Chapter 111).
II. Frequent re-examinations (and thoracic radiographs) are necessary to determine resolution of the pneumonia and to monitor for recurrence of disease.

Protozoal Lung Disease

Toxoplasma Pneumonia

Definition and Cause

I. *Toxoplasma gondii* is one of the most prevalent multisystemic protozoal organisms affecting warm-blooded vertebrates.
II. Feline species are the definitive host.
III. Infection occurs by ingestion of organisms or transplacentally.
IV. Immunodeficiency disease predisposes animals to develop clinical toxoplasmosis.

Clinical Signs

I. Pneumonitis is most commonly associated with acute toxoplasmosis.
II. Pulmonary symptoms are similar to other forms of pneumonia (see under Bacterial Pneumonia).
III. Generalized lymph node enlargement may be detected.
IV. Cysts readily form in the central nervous system, muscular tissue, and visceral organs, so other systemic signs are common (anorexia, diarrhea, hyperesthesia).
V. Anterior or posterior uveitis is also common.

Diagnosis

I. Thoracic radiography demonstrates a variety of abnormalities.
   A. Diffuse interstitial pattern
   B. Mottled interstitial to alveolar pattern
   C. Pleural effusion
II. Cytological evaluation of bronchial washes or transthoracic aspirates is more likely to yield bradyzoites or tachyzoites than with tracheal washes (interstitial location of disease); however, definitive demonstration of the organism antemortem is uncommon.
III. Histopathologic testing of lung tissues may be beneficial.
IV. Serologic testing combined with organism detection by polymerase chain reaction may confirm the diagnosis (see Chapter 116).

Differential Diagnosis

I. Bacterial pneumonia
II. Parasitic pneumonia
III. Complicated viral pneumonia
IV. Eosinophilic lung disease
V. Complicated chronic airway diseases
VI. Neoplastic lung disease

Treatment and Monitoring

I. See Chapter 116 for treatment protocols.
II. Prognosis is generally poor in cats with severe pulmonary disease.
III. Long-term therapy is often required.
IV. Recurrence of clinical signs may be noted, particularly if the duration of therapy is <4 weeks.

Pneumocystis Pneumonia

See Table 116-2.

INFLAMMATORY DISORDERS

Aspiration Pneumonia

Definition

I. Inhalation of fluid, food particles, or bacteria from the oropharynx often results in profound pulmonary inflammation.
II. Aspiration pneumonia can present as an acute fulminant illness or a chronic and insidious process.

Causes

I. The materials usually aspirated are acidic stomach contents and food.
II. Normal laryngeal and pharyngeal function ordinarily prevents aspiration.
III. Some disorders alter normal laryngeal-pharyngeal function, thereby predisposing to aspiration.

A. Local or systemic neuromuscular disease
B. Irritation and inflammation of oropharynx secondary to chronic reflux or regurgitation (megaesophagus, esophageal obstruction, esophagus, chronic vomiting)
C. Anesthesia or depressed mental states resulting in prolonged recumbency, reflux, and impaired oropharyngeal function

IV. Accidental intubation of the airway when administering medications or food, or lack of patient cooperation when administering such products, can result in aspiration pneumonia.

Pathophysiology

I. The severity of lung injury is related to various factors.
A. The volume of the aspirate
B. The pH of the aspirate, with pH values <2.5 being the most troublesome
C. Toxicity related to the specific particulate matter

II. Aspirated material may cause several reactions.
A. Obstruction and collapse of alveoli
B. Pulmonary hemorrhage and edema
C. Influx of inflammatory cells
D. Necrosis of airway epithelial cells
E. Bronchoconstriction

III. Infection is a common sequela owing to aspiration of oropharyngeal bacteria or secondary to the lung injury and impaired clearance mechanisms.

Clinical Signs

I. Acute onset of respiratory distress, tachypnea, and cough are typical.
II. Chronic, progressive respiratory signs may also occur.
III. Systemic signs such as fever, inappetence, lethargy, and shock are also common.
IV. Inspiratory and expiratory crackles and wheezes are usually ausculted in the cranioventral lung lobes.

Diagnosis

I. A history of chronic regurgitation or possible aspiration allows a presumptive diagnosis.
II. CBC often reveals an inflammatory leukogram.
III. Thoracic radiography may support the diagnosis (see Box 18-2).
A. Opacities may be diffuse or focal, interstitial to alveolar.
B. Increased alveolar opacities and consolidated regions are more prominent in the cranioventral and middle lung lobes (dependent areas).
C. Nodular opacities may be noted in chronic cases, or cases in which large solid particles have been aspirated.
D. A miliary nodular pattern may be found with aspiration of mineral oil.

IV. Respiratory secretions are evaluated by cytology and culture.
A. Cytological evaluation usually shows a predominance of neutrophils and some hemorrhage.
B. Bacteria may or may not be present.
C. Particulate matter (food) may be seen.

V. Also investigate the potential underlying causes.

Differential Diagnosis

I. Bronchopneumonia
II. Other forms of infectious pneumonia: viral, protozoal, mycotic, etc.
III. Acute respiratory distress syndrome
IV. Pulmonary thromboembolic disease
V. Pulmonary edema

Treatment and Monitoring

I. Improve pulmonary function.
A. Administer oxygen via nasal cannula, mask, or oxygen cage.
B. Intubate and apply positive-pressure ventilation if necessary.
C. Bronchodilators may be beneficial for bronchospasm.
1. Expiratory wheeze may be noted on physical examination.
2. Cats are especially prone to bronchospasm secondary to airway inflammation.
3. Methylxanthines relax bronchioles, enhance mucociliary clearance, and decrease respiratory muscle fatigue.
a. Aminophylline 6 to 11 mg/kg PO TID (dogs) and 4 to 6 mg/kg PO BID (cats)
b. Theophylline 4 to 5 mg/kg PO TID
4. Other bronchodilators may be empirically used.
a. Terbutaline 1.25-5.0 mg PO BID (dogs) and 0.625 mg to 1.25 mg PO BID (cats)
b. Albuterol 50 µg/kg PO TID or aerosolized and inhaled
c. Ipratropium bromide aerosol

II. Administer antibiotics according to culture results (no evidence for prophylactic use).
III. Treat for shock as indicated (see Chapter 132)
IV. Avoid overhydration with fluid therapy as increased tissue permeability may contribute to translocation of fluid into diseased lung.
V. Prevent further aspiration.
A. Intubate if animal is anesthetized or has a depressed state of consciousness.
B. Reposition feeding tubes.
C. Institute "upright" feeding for esophageal or pharyngeal disorders.

VI. Monitoring is similar to that described for Bacterial Pneumonia earlier in this chapter.

IDIOPATHIC DISORDERS

Acute Respiratory Distress Syndrome

Definition

I. Acute respiratory distress syndrome causes acute hypoxemic respiratory failure as a result of lung injury and increased tissue permeability.
II. ARDS is not a disease entity by itself, but is a syndrome identified secondary to numerous, critical illnesses.
III. Although well described, it is not known why the syndrome develops.

Causes

I. Sepsis
II. Acid aspiration
III. Multiple transfusions
IV. Shock
V. Pancreatitis
VI. Pneumonia, inhalation injury
VII. Drug reaction or overdose
VIII. Major trauma or surgery

Pathophysiology

I. In the early phase of ARDS, exudation of proteinaceous fluid (low-pressure pulmonary edema) occurs as a direct result of lung capillary injury and increased permeability.
II. In the later phases (7 to 10 days post insult), increased numbers of inflammatory cells, hyaline membrane formation, and fibrosis with increased dead-space fraction develop.
III. Severe hypoxemia occurs from arteriovenous shunting and ventilation-perfusion irregularities.
IV. Pulmonary hypertension (PH) occurs as a result of hypoxic-induced vasoconstriction and microembolization with capillary obstruction.

Clinical Signs

I. Acute, severe respiratory distress and tachypnea
II. Tachycardia
III. Anxiety, agitation
IV. Crackles and wheezes, particularly on expiration
V. Lung sounds sometimes quieter than expected (associated with hypovolemia)

Diagnosis

I. Onset of clinical signs hours to days after a precipitating event is highly suspicious.
II. Thoracic radiography reveals generalized interstitial or mixed pattern, consistent with noncardiogenic pulmonary edema (see Box 18-2).
III. Echocardiography may provide supportive information.
   A. It may be used to rule out left atrial and ventricular abnormalities that can be associated with high-pressure (cardiogenic) pulmonary edema.
   B. Evidence of acute PH (right ventricular [RV] and atrial dilation, estimation of pulmonary pressures from pulmonic or tricuspid regurgitation) supports the diagnosis of ARDS.
IV. Pulmonary capillary wedge pressure is low (<18 mm Hg) with ARDS and elevated with cardiogenic pulmonary edema.
V. Edema fluid analysis provides useful information in the early stages of ARDS.
   A. Fluid may be suctioned from the airways via tubing passed through an endotracheal tube.
   B. The ratio of protein content of the edema fluid (E) to the protein content in plasma (P) in ARDS is 79% to 90%, whereas the E:P ratio in cardiogenic edema is <50% (Bhorade, 1999).

Differential Diagnosis

I. Cardiogenic pulmonary edema
II. Other causes of noncardiogenic pulmonary edema: neurogenic, etc.
III. Pulmonary thromboembolic disease
IV. Acute pneumonia
V. Pulmonary contusions
VI. Aspiration pneumonia without ARDS

Treatment

I. Treat any defined underlying condition.
II. Oxygen therapy is essential.
   A. Supplemental oxygen is provided with a nasal cannula, Elizabethan collar method, or oxygen cage.
   B. Intubation and mechanical ventilation are sometimes indicated.
   C. Positive end-expiratory pressure methods are ideal in severe cases.
III. Maintain low-normal circulatory volume with cautious fluid therapy.
   A. Administer the smallest volume of fluids that maintains cardiac output and arterial blood pressure.
   B. A Swan-Ganz or other hemodynamic measuring catheter may be used to monitor cardiac output, and pulmonary capillary wedge and right heart pressures.
   C. Central venous pressure measurements are misleading if significant PH exists.
   D. Serial measurements of arterial blood pressure, PCV, TP, electrolytes, and renal function tests are useful to estimate hydration status.
IV. Corticosteroids are of unconfirmed benefit.
V. Diuretics may be clinically helpful in the initial phases but are of no benefit in the later phase (>5 to 7 days).
VI. Careful attention to hydration status is required with diuretic therapy.
VII. Nitric oxide as an endogenous mediator of vascular smooth muscle relaxation is under investigation (Bhorade, 1999).
VIII. Unfortunately, clinical trials in humans have not demonstrated any beneficial drug combination in improving survival.

Monitoring of Animal

I. Monitor respiratory rate and effort every 1 to 8 hours.
II. Assess serial blood gas measurements SID to QID.
III. Monitor hydration status by evaluating volume-related changes.
   A. Cardiac output, arterial blood pressure
   B. Pulmonary capillary wedge pressure
   C. Serial PCV, TP, electrolyte assays
   D. Renal function tests, urine output
IV. Thoracic radiographs are repeated SID to QOD.
V. Prognosis with severe ARDS is poor to guarded.

Lung Lobe Torsion

Definition and Causes

I. Lung lobe torsion is rotation of a lung lobe around its long axis.

II. The exact mechanism that results in increased mobility of a lung lobe is unknown.
III. Lung lobe torsion may be idiopathic, particularly in deep-chested breeds of dogs.
IV. The torsion may be associated with several events.
  A. Pleural effusion of alternate etiology
  B. Thoracic surgery and manipulation of tissues
  C. Trauma causing sudden lung lobe compression

Pathophysiology

I. Rotation of the lung lobe at the hilus strangles the bronchus and vascular pedicle.
  A. There is obstruction to ventilation and venous drainage.
  B. The artery remains partially patent.
  C. Progressive lobar engorgement of blood occurs.
  D. The lobe becomes an expansile mass.
  E. Increased hydrostatic pressure (venous congestion) causes exudation of bloody fluid into the pleural space.
    1. Pleural effusion may further impair tidal volume.
    2. Mild blood loss anemia can be observed.
II. Necrosis, fibrosis, and shrinkage of the lung lobe may eventually occur.

Clinical Signs

I. Historically, signs of preexisting pulmonary or pleural space disease may present.
II. Signs are usually acute and progressive.
  A. Respiratory distress and tachypnea
  B. Cough, with or without hemoptysis
  C. Hypotension and collapse
  D. Fever and lethargy

Diagnosis

I. Signalment may provide helpful clues, because deep-chested breeds (especially sight hounds) appear to have an increased incidence.
II. Physical examination is compatible with pleural effusion (see Chapter 19).
III. Thoracic radiographic findings vary depending on the stage of the disease.
  A. Pleural effusion usually obscures parenchymal detail.
  B. The pleural effusion may be removed and the radiographs repeated.
  C. Lobar consolidation is typically noted.
  D. Air bronchograms may occur early, but air is reabsorbed later.
  E. Rounding of the lung lobe edges is noted as the lung becomes engorged.
  F. The bronchus may lie in an incorrect anatomical plane.
IV. Pleural fluid analysis is consistent with a hemorrhagic modified transudate (see Chapter 19).
V. Underlying conditions may produce other laboratory abnormalities (e.g., hypoproteinemia associated with protein-losing enteropathy resulting in pleural effusion).
VI. Bronchoscopy is sometimes needed to verify rotation of the bronchus.
VII. Surgical exploration is necessary to confirm the diagnosis in some cases.
VIII. Histopathologic examination of the excised lung lobe is performed to rule out an underlying disease.

Differential Diagnosis

I. Other causes of bloody pleural effusion (see Chapter 19)
II. Lung mass and/or neoplasia
III. Lobar pneumonia
IV. Pleural space mass and/or neoplasia
V. Diaphragmatic hernia

Treatment

I. Improve tissue oxygenation.
  A. Provide supplemental oxygen with nasal cannula, mask, or oxygen cage.
  B. Remove pleural fluid to enhance lung expansion.
  C. Consider an indwelling chest tube, if warranted.
II. Support circulatory function with IV fluid therapy to maintain hydration and systemic blood pressure.
III. Surgical resection of the affected lobe is typically curative.

Monitoring of Animal

I. Anesthesia must be monitored carefully, because these animals are severely compromised.
II. Postoperatively, an indwelling chest tube is usually placed for the first 12 to 48 hours.
III. Respiratory rate and effort and mucous membrane color are monitored every 1 to 6 hours for the first 24 to 48 hours postoperatively.
IV. Prognosis is good with lobectomy, but underlying conditions may require additional therapy and monitoring.

Cystic-Bullous Lung Disease

Definition

I. Circumscribed regions of air and fluid occur in the lung parenchyma.
II. They form cysts, bullae, or pneumatoceles.
  A. Cysts are fluid- or air-filled lesions surrounded by respiratory epithelium.
  B. Bullae are large areas of air accumulation formed by the loss of alveolar walls.
  C. Pneumatoceles result from air entry into a necrotic lesion, such as an abscess, granuloma, or tumor.

Causes and Pathophysiology

I. Cysts may be congenital or acquired.
II. Bullae occur as a result of emphysema (bullous emphysema), inflammation, trauma, or undefined reasons.
  A. Emphysema results from enlargement and destruction of bronchial and alveolar walls secondary to obstructive pulmonary diseases, such as chronic bronchitis.
  B. The loss of radial traction from the alveoli contributes to airway collapse, because alveoli may fill with air, but expiration is impaired by airway closure.
III. *Paragonimus kellicotti* (lung fluke) can cause granuloma and/or pneumatocele formation in dogs and cats.
IV. Any of these lesions may rupture, creating a pneumothorax.

V. Depending on the number and severity of lesions, significant functional lung parenchyma may be lost, and large lesions may compress airways.

Clinical Signs

I. Signs may relate to the primary disease processes, such as chronic bronchitis or traumatic insult.
II. Acute respiratory distress and tachypnea can occur when cysts or bullae rupture, creating a pneumothorax.
III. Occasionally cystic-bullous lung disease is an incidental finding on thoracic radiography, and no clinical signs are reported.

Diagnosis

I. Thoracic radiography reveals solitary nodules or visible margins of cavitary lesions in the peripheral lung fields.
   A. Initially these lesions may be obscured by soft-tissue opacity from primary disease processes.
   B. Pneumothorax is identified if a cavitary lesion has ruptured.
II. Cytology from any specimens obtained via thoracocentesis (for fluid or air) may be helpful.
   A. *Paragonimus* spp. ova might be found.
   B. Aspiration of a bullous lesion is not recommended, owing to the risk of pneumothorax.
III. Thoracotomy, excision of the lesion, and histopathologic evaluation are often required for definitive diagnosis.

Differential Diagnosis

I. Trauma or any other cause of pneumothorax
II. Pleural effusion
III. Chronic bronchial disease

Treatment

I. Identify and treat acute pneumothorax, as needed (see Chapter 19).
II. Surgical exploration and removal of cavitary lesions is warranted in those animals with recurrent pneumothorax.
   A. Removal of localized lesions has the best long-term prognosis.
   B. Bullous emphysematous disease is difficult to surgically correct, because the bullae are numerous and the disorder is usually progressive.
   C. Even though recurrence is common, survival of >2 years is reported postoperatively (Hawkins, 2000).
III. Successful treatment of underlying diseases, such as chronic bronchial disease or lung flukes, provides the best chance of success.

Monitoring of Animal

I. Monitor anesthesia carefully because these animals are severely compromised.
II. An indwelling chest tube is usually placed for the first 12 to 48 hours after surgery.
III. Monitor respiratory rate and effort and mucous membrane color every 1 to 6 hours for the first 24 to 48 hours postoperatively.
IV. Monitor thoracic radiographs frequently for recurrence of bulla or cysts.
V. If bulla(e) are found radiographically, treatment is generally not advised unless the animal becomes symptomatic (i.e., development of pneumothorax).

PARASITIC DISEASES

Aelurostrongylus abstrusus

Definition and Cause

Aelurostrongylus abstrusus is a nematode that resides in the small airways and pulmonary parenchyma of cats (definitive host).

Pathophysiology

I. Ingestion of the intermediate host (snails, slugs) or the transport hosts (birds, lizards) results in infection.
II. Larvae migrate to small airways, mature into adults, and result in inflammatory and hypersensitivity reactions.
   A. Eosinophilic infiltrate
   B. Bronchospasm
   C. Airway exudate
III. Interstitial granuloma formation is common.
IV. First-stage larvae are expelled from the airways, swallowed, and passed in the feces.
V. Fecal spread of larvae to intermediate hosts and secondary spread to transport hosts then occur.

Clinical Signs

I. Most cats are asymptomatic, but young cats may be more likely to develop clinical signs.
II. The symptoms are indistinguishable from those of feline allergic bronchitis (primarily cough).

Diagnosis

I. Identification of larvae on bronchial wash samples or fecal flotation using the Baermann technique is definitive.
II. Multiple fecal samples must usually be evaluated (intermittent larval shedding).
III. Thoracic radiography may reveal a diffuse bronchointerstitial or a miliary and/or nodular interstitial pattern, similar to feline allergic bronchitis.

Differential Diagnosis

I. Feline allergic bronchitis
II. Bronchopneumonia
III. Other eosinophilic lung disease
IV. Capillariasis

Treatment and Monitoring

I. Fenbendazole 25 to 50 mg/kg PO BID for 14 days
II. Ivermectin 400 μg/kg PO once (Kirkpatrick and Megella, 1987)
III. Possibly corticosteroids for short-term control of clinical signs
IV. Signs monitored with thoracic radiographs
V. Prognosis excellent

Capillaria aerophila

Definition and Cause

Capillaria aerophila is a small nematode that lives beneath the epithelial surfaces of the large airways of dogs and cats.

Pathophysiology

I. Infection is via ingestion of ova or the paratenic host (earthworm).
II. Larvae migrate to the large airways and live beneath the epithelial surface.
III. Hypersensitivity to the parasite appears important for clinical symptoms.

Clinical Signs

I. Signs are uncommon.
II. Occasionally, animals present with signs of allergic bronchitis (cough).

Diagnosis

I. Thoracic radiography may be normal or reveal a bronchial to bronchointerstitial lung pattern.
II. Peripheral eosinophilia may be found.
III. Airway secretions obtained via bronchoalveolar lavage or tracheal wash are examined for *C. aerophila* ova.
IV. Fecal flotation may contain parasite ova, which may be confused with those of *Trichuris vulpis.*

Differential Diagnosis

I. Chronic bronchitis
II. Bronchopneumonia
III. Eosinophilic lung disease (nonparasitic)
IV. *Aelurostrongylus* spp. in cats

Treatment and Monitoring

I. Fenbendazole is given at a dose of 25 to 50 mg/kg PO BID for 14 days for dogs and cats.
II. Levamisole is administered at 8 mg/kg PO SID for 10 to 20 days in dogs.
III. Ivermectin 400 μg/kg PO is used except in ivermectin-sensitive dog breeds.
IV. Monitor clinical signs closely, but expect a good prognosis.

Paragonimus kellicotti

Definition and Cause

I. *Paragonimus kellicotti* is a small fluke that normally resides in the lung tissue of mink and other wild carnivores.
II. Snails and crayfish are necessary intermediate hosts, and the disease is most common in the Great Lakes region of the Midwest and in the southern United States.

Pathophysiology

I. Adult flukes live primarily in the caudal lung lobes and are walled off by an inflammatory, granulomatous response.
II. A connection from the granuloma to the airway allows for the passage of eggs.
III. Pneumatoceles (leakage of air into the granuloma) may occur.
IV. Granulomas may rupture, creating a pneumothorax.

Clinical Signs

I. Most animals are presented for chronic cough not responsive to traditional therapies.
II. Infection is more common in cats than dogs.
III. Some animals show no clinical signs.
IV. Occasionally, animals have signs of pneumothorax.

Diagnosis

I. Thoracic radiography often reveals solitary or cavitary mass lesions in the caudal (especially right side) lung lobes.
II. A bronchointerstitial or mixed interstitial-alveolar pattern may also be present.
III. Identification of the large operculated ova in fecal specimens or airway washes confirms the diagnosis.
IV. Fecal sedimentation may be needed to find ova.

Differential Diagnosis

I. Chronic bronchitis
II. Bronchopneumonia
III. Eosinophilic lung disease (nonparasitic)
IV. *Aelurostrongylus* spp. in cats
V. Other causes of cystic-bullous lung disease
VI. Neoplasia

Treatment and Monitoring

I. Give fenbendazole at doses of 25 to 50 mg/kg PO BID for 14 days for dogs and cats.
II. Thoracocentesis may be necessary to stabilize any pneumothorax.
III. Place chest tubes initially for large-volume pneumothorax.
IV. Surgical intervention is rarely needed.
V. Assess response to treatment through thoracic radiographs and serial fecal exams.
   A. Repeat treatment may be necessary in some cases.
   B. Prognosis is excellent.

IMMUNE/HYPERSENSITIVITY DISORDERS

Pulmonary Infiltration with Eosinophilia

Definition

I. Profound eosinophilic inflammation of the interstitium is sometimes referred to as pulmonary infiltration with eosinophilia (PIE) or eosinophilic pulmonary granulomatosis (EPG).
II. These disorders are characterized by pronounced eosinophilic interstitial pulmonary inflammation.

Causes

I. Eosinophilic inflammation is a hypersensitivity response to an underlying antigen source.
II. Heartworm disease is commonly associated with PIE and granulomatosis.

III. Other causes may include pulmonary parasites, inhaled allergens, and drugs.
IV. Some cases appear idiopathic or as a part of a hypereosinophilic syndrome.

Pathophysiology

I. Immunological mechanisms are likely responsible for the pathogenesis and progression.
II. Inflammation may result from various factors.
  A. Hypersensitivity to an antigenic stimulus
  B. Immune complex deposition and complement activation
  C. Cell-mediated (delayed) hypersensitivity in chronic disease

Clinical Signs

I. Coughing is the most common clinical complaint; however, other respiratory symptoms may be noted.
II. Auscultation can reveal normal lung sounds or crackles and expiratory wheezes.
III. Systemic signs (anorexia, weight loss), if present, are usually mild.

Diagnosis

I. Complete blood count
  A. Peripheral eosinophilia is a common finding, but is not present in every case.
  B. Basophilia may occasionally be noted.
II. Thoracic radiography
  A. A diffuse, patchy interstitial pattern is typical.
  B. Eosinophilic granuloma formation may produce a nodular or nodular-interstitial pattern.
  C. Hilar lymphadenopathy may be found, particularly in cases of EPG.
  D. Right ventricular (± atrial) enlargement and dilated pulmonary arteries (especially proximally) may occur as a result of prolonged PH.
III. Cytology of pulmonary specimens usually diagnostic
  A. Sources include tracheal or bronchial wash and transthoracic aspirate.
  B. Eosinophils predominate.
  C. A smaller, mixed population of inflammatory cells is also common.
  D. Mast cells are occasionally found.
IV. Definitive diagnosis: histopathology of lung biopsy
V. Identification of underlying source of antigenic stimulation
  A. Heartworm testing
  B. Fecal flotation for parasites
  C. Serological testing and/or cultures for systemic mycoses
  D. Careful examination of biopsy specimens for infectious agents or neoplasia

Differential Diagnosis

I. Chronic allergic bronchitis
II. Parasitic lung disease
III. Diffuse pulmonary neoplasia
IV. Lymphomatoid granulomatosis
V. Severe bronchopneumonia: bacterial or mycotic

Treatment

I. Identification and elimination of the underlying source of antigen may be curative.
II. Corticosteroids are the primary medical therapy.
  A. Prednisone 1 to 2 mg/kg PO BID is the most common therapy.
  B. Inhalant corticosteroids have been empirically used with reasonable success.
  C. Incomplete responses are possible, especially in dogs with EPG.
III. Immunosuppressive medications can be added in dogs that do not respond to prednisone alone.
  A. Cyclophosphamide 50 mg/m^2 PO QOD
  B. Azathioprine 2 mg/kg PO SID for 7 to 10 days, then QOD
IV. Antibiotics are indicated if secondary infection is confirmed on initial evaluation.
V. Bronchodilators can be helpful to reduce bronchospasm, enhance mucociliary clearance, and decrease respiratory muscle fatigue.
  A. Methylxanthine-derivatives
    1. Aminophylline 6 to 11 mg/kg PO TID (dogs) and 4 to 6 mg/kg PO BID (cats)
    2. Theophylline 4 to 5 mg/kg PO TID
  B. Other bronchodilators
    1. Terbutaline 1.25 to 5.0 mg PO BID (dogs) and 0.625 mg to 1.25 mg PO BID (cats)
    2. Albuterol 50 µg/kg PO TID or aerosolized, inhaled
    3. Ipratropium bromide aerosolized, inhaled

Monitoring of Animal

I. Clinical signs are used to monitor response to therapy.
  A. The animal's response to therapy is reassessed at least weekly.
  B. After resolution of clinical signs, medications are gradually tapered to the lowest effective dose.
  C. After 3 months of remission of clinical signs, medications may be stopped in some cases.
II. Thoracic radiography is also used to assess response to therapy.
III. Radiographs are reevaluated initially at least once weekly.
IV. Monitor a CBC every 2 weeks to look for signs of bone marrow suppression if immunosuppressive agents are administered.
V. Medication adjustments are frequently required over time based on clinical response and appearance of adverse reactions.
VI. Many animals require lifelong drug therapy.

VASCULAR DISORDERS

Pulmonary Thromboembolism

Definition

I. Pulmonary thromboembolism (PTE) is occlusion of the pulmonary arterial system with thrombi.
II. The emboli may arise from a distant site.

III. PTE is often a secondary phenomenon, and the predisposing condition is usually identifiable.

Causes

I. Hypercoagulable states
   A. Protein-losing disorders: enteropathies, nephropathies
   B. Hyperadrenocorticism
II. Sepsis
III. Disseminated intravascular coagulation
IV. Immune-mediated disorders, including anemia and thrombocytopenia
V. Vascular diseases: heartworm, vasculitis
VI. Neoplasia, especially adenocarcinomas (Goldhaber, 2000)
VII. Other chronic pulmonary inflammation, particularly when associated with significant PH
VIII. Systemic inflammatory syndromes (without sepsis), such as pancreatitis
IX. Trauma or surgery with immobilization
X. Iatrogenic: indwelling catheters, transfusions

Pathophysiology

I. One or more alterations of the components of Virchow's triad lead to thrombi formation.
   A. Endothelial trauma or disease
   B. Hypercoagulability
   C. Blood stasis
II. Thrombi lodge in pulmonary arteries, creating several sequelae.
   A. Ventilation-perfusion abnormalities
   B. Hypoxemia, tachypnea, and hypocapnia (hypercapnia in severe cases)
   C. Reflex pulmonary arterial vasoconstriction
   D. Bronchoconstriction mediated by vasoactive substances
III. PH arises from several factors.
   A. Increased pulmonary vascular resistance
   B. Vasoconstriction
   C. Arterial wall hypertrophy and fibrosis in chronic cases
IV. Right heart failure may ensue.
V. Systemic hypotension may result from diminished filling of the left ventricle (LV) and poor cardiac output.

Clinical Signs

I. Respiratory distress, tachypnea
II. Coughing ± hemoptysis
III. Jugular distention and pulsations
IV. Symptoms of right heart failure: pleural, abdominal effusion
V. Auscultation findings suggestive of PH (see next section)
VI. Crackles or increased bronchial sounds, possibly normal lung sounds

Diagnosis

I. A history of predisposing factors combined with appropriate clinical signs help make the diagnosis.
II. Thoracic radiography may be normal or reveal one or more abnormalities.
   A. Enlargement of proximal pulmonary arteries
   B. Attenuation of peripheral pulmonary vessels
   C. Right atrial ± RV enlargement
   D. Mild pleural effusion
   E. Increased interstitial opacities, particularly in the caudodorsal lung fields
   F. Focal oligemia with massive central artery occlusion (Westermark's sign)
III. Blood gas analysis is not specific for PTE, but may reveal several abnormalities.
   A. Hypoxemia, hypocapnia (hypercapnia in severe disease)
   B. Metabolic acidosis
   C. Normal blood gases in early, mild disease
IV. Echocardiography helps support the diagnosis of PTE by identifying PH (see next section).
V. Plasma D-dimer assays support the diagnosis of PTE, because D-dimer concentrations >1000 ng/dL have a specificity of 94% (sensitivity 80%) and concentrations >2000 ng/dL have a specificity of 98.5% (sensitivity 36%) in predicting PTE.
VI. A ventilation-perfusion nuclear scan is most helpful if it is clearly normal or clearly abnormal; however, most scans are inconclusive (Kress, 1999).
VII. Pulmonary angiography is the most sensitive and specific test for PTE.
   A. Identifies filling defects in the arteries or cessation of blood flow
   B. Can detect emboli as small as 1 to 2 mm (Goldhaber, 2000)
   C. Heavy sedation or anesthesia required and usually a disadvantage in the compromised animal
VIII. High resolution helical computed tomography may be performed at some institutions.

Differential Diagnosis

I. Airway obstruction
II. Acute pneumonia
III. Acute respiratory distress syndrome
IV. Other pulmonary parenchymal disorders
V. Other causes of PH

Treatment

I. Improve tissue oxygenation with supplemental oxygen (nasal cannula, mask, or oxygen cage).
II. Positive end-expiratory pressure ventilation is sometimes required in severe cases.
III. Cautious use of parenteral fluid therapy is necessary.
   A. These animals may be hypotensive because of pulmonary arterial obstruction and diminished filling of the LV.
   B. Aggressive IV fluids may exacerbate RV pressure overload and displace the interventricular septum, further impairing LV filling.
IV. Anticoagulant therapy prevents further clot formation while allowing for endogenous fibrinolysis.
   A. Heparins are the cornerstone of therapy.
      1. Give unfractionated heparin at 200 U/kg IV, followed by 75 to 200 U/kg SC TID to QID.

2. Assess a partial thromboplastin time (aPTT) SID to QID if the higher dosing ranges are used.
3. Have protamine sulfate available to antagonize a heparin overdose.
   a. Give 1 mg protamine for each 100 U of heparin to be inactivated.
   b. Reduce dose by half for every 30 minutes lapsed since heparin was administered.
4. Low-molecular-weight heparin has been experimentally shown to provide safer and more effective anticoagulant coverage for dogs; however, the dose is not well established in clinical patients.

B. Warfarin or coumarin derivatives can be used.
1. They provide long-term antagonism of coagulation.
2. Coagulation times must be closely monitored and can be difficult to regulate.
3. Warfarin 0.1 mg/kg PO SID is the recommended dose.

C. Antiplatelet drugs, such as aspirin, ticlopidine and clopidogrel, are used primarily for prevention in high-risk disease states.

V. Fibrinolytic therapy includes agents such as streptokinase and tissue plasminogen activator.
A. The therapy is most effective in relatively acute states (<2 weeks).
B. Excessive bleeding can be a significant side effect.

VI. Embolectomy may be considered if the thrombus is centrally located, but the mortality rate with surgery is high.

VII. Identification and treatment of the predisposing condition is very important.

Monitoring of Animal

I. Detect response to therapy and resolution of thrombi by improvements in the following parameters:
A. Respiratory rate and effort
B. Serial blood gases or pulse oximetry
C. Pulmonary and systemic blood pressures
D. Thoracic radiography

II. Monitor coagulation times, such as aPTT or prothrombin time (PT) carefully.
A. With unfractionated heparin therapy, a 1.5-fold to twofold increase in the PT is desirable.
B. With warfarin therapy, a 1.5-fold to twofold rise in the PT is desirable.

III. Prognosis is variable depending on the size and location of the thrombi and their underlying cause.

IV. The prognosis is especially poor with large central pulmonary artery thrombi.

Pulmonary Hypertension

Definition

I. Pulmonary hypertension is an increase in pulmonary vascular resistance caused by vasoconstriction, vascular obstruction, vascular volume overload, or lung resection, and occurs secondary to many pulmonary parenchymal disorders.

II. PH can be acute or chronic.

III. PH is typically a secondary phenomenon; recognizing the existence of PH necessitates a search for the underlying condition.

Causes

I. Acute pressure overload
A. Pulmonary thromboembolism
B. Acute respiratory distress syndrome
C. Acute hypoxic pneumonia
D. Extensive lung resection

II. Chronic pressure overload
A. Chronic airway diseases: bronchitis, bronchiectasis, emphysema
B. Chronic parenchymal disorders: neoplasia, PIE, etc.
C. Restrictive lung disease: pleural and pleural space disease
D. Chronic PTE
E. Heartworm disease
F. Congenital heart disease
G. Occasionally idiopathic forms

Pathophysiology

I. Elevations in pulmonary arterial pressure are accompanied by elevations in RV preload, afterload, intraventricular pressure, and heart rate.

II. As RV pressure rises, the interventricular septum shifts to the left, impairing LV filling.

III. A vicious cycle ensues wherein increases in RV pressure promote RV ischemia and dilatation, worsen LV filling and myocardial ischemia, and exacerbate hypotension.

IV. Right heart failure can also occur.

Clinical Signs

I. Signs are usually referable to the underlying disease process.

II. Tachypnea, cough, and exercise intolerance (hypoxia and hypotension) are common.

III. A sudden onset of respiratory distress may be noted if the cause of PH is an acute process or involves acute decompensation of a chronic process.

IV. Jugular distention and pulsations suggest elevated right heart filling pressures.

V. The precordial impulse may feel stronger on the right hemithorax.

VI. Right heart failure may be present (pleural effusion, ascites).

VII. Auscultation may reveal one or more abnormalities.
A. Tricuspid regurgitation
B. Split S2 and/or loud, "snappy" S2 sounds
C. Right-sided S3 sound

Diagnosis

I. A history of predisposing factors combined with appropriate clinical signs help make the diagnosis.

II. Thoracic radiography may be normal or reveal one or more abnormalities.

A. Enlargement of proximal pulmonary arteries
B. Attenuation of peripheral pulmonary vessels
C. Right atrial ± RV enlargement
D. Mild pleural effusion
E. Radiographic pulmonary patterns consistent with underlying causes

III. Echocardiographic signs of PH include the following:
A. A poorly contracting RV
B. Tricuspid regurgitation
C. Leftward shifting of the interventricular septum
D. Pulmonary artery dilatation and pulmonic regurgitation
E. Possibly a thrombus in the right atrium, RV, or main pulmonary artery
F. Loss of the respiratory variation of the diameter of the caudal vena cava

IV. Catheterization of the right side of the heart and the pulmonary artery definitively documents hypertension in these chambers.

V. Laboratory evidence of other underlying disease states also may be present.

Differential Diagnosis

I. Acute or chronic respiratory conditions without PH
II. Other cardiac diseases

Treatment

I. Enhance arterial oxygen saturation and attempt to keep it >96%.
II. Minimize oxygen demands via sedation, treatment of fever, and assisted ventilation.
III. Finding the optimal circulatory volume can be challenging.
A. Aggressive IV fluids may exacerbate RV pressure overload and displace the interventricular septum, impairing LV filling and output.
B. If no benefit is noted in response to discrete fluid therapy, consider vasoactive drug therapy.
IV. Vasoactive drugs may be beneficial in increasing right-sided cardiac output.
A. Dobutamine 5 to 7 μg/kg/min IV
B. Dopamine 5 to 7 μg/kg/min IV
V. Pulmonary arterial dilator therapy has received much attention, but specific therapy is not well established.
A. Calcium channel blockers have been advocated.
B. Sildenafil (2 to 3 mg/kg PO BID to TID) has been empirically used with reasonable success.
C. Inhaled nitric oxide is a potent pulmonary vasodilator.
VI. Treatment of any underlying condition is of utmost importance.

Monitoring of Animal

I. Use response to therapy to guide treatment.
A. Respiratory rate and effort
B. Serial blood gases or pulse oximetry
C. Pulmonary and systemic blood pressures
D. Thoracic radiography

II. The underlying condition and the effectiveness of therapy require close monitoring.

NEOPLASIA

Definition

I. Tumors of the pulmonary parenchyma can be primary, metastatic, or multicentric in origin.
II. Metastatic and multicentric neoplasms are more common than primary ones.
III. Older animals are affected most often, although young animals may sometimes develop lymphoma and lymphomatoid granulomatosis (dogs).

Causes

I. Primary lung tumors are typically malignant.
A. Carcinomas are the most common neoplasm.
1. Adenocarcinoma
2. Bronchoalveolar carcinoma
3. Squamous cell carcinoma
4. Small-cell carcinoma
B. Primary sarcomas and benign neoplasms are uncommon.
C. Lymphomatoid granulomatosis is a disease akin to lymphosarcoma.
II. There are numerous metastatic neoplasms involving the lungs.
A. Carcinomas: nonpulmonary and pulmonary origin
B. Osteosarcoma, fibrosarcoma
C. Hemangiosarcoma
D. Melanoma
E. Other malignant tumors
III. Multicentric neoplasms can involve the lung.
A. Lymphosarcoma
B. Mast cell tumor
C. Malignant histiocytosis

Pathophysiology

I. Environmental factors, such as passive cigarette smoke, have been implicated.
II. Genetic factors may play a role in some neoplasms (e.g., malignant histiocytosis in Bernese mountain dogs).
III. Metastasis to the lungs is common via hematogenous or lymphatic systems.
IV. Tumor emboli may be trapped in the lung owing to its extensive capillary network.
V. Hypertrophic pulmonary osteopathy is the most common paraneoplastic syndrome in dogs (see Chapter 81).
VI. Neoplasms may cause clinical signs from ventilation-perfusion abnormalities, compression or obstruction of airways, or pleural space disease (mass affect or effusion).
VII. Inflammatory reactions to the tumors contribute to the pathology (e.g., secondary infections, hemorrhage, PTE).

Clinical Signs

I. Cough
II. Tachypnea ± respiratory distress

III. Weight loss, anorexia, lethargy
IV. Fever
V. Lameness from hypertrophic pulmonary osteopathy

Diagnosis

I. Thoracic radiography often provides a tentative diagnosis of neoplasia.
   A. Left and right lateral projections and a dorsoventral projection are needed to thoroughly assess the pulmonary parenchyma.
   B. Tumor margins may be distinct or indistinct if inflammation and edema are present.
   C. Some general radiographic patterns are noted.
      1. A solitary nodule may be associated with primary lung tumors.
         a. Right caudal lung lobes are the most common location in dogs.
         b. Left lung lobes are affected more commonly in cats.
      2. Multiple circumscribed nodules are often seen with metastatic neoplasia.
      3. An interstitial generalized, reticulonodular pattern can be noted with multicentric or metastatic neoplasia.
      4. A mixed, disseminated alveolar pattern may indicate a concurrent secondary inflammatory process.
      5. Lobar consolidation is found in some cases.
   D. Other radiographic findings may include pleural effusion and thoracic or hilar lymphadenopathy.
II. Cytological evaluation of a percutaneous fine-needle aspirate, bronchoalveolar lavage, or pleural fluid can yield a tumor type.
III. Histopathologic evaluation of samples obtained at exploratory thoracotomy is sometimes necessary for a definitive diagnosis.

Differential Diagnosis

I. Nonneoplastic solitary lung lesions: cysts, granulomas
II. Lobar pneumonia
III. Mycotic pneumonia
IV. Parasitic lung disease

Treatment

I. Surgical intervention (lobectomy) is the treatment of choice for solitary lung tumors.
II. Chemotherapy is often recommended for neoplasms that are incompletely resected.
III. Chemotherapy may be a beneficial adjunctive therapy to surgery or may be indicated as the sole treatment depending on the tumor type.
IV. Lymphomatoid granulomatosis and malignant histiocytosis may be treated with lymphosarcoma protocols (see Chapters 69 and 77).

Monitoring of Animal

I. Prognosis depends on the tumor type, the tumor burden, and the degree of metastasis.
II. Surgical resection of a solitary tumor without metastasis carries the best long-term prognosis (>1 year).
III. Monitor thoracic radiographs every 1 to 3 months post-treatment.

TRAUMA

Pulmonary Contusions

Definition and Causes

I. Hemorrhage into the pulmonary parenchyma
II. Most often caused by blunt chest trauma
   A. Animals that have been hit by motorized vehicles commonly present with pulmonary contusions.
   B. Pulmonary hemorrhage can occur even when external thoracic damage is not detected.

Pathophysiology

I. Hemorrhage occurs from traumatic rupture of parenchymal vessels.
II. Bleeding occurs into the interstitium and alveoli in the region of the insult.
III. Flooding of the lung tissue with blood impairs normal gas exchange and results in clinical signs.

Clinical Signs

I. Acute tachypnea and respiratory distress are noted with severe contusions.
II. Tachypnea may also occur from pain, pneumothorax, or cardiovascular shock, which are common with acute pulmonary trauma.
III. Crackles are often ausculted over the contused area.
IV. Minimal clinical signs may be noted if only mild hemorrhage has occurred.

Diagnosis

I. History and physical examination (fractures, abrasions) may suggest a traumatic episode.
II. Thoracic radiography reveals regional, irregular patches of mixed interstitial-alveolar patterns (see Box 18-2).
III. Pneumothorax, lung consolidation, or rib fractures are sometimes identified.

Differential Diagnosis

I. Acute pneumonia
II. Acute respiratory distress syndrome
III. Pulmonary thromboembolic disease
IV. Lung lobe torsion

Treatment

I. Improve oxygenation with supplementation via nasal, mask, or oxygen cage.
II. Specific therapy for the contusions is not usually necessary.
III. Treatment for the other trauma-related problems is often more critical.

A. Blood loss
B. Circulatory shock
C. Fracture stabilization

Monitoring of Animal

I. Serial thoracic radiographs are evaluated for resolution of the abnormalities.
II. Frequency of radiography (every 1 to 5 days) depends on the severity of abnormality noted and the clinical signs.
III. Secondary complications such as abscessation, lung consolidation, or the formation of cavitary lesions may occur but are unusual.
IV. Prognosis is excellent for recovery from mild to moderate pulmonary contusions, provided that other injuries sustained are stabilized and fluid therapy is monitored carefully.

Near-Drowning

Definition

I. Near-drowning is aspiration of water during submersion.
II. The result is severe pulmonary damage.

Cause and Pathophysiology

I. Normal reflexes cause cessation of ventilation under water.
II. Increased levels of carbon dioxide in the bloodstream subsequently stimulate breathing efforts.
III. Aspiration of water dilutes surfactant, collapses alveoli, and causes severe oxygenation impairment.
IV. Aspiration of salt water exacerbates fluid flux into the alveoli (hypertonic solution).
V. Laryngospasm occurs in about 10% of cases, preventing aspiration of water and resulting in a "dry drowning" form of the condition (Hawkins, 1995).
VI. Bacteria, vomitus, or chemicals in the water may predispose to a secondary pneumonia.
VII. Severe hypoxia causes profound neurological disturbances from cerebral edema or herniation.

Clinical Signs

I. Loss of consciousness and severe respiratory distress or arrest are typical.
II. Cardiovascular shock and hypothermia may be noted.
III. Auscultation usually reveals inspiratory and expiratory crackles and wheezes.
IV. Neurological abnormalities and altered mentation may indicate cerebral edema.

Diagnosis

I. Diagnosis is based on the history of rescuing the animal from the water.
II. Thoracic radiography reveals generalized, mixed interstitial–alveolar pulmonary patterns.
A. Radiographic changes often lag 24 to 48 hours behind clinical symptoms.
B. The presence of radiopaque material in the airways (sand bronchograms) is a poor prognostic indicator.
III. Bronchial wash and cultures are indicated if there is suspicion of secondary bacterial infection.

Treatment

I. Ventilation is provided as soon as possible.
A. Cardiopulmonary or mouth-to-muzzle resuscitation is indicated during the initial rescue.
B. Provide oxygen with a nasal cannula, mask, or oxygen cage.
C. Positive-pressure ventilation is often required.
II. If neurological symptoms are present after metabolic stabilization, treatment for cerebral edema may be warranted (see Chapter 23).

Monitoring of Animal

I. Respiratory function as well as metabolic and neurological status are followed closely.
II. A poor prognosis is associated with coma, blood pH <7.0, respiratory arrest, and the need for mechanical ventilation.

Smoke Inhalation

See Chapter 133.

CHAPTER 19

Diseases of the Pleural Cavity

Graham Swinney

PLEURAL EFFUSION

Definition

I. Pleural effusion is the abnormal accumulation of fluid in the pleural space.
II. The pleura is a serosal surface that consists of a single layer of flattened mesothelial cells with an underlying thin layer of connective tissue that contains blood vessels and lymphatics (Forrester et al., 1991).
III. The pleura lining the thoracic walls, diaphragm, and mediastinum is the parietal pleura.
IV. The visceral pleura covers the serosal surface of the lungs.
V. The pleural space is the potential space between the parietal and visceral pleura.
VI. In normal animals, a small amount of fluid (2 to 3 mL) is present in the pleural space that serves as a lubricant for the lungs during respiration (Fossum, 2000).

Causes and Classification

I. Classification
   A. Based on physical characteristics (color, transparency, total protein, total nucleated cell count), effusions are classified as transudates, modified transudates, or exudates.
   B. Fluid can be further classified as pure transudates, hemorrhagic, inflammatory (nonseptic or septic), chylous, neoplastic, or pyogranulomatous types (Forrester et al., 1991).
II. Pure transudate (Table 19-1)
   A. Mechanism of production is usually reduced oncotic pressure from hypoalbuminemia.
   B. The cause of hypoalbuminemia can be reduced production (e.g., functional hepatic disease, portal vascular anomalies, malnutrition, malabsorption) or increased loss (e.g., protein-losing nephropathies, protein-losing enteropathies, vasculitis, inflammatory exudates, burns, wounds, hemorrhage, chronic gastrointestinal [GI] blood loss).
   C. Albumin is usually <1.5 g/dL, but a pure transudate can occur if albumin is >1.5 g/dL and there is also increased capillary hydrostatic pressure or lymphatic obstruction.
   D. With chronicity, a pure transudate may become modified from pleural irritation (Forrester et al., 1991).
III. Modified transudate
   A. It has a higher protein level and cellularity than a pure transudate.
   B. Factors increasing hydrostatic pressure or causing lymphatic obstruction can play a role (Forrester, 1988; Fossum, 2000).
      1. Heart failure in dogs: right-sided or combined right- and left-sided failure
      2. Heart failure in cats: right-sided failure, more commonly bilateral disease, or left-sided disease with pulmonary hypertension as pleural lymphatics drain into pulmonary veins (de Morais, 2000)
      3. Combined pleural and peritoneal effusions in cats: cardiac disease, neoplasia, hepatic or renal disease (Wright et al., 1999)
      4. Masses (usually neoplasms) obstructing pleural veins or lymphatics
      5. Pericardial effusion and cardiac tamponade or postpericardiectomy
      6. Lung lobe torsion
      7. Dirofilariasis
      8. Diaphragmatic hernia, especially with herniation of the liver into the thorax
      9. Pulmonary thromboembolism
IV. Exudate
   A. Mechanism of fluid production is often secondary to increased vascular or lymphatic permeability or to vessel obstruction.
   B. Inflammation of the pleural surface secondary to infection (pyothorax) is a potential cause.
      1. Obligate anaerobes are the most common isolates, especially in cats, followed by facultative organisms.
      2. Common organisms are listed in Table 19-2 (Walker et al., 2000).
      3. Unusual organisms may include *Mycoplasma* spp. and *Cryptococcus* spp. (Barrs et al., 2005).
      4. The source of infection can be extension from pneumonia (bacterial, viral, fungal, mycobacterial, parasitic); penetrating thoracic wounds; perforation of mediastinal structures, especially the esophagus; foreign bodies (e.g., grass awns); or hematogenous spread.
      5. Cats from multi-cat households are at a higher risk of pyothorax (Waddell et al., 2002).

TABLE 19-1

Characteristics of Pleural Effusions

TYPE OF EFFUSION	GROSS APPEARANCE	DIAGNOSTIC FEATURES	CYTOLOGY
Pure transudate	Clear, colorless No odor	Cell count <1000/μL Protein often <1.5 g/dL, s.g. <1.018 Low viscosity	Small lymphocytes, mesothelial cells, macrophages, neutrophils
Modified transudate	Serous serosanguineous Clear to moderately turbid	Cell count between 1000 and 5000/μL Protein variable, usually 2.5-3 g/dL s.g. 1.018-1.030	Variable: RBCs, neutrophils, lymphocytes ± eosinophils, macrophages, mesothelial cells May find neoplastic cells (e.g., lymphoblasts)
Exudate—nonseptic	Serous to serosanguineous to yellow Thick and viscous with FIP Hazy to turbid	Cell count >5000/mL Protein >3.0 g/dL s.g. >1.018	No bacteria Variable; if FIP: neutrophils, plasma cells, lymphocytes, macrophages, RBCs
Exudate—septic	Turbid or opaque White, yellow or red May have odor, especially if anaerobes involved ± Flocculent material or sulfur granules	Cell count >5000/μL Protein >3.0 g/dL s.g. >1.018	Neutrophils, may have degenerative changes, may see bacteria: intracellular ± extracellular
Chylothorax	Opaque, white, or pink	Cell count variable Protein 2.0-6.5 g/dL Fluid triglyceride concentration > serum triglyceride concentration Chylomicrons present	Lymphocytes perdominate but if chronic, neutrophils may be increased.
Hemothorax	Red	Cell counts similar to peripheral blood	RBCs, WBCs in similar proportions to peripheral blood May see erythrophagocytosis No platelets if present >45 min

s.g., Specific gravity; *RBC,* red blood cell; *FIP,* feline infectious peritonitis; *WBC,* white blood cell.

C. Other causes of exudative effusions include the following:
   1. Feline infectious peritonitis (FIP)
   2. Immune-mediated diseases: systemic lupus erythematosus, rheumatoid arthritis
   3. Uremia, pancreatitis
   4. Cardiac disease
   5. Neoplasia: chest wall or pulmonary (either primary or secondary) tumors, lymphosarcoma, mesothelioma
   6. Lymphomatoid or eosinophilic pulmonary granulomatosis (Bounous et al., 2000)

V. Hemorrhagic effusion
   A. Secondary to trauma, neoplasia, and coagulopathies (more likely coagulation system rather than platelet or vessel wall disease)
   B. Surgery, lung lobe torsion, dirofilariasis
   C. Pulmonary infarction

VI. Chylothorax effusion
   A. Idiopathic
   B. Thoracic lymphangiectasia
   C. Cardiac disease, pericardial effusion
   D. Trauma and rupture of the thoracic duct
   E. Neoplasia, thromboembolic disease
   F. Infectious causes: fungal granuloma and dirofilariasis
   G. Suspected breed predispositions for chylothorax: Afghan hound, Shiba inu, and purebred cats, particularly Asian breeds (Fossum et al., 1991; Fossum, 2000).
   H. Iatrogenic with cranial vena cava ligation or brachiocephalic vein ligation (Greenberg and Weisse, 2005)

VII. Other effusions
   A. Peritoneal fluid can cross the diaphragm via the lymphatics.
   B. Bile pleural effusion is reported in conjunction with biliary rupture (Barnhart and Rasmussen, 1996).
   C. Eosinophilic effusions occur with neoplasia, parasites, hypersensitivity reactions, and rarely pneumothorax (cat) (Fossum et al., 1993).
   D. Pseudochylous fluid is rare in small animals but can be associated with tuberculosis (Fossum, 2000).

TABLE 19-2

Characteristics of Common Bacterial Isolates with Pyothorax

BACTERIA	OXYGEN REQUIREMENT	GRAM'S STAIN	MORPHOLOGY	SENSITIVITY
Actinomyces spp.	Facultative or obligate anaerobe	Positive	Small bacillus, or filamentous with occasional branching, some sulfur granules	Penicillin, ampicillin, amoxicillin/clavulanate, erythromycin, doxycycline
Bacteroides spp.	Anaerobe	Negative	Bacillus, may stain poorly	Penicillin, metronidazole, amoxicillin/clavulanate, clindamycin, chloramphenicol
Escherichia coli	Facultative	Negative	Bacillus	Amikacin, gentamicin, ceftizoxime best; enrofloxacin possibly less effective
Fusobacterium spp.	Anaerobe	Negative	Bacillus—thin, may stain poorly	Penicillin, metronidazole, amoxicillin/clavulanate, clindamycin, chloramphenicol
Klebsiella spp.	Facultative	Negative	Bacillus, large capsule	Cefotaxime, amikacin, gentamicin, ticarcillin
Nocardia spp.	Aerobe	Positive, partially acid fast	Bacillus, filamentous, with beading from irregular staining, sulfur granules	Trimethoprim/sulphonamide, amikacin, ± imipenem, cephalosporin, ampicillin
Pasteurella spp.	Facultative	Negative	Bacillus, bipolar staining	Very susceptible to most drugs, including penicillin, amoxicillin/clavulanate
Peptostreptococcus spp.	Anerobe	Positive	Coccus	Penicillin, metronidazole, clindamycin, amoxicillin/clavulanate
Prophyromonas spp.	Anaerobe	Negative	Coccobacillus, pale staining	Penicillin, metronidazole, amoxicillin/clavulanate, clindamycin, chloramphenicol

Pathophysiology

I. Volume of pleural fluid is a result of a balance of fluid production by the parietal pleura and fluid absorption by the visceral pleura (Forrester et al., 1991).
II. Movement of pleural fluid is governed by Starling's forces (Forrester et al., 1991).
  A. The parietal pleura has a net force of approximately 9 cm H_2O, resulting in pleural fluid production.
  B. The visceral pleura has a net absorptive force of 10 cm H_2O.
III. The lymphatic drainage system removes fluid not absorbed by pleural capillaries (Forrester et al., 1991).
  A. Lymphatics are the only means for red blood cells (RBCs), proteins, and particulate matter to be absorbed.
  B. Lymphatic absorption is mainly via lower mediastinal pleura and costal parietal pleura.
  C. Hyperventilation increases lymphatic absorption, and hypoventilation reduces absorption of protein and RBCs.
IV. Mechanisms of pleural fluid production fall into one of four categories.
  A. Increased capillary hydrostatic pressure
  B. Reduced capillary oncotic pressure
  C. Lymphatic obstruction
  D. Increased vascular permeability

Clinical Signs

I. The severity of clinical signs varies with the underlying cause, the volume of the effusion, and the rate of fluid accumulation (Fossum, 2000).
II. A significant volume of fluid must be present before animals show signs of impaired ventilation.
III. Signs include a restrictive breathing pattern, increased inspiratory effort, tachypnea, shallow respiration, open-mouth breathing, cyanosis, lethargy, and coughing from irritation caused by the effusion.
IV. Depending on the cause, the signs also include a chronic cough, weight loss, inappetence, abdominal effusion, diarrhea, or concurrent signs of trauma.

Diagnosis and Differential Diagnosis

I. Physical examination
  A. Thoracic auscultation
    1. Muffled lung sounds ventrally, muffled heart sounds

2. Perhaps increased bronchovesicular lung sounds dorsally
3. Careful auscultation for cardiac murmurs, arrhythmias, and displacement of heart sounds to one side or caudally (suggesting a mass effect)

B. Thoracic percussion
1. In the presence of an adequate volume of fluid, thoracic percussion is hyporesonant (dull) ventrally.
2. Systematic percussion (with the animal standing or sternal) may detect a fluid line with normal resonance dorsally, and may determine if fluid accumulation is more severe on one side.

C. Thoracic compression
1. It is performed on the cranial thorax of all cats with an effusion.
2. Reduced compressibility occurs with a cranial mediastinal mass.

D. General physical examination
1. Abdominal fluid accumulation may occur with cardiac or hepatic disease, lymphosarcoma, or hypoalbuminemia.
2. In the presence of cardiac disease, jugular distension or pulses and/or altered peripheral pulse quality may be noted.
3. Other signs of systemic disease may be present, including pale mucous membranes, weight loss, lymphadenomegaly, signs of trauma, fever, and obtundation.

II. Thoracocentesis

A. Several methods have been described, but thoracocentesis is most commonly performed with the animal standing or in sternal recumbency (see Chapter 3).
1. Collect diagnostic samples using a 21- to 23-gauge butterfly needle connected to a three-way stopcock and a syringe, or by using a needle or an intravenous catheter with a three-way stopcock and an intravenous fluid extension set.
2. Place 5 mL of fluid into an ethylenediamine tetraacetic acid (EDTA) tube for cell analysis, and 5 mL into a plain tube for biochemical analysis.
3. Prepare four to six smears immediately and air dry these for cytological examination.
4. If fluid is of low cellularity, it can be centrifuged and smears made from the sediment (Forrester et al., 1991).

B. Also submit fluid for aerobic and anaerobic culture and sensitivity when cytological findings confirm the presence of an exudate.

III. Thoracic radiography

A. Ideally, pleural fluid is removed first, because more thorough evaluation of lung fields and other thoracic structures is then possible.

B. Take precautions not to stress the animal if significant fluid volume is still present, especially in cats.
1. Minimize handling.
2. Administer supplemental oxygen.
3. Perform dorsoventral rather than ventrodorsal views.
4. Standing lateral views may be taken.

C. Radiographic signs vary with the volume of fluid, but can include the following:
1. Increased number and thickness of interlobar fissures: seen with approximately ≥100 mL of fluid in a medium-sized dog (Thrall, 1998)
2. Decreased visualization of the heart, especially in the dorsoventral view
3. Retraction of lungs away from the thoracic wall, with a fluid density present between these two structures
   a. Lung retraction is typically uniform.
   b. If the pattern is not uniform, an underlying pulmonary disease may be present.
4. An increased radiopacity dorsal to the sternum on lateral views from fluid accumulation and scalloping of lungs ventrally
5. Blunting of lung margins at costophrenic angles on the ventrodorsal view
6. Obscured line of diaphragm on dorsoventral and lateral views
7. Widening of the mediastinum

D. Small-volume effusions are detected more readily on ventrodorsal views and expiratory films (Forrester et al., 1991).

E. Horizontal beam radiography can enhance detection of small fluid volumes, but it does not demonstrate a straight fluid line because fluid appearance is altered by the adjacent lung (Thrall, 1998).

F. Free pleural fluid is equally distributed between left and right pleural spaces, and its distribution is affected by changes in recumbency.

G. Fluid not affected by changes in recumbency suggests the following:
1. Encapsulation associated with pyothorax, chylothorax, or FIP
2. Altered lung compliance
3. Other intrathoracic pathology (Thrall, 1998).

H. Certain effusions (e.g., pyothorax, chylothorax) result in constrictive pleuritis, and the lungs do not fully expand after fluid drainage (Glennon et al., 1987).

IV. Ultrasonography

A. Ultrasound examination is often performed before drainage of the effusion.
1. Fluid provides an acoustic window.
2. Ultrasonography enhances the examination of the thoracic structures.

B. Ultrasonography is useful to examine the heart and pericardium for underlying diseases and the mediastinum for masses.

C. It may identify small-volume pleural effusion not detected radiographically (Reichle and Wisner, 2000).

D. It may also detect other pathology.
1. Consolidated lung lobe
2. Certain pulmonary abnormalities, such as masses or lung lobe torsion
3. Presence of abdominal contents in the thoracic cavity with diaphragmatic hernias (Reichle and Wisner, 2000)

E. It also helps guide drainage of loculated fluid or aspiration of mass lesions (Reichle and Wisner, 2000).
F. Echogenic fluid on ultrasound is more likely to be exudative in nature (Reichle and Wisner, 2000).

V. Physical and cytological examination of pleural fluid (see Table 19-1)
A. Pure transudates
1. Usually clear, colorless, and odorless, with low viscosity
2. Small lymphocytes, mesothelial cells, macrophages, and well-preserved neutrophils on cytology (Forrester et al., 1991)
B. Modified transudates
1. Serous to serosanguineous, clear to moderately turbid, low viscosity
2. Cytology variable: typically mesothelial cells, macrophages, well-preserved neutrophils, lymphocytes, sometimes eosinophils
3. Rarely neoplastic cells (lymphoblasts): many pulmonary neoplasms (primary or secondary) do not exfoliate
C. Exudates
1. Pyothorax fluids are often opaque, vary from white to yellow to blood-tinged, and may contain flocculent material or sulfur granules with *Nocardia* or *Actinomyces* spp. infections.
2. Chylothorax may be white or pink and opaque; it remains opaque after centrifugation (Fossum et al., 1991).
3. The effusion associated with FIP is often thick, tenacious, and straw colored; it also clots readily.
a. An albumin:globulin ratio >0.8 in effusion rules out FIP, and gamma globulin >32% is consistent with FIP (Shelly et al., 1988).
b. The protein electrophoretic pattern of an FIP effusion is the same as that of serum (Paltrinieri et al., 1998).
4. Viscosity is related to a high cell count and is manifested by a stringy or ropey appearance when fluid is manually pulled apart.
5. Inflammatory exudates typically have a majority of neutrophils, with some macrophages, lymphocytes, and mesothelial cells.
a. If the inflammation is septic, there may be degenerative changes in the neutrophils, such as karyolysis and karyorrhexis (Forrester et al., 1991).
b. The presence of intracellular bacteria is consistent with bacterial infection.
6. Neoplastic effusions contain macrophages, neutrophils, mesothelial cells, and possibly some lymphoblasts (Forrester et al., 1991).
7. Early chylothorax has a predominance of lymphocytes, and chronicity is characterized by increased numbers of nondegenerate neutrophils and some macrophages.
8. FIP effusions typically contain neutrophils, plasma cells, macrophages, and erythrocytes in a coarse, pink background.
9. Occasionally, neoplastic epithelial cells are seen in the effusion (Fossum, 2000).
a. Pulmonary carcinoma cells: rare, easily confused with reactive mesothelial cells
b. Mast cells
c. Melanoma cells
10. Hemorrhagic effusions may have a packed cell volume similar to peripheral blood, show erythrophagocytosis, and contain no platelets (Forrester, 1991).

VI. Culture and sensitivity testing of pleural fluid
A. It is always indicated if septic inflammation is suspected.
B. Submit fluid for both aerobic and anaerobic culture.
C. A negative culture in the face of apparent pyothorax indicates probable anaerobic infection.

VII. Pleural fluid triglyceride and cholesterol analyses
A. They are used to differentiate a true chylous effusion from a pseudochylous effusion.
B. In true chylous effusions, the triglyceride level is significantly higher than the serum triglyceride level (Fossum et al., 1991).
C. In true chylous effusions, the pleural fluid cholesterol: triglyceride ratio is ≤0.15 (Fossum et al., 1991).
D. In pseudochylous effusions, pleural fluid cholesterol is greater than serum cholesterol, and pleural fluid triglyceride is lower than or equal to the serum triglyceride level (Fossum, 2000).
E. In anorexic or fasted animals, the pleural fluid may not look milky and may have a triglyceride level below what is expected for chylous effusions.
F. Consider measuring pleural fluid and serum triglyceride levels postprandially.

VIII. Pleural fluid biochemical analysis
A. Pleural fluid pH, glucose, and white blood cell (WBC) differential counts help differentiate bacterial and nonbacterial causes of pleural effusion in cats (Stewart et al., 1990).
1. A pH <6.9, glucose <10 mg/dL, and neutrophils >85% of total WBC count are consistent with a pyothorax.
2. Malignant pleural effusions have pH >7.2 and neutrophils are <45% of total WBC count.
B. Pleural fluid is considered an exudate if the lactate dehydrogenase level is >200 IU/L (Stewart et al., 1990).
C. Fibronectin concentration in fluid (as compared with plasma concentration) also helps differentiate causes of pleural effusion (Hirschberger and Pusch, 1996).
1. Cardiogenic pleural effusions have a fibronectin level in the effusion of <31.5% of plasma level.
2. Malignant effusions have levels >31.5%.

IX. Biopsy
A. Open or thoracoscopic biopsy is often required for a diagnosis of mesothelioma.
B. Definitive diagnosis based on pleural fluid analysis alone is difficult, because reactive and neoplastic mesothelial cells are hard to differentiate (Fossum, 2000).

X. Thoracoscopy
   A. Provides adequate information to determine the underlying disease process
   B. Minimal morbidity and mortality
   C. Provides representative biopsy specimens in a large percentage of cases (Kovak et al., 2000)
   D. Pneumothorax is an uncommon but potential complication when combined with pulmonary biopsy (Kovak et al., 2002)

Treatment

I. General Recommendations
   A. If the effusion is causing significant compromise of ventilation, drainage of the effusion is warranted.
      1. Place a thoracic drain if continued fluid production is anticipated.
      2. An indwelling catheter drainage system, using a Seldinger technique is reportedly less traumatic and painful than thoracic drains (Frendin and Obel, 1997).
   B. Treatment of the underlying disorder may result in resolution of the effusion without necessitating drainage.

II. Pyothorax
   A. Place bilateral thoracic drains.
      1. Drain the effusion and lavage the pleural cavity with a warm isotonic physiologic solution (10 mL/kg).
      2. Repeat lavages until fluid withdrawn is relatively clear, then lavage BID to TID.
      3. The addition of heparin to the lavage solution (1500 U/100 mL lavage solution) appears to be of benefit, but proteolytic enzymes are of little value (Fossum, 2000).
      4. The addition of antibiotics to the lavage solution offers no advantage over systemic antibiotic therapy.
      5. The drains are left in place until minimal fluid is retrieved (<2 mL/kg daily), the effusion is clear, ventilation has improved, and there are no bacteria seen on Gram stains of drained materials (usually 5 to 7 days).
   B. Systemic antibiotics are chosen based on culture and sensitivity testing (see Table 19-2).
      1. Initial empirical choices are based on a Gram stain of the effusion.
      2. Antibiotics are continued for a minimum of 4 to 6 weeks.
   C. If an obvious underlying lesion is detected initially, or there is no response to therapy over 5 to 7 days, surgical intervention is indicated.
      1. Abnormal tissue is excised and submitted for microbiological and histopathologic examination, and the thoracic cavity is thoroughly lavaged.
      2. Thoracostomy tubes are placed at the time of surgery and left in place until the aforementioned criteria are met.
      3. Animals with a fibrosing pleuritis after pyothorax may have persistent restrictive respiratory signs, and require further treatment.
         a. Decortication techniques may be performed once the tissue is mature or becomes vascularized and adheres to the pleura (Fossum, 2000).
         b. Results on decortication are mixed: some attempts are successful, whereas others are not (Harpster, 1986; Fossum et al., 1992).
         c. Pulmonary edema may occur with reexpansion of the lungs.
   D. In cats, bradycardia or hypersalivation are indicators of poor outcome (Wadell et al., 2002).

III. Chylothorax
   A. Specific treatment of the underlying disease (e.g., cardiac disease, trauma), if identified, may be sufficient to resolve the condition.
   B. During the time the underlying disease is resolving, intermittent thoracocentesis may be required to manage ventilatory compromise.
   C. Medical management is indicated initially, unless there is rapid fluid accumulation or the underlying disease is correctable with surgery.
      1. Perform thoracocentesis, as required.
      2. Monitor electrolytes if frequent drainage is performed.
         a. Hyponatremia may occur from losses in pleural fluid.
         b. Hyperkalemia is associated with reduced renal excretion (Willard et al., 1991).
      3. A low-fat diet is given to help reduce the flow of chyle.
         a. The reduced fat in the effusion helps increase absorption from the pleural cavity (Fossum, 2000).
         b. Diets such as Hill's r/d or Eukanuba Restricted Calorie are recommended.
         c. If the animal refuses commercial diets, a homemade diet may be tried, but must be supplemented to make it a complete diet (Fossum, 1997).
            (1) Boiled rice or potato, oatmeal, or pasta (1 cup)
            (2) 1 cup low-fat cottage cheese
            (3) Appropriate vitamins and minerals
            (4) Calcium supplement: calcium carbonate
            (5) Can substitute skinless, boiled chicken breast or canned tuna in water
      4. Rutin (a benzopyrone drug used to treat lymphedema and that may stimulate macrophages to absorb chyle) may be tried.
         a. Dose: 50 mg/kg PO TID
         b. Questionable effect but some success reported (Thompson et al., 1999)
   D. If medical management is inadequate, surgical intervention may be indicated.
      1. Thoracic duct ligation in combination with mesenteric lymphangiography
         a. The technique involves cannulating a mesenteric lymphatic vessel (identified by feeding high-fat–content cream preoperatively) and injecting contrast.

b. Thoracic duct rupture is rarely identified.
c. Most dogs and cats have thoracic lymphangiectasia (Birchard et al., 1988; Kerpsack et al., 1994).
d. The thoracic duct and its branches are ligated via an intercostal thoracotomy or transdiaphragmatic approach using hemoclips or nonabsorbable suture (Birchard et al., 1988).
e. Lymphangiography is repeated after ligation to ensure that all branches of the thoracic duct have been ligated (Fossum, 2000).
f. Reported success rates for complete resolution of effusion in cats vary from 20% to 53% (Fossum et al., 1991; Kerpsack et al., 1994).
g. In dogs, the rate of resolution is around 53% (Birchard et al., 1988).
h. Successful thoracic duct ligation likely leads to formation of abdominal lymphaticovenous anastomoses to transport chyle to the venous system, therefore bypassing the thoracic duct (Fossum, 2000).

2. Passive pleuroperitoneal drainage (Peterson et al., 1989)
   a. Sections of the diaphragm are surgically resected, and fenestrated Silastic sheeting is sutured in place over the defects.
   b. An alternative is to place transdiaphragmatic Silastic tubes (Orton, 1993).
   c. The technique may be combined with thoracic duct ligation.
   d. The aim is to allow the pleural fluid to move into the peritoneal cavity to increase the potential surface area from which fluid can be resorbed.
   e. Documented success is limited (Jerram et al., 1999).
   f. Complications include obstruction of the shunts with fibrin or viscera, persistence of some chyle in the pleural cavity, and the potential long-term risk of fibrosing pleuritis.
3. Active pleuroperitoneal or pleurovenous shunting (Smeak et al., 1987; Wilauer and Breznock, 1987)
   a. Use a double-valve Denver shunt catheter (Denver Biomaterials Inc., Evergreen, Colo.).
   b. Place one end of the catheter in the thorax (via an intercostal thoracotomy), and the other end either into the peritoneal cavity through a subcutaneous tunnel (pleuroperitoneal) or into the azygous vein or caudal vena cava (pleural venous).
   c. With both techniques, place the pump chamber on the lateral aspect of a rib to facilitate pumping.
   d. Owners manually pump the chamber to move the fluid out of the pleural space, 100 to 300 times BID to QID.
   e. This technique is a more effective way of emptying the pleural space than with passive techniques.
   f. The pleurovenous technique alleviates the problem of fluid accumulation in the peritoneal cavity.
   g. Disadvantages include cost, thrombosis, obstruction of the catheter, air embolism, venous occlusion, sepsis, abdominal distention (if pleuroperitoneal), potential lack of owner compliance, and inability to resolve the underlying disease (Smeak et al., 1987; Wilauer and Breznock, 1987).
   h. Aspirin is recommended postoperatively to minimize risk of clot formation (Wilauer and Breznock, 1987).
4. Omentalization of the pleural space (Williams and Niles, 1999)
   a. A dorsal omental pedicle flap is brought through an incision in the pars costalis of the diaphragm and sutured to the mediastinum in the region of the lymphaticovenous anastomosis between the thoracic duct and cranial vena cava.
   b. The diaphragmatic incision is partially closed to avoid cranial displacement of abdominal contents.
   c. This technique exploits the large surface area of the omentum and its lymph-draining capability (Williams and Niles, 1999).

E. Thoracic duct ligation and pericardectomy (Fossum et al., 2004)
   1. Based on the theory that in some animals with chylothorax, chyle causes chronic irritation of the pericardium with resultant thickening.
   2. Thickened pericardium can increase right-sided venous pressure, which would impede drainage of chyle into lymphaticovenous communications after thoracic duct ligation.
   3. Success rates reported in one study are 100% in dogs and 80% in cats (Fossum et al., 2004).
F. Fibrosing pleuritis is a risk with chronic chylothorax.
   1. Pleura is thickened by diffuse fibrous tissue that restricts normal lung expansion.
   2. See preceding information on decortication under treatment of pyothorax.

IV. Hemothorax
A. Treatment depends on the severity of the hemorrhage.
   1. Therapeutic thoracocentesis is performed if there is significant respiratory compromise, but avoided if a coagulopathy is the cause.
   2. Most RBCs (70% to 100%) will be absorbed intact without hemolysis (Orton, 1993).
   3. If hemorrhage is severe, a blood transfusion or autotransfusion may be required.
B. Treatment of the underlying disease process must be addressed.
   1. Treat acquired coagulopathies (see Chapter 68).
   2. If a congenital coagulopathy is present, consider appropriate blood products to provide coagulation factors.
   3. Hemorrhage not responding to medical management necessitates surgical intervention.

V. Neoplastic effusions
A. Lymphosarcoma may respond to chemotherapy or radiotherapy if it is confined to the cranial mediastinum.

B. Thymoma, primary pulmonary neoplasms, cardiac neoplasms, or thoracic wall neoplasms may be resectable in some cases.
C. Chemotherapy may be tried for mesotheliomas and carcinomatosis (Moore et al., 1991).
1. Benefits have been reported with intracavitary administration of cisplatin, which reaches high concentrations in tissues within a few millimeters of the contact surface.
2. Combination therapy with systemic doxorubicin may also be tried (Hawkins and Fossum, 2000).
3. Cisplatin is administered intrapleurally at 50 mg/m^2 diluted in 0.9% NaCl at a rate of 250 mL/m^2 via a 16-gauge intravenous catheter.
D. If the underlying disease cannot be treated successfully, palliation is attempted.
1. Pleuroperitoneal shunting can be used, but there is a risk of seeding neoplasia in the peritoneal cavity.
2. Standard thoracocentesis is used for relieving symptoms of respiratory distress.

Monitoring of Animal

I. Monitor respiratory rate and effort, especially if respiratory distress is present.
II. Monitor mucous membrane color, thoracic percussion, heart rate and rhythm, thoracic auscultation (including air movement), and heart sounds.
III. Use pulse oximetry to assess oxygenation.
IV. Change fluid therapy as needed to maintain normal fluid, electrolyte, and acid-base status.
V. Monitor body weight and condition daily.

PNEUMOTHORAX

Definition

I. Pneumothorax is the accumulation of a gas (including air) in the pleural space, and may be traumatic or spontaneous in origin.
II. Sources of the air include the following:
A. Pleurocutaneous: air enters through a defect in the chest wall (open pneumothorax)
B. Pleuropulmonary: air enters from the lung (closed pneumothorax)
C. Mediastinal: air enters from mediastinal structures such as the trachea or esophagus
D. Pleurobronchial: air enters from an abnormal bronchus
E. Gas-producing organisms in the pleural space
III. Tension pneumothorax arises with very high positive intrapleural pressure during expiration (Holtsinger and Ellison, 1995).

Causes

I. Trauma
A. Most common cause: pneumothorax possible in nearly 50% of thoracic trauma cases (Holtsinger and Ellison, 1995)
B. Blunt trauma: automobile accidents, falling from heights, kick injuries
C. Penetrating injuries: bite wounds, penetrating foreign bodies, gunshot wounds, esophageal trauma
D. Rupture of pulmonary parenchyma or the bronchial tree with forceful compression of the thorax against a closed or open glottis (Fossum, 2000)
E. Torn pulmonary parenchyma by shearing forces (Fossum, 2000)
II. Spontaneous forms
A. A closed pneumothorax occurs from air leakage from the lung parenchyma with no history of trauma.
B. Primary pneumothorax occurs in the absence of any evidence of preexisting underlying pulmonary pathology.
1. It is associated with rupture of an air-containing space within or beneath visceral pleura (blebs or bullae) (Holtsinger and Ellison, 1995).
a. Blebs are contained entirely in the pleura (between the internal and external elastic laminae).
b. Bullae are lined partly by thickened fibrotic pleura, fibrous pulmonary tissue, and emphysematous lung (Holtsinger and Ellison, 1995).
2. Reported incidence in dogs varies from 0% to 50% (Holtsinger and Ellison, 1995; Valentine et al., 1996).
C. Secondary spontaneous pneumothorax occurs with recognizable underlying structural or functional pulmonary disease.
1. Most common cause in dogs
2. May arise with pneumonia, pulmonary abscesses, tuberculosis, parasitic infections (dirofilariasis, or *Paragonimus* spp., *Angiostrongylus* spp., *Aelurostrongylus* spp.), chronic obstructive pulmonary disease, pulmonary neoplasia, pulmonary thromboembolism, and congenital cysts
3. May occur with bullous emphysema
III. Iatrogenic pneumothorax
A. Diagnostic procedures such as venipuncture (Godfrey, 1997)
B. Transthoracic needle placement during pulmonary or cranial mediastinal aspiration or biopsy, and pericardiocentesis (Teske et al., 1991)
C. Placement of thoracostomy tubes
D. Endotracheal intubation
1. Overinflation of the tube cuff
2. Rotation of the animal without disconnecting it from the breathing circuit
3. Traumatic intubation with a stylet in place
4. Removal of the tube with the cuff inflated
E. Positive pressure ventilation with intraalveolar pressures greater than pressures within the perivascular sheath
F. Certain surgical procedures; circumcostal gastropexy, adrenalectomy, dorsolateral approaches to the thoracic spine

Pathophysiology

I. The entrance of air into the pleural space separates parietal and visceral pleura results in lung collapse and expansion of the thorax.
II. Pneumothorax is unilateral if the mediastinum is intact, but the free air is usually bilateral (Fossum, 2000).

III. Hypoventilation results in hypoxemia and respiratory acidosis when the pneumothorax is severe, especially if there is a large open chest wound (Orton, 1993).
IV. Ventilation-perfusion mismatching also plays a role in the hypoxemia.
V. The loss of negative intrapleural pressure reduces venous return to the right side of the heart, thereby decreasing cardiac output and compromising pulmonary perfusion.
VI. Tension pneumothorax may result from a pleuropulmonary or pleurocutaneous fistula acting as a one-way valve (Orton, 1993).
   A. Severely compromised ventilation from collapse of lungs
   B. Compresses the vena cava, adversely affecting cardiac function (Holtsinger and Ellison, 1995)
   C. Tends to be rapidly progressive

Clinical Signs

I. Animals with pneumothorax display a restrictive breathing pattern characterized by rapid, shallow ventilation.
II. Exercise intolerance is often apparent.
III. As pneumothorax progresses in severity, signs of respiratory distress become severe with extension of the head and neck, as well as elbow abduction.
IV. Signs of hypoxemia, such as cyanosis and recumbency, may be seen.
V. Pale mucous membranes and reduced amplitude of peripheral pulses often occur.
VI. Tension pneumothorax may cause a barrel-shaped thorax that appears to remain "fixed" in maximal expansion (Fossum, 2000).

Diagnosis

I. Historical evidence
   A. Known trauma or possibility of trauma
   B. Recent clinical signs of respiratory disease, such as coughing, dyspnea
   C. Recent thoracic diagnostic procedures, anesthesia, surgery, or pericardiocentesis
   D. Ingestion of foreign bodies or signs of regurgitation (suggestive of esophageal disease)
II. Physical examination
   A. Dyspnea, tachypnea, restrictive breathing pattern, possible "barrel" chest
   B. Pale mucous membrane color, poor pulse quality
   C. Evidence of trauma: lacerations, fractures, subcutaneous emphysema
   D. Auscultation
      1. Reduced ventilatory sounds dorsally and muffled heart sounds
      2. Possibly signs of pleural fluid
   E. Percussion
      1. May be hyperresonant dorsally
      2. Possibly tympanic with tension pneumothorax
III. Thoracocentesis
   A. Location of drainage is based on auscultation or radiographs, but the seventh through ninth intercostal spaces in the dorsal third of the thorax are recommended.
   B. Drainage of one side usually drains both hemithoraces.
   C. Consider removing some air before thoracic radiographs are taken.
IV. Thoracic radiography
   A. Radiographic changes depend on the volume of air in the pleural space and the views taken.
      1. Retraction of the lung away from the thoracic wall is seen on lateral, ventrodorsal, and dorsoventral views.
      2. As a result of lung collapse, there is an increase in the opacity of the lungs.
      3. The diaphragm is flattened and caudally displaced.
      4. Dorsoventral view is more sensitive than ventrodorsal for pneumothorax and less stressful for the animal.
      5. There is usually bilateral involvement because air easily diffuses across the mediastinum.
      6. If unilateral pneumothorax is suspected, it is better to have the affected hemithorax in a dependent position.
      7. Small volumes of air can be detected at the costophrenic angles on a dorsoventral view.
   B. In a recumbent lateral view, the heart appears to be displaced dorsally as it loses support from inflated lung (Thrall, 1998).
   C. With tension pneumothorax, the degree of lung collapse is greater.
      1. The lung may lose its normal shape and appear as an amorphous opacity compressed against the midline.
      2. If pneumothorax is unilateral, there is a contralateral mediastinal shift.
      3. There is also marked caudal displacement of the diaphragm.
   D. Also evaluate for evidence of trauma, such as fractured ribs, pulmonary contusions, diaphragmatic hernia, and other orthopedic injuries.
   E. Look for underlying pulmonary pathology, such as pneumonia, abscesses, and nodules, as well as for signs of esophageal disease, such as foreign bodies.
   F. Pulmonary blebs are rarely detected radiographically because they may have already ruptured, and larger bullae may be an incidental finding (Fossum, 2000).
V. Additional tests
   A. Arterial blood gas analysis to determine the severity of respiratory compromise
   B. Fecal parasitology
   C. Heartworm test
   D. Pulmonary cytology and microbiology (± bronchoscopy) for underlying pulmonary disease
   E. Esophagoscopy or contrast esophagography for suspected pleuroesophageal leakage
   F. Bronchography for suspected bronchopleural fistula
   G. Exploratory thoracotomy: lateral approach or median sternotomy (location of lesion unknown)
   H. Thoracoscopy: less invasive, allows direct visual examination of the pleural cavity

Differential Diagnosis

I. Pleural effusion
II. Diaphragmatic hernia
III. Pulmonary diseases: inflammation, neoplasia, thromboembolism, contusion, edema
IV. Pneumomediastinum

Treatment

I. Traumatic pneumothorax
  A. Cover open thoracic wounds immediately with an occlusive dressing.
    1. Once the wound is covered, perform thoracocentesis.
    2. Delay surgical closure of an open wound until the animal is clinically stable.
  B. If signs are mild, conservative management may be adequate.
    1. Cage rest alone may allow pleural air to resorb over 5 to 14 days (Kern et al., 1994).
    2. Closely monitor for respiratory distress or signs of cardiovascular compromise.
    3. If dyspnea is present, needle thoracocentesis is performed and repeated as necessary.
    4. Give oxygen therapy if the animal is hypoxemic, especially if there is concurrent pulmonary disease.
    5. If animals are in pain from rib fractures or soft-tissue trauma, use analgesics to help relieve respiratory signs.
  C. If dyspnea is severe or frequent needle thoracocenteses is required, tube thoracostomy is recommended (see Chapter 3).
  D. Surgery is rarely required in cases of traumatic pneumothorax, but is indicated if air accumulation fails to resolve after 5 days or esophageal perforation is suspected.
II. Spontaneous pneumothorax
  A. Conservative management of spontaneous pneumothorax is often unrewarding.
    1. Tube thoracostomy and continuous drainage is preferable to intermittent thoracocentesis.
    2. If the underlying pulmonary pathology (e.g., pneumonia, dirofilariasis) can be corrected, the pneumothorax may resolve.
    3. Conservative therapy is contraindicated if pulmonary abscessation is suspected.
    4. Recurrence rates are high.
  B. Surgical intervention is often required.
    1. If significant pneumothorax persists for more than 48 hours, surgery is indicated (Holtsinger et al., 1993).
    2. Median sternotomy is often the ideal approach because it allows thorough inspection of both hemithoraces, and provides good exposure of the lung apices, which are common sites of pathology (Holtsinger and Ellison, 1995).
    3. If an obvious lesion cannot be seen, filling the thorax with saline can aid in localizing the lesion.
    4. Treatment involves excision of diseased tissue via partial or complete lobectomy.
    5. With bullous emphysema, the rate of recurrence is significant (12.5%) (Valentine et al., 1996).
    6. Mechanical pleurodesis for bullous emphysema, while not obliterating the pleural space, may result in pleural fibrosis sufficient to limit air leakage from blebs or bullae (Jerram et al., 1999).

Monitoring of Animal

I. Respiratory rate and effort, lung sounds, heart rate, mucous membrane color, and refill time are monitored frequently.
II. Pulse oximetry can be used to assess oxygenation.
III. The volume of air drained from the thorax is measured and recorded.
IV. Commercial thoracostomy tubes have depth measurements and radiopaque markers allowing visual and radiographic monitoring of tube placement and position.
V. Animals with thoracostomy tubes are monitored closely to ensure that they do not damage the tube, with resultant air leakage into the thorax.
  A. Loosening of connectors and three-way stopcocks are additional sources of air leakage.
  B. Use clamps (such as a bulldog clamp) more proximally on the tube to minimize these risks.
  C. Suture or wire adaptors to the tube to help reduce leakage.
VI. Thoracostomy tubes must be monitored continuously.
VII. Thoracic radiography is an objective way to monitor resolution of the pneumothorax and any other pulmonary abnormalities.

DIAPHRAGMATIC HERNIA

Definition

I. Diaphragmatic hernia is a condition in which abdominal contents enter the thoracic cavity through an abnormal opening in the diaphragm.
II. Hernias may be congenital or acquired.
III. The abdominal contents may enter the pleural space (pleuroperitoneal hernia) or the pericardial sac (peritoneopericardial diaphragmatic hernia).
IV. A rare form is a hiatal hernia, which may be either paraesophageal or gastroesophageal (Wilson and Hayes, 1986).
V. True diaphragmatic hernias (or eventrations) are subtotal diaphragmatic tears in which the serosa on the thoracic surface of the diaphragm is intact (Voges et al., 1997).

Causes

I. Traumatic hernias
  A. Any trauma to the abdomen can potentially result in a diaphragmatic hernia.
  B. Usually there is a sudden increase in intraabdominal pressure, with resultant rapid deflation of the lungs when the glottis is open, causing a significant pleuroperitoneal pressure gradient.
  C. The diaphragm usually tears at its weakest point (i.e., the muscular portion).
  D. The location and size of the tear depend on the position of the animal during the episode of trauma.

II. Congenital hernias
  A. Pleuroperitoneal forms are infrequently reported in dogs and cats (Wilson and Hayes, 1986; Fossum, 2000).
  B. The peritoneopericardial form is more commonly recognized.
    1. Failure of the lateral pleuroperitoneal folds and the ventromedial pars sternalis to unite
    2. Faulty development of the dorsolateral septum transversum
    3. Prenatal injury to the septum transversum
    4. Heritability not known for this condition, but Weimaraners overrepresented (Evans and Biery, 1980)

Pathophysiology

I. Traumatic diaphragmatic hernia
  A. Presence of abdominal organs in the thoracic cavity restricts ventilation.
  B. Loss of diaphragmatic continuity results in loss of lung contact with parietal pleura, and negative intrathoracic pressure becomes continuous with pressure in the abdominal cavity.
  C. The thoracic and abdominal wall musculature must assume the workload of the diaphragm.
  D. Pain may reduce thoracic wall motion.
  E. Lung collapse and/or atelectasis may occur secondary to organ entrapment or the accumulation of pleural fluid or air.
  F. Pulmonary contusion often occurs as a direct result of trauma to the parenchyma.
  G. Myocardial contusion also may occur with trauma.
  H. Hypovolemia may be present, which may further exacerbate respiratory signs and ventilation-perfusion mismatch.
  I. Increased pulmonary capillary permeability and consequent pulmonary edema also play a role.
  J. Entrapment of part of the GI tract or other abdominal organs may produce signs related to specific organ systems other than the respiratory tract.
II. Congenital hernias
  A. Signs are related to the space-occupying effect of the abdominal contents in the thoracic cavity, and to the effects on the abdominal organs themselves.
  B. Other signs may relate to concurrent congenital defects such as cardiac anomalies, portosystemic shunts, or polycystic kidneys (Neiger, 1996).

Clinical Signs

I. Congenital diaphragmatic hernia
  A. There is wide variation in presentation and signs.
    1. Some animals are asymptomatic, whereas others may have severe clinical signs.
    2. Respiratory signs are the most common manifestation and (depending on the abdominal contents displaced into the thorax) may be exacerbated by ingestion of food.
    3. Gastrointestinal signs, such as vomiting and diarrhea, may occur in both dogs and cats (Evans and Biery, 1980; Neiger, 1996).
    4. Nonspecific signs of anorexia, weight loss, and lethargy may also be present, and are common with chronic hernias.
  B. The hernia may be diagnosed incidentally if the animal develops an unrelated illness that prompts diagnostic imaging of the thoracic or abdominal cavities.
II. Traumatic hernias
  A. It is more frequently recognized in young animals (1 to 2 years of age).
  B. It is more frequent in male dogs in some studies (Boudrieu and Muir, 1987; Fossum, 2000), but not others (Gibson et al., 2005).
  C. Duration varies from hours to years.
    1. There may be no specific signs of herniation even in animals with severe, life-threatening injuries.
    2. The hernia may have been present for years in animals presented with respiratory signs.
    3. In one study of chronic diaphragmatic hernias, only 38% of affected animals were dyspneic (Minihan et al., 2004).
  D. Clinical signs are variable.
    1. Shock with pale membranes, cyanosis, tachypnea, dyspnea, and tachycardia
    2. Cardiac arrhythmias: commonly ventricular, associated with significant mortality (Boudrieau and Muir, 1987)
    3. Other signs
      a. If the liver is displaced, hydrothorax is common.
      b. Icterus may occur if there is extrahepatic bile duct obstruction (Boudrieau and Muir, 1987).
      c. If the stomach is displaced, there is a risk of gastric dilatation.

Diagnosis

I. Physical examination
  A. Congenital hernias
    1. Possibly muffled heart sounds, displacement of the apex beat, and heart murmurs
    2. Possibly increased amplitude of heart sounds over the contralateral hemithorax
    3. Other abnormalities
      a. Ventral body wall defects, such as umbilical hernia or sternal abnormalities
      b. Concurrent congenital cardiac anomalies resulting in murmurs
  B. Traumatic hernias
    1. Respiratory distress, thoracic wall injury, muffled heart and lung sounds
    2. Altered lung sounds and cardiac arrhythmias if pulmonary contusions present
    3. Absence of normally palpated structures in abdomen
    4. Concurrent orthopedic injuries
II. Radiography
  A. Congenital hernias
    1. Plain radiographic findings may include some or all of the following:
      a. An enlarged, globoid, or spherical cardiac silhouette

b. Altered opacity within the pericardium (gas or fat)
c. Loss of distinct ventral border of the diaphragm in the absence of significant pleural fluid
d. Persistent dorsal mesothelial remnant detected between the cardiac silhouette and the diaphragm
e. Mesothelial remnant usually ventral to or superimposed on the caudal vena cava on a lateral radiograph
f. Mesothelial remnant representing the dorsal border of the hernia
g. Small liver or cranial displacement of the stomach
h. Soft-tissue mass in the caudal thorax in cats (Voges et al., 1997)

2. Contrast radiography is indicated if results of plain radiographs are equivocal, and include positive contrast studies of the GI tract and positive contrast celiography.

B. Traumatic hernias
1. Plain radiographic findings are frequently definitive.
a. Loss of continuous diaphragmatic outline, to which pleural fluid is often a contributing factor
b. Presence of abdominal contents in the thorax
c. Displacement of the lung fields and heart cranially and/or laterally
d. Cranial displacement of abdominal viscera, especially stomach and intestines
e. Displacement of bronchial structures (Hyun, 2004)
f. Other signs of trauma, including rib, orthopedic, or soft-tissue injuries (Williams et al., 1998)

2. On positional radiography, look for gravitational shifting of herniated viscera compared to survey films (e.g., reduction of hernia with erect ventrodorsal view).
3. Contrast radiography may be helpful.
a. An upper GI series determines whether the stomach or intestines are herniated.
b. Positive contrast celiography may be of value in some cases.
(1) Inject 1 to 2 mL/kg of warmed water-soluble iodinated contrast medium via a catheter placed into the peritoneal cavity to the right of midline and cranial to the umbilicus to avoid the spleen.
(2) Roll the animal from side to side or around the long axis with the pelvis elevated.
(3) Herniation is confirmed if contrast appears in the pleural cavity and there is roughening or irregularity of the abdominal surface of the diaphragm.
(4) If no hepatic outline is present, a hernia is likely.
(5) False negatives occur with injection into the falciform fat, if large volumes of free peritoneal or pleural fluid dilute the contrast, or if there is plugging of the diaphragmatic defect by falciform fat, omentum, or adhesions (Williams et al., 1998).

III. Ultrasonography
A. With a congenital peritoneopericardial hernia, echocardiography potentially demonstrates the presence of fat, intestine, or liver in the pericardial sac.
B. Traumatic hernias may be recognized either by discontinuity of the diaphragm (with transhepatic evaluation of the diaphragm) or if abdominal soft tissues are seen adjacent to the cardiac silhouette.
1. Care must be taken to avoid mistaking mirror-image artifact as an indication of a hernia, because the liver may appear on both sides of the diaphragm (Williams et al., 1998).
2. Ultrasonography has an advantage over radiography, because it is not affected by the presence of pleural fluid.

IV. Other tests
A. Computed tomography or magnetic resonance imaging is preferable to celiography.
B. Thoracoscopy detects herniation of abdominal contents.
C. Exploratory laparotomy and careful examination of the diaphragm are also options.
D. Electrocardiography may be normal or reveal axis deviation, but these findings are nonspecific (Neiger, 1996).
E. Serum biochemistries in animals with gastric outflow obstruction may reveal metabolic alkalosis, hypochloremia, and hypokalemia (Roe et al., 1986).

Treatment

I. Congenital hernias
A. Repair hernias as they are detected and when the animal is old enough to cope with the anesthesia.
B. If the hernia is detected in a young animal, early correction minimizes the risk of adhesion formation (Johnson, 1993).
C. A ventral midline approach is preferred because the hernias are usually ventral (Johnson, 1993; Neiger, 1996).

II. Traumatic hernias
A. Perform surgical correction of the hernia as early as possible once the animal has been stabilized.
1. Surgery undertaken within 24 hours of trauma has the highest mortality rate in one study (Boudrieau and Muir, 1987), but in another study was low at 10.3% (Gibson et al., 2005).
2. Surgery may need to be performed early on an emergency basis if there is life-threatening hypoventilation related to lung compression by abdominal viscera, and/or if there is significant gastric distention (Roe et al., 1986).
3. If surgery is to be delayed, monitor closely for worsening of respiratory signs.
B. The surgical techniques used are similar to those for congenital hernias (Wilson and Hayes, 1986; Johnson, 1993).
C. With a long-standing traumatic hernia, surgical correction is potentially risky because of the presence of adhesions (with potential for pneumothorax and

hemorrhage when they are broken down) and long-term lung atelectasis.
D. A recent study showed similar mortality for acute and chronic hernias (Minihan et al., 2004).
E. Median sternotomy may be required for chronic hernia correction (Minihan et al., 2004).

Monitoring of Animal

I. Monitor cardiorespiratory status closely after surgery.
A. Pneumothorax may occur from incomplete removal of air after surgery or continued leakage of air.
B. After closure of a large, chronic hernia, there is a significant rise in intraperitoneal pressure, which can compromise venous return and necessitate aggressive fluid therapy.
II. Reexpansion pulmonary edema can develop after rapid lung reexpansion in chronic cases.
A. The condition occurs most frequently in cats (Soderstrom et al., 1995; Stampley and Waldron, 1993).
B. The edema is associated with accumulation of a protein-rich fluid in the alveoli.
C. Reperfusion injury is considered the most likely cause.
D. The edema may develop immediately postoperatively, or up to a few hours later.
E. The respiratory compromise is progressive, with worsening hypoxia that is poorly responsive to oxygen supplementation.
F. Recommendations to minimize risks of reexpansion pulmonary edema include the following:
1. Reinflate atelectatic lungs gradually.
2. If lung expansion does not occur with pressures of 20 to 30 cm H_2O, place a chest drain to allow for spontaneous reexpansion.
3. The pleural space is drained with continuous low-pressure suction at <10 cm H_2O (Johnson, 1993; Stampley and Waldron, 1993).
G. Positive end-expiratory pressure ventilation may be necessary to maintain alveolar patency and adequate oxygenation, but the mortality is still significant.
H. Potential future therapy includes the use of free radical scavengers and glucocorticoids (Soderstrom et al., 1995).

FLAIL CHEST

Definition and Cause

I. Flail chest is thoracic wall instability with paradoxical movement of the flail segment that is the consequence of trauma.
II. Flail chest occurs when two or more ribs are fractured dorsally and ventrally, resulting in loss of continuity with adjacent tissues (Fossum, 2000).

Pathophysiology

I. The flail segment results in pendulous movement of air in the thorax, causing a functional increase in dead space.
II. Concurrent injury to lung parenchyma, such as pulmonary edema or contusions, contributes to the severity of signs.
III. Additional factors include reduced pulmonary compliance, hypoventilation, pulmonary arterial-to-venous shunting, increased airway resistance, and increased work of breathing (Anderson et al., 1993; Fossum, 2000).
IV. Pain also contributes to hypoventilation.
V. The trauma may be severe enough to result in concurrent pneumothorax, pleural effusion, diaphragmatic hernia, and cardiac dysfunction.

Clinical Signs

I. Paradoxical movement of the flail segment
II. Reluctance to move from pain
III. Dyspnea, cyanosis, open-mouth breathing

Diagnosis

I. Clinical signs, particularly the paradoxical thoracic movement, are supportive.
II. Radiography confirms the diagnosis.
A. Examine for a rib fracture pattern consistent with flail segment.
B. Pulmonary contusions, pulmonary edema, pneumothorax, pleural fluid, and diaphragmatic hernia may be noted.
III. Arterial blood gas analysis is consistent with hypoxemia.

Treatment

I. Initial treatment is directed at stabilizing the cardiovascular system with fluid therapy.
II. Temporary limitation of motion of the flail segment is achieved by placing the animal in lateral recumbency with the flail segment in a dependent position.
A. This is undertaken only for short periods to prevent the development of atelectasis in the dependent lung.
B. Some animals may have too much pain to lay on the injured side.
III. A simple surgical technique to stabilize the flail segment may be performed (McAnulty, 1995).
A. Place a nonabsorbable suture around the center of each free-floating rib in the flail segment, and tie the suture to the middle of an external splint (wooden tongue depressors or a stiff plastic splint) that lies parallel to the ribs.
B. Place dorsal and ventral countertraction splints perpendicular to the rib axis between the skin and the traction splints. Be sure they extend at least one undamaged rib beyond the flail segment both cranially and caudally.
C. Place material such as gauze sponges between the traction and countertraction splints until the free ends of the flail segment are retracted and compressed against the underside of the countertraction splints.
D. The flail segment is stabilized relative to adjacent, unfractured ribs and moves with them during respiration.
E. Tape splints and gauze together, and cover with a light bandage.
IV. Occasionally, open surgical techniques to stabilize the ribs are required.

A. Intramedullary pins
B. Removal of the fracture segments with repair of the defect with a muscle flap or mesh
C. Suturing ribs to adjacent ribs

V. A more recent study showed no difference in outcome between patients treated with fracture stabilization and those not stabilized (Olsen et al, 2002).
VI. Analgesia is important to minimize pain-related hypoventilation.
A. Narcotics can be used so long as depression of the respiratory center is avoided.
B. Intercostal nerve blocks using 0.5% bupivacaine (maximum, 2 mg/kg) are helpful.
C. Intrapleural administration of 0.25% bupivacaine solution is followed by placement of the animal in lateral recumbency for 20 minutes with the affected side down (Anderson et al., 1993).
VII. Provide oxygen supplementation as needed.
VIII. Mechanical ventilation may be necessary in animals with severe respiratory compromise.

Monitoring of Animal

I. Closely monitor respiratory and cardiovascular function until the animal is stable.
II. Monitor serial arterial blood gases or utilize continuous pulse oximetry.
III. Repeat thoracic radiographs every 24 to 72 hours to monitor resolution of underlying pulmonary parenchymal disease.
IV. Cats with flail chest are significantly more likely to die than those with simple rib fractures (Kraje et al., 2000).

CHAPTER 20

Diseases of the Mediastinum and Chest Wall

Graham Swinney | Trevor N. Bebchuk

PNEUMOMEDIASTINUM

Graham Swinney

Definition

I. Pneumomediastinum is the accumulation of free air or gas in the mediastinal space.
II. The mediastinum is the anatomic region that divides the thorax into the left and right pleural cavities.
III. The mediastinum is lined by parietal pleura.

Causes

I. Air may enter the mediastinum from the head, pharynx, and cervical region because it is contiguous with the cervical fascia cranially.
   A. Penetrating wounds caused by bites and foreign bodies, including injuries, such as stick penetration in the pharynx (White and Lane, 1988)
   B. Jugular venipuncture or central venous catheter placement (Biller, 2000)
II. Pulmonary and airway disease and/or rupture can lead to pneumomediastinum.
   A. Secondary to severe parenchymal disease
      1. Inflammation, neoplasia
      2. Fibrosis, such as that seen in paraquat toxicity
   B. Trauma
   C. Iatrogenic sources
      1. Tracheal rupture associated with intubation
         a. Cuff overinflation
         b. Change in the position of the animal without disconnection from the breathing circuit
         c. Damage from a stylet used for intubation
         d. Direct trauma from the tube during placement
         e. Removal of the endotracheal tube with the cuff inflated (Mitchell et al., 2000)
      2. Transtracheal wash
      3. Mechanical ventilation
         a. It is most likely related to marginal alveolar rupture (Brown and Holt, 1995).
         b. Air migrates into the mediastinum via the perivascular connective tissue sheaths (Brown and Holt, 1995).
      4. Tracheostomy tube placement
      5. Pericardiocentesis (Van den Broek, 1986)
III. Esophageal rupture and/or leakage can be a cause of pneumomediastinum.
   A. Foreign bodies, or associated with removal of foreign bodies
   B. Esophagitis and ulceration
   C. Esophageal dilatation procedures
   D. External trauma
   E. Perforation secondary to neoplasia
IV. Air may enter from the retroperitoneal space following surgery or gastrointestinal (GI) rupture because the mediastinum communicates directly with this space via the aortic and esophageal hiatuses (Van den Broek, 1986).
V. Gas-producing infections in the mediastinum are potential causes.
VI. Spontaneous pneumomediastinum has been reported in a racing greyhound (Jones et al., 1975).

Pathophysiology

I. Typically, pneumomediastinum is a benign condition with no obvious clinical signs, other than those related to the causative condition.
II. Subcutaneous emphysema may occur from communication between the mediastinum and cervical fascia.
III. If mediastinal pressure increases abruptly, the mediastinal pleura may rupture and result in pneumothorax (usually pressures >20 mm Hg) (Brown and Holt, 1995).
IV. If mediastinal pressures becomes very high and air cannot escape from the mediastinal space, there can be circulatory complications (Rudloff et al., 1996).
   A. The increased mediastinal pressure results in compression of the vena cava, azygos vein, and pulmonary artery, causing congestive signs (Rudloff et al., 1996; Biller, 2000).
   B. Cardiac output may be reduced (Rudloff et al., 1996).
   C. An "airlock" has been proposed as a cause of circulatory collapse with pneumomediastinum.
   D. Bubbles in perivascular sheaths may compress pulmonary arteries and veins, reducing venous return (Brown and Holt, 1995).
V. High pressures in the mediastinum may also compromise ventilation.

Clinical Signs

I. The clinical signs vary with the severity of the pneumomediastinum and with the underlying etiology.
II. Some animals are clinically normal.
III. Subcutaneous emphysema may be present and can vary from mild, localized emphysema to severe and generalized changes.
IV. Signs relating to underlying disease vary depending on organ involvement.
V. In cases of very high mediastinal pressures or an extension to a severe pneumothorax, additional respiratory and circulatory signs can be expected.
   A. Severe dyspnea
   B. Jugular venous distention
   C. Signs of hypotension: tachycardia, weak pulse, pale mucous membranes, delayed capillary refill time
   D. Cyanosis with significant respiratory compromise
VI. Horner's syndrome occurs if the sympathetic trunk is affected.

Diagnosis

I. History of trauma, foreign body ingestion, respiratory disease, GI-related illness, abdominal procedures, toxin exposure (paraquat), or diagnostic procedures involving cervical region, respiratory tract, or esophagus
II. Physical examination findings, as discussed previously
III. Thoracic radiographic findings
   A. The entrance of free air into the mediastinum provides a negative contrast, allowing increased visibility of the left subclavian artery, brachycephalic trunk, cranial vena cava, and azygos vein (Van den Broek, 1986; Fagin, 1988).
   B. The changes are most readily visible on lateral views of the thorax.
   C. Subcutaneous emphysema may also be apparent.
   D. Radiographs are also evaluated for concurrent pulmonary or tracheal disease, esophageal foreign bodies, pneumothorax, pleural effusion, and pneumopericardium (rare).
   E. Take care not to interpret a dilated esophagus or pulmonary overinflation as pneumomediastinum.
   F. In cases of suspected esophageal perforation, contrast radiography using water-soluble contrast agents may be indicated (see Chapter 4).
IV. Abdominal radiographs: ± pneumoretroperitoneum
V. Tracheoscopy, bronchoscopy to search for underlying etiology
   A. Check for airway damage.
      1. Tracheal perforations may not be detected.
      2. The tracheal membrane may obscure a lesion (Mitchell et al., 2000).
   B. Use esophagoscopy to search for perforation secondary to foreign bodies, esophagitis, or neoplasia.
VI. Bronchoalveolar lavage, bronchial wash, or pulmonary fine-needle aspiration
   A. Helps define underlying pulmonary disease
   B. May worsen pneumomediastinum
VII. Arterial blood gas measurement to assess ventilatory function and gas exchange

Treatment

I. If the animal is asymptomatic or the signs are mild, the disease is usually self-limiting.
   A. Specific therapy not required
   B. Resolution within 2 weeks with no ongoing leakage of air (Biller, 2000)
II. Subcutaneous emphysema spontaneously resolves and only requires drainage (using a needle) if it is causing discomfort.
III. Deep cervical wounds are sutured, and bandages may help limit further air leakage.
IV. If pneumothorax is causing dyspnea, treat with thoracocentesis (see Chapter 19).
V. Treatment of tracheal laceration depends on the severity of clinical signs and endoscopic findings (Brown and Holt, 1995; Mitchell et al., 2000).
   A. Medical therapy is indicated if dyspnea is mild to moderate, and subcutaneous emphysema is not progressive.
      1. Cage rest
      2. Oxygen supplementation
      3. Sedation
   B. Surgical intervention to suture the defect is indicated with severe dyspnea or tears that involve greater than one third of the airway diameter (Brown and Holt, 1995; Mitchell et al., 2000).
VI. If pneumomediastinum is associated with positive pressure ventilation, discontinue mechanical ventilation.
VII. If pneumomediastinum is secondary to pulmonary parenchymal disease, treatment is directed at the underlying problem.

Monitoring of Animal

I. Regular monitoring of respiratory rate and effort, mucous membrane color, capillary refill time, and heart rate is recommended.
II. In more critical animals, monitoring of pulse oximetry or blood gas measurements may be indicated.
III. Thoracic radiographs are used to monitor resolution or progression of pneumomediastinum and any associated underlying pathology.

MEDIASTINAL FLUID

Graham Swinney

Definition and Causes

I. Any accumulation of fluid in the mediastinal space
II. Mediastinal edema secondary to any disease process that can cause edema
III. Mediastinal hemorrhage
   A. Trauma
   B. Coagulopathy
   C. Neoplasia

D. Spontaneous aortic dissection (Boulineau et al., 2005)
E. Idiopathic thymic hemorrhage (Coolman et al., 1994)

Pathophysiology

I. Mediastinal edema: signs usually related to underlying disease
II. Mediastinal hemorrhage
  A. With severe hemorrhage, signs of acute blood loss
  B. May progress to hemothorax
  C. Respiratory signs with airway compression or hemothorax

Clinical Signs

I. Mediastinal edema is often asymptomatic.
II. Mediastinal hemorrhage may produce signs of blood loss.
  A. Pale mucous membranes
  B. Tachycardia, tachypnea
  C. Weakness, collapse
  D. Signs of pleural effusion with extension to hemothorax (see Chapter 19)

Diagnosis

I. Mediastinal edema: often an incidental finding of a widened mediastinum on thoracic radiographs
II. Mediastinal hemorrhage
  A. History of trauma or potential rodenticide exposure
  B. Physical examination findings of blood loss, anemia
  C. Thoracic radiographs: mediastinal widening, possible pleural effusion
  D. Ultrasonography: mediastinal fluid, possible mass(es)
  E. Hematology: low hematocrit, platelet count
  F. Possible coagulation abnormalities

Treatment

I. Mediastinal edema: treatment of underlying disease
II. Mediastinal hemorrhage
  A. Supportive care
  B. Transfusion if required
  C. Vitamin K therapy for rodenticide toxicity
  D. Treatment of hemothorax (see Chapter 19)

Monitoring of Animal

I. Mediastinal edema: rarely requires monitoring
II. Mediastinal hemorrhage: respiratory rate and effort, hematocrit, total solids

MEDIASTINITIS

Graham Swinney

Definition

I. Inflammation within the mediastinal space
II. Can be acute or chronic in nature
III. Typically the result of infection

Causes

I. Extension from esophageal leakage
  A. Foreign bodies causing perforation
  B. Esophagitis from ingested irritants, gastric reflux, or persistent vomiting resulting in ulceration and perforation
  C. Trauma
  D. Iatrogenic sources
    1. Diagnostic endoscopy
    2. Therapeutic procedures: foreign body removal, balloon dilatation
  E. Neoplasia resulting in esophageal wall necrosis
  F. Postesophageal surgery
II. Extension from tracheal or large airway rupture
  A. Trauma
  B. Iatrogenic causes: endoscopy, intubation
III. Extension from adjacent tissues
  A. Fascial planes from neck, axilla, and thoracic inlet
  B. Pleura, pericardium, lungs, and lymph nodes
IV. Penetrating thoracic injury
  A. Bite or bullet wounds
  B. Migrating foreign bodies: plant material
V. Following certain procedures
  A. Following thoracic surgery
  B. Thoracostomy tubes
  C. Mediastinal fine-needle aspiration or percutaneous needle biopsy
VI. Hematogenous or lymphatic spread of infections to the mediastinum
  A. Agents involved are usually bacterial or fungal.
  B. Acute mediastinitis is most commonly bacterial in nature.
    1. Organisms include *Staphylococcus* spp., *Streptococcus* spp., *Escherichia coli,* and *Corynebacterium* spp. (Dunn, 1994; Rogers, 1997).
    2. If esophageal perforation is the inciting agent, anaerobes may be involved.
  C. Chronic mediastinitis may be bacterial or fungal in nature.
    1. Bacterial agents include *Nocardia* spp., *Actinomyces* spp., *Corynebacterium* spp., and *Staphylococcus* spp., with granuloma formation (Lemire and Hoover, 1995; Biller, 2000).
    2. Fungal agents include *Histoplasma* spp., *Blastomyces* spp., *Cryptococcus* spp., and *Coccidioides* spp.

Pathophysiology

I. Systemic signs arise if sepsis is present.
II. Pleural effusion may develop secondarily.
  A. Extension of infection into pleural space
  B. Contributes to the respiratory manifestations of the disease
III. Chronic mediastinitis may result in a mass lesion.
  A. Compresses blood vessels and lymphatics
  B. Compresses the trachea or large airways
  C. Alters esophageal function
  D. Predisposes to recurrent laryngeal nerve dysfunction (Biller, 2000)

Clinical Signs

I. Animals with acute mediastinitis may have severe systemic signs related to sepsis, such as fever and/or obtundation.

II. Animals with chronic mediastinitis may have more insidious signs or signs related to a mass lesion in the thorax.
  A. Dyspnea, tachypnea
  B. Head, neck, and thoracic edema consistent with cranial vena cava syndrome
  C. Dysphagia or regurgitation from esophageal compression
III. Coughing may be present.
IV. Thoracic pain may be detected if the inflammation is acute.
V. Stridor, dyspnea, or dysphonia are often present if there is recurrent laryngeal nerve dysfunction.
VI. Dull thoracic percussion is noted with concurrent pleural fluid.
VII. If a granuloma is present, there may be reduced cranial thoracic compressibility.
VIII. Some signs relate to the underlying disease, such as with tracheal or esophageal perforation.

Diagnosis

I. History of inciting causes, respiratory or esophageal disease, and prior diagnostic or therapeutic procedures
II. Compatible clinical signs
III. Thoracic radiographic findings
  A. In acute mediastinitis, radiographs are normal early in the course of disease.
  B. Increased mediastinal width, either localized (suggesting a mass) or diffuse, may be apparent on dorsoventral or ventrodorsal views.
    1. Mediastinal fluid and masses can also cause widening.
    2. Pleural fluid may result in apparent widening of the mediastinum.
  C. Dorsal displacement of the trachea may be present on the lateral views, but this appearance can also occur with pleural fluid.
  D. In some cases of mediastinitis, pleural fluid is present concurrently.
  E. If mediastinitis is secondary to esophageal or tracheal perforation, pneumomediastinum and cervical subcutaneous emphysema may also be present.
  F. Mediastinal lymphadenomegaly may be detected (Thrall, 1998).
  G. Pulmonary pathology may also be seen.
IV. Contrast radiography sometimes helpful
  A. Esophagogram for suspected perforation using an iodine based contrast agent
  B. Angiography if cranial vena cava syndrome present
V. Computed tomography (CT) or magnetic resonance imaging (MRI) to provide more detailed structural information
VI. Fine-needle aspiration of cranial mediastinal pathology followed by cytology and microbiology
VII. Thoracoscopy for visual examination and biopsy
VIII. Endoscopy of the esophagus or trachea if perforation suspected
IX. Thoracotomy to explore the chest and obtain biopsies

Differential Diagnosis

I. Mediastinal fluid: hemorrhage, edema
II. Mediastinal masses: lymphosarcoma, thymoma
III. Mediastinal fat accumulation
IV. Pleural fluid

Treatment

I. Initial therapy: treat the underlying cause
II. Antimicrobial therapy
  A. Empirically, broad-spectrum antibiotics that have anti-anaerobic activity may be tried.
  B. It is best to obtain samples for cytology and microbiology before instituting therapy.
  C. Choose an appropriate drug based on culture and sensitivity testing.
    1. If the infection is bacterial, continue therapy for at least 4 to 6 weeks.
    2. If the infection is fungal, several months of treatment are usually necessary.
III. Supportive therapy
  A. Possible fluid therapy
  B. Thoracostomy tube if pleural fluid present
  C. Rest, analgesia
IV. Surgical therapy
  A. Repair esophageal or tracheal perforations surgically.
  B. Cranial vena cava syndrome arising from a large granuloma usually requires surgery and may be very challenging to treat.
  C. Abscesses are surgically drained.
  D. Thoracostomy tubes are inserted at the end of surgery.

Monitoring of Animal

I. With the acute form, monitor body temperature, respiratory rate and effort, and hydration status.
II. Serial thoracic radiographs are used to monitor resolution of the disease.
III. Monitoring the leukogram is not specific for resolution of mediastinitis, but may indicate decreased inflammation.
IV. Close monitoring of any thoracostomy tube and resolution of any infection is mandatory (see Chapter 19).
V. Renal function is monitored closely if an aminoglycoside antibiotic or amphotericin B is administered.

MEDIASTINAL MASSES

Definition

I. A space-occupying lesion in the mediastinum
II. Includes tumors, cysts, granulomas, and hematomas

Causes

I. Neoplasia
  A. May arise from a number of different tissue origins
    1. Lymph nodes, thymus, great vessels, trachea, esophagus, paravertebral tissue (Biller, 2000)
    2. Ectopic thyroid or parathyroid tissue, ectopic tissue of third and fourth branchial pouches (Rogers, 1997)
    3. Extension from adjacent tissues: lung, mesothelium

4. Metastatic lesions

B. Lymphosarcoma
1. In dogs, lymphosarcoma may occur alone (approximately 3% of cases) or as part of the multicentric form of the disease (Vail, 2000).
2. In cats, it may be part of a multicentric form or occur alone.
a. The incidence is higher and there is a strong association with feline leukemia virus in young cats, but overall the prevalence is decreasing (Vail, 2000).
b. In one study, most cats with mediastinal lymphosarcoma were young and Siamese (Court et al., 1997).
3. Three groups of lymph nodes are present in the cranial mediastinum.
a. Cranial mediastinal: lying along major vessels just ventral to trachea
b. Sternal: just dorsal to sternum, cranioventral to internal thoracic vessels, medial to second costal cartilage
c. Tracheobronchial or hilar nodes: at tracheal bifurcation (Biller, 2000)
4. Lymphosarcoma of the thymus is also possible (Day, 1997).

C. Thymoma
1. Rare tumors in dogs and cats that originate from epithelial cells of the thymus (Biller, 2000)
2. Classified as noninvasive or invasive rather than benign or malignant, because classification is difficult histologically (Bellah et al., 1983)
3. Rarely metastasizes

D. Other less commonly reported neoplasms
1. Lymphangioma, lymphangiosarcoma
2. Histiocytic neoplasms
3. Chemodectoma

II. Thymic cysts
A. Branchial cysts that arise from remnants of branchial pouch epithelium, usually in older dogs (Biller, 2000)
B. Other cysts of pleural, lymphatic, bronchogenic, and thymic origin (Day, 1997; Biller, 2000)

III. Lymphadenopathy (nonneoplastic)
A. Bacterial origin: often associated with mediastinitis or pyothorax
B. Fungal: usually with mediastinitis or pulmonary involvement (see previous section)
C. Mycobacteriosis: rare
D. Secondary to lymphatic drainage from abdominal pathology, such as pancreatitis
E. Granulomatosis disorders
1. Lymphomatoid: either inflammatory or neoplastic
2. Eosinophilic: likely related to hypersensitivity (Biller, 2000)

IV. Thymic enlargement in young animals before thymic involution

V. Esophageal diseases with a secondary mediastinal mass
A. Neoplasia, granuloma
B. Hiatal hernia, gastroesophageal intussusception

Pathophysiology

I. Respiratory signs occur secondary to a number of potential causes.
A. Space-occupying mediastinal mass
B. Compression of trachea or primary bronchi
C. Pleural fluid accumulation

II. Gastrointestinal signs occur from compression of the esophagus, or because the primary disease involves the esophagus.

III. Other signs are related to the space-occupying nature of some mediastinal masses, and include the following:
A. Swelling of the head, neck, and forelimbs can occur with vascular or lymphatic compression and/or invasion, or with secondary venous thrombosis (Sottiaux and Franck, 1998).
B. If there is entrapment of peripheral nerves, laryngeal paralysis or Horner's syndrome may result (Biller, 2000).
C. Neurological signs are related to thoracolumbar vertebral or spinal involvement (Day, 1997).

IV. A number of systemic consequences may develop from cranial mediastinal masses (paraneoplastic syndromes).
A. Immune-mediated diseases
1. Myasthenia gravis occurs secondarily with thymoma and may be localized or generalized in nature.
2. Myasthenia gravis arises rarely with mediastinal cysts in cats (Malik and Gabor, 1997).
3. Polymyositis has also been recognized.
4. Immune-mediated skin disease, sometimes exfoliative in nature, may occur in cats with thymomas (Day, 1997) (see Chapters 73 and 93).
B. Hypercalcemia: lymphosarcoma (primarily), thymoma
C. Monoclonal gammopathy secondary to lymphosarcoma, with possible consequences of hyperviscosity

V. Metastasis of thymomas is uncommon, but they may spread to the lungs, central nervous system, and heart (Aronsohn et al., 1984; Sorde et al., 1994).

Clinical Signs

I. Clinical signs often reflect an underlying disease process (e.g., granuloma secondary to esophageal perforation).

II. Some animals are asymptomatic if the lesion is small or growing slowly.

III. Nonspecific signs of lethargy, inappetence, and weight loss may be present.

IV. Signs relating to the mass include one or more of the following:
A. Respiratory signs
1. Dyspnea, tachypnea
2. Cough, stridor
3. Reduced air movement on auscultation and dullness ventrally if pleural effusion present
B. Gastrointestinal signs
1. Dysphagia, regurgitation

2. Hypersalivation
C. Possibly edema of the head, neck, and thoracic area
D. Laryngeal paralysis or Horner's syndrome

V. Paraneoplastic signs may include the following:
A. Weakness secondary to myasthenia gravis, polymyositis, or hypercalcemia
B. Regurgitation, cranial nerve deficits with myasthenia gravis
C. Polyuria, polydipsia, vomiting, diarrhea, cardiac arrhythmia with hypercalcemia
D. Mucocutaneous skin disease in cats
E. Hyperviscosity syndrome (rare) with lymphosarcoma and monoclonal gammopathy (see Chapter 73)

Diagnosis

I. Signalment
A. Young Siamese cats: lymphosarcoma
B. Labrador retrievers and German shepherd dogs: thymoma (Day, 1997)
C. Older animals: thymoma

II. Historical signs and physical findings consistent with a cranial mediastinal mass

III. Thoracic radiography
A. Elevation or compression of the trachea on a lateral radiograph
B. Widening of the mediastinum on dorsoventral or ventrodorsal projections
1. With thymoma, the widening may be more left sided.
2. Mass may displace the heart and lungs caudodorsally and to the right (Bellah et al., 1983).
C. Complete or partial collapse of cranial lung lobes
D. Possibly pleural fluid
E. Displacement of trachea, lungs, and heart
F. Metastasis to lungs or interstitial infiltration with lymphosarcoma
G. Lymphadenomegaly
H. Esophageal dilatation from obstruction or secondary to myasthenia gravis

IV. Contrast radiography: esophageal, angiographic studies (see Chapter 4)

V. Ultrasonography
A. Determines size and internal structure of mediastinal lesion(s)
B. Helps detect vascular invasion of the mass
C. Determines vascularity of mass
D. Helps guide aspiration or biopsy sampling

VI. Advanced imaging
A. CT can be compromised by the presence of pleural fluid.
B. CT appearance does not help differentiate the different histological types of lesions (Yoon et al., 2004).
C. MRI is difficult because of movement associated with respiration.
D. Scintigraphy is indicated if the mass is suspected of being thyroid in origin.

VII. Laboratory tests
A. Hematology for neoplastic-related cytopenias
B. Biochemistry profile to assess calcium levels, presence of organ dysfunction secondary to neoplasia, or paraneoplastic syndromes
C. Acetylcholine receptor antibody assay for suspected myasthenia gravis (see Chapter 25)
D. Serological evaluation for possible fungal diseases

VIII. Cytological examination of transthoracically collected aspirates
A. Lymphosarcoma: malignant lymphocytes predominate
B. Thymoma
1. Many lymphocytes may be detected.
2. If mast cells are present, the diagnosis is unclear, and primary mast cell tumor must be ruled out (Day, 1997).
3. Small numbers of epithelial cells are suggestive of thymoma (Biller, 2000).
C. Inflammatory cells: granuloma, abscess

IX. Culture and sensitivity testing of aspirates if infection suspected

X. Bronchoscopy with bronchoalveolar lavage, bronchial wash, or transtracheal wash for underlying pulmonary pathology

XI. Biopsy and histopathology
A. Transthoracic: ultrasound-guided, CT-guided (Zekas et al., 2005)
B. Via thoracoscopy
C. Via thoracotomy

Differential Diagnosis

I. Other mediastinal diseases that cause widening, such as mediastinitis

II. Mediastinal fluid or fat

III. Other causes of pleural effusion (see Chapter 19)

IV. Pulmonary consolidation in the cranial thorax

Treatment

I. Lymphosarcoma
A. Chemotherapy is the treatment of choice (see Chapter 69).
B. Chemotherapy also helps control paraneoplastic syndromes.
C. Radiotherapy is rarely used as an adjunct to chemotherapy.
1. Both normal and malignant lymphocytes are extremely radiosensitive (Maleo, 1997).
2. Radiotherapy can be used to reduce dyspnea early in the course of treatment.
3. It may help decrease the need for repeated thoracocenteses to drain pleural fluid.
4. It can be useful if the tumor is resistant to chemotherapy (Maleo, 1997).

II. Thymoma
A. Surgical excision is the treatment of choice.
1. Complete excision is more difficult if the thymoma is invasive (Hunt et al., 1997).
2. Paraneoplastic syndromes may improve after excision.

3. Complication rates for surgery are higher if there is concurrent megaesophagus.
4. If excision is incomplete, recurrence is likely.

B. Radiation is an option for nonresectable lesions, but complete resolution is unlikely, and survival over 12 months is rare (Maleo, 1997).
C. Treat severe hypercalcemia medically with fluids, furosemide, and glucocorticoids (see Chapters 48 and 73).
D. See Chapter 25 for treatment of myasthenia gravis.

III. Other neoplasms: surgical excision
IV. Mediastinal cysts
A. Transthoracic aspiration may relieve signs.
B. If they recur following aspiration, consider excision.
V. Inflammatory diseases: see Mediastinitis

Monitoring of Animal

I. Animals with mediastinal masses are monitored for deterioration in respiratory function, development or exacerbation of cranial vena cava syndrome, or GI signs.
II. Animals with myasthenia gravis and megaesophagus are monitored closely for the development of aspiration pneumonia.
III. If surgery is performed, close monitoring of respiratory and cardiovascular function postoperatively is important.
IV. Appropriate, postoperative thoracostomy tube care is necessary (see Chapter 19).
V. Follow-up thoracic radiography is recommended after thymectomy.
VI. If hypercalcemia is present, monitor serum calcium levels following medical therapy or surgery (see Chapter 73).

CHEST WALL NEOPLASIA

Trevor N. Bebchuk

Definition

I. Most tumors of the chest wall are malignant.
II. Benign lesions include tumors, exostoses, and cysts.

Causes

I. Primary malignant rib tumors (Montgomery et al., 1993; Pirkey-Ehrhart et al., 1995)
A. Osteosarcoma
1. It comprises 54% to 63% of all rib tumors.
2. Rib form comprises 4% to 13% of all osteosarcomas.

B. Chondrosarcoma
1. It comprises 28% to 40% of all rib tumors.
2. Rib form comprises up to 33% of all chondrosarcomas.

C. Hemangiosarcoma: 0 to 22% of all rib tumors
D. Fibrosarcoma: 0 to 4% of all rib tumors

II. Metastatic rib tumors
A. Much less common than primary tumors
B. Often a result of local extension
C. Usually osteosarcoma or hemangiosarcoma

III. Benign lesions
A. Multiple cartilaginous exostoses
1. Also known as *osteochondromatosis*
2. May undergo malignant transformation to chondrosarcoma

B. Chondroma
C. Osteoma
D. Hemangioma
E. Bone cyst

Clinical Signs

I. Signalment
A. Dogs: age 2 to 14 years
B. Rare in cats
C. No sex or breed predilection
D. Usually medium- to large-breed dogs (4 to 55 kg)

II. May be asymptomatic (Montgomery et al., 1993; Pirkey-Ehrhart et al., 1995)
A. The tumor may have extensive intrathoracic expansion, with only a small externally palpable mass.
B. Osteosarcomas are often present for up to 12 weeks before detection.
C. Chondrosarcomas may be present for up to 33 weeks before diagnosis.
D. Hemangiosarcomas are usually detected within 2 to 4 weeks.

III. Weight loss, lethargy
IV. Dyspnea
V. Thoracic limb lameness
VI. Chylothorax (Watine et al., 2003)

Diagnosis

I. Thoracic radiography
A. Take three views, including right lateral, left lateral, and ventrodorsal.
B. Frequently there is a mixed proliferative and/or osteolytic lesion of the affected rib.
C. The tumor is usually at or near the costochondral junction.
D. There is no predilection for the side or specific rib involved.
E. Pulmonary metastases may be noted in up to 50% of the cases.

II. Fine-needle aspiration of mass for cytological evaluation
A. Results often indicate malignancy.
B. The definitive tumor type may not be identified.

III. Incisional or excisional biopsy with histopathology
IV. CT or MRI
A. Advanced imaging may provide more information on the extent of the tumor.
B. MRI is hampered by movement of the thoracic wall with respiration.

V. Nuclear scintigraphy: bone scan to define extent of tumor and presence of metastases
VI. Laboratory tests
A. Complete blood count, serum chemistry, and urinalysis are indicated, especially before surgery.
B. Results may reflect geriatric changes rather than specific tumor-induced abnormalities.

TABLE 20-1

Types of Chest Wall Tumors

TUMOR TYPE	INCIDENCE	BEHAVIOR	METASTATIC POTENTIAL	TREATMENT	PROGNOSIS
Osteosarcoma	Common	Malignant	High	Complete excision and adjunctive chemotherapy	Poor: 240-day median survival time with treatment
Chondrosarcoma	Common	Malignant	Low	Complete excision	Fair: 320-day to 1080-day median survival time
Hemangiosarcoma	Rare	Malignant	High	Complete excision	Poor: 30- to 210-day median survival time
Fibrosarcoma	Rare	Malignant	Moderate	Complete excision	Fair
Multiple cartilaginous exostoses	Rare	Benign, but can undergo malignant transformation	None	Generally none required	Good
Chondroma	Uncommon	Benign	None	Complete excision	Good

Differential Diagnosis

I. Osteomyelitis
II. Healed or nonunion rib fractures
III. Pulmonary pathology adjacent to the chest wall

Treatment

I. Aggressive en bloc resection of the tumor with extensive tissue margins is recommended for most lesions (Table 20-1).
   A. Excise all affected ribs and soft tissue, because rib tumors are locally aggressive.
   B. Repair the resulting chest wall defect using local muscle flaps and/or diaphragmatic advancement procedures.
   C. Very large or cranial defects require reconstruction using polypropylene mesh.
II. Adjunctive chemotherapy may be considered for some tumors.
   A. Improves survival times with osteosarcoma
      1. Cisplatin: dogs, not cats
      2. Carboplatin
      3. Doxorubicin
      4. Combination cisplatin and doxorubicin
   B. Not effective for hemangiosarcoma, chondrosarcoma, fibrosarcoma
III. The effectiveness of radiation therapy is unknown, but it may be useful for palliation.

Monitoring of Animal

I. Monitor for postoperative complications, such as blood loss, pain, hypoventilation, and increased risk of infection with use of polypropylene mesh.
II. Prognosis varies depending on the tumor type (Montgomery et al., 1993; Pirkey-Ehrhart et al., 1995).
   A. Osteosarcoma in dogs
      1. High metastatic potential
      2. Surgical excision alone: 90-day median survival and 60-day disease-free interval
      3. Surgical excision plus chemotherapy: 240-day median survival and 225-day disease-free interval
   B. Chondrosarcoma
      1. Low metastatic potential
      2. Surgical excision alone: 320- to 1080-day median survival and up to 1080-day disease-free interval
      3. Local recurrence common
   C. Hemangiosarcoma
      1. High metastatic potential
      2. Surgical excision alone: 30- to 210-day median survival and 30- to 150-day disease-free interval
III. Other factors also affect the prognosis.
   A. Complete resection on histopathologic examination is a good prognostic factor.
   B. Mark surgical margins with ink to improve the accuracy of histological evaluation.
   C. Prognosis is poor if the tumor has invaded through the parietal pleura into the thoracic cavity.
   D. The number of ribs resected has no bearing on the prognosis.

CHAPTER 21

Introduction

Marc Kent

ANATOMICAL ORGANIZATION

Gross Anatomical Divisions

I. The nervous system is divided into the central and the peripheral nervous system.
II. The central nervous system (CNS) includes the brain and spinal cord.
  A. Divisions of the brain based on embryology (deLahunta, 1983; Jenkins, 1978)
    1. Prosencephalon
      a. Telencephalon (cerebrum): paired hemispheres containing the lateral ventricles
      b. Diencephalon: contains the thalamus and the third ventricle
      c. Mesencephalon: midbrain containing the narrow mesencephalic aqueduct
    2. Rhombencephalon
      a. Divides into two segments and contains the fourth ventricle
      b. Metencephalon: contains the pons ventrally and the cerebellum dorsally
      c. Myelencephalon: medulla oblongata
  B. Divisions of the spinal cord
    1. The spinal cord is divided into numbered segments in each region of the vertebral column, namely cervical (C), thoracic (T), lumbar (L), sacral (S), coccygeal or caudal (Cd).
    2. The spinal cord segments are also divided into functional segments, such as C1-C5, C6-T2, T3-L3, L4-S1, and S1-S3.
III. The peripheral nervous system includes motor, sensory, and autonomic nerves.
  A. The motor aspect of the peripheral nervous system is the lower motor neuron (LMN) system or neuromuscular system.
    1. The LMN unit is composed of the motor neuron cell body in the spinal cord or brainstem, the spinal or cranial nerve, the peripheral nerve, the neuromuscular junction, and the muscle.
    2. The motor neuron cell bodies for the nerves of the limbs reside in the C6-T2 and L4-S1 segments of the spinal cord for the thoracic and the pelvic limbs, respectively.
    3. Spinal nerves coalesce to form the brachial plexus and lumbosacral plexus before forming specific peripheral nerves of the thoracic and pelvic limbs respectively.
  B. The sensory nervous system consists of sensory nerves, their receptors, peripheral nerves, spinal or cranial nerves, cell bodies located in craniospinal ganglia, and projections in the CNS.
  C. The autonomic nervous system is divided into the sympathetic and parasympathetic branches.
    1. The preganglionic (first order) neuron cell body is located in the CNS, whereas the postganglionic (second order) neuron cell body is located outside the CNS.
    2. Preganglionic sympathetic neuron cell bodies are distributed in the thoracolumbar spinal cord.
    3. Preganglionic parasympathetic neuron cell bodies are located in the sacral spinal cord segments and within the nuclei of cranial nerves (CN) III, VII, IX, and X.
  D. Innervation of the head is supplied by 12 CN, which are referred to by either Roman numerals or their common names.

NEUROLOGICAL EXAMINATION

Components to Evaluate

I. Evaluation of the sensorium (mentation or mental status)
  A. *Sensorium* refers to an animal's behavior and how it interacts with individuals and responds to various environmental stimuli.

1. Commonly used qualifiers include obtunded, quiet, dull, depressed, hyperactive, and aggressive.
2. Stupor is used to describe animals that appear unconscious, but a noxious stimulus rouses them.
3. Comatose animals appear to be unconscious and cannot be aroused with a noxious stimulus.
4. The sensorium is also affected by sedatives, pain, analgesic medications, anticonvulsants, and during the postictal period.

B. Mentation is determined by the activity of the cerebrum and the ascending reticular activating system (ARAS) located in the brainstem.
C. Any intracranial lesion can alter the sensorium.
D. In general, structural lesions affecting the ARAS tend to result in more severe alterations in the sensorium than similar structural lesions in the cerebrum (deLahunta, 1983; Lorenz and Kornegay, 2004).

II. Evaluation of gait
A. Proper evaluation of gait is an important aspect of the neurological examination.
B. Evaluate gait by observing the animal walking away from and toward the examiner, as well as from the side, with the animal on a surface with good traction.
C. Gait can be divided into three broad categories, namely normal, ataxia, or consistent with LMN (neuromuscular).
1. Ataxia simply implies incoordination.
a. Vestibular ataxia is characterized by leaning, listing, and falling to one side with the animal appearing to be off balance, often having an altered head position (head tilt) or abnormal nystagmus.
b. Cerebellar ataxia is characterized as a dysmetria, as there is an alteration in the rate, range, and force of motion of the limbs (deLahunta, 1983).
c. Proprioceptive ataxia is characterized by a long-strided, often hypermetric gait in which there can be crossing of the limbs under the body and walking on the dorsum of the paw.
2. A gait consistent with LMN disease (neuromuscular) is characterized by a short-strided, choppy gait, and overflexion of the joints, which gives the animal a crouched appearance.

III. Evaluation of postural reactions
A. Postural reaction tests are designed to uncover deficits not apparent by gait observation alone (deLahunta, 1983).
B. Postural reaction tests require normal function of the sensory nerves; ascending general proprioceptive (GP) tracts that project to the ipsilateral cerebellum, contralateral thalamus, and cerebrum; descending upper motor neuron (UMN) tracts; and LMN units.
C. Postural reaction tests include hopping, proprioceptive placing, hemiwalking, wheelbarrowing with the head up, and extensor postural thrust (Lorenz and Kornegay, 2004).

IV. Evaluation of segmental spinal reflexes
A. Spinal reflexes test the integrity of a specific segment of the spinal cord that contains the reflex arc (Table 21-1), and do not rely on spinal cord function cranial to that segment.
B. Reflexes are graded as absent/areflexia (0), reduced/hyporeflexia (+1), normal (+2), increased/hyperreflexia (+3), and hyperreflexia with clonus (+4).
C. Evaluation of the spinal reflexes allows differentiation between LMN and UMN lesions.
1. Lesions affecting the spinal cord that contain the reflex arc result in hypo- to areflexia (LMN).
2. Lesions affecting the spinal cord cranial to the reflex arc result in normal to hyperreflexia (UMN, GP/UMN).
D. In addition to reflexes, strength, muscle tone, and muscle mass are assessed.
1. Decreased tone (hypotonia) and severe atrophy are consistent with LMN lesions.
2. Normal to increased tone (hypertonia), with little to no atrophy is consistent with UMN lesions.

V. Evaluation of CN function
A. Like spinal reflexes, CN reflex arcs are contained within a specific region of the brain (Table 21-2).
B. Exceptions to this rule are the menace response and the evaluation of nasal sensation, which require the integrity of the contralateral thalamus and somesthetic cerebral cortex.

VI. Sensory evaluation
A. A specific cutaneous area innervated by a single sensory nerve is an autonomous zone.
B. Testing autonomous zones provides functional information about specific sensory nerves (Table 21-3).

VII. Establishing the neuroanatomic diagnosis
A. Lesions affecting GP/UMN tracts are detected through postural reaction testing and provide the examiner with evidence of a neurological disorder affecting this pathway.
B. The exact location of the lesion along this long pathway is identified through the evaluation of spinal and CN reflexes.

Brain

I. Prosencephalic lesions
A. Clinical signs include seizures and changes in sensorium with preservation of a normal gait.
B. Contralateral postural reaction and menace deficits, and hypalgesia of the face can be seen.
C. Lesions affecting the diencephalon can also cause abnormal thermal regulation, autonomic, metabolic (e.g., animal loses weight despite normal caloric intake), and endocrine function.

II. Mesencephalic lesions
A. Lesions can affect the sensorium and cause gait (proprioceptive ataxia), GP/UMN, and postural reaction deficits, which are generally ipsilateral to the lesion.
B. Clinical signs relate to dysfunction of CN III and IV.

III. Metencephalon lesions
A. Abnormalities of the pons may occur.
1. Lesions can affect the sensorium and cause gait deficits (i.e., proprioceptive ataxia).

TABLE 21-1

Segmental Reflexes

REFLEX	METHOD OF TESTING	RESPONSE	NERVES	SPINAL CORD SEGMENT	VERTEBRAL SEGMENT
Thoracic Limb					
Withdrawal reflex*	Noxious stimulus is applied to the digit	Flexion of limb	S: Dorsal surface radial = palmar surface = ulnar/median M: All nerves of the brachial plexus	C6-T2	C5-T1
Biceps reflex	With elbow in slight extension, percuss biceps tendon at its insertion	Elbow flexion	S, M: Musculocutaneous	C6-C8	C5-C7
Triceps reflex	With elbow in slight flexion, percuss the triceps tendon at its insertion	Elbow extension	S, M: Radial	C7-T2	C6-T1
Extensor carpi radialis	Percuss the proximal muscle belly	Carpal extension	S, M: Radial	C7-T2	C6-T1
Pelvic Limb					
Patellar reflex*	With stifle in neutral position, percuss patellar tendon	Stifle extension	S, M: Femoral	L4-L6	L3-L4
Withdrawal reflex*	Noxious stimulus is applied to the digit	Flexion of limb	Dorsal surface = peroneal branch of sciatic, palmar surface = tibial branch, 5th digit = femoral (S), sciatic (M)	L6-S1	L4-L5
Cranial tibial reflex	Percuss the proximal muscle belly	Hock flexion	S, M: Peroneal branch of sciatic	L6-L7	L4-L5
Gastrocnemius reflex*	With hock in flexion, percuss the gastrocnemius tendon at its insertion	Hock extension	S, M: Tibial branch of sciatic	L7-S1	L4-L5
Other Sites					
Perineal reflex	Noxious stimulus is applied to the perianal region	Anal sphincter contraction	S, M: Perineal branch of pudendal	S1-S3	L5
Cutaneous trunci reflex	Noxious stimulus is applied to skin dorsal of midline	Skin twitch over thorax	S: Segmental M: Lateral thoracic	C8-T1(M)	C7-T1

S, Sensory; *M,* motor.
*Reflex is reliable.

2. GP/UMN and postural reaction deficits, ipsilateral to the lesion.

B. Clinical signs dysfunction of CN V may occur.
C. Cerebellar signs may develop.
1. Unilateral lesions can affect gait (cerebellar ataxia) and cause mild postural reaction deficits.
2. Menace deficits, despite normal vision and intention tremors of the head, are also possible.

IV. Myelencephalon lesions
A. Lesions can affect the sensorium, cause gait deficits (i.e., proprioceptive ataxia), GP/UMN, and postural reaction deficits ipsilateral to the lesion.
B. Deficits involving the function of CN VI through XII.
C. Specifically, deficits in CN VIII function cause a head tilt, vestibular ataxia, and abnormal nystagmus.

TABLE 21-2

Cranial Nerve Function and Testing

CRANIAL NERVE NUMBER AND NAME	RELATIONSHIP TO THE BRAIN	ANATOMIC COURSE	FUNCTION	METHOD OF TESTING	DEFICIT
I—Olfactory	Rostral aspect of cerebrum and piriform lobe	Enters cribriform plate	Smell (SVA)	Not usually performed Avoidance of noxious smell (alcohol)	Difficult to appreciate
II—Optic	Diencephalon (thalamus)	Enters the optic canal, decussates at the chiasm and projects via the optic tract to thalamus and then to the occipital cortex of cerebrum	Vision (SSA) Carries afferent information for pupil response to light	Menace response PLR	Blindness Bumping into objects Mydriasis
III—Oculomotor	Mesencephalon (midbrain)	Exits the midbrain ventrally to leave cranial cavity via orbital fissure	Adjusts pupil diameter in response to light (SVE-parasympathetic) Motor to the medial, dorsal, and ventral rectus and ventral oblique muscles (GSE)	PLR Detection of strabismus, physiological nystagmus	Mydriasis Resting strabismus (ventrolateral)
IV—Trochlear	Mesencephalon (midbrain)	Projects dorsally over the midline of the midbrain to exit cranial cavity ventrally via orbital fissure	Motor to the dorsal oblique extraocular eye muscle (GSE)	Detection of strabismus, physiological nystagmus	Resting strabismus (dorsolateral)
V—Trigeminal	Pons	Mandibular branch exits the pons to leave cranial cavity via oval foramen Maxillary branch exits the round foramen Ophthalmic branch exits the orbital fissure All three branches have GSA and mandibular contains SVE	Cutaneous sensation and proprioception of the head (GSA) Motor to the muscles of mastication (SVE)	Palpebral reflex Response to noxious stimulation of the nasal septum and face Palpation of the muscle of mastication Testing jaw tone	Absent palpebral reflex Hypalgesia to analgesia to the face Muscle atrophy of the muscles of mastication Reduced jaw tone Dropped jaw with bilateral deficit
VI—Abducens	Rostral medulla oblongata	Exits the cranial cavity via the orbital fissure	Motor to the lateral rectus and retractor bulbi muscles (GSE)	Detection of strabismus, physiological nystagmus	Resting strabismus (ventromedial)

SVA, Special visceral afferent; *SSA,* special somatic afferent; *PLR,* pupillary light reflex; *SVE,* special visceral efferent; *GSE,* general somatic efferent.

TABLE 21-2

Cranial Nerve Function and Testing—*cont'd*

VII—Facial	Rostral medulla oblongata	Exits the cranial cavity via internal acoustic meatus, petrosal bone (middle ear), and stylomastoid foramen	Motor to the muscles of facial expression (SVE) Cutaneous innervation of the concave surface of the ear (GSA) Innervation of the lacrimal gland (GVE-parasympathetic) Taste (SVA)	Menace response Palpebral reflex Observing facial muscle movements (ears, lips, eyelids)	Inability to blink Absence of facial expression Drooping of lip Drooling/dropping food from mouth Absent tear production Cutaneous sensation is difficult to test (overlapped by other nerves)
VIII—Vestibulocochlear	Rostral medulla oblongata	Exits the cranial cavity via the internal acoustic meatus	Hearing and balance Special proprioception (SSA)	Detection of physiological nystagmus Observing balance problems Behavioral responses to noise (hearing)	Head tilt Abnormal nystagmus Vestibular strabismus Vestibular ataxia (generally directed toward the affected side)
IX—Glossopharyngeal	Caudal medulla oblongata	Exits the cranial cavity internally via the jugular foramen and leaves via the tympanooccipital fissure	Motor and sensory to the pharynx (SVE, GSA) Innervation of the parotid and zygomatic salivary glands (GVE-parasympathetic) Taste (SVA)	Gag reflex	Dysphagia
X—Vagus	Caudal medulla oblongata	Exits the cranial cavity internally via the jugular foramen and leaves via the tympanooccipital fissure	Motor and sensory to the pharynx (SVE, GSA) Innervation of the viscera (GVE-parasympathetic) Taste (SVA)	Gag reflex	Dysphagia Laryngeal paresis/paralysis
XI—Accessory	Caudal medulla oblongata	Exits the cranial cavity internally via the jugular foramen and leaves via the tympanooccipital fissure	Motor to the trapezius, sternocephalicus, and portions of the brachiocephalicus muscles (SVE)	Palpation of neck and shoulder muscle mass	Atrophy of the neck and shoulder muscles
XII—Hypoglossal	Caudal medulla oblongata	Exits the cranial cavity via the hypoglossal canal	Motor to the tongue muscles (GSE)	Observation of tongue movements	Atrophy of the tongue musculature

GVE, General visceral efferent.

TABLE 21-3

Autonomous Zones of Cutaneous Innervation

NERVES	SPINAL NERVE ROOTS	CUTANEOUS SITE OF TESTING
Thoracic Limb		
Radial	C7-T1	Dorsal aspect of 3rd or 4th digit
Ulnar/median*	C8-T2	Palmar surface of paw
Musculocutaneous	C6-C8	Distal (2 cm) to medial epicondyle of humerus
Pelvic Limb		
Saphenous-femoral†	L4-L6	Distal (4 cm) to medial epicondyle of femur
Peroneal-sciatic	L6-L7	Dorsal surface between 2nd and 3rd digits
Tibial-sciatic	L7-S1	Proximal to metatarsal pad

*Both the median and ulnar nerves innervate the palmar aspect of the paw.
†The femoral nerve cutaneous area is overlapped by the peroneal nerve.

D. Lesions involving the caudal cerebellar peduncle, flocculonodular lobe, or fastigial nucleus of the cerebellum can cause paradoxical vestibular disease, which involves signs that are opposite the side of the lesion.

Spinal Cord

I. C1-C5 myelopathies
   A. Clinical signs include GP/UMN deficits and proprioceptive ataxia in all four limbs.
   B. Severe lesions can cause respiratory failure from paralysis of the diaphragm and intercostal muscles.
II. C6-T2 myelopathies
   A. Clinical signs include LMN deficits in the thoracic limbs, with GP/UMN deficits in the pelvic limb.
   B. The T1-T3 spinal cord segments contain the preganglionic neurons of the sympathetic nervous system that innervate the eye; therefore, ipsilateral Horner's syndrome may be seen.
III. T3-L3 myelopathies
   A. Clinical signs include GP/UMN deficits in the pelvic limbs.
   B. A more precise lesion location within the T3-L3 vertebral column can be identified by detecting a painful area (region of hyperesthesia), point of absence of the cutaneous trunci reflex, or a line caudal to which the animal is analgesic.
IV. L4-S1 myelopathy
   A. Clinical signs consist of LMN signs to the pelvic limbs.
   B. It can be difficult to separate spinal cord lesions involving the L4-S1 segments from diseases of the accompanying peripheral nerves.
V. Lesions affecting spinal cord segments S1-S3 cause urinary and fecal incontinence owing to decreased to absent anal and urethral sphincter tone (LMN bladder).

DIAGNOSTIC EVALUATION

I. A minimum database consists of a complete blood count (CBC), biochemistry profile, and urinalysis.
II. Magnetic resonance imaging (MRI) provides superior contrast of soft-tissue structures (Tidwell and Jones, 1999).
   A. Standard sequences include T1-weighted (T1), T2-weighted (T2), and post-contrast T1-weighted images (Thomson et al., 1993).
   B. Additional sequences (e.g., fluid attenuated inversion recovery, short tau inversion recovery, fat suppression T1 and T2, and plain T2) can provide information regarding the characteristic of lesions.
   C. Gadolinium containing contrast media is utilized to better identify lesions (Thomson, 1993).
   D. MRI characteristics and topographic features can often provide an accurate antemortem diagnosis.
III. Computed tomography (CT) images are constructed from the attenuation of an x-ray beam that is passed through the animal (Bailey, 1990).
   A. Images can be reconstructed in different planes and manipulated to better visualize bony or soft-tissue structures (Tidwell and Jones, 1999).
   B. Iodinated contrast media are used to enhance visualization of lesions and normal anatomic structures.
IV. Cerebrospinal fluid (CSF) analysis is a sensitive test for CNS pathology, but rarely provides a specific etiology.
   A. CSF can be obtained from the cisterna magnum or from the lumbar subarachnoid space (Cook and Denicola, 1988).
   B. CSF is examined for color, clarity, white and red blood cells, and protein content.
   C. Normally, CSF is clear and colorless.
      1. Normal CSF contains 0 to 5 white blood cells (WBC)/μL in the dog and 0 to 3 WBC/μL in the cat.
      2. Most cells are mononuclear.
      3. Protein content is normally <24 mg/μL (Bailey and Higgins, 1985; Rand et al., 1990).
V. Electromyography (EMG) provides information regarding the function of the LMN unit.
   A. EMG evaluates the electrical activity of the muscle through the measurement of the electrical potential of the extracellular fluid at the recording site (muscle) (Kimura, 2001).
   B. Abnormalities are generally nonspecific and can arise with disease of the nerve or muscle (Farnbach, 1980).
VI. Several types of evoked potentials may be measured.
   A. Motor nerve studies involve the stimulation of a motor nerve and recording the muscle action potential and they provide information regarding axons and myelination (Farnbach, 1980).
   B. Sensory nerve studies involve the stimulation of sensory or mixed sensory–motor nerves and recording latency

and they provide information regarding the integrity of the sensory nervous system (Holliday et al., 1977).

C. The F-waves are generated by the antidromic depolarization of a motor neuron, and F-wave evaluation provides information regarding the function of the proximal portion of the motor nerve (Knecht et al., 1983; Kimura, 2001).

D. Repetitive nerve stimulation consists of a series of consecutive stimulations in which decremental measurements are suggestive neuromuscular junction disease (myasthenia gravis) (Malik and Cook, 1989; Sims and McLean, 1990).

CHAPTER 22

Seizures and Sleep Disorders

Fredrik Gruenenfelder

SEIZURES

Definition

I. A seizure is a nonspecifical, paroxysmal event or episode that may have a neurological or nonneurological etiology.
II. An epileptic seizure implies a neural cause.
III. An epileptic seizure is the clinical manifestation of involuntary alterations in behavior and locomotion caused by hypersynchronous, abnormal, neuronal activity in the cerebral cortex.
IV. Partial seizures arise from events in focal areas of the cerebral cortex.
  A. Paroxysmal alterations in motor function involve certain muscle groups, resulting in facial-muscle twitching, single-limb movements, or twisting of the head or neck.
  B. Paroxysmal alterations in vegetative or sensory functions cause abnormal behaviors, such as fly biting, excessive unmotivated vocalization, restlessness, unprovoked aggressiveness, drooling, or rapid running.
  C. No alteration in consciousness occurs during simple partial seizures, but consciousness is altered during complex partial seizures.
V. Generalized seizures originate from the cerebral hemispheres or thalamus and may begin with a focal event that progresses to involve the entire prosencephalon.
  A. Generalized seizures may be classified as tonic-clonic, clonic, atonic, or myoclonic.
  B. Autonomic disturbances, such as urination, defecation and hypersalivation, are common.
  C. Generalized seizures are often accompanied by alterations in consciousness.
VI. Unclassified seizures cannot be classified because of incomplete or inconsistent data.
VII. Certain events or phases may occur with seizures.
  A. The prodrome is the period before the onset of seizure activity.
    1. Prodromal signs include changes in behavior, such as anxiousness, increased attentiveness, or hiding.
    2. This phase can last for several days.
  B. The aura is the initial manifestation of a seizure.
    1. Signs include drooling, vomiting, pacing, or barking.
    2. The aura can last from seconds to minutes.
  C. Ictus is the actual seizure event and may include involuntary motor movements, abnormal muscle tone, abnormal sensation and behaviors; ictus usually lasts from seconds to minutes.
  D. The postictal phase is characterized by abnormal behavior, disorientation, weakness, blindness, and sensory or motor dysfunction that can last from minutes to 48 hours.
  E. The interictal period is the time between seizures, during which the animal is clinically and neurologically normal.
  F. Status epilepticus is a seizure lasting >5 minutes or repeated seizures without a return to consciousness between them (Thomas, 2003).
  G. Cluster seizures are defined as ≥2 seizures within 24 hours.
VIII. Epilepsy is defined as recurrent seizure activity caused by a chronic brain disorder (Berendt and Gram, 1999).
  A. Strictly defined, epilepsy does not imply an underlying cause of recurrent seizures.
  B. Epilepsy is commonly applied to situations in which an underlying cause is not defined and there may be a possible inheritance of the seizures.
    1. There is a familial predisposition for idiopathic epilepsy in certain breeds of dogs.
    2. In dogs, the age at onset is 1 to 5 years.
    3. Often the seizures are generalized, but they can be partial.
    4. Seizures occur spontaneously, often during rest or sleep.
    5. Seizure frequency initially is every 4 to 6 weeks.
    6. There is a tendency for frequency to increase if left untreated.
  C. Refractory epilepsy is frequent or severe seizure activity despite appropriate therapy.

Causes

I. Epilepsy can be classified based on the underlying etiology (Table 22-1).
II. Symptomatic epileptic seizures are caused by structural brain disorders.
III. Reactive epileptic seizures arise from disturbances in systemic metabolism or from toxicoses (no structural brain abnormalities).
IV. Cryptogenic epileptic seizures may occur from metabolic or structural brain disorders that are undetectable.

TABLE 22-1

Potential Causes of Seizures

CLASS OF DISORDERS	EXAMPLES
Degenerative diseases	Storage diseases: gangliosidosis, glucocerebrosidosis, glycoproteinosis, mucopolysaccharidosis glycogenosis, ceroid lipofuscinosis, leukodystrophy
	Diseases affecting intermediate metabolism
Anatomical anomalies	Hydrocephalus (primary, secondary), lissencephaly, hydranencephaly, porenecphaly
	Vascular malformations
Metabolic disturbances	Hepatic encephalopathy: portosystemic shunt, acquired liver disease
	Uremic encephalopathy
	Hypoglycemia: see Chapters 36 and 73
	Hypocalcemia: puerperal tetany, hypoparathyroidism
	Hypercalcemia, hypernatremia, hyponatremia, hyperlipoproteinemia
	Hypoxia, acid-base disturbances, polycythemia vera
Neoplasia	
Primary	Meningioma, meningiosarcoma, astrocytoma, glioblastoma multiforme
	Oligodendroglioma, oligoastrocytoma, gliomatosis cerebri
	Primitive neuroectodermal tumors, ependymoma, chorioid plexus papilloma
Secondary	Metastatic neoplasia, lymphoma
	Pituitary macroadenoma, hamartoma, suprasellar germ cell tumor
Inflammatory conditions	
Infections	
Bacterial	*Streptococcus* spp., *Staphylococcus* spp., *Escherichia coli, Pasteurella* spp., *Listeria monocytogenes*
Rickettsial	Rocky Mountain spotted fever, ehrlichiosis
Viral	Rabies, canine distemper virus, canine herpesvirus
	Feline infectious peritonitis, leukemia virus, immunodeficiency virus
Fungal	Cryptococcosis, blastomycosis, histoplasmosis, coccidiomycosis, phaeohyphomycosis
Protozoal	Neosporosis, toxoplasmosis
Parasitic	Dirofilariasis, toxascariasis, ancylostomiasis
Noninfectious causes	Granulomatous meningoencephalitis, necrotizing meningoencephalitis
	Necrotizing leukoencephalitis, eosinophilic meningoencephalitis
	Feline polioencephalomyelitis
Trauma	Head trauma: automobile crashes, high-rise building syndrome, bite wounds
Toxins	Organophosphates, carbamates, metaldehyde, pyrethrin (cats), ethylene glycol, bromethalin, lead
Vascular disorders	Hemorrhagic or ischemic infarction
	Feline ischemic encephalopathy from intracranial *Cuterebra* spp. larval migration

V. Idiopathic epileptic seizures have no recognized underlying metabolic or structural cause, and may be genetic in origin.

Pathophysiology

I. A seizure develops from transient, paroxysmal, uncontrolled, synchronized electrical discharge of neurons (Gandini et al., 2005).
II. The activity disperses to different areas of the brain over thalamocortical pathways, intrahemispheric association or commissural pathways (Podell, 2004).
III. The cause of the excessive electrical discharge may be an increased excitability of neurons (Gandini et al., 2005).
IV. A common mechanism may involve changes in equilibrium between the main inhibitory neurotransmitter (gamma aminobutyric acid [GABA]), and the main excitatory neurotransmitter (glutamate), with greater concentrations of glutamate (Fenner and Hass, 1989).
V. If the epileptic focus activates a critical number of areas, a generalized seizure occurs (March, 1998).
VI. Theoretically, the more new seizure foci that are recruited, the more difficult the seizures are to control medically (Podell, 2004).
VII. The end of the seizure is normally caused by active inhibition (Gandini et al., 2005).
VIII. Seizures can result in various secondary intracranial consequences.
   A. Accumulation of excitatory neurotransmitters (glutamate) can lead to neurotoxicity and neuronal cell death (Fujikawa, 2005).
   B. The disruption of neuronal function and integrity can lead to cerebral edema with increased intracranial

pressure and generalized, reduced perfusion of the brain (Podell, 2004).
C. Neurons have a much higher demand for energy during a seizure, which leads to anaerobic glycolysis, cerebral acidosis, and further neuronal dysfunction and death.

IX. Extracranial changes include hyperthermia, hypoventilation, hypoxia, and systemic hypertension.

Clinical Signs

I. Simple partial seizures
   A. Motor movements in a single group of muscles: facial muscle or one leg twitching
   B. No changes in consciousness
II. Complex partial seizures
   A. Altered consciousness
   B. Abnormal psychomotor function: fly biting, restlessness, barking, chasing of extremities
III. Generalized seizures
   A. Impairment of consciousness
   B. Excessive motor movements of the body and head (tonic/clonic movements)
      1. In the tonic phase, the animal is in a rigid, hyperextended posture.
      2. The clonic phase includes strong, jerky movements of the extremities, jaw, and neck muscles.
   C. Autonomic disturbances: hypersalivation, urination, defecation
IV. Atonic, myoclonic, and absent seizures: difficult to recognize, poorly defined in animals
V. Other signs: pacing, transient loss of vision, disorientation, changes in personality

Diagnosis

I. Ultimate goal: determine the cause of the seizures
II. Important historical information
   A. Vaccination status and travel history
   B. Potential of trauma and exposure to toxins
   C. Breed and familial history of seizures
   D. Previous medical and surgical history
   E. Onset and frequency of seizures
   F. Duration of ictus
   G. Duration and characteristics of the postictal phase
III. Physical examination
   A. Detection of systemic illness that may result in reactive epilepsy
   B. Identification of episodic nonneurological and neurological disorders easily confused with epileptic seizures
IV. Neurological examination
   A. Perform a complete neurological examination to identify interictal deficits (see Chapter 21).
   B. Asymmetrical, interictal deficits unrelated to postictal changes are suggestive of structural brain disease.
V. Minimal laboratory database
   A. Complete blood count (CBC)
   B. Serum biochemistry profile
   C. Urinalysis
VI. Advanced clinicopathologic testing based on initial laboratory results
   A. Liver function testing: bile acids, fasting serum ammonia, ammonia tolerance test
   B. Simultaneous serum glucose and insulin levels in hypoglycemic animals
   C. Serial blood glucose measurements in animals with suspected hypoglycemia
   D. Endocrine assays: hyperadrenocorticism, hypoadrenocorticism, hypothyroidism
   E. Toxicology testing: blood lead, acetylcholinesterase activity for organophosphate toxicities
   F. Systemic blood pressure measurement
VII. Specific testing for intracranial disorders
   A. Cerebrospinal fluid (CSF) analysis
   B. Measurement of serum and CSF antibody or antigen titers
      1. Feline enteric coronavirus/feline infectious peritonitis (FIP) virus
      2. Canine distemper virus, *Neospora caninum*, *Toxoplasma gondii*
      3. *Cryptococcus neoformans*, other fungal organisms
VIII. Imaging studies
   A. Thoracic and abdominal radiography
   B. Abdominal ultrasonography
   C. Transcolonic portal scintigraphy
   D. Magnetic resonance imaging (MRI) of the brain
IX. Establishing the type of seizures present
   A. Idiopathic epilepsy (Table 22-2)
      1. To classify the seizures as idiopathic epilepsy, the animal must have normal physical and neurological examinations and remain normal interictally.
      2. Ultimately, the diagnosis of idiopathic epilepsy is made through the exclusion of other causes of epilepsy (i.e., symptomatic or reactive).
      3. Clinicopathologic data are normal.
   B. Symptomatic epilepsy
      1. Hallmark findings are asymmetrical, neurological deficits or the persistence of any neurological deficit during the interictal period.
      2. Age of onset is often <1 or >6 years.
      3. Animals often have partial seizures, which may be generalized.
      4. Clinicopathologic test results are usually normal.
      5. Most cats have symptomatic or reactive epilepsy (Barnes et al., 2004; Quesnel et al., 1997).
   C. Reactive epilepsy
      1. Classic features are signs of systemic illness from metabolic disorders or toxicities (e.g., fever, lethargy, weight loss, anorexia, vomiting, diarrhea).
      2. If present, interictal neurological deficits are symmetrical.
      3. Seizures are often generalized.
      4. Abnormalities are often found in clinicopathologic tests.
   D. Cryptogenic epilepsy
      1. Physical and neurological examination findings may be normal or abnormal.

TABLE 22-2

Clinical Features of Idiopathic Epilepsy

CLINICAL PARAMETER	DOGS	CATS
Cause	Genetic defects causing abnormalities in neuronal ion channels are suspected	Unknown
Incidence	50% to 60% of seizure disorders	10% to 20% of seizure disorders
Age of onset	1 to 5 years	Unknown
Affected breeds	Proven genetic factor: Keeshond Multiple factors (genetic and environmental): beagle, German shepherd dog, golden retriever, Belgian tervuren, Labrador retriever, Bernese mountain dog, boxer, Shetland sheep dog, viszla, Irish wolfhound High incidence: cocker spaniels, poodles, St. Bernard, Irish setter, miniature schnauzer, collie, wiredhaired fox terrier, dachshund, Greater Swiss mountain dog, Horaks laborhound, border collie	No breed predilection identified
Clinical signs	Sudden onset Seizures often generalized (tonic-clonic) Commonly occur at night or during rest/sleeping	Sudden onset Seizures often generalized: excessive activity, vocalizing, hypersalivation, defecation, urination

2. Clinicopathologic data may be normal or abnormal.
3. Despite lack of evidence or identification of an underlying etiology, cryptogenic epilepsy is often presumed in dogs <1 year or >5 years and in most cats with seizures.

X. Age relationship to causes in dogs (see Table 22-2)
   A. Age <1 year
      1. Dogs often have symptomatic or reactive epilepsy.
      2. Seizure activity often arises from congenital anomalies or inflammatory diseases of the central nervous system.
         a. Hydrocephalus: Chihuahua, Maltese, Yorkshire terrier, potentially any breed
         b. Canine distemper virus
         c. Noninfectious inflammatory diseases: necrotizing meningoencephalitis in the pug, necrotizing leukoencephalomyelitis in the Yorkshire terrier, Maltese, Chihuahua, and other small breeds
      3. Portosystemic shunts must always be ruled out in this age group.
   B. Age 1 to 5 years
      1. Most common cause: idiopathic epilepsy
      2. Later onset of seizure possible with congenital anomalies
   C. Age >5 years
      1. Intracranial neoplasia is a common cause.
      2. Cryptogenic epilepsy is suspected when an underlying etiology cannot be found.

XI. Age relationship to causes in cats
   A. Age <1 year
      1. Infectious inflammatory diseases: FIP, protozoal diseases
      2. Congenital anomalies of the brain
      3. Metabolic disorders, portosystemic shunts
   B. Age 1 to 7 years
      1. Infectious, inflammatory diseases
      2. Trauma
      3. Vascular insults: feline ischemic encephalopathy from *Cuterebra* spp. larval migration
      4. Neoplasia
   C. Age >7 years
      1. Neoplasia
      2. Metabolic diseases: renal encephalopathy
      3. Vascular insults: feline ischemic encephalopathy

Differential Diagnosis

I. Nonneurological disorders
   A. Syncope
   B. Stereotypy with abnormal behavior
   C. Strychnine intoxication

II. Neurological disorders
   A. Vestibular disorders
   B. Myasthenia gravis
   C. Narcolepsy, cataplexy
   D. Involuntary motor movements: myoclonus, generalized tremors, dyskinesia

Treatment

I. The goal of emergency treatment is to stop the seizure activity without causing any harm to the animal.
   A. Emergency treatment is required for isolated seizures lasting >3 minutes, seizures occurring hourly, three or more seizures within 12 hours, cluster seizures, and status epilepticus (Box 22-1).
   B. Initial emergency treatment involves controlling the seizure with short-acting anticonvulsants and initiating treatment with long-acting anticonvulsants.
      1. Benzodiazepines are used for initial treatment.

Box 22-1

Emergency Treatment of Status Epilepticus or Cluster Seizures in Dogs and Cats

1. Give diazepam 0.5 to 2 mg/kg IV or midazolam 0.07 to 0.22 mg/kg IV, IM and phenobarbital 2 mg/kg IV.
2. If seizures continue or recur within 2 hours, give an additional dose of diazepam or midazolam.
   a. A loading dosage of phenobarbital can also be given.
   b. The loading dosage of phenobarbital is 12 to 15 mg/kg IV divided into 2 to 4 mg/kg dosages every 1 to 2 hours over 24 hours until seizures are controlled or the animal is extremely sedated.
3. If seizures continue or recur within 2 hours, then consider propofol 4 to 8 mg/kg IV bolus and start constant rate infusion (CRI) of diazepam or midazolam at 0.5 mg/kg/hr IV.
4. If seizures do not stop, increase the CRI to 2 mg/kg/hr IV in 0.5 mg/kg/hr increments; at higher dosages animals can develop apnea.
5. If seizures stop, continue CRI of diazepam or midazolam for 4 to 6 hours, then gradually discontinue the CRI over 4 to 6 hours.
6. If seizures recur after stopping the CRI, restart a diazepam or midazolam CRI for another 6 hours and continue phenobarbital 2 mg/kg IV, IM, PO BID.
7. If seizures do not stop with repeated diazepam or midazolam, then give propofol 4 to 8 mg/kg IV and start a propofol CRI at 0.1 to 0.6 mg/kg/min IV for 4 to 6 hours.
8. If seizures stop, then gradually discontinue propofol CRI over 4 to 6 hours.
9. If seizures do not stop with diazepam, midazolam, or propofol, then consider pentobarbital 2 to 15 mg/kg IV over several minutes, then a pentobarbital CRI of 0.5 mg/kg/hr IV for 4 to 6 hours.
   Caution:
   a. Severe cardiopulmonary depression can occur.
   b. Endotracheal intubation may be necessary.
   c. Intensive monitoring is essential.
   d. Animal may be neurologically abnormal for up to 1 week after pentobarbital CRI.

   2. Diazepam is the drug of choice.
      a. It can be used for seizures or during the postictal phase.
      b. It may be administered IV, rectally, or intranasally.
   3. Midazolam can be used as an alternative.
C. In reactive epilepsy, treatment of the underlying etiology is undertaken.
D. With cryptogenic or idiopathic epileptic seizures, long-term anticonvulsive drugs are initiated simultaneously with benzodiazepine administration.
E. If seizures stop after emergency treatment, then continue with long-term anticonvulsants.

II. The goal of long-term treatment is to provide chronic control of seizure activity.
A. Theoretically, the goal is complete control of seizure activity (without side effects); however, this is rarely achieved.
B. A more realistic goal is to decrease the severity and frequency of seizures, and to prevent cluster seizures and status epilepticus while maintaining a good quality of life.
C. Successful long-term treatment requires dedication and understanding of realistic goals by the owners.
   1. Treatment is lifelong.
   2. Anticonvulsants must be given on a regular, daily basis.
   3. Seizure emergencies may occur despite appropriate treatment.
   4. Good knowledge of the potential side effects of anticonvulsants is imperative.
D. Reasons to initiate long-term anticonvulsive therapy include the following:
   1. After status epilepticus or cluster seizures
   2. After the occurrence of two or more isolated seizure events within a 6- to 8-week period
   3. After prolonged postictal periods
   4. In cases where an identifiable structural lesion is causing seizures
   5. Delayed onset of seizure activity after head trauma

III. Long-term anticonvulsants are initiated after emergency control of seizures (Table 22-3).
A. Phenobarbital is the anticonvulsant of choice and can be used in both dogs and cats.
   1. After emergency treatment, start phenobarbital at 2 to 5 mg/kg PO, IM, IV BID.
   2. If seizures persist despite initial emergency treatment, a loading dosage of phenobarbital can be administered (See Box 23-1).
   3. Alternatively, a loading dose can be calculated as follows:

$$\textbf{Loading dose (mg)} = \textbf{desired serum level } (\mu\text{g/mL}) \times \textbf{body weight (kg)} \times 0.8\ \text{L/kg}$$
$$(\textbf{volume of distribution [Vd]})$$

   4. Animals are often heavily sedated for ≥24 hours when using the loading dose.
B. Potassium bromide (KBr) is a good second choice.
   1. It can be used in animals already receiving phenobarbital.
   2. In an emergency, KBr is administered as a loading dose because of its long half-life.
   3. Loading dosage is 400 to 600 mg/kg PO divided into six equal doses given over 1 to 5 days, depending on the severity of the seizures.
   4. Alternatively, a target steady state can be achieved based on the following formula:

$$\textbf{Target steady state concentration (Css)} \times 0.45\ \text{L/kg}$$
$$(\textbf{[Vd]}) = \textbf{total dose administered}$$

   5. Target serum concentration for KBr as monotherapy is 1 to 3 mg/mL, and as adjunctive therapy with phenobarbital is 1 to 2 mg/mL.

TABLE 22-3

Anticonvulsant Drugs Available for Use in Dogs and Cats

DRUG	USE AND MECHANISM OF ACTION	PHARMACOLOGY	DOSAGES	SIDE EFFECTS AND CAUTIONS
Diazepam	Prolongs opening of GABA receptors; used for short-term control of seizures; drug of choice for emergency treatment of status epilepticus/cluster seizures; can be used for long-term management in cats	Metabolized in liver, excreted by kidneys (90%) and in feces (10%) Bioavailability: 80% $t_{1/2}$ (dogs): 3 hours $t_{1/2}$ (cats): 5 hours $t_{1/2}$ of active metabolite nordiazepam in cats = 21-hour maximum CNS concentration reached 1 minute after IV administration	*Dogs, cats:* 0.5-2 mg/kg IV, rectally CRI: 0.5-2 mg/kg/hr IV in 0.9% NaCl *Cats:* 0.5-2 mg/kg PO BID for long-term use	Sedation CRI can cause apnea Dogs develop tolerance Acute fulminant hepatic necrosis in cats (idiosyncratic) Used cautiously in animals with liver dysfunction
Midazolam	Prolongs opening of GABA receptors; used for short-term control of seizures; drug of choice for emergency treatment of seizures	Metabolized in liver, excreted by kidneys (>90%) and in feces (<10%) Bioavailability: 90% $t_{1/2}$ (dogs): 77 minutes	*Dogs:* 0.07-0.22 mg/kg IV, IM, intranasally, rectally CRI: 0.5-2 mg/kg/hr IV	Sedation CRI can cause apnea Used cautiously in animals with liver dysfunction No data for cats
Propofol	Effects GABA receptor ionophor complex; used for short-term control of seizures; drug of choice for emergency treatment of seizures not controlled with benzodiazepines; used for hepatopathy-induced seizures	Metabolized via extrahepatic routes; rapidly distributed to whole body; effects seen within 1 minute; anesthesia lasts 5 minutes after single bolus	*Dogs, cats:* 4-8 mg/kg IV to effect CRI: 0.1-0.6 mg/kg/min IV	Induces anesthesia (intubation necessary) Apnea and hypoxemia Myocardial depression
Phenobarbital	Increases neuronal response to GABA; prevents glutamate-induced postsypnatic decrease in neuronal calcium influx; used for generalize seizures	Metabolized in liver Bioavailability: 90% $t_{1/2}$ (dogs): 24-40 hours Tss: 10-14 days	*Dogs, cats:* 2-5 mg/kg PO BID	Transient: ataxia, lethargy, behavioral changes Persistent: PU/PD polyphagia, obesity, lethargy, splenomegaly, hepatomegaly, increased ALT and ALP, decreased serum thyroxine Severe side effects: hepatotoxicity, myelofibrosis, necrotizing superficial dermatitis
Potassium bromide	Hyperpolarization of neuronal membranes through chloride channels; used for generalized seizures	Excreted unmetabolized by kidneys Bioavailability: 60% $t_{1/2}$ (dogs): 25 days $t_{1/2}$ (cats): 10 days Tss (dogs): 90-120 days Tss (cats): 50 days	*Dogs, cats:* 30-60 mg/kg PO SID	Transient: ataxia, sedation, hyperactivity, vomiting Persistent: PU/PD Rare: aggression, dermatitis, pancreatitis Increased risk of asthma in cats; impaired renal function elevates blood levels; high salt diet increases bromide secretion

GABA, Gamma-aminobutyric acid; $t_{1/2}$, half-life time; *CNS,* central nervous system; *CRI,* constant rate infustion; *Tss,* time-to-steady rate; *PU/PD,* polyuria/polydipsia; *ALT,* alanine aminotransferase; *ALP,* alkaline phosphatase.

Continued

TABLE 22-3

Anticonvulsant Drugs Available for Use in Dogs and Cats—*cont'd*

Felbamate	Inhibition of NMDA receptors; potentiation of GABA receptors; used for partial seizures; added to phenobarbital and potassium bromide	Metabolized in liver (30%), excreted by kidneys (70%) Bioavailability: 85% $t_{1/2}$: 5-6 hours Tss: 24-30 hours	*Dogs:* 15-70 mg/kg PO BID-TID, increased in 15-mg/kg increments up to 70 mg/kg/day PO	Rare: nervousness, hyperexcitability, liver toxicity, bone marrow suppression No data for cats
Gabapentin	Mechanism of action not completely understood; may enhance effects of phenobarbital, diazepam, felbamate; added to phenobarbital and potassium bromide; also used for neurogenic pain management	Minimally metabolized in liver, excreted by kidneys Bioavailability: 80% $t_{1/2}$: 3-4 hours	*Dogs:* 25-60 mg/kg PO BID-TID	Rare: sedation Questionable efficacy in dogs, owing to short $t_{1/2}$ Can be used in cats, but no data available
Levetiracetam	Mechanism of action unknown; added to phenobarbital and potassium bromide; potentially a monodrug therapy; used for generalized seizures and hepatopathy-related seizures	Excreted unchanged or hydrolyzed by kidneys Bioavailability: ≈100% $t_{1/2}$: 4 hours Anticonvulsant effects last longer despite short $t_{1/2}$	*Dogs:* 25-60 mg/kg PO BID-TID	Rare: salivation, restlessness, vomiting, ataxia
Zonisamide	Blocks voltage-dependent sodium channels and t-type calcium channels; enhances dopaminergic and serotonergic neurotransmission; inhibits glutamate-induced excitation; added to phenobarbital and potassium bromide; used for generalized seizures	Metabolized in liver Bioavailability: 80% $t_{1/2}$: 15 hours Tss: 3 days	*Dogs:* 10 mg/kg PO BID	Rare: drowsiness, ataxia, gastrointestinal upset

NMDA, N-methyl-D-aspartic acid.

6. In animals already receiving KBr, the formula for a new oral dose for recurrent seizures is (Podell, 2004):

(Target Css) − actual Css × Vd L/kg = (target desired Css − actual Css) × 0.45 L/kg = mg/kg divided into 4 equal doses QID

7. KBr can be given PO or per rectum, but not IV.
8. Rectal administration can lead to severe diarrhea.
9. Maintenance dose is 30 to 40 mg/kg PO SID.
10. KBr is slowly increased to effect, to a maximum dose of 60 mg/kg/day PO.
11. KBr can be used safely in dogs.
12. KBr should be used with caution in cats, because it can result in tachypnea, dyspnea, and coughing (Boothe et al., 2002).
    a. Dosage is the same as in the dog.
    b. The half-life is 10 days, with steady-state serum concentrations being reached in 50 days (Boothe et al., 2002).
    c. KBr is avoided in cats because it may increase the risk of asthma.
    d. Discontinued if respiratory signs or radiographic changes develop.

C. Sodium bromide (NaBr; 3%) can be given IV.
1. It is dissolved in sterile water (0.375 mEq Br/mL + 1.3 mEq Na/mL)
2. An IV loading dose is calculated using the following formula:

Steady-state concentration (Css) × Vd = total dose administered by constant rate infusion (CRI) in a central vein

D. In cats, the pharmacokinetics of diazepam supports its use as a long-term anticonvulsant.
   1. Diazepam is given at 0.25 to 1 mg/kg PO BID.
   2. Side effects include sedation and polyphagia.
   3. In cats, oral administration can cause fulminant hepatic failure (idiosyncratic reaction), so it is only used as a last choice.
   4. Diazepam is not used as a long-term anticonvulsant in dogs.
      a. Dogs develop tolerance to long-term therapy.
      b. In dogs, the half-life is very short (3 hours).

E. Felbamate can be used in dogs if seizure control is insufficient with phenobarbital and KBr.
   1. Felbamate is given at 15 to 70 mg/kg PO BID to TID.
   2. Rare side effects include nervousness, hyperexcitability, liver toxicity, and bone marrow suppression.
   3. Felbamate may be useful for partial seizures (Ruehlmann et al., 2001).
   4. No data are available on its use in cats.

F. Gabapentin can be used in dogs if seizure control is insufficient with phenobarbital and KBr.
   1. Gabapentin is given at 25 to 60 mg/kg PO TID to QID.
   2. Short-term side effects include sedation; long-term side effects are unknown.
   3. No data are available on its use in cats, but administration of up to 30 mg/kg PO TID is anecdotally well tolerated in cats.

G. Levetiracetam can be used as a second-choice anticonvulsant in dogs if seizure control is insufficient with phenobarbital and KBr.
   1. Levetiracetam is given at 5 to 30 mg/kg PO BID to TID.
   2. It can be used in animals with hepatic dysfunction.
   3. Rare side effects include salivation, restlessness, vomiting, and ataxia.

H. Zonisamide can be used in dogs if seizure control is insufficient with phenobarbital and KBr.
   1. Zonisamide is given at 10 mg/kg PO BID (Dewey et al., 2004).
   2. Animals concurrently receiving phenobarbital may require higher dosages of zonisamide.
   3. Rare side effects include drowsiness, ataxia, and gastrointestinal irritation.
   4. Minimal side effects are seen at dosages up to 75 mg/kg/day.

IV. Recommendations for long-term management of seizures is as follows:
   A. Phenobarbital is the first-choice anticonvulsant because of its faster onset of action, shorter half-life, and more predictable anticonvulsant effects.
      1. Animals are initially started on phenobarbital at 2 mg/kg PO BID.
      2. If seizure control is poor after reaching the steady state, the dosage of phenobarbital is gradually increased to approximately 5 mg/kg PO BID.
   B. If seizure control remains poor or severe side effects occur, KBr therapy is initiated at 30 mg/kg PO SID.
   C. If seizure control remains poor despite the addition of KBr, the dosage of KBr is gradually increased to a maximum of 60 mg/kg PO SID.
   D. If the animal does not tolerate phenobarbital well, monotherapy with KBr is initiated.
   E. In animals experiencing side effects or in those that are seizure-free for >1 year, the dosage of anticonvulsants can be gradually decreased.
   F. Second-choice anticonvulsants are typically used if seizures cannot be controlled with a combination of phenobarbital and KBr, or if side effects are intolerable.

Monitoring of Animal

I. Animals undergoing emergency treatment for seizures require intensive supportive care and monitoring.
   A. IV fluid therapy is administered for maintenance needs and any ongoing losses.
   B. Fluid input and output are closely monitored to maintain hydration.
   C. Supplementation with thiamine 25 to 50 mg IM, IV may be helpful, as thiamine is essential for glucose metabolism in the brain.
   D. Periodic monitoring of packed cell volume, total solids, blood glucose, serum calcium, and blood urea nitrogen is done.
   E. Monitor body temperature to avoid hyperthermia or hypothermia.
   F. Recumbent animals are turned every 4 to 6 hours.
   G. Animals receiving anticonvulsants by CRI are monitored as follows:
      1. Heart rate, respiratory rate, and temperature are measured every hour.
      2. Blood pressure and oxygenation via pulse oximetry or arterial blood gas analysis are monitored every 4 hours
      3. Monitor for slowing of respiratory rate, hypoventilation, and apnea, which may necessitate mechanical ventilation.
      4. Tracheal intubation may be necessary.
      5. Supplemental oxygen may be needed for hypoxemia.
      6. Change endotracheal tubes every 6 hours.

II. Owners may be taught to provide emergency treatment at home for seizures lasting >5 minutes, status epilepticus, cluster seizures, or postictal phases >2 hours.
   A. Diazepam can be administered rectally in dogs at 1 to 2 mg/kg (Podell, 1995).
      1. Use parenteral diazepam solution or commercially available rectal compounds.
      2. Diazepam is absorbed quickly across the rectal mucosa, reaching peak plasma concentration within 15 minutes.
      3. The first-pass effect is avoided with rectal application.
      4. Effects of rectal diazepam last for about 1 hour.
   B. Diazepam can be administered rectally in cats at 0.5 to 1 mg/kg.
      1. Pharmacokinetics are unknown, but may be similar to the dog.

2. Effects are seen within 10 to 15 minutes.
3. Diazepam may be less effective if the cat is also receiving long-term treatment with diazepam.

III. Monitoring of long-term anticonvulsant therapy is done through evaluations of clinical signs, seizure frequency, and measurement of serum drug levels.
   A. If an anticonvulsant is used within the recommended dosage range and the seizures are under control, serum levels may not be needed.
   B. Avoid under- or overdosing of drugs.
   C. Note that an animal can develop severe side effects despite having normal to low serum levels.
   D. Serum monitoring is recommended if seizure control is poor, the animal shows signs of toxicity, or severe side effects occur after initial adaptation to the drug.
   E. Monitoring serum levels allows for individualized treatment and minimizes the potential for side effects.
   F. Phenobarbital or KBr dosages can be incrementally increased when seizure control is poor or decreased to reduce side effects or toxicity.

IV. Dose adjustment of phenobarbital is initially based on the degree of seizure control.
   A. If the high end of the dosage range is needed to control seizures, serum phenobarbital levels are measured to prevent toxicity.
      1. Levels can be checked at any time during the day after steady state has been reached.
      2. Avoid serum separator tubes, because silicon binds phenobarbital and results in artificially low serum levels.
      3. Therapeutic serum phenobarbital levels (dependent on laboratory) are as follows:
         a. Dogs: 20 to 40 μg/mL
         b. Cats: 10 to 30 μg/mL
   B. Side effects of phenobarbital are listed in Table 22-3.
   C. A CBC, biochemistry profile, and urinalysis are performed every 6 months.
   D. When using serum phenobarbital levels to change dosages, a formula can be used:

(Desired concentration ÷ actual concentration) × total mg/day = new total mg dose phenobarbital/day

V. Serum KBr levels are evaluated if seizure control is poor or if toxicity is suspected.
   A. Serum levels can be checked at any time during the day after steady state has been reached.
   B. If used as monotherapy, therapeutic levels in dogs are 2 to 3 mg/mL.
   C. If used in combination with phenobarbital, therapeutic levels in dogs are 1 to 2 mg/mL (March et al., 2002).
   D. KBr can be adjusted using the following formula (Podell, 2004):

(Target Css – actual Css) × (0.02 × clearance/bioavailability) = new maintenance dose (added mg/kg/day)

   E. Side effects are listed in Table 22-3.
   F. Monitor CBC, serum biochemical profile, and urinalysis every 6 months.

VI. Optimizing seizure control involves several steps.
   A. It is imperative that an underlying cause be established, if possible.
      1. The earlier proper treatment is initiated, the better the chance for optimal control.
      2. In idiopathic epilepsy, anticonvulsive treatment is lifelong.
   B. Underdosing anticonvulsant drugs can lead to poor seizure control.
   C. Client education regarding realistic goals of seizure control and anticonvulsant side effects is required.
   D. If the animal is seizure free for >1 year, a slow, incremental reduction of the drugs may be tried over 6 months.

SLEEP DISORDERS

Definition

I. Narcolepsy is an abnormality in the sleep–wake cycle that manifests as excessive sleepiness and uncontrollable episodes of sleep.
II. Cataplexy is a short episode of complete loss of muscle tone, usually provoked by excitement and emotion.
   A. Loss of muscle tone is caused by central-mediated inhibition of α-motor neurons.
   B. Episodes are reversible.
   C. Consciousness is not altered in pure cataplexy.
   D. Cataplexy occurs often together with narcolepsy.

Causes

I. In dogs, narcolepsy can be caused by an inherited, autosomal, recessive defect of the hypocretin-receptor-2 gene (Lin et al., 1999).
II. Affected breeds include the Doberman pinscher, Labrador retriever, dachshund, and poodle.
III. Narcolepsy can also result from a decreased level of hypocretin-1 protein.
   A. Although the cause remains unknown, an autoimmune process is suspected.
   B. Affected breeds include the Airedale terrier, Afghan hound, Irish setter, malamute, St. Bernard, rottweiler, English springer spaniel, Weimaraner, Welsh corgi, and giant schnauzer.
IV. Inflammatory, neoplastic, or vascular lesions involving the hypothalamus may also be causes.
V. Narcolepsy is rare in cats.

Pathophysiology

I. Hypocretin-1 protein and the hypocretin-receptor-2 play important roles in the sleep–wake cycle and in control of α-motor neurons in the spinal cord (Yamuy et al., 2004).
II. Neurons containing hypocretin-1 are located predominantly in the posterior hypothalamus.
III. Fibers from these neurons are distributed to the locus coeruleus, nucleus raphe, and cerebral cortex.
   A. Binding of hypocretin-1 to the hypocretin-receptor-2 has a rousing effect and increases motor activity.

B. Deficiency in the numbers of functional hypocretin-receptor-2 leads to decreased effects of hypocretin-1 protein.
C. Similarly, a deficiency in the amount of hypocretin-1 protein also leads to diminished effects.
D. The result is an abnormal sleep–wake cycle regulation, leading to excessive sleepiness and episodes of sleep.
E. A loss of hypothalamic hypocretinergic control of α-motor neuron leads to loss of muscle tone and cataplexy.

Clinical Signs

I. Affected animals are typically <6 months; however, onset can occur in young adult animals.
II. Episodes are often provoked by excitement (e.g., feeding, drinking, playing).
III. Episodes consist of immediate onset of active sleep with rapid eye movement followed by a sudden return to a normal awake state (narcolepsy).
IV. Generalized muscle atonia (cataplexy) may also occur.
V. Affected animals often have prolonged sleep periods, as well as marked drowsiness during the day.
VI. Onset and termination of the episodes are abrupt.
VII. Duration of episodes ranges from seconds to 30 minutes.
VIII. External stimuli can often interrupt the episode.

Diagnosis

I. Presumptive diagnosis is made by observing an episode.
II. Breed, history, and clinical signs are supportive.
III. Episodes can be induced.
  A. Food-elicited cataplexy test (FECT)
    1. Line up about 10 small treats, 30 cm apart.
    2. Observe the animal for loss of muscle tone or sleep episodes.
    3. Record the time it takes for the animal to eat all the treats.
    4. A normal dog can eat the food within 1 minute without an episode occurring.
    5. A positive test result involves the following observations:
      a. The animal has two or more episodes and takes >2 minutes to eat all the treats.
      b. The animal falls completely asleep.
      c. The dog drops to the floor, but the head stays in a normal position.
  B. Pharmacological tests
    1. Yohimbine response test
      a. Yohimbine is administered at 50 μg/kg IV.
      b. A positive response is a 75% reduction in number or duration of episodes.
      c. The effect of yohimbine lasts 30 to 240 minutes.
    2. Anticholinergic drugs
      a. They can increase the duration and/or frequency of the episodes.
      b. The FECT is performed after administration of atropine 0.1 mg/kg IV or physostigmine 0.025 to 0.1 mg/kg IV.
      c. Affected animals have increased frequency and/or duration of episodes.
    3. Imipramine challenge
      a. Imipramine is administered at 0.5 mg/kg IV.
      b. A positive response consists of a decrease in episodes, but is not specific for narcolepsy and/or cataplexy.
IV. CSF analysis may be helpful (Mignot et al., 2002).
  A. Hypocretin-1 concentration can be measured in CSF by the Center for Narcolepsy, Department of Psychiatry, Stanford University School of Medicine.
    1. A level <100 pg/mL is consistent with narcolepsy from hypocretin-1 deficiency.
    2. A level of 101 to 200 pg/mL is suspicious for narcolepsy from hypocretin-1 insufficiency.
    3. Levels of 200 to 350 pg/mL are normal (Ripley et al., 2001).
  B. CSF analysis can help establish an underlying cause or rule out other disorders.
V. Genetic analysis also can be performed at Stanford University School of Medicine.

Differential Diagnosis

I. Myasthenia gravis
II. Syncope
III. Seizures
IV. Metabolic disturbances: hypoglycemia, hypocalcemia, hypokalemia, hyperkalemia, hypoadrenocorticism

Treatment

I. Cataplexy is usually treated with tricyclic antidepressants or selective serotonin reuptake inhibitors (Thomas, 2003).
  A. Imipramine 0.5 to 1 mg/kg PO BID to TID
  B. Desipramine 3 mg/kg PO BID
  C. Amitriptyline 1 to 2 mg/kg PO BID
  D. Protriptyline 5 to 10 mg/kg PO SID
II. Excessive sleepiness and sleep attacks are treated with sympathomimetics or monoamine oxidase-B inhibitors.
  A. Methylphenidate 0.25 mg/kg PO BID to TID
  B. Dextroamphetamine 5 to 10 mg PO BID to TID
  C. Selegiline 1 mg/kg PO SID (Thomas, 2003)
III. If an underlying etiology is identified, treatment is directed at the cause.
IV. Side effects of medical therapy include the following:
  A. Amphetamines can cause behavioral changes.
  B. If a combination of amphetamine and imipramine is used, severe catecholamine accumulation may occur from increased release and inhibition of reuptake.

Monitoring of Animal

I. Prognosis for a good quality of life is moderate to good.
II. Some animals improve with age.
III. Lifelong therapy is often required.
IV. Lifestyle changes that decrease triggering events help to improve the quality of life.

CHAPTER 23

Disorders of the Brain

Scott J. Schatzberg

CONGENITAL/DEVELOPMENTAL DISORDERS

Congenital Vestibular Disease

Definition and Causes

I. Dysfunction of the peripheral vestibular system is seen in young dogs and cats, possibly from a congenital defect.
II. The disorder is presumed to be inherited.
III. It has been reported in the following breeds:
  A. Dogs: Doberman pinscher, American cocker spaniel, German shepherd dog, Akita, beagle
  B. Cats: Siamese, Burmese
IV. Aggregates of lymphocytes occur within the inner ear of affected Doberman puppies, but the significance of these lesions is unclear.

Clinical Signs and Diagnosis

I. Onset of signs is usually 3 to 12 weeks of age.
II. Head tilt, vestibular ataxia, circling, and deafness may be seen.
III. Nystagmus is not a feature of this disorder.
IV. Diagnosis is one of exclusion: rule out other causes of vestibular signs.

Differential Diagnosis

I. Otitis media/interna
II. Ototoxicity: aminoglycoside antibiotics, topical antiseptics (iodophors, chlorhexidine)

Treatment and Monitoring

I. No treatment is available.
II. Compensation for the vestibular signs may occur over several weeks.
III. Deafness (if present) is typically permanent.

Hydrocephalus

Definition

I. It is an increase in the volume of cerebrospinal fluid (CSF) within the ventricular system or subarachnoid space of the brain (de Lahunta, 1983).
II. In compensatory hydrocephalus, CSF accumulates in spaces within the cranial cavity not occupied by brain parenchyma.
III. In obstructive hydrocephalus, obstruction to flow or absorption of CSF causes ventricular dilation (especially of the lateral ventricles) with subsequent loss of brain parenchyma.

Causes

I. Compensatory hydrocephalus may result from the following:
  A. Developmental malformations: cerebral hypoplasia or aplasia
  B. Destruction of brain parenchyma from in utero viral infections: feline panleukopenia
  C. Cerebral necrosis secondary to cerebrovascular accidents: acquired hydrocephalus
II. Obstructive hydrocephalus may result from the following:
  A. Fusion of rostral colliculi (midbrain) with CSF outflow obstruction at the mesencephalic aqueduct
  B. Dysfunction of the arachnoid villi with poor reabsorption of CSF through the dorsal sagittal venous sinus
III. Acquired hydrocephalus may result from the following:
  A. Mass lesions blocking CSF flow: neoplasia, abscess, granuloma
  B. Neoplasia preventing CSF absorption by the arachnoid villi
  C. Infections (viral, bacterial) or inflammation of the ependyma of the mesencephalic aqueduct or leptomeninges blocking flow of CSF
  D. Intraventricular hemorrhage blocking CSF outflow: leptomeningeal, intraventricular

Clinical Signs

I. No or variable signs may be seen, even in the presence of considerable ventricular dilatation.
II. Prosencephalic signs include disturbed consciousness (lethargy to severe depression), increased tendency to sleep, hypoactivity, propulsive circling, head pressing, seizures, behavioral changes, dementia, and visual deficits (with normal pupillary responses).
III. Motor deficits include spastic paresis, particularly if the brainstem is involved.
IV. Occasionally cerebellar ataxia may occur if there is involvement of the cerebellum.
V. Sensory deficits include proprioceptive ataxia.

Diagnosis

I. Presumptive diagnosis is based on physical examination findings.
   A. Animals with congenital hydrocephalus often have palpable open fontanelles and develop a dome-shaped calvaria.
   B. Ventral-lateral strabismus may be noted.
II. Imaging findings
   A. Skull radiographs may reveal a homogenous "ground glass" appearance within the calvaria and open cranial suture lines.
   B. Ventriculomegaly may be demonstrated by computed tomography (CT), magnetic resonance imaging (MRI), and occasionally ultrasonography.

Differential Diagnosis

I. Metabolic or toxic encephalopathies
II. Meningoencephalitis
III. Other congenital brain anomalies
IV. Degenerative encephalopathies

Treatment and Monitoring

I. Corticosteroids may decrease CSF production.
   A. Prednisone 0.25 to 0.5 mg/kg PO BID, then tapered to QOD
   B. Dexamethasone 0.05 mg/kg PO SID, then tapered to QOD
   C. May be discontinued in some dogs
II. Diuretics may decrease the volume of CSF.
   A. Furosemide 1 to 2 mg/kg PO BID
   B. Acetazolamide 0.1 mg/kg PO TID
III. Anticonvulsants may help control seizures.
   A. Phenobarbital 1 to 2 mg/kg PO BID
   B. Potassium bromide (KBr) 20 to 30 mg/kg PO SID
IV. Ventriculoperitoneal shunting of CSF to the abdominal cavity may be effective in some cases that are refractory to medical management, but complications include infections and shunt failure.
V. Prognosis is guarded to poor in severely affected animals.
VI. Animals with minimal clinical signs can often be managed long term.

Hydranencephaly and Porencephaly

Definition

I. Hydranencephaly is the congenital absence of a large portion of cerebrum in which cerebral cortex is absent and a fluid-filled, membranous sac takes its place (Summers et al., 1995).
II. Porencephaly is a disorder in which single or multiple cavities within the cerebrum usually communicate with the lateral ventricles or the subarachnoid space (Summers et al., 1995).

Causes

I. Hydranencephaly in cats is associated with in utero vaccine-induced feline panleukopenia infection.
II. Porencephaly may occur when in utero infection with feline panleukopenia virus occurs later in the period of fetal central nervous system (CNS) vulnerability, or from less virulent viruses.

Pathophysiology

I. The pathophysiology is not well understood.
II. Parvoviral destruction of cerebral tissues is one potential mechanism.
III. Hydranencephaly may arise from a fetal cerebrovascular accident that results in severe necrosis and resorption of cerebral tissue (Barone et al., 2000).

Clinical Signs

I. Signs typically occur within several weeks of birth and are proportional to the extent of cerebral loss.
II. Prosencephalic signs include blindness and behavioral abnormalities, such as compulsive behavior, indifference to surroundings, episodes of rage, and central blindness.

Diagnosis

I. Presumptive diagnosis is based on clinical signs.
II. Antemortem diagnosis can be made with MRI or CT.

Differential Diagnosis

I. Metabolic or toxic encephalopathies
II. Meningoencephalitis
III. Other congenital brain anomalies
IV. Degenerative encephalopathies

Treatment and Monitoring

I. Treatment is similar to that for hydrocephalus.
II. The prognosis is guarded to poor.

Lissencephaly and Pachygyria

Definition and Cause

I. Lissencephaly is a congenital abnormality in which the cerebral hemispheres have a smooth surface and absence of normal development of gyri and sulci (Summers et al., 1995).
II. Pachygyria is a condition in which the neocortex is much thicker than normal.
III. In most cases the cause is unknown, but lissencephaly may be genetic in the Lhasa apso.

Pathophysiology

I. The normal laminar pattern of the neuronal cell body organization is disrupted.
II. Bundles of white matter are randomly scattered throughout a thick cortex.
III. There is no development of corona radiata.

Clinical Signs

I. Lissencephaly is most commonly observed in the Lhasa apso.
II. Many dogs are difficult to house break but have relatively normal behavior.
III. Prosencephalic signs include seizures starting around 1 year of age, behavioral changes, and visual deficits.

Diagnosis

I. MRI reveals an absence of cerebral sulci and gyri, pachygyria, and decreased organization of white mater.
II. Definitive diagnosis is made by postmortem examination.

Differential Diagnosis

I. Metabolic or toxic encephalopathies
II. Meningoencephalitis
III. Other congenital brain anomalies, such as hydrocephalus
IV. Degenerative encephalopathies

Treatment and Monitoring

I. No definitive treatment exists.
II. Treat seizures symptomatically with anticonvulsants (see Chapter 22).
III. Prognosis is guarded.

CONGENITAL CEREBELLAR DISORDERS

Definition and Causes

I. These include developmental defects or malformations of the cerebellum.
II. The cause of most malformations is unknown; however, some may be genetic in origin.
III. Hypoplasia can result from in utero infections with feline and canine parvoviruses (Schatzberg et al., 2003).

Pathophysiology

I. Malformations
   A. Various forms of cerebellar agenesis and hypoplasia have been reported in dogs (Summers et al., 1995).
   B. A unique cerebellar malformation (Dandy-Walker syndrome) is characterized by a hypoplastic or aplastic cerebellum, cystic lesions of the caudal fossa or fourth ventricle, and hydrocephalus (Summers et al., 1995).
II. Hypoplasia
   A. The external germinal layer of the cerebellum is destroyed in utero by a parvovirus, with hypoplasia of the granule layer and disorganization of the Purkinje cells.
   B. Viruses or their resulting inflammation may destroy previously differentiated Purkinje neurons and cerebellar parenchyma, causing atrophy of the cerebellum (de Lahunta 1983).

Clinical Signs

I. Signs are present from the time the animal is able to walk and are usually nonprogressive.
II. Signs include a wide stance, spastic-hypermetric gait (cerebellar ataxia), loss of balance, and intention tremors.

Diagnosis

I. Presumptive diagnosis is based on clinical signs present at or soon after birth.
II. Multiple animals in the litter may be affected.
III. MRI may reveal a small cerebellum and increased amounts of CSF between the folia.
IV. Definitive diagnosis is made by postmortem examination.

Differential Diagnosis

I. Degenerative encephalopathies
II. Congenital cerebellar and abiotrophies
III. Meningoencephalitis

Treatment and Monitoring

I. No definitive treatment exists.
II. Clinical signs are typically nonprogressive.
III. Although signs persist, some animals make good pets.

Caudal Occipital Malformation and Syringohydromyelia

Definition

I. Occipital bone malformation and/or hypoplasia causes overcrowding of the caudal fossa and foramen magnum, obstruction of CSF, and syringohydromyelia.
II. Syringohydromyelia is a fluid-filled cavity within the spinal cord (syrinx) and central canal (hydromyelia).

Causes and Pathophysiology

I. Malformation of the occipital bone causes elongation and caudal displacement of the cerebellar vermis through the foramen magnum.
II. The spinal cord is pushed caudally by the medulla and may have a kinked appearance.
III. Occasionally, mild to moderate obstructive hydrocephalus is present.
IV. Syringohydromyelia may develop secondarily, but the pathogenesis is uncertain.

Clinical Signs

I. The Cavalier King Charles spaniel is overrepresented, but any breed may be affected.
II. Affected animals range in age from 6 months to 10 years.
III. Signs may manifest acutely or have an insidious course over months to years.
IV. An unusual manifestation is the observation of paroxysmal involuntary flank or neck scratching in Cavalier King Charles spaniels.
V. Spinal cord signs include cervical pain, cervical dystonia (torticollis), hyperesthesia, proprioceptive ataxia, abnormal postural reactions, varying degrees of paresis and hypermetria, and exercise intolerance.
VI. Intracranial signs include seizures and deficits of cranial nerves VII and VIII.
VII. Denervation of epaxial muscles and lesions in the dorsal tracks of the spinal cord can lead to muscle atrophy and scoliosis.

Diagnosis

I. MRI reveals varying degrees of ventriculomegaly, syringohydromyelia, compression of the cerebellum by the occipital bone, caudal displacement and herniation of the cerebellar vermis, and obstruction of the subarachnoid space at the foramen magnum.
II. CSF analysis occasionally reveals a mild elevation in nucleated cells and total protein.

Differential Diagnosis

I. Intervertebral disc disease
II. Meningoencephalitis
III. Neoplasia
IV. Atlantoaxial subluxation

Treatment and Monitoring

I. Prednisone 0.5 mg/kg PO QOD may control signs (Rusbridge et al., 2000).
II. Surgical management (subtotal occipital craniectomy, dorsal laminectomy of first cervical vertebra and durotomy to relieve obstruction) may be indicated for dogs with progressive signs (Dewey et al., 2005).
III. Prognosis is fair to good depending on the severity of clinical signs.

DEGENERATIVE DISORDERS

Neuronal Abiotrophies and Dystrophies

Definition and Causes

I. Many of these disorders (Table 23-1) are familial, hereditary, and cause degeneration of the CNS within the first few months of life (Summers et al., 1995).
II. Abiotrophies are characterized by early or premature neuronal degeneration and cell death.
    A. They are typically associated with an inherent lack of vital trophic or nutritive factors.
    B. They are categorized by the location of the affected neurons.
        1. Cerebellar abiotrophies are the most common and affect cerebellar Purkinje cells.
        2. Multisystem neuronal abiotrophies affect neurons throughout the CNS.
        3. Motor neuron abiotrophies affect motor neurons and cause lower motor neuron signs, with marked denervation atrophy and debilitating muscle contractures (arthrogryposis).
III. Neuraxonal dystrophies are a group of inherited (often autosomal recessive) disorders characterized by axonal swellings (spheroids) in preterminal portions of axons and synaptic terminals.
IV. Leukodystrophies (demyelinating disorders) are primary disorders of myelin synthesis.
    A. Leukodystrophies can involve CNS and peripheral nervous system (PNS) myelin.
    B. White matter involvement is usually regional, bilateral, and symmetrical.
V. Hypomyelinogenesis is absent, delayed, or abnormal production of myelin.
    A. Histologically, oligodendrocytes are diminished in number or may be dysfunctional.
    B. An X-linked inheritance pattern is known or suspected.
    C. Other possible causes include in utero infections or intoxications.
VI. Spongy degenerations are characterized by diffuse CNS vacuolation in the white and grey matter.
VII. Axonopathies are characterized by diffuse CNS degeneration that result predominantly in encephalomyelopathies and neuropathies.
    A. A subset of these disorders (spinocerebellar degenerations) induces bilaterally symmetrical degeneration of ascending and descending tracts of the spinal cord.
    B. Despite lesions predominantly affecting the spinal cord, progressive cerebellar signs are seen clinically.

Clinical Signs

I. With cerebellar abiotrophies, signs are noted in the first few weeks to months of life.
    A. Affected animals slowly develop progressive signs over months to years.
    B. Signs of cerebellar disease include a wide stance, spastic-hypermetric gait, loss of balance, intention tremors, and absent menace response.
II. With neuraxonal dystrophies signs of spinal cord and cerebellar dysfunction occur.
    A. Lesions occur diffusely throughout the CNS, but spinal cord lesions predominate.
    B. Affected breeds include the rottweiler, Chihuahua, German shepherd dog, and domestic short-haired cat.
III. Hypomyelinating disorders are characterized by generalized tremors, especially in the pelvic limbs.
    A. They often abate with rest.
    B. Signs may resolve spontaneously or persist indefinitely.

Diagnosis

I. Diagnosis is suspected based on the signalment and clinical signs (see Table 23-1).
II. MRI may be useful to demonstrate the distribution of lesions.
III. Definitive diagnosis often requires postmortem examination.

Differential Diagnosis

I. Disorders of intermediary metabolism
II. Metabolic disorders
III. Meningoencephalitis
IV. Neoplasia

Treatment and Monitoring

I. No definitive treatment exists for these degenerative disorders.
II. Prognosis is variable and often poor for long-term survival.

DISORDERS OF INTERMEDIARY METABOLISM

Definition and Causes

I. These disorders are caused by inherited errors in intermediary metabolism that arise from abnormal or deficient enzyme systems (Summers et al.,1995).
II. Some disorders are storage diseases.

TABLE 23-1

Breed-Associated Degenerative Disorders of the Brain

BREEDS	DISEASE	ONSET AND CLINICAL SIGNS	DIAGNOSIS
Cats			
Birman cat	Distal central-peripheral axonopathy	8-10 months; hypermetria, progressive paraparesis, plantigrade pelvic limb posture	Nerve biopsy
	Spongiform encephalopathy	7 weeks; hypermetria, paraparesis, depression	Histopathology
Domestic short-haired cat	Neuraxonal dystrophy	5-6 weeks; head tremors, ataxia, hypermetria	Histopathology
Egyptian mau	Spongiform encephalopathy	7 weeks; hypermetria, paraparesis, depression	Histopathology
Dogs			
Airedale terrier	Cerebellar degeneration	Cerebellar signs*	Histopathology
	Cerebellar hypoplasia	Cerebellar signs	Histopathology, MRI
Akita	Cerebellar abiotrophy	Cerebellar signs	Histopathology, MRI
American cocker spaniel	Neuronal degeneration	10-14 months; behavior and personality changes, absent menace response, variable hypermetria and falling	Histopathology
	Cerebellar signs	1-2 months; cerebellar signs that may stabilize by 12 months	Histopathology
	Neuraxonal dystrophy	2-4 months; hypermetria, ataxia, intention tremor	Histopathology
Australian kelpie	Cerebellar abiotrophy	6-12 weeks; cerebellar signs	Histopathology, MRI
Beagle	Cerebellar abiotrophy	3 weeks; cerebellar signs	Histopathology, MRI
Bernese mountain dog	Hypomyelination	2-8 weeks; fine tremor of the head and limbs, weakness, stiffness; may improve with age	Histopathology, MRI
Border collie	Cerebellar abiotrophy	6-8 weeks; cerebellar signs	Histopathology, MRI
Boxer	Progressive axonopathy	2 months; progressive ataxia and weakness; diminished proprioception, muscle tone, patellar reflexes; intact nociception	EMG and nerve conduction studies, nerve biopsy, histopathology
Brittany spaniel	Cerebellar abiotrophy	7-13 years; progressive cerebellar signs	Histopathology, MRI
Bullmastiff	Cerebellar abiotrophy	4-9 weeks; progressive cerebellar signs	Histopathology, MRI
	Spongiosis of gray matter	6-9 weeks; ataxia, hypermetria, intention tremor, decreased menace response, visual deficits, poor proprioception	Histopathology
Bull terrier	Cerebellar abiotrophy	Cerebellar signs	Histopathology, MRI
Cairn terrier	Cerebellar abiotrophy	Cerebellar signs	Histopathology, MRI
	Multifocal neuronal degeneration	4-7 months; progressive tetraparesis, cataplexy, cerebellar dysfunction	Histopathology
Chow chow	Hypomyelination	2-4 weeks; intention tremors, dysmetria, bunny hopping, improves after 1 year	Histopathology, MRI
Dalmatian	Leukodystrophy	3-6 months; visual deficits, progressive ataxia	Histopathology
English springer spaniel	Hypomyelination	1-2 weeks; severe tremors	Histopathology, MRI
Finnish harrier	Cerebellar abiotrophy	Cerebellar signs	Histopathology, MRI
Gordon setter	Cerebellar abiotrophy	6-30 months; slowly progressive cerebellar and vestibular signs	Histopathology, MRI
Jack Russell terrier	Spinocerebellar degeneration	2-4 months; cerebellar ataxia, progressive dysmetria and spasticity	Histopathology
Kerry blue terrier	Cerebellar abiotrophy	8-16 weeks; pelvic limb stiffness and head tremors, then dysmetria	Histopathology, MRI

Adapted with permission from Platt RS, Olby N: BSAVA Manual of Canine and Feline Neurology. 3rd Ed. British Small Animal Veterinary Association, Quedgeley, England 2004.

MRI, Magnetic resonance imaging; *EMG*, electromyography.

*Cerebellar ataxia (dysmetria, hypermetria), intention tremors of the head, wide based stance, and occasionally lack of menace with normal vision.

Continued

TABLE 23-1

Breed-Associated Degenerative Disorders of the Brain—*cont'd*

BREEDS	DISEASE	ONSET AND CLINICAL SIGNS	DIAGNOSIS
Labrador retriever	Cerebellar abiotrophy	12 weeks; cerebellar signs	Histopathology, MRI
	Axonopathy	Birth; crouched, short-strided gait in thoracic limbs, hypermetria, unable to stand by 5 months	Histopathology
Old English sheepdog	Cerebellar abiotrophy	Progressive cerebellar signs	Histopathology, MRI
Papillon	Neuroaxonal dystrophy	14 weeks; rapidly progressive ataxia and hypermetria, decreased postural reactions	Histopathology
Poodle	Cerebellar abiotrophy	Cerebellar signs	Histopathology, MRI
Rottweiler	Spongiform degeneration with encephalomyelopathy and polyneuropathy	6-16 weeks; progressive ataxia and dysmetria, laryngeal paralysis, congenital cataracts, microphthalmia	Histopathology
	Leukoencephalopathy	1-4 years; ataxia, tetraparesis, hypermetria, increased muscle tone/spinal reflexes, often more severe in thoracic limbs	Histopathology
	Neuraxonal dystrophy	Within 12 months; slowly progressive ataxia, hypermetria, wide-based stance, eventually intention tremors and nystagmus	Histopathology
Rough-coated collie	Cerebellar abiotrophy	4-8 weeks; progressive cerebellar signs	Histopathology, MRI
Saluki	Spongiosis of gray matter	Behavior changes, seizures, aimless wondering electroencephalography	Histopathology
Samoyed	Hypomyelination	3 weeks; generalized tremors, nystagmus, absent menace response	Histopathology, possibly MRI
	Cerebellar abiotrophy	Cerebellar signs	Histopathology, MRI
Shetland sheepdog	Hypomyelination	2-4 weeks; severe generalized tremors, difficulty standing, seizures, progressive debilitation	Histopathology, MRI
Weimaraner	Hypomyelination	3 weeks; generalized tremors, dysmetria; several dogs normal by 12 months	Histopathology, MRI

Pathophysiology

I. Storage disorders are characterized by defective lysosomal enzymes that are catabolic or obligatory to cellular processes (Skelly and Franklin, 2002).
   A. Loss or dysfunction of a degradative enzyme results in the accumulation of specific substrates in the lysosomes that distend cells with stored products.
   B. Lesions may be multisystemic or limited to the CNS and/or PNS.
   C. Most storage diseases are autosomal recessive traits (Table 23-2).

II. Disorders of intermediary metabolism affect enzyme systems that are not catabolic and do not result in stored substrate.
   A. They typically result in a unique, degenerative encephalopathy.
   B. Most are breed specific, with an autosomal recessive mode of inheritance (see Table 23-2).

Clinical Signs

I. Signs often reflect diffuse CNS involvement; however, cerebellar signs often predominate in storage diseases.
II. See Table 23-2 for specific signs.

Diagnosis

I. Diagnosis is often suspected based on signalment and clinical signs.
II. DNA testing is available for some disorders (see Table 23-2).
III. Diagnosis can be made through metabolite analysis of tissues or body fluids (urine or blood).

Differential Diagnosis

I. Congenital cerebellar disorders or cerebellar abiotrophy (storage disorders)
II. Meningoencephalitis
III. Neoplasia
IV. Other degenerative encephalopathies

TABLE 23-2

Disorders of Intermediary Metabolism (Storage Diseases)

BREEDS	DISEASE	ONSET AND CLINICAL SIGNS	DIAGNOSIS
Cats			
Balinese cat	Niemann-Pick type A	Cerebellar/vestibular signs, depression, peripheral neuropathy	Enzyme assay in leukocytes, cultured fibroblasts
Domestic short-haired cat	Mannosidosis	Onset <6 months; connective tissue and skeletal malformation, possible peripheral neuropathy	DNA testing*
	GM_1 gangliosidosis	Cerebellar signs, dwarfism, facial dysmorphism	Oligosaccharide analysis in urine* Enzyme assay in skin fibroblasts, liver, leukocytes
	GM_2 gangliosidosis	Cerebellar/vestibular signs	Oligosaccharide analysis in urine* Enzyme assay in skin fibroblasts, liver, leukocytes
	Globoid cell leukodystrophy (Krabbe's disease)	Early cerebellar signs and ascending paralysis, cerebellar signs later or peripheral neuropathy	DNA testing† Peripheral nerve biopsy suggestive Enzyme assay in leukocytes, cultured fibroblasts
	Niemann-Pick type C	Ataxia, cerebellar/vestibular signs, peripheral neuropathy, possible hepatomegaly	Enzyme assay in leukocytes or cultured fibroblasts
	MPS VII	Progressive paraparesis	Urine metabolite screening*
	Mucolipidosis II (I-cell disease)	Dysmorphism, failure to thrive, delayed skeletal mineralization and abnormalities, retinal degeneration at 2.5 months of age	Inclusions in cultured fibroblasts, serum lysosomal enzyme assay
Korat cat	GM_2 gangliosidosis	Cerebellar/vestibular signs	Oligosaccharide analysis in urine* Enzyme assay in skin fibroblasts, liver, leukocytes
Norwegian forest cat	Glycogenosis	Incoordination, exercise intolerance	DNA testing*
Persian	Mannosidosis	Onset at 8 weeks; connective tissue and skeletal malformation, possible peripheral neuropathy	DNA testing* Oligosaccharide analysis in urine
Siamese	GM_1 gangliosidosis	Cerebellar signs, dwarfism, facial dysmorphism	Oligosaccharide analysis in urine* Enzyme assay in skin fibroblasts, liver, leukocytes
	Niemann-Pick type A	Cerebellar/vestibular signs, depression, peripheral neuropathy	Enzyme assay in leukocytes and cultured fibroblasts
	MPS VI	Dysmorphism, paraparesis from spinal abnormalities	DNA testing* Urine metabolite screening*
Dogs			
Akita	Glycogenosis (type III)	Muscular weakness, hepatomegaly	Liver, muscle, nervous system pathology
Bassett hound	Lafora's Disease	Myoclonic epilepsy	Intracytoplasmic PAS-positive inclusions in muscle biopsy
Beagle	GM_1 gangliosidosis	Cerebellar signs, dwarfism, facial dysmorphism	Oligosaccharide analysis in urine* Enzyme assay in skin biopsy fibroblasts, liver leukocytes
	Lafora's Disease	Myoclonic epilepsy	Intracytoplasmic PAS-positive inclusions in muscle biopsy

Adapted with permission from Platt RS, Olby N: BSAVA Manual of Canine and Feline Neurology. 3rd Ed. British Small Animal Veterinary Association, Quedgeley, England, 2004.

DNA, Deoxyribonucleic acid; *MPS,* mucopolysaccharidosis; *PAS*, periodic acid Schiff.

*DNA testing, oligosaccharide analysis, organic acid and metabolite screening in the urine, and serum lysosomal enzyme assays are performed by PennGenn/Section of Medical Genetics, Veterinary Hospital 4006, University of Pennsylvania, 3900 Delancey Street, Philadelphia, PA 19104.

†Lysosomal Diseases Testing Laboratory, Jefferson Medical College, Department of Neurology, 1020 Locust Street, Room 394, Philadelphia, PA 19107.

TABLE 23-2

Disorders of Intermediary Metabolism (Storage Diseases)—*cont'd*

BREEDS	DISEASE	ONSET AND CLINICAL SIGNS	DIAGNOSIS
Dogs—*cont'd*			
Beagle—*cont'd*	Globoid cell leukodystrophy (Krabbe's disease)	Early cerebellar signs and ascending paralysis, cerebellar signs later or periheral neuropathy	DNA testing† Peripheral nerve biopsy suggestive Enzyme assay in leukocytes, cultured fibroblasts
Border collie	Ceroid lipofuscinosis	Adult and juvenile forms Ataxia, seizures, progressive blindness (central ± retinal)	Lipopigment in skin biopsy
Boxer	Niemann-Pick type C	Ataxia, cerebellar/vestibular signs, peripheral neuropathy, possible hepatomegaly	Enzyme assay in leukocytes, cultured fibroblasts
Cairn terrier	Globoid cell leukodystrophy (Krabbe's disease)	Early cerebellar signs and ascending paralysis, cerebellar signs later or peripheral neuropathy	DNA testing† Peripheral nerve biopsy suggestive Enzyme assay in leukocytes, cultured fibroblasts
Dachshund	Lafora's Disease	Myoclonic epilepsy	Intracytoplasmic PAS-positive inclusions in muscle biopsy
	Ceroid lipofuscinosis	Ataxia, seizures, progressive blindness (central ± retinal) Adult and juvenile forms	Lipopigment in skin biopsy
Dashshund, wire-hired	MPS III-A	Ataxia, intention tremor, dysuria	Urine metabolite screening*
English setter	Ceroid lipofuscinosis	Ataxia, seizures, progressive blindness (cental ± retinal) Adult and juvenile forms	Lipopigment in skin biopsy
English springer spaniel	Fucosidosis	Onset at 1-4 years; cerebral signs	DNA testing to detect carrier or affected dogs*
	GM_1 gangliosidosis	Cerebellar signs, dwarfism, facial dysmorphism	Oligosaccharide analysis in urine* Enzyme assay in skin fibroblasts, liver, leukocytes
	Glycogenosis	Incoordination, exercise intolerance	Liver, muscle, nervous system pathology
German shepherd dog	Glycogenosis (type III)	Muscular weakness, hepatomegaly	Liver, muscle, nervous system pathology
German short-haired pointer	GM_2 gangliosidosis	Cerebellar/vestibular signs	Oligosaccharide analysis in urine* Enzyme assay in skin fibroblasts, leukocytes
Irish setter	Globoid cell leukodystrophy (Krabbe's disease)	Early cerebellar signs and ascending paralysis, cerebellar signs later or peripheral neuropathy	DNA testing† Peripheral nerve biopsy suggestive Enzyme assay in leukocytes, cultured, fibroblasts
Japanese spaniel	GM_2 gangliosidosis	Cerebellar/vestibular signs	Oligosaccharide analysis in urine* Enzyme assay in skin fibroblasts, liver, leukocytes
Labrador retriever	MPS II	Incoordination, exercise intolerance, visual deficits	Urine metabolite screening*
Lapland dog	Glycogenosis (type II)	Muscle weakness, vomiting, megaesophagus, cardiac and respiratory abnormalities	Liver, muscle, nervous system pathology, EMG abnormalities
Maltese	Malonic aciduria	Seizures, stupor	Organic acid screening*
Miniature pinscher	MPS VI	Dysmorphism, paraparesis from spinal abnormalities	DNA testing* Urine metabolite screening*
Mix-breed dogs	MPS VII	Pelvic limb weakness, joint laxity, atrioventricular valve incompetence	DNA testing* Urine metabolite screening*

EMG, Electromyography.

TABLE 23-2

Disorders of Intermediary Metabolism (Storage Diseases)—*cont'd*

BREEDS	DISEASE	ONSET AND CLINICAL SIGNS	DIAGNOSIS
Dogs—*cont'd*			
Plott hound	MPS I	Dysmorphism, paraparesis from spinal abnomalities	Urine metabolite screening*
Poodle	Globoid cell leukodystrophy (Krabbe's disease)	Early cerebellar signs and ascending paralysis, cerebellar signs later or peripheral neuropathy	DNA testing† Peripheral nerve biopsy suggestive Enzyme assay in leukocytes, cultured fibroblasts
Portuguese water dog	GM_1 gangliosidosis	Cerebellar signs, dwarfism, facial dysmorphism	Oligosaccharide analysis in urine* Enzyme assay in skin fibroblasts, liver, leukocytes
Siberian husky	GM_1 gangliosidosis	Cerebellar signs, dwarfism, facial dysmorphism	Oligosaccharide analysis in urine* Enzyme assay in skin fibroblasts, liver, leukocytes
Silky terrier	Glucocerebrosidosis (Gaucher disease)	Onset at 4-10 months; cerebellar signs, ataxia, seizures, dementia	Enzyme assay (β-glucosidase) in leukocytes
Staffordshire bull terrier	L-2-hydroxyglutaric aciduria	Onset at 6-8 months; ataxia, hypermetria	Urine organic acid screening*
Sydney silky dog	Glucocerebrosidosis (Gaucher disease)	Ataxia, seizures, progressive blindness (central ± retinal) Adult and juvenile forms	Enzyme assay in leukocytes, cultured fibroblasts
Tibetan terrier	Ceroid lipofuscinosis	Early cerebellar signs and ascending paralysis; late cerebellar signs or peripheral neuropathy	Lipopigment in skin biopsy
West highland white terrier	Globoid cell leukodystrophy (Krabbe's disease)	Ataxia, intention tremor	DNA testing† Peripheral nerve biopsy suggestive Enzyme assay in leukocytes, cultured fibroblasts

Treatment and Monitoring

I. Definitive treatment does not exist.
II. Prognosis is variable and often poor for long-term survival.

INFECTIOUS DISORDERS

Rickettsial Meningoencephalitis

Definition and Causes

I. Rickettsial disorders that can infect the brain include Rocky Mountain spotted fever *(Rickettsia rickettsii),* ehrlichiosis, and salmon poisoning (Greene, 2006).
II. Rocky Mountain spotted fever is transmitted by *Dermacentor andersoni*, *Dermacentor variabilis,* and *Amblyomma americanum* ticks.
III. Canine ehrlichiosis *(Ehrlichia canis)* is transmitted by the brown dog tick, *Rhipicephalus sanguineus.*
IV. Salmon poisoning *(Neorickettsia helminthoeca)* is acquired by consumption of salmonid and other fish that carry the metacercaria of the fluke, *Nanophyetus salmincola,* which is the intermediate host.

Clinical Signs

I. Signs arise from a nonsuppurative meningoencephalitis composed mostly of plasma cells.
II. See Chapter 115 for systemic signs.
III. Neurological signs reflect diffuse brain involvement.

Diagnosis

I. CSF analysis reveals a mononuclear pleocytosis, with mild to moderate elevations in protein content.
II. A complete blood count (CBC) may reveal thrombocytopenia, anemia, and leukopenia early in the course, followed by leukocytosis.
III. Intracytoplasmic ehrlichia morulae are occasionally identified in blood and CSF mononuclear cells.
IV. Definitive diagnosis is based on elevated serum titers, a four-fold rise in antibody titer, or positive polymerase chain reaction (PCR) assays (see Chapters 2 and 115).

Differential Diagnosis

I. Immune-mediated, noninfectious meningoencephalitis
II. Other CNS infections
III. CNS neoplasia: lymphoma, metastatic neoplasia

Treatment and Monitoring

I. Doxycycline is given 5 to 10 mg/kg PO BID for 2 to 3 weeks.
   A. Antibiotics may be effective if initiated early in disease course.
   B. Dogs may respond dramatically within 1 to 2 days, but prognosis is guarded to poor when severe neurological deficits are present.
II. Recovery may be prolonged, and residual neurological deficits are possible.

Mycotic and Algal Infections

Definition and Causes

I. Most mycotic infections are regional diseases that produce pyogranulomatous inflammation of the CNS and are treated similarly (Lavely and Lipsitz, 2005).
   A. Mycoses that may affect the CNS include *Cryptococcus ghatti*, *Blastomyces dermatitidis*, *Histoplasma capsulatum, Coccidioides immitis, Aspergillus* spp., phaeohyphomycosis, and hyalohyphomycosis.
   B. *Cryptococcus neoformans* may be the most common CNS mycotic infection.
II. Protothecosis is a rare CNS infection of dogs caused by the achlorophyllous algae, *Prototheca wickerhamii* and *Prototheca zopfii*.

Pathophysiology

I. Cryptococcosis is typically acquired from the environment (e.g., pigeon droppings, dead trees) rather than directly from infected animals.
II. The natural route of these infections is thought to be via the respiratory tract, with subsequent hematogenous and lymphogenous dissemination.

Clinical Signs

I. Clinical signs may reflect a focal mass lesion or a diffuse, multifocal process.
II. Signs also reflect the location of the lesions within the CNS and are variable.
III. A profound elevation in intracranial pressure may cause severe changes in mentation (depression, stupor, coma).
IV. Ocular and nasal discharge may be noted.
V. See Chapter 111 for systemic signs.

Diagnosis

I. Diagnosis of cryptococcosis utilizes the latex agglutination test (LAT), which detects capsular antigen in serum, urine, or CSF.
II. Serological testing for other agents is described in Chapters 2 and 111.
III. CSF analysis sometimes reveals cryptococcal organisms by staining with India ink.
   A. Mononuclear, neutrophilic, or eosinophilic pleocytosis, and elevated protein levels are often present.
   B. Fungal culture of CSF is usually unrewarding.
IV. MRI may show multiple inflammatory lesions that are hypointense on T1-weighted images and hyperintense on T2-weighted images, with multifocal parenchymal and leptomeningeal enhancement.

Differential Diagnosis

I. Immune-mediated, noninfectious meningoencephalitis
II. Other CNS infections
III. CNS neoplasia: lymphoma, metastatic neoplasia

Treatment and Monitoring

I. Amphotericin B may be given at 0.1 to 0.5 mg/kg IV, SC three times weekly.
   A. Animals treated with amphotericin B require weekly assessment of renal function, and it is contraindicated in animals with renal dysfunction.
   B. Liposome encapsulated preparations may be safer.
II. Imidazole drugs may be tried alone or in conjunction with amphotericin.
   A. Fluconazole 5 to 15 mg/kg PO BID (preferred)
   B. Itraconazole 5 to 10 mg/kg PO BID
III. For cryptococcosis, the LAT is monitored monthly during treatment.
   A. Treatment is discontinued after two negative LAT tests are documented 1 month apart or 1 month after resolution of clinical signs.
   B. Treatment is often prolonged (3 to 12 months).
   C. Prognosis is guarded, especially for disseminated disease.

Canine Distemper Encephalomyelitis

Definition and Cause

I. Canine distemper virus is a multisystemic disease affecting the respiratory, alimentary, urogenital, ocular, and nervous systems in dogs.
II. It is an RNA Morbillivirus of the family Paramyxoviridae.

Pathophysiology

I. Several forms and stages of CNS disease exist (Summers et al., 1995).
II. Lymphocytic meningoencephalomyelitis occurs during the first week of exposure.
   A. No neurological signs are seen during this phase.
   B. Infection may be self-limiting or may progress to affect either grey or white matter (more commonly).
III. Grey matter disease occurs approximately 1 week after initial infection.
   A. Typical sites of infection include the cerebral cortex, brainstem, and spinal cord.
   B. Grey matter disease typically occurs in puppies at 6 to 12 weeks of age; certain viral strains may cause disease in adult dogs.
   C. Postvaccinal disease (inadequately attenuated virus) can occur 7 to 10 days after vaccination and may result in severe brainstem lesions and death.
   D. Old-dog encephalitis is a rare, chronic form of the disease.
   E. Pathologic lesions include neuronal degeneration, gliosis, and eosinophilic inclusions in neurons and glial cells.

IV. White matter disease is the most common form of infection and occurs approximately 1 month after initial infection.
  A. Demyelination is the hallmark finding.
  B. Lesions occur in sites that are adjacent to CSF pathways (optic tracts, hippocampus, cerebellar peduncles, spinal cord).
  C. White matter lesions may be noninflammatory for 1 month, then progress to nonsuppurative meningitis and perivascular encephalitis.
  D. Inflammatory lesions ultimately become necrotizing.
  E. Eosinophilic inclusions can be observed in glial cells.

Clinical Signs

I. With grey matter disease, signs reflect nonsuppurative meningitis.
  A. Seizures, stupor, hysteria, and ataxia can be observed.
  B. Dogs may die within 2 to 3 weeks, recover, or develop white matter disease.
II. With white matter disease, signs are multifocal and variable.
  A. Commonly observed signs include cerebellovestibular ataxia and spinal cord paresis.
  B. Occasionally myoclonus develops of a single limb or the temporalis and/or masseter muscles.
  C. Some dogs die 4 to 5 weeks after initial infection, and some may recover with minimal CNS injury.
  D. Other dogs may have persistent CNS demyelination and nonsuppurative inflammation, with or without clinical signs.

Diagnosis

I. Presumptive diagnosis is based on history, signalment, vaccination status, and clinical signs, especially in nonvaccinated dogs.
II. Immunofluorescent or immunocytochemical techniques can detect canine distemper viral antigen in brain sections and other tissues (mononuclear cells in blood, conjunctival or tracheal washes, foot pad biopsies).
III. CSF analysis reveals moderate pleocytosis of mononuclear cells (lymphocytes, macrophages).
  A. Neutralizing antibody in CSF develops 2 to 3 weeks after onset of disease.
  B. The immunoglobulin G (IgG) index (calculated quotient of IgG and albumin levels in CSF compared to serum that detects intrathecal IgG synthesis) is elevated in most dogs except those with acute, noninflammatory distemper.
IV. Reverse transcriptase PCR of urine, CSF, and conjunctival swabs may identify the virus.

Differential Diagnosis

I. Affected puppies: congenital and developmental diseases
II. Immune-mediated or noninfectious meningoencephalitis
III. Other causes of infectious meningoencephalitis: bacteria, parasites, protozoa, rickettsia
IV. Other viral CNS infections
  A. Borna disease (staggering disease), LaCrosse virus
  B. Canine herpesvirus
  C. Rabies
  D. Tickborne encephalitis virus
  E. Eastern equine encephalitis virus
  F. West Nile virus
V. CNS neoplasia: lymphoma, metastatic disease

Treatment and Monitoring

I. No definitive treatment exists for the virus.
II. Treatment is largely supportive (fluid therapy, nutritional support).
III. Euthanasia is considered for dogs with progressive neurological signs that lead to incapacitation.

Feline Infectious Peritonitis Meningoencephalitis

Definition and Cause

I. Feline infectious peritonitis (FIP) is a fatal, systemic immunopathologic disease caused by a feline coronavirus.
II. Although meningitis may accompany the more acute form of peritoneal exudation, a second form affects the CNS and eye with little or no peritoneal involvement (Foley et al., 1998).

Pathophysiology

I. The underlying pathogenesis involves a type III immune reaction and immune complex-induced vasculitis.
II. This CNS infection is characterized by meningitis, ependymitis, and encephalomyelitis (Summers et al., 1995).
III. The mesencephalic aqueduct may be obstructed, causing hydrocephalus and hydromyelia.
IV. Focal brain or spinal cord lesions may also occur.

Clinical Signs

I. Signs are usually nonspecific, but often include profound cerebellovestibular involvement.
II. Signs from focal lesions reflect the site of the lesion.
III. See Chapter 112 for systemic signs.

Diagnosis

I. Antemortem diagnosis is very challenging.
II. CSF analysis reveals profound neutrophilic or mononuclear pleocytosis, with high elevations of protein.
III. Identification of antibody titers in CSF is supportive.
IV. Serum titers are difficult to interpret (see Chapter 112).
V. Serum hypergammaglobulinemia and increased fibrinogen levels may occur.
VI. MRI may show marked dilation of the ventricular system and enhancement of ependymal (periventricular) surfaces and the choroid plexus.
VII. Definitive diagnosis requires histopathology.

Differential Diagnosis

I. Congenital or developmental diseases
II. CNS neoplasia: lymphosarcoma
III. Other viral diseases: feline immunodeficiency virus, Borna disease

IV. Bacterial meningoencephalitis
V. Toxoplasmosis

Treatment and Monitoring

I. Because no definitive treatment exists, supportive care (fluid therapy, nutritional support) may be tried.
II. Prednisone 2 to 4 mg/kg PO SID to BID may provide palliative relief.
III. The prognosis is grave for long-term survival.

Bacterial Meningoencephalitis

Definition and Causes

I. It is inflammation of the brain and/or meninges from aerobic or anaerobic bacterial infections.
II. Organisms that can infect the CNS include *Pasteurella, Staphylococcus, Actinomyces, Nocardia, Streptococcus,* and *Klebsiella* spp., and *Eschericia coli*.

Pathophysiology

I. A variety of mechanisms allow bacterial entry into the CNS.
   A. Hematogenous spread from distant foci: lung abscess, vegetative endocarditis, urinary tract infection
   B. Direct extension from nasal and paranasal sinuses, ears, and eyes
   C. Secondary to trauma and wound contamination (bite wound)
   D. Meningeal spread along nerve roots
   E. Contaminated surgical instruments: spinal needles
II. Organisms usually disseminate through CSF pathways and produce meningitis and microabscesses of the brain and spinal cord.
III. Formation of inflammatory cytokines and tumor necrosis factor by monocytes and neural cells leads to altered blood-brain barrier permeability, recruitment of neutrophils, and purulent exudates in the subarachnoid space.
IV. Vasculitis leads to vasogenic brain edema.
V. Toxic oxygen metabolites released from degranulating leukocytes also cause cytotoxic brain edema.

Clinical Signs

I. Clinical signs begin acutely.
II. Systemic signs include fever, vomiting, bradycardia, anorexia, shock, and hypotension.
III. Neurological signs consist of hyperesthesia, cervical pain and rigidity (common), seizures (occasionally), and cranial nerve deficits (Radaelli and Platt, 2002).

Diagnosis

I. CSF analysis typically shows a profound neutrophilic pleocytosis and protein elevation.
   A. Organisms sometimes may be seen on CSF cytology.
   B. Bacterial culture of CSF (aerobic and anaerobic) provides a definitive diagnosis, but negative cultures do not rule out the disease.
II. Blood and urine cultures may yield a pathogenic organism.
III. A CBC may reveal a neutrophilic leukocytosis and left shift.
IV. MRI and CT can show meningeal, brain and/or ventricular enhancement, as well as abscessation.

Differential Diagnosis

I. Immune-mediated meningoencephalitis, especially steroid-responsive meningitis/arteritis
II. Intervertebral disc disease
III. Other CNS infections
IV. CNS neoplasia: lymphoma, metastatic neoplasia
V. Systemic bacterial infections

Treatment and Monitoring

I. Preferred antibiotic therapy is based on culture results and is continued for several weeks after clinical signs have resolved.
II. Empirical treatment choices in dogs are as follows:
   A. Chloramphenicol 50 mg/kg IV, IM, SC, PO BID
   B. Metronidazole 10 to 15 mg/kg PO TID
   C. Enrofloxacin 10 mg/kg IV, PO SID
   D. Azithromycin 5 to 10 mg/kg PO SID
   E. Trimethoprim-sulfonamide 15 to 30 mg/kg PO BID
III. Corticosteroids are generally contraindicated, but anti-inflammatory doses may be beneficial upon initiation of treatment.
IV. Prognosis is guarded.
   A. Death is common even if appropriate therapy is administered.
   B. Relapses are frequently encountered.

Toxoplasmosis

Definition and Cause

I. Toxoplasmosis may be the most common protozoa to affect the CNS in dogs and cats.
II. The causative agent is *Toxoplasma gondii.*

Pathophysiology

I. Organisms may form cysts in the CNS and in the skeletal and heart muscles.
II. Parasites are mainly intracellular, and subclinical infection may persist for life.
III. Activation may occur with severe immunosuppression, especially from viral infections.
IV. Nonsuppurative (focal or multifocal) necrotizing meningoencephalomyelitis occurs in the CNS, whereas radiculitis and myositis develop in the PNS.
V. Chorioretinitis commonly accompanies CNS lesions.
VI. Lesions may also occur in lungs, liver, spleen, and lymph nodes.

Clinical Signs

I. The disease most commonly affects animals <1 year of age or animals that are immunocompromised.
II. Clinical signs relate to either focal (granulomas) or multifocal CNS disease.

III. Possible signs include hyperexcitability, depression, intention tremors, paresis, paralysis, head tilt, and seizures.
IV. Spinal cord signs are more common in cats.
V. See Chapter 116 for systemic signs.

Diagnosis

I. Definitive diagnosis is often difficult to establish (see Chapter 116).
II. CSF analysis may demonstrate a mononuclear, neutrophilic, or eosinophilic pleocytosis, with elevated protein levels.
III. PCR may reveal the presence of the organism in CSF, muscle, or liver biopsies.
IV. Electromyography (EMG) may show abnormal spontaneous activity in animals with muscle and nerve involvement, and nerve conduction velocities may be decreased in animals with nerve involvement.
V. MRI or CT may reveal focal or multifocal CNS lesions.

Differential Diagnosis

I. Dogs
  A. *Neospora caninum*
    1. Most often affects dogs <2 years of age
    2. Predilection for lumbosacral nerve roots (radiculitis, neuritis, see Chapter 24)
    3. May cause encephalitis (especially cerebellitis) in adult dogs
  B. Sarcocystosis, encephalitozoonosis, trypanosomiasis
  C. Acanthamebiasis, babesiosis
  D. Leishmaniasis
  E. Autoimmune, bacterial, viral meningoencephalitis
  F. Neoplasia: lymphosarcoma, histiocytic tumors
II. Cats
  A. FIP
  B. Neoplasia: lymphosarcoma
  C. Borna disease
  D. Bacterial meningoencephalitis

Treatment and Monitoring

I. Clindamycin is the drug of choice and is given at 10 to 20 mg/kg PO, IM BID for 3 to 6 weeks.
II. Alternatively, trimethoprim-sulfonamide (15 to 20 mg/kg PO BID) is combined with pyrimethamine at 1 mg/kg PO SID for 4 to 8 weeks.
III. Prognosis is guarded with CNS involvement, but some animals survive with minimal residual neurological deficits.

NONINFECTIOUS INFLAMMATORY DISORDERS

Granulomatous Meningoencephalomyelitis

Definition and Cause

I. Granulomatous meningoencephalomyelitis (GME) is an idiopathic (mononuclear) meningoencephalomyelitis that most commonly occurs in young to middle-age dogs.
II. GME is thought to be an immune-mediated (delayed-type hypersensitivity) disease based on the presence of major histocompatibility complex class II and cluster differentiation (CD3) antigen-positive lymphocytes (Kipar et al., 1998).

Pathophysiology

I. Three morphological forms exist, namely disseminated, focal, and ocular disease (Summers et al., 1995).
II. Lesions consist of perivascular, concentric proliferations of inflammatory cells predominantly in the white matter.
III. Perivascular cellular accumulations consist of lymphocytes, plasma cells, and mononuclear cells.

Clinical Signs

I. Onset ranges from 9 months to 10 years of age.
II. Signs may be acute, rapidly progressive and fatal, or chronic and insidious.
III. The focal form of GME results in focal deficits, whereas the disseminated form causes multifocal signs.
IV. Neurological signs reflect lesion location and distribution.
  A. Brainstem (varying degrees of depression and spastic tetraparesis, vestibular ataxia, head tilt, abnormal nystagmus) and cerebellar signs are most common.
  B. Prosencephalic signs include seizures, depression, circling, and visual deficits.
  C. The ocular form causes visual deficits, anisocoria, and abnormalities in pupillary light reflexes.
V. A fever is often present.

Diagnosis

I. The CSF usually reveals a mild to severe pleocytosis of monocytes and lymphocytes, with mild protein elevation.
II. MRI and CT may reveal multifocal lesions, predominantly in the white matter of the CNS.
III. Definitive diagnosis requires histopathology.

Differential Diagnosis

I. Necrotizing meningoencephalitis
II. Necrotizing leukoencephalitis
III. Infectious meningoencephalitis
IV. CNS neoplasia: lymphoma, metastatic neoplasia

Treatment and Monitoring

I. Immunosuppression is the primary therapy.
II. Prednisone is given at 1.0 to 3.0 mg/kg PO BID for 1 month, then gradually tapered over several months to 0.5 mg/kg PO SID to QOD.
III. Additional drugs may allow a reduction in prednisone and ameliorate its side effects.
  A. Cytosine arabinoside 50 mg/m^2 SC BID for 2 days, repeated every 3 weeks (Zarfoss et al., 2006)
  B. Cyclosporine 5 to 10 mg/kg PO BID (Adamo and O'Brien, 2004)
  C. Others: leflunomide, procarbazine, CCNU (lomustine)
IV. Radiation therapy may be beneficial for the focal form.
V. GME is rarely cured and often requires lifelong therapy to control the inflammation.

Necrotizing Meningoencephalitis

Definition and Cause

I. It is an idiopathic meningoencephalitis of young pugs, Maltese, Shih tzus, and occasionally other small-breed dogs (Cordy and Holliday, 1989; Stalis et al., 1995).
II. It is presumed to be an immune-mediated disease.

Pathophysiology

I. Lesions consist of nonsuppurative meningoencephalitis and mild cerebral necrosis.
II. It typically affects the cerebral hemispheres, with inflammation extending from the leptomeninges through the cortex and into the corona radiata.
III. This pattern leads to a loss of demarcation between cortical grey and white matter in the brain.

Clinical Signs

I. Onset ranges from 9 months to 4 years of age.
II. Signs may be rapidly progressive and fatal.
III. Signs consist of prosencephalic signs, such as seizures, depression, circling, and visual deficits.
IV. Motor and sensory problems (ataxia, paresis), brainstem and cerebellar signs are also possible.

Diagnosis

I. CSF analysis shows a moderate to severe pleocytosis composed of monocytes and lymphocytes, with mild protein elevation.
II. MRI findings mirror the topography of the histopathologic lesions.
III. MRI typically demonstrates multifocal lesions in the superficial cortical grey matter at the junction of the cerebrum and leptomeninges.

Differential Diagnosis

I. Granulomatous meningoencephalomyelitis
II. Necrotizing leukoencephalitis
III. Infectious meningoencephalitis
IV. CNS neoplasia: lymphoma, metastatic neoplasia
V. Metabolic, toxic encephalopathies
VI. Other causes of seizures: see Chapter 22

Treatment and Monitoring

I. Immunosuppression is the primary therapy and is similar to that for GME.
II. The prognosis is grave.
III. If a response is seen to immunosuppression, lifelong therapy is necessary to control the inflammation.

Necrotizing Leukoencephalitis

Definition and Cause

I. It is an idiopathic (mononuclear) meningoencephalitis of young Yorkshire terriers, Chihuahuas, and occasionally other small-breed dogs (Tipold et al., 1993).
II. It is presumed to be an immune-mediated disease.

Pathophysiology

I. Lesions consist of nonsuppurative meningoencephalitis and moderate to severe cerebral necrosis.
II. Gross cavitations occur in periventricular cerebral and diencephalic (thalamocortical) white matter.

Clinical Signs

I. Onset is from 1 to 5 years of age.
II. The clinical course is slowly progressive, usually over many weeks to months.
III. Clinical signs reflect caudal brainstem or prosencephalic lesions.
IV. Brainstem signs often predominate and include varying degrees of depression, spastic tetraparesis, vestibular ataxia, head tilt, and abnormal nystagmus.
V. Prosencephalic signs consist of seizures, propulsive activity, and visual deficits.

Diagnosis

I. The CSF analysis usually reveals a moderate to severe pleocytosis of monocytes and lymphocytes and a mild protein elevation.
II. MRI and CT may show multifocal cavitating lesions predominantly in deep white matter.

Differential Diagnosis

I. Granulomatous meningoencephalomyelitis
II. Necrotizing meningoencephalitis
III. Infectious meningoencephalitis
IV. CNS neoplasia: lymphoma, metastatic neoplasia
V. Metabolic or toxic encephalopathies
VI. Other causes of seizures: see Chapter 22

Treatment and Monitoring

I. Immunosuppression is the mainstay of therapy (see under GME).
II. The prognosis is grave and therapy may be life-long.

Canine Meningeal Polyarteritis

Definition and Cause

I. The disease is a neutrophilic meningitis of young dogs that is characterized by episodes of severe pain, depression, and fever (Cizinauskas et al., 2000).
II. It is presumed to be immune-mediated.
III. It is also known as *steroid-responsive* (or *sterile*) *meningitis-arteritis, immune-mediated meningitis, Beagle pain syndrome, systemic necrotizing vasculitis,* and *juvenile polyarteritis syndrome.*

Pathophysiology

I. Inflammation occurs in the leptomeningeal arteries.
II. Leptomeningeal vascular lesions may be accompanied by lymphocytic thyroiditis, amyloidosis (splenic, hepatic, renal), or polyarthritis (Webb et al., 2002).

Clinical Signs

I. Affected dogs range in age from 6 months to a few years.
II. It affects the beagle, Bernese mountain dog, boxer, German short-haired pointer, and is sporadically reported in other breeds.
III. The predominant clinical signs are profound neck pain, depression, anorexia, and fever.
IV. Occasionally, ataxia and varying degrees of paresis are also present (see Chapter 24).
V. The clinical course is typically acute in onset.

Diagnosis

I. Signalment and clinical signs are suggestive.
II. CSF analysis reveals the following:
   A. CSF has a severe neutrophilic pleocytosis, with excessive protein and phagocytosed red blood cells (RBCs).
   B. Neutrophils in CSF do *not* show toxic changes, and intracellular bacteria are not observed.
   C. CSF aerobic and anaerobic bacterial cultures are negative.
   D. Consistent elevation of CSF and serum immunoglobulin (Ig) A concentrations occur.
III. Occasionally peripheral neutrophilia with a left shift and an elevated serum α2-globulin fraction are found.
IV. CT or MRI may demonstrate contrast enhancement of the meninges, spinal cord, or brain.

Differential Diagnosis

I. Intervertebral disc disease
II. Bacterial meningoencephalitis
III. Other immune-mediated meningoencephalitides
IV. CNS neoplasia

Treatment and Monitoring

I. Long-term immunosuppression is achieved with prednisone at 1 to 2 mg/kg PO BID, then tapered monthly over 6 months.
II. In refractory cases, azathioprine (1.5 mg/kg PO SID to QOD) may be added and eventually alternated with prednisone QOD.
III. Prognosis is guarded to favorable; recurrences are common.
IV. Monitor for recurrences, and consider repeating the CSF analysis if clinical signs persist.

Eosinophilic Meningoencephalitis

Definition and Cause

I. Eosinophilic meningoencephalitis is an uncommon disease, primarily of rottweilers and golden retrievers, that is characterized by severe, multifocal neurological signs (Smith-Maxie et al., 1989; Schultze et al., 1986).
II. It is presumed to be an immune-mediated disease.

Clinical Signs

I. Prosencephalic signs consist of behavioral and mentation changes, circling, pacing, head pressing, blindness, and generalized or partial seizures.
II. Brainstem signs include episodic collapse, facial paralysis, absent gag reflex, reduced pupillary light reflexes, torticollis, and varying degrees of ataxia and incoordination.

Diagnosis

I. CSF analysis shows variable pleocytosis, with 21% to 98% eosinophils, and elevated protein content.
II. Mild to moderate systemic eosinophilia may be observed.
III. Serology for infectious diseases is negative.

Differential Diagnosis

I. Other CNS infections: primary protozoal, fungal, parasitic
II. Other noninfectious meningoencephalitides
III. CNS neoplasia

Treatment and Monitoring

I. Prednisone therapy (and possibly additional immunosuppressive agents) is instituted similar to that for GME.
II. Prognosis is favorable to guarded.

IDIOPATHIC DISORDERS

Idiopathic Tremor Syndrome

Definition and Cause

I. Idiopathic tremor syndrome (shaker dog disease) is a meningoencephalitis of young, small, white dogs (de Lahunta, 1983).
II. Occasionally, dogs with pigmented coats are affected.
III. The exact pathogenesis remains uncertain, although it may be immune-mediated.
IV. Mild lymphoplasmacytic meningoencephalitis is the predominant lesion.

Clinical Signs

I. It most commonly affects Maltese and West Highland white terriers.
II. Other affected breeds include the bichon frisé, Spitz, samoyed, beagle, dachshund, and Yorkshire terrier.
III. The predominant clinical sign is continuous, whole-body tremors that worsen with exercise, stress, and excitement, but disappear with sleep.
IV. Neurological examination often is normal, with the exception of generalized tremors.
V. When present, neurological signs may include absent menace response, spontaneous nystagmus, poor to absent oculocephalic reflexes (physiological nystagmus), vestibular or cerebellar ataxia, head tilt, varying degrees of paresis, and seizures.

Diagnosis

I. CSF analysis reveals mild lymphocytic pleocytosis, with normal or mildly elevated protein levels.
II. MRI typically is normal, but may disclose symmetrical ventricular enlargement in some dogs.

Differential Diagnosis

I. Metabolic or toxic encephalopathies
II. Meningoencephalitis
III. Dysmyelinogenic disorders

Treatment and Monitoring

I. Prednisone is administered at 1 to 2 mg/kg PO SID for 4 weeks, then tapered to 0.5 to 1 mg/kg PO SID for 2 weeks, then to QOD for 2 weeks, then to every 72 hours for 4 weeks.
II. Diazepam 0.25 mg/kg PO BID to TID or propanolol 1 mg/kg PO TID may be beneficial in refractory cases.
III. Prognosis is favorable, with tremors usually decreasing by the end of the first week of therapy.
IV. Relapses can occur and may require additional immunosuppressive therapy (e.g., azathioprine).

Trigeminal Neuropathy

Definition and Cause

I. It is an idiopathic disorder characterized by acute onset of trigeminal nerve paresis or paralysis (de Lahunta, 1983).
II. It may be an immune-mediated condition.

Clinical Signs

I. Clinical signs include an acute onset of jaw paresis or paralysis with an inability to close the mouth, drooling, and difficult prehension of food and water.
II. Trigeminal sensory deficits are common.
III. Horner's syndrome (from effects on postganglionic sympathetic fibers incorporated in segments of the ophthalmic branch of the trigeminal nerve) is occasionally seen.
IV. Occasionally, the facial nerve is also involved.

Diagnosis

I. EMG of the muscles of mastication is abnormal.
II. CSF analysis may reveal a mild mononuclear pleocytosis, often with normal or mildly elevated protein content.
III. Definitive diagnosis of trigeminal neuropathy requires biopsy of the trigeminal nerve, but it is rarely done.

Differential Diagnosis

I. Lymphoma infiltrating the trigeminal nerves
II. Polyradiculoneuritis
III. Rabies
IV. Masticatory muscle myositis

Treatment and Monitoring

I. The condition is often self-limiting, with recovery occurring over 3 to 4 weeks to several months.
II. Corticosteroids do not seem to affect the clinical course.
III. Fluid and nutritional support may be necessary for animals unable to eat and drink on their own.
IV. The severity of muscle atrophy, clinical course, and recovery depends upon the extent of axonal degeneration.
V. Prognosis is favorable in most cases, but can be guarded in severely affected animals.

Idiopathic Facial Nerve Paralysis

Definition and Cause

I. It is a disorder of mature dogs and cats that is characterized by facial palsy or paralysis (Kern and Erb, 1987).
II. The cause is unknown.

Clinical Signs

I. Predisposition exists in the American cocker spaniel, Pembroke Welsh corgi, boxer, English setter, and domestic long-haired cat.
II. Clinical signs include ear drooping, commissural paralysis of the lip, sialosis, deviation of the nose away from the affected side, and collection of food on the paralyzed side of the mouth.
III. Menace response and palpebral reflexes are absent ipsilaterally.
IV. Facial paralysis is usually unilateral, but may be bilateral in some animals.
V. Horner's syndrome is not seen.

Diagnosis

I. Diagnosis is often presumptive, based on clinical signs and exclusion of other disorders.
II. EMG may reveal spontaneous denervation potentials in superficial facial muscles.

Differential Diagnosis

I. Polyradiculoneuritis (coonhound paralysis)
II. Endocrine disorders: hypothyroidism, insulinoma
III. Laryngeal paralysis syndrome
IV. Myasthenia gravis, botulism
V. Trauma near the stylomastoid foramen or in conjunction with petrosal bone fracture
VI. Middle ear infection, neoplasia
VII. Surgery of the external or middle ear, or side of the face
VIII. Extracranial tumors

Treatment and Monitoring

I. Application of ophthalmic lubricants helps prevent corneal drying.
II. Prognosis for a complete return to function is guarded.
III. Chronic lip paralysis may result in permanent contracture, and the inability to close the eyelids often leads to keratitis.

Peripheral Vestibular Syndrome

Definition and Cause

I. It is an acute disorder that occurs in cats of all ages and in older dogs (de Lahunta, 1983).
II. Mechanism and cause are unknown.
III. Most feline cases (80%) occur in the summer (Burke et al., 1985).

Clinical Signs

I. Clinical signs occur acutely.
II. Only signs of peripheral vestibular dysfunction (no evidence of facial nerve paralysis or Horner's syndrome) are present.

III. Signs include head tilt, asymmetrical ataxia, and horizontal or rotatory nystagmus with the fast phase directed away from the head tilt.
IV. More severe signs of falling, rolling, and vomiting (especially in dogs) are seen occasionally.

Diagnosis

I. Presumptive diagnosis is based on signalment, history, clinical signs, and exclusion of other etiologies.
II. Absence of otoscopic and radiographic abnormalities of the middle ear is supportive.
III. MRI or CT scan is normal.
IV. CSF analysis is normal.

Differential Diagnosis

I. Otitis media/interna
II. Neoplasia
III. Cerebrovascular accident of brainstem

Treatment and Monitoring

I. Supportive care is administered, as needed.
II. Affected animal tends to stabilize in a few days and improve gradually over several weeks.
III. Prognosis for spontaneous remission is good; however, residual deficits (e.g., mild head tilt) may occur.

PARASITIC DISORDERS

Parasitic Encephalomyelitis

Definition

I. Aberrant migration of parasite larvae through the CNS results in parenchymal damage and neurological signs (Braund, 2005).
II. It is also known as *cerebral larval migrans.*

Causes

I. *Toxocara canis*
II. *Ancylostoma caninum*
III. *Angiostrongylus cantonensis*
IV. *Dirofilaria immitis*
V. *Angiostrongylus vasorum*
VI. *Cysticercus cellulosae*
VII. *Baylisascaris procyonis*
VIII. *Coenurus serialis*

Pathophysiology

I. Migrating larvae damage neural tissue by two mechanisms.
II. Necrosis can occur in tissue along the migratory pathway.
III. Migrating larvae evoke an inflammatory response, which causes ischemia, edema, and toxic injury to myelin, axons, and neurons.

Clinical Signs

I. Clinical signs are acute in onset and rapidly progressive.
II. Signs reflect the location of the migratory pathway.
   A. Prosencephalon signs include blindness, circling, behavioral changes, seizures, and postural reaction deficits.
   B. Brainstem signs include varying degrees of ataxia and paresis, changes in mentation, cranial nerve deficits, head tilt, and spontaneous nystagmus.
   C. Cerebellar signs include a wide stance; a spastic, hypermetric gait; loss of balance; intention tremors; and absent menace response.
III. Neurological signs may reflect focal or multifocal disease.

Diagnosis

I. CSF is characterized by an eosinophilic or neutrophilic pleocytosis, and protein elevation.
II. A positive test for *D. immitis* is suggestive.
III. Definitive diagnosis requires histological demonstration of the parasite within the CNS.

Differential Diagnosis

I. Infectious meningoencephalitis
II. Eosinophilic meningoencephalomyelitis
III. GME
IV. Neoplasia

Treatment and Monitoring

I. No successful therapy to date
II. Guarded prognosis

Intracranial Myiasis

Definition and Cause

Aberrant migration of *Cuterebra* spp. larvae can occur within the CNS of cats and dogs (rarely) (Glass et al., 1998).

Pathophysiology

I. Larvae may migrate through the nose, ethmoids, and cribriform plate and enter the brain through the olfactory lobe.
II. Alternatively, larvae can migrate through foramina of the skull, travel through the external and middle ear, penetrate the mastoid region, invade venous sinuses and meninges, or enter hematogenously after penetrating a large vessel.
III. Microscopic necrosis of the brain occurs secondary to ischemia.
IV. Lesions are usually unilateral in regions supplied by the middle cerebral artery (see Cerebral Vascular Disease).
V. It is hypothesized that the larvae produce a toxin that causes vasospasm and cerebral infarction and may cause superficial laminar cerebrocortical necrosis (Williams et al., 1998).

Clinical Signs

I. Animals are often affected in summer months, when adult flies deposit their ova.
II. Typically outdoor cats (rarely dogs) are affected.
III. Many cats have signs consistent with upper respiratory disease (especially sneezing) before the appearance of neurological signs.
IV. Neurological signs are peracute in onset.
V. Prosencephalic signs, including unilateral postural reaction deficits, unilateral facial (and occasionally whole-body)

hypalgesia, and a menace deficit with a dilated, nonresponsive pupil from involvement of the optic tracts are noted.
VI. Seizures and profound behavioral and mentation changes are often present.

Diagnosis

I. CSF analysis may be normal or show a mild to moderate pleocytosis (neutrophilic, mononuclear, or occasionally eosinophilic), with mild protein elevation.
II. MRI may reveal the migratory path of the larvae, cerebrocortical lesions, and evidence of a focal or regional infarction.
III. Definitive diagnosis requires histopathology.

Differential Diagnosis

I. Other infectious or parasitic meningoencephalitis
II. Eosinophilic meningoencephalitis
III. Neoplasia

Treatment and Monitoring

I. The following may be beneficial, but controlled studies have not been done.
   A. Pretreat with diphenhydramine 4 mg/kg IM.
   B. Give ivermectin 400 µg/kg SC and dexamethasone 0.1 mg/kg IV.
   C. Repeat the treatment 24 to 48 hours later.
II. A third-generation cephalosporin, trimethoprim-sulfa drug, or metronidazole may be given to prevent bacterial infection associated with larval migration.
III. Although prognosis is guarded; some cats may recover over weeks to months with residual neurological deficits.

METABOLIC/TOXIC DISORDERS

General Information

Definition and Causes

I. These include disturbances in cerebral function from metabolic derangements or toxicoses that usually manifest as diffuse prosencephalic signs.
II. See Table 23-3 for a list of causes.

Pathophysiology

I. Energy deprivation leads to alterations in neuronal resting membrane potentials, and may disrupt neurotransmitter function and metabolism.
II. Certain toxins and metabolic abnormalities may interfere with energy metabolism in the brain, potentially causing neuronal death.
III. Electrolyte imbalances may alter neuronal excitability and neurotransmission.
IV. Changes in serum osmolality and water content lead to altered osmotic balance in neural cells, which may cause either brain cell swelling (edema) or dehydration.

Clinical Signs

I. Metabolic encephalopathies typically cause diffuse, symmetrical prosencephalic signs, such as seizures, altered mentation (confusion, disorientation, dementia, pacing, head pressing), circling, and altered consciousness (obtundation, stupor, coma).
II. Onset may be acute or chronic, and signs may wax and wane.
III. Motor signs include tremors, myoclonus, and varying degrees of paresis/paralysis.

TABLE 23-3

Causes of Metabolic or Toxic Encephalopathies

DISORDER	CAUSES
Hypoxia	Cardiopulmonary failure, disturbances in hemoglobin function, carbon monoxide poisoning, methemoglobinemia, cellular hypoxia (cyanide poisoning)
Hypoglycemia	Pancreatic beta-cell tumor (insulinoma), iatrogenic insulin overdose, hepatic dysfunction, septicemia, hypoadrenocorticism, paraneoplastic syndromes (e.g., leiomyosarcoma, hepatoma, lymphoma), neonatal animals, hunting dogs, storage diseases
Acidosis, alkalosis, hyperosmotic states	Hyperglycemia (diabetes mellitus), hypernatremia, dehydration, diabetes insipidus, nonketotic, hyperosmolar diabetes mellitus, hyperaldosteronism
Hypoosmotic states, hyponatremia	Hypoadrenocorticism, water intoxication, inappropriate secretion of antidiuretic hormone
Alterations in calcium homeostasis	
Hypercalcemia	Paraneoplastic syndromes, rodenticide toxicity (cholecalciferol-containing products), hyperparathyroidism, Vitamin D toxicity, renal disease, hypoadrenocorticism, certain granulomatous diseases
Hypocalcemia	Eclampsia, hypoparathyroidism
Endogenous neurotoxins	Hepatic insufficiency/failure, renal failure, pancreatitis
Endocrine disorders	Hyperthyroidism, hypothyroidism

Diagnosis

I. Other evidence of metabolic disturbances may be identified from the history or the physical examination.
II. A minimum laboratory database includes a complete blood count, biochemistry profile, and urinalysis.
III. Other diagnostic tests are considered based on initial findings.
  A. Serum bile acids
  B. Blood gas analysis
  C. Measurement of serum osmolality
  D. Endocrine function tests
  E. Cardiopulmonary function tests: electrocardiography, blood pressure measurement, radiography, echocardiography
  F. Abdominal radiography and ultrasonography

Differential Diagnosis

I. Degenerative encephalopathies
II. Meningoencephalitis
III. Neoplasia
IV. Brain malformations

Treatment and Monitoring

I. Ensure an adequate airway; support breathing and circulation if the animal is comatose.
II. Correct the underlying metabolic disturbance.
III. Consider anticonvulsants for seizures.
IV. Take care when treating seizures in animals with hepatic insufficiency, because they are unable to metabolize many anticonvulsants.
  A. Give diazepam (0.5 mg/kg IV), but reduce the dosage if hepatic encephalopathy is a primary concern.
  B. Give phenobarbital initially at 2.0 mg/kg PO, IV, IM BID, with caution.
    1. Metabolism may be compromised with hepatic dysfunction.
    2. Acidosis causes increased penetration of barbiturates into the brain.
  C. Seizures may be difficult to control until the underlying metabolic imbalance is corrected.
V. Administer dextrose if hypoglycemia is identified (see Chapter 46).
VI. In most cases, neurological signs resolve once the metabolic disturbance is corrected.

Hepatic Encephalopathy

See Chapter 37.

Cerebrovascular Disease

Definition

I. Cerebrovascular disease refers to conditions that result in brain ischemia, infarction, or hemorrhage.
II. These conditions include the following:
  A. Cerebrovascular accidents: thromboembolism and infarction, hemorrhage (Garosi et al., 2005)
  B. Vascular anomalies: aneurysm, hamartoma
  C. Cerebral arteriosclerosis secondary to severe hypothyroidism
  D. Meningoencephalitis
  E. Intravascular neoplasms: lymphoma

Causes and Pathophysiology

I. Cerebral ischemia occurs as a result of insufficient blood supply to the brain.
  A. Dogs may have transient ischemic attacks, possibly from vasospasm.
    1. Attacks are often of unknown etiology.
    2. Occasionally they are associated with hypertension.
  B. Feline ischemic encephalopathy (FIE) occurs in the late summer, most commonly in eastern North America.
    1. Aberrant migration of *Cuterebra* spp. larva is thought to be the primary cause (Glass et al., 1998).
    2. It is hypothesized that a toxin from the larva causes vasospasm (of the middle cerebral artery), resulting in a unilateral ischemic brain lesion (Williams et al., 1998).
II. Hypoperfusion of the brain is associated with atherothrombosis or embolism.
  A. With atherothrombosis, a localized thrombus forms and disrupts blood flow, with subsequent ischemia and/or infarction.
  B. With embolization, an artery is suddenly occluded, usually by a thrombus that arises from a distant site, such as in the heart (blood clot) or a neoplasm (e.g., neoplastic cells from hemangiosarcoma).
III. Systemic hypoperfusion causes a decrease in cerebral blood flow and can lead to infarction in the border zones between major cerebral arteries (watershed infarction).
IV. Impaired blood supply to the brain results in a decline in tissue oxygen levels (stagnant hypoxia), which cause brain ischemia.

Clinical Signs

I. Clinical signs are peracute and may be followed by progressive recovery over days to weeks.
II. Clinical signs reflect the location of brain infarction.
III. Although gait deficits are not typically seen with prosencephalic lesions, a transient gait deficit (hemiparesis) may be seen with prosencephalic infarcts.
IV. Vestibular signs may be seen with thalamic infarcts.

Diagnosis

I. Serial blood pressure measurements may indicate hypertension.
II. Results of a CBC, biochemistry profile, and urinalysis vary, depending on the presence of an underlying systemic disease.
III. Additional tests may include urine protein: creatinine ratio, serum antithrombin III activity, coagulation profile, and endocrine testing for hyperadrenocorticism, thyroid diseases, and pheochromocytoma.
IV. Thoracic radiography and abdominal ultrasonography may reveal evidence of an underlying disease.

V. MRI (and occasionally CT) may reveal ischemic brain lesions.
VI. CSF analysis usually shows normal to mild increases in nucleated cells, with elevated protein content.

Differential Diagnosis

I. Meningoencephalitis
II. Metabolic encephalopathy
III. Neoplasia

Treatment and Monitoring

I. No definitive treatment for the neurologic signs has been defined in animals.
II. Osmotic therapy (as described for cranial trauma) may be beneficial in severely affected animals.
III. Treatment is usually directed at the underlying disease.
IV. Prognosis and recovery are highly variable.

NUTRITIONAL DISORDERS

Thiamine Deficiency

Definition and Causes

I. Metabolic encephalopathy can arise from thiamine deficiency (de Lahunta, 1983).
II. Commercial rations or homemade diets may be low in thiamine.
III. Overcooking food before feeding or during food processing can affect thiamine levels.
IV. Thiamine can be destroyed by sulfites or sulfur dioxide used as a preservative in canned food.
V. All-fish diets may result in thiamine deficiency, as many fish contain thiaminase.
VI. Severe hepatic or renal disease can be associated with thiamine deficiency.

Pathophysiology

I. Thiamine is essential for complete oxidation of glucose through the Krebs cycle.
II. Tissues that derive energy from glucose or lactate-pyruvate are compromised.
III. Several proposed mechanisms for neuronal cell death include impaired vascular function, increased blood-brain barrier permeability, N-methyl-D-aspartic acid receptor-mediated excitotoxicity, and increased free radical formation (Leong and Butterworth, 1996).
IV. CNS lesions include bilateral, symmetrical degeneration of brainstem nuclei (caudal colliculi, vestibular, lateral geniculate, oculomotor and red nuclei), and cortical lesions (less common).

Clinical Signs

I. Signs are related to dysfunction of brainstem nuclei and include vestibular ataxia, seizures, dilated pupils, opisthotonus, coma, and death.
II. Severe head and neck ventriflexion is often present from neuromuscular weakness.
III. Dogs may have signs of central (bilateral) vestibular disease or cervical myelopathy (Garosi et al., 2003).

Diagnosis

I. History, signalment, clinical signs, and response to treatment allow a presumptive diagnosis.
II. MRI may disclose symmetrical lesions in affected brainstem nuclei (Garosi et al., 2003).
III. Serum levels of pyruvate and lactate may be increased.
IV. Red blood cell transketolase activity is usually decreased.

Differential Diagnosis

I. Meningoencephalitis
II. Metabolic or toxic encephalopathies
III. Neoplasia
IV. Other causes of central vestibular disease

Treatment and Monitoring

I. Even in severely affected animals, prognosis is fair to good if signs are recognized early.
II. Thiamine HCl (vitamin B_1) is administered at 25 to 50 mg/day IM to dogs for 3 to 7 days, and at 10 to 20 mg/day IM to cats until signs abate, or for 21 days.
III. Higher doses may be required in some animals.
IV. Dietary abnormalities should also be corrected.

NEOPLASIA

Definition

I. Primary brain tumors arise from neuroectodermal or mesodermal cells that are normally present within or associated with the brain (Summers et al., 1995).
II. Secondary tumors originate from surrounding tissues and extend into the brain or arise from hematogenous metastasis.
III. Classification of brain tumors (primary or secondary) is based on characteristics of the constituent cell types (Bagley et al., 1993).

Causes and Classification

I. Primary tumors
  A. Tumors of neuroepithelium
    1. Astrocytic tumors: astrocytoma, glioblastoma multiforme
    2. Oligodendroglial tumors: oligodendroglioma
    3. Mixed glial tumors: oligoastrocytoma, gliomatosis cerebri
    4. Embryonal tumors: primitive neuroectodermal tumors (PNETs), medulloblastoma
    5. Ependymoma
    6. Choroid plexus tumors
  B. Tumors of meninges: meningioma, meningeal sarcoma
  C. Tumors of hematopoietic tissue: lymphoma, histiocytic tumors
  D. Nerve sheath tumors
  E. Tumors of the sellar region
    1. Pituitary tumors: adenoma, adenocarcinoma
    2. Suprasellar germ cell tumors

II. Metastatic tumors
  A. Hemangiosarcoma
  B. Urogenital tumors: prostatic carcinoma, mammary gland adenocarcinoma
  C. Malignant melanoma
III. Secondary tumors of adjacent tissues
  A. Tumors arising from the calvaria: osteosarcoma, multilobulated tumor of bone
  B. Local extension of regional tumors
    1. Nasal tumor: adenocarcinoma, fibrosarcoma
    2. Tumors arising from the ear or osseous bullae: adenocarcinoma, squamous cell carcinoma

Pathophysiology

I. Direct effects of tumor growth include compression and invasion of normal brain parenchyma.
II. Indirect effects are often more significant than direct effects.
  A. Damage to the blood-brain barrier can result in cerebral edema.
  B. Obstruction to CSF flow causes secondary hydrocephalus.
  C. Brain herniation can occur as a result of increased intracranial pressure from an enlarging space-occupying mass within the rigid calvaria.
  D. Hemorrhage is also a possibility.

Clinical Signs

I. Breed predisposition has been reported for several tumors.
  A. Brachycephalic breeds (especially the boxer, English bulldog, and Boston terrier) are predisposed to gliomas (astrocytomas, oligodendrogliomas, mixed tumors) and pituitary tumors.
  B. Dolichocephalic dogs and Siamese cats may be predisposed to meningiomas.
II. Onset of disease may be acute or insidious, depending on the location, rate of growth, and indirect effects of the tumor.
III. Neurological signs reflect the location of the tumor.
  A. Cerebral or thalamic tumors (prosencephalic tumors) may cause seizures, circling, behavioral changes, contralateral postural reaction deficits, contralateral visual deficits, and contralateral nasal hypalgesia.
  B. Brainstem tumors can induce vestibular signs, ipsilateral postural reaction deficits, cranial nerve deficits, ataxia (both proprioceptive and vestibular), and changes in mentation.
  C. Cerebellar tumors can result in a wide stance; spastic, hypermetric gait (cerebellar ataxia); loss of balance; intention tremors; ipsilateral postural reaction deficits; and ipsilateral, absent menace response without visual deficits.
  D. Tumors of the floor of the calvaria may cause deficits of the oculomotor, trochlear, abducens nerves, and the ophthalmic branch of the trigeminal nerve.
    1. Disruption of the sympathetic innervation to the head may also occur.
    2. Clinical signs may include ophthalmoplegia, Horner's syndrome, mydriasis, and trigeminal sensory deficits involving the eye and the medial canthus.
IV. Metastatic tumors may involve single or multiple areas within the CNS and be associated with focal or multifocal signs.
V. Tumors involving the frontal and olfactory lobes of the cerebrum may cause seizures or changes in mentation without other deficits.

Diagnosis

I. A minimum database includes a CBC, biochemistry profile, urinalysis, and three radiographic views of the thorax.
II. MRI and CT may allow a presumptive diagnosis.
  A. Meningiomas often are extraaxial (on the periphery of the brain), have a broad-based attachment, and exhibit strong, homogeneous contrast enhancement.
  B. Glial tumors often are intraaxial (within brain parenchyma), display variable contrast enhancement, and occasionally have a ring-enhancement pattern.
  C. Choroid plexus tumors are located intraventricularly or at the cerebellomedullary angle and typically exhibit strong, uniform contrast enhancement.
  D. Tumors can occur in the ventricles, such as choroid plexus and ependymal tumors.
  E. Secondary consequences include compression of normal brain structures with shifting of midline structures, obstructive hydrocephalus, and cerebral (vasogenic) edema.
III. CSF analysis often reveals nonspecific abnormalities.
  A. An increased protein concentration and a normal cell count are typical.
  B. Neoplastic lymphocytes may be seen with lymphoma.
  C. Meningiomas may result in a neutrophilic pleocytosis from tumor necrosis.
  D. An increased risk of brain herniation is associated with elevated intracranial pressure and is a contraindication to CSF tap.
IV. Definitive diagnosis requires histopathologic evaluation.

Differential Diagnosis

I. Metabolic or toxic encephalopathies
II. Meningoencephalitis: infectious, noninfectious
III. Vascular disorders
IV. Other causes of seizures, altered mentation

Treatment and Monitoring

I. Certain treatments are directed at the secondary consequences.
  A. Osmotic diuretics are used to draw edema out of the brain.
    1. Give mannitol at 0.25 to 1.0 g/kg IV over 10 to 15 minutes.
    2. Administer furosemide (0.7 mg/kg IV) 15 minutes after mannitol to prolong the effects of mannitol.
    3. Administer hypertonic saline at 1.0 to 2.0 mL/kg IV over 10 to 15 minutes.

4. Repeat osmotic therapy up to every 6 hours unless the animal becomes dehydrated or hypovolemic.
5. Evaluate packed cell volume (PCV) and total solids (TS) before administration of osmotic therapy to evaluate hydration status.
6. Do not use osmotic therapy in dehydrated, hypovolemic animals, or in animals with decreased cardiac function.

B. Prednisone (0.5 to 1.0 mg/kg PO, IV) can be administered to reduce peritumoral (vasogenic) edema and inflammation.
C. Anticonvulsants are administered for seizures.
1. Phenobarbital (2.0 to 4.0 mg/kg PO, IM, IV BID) is usually the first option.
2. KBr (30 mg/kg PO SID) may also be added.
3. Animals with intracranial neoplasia may become extremely sedate with anticonvulsants.
4. Dosages less than the recommended amount may be used initially to avoid extreme sedation.

II. Definitive treatment includes surgery and/or radiation therapy.
A. Surgery allows for tumor resection or cytoreduction and provides a histological diagnosis.
B. Surgery often is reserved for tumors that are extraaxial (superficial), and more easily approached and removable.
C. Radiation therapy (alone or in combination with surgery) has been shown to increase survival time (Axlund et al., 2002; Bley et al., 2005).
D. Overall prognosis is fair to guarded and depends on the location and type of tumor.

CRANIAL TRAUMA

Definition and Causes

I. Neurological dysfunction secondary to head trauma is caused by brain contusion, laceration, edema, or hemorrhage.
II. Trauma may occur from a fall, automobile accident, or blunt or penetrating injuries.

Pathophysiology

I. Depressed skull fractures may cause compression and injury to underlying brain parenchyma.
II. Angular acceleration of the brain can cause diffuse, axonal injury.
III. The impact of the brain against the skull results in coup (occurring in tissue under the area of impact) and contrecoup injuries (occurring in tissue on the side opposite the impact).
IV. Hemorrhage and hematoma formation can compress brain parenchyma.
V. The end result is vasogenic edema of the brain.

Clinical Signs

I. Signs may be indicative of focal or diffuse brain disease.
II. Prosencephalic injury may result in loss of consciousness in severe cases, but more frequently leads to circling, altered mentation, and contralateral postural reaction deficits, blindness, and facial hypalgesia.
III. Brainstem injury typically causes altered mentation (depression, obtundation, or sometimes a comatose state), pupillary changes, and loss of conjugate eye movements
IV. Cerebellovestibular injury can result in dysmetria, cerebellar or vestibular ataxia, dysequilibrium, head tilt, and spontaneous or positional nystagmus.
V. Evidence of progressive clinical signs suggests cerebral edema, herniation, or hematoma formation.

Diagnosis

I. Signs of brain dysfunction in an animal known to have suffered an injury are suggestive.
II. Abrasions, penetrating wounds, or other evidence of head trauma are supportive.
III. Although difficult to interpret, radiographs may reveal skull fractures.
IV. MRI or CT can identify skull fractures, areas of hemorrhage, hematoma formation, and edema within the brain.

Differential Diagnosis

I. Other disorders are considered if trauma was not witnessed or if external evidence of trauma is absent.
II. Consider metabolic and toxic encephalopathies, as well as inflammatory, vascular, and neoplastic disorders.

Treatment and Monitoring

I. Nonspecific therapy is often initiated before or in conjunction with specific therapies.
A. Ensure airway patency, adequate ventilation, and stabilize cardiovascular function.
B. Institute fluid therapy to correct any hypovolemia and associated hypotension.
C. Provide oxygen to prevent further tissue hypoxia.
D. Turn recumbent animals every 6 hours, and keep them clean and well padded.
E. Provide nutritional support after they are stabilized.

II. Specific therapy is directed at reducing cerebral edema and intracranial pressure.
A. Recumbent animals are positioned with their heads slightly elevated (15 to 30 degrees).
B. Osmotic therapy is started for cerebral edema.
1. Mannitol 0.25 to 1.0 g/kg IV over 10 to 15 minutes
2. Hypertonic saline 7% 1 to 5 mL/kg IV over 3 to 5 minutes
3. Furosemide (0.7 mg/kg IV) can be given 15 minutes after mannitol to prolong its effect.
4. Osmotic therapy can be repeated every 6 to 8 hours unless dehydration or hypernatremia develops.
5. Electrolytes, PCV, and TS are monitored closely with osmotic therapy.

C. Osmotic therapy is contraindicated in hypovolemic animals and those with clinical signs suggestive of active intracranial hemorrhage.
D. Surgery is indicated for depressed skull fractures or if the animal's condition deteriorates despite medical management.

III. Prognosis depends on the severity and location of the injury.
IV. Although most improvements are seen within the first month of the injury, recovery may take weeks to months.
V. Long-term sequelae may include seizures and persistent neurological deficits.

CHAPTER 24

Disorders of the Spinal Cord

Simon R. Platt

CONGENITAL AND DEVELOPMENTAL DISORDERS

Atlantoaxial Subluxation

Definition

I. Instability or malformation of the atlantoaxial joint allows excessive flexion of the cervical (C) 1-2 vertebral joint.
II. Subsequent ventral cord compression occurs from the cranial aspect of the body of the axis.

Causes and Pathophysiology

I. It most commonly occurs in young, toy, and small-breed dogs (<2 years).
II. Subluxation is often associated with failure of normal structural development of the atlas, axis, and their supporting ligaments.
III. It can occur following minor trauma in the presence of joint instability.
IV. Clinical signs arise from concussion and compression of the spinal cord by the axis.

Clinical Signs

I. Onset is usually acute; however, signs can be slowly progressive and may wax or wane.
II. Neck pain occurs in at least 60% of cases (Beaver et al., 2000).
III. Ataxia, tetraparesis, postural reaction deficits, with normal to exaggerated spinal reflexes occur in 85% of cases (Beaver et al., 2000).
IV. Animals with tetraplegia are at risk of death from respiratory failure.
V. Occasionally, signs of brainstem dysfunction are seen.

Diagnosis

I. Confirm the diagnosis with lateral survey radiographs of the cervical spine.
II. Note an increased space between the dorsal lamina of C1 and the spinous process of the C2.
III. Use ventrodorsal views to assess most accurately the presence and size of the dens.
IV. Flex the neck carefully to confirm instability, if subluxation is not readily apparent.
V. Computed tomography (CT) can provide accurate information about the dens.
VI. Magnetic resonance imaging (MRI) can provide important information about spinal cord compression, parenchymal pathology, and ligamentous involvement.

Differential Diagnosis

I. Trauma
II. Intervertebral disc disease
III. Meningomyelitis: various forms

Treatment

I. Treat cases with acute onset of severe neurological signs with external head and neck splinting.
II. Conservative therapy may be appropriate for some dogs with mild signs.
III. Apply external splinting and restrict exercise strictly for 6 to 8 weeks.
   A. Long-term efficacy of this approach is uncertain.
   B. Dogs are always at risk of repeated injury following splint removal.
IV. Surgical management is recommended for dogs with neurological deficits.
   A. Dorsal and ventral approaches to the atlanto-axial junction have been described (McCarthy et al., 1995; Platt et al., 2004).
   B. Surgery is aimed at realignment of the vertebrae, decompression of the spinal cord, and osseous fusion of the atlantoaxial joint.
   C. Surgical complications include injury to soft tissues, laryngeal paralysis, implant failure, and death in up to 20% of cases (Beaver et al., 2000).

Monitoring of Animal

I. Nonsurgical approach is most successful in dogs that are affected for ≤30 days (Havig et al., 2005).
II. Surgical success ranges from 50% to 90% (McCarthy et al., 1995; Beaver et al., 2000).
III. Prognosis is better in young dogs (<24 months) and in those with clinical abnormalities for ≤10 months (Beaver et al., 2000).
IV. Prognosis is fair to good for those with mild to moderate neurological deficits, and guarded for those with an acute onset of tetraplegia.
V. Radiographs repeated 6 to 8 weeks after surgery may help determine the presence of osseous healing.

Congenital Vertebral Anomalies

Definition

I. Several distinct types of malformation are recognized.
II. Hemivertebrae are wedge-shaped, with the apex directed dorsally, ventrally, or medially across the midline, which often results in angulation of the vertebral column.
III. Block vertebrae appear as fusion of adjacent vertebrae, which may involve the vertebral bodies, vertebral arches, dorsal spinous processes, or entire vertebrae at any level of the vertebral column.
IV. Butterfly vertebrae have a sagittal cleft in the vertebral body.
V. Transitional vertebrae have the characteristics of, and occur at, two major divisions of the vertebral column.

Causes and Pathophysiology

I. Vertebral malformations are the result of a disturbance in embryonic development.
II. Hemivertebrae are inherited in the German shorthaired pointer, English bulldog, and Yorkshire terrier.
III. High prevalence of hemivertebrae and butterfly vertebrae occurs in the French bulldog, pug, and Boston terrier.

Clinical Signs

I. Most congenital malformations of the vertebrae cause no clinical signs.
II. Spinal cord compression can occur from canal stenosis, vertebral malalignment, or instability.
III. Hemivertebrae are most commonly associated with clinical signs.
IV. Signs are often slowly progressive, owing to the chronic compression.
V. Neurological deficits are consistent with a transverse myelopathy and include the following:
   A. Conscious proprioception deficits
   B. Ataxia
   C. Paresis or paralysis

Diagnosis

I. Confirmation of a vertebral anomaly is done by survey radiography.
II. Myelography is useful for determining the extent of associated cord compression or stenosis.
III. MRI is valuable in determining associated spinal cord compression or concurrent spinal cord anomalies.

Differential Diagnosis

I. Compression caused by traumatic or pathologic vertebral fractures
II. Vertebral neoplasia
III. Healed osteomyelitis (diskospondylitis)

Treatment

I. If clinical signs are nonprogressive, conservative management is recommended.
II. Surgical decompression combined with stabilization is recommended for progressive clinical signs from spinal cord compression.

Monitoring of Animal

I. Prognosis is good if the defect is an incidental finding; vertebral anomalies can become clinical later in life.
II. Prognosis is guarded with chronic, progressive cord compression.

Spina Bifida

Definition

I. Spina bifida is characterized by a midline cleft in the vertebral arch.
II. Spina bifida occulta indicates that the spinal cord and meninges are normal.
III. Clinical spina bifida is accompanied by a meningocele or a meningomyelocele.
IV. Meningocele is a protrusion of the meninges through the vertebral cleft.
V. Meningomyelocele is a protrusion of the meninges and spinal cord through the vertebral cleft.

Causes and Pathophysiology

I. Spina bifida is likely the result of abnormal development of the neural tube.
II. Teratogenic compounds, nutritional deficiencies, and environmental factors may be associated with spina bifida.
III. A high incidence in the bulldog and Manx cats suggests a heritable cause.
IV. In Manx cats and bulldogs, there is an association with sacrocaudal dysgenesis.
V. In the Manx, an autosomal-dominant condition leads to absence of the tail and to several sacral-related abnormalities.

Clinical Signs

I. Spina bifida is rarely associated with clinical signs.
II. When present, signs vary with the degree of spinal cord and meningeal involvement.
III. Most lesions occur in the caudal lumbar region, but can occur in any vertebra.
IV. Physical examination may reveal abnormal directions of hair growth, a skin dimple, or an open tract draining cerebrospinal fluid (CSF) at the site of the lesion.
V. Fistulous meningocele can cause hypochloremia and hyponatremia subsequent to CSF loss.

Diagnosis

I. Caution must be used when attributing clinical signs to a vertebral anomaly.
II. Dorsoventral radiographs of the vertebral column may reveal an absence of the spinous process(es).
III. CT is useful for confirmation of subtle lesions.
IV. Myelography may detect a meningocele.
V. MRI may detect specific spinal cord changes and is advised before surgical intervention.

Differential Diagnosis

I. Other congenital spinal cord anomalies
II. Meningomyelitis

Treatment and Monitoring

I. Treatment is not necessary for spina bifida occulta.
II. Meningoceles can be surgically resected in cases without concurrent spinal cord lesions.
III. Tethered spinal cord syndrome can be treated surgically by severing the filum terminale.
IV. Surgical closure of spina bifida aperta, removal of the fistulous tract, and broad-spectrum antibiotics may be necessary to reduce the incidence of bacterial meningomyelitis.
V. Prognosis is poor in cases with fecal and urinary incontinence, or severe neurological deficits.
VI. Frequent bladder and bowel expression may be necessary in some cases.

Myelodysplasia

Definition

I. Myelodysplasia refers to a variety of embryologic abnormalities of the spinal cord.
II. A specific form of myelodysplasia, spinal dysraphism, maybe hereditary in Weimaraners.

Causes and Pathophysiology

I. Myelodysplasia results from incomplete closure or development of the neural tube.
II. Anomalies of the central canal include hydromyelia, duplication, or absence of the canal.
III. Anomalies of the grey matter involve the ventral median fissure or dorsal median septum.
IV. Grey matter ectopias, chromatolysis, and loss of nerve cell bodies may also be present.
V. Syringomyelia is a fluid dilatation, usually in the dorsal funiculus of the spinal cord.
VI. With the exception of the Weimaraner, the pathogenesis of this condition is unknown.

Clinical Signs

I. The most common sign is a symmetrical, "bunny hopping" pelvic limb gait.
II. A variable transverse thoracolumbar myelopathy usually occurs in young animals (4 to 6 weeks), which is typically nonprogressive.
   A. Proprioception deficits
   B. Ataxia
   C. Paresis or paralysis
III. A classic finding is a bilateral flexor reflex in the pelvic limbs (both limbs respond to stimulation of one limb).
IV. In Weimaraners, myelodysplasia may be associated with abnormal hair "streams" on the dorsum and koilosternia.

Diagnosis

I. A tentative diagnosis is made on the basis of history, signalment, and clinical signs.
II. Radiographs, CSF analysis, CT, and MRI are usually normal.
III. MRI can detect the presence of hydromyelia and syringomyelia.

Differential Diagnosis

I. Vertebral malformation
II. Spina bifida
III. Myelitis

Treatment and Monitoring

I. No effective treatment exists.
II. Prognosis varies with severity of the clinical signs.

Syringomyelia and Hydromyelia

Definition

I. Hydromyelia is a fluid dilatation of the central canal.
II. Syringomyelia is a fluid dilatation in the spinal cord that may communicate with the central canal.
III. It is often difficult to distinguish between these two conditions.

Causes and Pathophysiology

I. Both conditions can be a secondary, long-term complication of any spinal cord disease.
II. Any condition that causes obstruction of normal CSF flow along the spinal cord can cause these abnormalities.
III. They are most commonly seen in the cervical region, but lesions can occur in any portion of the spinal cord.
IV. Cervical syringohydromyelia occurs as a component of congenital anomalies associated with caudal occipital malformation syndrome, which is most commonly reported in the Cavalier King Charles spaniel, but can be seen in other small breed dogs.
V. Occipital bone malformation causes "overcrowding" of the caudal fossa that interferes with the normal flow of CSF between the intracranial and spinal compartments.

Clinical Signs

I. Clinical signs vary with lesion location.
II. Signs are often progressive, but can be acute and can occur at any age.
III. Clinical signs do not correlate with the severity of the syringohydromyelia or with the concurrent severity of cerebellar herniation and hydrocephalus (Lu et al., 2003).
IV. Typical signs consistent with a transverse myelopathy include the following:
   A. Proprioception deficits
   B. Ataxia
   C. Paresis or paralysis
V. Additional signs include pain, paresthesia, spinal deformity (torticollis, scoliosis), and persistent flank scratching (Rusbridge et al., 2000).

Diagnosis

I. MRI is essential to document parenchymal changes and associated lesions, such as occipital malformation.
II. Survey radiographs are usually normal unless concurrent scoliosis is present.
III. Myelography may show obstruction of the flow of CSF at the foramen, but is often normal.

IV. Cisterna magna puncture is contraindicated given the likelihood of inadvertent puncture of the spinal cord.
V. Lumbar CSF analysis may show chronic inflammation, but is frequently normal.

Differential Diagnosis

I. Other developmental disorders
II. Intervertebral disc disease
III. Meningomyelitis
IV. Neoplasia

Treatment

I. Medical therapy involves antiinflammatories (prednisone 0.5 to 1.0 mg/kg PO SID and carprofen 2.0 mg/kg PO BID).
II. A diuretic, such as acetazolamide (10 mg/kg PO TID to QID), may be used concurrently on a short-term basis to reduce CSF production.
III. Gabapentin (10 mg/kg PO BID) can be used for neuropathic pain and paraesthesia.
IV. Physical therapy (e.g., massage, passive range-of-motion exercises) may be helpful.
V. Surgical therapy can be performed in cases of caudal occipital malformation syndrome.
   A. Foramen magnum decompression with dura and arachnoid excision is preferred for syringohydromyelia associated with occipital malformation syndrome (Vermeersch et al., 2004).
   B. Myelotomy with syrinx decompression and marsupialization of the dura can be used for treatment when the condition is related to other causes.

Monitoring of Animal

I. Medical therapy may be effective in mildly affected animals.
II. Surgical therapy aims to stabilize the condition rather than improve it.
III. Surgical therapy often alleviates neck pain.
IV. Recurrence of signs from reformation of the syrinx requires repeated surgery.
V. Overall prognosis depends on the severity of signs.

Spinal Intraarachnoid Cysts

Definition

I. These lesions are CSF-filled diverticuli of the arachnoid membrane rather than true cysts.
II. Synonyms include *subarachnoid cyst, meningeal cyst,* and *leptomeningeal cyst.*

Causes and Pathophysiology

I. Most commonly a congenital malformation, these lesions may be secondary to trauma, inflammation, subarachnoid hemorrhage, and neoplasia.
II. The intraarachnoid accumulation of CSF in the diverticulum results in compression of the spinal cord.
III. Typically solitary lesions occur commonly at the C2 to C3 and C5 to C6 intervertebral sites or in the caudal thoracic region; however, they can occur at any site (Jurina et al., 2004).
IV. The diverticuli are usually located dorsally over the spinal cord.

Clinical Signs

I. They can occur as an incidental finding.
II. They are most commonly seen in the cranial cervical cord of young adult, large-breed dogs, particularly rottweilers, or in the thoracolumbar spinal cord of older, smaller breeds (e.g., pug) (Rylander et al., 2002; Skeen et al., 2003).
III. Signs usually consist of a chronic and progressive transverse myelopathy.
   A. Proprioception deficits
   B. Ataxia
   C. Paresis or paralysis
IV. Neurological deficits may be asymmetrical and pain is a variable feature.
V. Dogs may have early onset of fecal or urinary incontinence (Skeen et al., 2003).

Diagnosis

I. Survey radiographs are unremarkable.
II. Myelography reveals a focal "tear-drop" accumulation of contrast medium in the subarachnoid space or an intradural filling defect.
III. Contrast-enhanced CT or MRI demonstrates the CSF-filled diverticulum within the arachnoid membrane and spinal cord compression.
IV. MRI can also identify associated parenchymal abnormalities, especially in rottweilers.
V. Surgical findings and histopathology of excised tissues confirm the diagnosis.

Differential Diagnosis

I. Cystic neoplasms
II. Meningomyelitis
III. Other developmental disorders
IV. Intervertebral disc disease

Treatment

I. Medical therapy may improve a small proportion of dogs and is only recommended in cases with mild neurological deficits.
II. Medical therapy involves antiinflammatory drugs and exercise restriction.
   A. Prednisone 0.5 to 1.0 mg/kg PO SID
   B. Carprofen 2.0 mg/kg PO BID
III. Surgical exploration is used to confirm the diagnosis and decompress the spinal cord.
IV. Complete surgical excision is usually not possible.
V. Partial excision (fenestration) and marsupialization of the dura is recommended.

Monitoring of Animal

I. Depending of the degree of signs, the overall prognosis is good following surgery.

II. Factors associated with a good outcome include an age <3 years and duration of clinical signs <4 months (Skeen et al., 2003).
III. Recurrence of signs from reformation of the diverticulum is possible.
IV. Lifelong antiinflammatory therapy has been advised in some cases.

Dermoid Sinus

Definition

I. A dermoid or pilonidal sinus is an invagination of the skin, dorsal to the spine, that extends below the skin to variable depths.
II. It can extend to the dura mater and may communicate with the subarachnoid space.

Causes and Pathophysiology

I. Sinus formation results from a failure of separation of the neural tube from the ectoderm.
II. An autosomal dominant mutation causing the presence of a dorsal ridge predisposes for dermoid sinus formation in the Rhodesian ridgeback.
III. Communication with the subarachnoid space predisposes to meningomyelitis.

Clinical Signs

I. Signs depend on location, with most occurring in the cervical region.
II. Clinical signs of meningitis and myelitis may be seen as a result of extension of infection.
III. Localized or generalized spinal pain and rigidity may occur with meningitis.
IV. Neurological deficits indicative of a transverse myelopathy may occur from myelitis.
    A. Proprioception deficits
    B. Ataxia
    C. Paresis or paralysis

Diagnosis

I. A dermoid sinus may be palpable or visualized as an opening of the skin on the dorsum.
II. Fistulography can be used to determine communication with the spinal canal.
III. CSF analysis can identify meningitis.
IV. Myelography identifies communication with CSF or compression of the spinal cord.
V. MRI defines the extent of the sinus and secondary compression of the spinal cord.

Differential Diagnosis

I. Meningomyelitis
II. Neoplasia
III. Intervertebral disc disease
IV. Other congenital or developmental anomalies of the vertebrae or spinal cord

Treatment and Monitoring

I. Antimicrobial therapy is indicated for meningomyelitis based on culture and sensitivity results.
II. Surgical excision, possibly combined with laminectomy, is warranted in symptomatic cases.
III. Prognosis is excellent in cases with no communication between the sinus and spinal cord.

Storage Disorders

Globoid Cell Leukodystrophy

See Chapter 23, Table 23-2.

Mucopolysaccharidosis

See Chapter 23, Table 23-2.

Degenerative Disorders

Intervertebral Disc Disease

Definition

I. Intervertebral disc disease (IVDD) implies degeneration of the intervertebral disc structures and subsequent herniation of disc material into the vertebral canal.
II. Extrusion of the nucleus pulposus through the annulus fibrosis is a Hansen type I lesion.
III. Protrusion of the annulus caused by shifting of nucleus pulposus is a Hansen type II lesion.
IV. Explosive disc disease that occurs peracutely, without compression, is a type III or high-velocity low-volume disc herniation.

Causes and Pathophysiology

I. Type I disc disease commonly affects chondrodysplastic breeds (e.g., dachshund, beagle, Pekingese, Lhasa apso, shih tzu) and chondrodystrophic-like breeds (e.g., American and English cocker spaniel, miniature poodle) (Cherrone et al., 2004).
    A. Type I disc disease is most commonly associated with chondroid disc degeneration.
    B. Disc degeneration occurs in 75% to 100% of all discs by 1 year of age in chondrodystrophoid breeds (Morgan and Miyabayashi, 1988).
    C. Type I disc disease is associated with an acute onset of signs.
    D. Often there is mineralization of the nucleus pulposus.
II. Type II disc disease commonly affects older, large-breed, achondrodystrophic dogs.
    A. Type II disc disease is associated with degeneration characterized by fibrous metaplasia of the nucleus pulposus.
    B. Type II disc disease causes slow, progressive spinal cord compression.
III. Although uncommon in cats, type I disc disease occurs most frequently (Munana et al., 2001).

Clinical Signs

I. Type I disc disease typically occurs in dogs between 3 and 5 years of age.

II. Type II disc disease typically occurs in dogs between 6 and 9 years of age.
III. On average, affected cats are 10 years of age (Munana et al., 2001).
IV. Signs reflect the region of the affected spinal cord.
V. Cervical disc disease accounts for 15% of cases (Coates, 2000).
VI. Thoracolumbar (T-L) disc disease accounts for 85% of cases (Coates, 2000).
VII. Thoracolumbar disc disease typically occurs between T11 to L3 vertebrae.
VIII. Severity of signs ranges from pain, paresis and ataxia, loss of motor abilities, or loss of nociception (deep pain perception).
IX. IVDD most commonly causes a transverse myelopathy.
  A. Proprioception deficits
  B. Ataxia
  C. Paresis and paralysis
X. Asymmetrical clinical signs are often seen.
XI. Cervical disease usually results in less-severe clinical signs than thoracolumbar disease.
  A. Apparent neck pain is the most common clinical sign with cervical disc disease.
  B. Nonambulatory tetraparesis is more common in large-breed dogs with cervical disease than small-breed dogs (Cherrone et al., 2004).
  C. Lower motor neuron (LMN) deficits or monoparesis can be seen with caudal cervical disc disease.
XII. LMN deficits may be seen in the pelvic limbs with herniations caudal to L3 that cause compression of the lumbosacral spinal cord or cauda equina.
XIII. Progressive hemorrhagic myelomalacia occurs in up to 11% of dogs that have lost nociception (Olby et al., 2003).
  A. The lesion may ascend, resulting in cranial progression of analgesia, and ultimately cause tetraplegia and respiratory failure.
  B. The lesion may descend, resulting in LMN signs in the pelvic limbs, as well as urinary and fecal incontinence.

Diagnosis

I. Spinal radiographs may be suggestive of disc herniation or be normal.
  A. Characteristic findings include a narrowed or wedged intervertebral disc space, small intervertebral foramen with narrowed articular processes, or mineralized disc material in the vertebral canal.
  B. Type I disease is not associated with spondylosis, although spondylosis may be associated with type II disease (Levine et al., 2006).
II. Myelography is important for determining the site (or sites) of disc herniation before surgery.
  A. Characteristic findings include extradural spinal cord compression or diffuse spinal cord swelling.
  B. Myelography may be normal when there is lateral or intraforaminal extrusion.
III. CSF analysis is needed before myelography.
IV. CT can accurately identify the site and lateralization of type I disc herniation, without the need for concurrent myelography (Olby et al., 2000).
V. MRI is extremely sensitive in localizing disc disease, extradural compressions, and associated parenchymal disease (Ito et al., 2005; Besalti et al., 2006; Chang et al., 2006)

Differential Diagnosis

I. Type I disc disease
  A. Trauma
  B. Diskospondylitis
  C. Atlantoaxial subluxation
  D. Fibrocartilaginous embolic myelopathy
  E. Meningomyelitis
II. Type II disc disease
  A. Neoplasia affecting the spinal cord
  B. Degenerative myelopathy
  C. Myelitis
  D. Orthopedic disease

Treatment

I. Medical therapy
  A. Medical therapy is reserved for cases with only pain or cases with mild, nonprogressive neurological deficits.
  B. Medical therapy consists of corticosteroid or nonsteroidal antiinflammatory therapy.
    1. Prednisone 0.5 to 1.0 mg/kg PO, IV SID, tapered over 1 to 2 weeks
    2. Carprofen 2.0 mg/kg PO BID
  C. Consider concurrent use of centrally acting muscle relaxants for 1 to 2 weeks (diazepam 0.25 mg/kg PO TID).
  D. Strict exercise restriction is of equal importance and is done concurrently for 4 to 6 weeks.
II. Surgical therapy
  A. Surgery is considered for cases with severe motor dysfunction or recurrent, refractory spinal pain.
  B. Rapid decompression is undertaken to avoid further damage to the spinal cord from continued compression.
  C. Cervical lesions are decompressed via a ventral slotting technique for ventral midline lesions.
  D. Lateralized cervical disc herniation can be treated via a dorsal or modified lateral laminectomy (Rossmeisl et al., 2005).
  E. Thoracolumbar lesions cranial to L4 are decompressed via a dorsolateral hemilaminectomy.
  F. Lesions caudal to L4 are decompressed via a dorsal laminectomy.
  G. Postoperatively, exercise restriction is continued for 4 to 6 weeks.
  H. Bladder care, such as manual expression, catheterization, and pharmacological manipulation is crucial to reduce the potential for detrusor muscle atony and secondary urinary tract infections.
III. Methylprednisolone sodium succinate therapy
  A. High doses of methylprednisolone sodium succinate *(Solu-Medrol)* have been used in acute disc disease as a component of medical or surgical therapy.

B. Contradictory data exist on its efficacy when administered within 8 hours of the onset of the disc extrusion (Olby et al., 1999).
C. The recommended dose is 30 mg/kg IV followed 2 and 6 hours later by 15 mg/kg IV and continued QID for a maximum of 48 hours.
D. Potential side effects include pancreatitis, gastrointestinal hemorrhage, diarrhea, and colonic perforation.

Monitoring of Animal

I. Recovery of nonambulatory dogs varies according to the time interval from onset of signs to surgery, initial severity of neurological dysfunction, and speed of onset of signs.
II. The prognosis is good for dogs with mild to moderate sensory and/or motor deficits.
III. Success rates following cervical disc surgery range from 87% to 100%, whereas success following thoracolumbar disc surgery range from 58% to 95% (Coates, 2000).
IV. Recovery rates with medical therapy in nonambulatory dogs with thoracolumbar disc disease range from 43% to 51% (Coates, 2000).
V. Paraplegic dogs with loss of nociception have a 69% chance of recovering the ability to walk and a 58% chance of recovering nociception, if treated within 48 hours of onset of signs (Olby et al., 2003).
VI. The return of nociception within 2 weeks of surgery is a good prognostic indicator for recovery (Olby et al., 2003; Laitinen and Puerto, 2005)
VII. Recurrence rates after surgery range from 2.7% to 41.7% with thoracolumbar IVDD (Coates, 2000).
VIII. Recurrence rates after surgery range from 10% to 33% with cervical IVDD (Cherrone et al., 2004).
IX. Recurrences usually (96%) develop within 3 years of the initial event (Mayhew et al., 2004).
X. Recurrence rates of 34% to 40% have been reported following conservative therapy, with an average interval to recurrence of 1.7 years (Coates, 2000).

Cervical Spondylomyelopathy

Definition

I. Cervical vertebral malformation or malarticulation results in compression of the cervical spinal cord segments.
II. Synonyms include wobbler syndrome, caudal cervical malformation-malarticulation, cervical spondylopathy, cervical vertebral instability, and cervical vertebral stenosis.

Causes and Pathophysiology

I. The etiology remains undetermined.
II. It commonly affects male, large to giant breeds of dogs.
III. Genetic factors are suspected for the Doberman pinscher and Great Dane.
IV. Clinical disease occurs most frequently in young Great Danes (<2 years) and middle-aged Doberman pinschers (3 to 9 years).
V. The C5-C6 and C6-C7 vertebrae and discs are affected most commonly.
VI. Compression of the spinal cord can be static or dynamic.
A. Great Danes most commonly have a static compression from dorsal or dorsolateral osseous malformation (Abramson et al., 2003).
B. Dobermans most commonly have a ventral dynamic compression, and possibly dorsal soft-tissue hypertrophy.
1. Dorsal compression occurs from hypertrophy of the ligamentum flavum and joint capsules.
2. Ventral compression occurs from annulus hypertrophy and dorsal longitudinal ligament pathology.

Clinical Signs

I. Clinical signs reflect chronic compression of the cervical spinal cord.
II. Onset of clinical signs is gradually progressive over several months or years; however, acute onset is occasionally seen.
III. Initial signs usually begin in the pelvic limbs and progress to tetraparesis.
IV. Signs usually reflect a C1-C5 or C6-T2 myelopathy.
V. Neck pain is uncommon, although the dogs may resist movement of the neck.

Diagnosis

I. Survey radiography may be normal or show a variety of pathologic changes.
II. Radiographic changes include malalignment remodeling and sclerosis of the vertebrae, narrowing of the intervertebral disc (IVD) space, degenerative changes of the articular facets, and spondylosis.
III. Myelography is essential to determine neural involvement, and to identify static and dynamic lesions.
IV. CT or MRI can identify spinal cord compression and atrophy, as well as parenchymal pathology secondary to chronic compression.

Differential Diagnosis

I. Intervertebral disc disease
II. Neoplasia affecting the spinal cord
III. Myelitis
IV. Trauma
V. Diskospondylitis

Treatment

I. Therapy for dogs with mild clinical signs is conservative.
A. Prednisone 0.5 to 1.0 mg/kg PO SID
B. Carprofen 2.0 mg/kg PO BID
C. Exercise restriction
D. Dietary protein restriction in young Great Danes
II. Surgical therapy is often used for moderately to severely affected dogs.
III. The primary objectives of all surgical procedures are to decompress the spinal cord and/or stabilize of the affected vertebrae.
IV. Available surgical techniques include ventral slotting; ventral distraction and fusion, with or without ventral slotting; or continuous dorsal laminectomy (De Risio et al., 2002).

V. The high potential for morbidity and postoperative complications must be considered and discussed with the owner.

Monitoring of Animal

I. Most affected dogs require surgical therapy for long-term relief.
II. The prognosis with surgery depends on the number of sites affected, chronicity, and neurological status of the dog; it can vary from 20% to 80%.
III. Recurrence can occur from implant failure or adjacent disc disease (domino effect).

Spondylosis Deformans

Definition

I. Spondylosis deformans is a chronic, degenerative, noninflammatory disease characterized by the production of osteophytes on the spine that result in the formation of spurs or complete bony ridges across the intervertebral disc space.
II. Ankylosing spondylosis and ankylosing spondylitis are sometimes used synonymously; however, ankylosis is uncommon and the condition is not inflammatory.

Causes and Pathophysiology

I. Osteophyte production occurs in response to degenerative changes in the intervertebral discs.
II. The changes may be secondary to aging and trauma.
III. The disease has been reported in dogs >2 years of age, with 75% of dogs affected to some extent by 9 years of age (Levine et al., 2006).
IV. Because of the high prevalence in female boxers, it is possibly an inherited disease; however, all dog breeds can be affected.
V. The caudal thoracic, lumbar, and lumbosacral spinal segments are most frequently affected in dogs, and the highest incidence occurs at the level of T7-T8 in cats.
VI. An association may exist between radiographically apparent spondylosis and type II disc disease (Levine et al., 2006).

Clinical Signs

I. Compression of the cord or spinal nerves from osteophytic projections into the spinal canal is rare.
II. Rarely, compression of neural tissue may result in a transverse myelopathy or neuropathy.

Diagnosis

I. Diagnosis is based on radiographic identification of osteophyte formation on the ventral surface (in the region of the metaphysis) of the vertebral body or bodies.
II. Osteophytes may occur at either normal or narrowed disc spaces.
III. Myelography can detect associated spinal cord compression and its cause.
IV. CT or MRI helps identify spinal cord compression or foraminal stenosis.

Differential Diagnosis

I. Diskospondylitis
II. Trauma
III. Intervertebral disc disease

Treatment and Monitoring

I. Treatment is usually not necessary.
II. Analgesia and exercise restriction may help dogs that exhibit only discomfort.
III. Surgical decompression may be necessary in cases with clinical signs.
IV. If clinical, the prognosis is guarded owing to the high risk of recurrence.

Spinal Synovial Cyst

Definition

Spinal extradural synovial cysts arise from the articular facets and surrounding connective tissues of the cervical and thoracolumbar vertebrae of dogs.

Causes and Pathophysiology

I. The cysts commonly occur in the cervical spine of young, large-breed dogs and in the thoracolumbar spine of older, large-breed dogs (Dickinson et al., 2001b).
II. Occurrence has been associated with degenerative disc disease and trauma.
III. Increased mechanical stress and joint motion may predispose the thoracolumbar junction to osteoarthritis and synovial cyst formation.
IV. Histopathology of the cyst reveals fibrous connective tissue with a synovial cell lining.

Clinical Signs

I. Clinical signs are consistent with a transverse myelopathy at the site of the lesion.
II. Signs include proprioception deficits, ataxia, paresis or paralysis, often accompanied by paraspinal hyperesthesia.

Diagnosis

I. Degeneration and remodeling of the articular processes are seen at the site of the lesion.
II. Myelography demonstrates spinal cord compression.
III. CT and MRI better define the lesion.

Differential Diagnosis

I. Spinal stenosis
II. Intervertebral disc disease
III. Cervical spondylomyelopathy
IV. Neoplasia

Treatment and Monitoring

I. Surgical decompression of the spinal cord with cyst removal is indicated in dogs with neurological deficits or refractory pain.
II. Recurrence rates are unknown, but surgery usually provides long-term resolution of signs (Dickinson et al., 2001b).

Spinal Stenosis

Definition

I. Spinal stenosis indicates a narrowing of the vertebral canal that may be focal, segmental (affecting several adjacent vertebrae), or generalized (present throughout the vertebral column).
II. Bony impingement on neural elements may be congenital, developmental, acquired, or idiopathic.
III. Compression of neural tissue occurs by nonosseous components of the vertebral canal.
IV. Hypertrophy of the dorsal, longitudinal ligament and the ligamentum flavum may be involved.
V. Disc extrusion or protrusion may occur.

Causes and Pathophysiology

I. Congenital stenosis may occur as a primary lesion or may be seen in association with other congenital vertebral anomalies.
II. Segmental vertebral stenosis occurs in the cranial thoracic spine of several dog breeds (e.g., Doberman pinscher).
III. Developmental stenosis may result from inborn errors of skeletal growth in dogs.
IV. Hypertrophy of the nonosseous components of the vertebral canal has been reported in rottweilers secondary to ligamentous proliferation at C2-C3.

Clinical Signs

I. Clinical signs reflect the location of the lesion, regardless of the precise cause.
II. Onset of signs is usually insidious and progressive.

Diagnosis

I. Diagnosis can be made by survey radiography.
II. Myelography is essential for precise localization of the spinal stenosis.
III. CT or MRI may aid in identification of the location and the extent of soft tissue and parenchymal involvement (Abramson et al., 2003).

Differential Diagnosis

I. Other congenital anomalies of the vertebrae
II. Intervertebral disc disease
III. Cervical spondylomyelopathy
IV. Spinal synovial cysts

Treatment and Monitoring

I. Conservative therapy may be appropriate in mildly affected cases.
   A. Prednisone 0.5 to 1.0 mg/kg PO SID
   B. Carprofen 2.0 mg/kg PO BID
   C. Exercise restriction
II. Decompressive surgery is indicated in animals with persistent pain or progressive neurological deficits.

Osteochondromatosis

Definition

I. A skeletal osteochondroma is a cartilage-capped exostosis arising from the surface of a bone formed by endochondral ossification.
II. Synonyms include multiple or solitary cartilaginous exostoses, hereditary multiple exostoses, multiple osteochondromatosis, diaphyseal aclasis, dyschondroplasia, and hereditary deforming chondrodysplasia.

Causes and Pathophysiology

I. Outgrowths are related to the metaphysis of growing bones in the appendicular and axial skeleton, particularly affecting vertebrae.
II. Feline osteochondromatosis is seen in mature cats (2 to 4 years) in association with feline leukemia virus (FeLV) and feline sarcoma virus.
III. Canine osteochondromatosis is usually seen before 18 months of age and may have an hereditary basis.
IV. Malignant transformation has been reported.

Clinical Signs

I. Clinical signs reflect the location of any vertebral exostosis producing a transverse myelopathy (if there is associated cord compression).
   A. Proprioception deficits
   B. Ataxia
   C. Paresis or paralysis
II. Lesion may result in asymmetrical signs.
III. Pain may be the only clinical sign.

Diagnosis

I. Radiographically, vertebral lesions tend to be circular and smooth with sclerotic borders and are often radiopaque, with radiolucent areas.
II. Myelography is necessary to demonstrate associated spinal cord compression.
III. CT may better define the extent of the bony proliferation within the vertebral canal.
IV. Surgical biopsy is necessary to confirm the diagnosis.

Differential Diagnosis

I. Benign bone tumors: osteomas
II. Neoplasia
III. Osteomyelitis

Treatment

I. Asymptomatic lesions do not require treatment.
II. Surgical excision is indicated if spinal cord compression is causing neurological signs.

Monitoring of Animal

I. For dogs, prognosis varies with severity of signs.
II. The prognosis for dogs having reached skeletal maturity is better than for immature dogs.

III. The prognosis for cats concurrently infected with FeLV is guarded because of increased risk of recurrence.

Degenerative Myelopathy

Definition

I. It is a slowly progressive noninflammatory disease of the spinal cord consisting of axonal degeneration and demyelination.
II. It is synonymous with *chronic degenerative radicular myelopathy.*

Causes and Pathophysiology

I. The etiology remains unknown.
II. Immune-related degeneration has been proposed.
III. German shepherd dogs may have a genetic predisposition.
IV. Pathologic changes have been identified throughout the spinal cord, as well as in the red, lateral vestibular, and dentate nuclei (Johnston et al., 2000).
V. Lesions are most prominent in thoracic segments of the spinal cord.

Clinical Signs

I. Signs are usually nonpainful, insidious, progressive ataxia and paraparesis of the pelvic limbs that ultimately leads to bladder incontinence and paraplegia over 6 to 12 months.
II. It occasionally (10% to 20%) causes reduced patella reflexes from dorsal nerve root involvement (Averill, 1973).
III. Nociception (deep pain perception) is usually unaffected.
IV. It occurs most frequently in the German shepherd dog, and is also recognized in the Pembroke Welsh corgi, boxer, and other breeds.
V. It is rare in cats.
VI. Average age of affected dogs is 9 years old; dogs younger than 5 years are rarely affected (Longhofer et al., 1990).

Diagnosis

I. Tentative antemortem diagnosis is based on classic clinical signs and the exclusion of other diseases.
II. An increased protein level may be found in lumbar CSF.
III. CT and myelography reveal spinal cord atrophy (Jones et al., 2005).

Differential Diagnosis

I. Intervertebral disc disease
II. Neoplasia
III. Myelitis
IV. Orthopedic disease

Treatment and Monitoring

I. Effective treatment has not been reported.
II. Medical treatments that have been advised but not proven include the following:
   A. Aminocaproic acid 500 mg PO TID
   B. N-acetylcysteine 70 mg/kg PO TID for 2 weeks then TID every other day
III. Long-term prognosis is uniformly poor.

Leukoencephalomyelopathy of Rottweilers

Definition

I. It is a demyelinating disorder of the brain and spinal cord.
II. It is reported in rottweilers in United States and Europe.

Causes and Pathophysiology

I. Bilateral symmetrical demyelination occurs in the white matter of the spinal cord, brainstem, and cerebellum.
II. Lateral and dorsal funiculi are commonly affected in the cervical and thoracic spinal cord.
III. The precise etiology is unknown, but the condition may be heritable.

Clinical Signs

I. Onset is at 18 to 42 months of age.
II. Slow progressive clinical signs develop over a 6- to 12-month period.
III. Clinical signs are consistent with a C1-C5 myelopathy and include tetraparesis, hypermetria, and exaggerated segmental reflexes.

Diagnosis

I. Tentative diagnosis is based on signalment, clinical signs, and exclusion of other diseases.
II. Definitive diagnosis is made with histopathology.

Differential Diagnosis

I. Myelitis
II. Neoplasia
III. Cervical spondylomyelopathy
IV. Other degenerative diseases of the spinal cord

Treatment and Monitoring

I. No effective treatment exists.
II. Progression of the disease frequently leads to recumbency and euthanasia.

INFLAMMATORY AND INFECTIOUS DISORDERS

Diskospondylitis/Vertebral Osteomyelitis

Definition

I. Diskospondylitis is infection of the intervertebral disc and adjacent vertebrae.
II. Vertebral osteomyelitis is infection of only the vertebra.
III. Vertebral physitis is infection restricted to the physis.

Causes and Pathophysiology

I. Infection of the intervertebral disc is most commonly associated with *Staphylococcus intermedius*.
II. Other less commonly identified organisms include *Streptococcus* spp., *Escherichia coli*, *Actinomyces* spp., *Brucella canis*, and *Aspergillus* spp.
III. Young German shepherd dogs are predisposed to aspergillosis.

IV. Young basset hounds may be predisposed to diskospondylitis associated with systemic tuberculosis.
V. Infection may arise from hematogenous spread from distant foci of infection, extension of a paravertebral infection, penetrating wounds, surgery, or plant material (grass awn) migration.
VI. Infection causes extradural spinal cord or cauda equina compression.
VII. It is infrequently seen in cats.

Clinical Signs

I. It occurs most commonly in intact male, middle-aged, large- and giant-breed dogs.
II. Single or multiple sites can be infected.
III. The L7-S1 IVD space is most commonly affected.
IV. The thoracolumbar spine is more commonly affected than the cervical spine.
V. Clinical signs reflect the location of the lesion.
VI. Spinal pain is the most frequent initial clinical sign.
VII. Approximately 30% of dogs have signs of systemic illness (e.g., fever, weight loss) (Thomas, 2000).
VIII. Clinical signs may be present for several weeks or months before diagnosis.

Diagnosis

I. Diskospondylitis should be considered in animals with spinal pain or pyrexia.
II. Imaging of the entire spine is done to look for foci of infection.
III. Hematological changes are not usually present unless there is concurrent, systemic infection.
IV. Urinalysis may reveal bacterial or fungal agents.
V. Aerobic, anaerobic, and fungal cultures of blood and urine are positive in up to 75% and 50% of cases, respectively (Thomas, 2000).
VI. Serology for brucellosis is positive in 10% of cases and is performed in all dogs suspected of having diskospondylitis, because of its zoonotic potential (Thomas, 2000).
VII. Definitive diagnosis is usually made with spinal radiography.
   A. Radiographic changes include narrowing of the IVD space and lysis of the vertebral endplates, which are surrounded by sclerosis.
   B. The entire spine must be evaluated.
   C. Radiographs also are used to monitor response to therapy (Shamir et al., 2001).
   D. Radiographic changes often lag behind clinical improvement.
VIII. Myelography is indicated in animals with substantial neurological deficits.
IX. CSF analysis may be normal or may have an increased white blood cell (WBC) count and/or protein content.
X. CT can identify subtle endplate erosion and paravertebral soft-tissue swelling.
XI. MRI can identify inflammatory lesions within the disc space and adjacent soft tissues (Gonzalo-Orden et al., 2000; Cherubini et al., 2004).
XII. Percutaneous, fluoroscopic-guided needle aspiration and culture of the disc space may confirm the etiology in up to 75% of cases (Thomas, 2000).
XIII. Surgical biopsy of the lesion may be warranted in refractory cases.

Differential Diagnosis

I. Spondylosis deformans
II. Vertebral neoplasia
III. Intervertebral disc disease
IV. Meningomyelitis
V. Myositis
VI. Polyarthritis

Treatment and Monitoring

I. Treatment consists of long-term use of an antimicrobial that is effective against the causative organism, as determined by culture and sensitivity testing.
II. If an organism is not cultured, direct empirical therapy against *Staphylococcus* spp. is started.
   A. Cephalexin 20 to 30 mg/kg PO TID
   B. Cefazolin 20 mg/kg IV, IM, SC QID
   C. Amoxicillin 20 mg/kg PO BID
III. Intravenous antimicrobials are given to animals with severe neurological deficits.
IV. Antimicrobials are provided for a minimum of 6 to 8 weeks.
V. Resolution of signs usually occurs within 2 weeks of instituting therapy; however, neurological deficits can persist.
VI. Continued pain is indicative of active disease.
VII. Failure to respond to first-line antimicrobials requires the addition of a second antimicrobial.
   A. Enrofloxacin 5 to 11 mg/kg PO BID (dogs)
   B. Doxycycline 25 mg/kg PO SID (dogs); may cause vomiting
   C. Trimethoprim-sulfadiazine 15 mg/kg PO BID
VIII. Surgical exploration for internal decompression and possible stabilization may be necessary in refractory cases (Auger et al., 2000; Kinzel et al., 2005).
IX. Fluconazole 2.5 to 5 mg/kg PO BID is recommended for *Aspergillus* spp. infections.
X. Ideally, fungal infections are treated based on sensitivity testing.
XI. Nonsteroidal antiinflammatory drugs can be used to alleviate pain.
   A. Carprofen 2 mg/kg PO BID
   B. Ketoprofen 1 mg/kg PO SID for 5 days
XII. The prognosis is very good unless there is an associated endocarditis or a fungal etiology.

Steroid-Responsive Meningitis-Arteritis

Definition

I. It is a noninfectious, inflammatory disease affecting the meninges and associated vasculature.
II. Synonyms include necrotizing vasculitis, juvenile polyarteritis syndrome, corticosteroid-responsive meningitis/

meningomyelitis, aseptic suppurative meningitis, and pain syndrome.

Causes and Pathophysiology

I. The etiology and pathogenesis of this condition are not well understood.
II. The disease may be triggered by an environmental factor that leads to dysregulation of the immune system (Tipold et al., 1999).
III. Immunoglobulin (Ig) A may play a role in the pathogenesis (Tipold et al., 1995).

Clinical Signs

I. It is reported in the beagle, Bernese mountain dog, boxer, German short-haired pointers; it may occur in other breeds.
II. Affected dogs are often young, large-breed dogs between 7 and 18 months old.
III. Signs occur acutely or may follow a waxing and waning course over weeks to months.
IV. Dogs are usually febrile, anorexic, and hyperesthetic, with cervical rigidity.
V. Concurrent immune-mediated polyarthritis or glomerulonephritis may be present.
VI. Neurological deficits, weakness, and ataxia can be seen in the chronic cases.

Diagnosis

I. A marked neutrophilia with a left shift is often seen on a CBC.
II. CSF analysis reveals severe neutrophilic pleocytosis and protein elevation.
   A. Cell counts >100 cells/μL are common.
   B. Neutrophils are nondegenerate.
   C. Marked elevations of protein are common (40 to 350 mg/dL).
   D. Infectious agents are not identified.
III. Blood and CSF cultures, serology, and polymerase chain reaction (PCR) analysis are negative for infectious agents.
IV. Nonspecific elevations of IgA are detected in the CSF and serum (Tipold et al., 1995).

Differential Diagnosis

I. Infectious meningomyelitis
II. Granulomatous meningoencephalomyelitis
III. Diskospondylitis
IV. Polyarthritis, polymyositis
V. Intervertebral disc disease

Treatment and Monitoring

I. Treatment consists of long-term immunosuppressive doses of corticosteroids.
   A. Prednisone 4 mg/kg PO, IV SID for 2 days, *then*
   B. Prednisone 2 mg/kg PO, IV SID for 14 days, and if clinical signs have improved, *then*
   C. Prednisone 1 mg/kg PO SID for 28 days, and if clinical signs have resolved, *then*
   D. Prednisone 0.5 mg/kg PO SID for 2 months, then stopped if dog remains normal
II. Approximately 50% of dogs have a recurrence after discontinuation of the corticosteroids.
III. CSF analysis should be normal before stopping the prednisone.
IV. Additional immunosuppressive therapy may be necessary in some cases (see Chapter 23).

Granulomatous Meningoencephalomyelitis

See Chapter 23.

Distemper Myelitis

Definition and Cause

I. Distemper myelitis is infection of the canine spinal cord with canine distemper virus (CDV).
II. CDV is a Morbillivirus of the family of Paramyxoviridae.
III. Infection of the CNS can cause focal or diffuse lesions in both the grey and white matter.

Pathophysiology

I. Focal or diffuse demyelination can occur in the white matter of the spinal cord.
II. Resultant lesions depend upon host immunity, age, and duration of infection.
   A. Acute polioencephalomyelopathy with glial and neuronal necrosis occurs in immature or immunodeficient dogs.
   B. Chronic leukoencephalomyelopathy with demyelination occurs in older or immunosuppressed dogs.
   C. Demyelination is more frequent in the chronic stages of the disease.
   D. The mechanism by which demyelination occurs may be a primary effect of the virus on glial cells or may occur secondary to immunological mechanisms (Vandevelde and Zurbriggen, 2005).
   E. The white matter of cerebellum, cerebellar peduncles, optic nerves, optic tracts, and spinal cord are most frequently affected.

Clinical Signs

I. Distemper myelitis can occur in any age or breed of dog and vaccination does not always confer protection.
II. The CNS may be the only system affected.
III. Spinal cord signs depend on the location of the lesion, with T3-L3 segments frequently involved.
IV. Signs may be acute or chronic, progressive or relapsing, and occur bilaterally, with occasional asymmetry (Vandevelde and Zurbriggen, 2005).
V. In addition to a transverse myelopathy causing paraparesis and/or plegia, several other signs have been associated with this infection.
   A. Self-mutilation of the limbs and tail
   B. Paraphimosis and/or urinary incontinence
   C. Infrequent paraspinal hyperesthesia from pia arachnoid inflammation
   D. Myoclonus of the limbs that persists during sleep

Diagnosis

I. A tentative antemortem diagnosis is based on history and compatible clinical signs.
II. Diagnosis is often based on exclusion, as a definitive antemortem diagnosis is often difficult to obtain.
III. Hematological and CSF findings are nonspecific.
IV. Positive immunofluorescent assays for CDV antigen on conjunctival tissue, CSF, urine, skin, or blood can facilitate a diagnosis.
V. Analysis of CSF-specific IgG levels and determining the CSF:serum IgG ratio can be used to detect chronic CDV infections.
VI. PCR analysis of CSF and urine is a sensitive method for detecting infection (Amude et al., 2006; Saito et al., 2006).

Differential Diagnosis

I. Infectious meningomyelitis
II. Congenital, inherited neurodegenerative diseases
III. Degenerative myelopathy
IV. Type II disc disease
V. Neoplasia affecting the spinal cord

Treatment and Monitoring

I. Specific antiviral therapy is not available.
II. Administration of modified-live virus vaccines is only effective if given before clinical signs appear.
III. Short-duration prednisone therapy (0.5 to 1.0 mg/kg PO SID to BID for 1 to 3 days) may provide some relief.
IV. The prognosis for recovery is poor.

Infectious Meningomyelitis

Definition

I. Meningitis is inflammation of the meninges.
II. Myelitis is inflammation of the parenchyma of the spinal cord.

Causes

I. Viral causes include feline infectious peritonitis (FIP), FeLV, rabies, CDV, and canine adenovirus.
II. Bacterial causes include *Staphylococcus* spp., *Pasteurella* spp., *Actinomyces* spp., and *Nocardia* spp.
III. Protozoal causes include *Toxoplasma gondii* (dogs, cats), *Neospora caninum* (dogs), and *Sarcocystis* spp. (dogs, cats) (Dubey et al., 2006).
IV. Rickettsial causes include *Rickettsia rickettsii* (Rocky Mountain spotted fever [RMSF]) and *Ehrlichia canis*.
V. Fungal causes include *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, and *Coccidioides immitis*.

Pathophysiology

I. FIP causes granulomatous inflammation of the meninges, ependymal cells, and choroid plexus.
II. FeLV-associated myelopathy has been reported in chronically infected cats (Carmichael et al., 2002).
III. Bacteria and fungal diseases can infect the spinal cord through extension, penetration, and hematogenous routes.
IV. *T. gondii* and *N. caninum* can infect the spinal cord, peripheral nerves, and muscles.
V. Rickettsial disease affects the spinal cord through immune-mediated vasculitis.

Clinical Signs

I. The hallmark of infectious diseases is multifocal clinical signs.
II. Neurological signs reflect the region of the spinal cord affected.
III. Signs include paresis and ataxia.
IV. Often there are concurrent, systemic signs of inflammation.
V. Viral diseases may produce the following:
   A. FIP
      1. Cats can be affected at any age but are often between 6 months and 5 years of age.
      2. Signs are insidious and may reflect multiorgan involvement.
      3. The CNS signs may be focal, diffuse, or multifocal.
      4. Intracranial signs are more common than spinal signs.
      5. Clinical signs reflect the location of the pathology.
   B. FeLV causes hyperesthesia and progressive paraparesis to paralysis.
VI. Bacterial and fungal diseases
   A. Signs reflect the location and severity of the pathology.
   B. Neurological signs are often acute and rapidly progressive, but occasionally fungal infections can be slowly progressive.
   C. Fever occurs intermittently and is more likely with concurrent bacteremia or disseminated fungal infection.
VII. Protozoal diseases are characterized by the following:
   A. *T. gondii*
      1. Affected animals usually have signs of progressive multifocal disease.
      2. A focal transverse or diffuse myelopathy may be seen.
      3. Neurological signs reflect the location of the infection.
      4. In dogs <1 year of age, a syndrome of progressive paralysis and rigid extension of one or both pelvic limbs may be seen, as well as muscle contracture of the affected limbs.
      5. Concurrent signs of systemic infection include fever, lymphadenopathy, pneumonia, gastrointestinal disease, and chorioretinitis.
   B. *N. caninum*
      1. Puppies are more severely affected than adult dogs.
      2. Young dogs develop an ascending paralysis.
      3. Concurrent signs include dysphagia and jaw paresis.
VIII. Rickettsial disease may affect dogs of all ages.
   A. Mental depression is the most common clinical finding.
   B. Concurrent, systemic signs include fever, anorexia, lymphadenopathy, dyspnea, diarrhea, vomiting, hemorrhagic diatheses, and joint pain.

C. Clinical signs of spinal disease may be accompanied by those of intracranial disease and reflect the location of the lesion.
D. Cervical rigidity and pain may occur with RMSF.

Diagnosis

I. Viral diseases
  A. FIP
    1. Confirmation antemortem is difficult.
    2. Biopsy of affected tissue is necessary for definitive diagnosis.
    3. CSF analysis reveals a neutrophilic pleocytosis and markedly elevated protein levels.
    4. Indicators of disease are a positive coronavirus titer or PCR analysis in CSF, a high serum total protein concentration, and findings on imaging that include CNS periventricular enhancement, ventricular dilation, and hydrocephalus.
  B. FeLV-associated disease can only be definitively confirmed postmortem.
II. Bacterial and fungal diseases
  A. A diagnosis of bacterial or fungal meningomyelitis is made by isolating a causative organism in CSF.
  B. CSF cytology may demonstrate the presence of organisms.
    1. Classically bacterial diseases produce marked neutrophilic pleocytosis, and fungal diseases are associated with a mixed mononuclear and polymorphonuclear pleocytosis frequently with eosinophils.
    2. Aerobic, anaerobic, and fungal cultures are performed in suspected cases.
  C. Serology may be useful for diagnosis of fungal infections.
III. Protozoal diseases
  A. Tentative antemortem diagnosis is based upon serological evidence, compatible clinical signs, and positive response to treatment.
  B. CSF analysis shows a mixed-cell or mononuclear pleocytosis, and elevated protein levels.
  C. PCR of the CSF may confirm the diagnosis (Schatzberg et al., 2003).
IV. Rickettsial diseases
  A. CSF analysis may be normal or show mild increases in protein and pleocytosis (predominantly lymphocytes).
  B. Serology can confirm the diagnosis.

Differential Diagnosis

I. Steroid-responsive meningitis-arteritis
II. Diskospondylitis
III. Polyarthritis, polymyositis
IV. Cervical disc disease
V. Neoplasia

Treatment and Monitoring

I. Viral diseases
  A. Treatments include immunosuppression and prevention of secondary bacterial infections.
    1. Give prednisolone 2 to 4 mg/kg PO, IV SID.
    2. Cyclophosphamide 2 mg/kg PO SID for 4 consecutive days of each week has also been used.
    3. Give broad-spectrum antibiotics for 2 to 3 weeks.
  B. Despite aggressive therapy, the prognosis for FIP infection is poor.
II. Bacterial and fungal diseases
  A. Use high-dose, IV bactericidal drugs for at least 4 to 6 weeks in bacterial infections.
    1. Penicillin and penicillin derivatives in high doses (10 to 30 mg/kg IV, IM, PO BID to QID) are recommended for gram-positive infections for the first week.
    2. Most cephalosporins penetrate the CNS poorly.
      a. Several third-generation cephalosporins may reach therapeutic levels in the CNS and are advisable for gram-negative infections.
      b. Drugs to consider include cefotaxime 30 to 40 mg/kg IV, IM, SC TID to QID and ceftazidime 20 to 50 mg/kg IV BID to TID.
    3. Use metronidazole 10 mg/kg IV, PO TID for the treatment of anaerobic infections.
    4. Trimethoprim-sulfadiazine 15 mg/kg SC, PO BID penetrates the CNS effectively.
  B. Surgical drainage of an abscess may be necessary.
  C. Prognosis for bacterial infections is guarded.
  D. Several antifungals may be tried.
    1. Amphotericin B
      a. Dose is 0.15 to 0.5 mg/kg IV three times a week.
      b. When the total dose reaches 4 to 6 mg/kg, a maintenance dose of amphotericin is used (0.15 to 0.25 mg/kg IV once monthly), and rifampin 10 to 20 mg/kg PO TID is started.
    2. Ketoconazole (poor CNS penetration)
      a. Initial dose is 15 to 20 mg/kg PO BID for at least 2 to 3 months or until remission
      b. Maintenance dose is 10 mg/kg PO SID.
    3. Fluconazole
      a. Option 1: 2.5 to 5.0 mg/kg PO, IV BID
      b. Option 2: 5 to 10 mg/kg PO, IV SID for 56 to 84 days
  E. Fungal infections are difficult to eliminate from the CNS, and the prognosis is poor.
III. Protozoal diseases
  A. Early treatment for 2 to 4 weeks is essential.
  B. Trimethoprim-sulfadiazine 15 mg/kg SC, PO BID or ormetoprim-sulfadimethoxine 15 mg/kg PO BID, and clindamycin 15 mg/kg IV, PO for 28 days may improve clinical signs.
  C. Pyrimethamine 0.25 to 0.5 mg/kg PO SID for 28 days can be used adjunctively, but bone marrow suppression can occur in young animals.
  D. Prognosis is poor with rapidly progressive disease, pelvic limb hyperextension, and disease chronicity.
IV. Rickettsial diseases
  A. Give tetracycline 22 to 30 mg/kg PO TID for at least 14 days.
  B. Doxycycline 10 to 20 mg/kg PO BID is often used because of its excellent CNS penetration.
  C. Chloramphenicol 15 to 30 mg/kg PO TID for 7 days has good CNS penetration and is indicated in young (<6 months) dogs to avoid dental staining.

VASCULAR DISORDERS

Ischemic Myelopathy

Definition

I. Ischemic myelopathy involves vascular compromise of the spinal cord that often progresses to local infarction.
II. The term is often used synonymously with fibrocartilaginous embolic myelopathy (FCEM), which denotes a specific cause of the ischemia.

Causes and Pathophysiology

I. Acute spinal cord infarction can be secondary to FCEM, neoplastic emboli, and intravascular coagulation.
II. FCEM is characterized by acute spinal cord infarction from embolization of fibrocartilage identical to that of the nucleus pulposus.
   A. Many theories exist as to the pathophysiology of the embolization, but none are proven.
   B. Fibrocartilaginous emboli occlude arteries and/or veins of the leptomeninges and spinal cord parenchyma.
   C. Achondrodystrophic, medium- to large-breed dogs are predisposed.
   D. There is an increased incidence in miniature schnauzers.
   E. It is infrequently reported in cats (Mikszewski et al., 2006).

Clinical Signs

I. Classically, clinical signs are peracute in onset, nonprogressive, nonpainful, and often asymmetrical.
II. Transverse myelopathy occurs, with signs compatible with the location of the infarction.
   A. Proprioception deficits
   B. Ataxia
   C. Paresis or paralysis
III. Thoracolumbar signs are more common than cervicothoracic, but signs can occur in any region and often involve the intumescence.
IV. Clinical onset is frequently associated with trauma or exercise.
V. Maximal neurological deficits develop within 12 hours and are then nonprogressive.
VI. Severe signs are accompanied by loss of nociception (deep-pain perception).

Diagnosis

I. Tentative diagnosis is based upon history, signalment, and compatible clinical signs.
II. Myelography may demonstrate intramedullary spinal cord swelling in the early stages (Gandini et al., 2003).
III. MRI documents parenchymal pathology (Abramson et al., 2005; Mikszewski et al., 2006).
IV. CSF may reveal mild pleocytosis or a normal cell count with an elevated protein level (albumino-cytological dissociation).

Differential Diagnosis

I. Trauma of the spinal cord
II. Intervertebral disc disease
III. Myelitis
IV. Neoplasia affecting the spinal cord
V. Hemorrhage of vessels in or around the spinal cord

Treatment and Monitoring

I. There is no specific medical therapy for FCEM; however, the use of high-dose corticosteroid therapy has been considered.
   A. The dose of methylprednisolone recommended is 30 mg/kg IV followed 2 and 6 hours later by 15 mg/kg IV and continued QID for a maximum of 48 hours.
   B. Potential side-effects include pancreatitis, gastrointestinal hemorrhage, diarrhea, and colonic perforation.
II. Clinical improvement depends on the severity of sensorimotor dysfunction.
III. A poor prognosis has been correlated with lack of improvement within 14 days, involvement of the intumescences, and a lack of deep pain perception.
IV. Supportive care, physiotherapy, and hydrotherapy may aid in recovery.

NEOPLASIA

Vertebral and Spinal Tumors

Definition and Causes

I. Primary and secondary tumors can affect the vertebrae, meninges, and spinal cord.
II. Feline lymphoma may be associated with FeLV infection.
III. Neoplasia can be classified as extradural, intradural-extramedullary, or intramedullary.
   A. Extradural tumors can be primary or secondary.
      1. Primary vertebral tumors: fibrosarcoma, osteosarcoma, chondrosarcoma, hemangiosarcoma, myeloma
      2. Secondary vertebral tumors: mammary, prostatic, thyroid carcinomas, malignant melanoma, metastatic osteosarcoma
      3. Epidural tumors: lymphoma, metastatic tumors
   B. Intradural extramedullary tumors include meningioma, peripheral nerve sheath tumor, lymphoma, and nephroblastoma.
   C. Intramedullary tumors include astrocytoma, oligodendroglioma, ependymoma, and metastases.
IV. Primary and secondary extradural tumors are more common than intradural extramedullary tumors; intramedullary tumors are rare.
V. Spinal neoplasia accounts for 27% of all spinal disease in cats (Marioni-Henry et al., 2004).
   A. Epidural lymphoma is the most common spinal tumor of cats.
   B. Meningioma is the most common benign, nonlymphoid tumor of cats (Rossmeisl et al., 2006).
   C. Osteosarcoma is the most common malignant, nonlymphoid tumor of cats.

Pathophysiology

I. Spinal tumors occur most commonly in animals >5 years old (Dernell et al., 2000).

A. Dogs with spinal nephroblastoma are usually 4 to 38 months old (Summers et al., 1988).
B. Median age for cats with spinal lymphoma is 4.5 years (Marioni-Henry et al., 2004).

II. Any breed can be affected.
A. All classes of spinal neoplasia occur more frequently in large-breed dogs.
B. German shepherd dogs and golden retrievers may be predisposed to spinal nephroblastoma.

III. Spinal neoplasia occurs throughout the spinal cord and vertebral column.
A. Meningiomas most commonly occur in the cervical spine.
B. Nephroblastoma occurs most commonly between T10 and L2 vertebrae.
C. Feline lymphoma has a predilection for the thoracic and lumbar spinal cord.

Clinical Signs

I. Clinical findings depend on the location of the tumor.
II. Pain is the most common initial clinical signs.
III. The most common sign is a transverse myelopathy that is often bilateral, but can be asymmetrical.
A. Proprioception deficits
B. Ataxia
C. Paresis and paralysis
IV. Signs may progress over 1 week to 1 year.
V. An acute onset may occur from pathologic fractures, hemorrhage, or ischemia.

Diagnosis

I. Tentative diagnosis is based on clinical, radiographic, and CSF analysis, and on advanced imaging findings.
II. Thoracic radiography (three views) and abdominal ultrasonography are performed to identify primary or secondary neoplastic lesions.
III. Radiography can identify bony lesions of the vertebrae.
A. Bone lysis is most common finding associated with a vertebral tumor.
B. Punched-out lytic lesions in multiple vertebrae commonly occur with multiple myeloma.
C. Usually only one vertebra is involved (unless secondary).
IV. CSF analysis often reveals nonspecific changes.
A. The CSF may be normal or may have elevated protein levels.
B. Mild to moderate neutrophilic pleocytosis may occur with tumors affecting the leptomeninges.
C. Tumor cells are rarely identified, except with lymphoma.
V. Advanced imaging may be useful.
A. Myelography helps to differentiate intramedullary, intradural-extramedullary, and extradural lesions.
B. CT is used to identify bony lesions.
C. MRI is the best imaging modality for spinal neoplasia.
1. MRI allows specific determination of extramedullary or intramedullary lesions (McConnell et al., 2003).
2. Intravenous contrast administration helps determine the soft-tissue and osseous extent of the tumor.
3. MRI determines extent of disease and assists with surgical planning (McDonnell et al., 2005).

VI. Definitive diagnosis requires histopathologic interpretation of biopsy specimens.

Differential Diagnosis

I. Intervertebral disc disease
II. Diskospondylitis, osteomyelitis
III. Meningomyelitis
IV. Degenerative myelopathy
V. Spinal trauma

Treatment and Monitoring

I. Long-term prognosis is poor, with survival time often inverse to the severity of neurological deficits (Dernell et al., 2000).
II. Medical therapy consists of the following:
A. Prednisone 0.5 to 1.0 mg/kg PO SID can be used palliatively.
B. Chemotherapy may be tried for certain tumors.
1. Tumors amenable to chemotherapy include lymphoma and multiple myeloma.
2. In cats with spinal lymphoma, remission rate is 50%, with complete remission duration of 14 weeks, and partial remission duration of 6 weeks (Spodnick et al., 1992).
3. Long-term control of solitary plasmacytomas can be achieved with chemotherapy and radiation (Rusbridge et al., 1999).
C. Radiation therapy may be tried as primary, adjunctive, or palliative therapy (Dickinson et al., 2001a).

III. Surgical therapy involves surgical decompression of the spinal cord and debulking of the tumor.
A. Most vertebral tumors are not surgically respectable.
B. The median survival time of dogs with vertebral tumors was 135 days following multimodality therapy that included surgical resection (Dernell et al., 2000).
C. Surgical resection of meningiomas in dogs may lead to remissions of >6 months, and adjunctive radiotherapy may increase remission time to approximately 15 months (Levy et al., 1997).
D. Cytoreductive surgery of malignant, nonlymphoid spinal tumors in cats provides a median survival time of 110.5 days (Rossmeisl et al., 2006).
E. Cytoreductive surgery of benign, nonlymphoid spinal tumors in cats provides a median survival time of 518 days (Rossmeisl et al., 2006).
F. Intramedullary tumors are often difficult to excise without damage to the surrounding parenchyma (Sanders et al., 2002).

TRAUMATIC DISORDERS

Spinal Cord Trauma

Definition

I. Injury to the spinal cord may be caused by endogenous (intervertebral disc disease) or exogenous (vehicular trauma) factors.

II. Direct trauma to the spinal cord results in primary and secondary injuries.
III. Direct trauma to the spinal cord (concussion) may be followed by sustained compression, distraction, or both.

Causes

I. Type I intervertebral disease
II. Vertebral fractures and luxations
III. Fibrocartilaginous embolism
IV. Spinal instability: atlantoaxial subluxation

Pathophysiology

I. Acute spinal cord injury is often caused by a combination of events that can include concussion, compression, ischemia, and laceration (primary injuries).
II. Each of these primary injuries can lead to secondary injury, which is a series of biochemical and metabolic events that expand the primary zone of tissue necrosis.
III. Most secondary injuries occur within 24 hours and contribute to clinical deterioration.

Clinical Signs

I. Neurological examination is performed (carefully) to localize the site of the trauma before any sedation or analgesia is done.
II. Concurrent trauma involving other organ systems is frequently present and must also be assessed.
III. Neurological signs reflect the site of injury.
IV. Progressive hemorrhagic myelomalacia is suspected with continued deterioration.

Diagnosis

I. The diagnosis is made based on history and supportive clinical signs.
II. Thorough evaluation of the entire animal is essential to identify concurrent abnormalities.
III. Survey spinal radiography commonly delineates traumatic luxation and/or subluxation and fractures of the vertebral column.
   A. Lateral survey radiographs are taken of the whole spine before manipulation of the animal.
   B. General anesthesia maybe necessary for accurate positioning, but is delayed until the animal is stabilized.
   C. Sedation or analgesia may assist with positioning, but increases the risk of neurological deterioration secondary to paravertebral muscle relaxation.
IV. Advanced imaging is required to assess nervous tissue.
V. Myelography assists in assessing the degree of associated spinal cord compression.
VI. CT is invaluable in identifying bony defects that may not be apparent on survey radiography.
VII. MRI provides information about spinal cord compression, extradural hemorrhage, and parenchymal structure, but may not provide much detail about fractures and luxations.

Differential Diagnosis

I. Type I intervertebral disc disease
II. Pathologic fracture secondary to neoplasia
III. Fibrocartilaginous embolic myelopathy
IV. Ischemic neuromyopathy

Treatment and Monitoring

I. Initiate stabilization of the cardiovascular and respiratory systems before assessing and treating the spinal injury.
II. Immobilize the spine to prevent further vertebral displacement.
III. Delay administration of analgesia or sedation until the initial assessments, neurological examination, and diagnostics have been performed.
IV. Medical treatment is indicated for animals with mild clinical signs and no evidence of vertebral instability.
   A. Methylprednisolone sodium succinate
      1. The dose recommended is 30 mg/kg IV followed 2 and 6 hours later by 15 mg/kg IV and continued QID for a maximum of 48 hours.
      2. Potential side effects include pancreatitis, gastrointestinal hemorrhage, diarrhea, and colonic perforation.
   B. Cage rest for 6 weeks.
V. If spinal instability is detected but the owner declines surgery, an external splint is required to immobilize the area for 6 to 8 weeks.
VI. Surgical treatment is indicated in cases with instability, vertebral malalignment, or spinal cord compression.
   A. Laminectomy ± durotomy are necessary for decompression.
   B. Realignment and fixation can be achieved using Steinmann pins, screws, and polymethylmethacrylate, or vertebral body plates.
   C. Postoperative care involves exercise restriction, analgesia, soft bedding, and management of bladder evacuation.
   D. Physiotherapy and hydrotherapy may also help recovery.
   E. Prognosis depends on the degree of sensorimotor loss and chronicity of lesion at time of surgery, in addition to severity of any systemic disorders.

CHAPTER 25

Disorders of the Peripheral Nerves

Laurent Garosi

CONGENITAL/DEVELOPMENTAL DISORDERS

Inherited Motor Neuron Diseases

Definition

I. Motor neuron diseases are a group of neurodegenerative disorders characterized by premature degeneration and loss of motor neurons in the spinal cord and/or brainstem.
II. These processes can affect both upper and lower motor neurons.
III. The term *spinal muscular atrophy* can be used to describe cases in small animals in which lower motor neuron (LMN) signs predominate.

Causes and Pathophysiology

I. In most cases, a presumed genetic or inherited basis is suspected; however, in only a few disorders is the exact mode of inheritance known.
II. Affected breeds include the Swedish Lapland, English pointer, German shepherd dog, Doberman pinscher, Saluki, giant-breed crosses, and Griffon bassett vendeen.

Clinical Signs

I. Clinical signs are usually progressive and dominated by LMN signs
   A. Generalized weakness
   B. Generalized muscle atrophy
   C. Decreased to absent segmental spinal reflexes
   D. Decreased muscle tone
II. Arthrogryposis can be observed as a result of neurogenic atrophy of the appendicular musculature (Kent et al., 1999).

Diagnosis

I. Presumptive diagnosis is made based on signalment and neurological examination (Table 25-1).
II. Electrophysiology can also be used to support the diagnosis.
   A. Abnormalities that can be identified with electromyography (EMG) include positive sharp wave and fibrillation potentials.
   B. Abnormalities can also be identified with motor nerve studies and include motor nerve conduction velocities (NCV) in the low to normal reference range.
III. Diagnosis is supported by evidence of denervation atrophy on evaluation of muscle biopsies.
IV. Definitive diagnosis requires histopathologic evaluation of the spinal cord to demonstrate neuronal loss and gliosis in the ventral horn of the spinal cord.

Differential Diagnosis

I. Toxic neuropathies (Table 25-2)
II. Metabolic neuropathies (see Table 25-2)
III. Infectious diseases of the spinal cord, peripheral nerve, or muscles (see Chapters 24 and 82)

Treatment and Monitoring

I. No therapy exists for any of the congenital neuropathies.
II. Affected animals, as well as parents and siblings, should not be used for breeding.
III. The prognosis is guarded to poor, with most affected animals having a progressive course leading to euthanasia.

INFECTIOUS DISORDERS

Protozoal Polyradiculoneuritis

Definition and Causes

I. *Neospora caninum* and *Toxoplasma gondii* are the most common infectious causes of neuropathy and myopathy (Evans et al., 2004).
II. *T. gondii* infection has been associated with concurrent canine distemper infection.
III. *N. caninum* appears to be a primary pathogen (Ruehlmann et al., 1995).
IV. *N. caninum* is a more common pathogen than *T. gondii*.

Pathophysiology

I. *N. caninum* has a predilection for lumbosacral roots in puppies, resulting in pelvic limb atrophy and immobile joints (contractures) (Ruehlmann et al.,1995).
II. Inflammation consisting of macrophages, lymphocytes, and plasma cells are frequently identified in the nerve roots of the lumbosacral spinal cord.
III. Muscle biopsy is indicated and may reveal nonsuppurative inflammation and tachyzoites within myocytes (Dubey and Lindsay, 1996).

TABLE 25-1

Congenital/Developmental Disorders of Peripheral Nerves

DISORDER/BREEDS	CAUSE/PATHOLOGY	CLINICAL SIGNS/PROGRESSION	REFERENCES
I. Inherited Neuropathies Characterized by Loss of Motor Neuron (Ventral Horn Cell)			
Progressive neuronopathy in Cairn terriers	Both sexes are affected; genetics uncertain; chromatolysis of neurons in spinal ventral gray matter, numerous brain stem nuclei, and spinal, autonomic, and myenteric ganglia.	Pelvic limb weakness begins between 12 and 24 wk of age and progresses to tetraparesis over 2 mo. Head tremor is a consistent finding. Nystagmus, head tilt, and cataplexy were reported in a single case.	Cummings et al. (1988, 1991) Palmer and Blakemore (1989)
Focal spinal muscular atrophy in German shepherd dogs	Both sexes are affected; genetics uncertain; asymmetrical loss of motor neurons in cervical intumescence.	Forelimb weakness begins around 2 wk of age. One animal was euthanized; the other case reached a plateau around 8 wk.	Cummings et al. (1989)
Hereditary progressive spinal muscle atrophy in pointers	Both sexes are affected; probable autosomal recessive condition; lipid accumulation in spinal motor neurons and brainstem neurons.	Pelvic limb weakness begins between 18 and 23 wk of age and progresses to tetraparesis over 3-4 mo.	Inada et al. (1978)
Spinal muscular atrophy in rottweilers	Only affected females have been reported; genetics uncertain; chromatolysis and perikaryal swelling noted in spinal motor neurons and neurons in the brainstem.	Paraparesis at 4 wk of age progresses to tetraparesis within 1-2 wk with pelvic limb rigidity. Megaesophagus is present in some.	Shell et al. (1978)
Spinal muscular atrophy in Brittany spaniels	Both sexes are affected; autosomal dominant inheritance with variable penetrance. Motor neurons have chromatolysis secondary to internodal swellings in proximal axons. Swellings contain massive accumulations of neurofilaments. Neurofilaments are also present in cell body and proximal dendrites of some motor neurons. Nerves that innervate proximal muscle groups are preferentially affected.	Paraparesis progresses to tetraparesis. Late features include respiratory muscle paresis causing dyspnea and ineffective thermoregulation, and cranial nerve involvement causing difficulty grasping food and swallowing. There are three variants of the disease: 1. Accelerated form occurs in homozygotes. Onset occurs between 6 and 8 wk, with tetraparesis by 3-4 mo of age. 2. Intermediate form occurs in heterozygotes. Onset between 6 and 12 mo, with tetraparesis by 2-3 yr. 3. Chronic form occurs in heterozygotes, with onset during adulthood and mild clinical signs that are gradually progressive.	Cork et al. (1979, 1982) Sack et al. (1984)
Neuronal abiotrophy in Swedish Lapland dogs	Both sexes are affected; probable autosomal recessive. Chromatolysis occur in spinal motor neurons, neurons in dorsal root ganglia, cerebeller Purkinje cells, and other brainstem nuclei.	Thoracic or pelvic limb weakness begins at 5-7 wk of age and progresses to tetraparesis within 1-2 wk.	Sandefelt et al. (1973)

From Inzana KD: Disorders of peripheral nerves. p. 276. In Morgan RV, Bright RM, Swartout MS (eds): Handbook of Small Animal Practice. 4th Ed. WB Saunders, Philadelphia, 2003.

TABLE 25-1

Congenital/Developmental Disorders of Peripheral Nerves—*cont'd*

DISORDER/BREEDS	CAUSE/PATHOLOGY	CLINICAL SIGNS/PROGRESSION	REFERENCES
II. Inherited Neuropathies Characterized by Loss of Motor Axon			
Giant axonal neuropathy in Alsatians (German shepherd dogs)	Both sexes are affected; probable autosomal recessive. Giant axonal swelling containing masses of neurofilaments is found in distal segments of myelinated and unmyelinated axons. Both central and peripheral nervous systems are involved.	Paraparesis begins at 14-15 mo, with gradual progression to thoracic limbs. Megaesophagus and laryngeal paralysis are also features of the disease.	Griffiths et al. (1980b) Duncan and Griffiths (1981)
Hereditary polyneuropathy in Alaskan malamutes	Both sexes are affected; probable autosomal recessive. Axonal loss of both motor and sensory fibers occurs in peripheral nerves and in spinal nerve roots, and white matter degeneration is seen in spinal cord and brainstem.	Paraparesis begins in pelvic limbs between 7 and 18 mo of age, with gradual progression to thoracic limbs. Megaesophagus is a prominent feature.	Moe (1992)
Neuropathy in Birman cats	Only affected females have been reported; genetics uncertain. Diffuse loss of myelinated fibers occurs in peripheral nerves, spinal cord, and cerebellum, with a predominantly distal distribution.	Paraparesis begins between 8 and 10 wk of age; data insufficient to report progression.	Moreau et al. (1991)
Polyneuropathy in rottweilers	Both sexes are affected; possible autosomal recessive. Distal axonal degeneration occurs in both motor and sensory fibers, with secondary demyelination.	Paraparesis in adult dogs (1.5-4 yr) that gradually progresses over 1 yr to tetraparesis	Braund et al. (1994)
Progressive axonopathy in boxers	Both sexes are affected; autosomal recessive inheritance. Paranodal axonal swellings containing accumulations of disorganized neurofilaments and vesiculotubular structures are present in spinal nerve roots and in lateral and ventral funiculi of spinal cord. This is associated with reduced axonal diameter in distal segments of peripheral nerves.	Pelvic limb ataxia with paraparesis is seen at 1-3 wk, with gradual progression to involve the thoracic limbs by 1 yr of age and then reaches a plateau. Head bobbing and ocular tremor are seen in a few cases.	Griffiths et al. (1980a) Griffiths (1985)
III. Inherited Neuropathies Characterized by Schwann Cell Dysfunction			
Hypomyelinating neuropathy in golden retrievers	Both sexes are affected; genetics uncertain; reduced myelination in peripheral nerves.	Pelvic limb ataxia begins between 5 and 7 wk of age, with minimal progression.	Matz et al. (1990) Braund et al. (1989)
Hypertrophic neuropathy in Tibetan mastiffs	Both sexes are affected; probable autosomal recessive. Recurrent demyelination and remyelination create thickening of peripheral nerves. Schwann cells have accumulations of 6- to 7-nm filaments.	Paraparesis by 7.5-10 wk of age rapidly progresses over a few days to tetraplegia. Clinical signs improve over the following 4-6 wk, but animals remain weak.	Cummings et al. (1981a) Cooper et al. (1984a, 1984b)

Continued

TABLE 25-1

Congenital/Developmental Disorders of Peripheral Nerves—*cont'd*

DISORDER/BREEDS	CAUSE/PATHOLOGY	CLINICAL SIGNS/PROGRESSION	REFERENCES
IV. Inherited Neuropathies Characterized by Loss of Sensory Neuron or Axon			
Sensory neuronopathy in long-haired dachshunds	Both sexes are affected; probable autosomal recessive; Loss of axons in distal peripheral nerve segments (including vagus nerve) and terminal regions of primary sensory axons in fasciculus gracillis suggests a distal axonopathy of primary sensory neurons.	Generalized ataxia is noted around 8 wk of age. Diminished pain perception noted over whole body. Urinary and fecal incontinence and genital self-mutilation are prominent features. Disease appears nonprogressive.	Duncan and Griffiths (1982) Duncan et al. (1982)
Acral multilation in English pointers and German short-haired pointers	Both sexes are affected; probable autosomal recessive. Reduction in the size of neurons in dorsal root ganglia and degeneration of primary sensory neurons in peripheral nerves and spinal cord are accompanied by a loss of substance P immunoreactivity in the spinal cord.	Onset is between 2 and 12 mo of age. Loss of pain perception and multilation of feet are the most prominent signs.	Cummings et al. (1981b, 1983)
V. Inherited Neuropathies Associated with Inborn Errors of Metabolism			
Hyperchylomicronemia in cats (domestic short-haired, Himalayan, Persian, Siamese breeds)	Both sexes are affected; probable autosomal recessive condition. Deficiency in lipoprotein lipase activity causes hyperlipidemia, and xanthomas with infiltration and entrapment of peripheral nerves near intervertebral foramen and other bony prominences.	Clinical signs of dysfunction of one or more peripheral nerves usually begin around 8 mo of age. Loss of sympathetic supply to the eye (Horner's syndrome), and tibial and radial nerve paralysis are common.	Jones (1993)
Hyperoxaluria in domestic short-haired cats	Both sexes are affected; autosomal recessive condition. Deficiency in D-glycerate dehydrogenase occurs. Peripheral nerve changes are characterized by marked accumulations of neurofilaments in proximal axons of motor and sensory axons.	Animals develop acute signs of renal failure and generalized weakness between 5 and 9 mo of age.	McKerrell et al. (1989)
α-L-Fucosidosis in English springer spaniels	Both sexes affected; autosomal recessive deficiency in the lysosomal enzyme α-L-fucosidase. Proximal enlargements of multiple cranial and spinal nerves occur from infiltration by foamy macrophages and fibroedematous tissue containing fructose-containing substances. There is extensive cytoplasmic vacuolation in neurons and glia in central nervous system.	Behavioral changes may be noted as early as 4-6 mo of age and progress slowly over 2-3 yr. Aphonia, depressed gag reflex, and dysphagia reflect cranial neuropathies. Spinal nerves are affected during the terminal stages.	Taylor et al. (1987) Barker et al. (1988)

TABLE 25-1

Congenital/Developmental Disorders of Peripheral Nerves—*cont'd*

DISORDER/BREEDS	CAUSE/PATHOLOGY	CLINICAL SIGNS/PROGRESSION	REFERENCES
Globoid cell leukodystrophy in West Highland white terriers, Cairn terriers, Pomeranians, basset hounds, bluetick hounds, domestic short-haired cats	Both sexes are affected; probable autosomal recessive deficiency of lysosomal enzyme galactocerebroside β-galactosidase. Accumulations of lipid-laden macrophages (globoid cells) are found in both peripheral and central nervous systems, accompanied by a loss of myelination and a decrease in oligodendrocyte and Schwann cell numbers.	Pelvic limb ataxia and generalized tremor typically begin between 3 and 5 mo of age. They progress to paraplegia, then tetraplegia, hyporeflexia, and eventually blindness and dementia by 1 yr of age.	Blakemore et al. (1974) Vicini et al. (1988)
Niemann-Pick disease in Siamese cats	Both sexes are affected; probable autosomal recessive deficiency of sphingomyelinase. Sphingomyelin and other lipids acumulate in liver, renal tubular cells, bone marrow cells, neurons, and glia. Siamese cats also have demyelinating peripheral neuropathy.	Pelvic limb ataxia and generalized tremor typically begin between 2 and 5 mo of age.	Cuddon et al. (1989)
Glycogen storage disease type IV in Norwegian forest cats	Both sexes are affected; probable autosomal recessive deficiency in glycogen branching enzyme. Intracytoplasmic storage of glycogen occurs in nervous system and cardiac and skeletal muscles, with loss of spinal motor neurons.	Generalized tremors, weakness, and fever begin at 5 mo of age and progress to tetraplegia by 8 mo of age.	Fyfe et al. (1990) Coates et al. (1996)
VI. Inherited Neuropathies Associated with Laryngeal Paralysis			
Laryngeal paralysis in Bouviers des Flandres	Both sexes are affected; autosomal dominant. Degeneration of recurrent laryngeal nerves occurs, with loss of neurons in nucleus ambiguous and occasional axonal loss in tibial nerve.	Inspiratory dyspnea, laryngeal stridor, and exercise intolerance begins between 4 and 6 mo of age. Progression of the syndrome is not reported.	Venker-van Haagen et al. (1978, 1981)
Laryngeal paralysis in Siberian husky dogs and their crosses	Both sexes are affected; genetics not determined. Degeneration is reported only in recurrent laryngeal nerve. Spontaneous activity may occur in other muscles as well.	Inspiratory dyspnea, laryngeal stridor, and exercise intolerance are noted between 2 and 6 mo of age. Progression of this syndrome has not been reported.	O'Brien and Hendriks (1986)
Laryngeal paralysis in dalmatians	Both sexes are affected; inheritance uncertain. Distal axonal degeneration of medium- and large-diameter fibers occurs in all peripheral nerves, including the recurrent laryngeal nerves. Megaesophagus is also present in more than 50% of cases.	Inspiratory dyspnea, laryngeal stridor, exercise intolerance, and regurgitation are first noticed between 2 and 6 mo of age. Clinical signs of more generalized polyneuropathy may develop before, concurrently, or after laryngeal paralysis. Aspiration pneumonia results in death within a year of diagnosis in most cases.	Braund et al. (1994)

Continued

TABLE 25-1

Congenital/Developmental Disorders of Peripheral Nerves—*cont'd*

DISORDER/BREEDS	CAUSE/PATHOLOGY	CLINICAL SIGNS/PROGRESSION	REFERENCES
Laryngeal paralysis-polyneuropathy complex in young rottweilers	Both sexes are affected; inheritance uncertain. Axonal degeneration is noted in both proximal and distal levels of limb nerves, with degeneration more severe in distal recurrent laryngeal nerve. Brain and spinal cord are normal.	Inspiratory dyspnea, laryngeal stridor, exercise intolerance are noted between 2 and 3 mo of age. Clinical signs rapidly progress to generalized weakness. Three of 5 dogs were euthanized within a week of diagnosis because of rapid deterioration.	Mahony et al. (1998)

TABLE 25-2

Summary of Neuromuscular Disorders

CLASS OF DISORDER	NEUROPATHY	JUNCTIONOPATHY	MYOPATHY
Congenital/degenerative	Inherited motor neuron disease Inherited peripheral neuropathy	Congenital myasthenia gravis	Muscular dystrophies Labrador retriever myopathy Inherited myopathy of Great Danes Congenital myotonia
Infectious	Protozoal polyradiculoneuritis/myositis	Botulism Tick paralysis	Infectious myopathies
Inflammatory	Chronic inflammatory demyelinating polyneuropathy Acute polyradiculoneuritis Hypertrophic neuritis	None	Idiopathic polymyositis Familial dermatomyositis Extraocular muscle myositis Masticatory muscle myositis
Idiopathic	Distal denervating disease	Acquired myasthenia gravis	Exercise-induced collapse in Labrador retrievers Exertional rhabdomyolysis
Metabolic	Diabetes mellitus Hypothyroidism Hyperadrenocorticism Hypoglycemic neuropathy	None	Mitochondrial myopathies Lipid storage myopathies Glycogen storage myopathies Hypothyroid myopathies Hyperthyroid myopathies Myopathies related to glucocorticoid excess Adrenocortical insufficiency Hypokalemic myopathy
Toxic	Drug-induced toxic neuropathy	Iatrogenic muscular blockade Organophosphate/carbamate toxicosis	Drug-induced myositis Toxic myopathy
Vascular	Ischemic neuromyopathy	None	Ischemic neuromyopathy
Neoplastic	Peripheral nerve sheath tumor Other primary or secondary tumor Paraneoplastic neuropathy	Paraneoplastic myasthenia gravis	Paraneoplastic inflammatory myopathies
Traumatic	Traumatic neuropathy Brachial plexus avulsion	None	Fibrotic myopathy Myositis ossificans

Clinical Signs

I. Onset of signs is usually observed before 6 months of age.
II. Affected dogs have progressive, ascending paralysis and muscle atrophy, usually with the pelvic limbs more severely affected.
III. Bilateral rigidity of the pelvic limbs is a frequent finding in puppies from polyradiculitis and polymyositis.

Diagnosis

I. Clinicopathologic values are usually not altered.
II. Serum creatine kinase (CK) levels are often increased.
III. Elevated serum and cerebrospinal fluid (CSF) antibody concentrations for N. *caninum* or T. *gondii* support the presence of infection.
IV. Definitive diagnosis can be made by identification of organisms in muscle biopsies.

Treatment and Monitoring

I. Treatment consists of an 8-week course of the combination of trimethoprim-sulfadiazine 15 to 20 mg/kg PO BID, pyrimethamine 1 mg/kg PO SID, and clindamycin 20 to 30 mg/kg PO BID.
II. Although improvement in neurological function is commonly observed, complete resolution of pelvic limb hyperextension is unlikely.

INFLAMMATORY/IMMUNE-MEDIATED DISORDERS

Acute Polyradiculoneuritis

Definition

Polyradiculoneuritis is an inflammatory disorder involving spinal nerve roots.

Causes and Pathophysiology

I. Acute canine polyradiculoneuritis (inflammation of the nerve roots and peripheral nerves) is considered the most common peripheral neuropathy in dogs.
II. A similar condition has been reported in cats, but is less common than in dogs (Gerritsen et al., 1996; Lane and de Lahunta,1984).
III. Acute canine polyradiculoneuritis can be subclassified into three categories according to the presumptive cause.
    A. Coonhound paralysis appears in dogs 7 to 10 days after they have been bitten or scratched by a raccoon.
        1. A protein constituent of raccoon saliva may induce a delayed hypersensitivity against myelin.
        2. Dogs that have recovered from coonhound paralysis are not immune to future attacks.
    B. Vaccination (especially against rabies) has been incriminated as a possible cause of acute canine polyradiculoneuritis.
    C. Another condition exists that appears to be identical to coonhound paralysis with respect to onset, clinical signs, course, and pathologic findings.
        1. It occurs worldwide in dogs that have had no possible exposure to raccoons and is named *idiopathic polyradiculoneuritis*.
        2. The exact pathogenesis is unknown; however, it may be an immune-mediated process.

Clinical Signs

I. Signs are caused by an inflammatory reaction affecting axons and myelin sheaths, mainly in ventral nerve roots.
II. Signs consist of a stiff, stilted, short-strided gait in all four limbs.
III. Weakness initially develops in the pelvic limbs and then ascends rapidly, resulting in a flaccid symmetrical tetraparesis or tetraplegia that usually peaks within 10 days of onset.
IV. Cranial nerves (CN) are rarely affected, although there may be signs of facial weakness and aphonia.
V. Nociception remains intact, and some dogs seem to be hyperesthetic and experience considerable discomfort with light palpation of the extremities.
VI. Some dogs can develop significant respiratory compromise as a result of paralysis of the intercostal muscles and diaphragm that can progress to complete respiratory paralysis.

Diagnosis

I. Diagnosis is usually based on history and compatible clinical findings.
II. CSF analysis may be normal or may reveal an increased total protein concentration, with a normal nucleated cell count (albumino-cytological dissociation).
III. The most reliable electrophysiologic indicators are EMG changes, such as significantly decreased compound-muscle action potential amplitudes, increased minimum F-wave latencies, increased F ratios, and decreased F-wave amplitudes (Cuddon, 1998).
IV. An enzyme-linked immunosorbent assay (ELISA) test is available, and it is sensitive and specific for detecting circulating antibodies to raccoon saliva in dogs.

Differential Diagnosis

I. Tick paralysis
II. Botulism
III. Myasthenia gravis

Treatment and Monitoring

I. Treatment is mainly supportive.
    A. Physiotherapy and rehabilitation efforts are needed.
    B. Adequate nutrition and hydration are essential.
    C. Provide soft bedding to prevent pressure sores related to recumbency.
II. Affected dogs must be closely monitored for respiratory depression.
III. Most dogs recover fully within a few weeks, but recovery can take up to 6 months depending on the severity.

Myasthenia Gravis

Definition and Causes

I. Myasthenia gravis (MG) is a disorder characterized by a deficiency of functional acetylcholine receptor (AChR) that results in reduced sensitivity of the postsynaptic membrane

to the neurotransmitter acetylcholine (ACh) and failure of neuromuscular transmission.

II. Two forms of the disease occur: acquired and congenital.
   A. The acquired form of MG arises from antibody-mediated (predominantly immunoglobulin [Ig] G) destruction of nicotinic AChR on the postsynaptic membrane of the neuromuscular junction (Shelton et al., 1988).
      1. The acquired form can either be idiopathic or secondary.
      2. Acquired MG has been reported as a paraneoplastic syndrome associated with a variety of tumors, including thymomas.
      3. Other predisposing causes in dogs include hypothyroidism, hypoadrenocorticism, systemic lupus erythematosus, and polymyositis.
      4. Acquired MG also has been reported in hyperthyroid cats receiving methimazole therapy (Kuroda et al., 1991; Shelton et al., 2000).
      5. Dogs with acquired MG range in age from 7 weeks to 15 years, with all breeds and genders potentially affected.
      6. Breeds with the highest risk are the Akita, several terrier breeds, German short-haired pointer, and Chihuahua (Shelton et al., 1997).
      7. A familial predisposition has been suggested in Newfoundlands (Lipsitz et al., 1999).
      8. In cats, Abyssinians and related Somalis are predisposed.
   B. Congenital MG is a rare disease and is defined as an inherited disorder in which the safety margin of neuromuscular transmission is compromised by one or more specific mechanisms.
      1. It can arise from presynaptic, synaptic, or postsynaptic defects (Engel et al., 2003).
      2. Decreased muscle AChR content is a consistent finding in congenital MG secondary to postsynaptic defects.
      3. An inherited, autosomal recessive form of MG has been recognized in the Parson (Jack) Russell terrier, English springer spaniel, and smooth fox terrier (Shelton, 1998).
      4. Suspected cases of congenital MG have also been reported in two related mongrel dogs (Van Ham, 1992).

Pathophysiology

I. Antibodies bound to postsynaptic AChR of the muscle membrane (acquired MG) block neuromuscular transmission.

II. Deficiency in AChR (congenital MG) results in a failure of neuromuscular transmission.

Clinical Signs

I. The hallmark sign of MG is episodic weakness that is exacerbated by exercise and resolves with rest.

II. Acquired MG can occur in three distinct clinical forms.
   A. The focal form is characterized by weakness of an isolated muscle group.
      1. It has been associated with regurgitation (megaesophagus), dysphagia (pharyngeal dysfunction), and decreased palpebral reflex (facial muscles), without detectable limb muscle weakness.
      2. Alternatively, megaesophagus may be the sole abnormality.
      3. The reason for selective involvement of particular muscle groups is unknown (Shelton et al., 1990).
   B. The generalized form consists of generalized appendicular weakness.
      1. Concurrent megaesophagus causing regurgitation and aspiration pneumonia is also common in dogs because of the large amount of skeletal muscle in the esophagus of dogs.
      2. Occasionally, facial, laryngeal, or pharyngeal weakness accompanies the appendicular muscle weakness (Dewey et al., 1997).
   C. An acute, fulminating form of MG also has been described in dogs.
      1. It is characterized by frequent regurgitation of large volumes of fluid associated with megaesophagus, and rapid loss of muscle strength resulting in recumbency.
      2. Respiratory failure is a consistent complication and a common cause of death.

III. Congenital MG generally occurs in puppies 6 to 9 weeks of age, with multiple pups in a litter affected.

Diagnosis

I. A presumptive diagnosis can be made with dramatic improvement in strength in response to the administration of edrophonium hydrochloride *(Tensilon)*, which is referred to as the *Tensilon test.*
   A. Edrophonium chloride is an ultrashort-acting anticholinesterase drug that blocks the hydrolysis of ACh by ACh-esterase, thereby increasing the concentration of ACh within the synaptic cleft.
   B. Edrophonium chloride is administered at 0.22 mg/kg IV.
   C. Tensilon testing is not a sensitive or specific testing method for MG.
   D. A lack of response to *Tensilon* administration does not rule out the diagnosis of MG (especially in cases of acute fulminant MG), because some dogs with other myopathic and neuropathic disorders have mild improvements in their weakness (Shelton, 1998).
   E. Occasionally, Tensilon testing can cause a cholinergic crisis by overstimulation of AChR, thereby producing a depolarizing blockade.
      1. Cholinergic crisis consists of dyspnea, bradycardia, profuse salivation, miosis, cyanosis, and limb tremors.
      2. Cholinergic crisis can be reversed with atropine 0.05 mg/kg IV.

II. The definitive diagnosis of acquired MG is based on demonstration of serum antibodies to muscle AchRs by immunoprecipitation radioimmunoassay (Shelton, 1998).
   A. The prevalence of seronegative canine myasthenia is considered to be very low, and false-positive results have not been documented.

B. Seronegative, acquired MG may occur from very low titers of high-affinity AChR antibodies, where most antibodies are complexed to AChRs in muscles or are antibodies directed against other end-plate proteins.
C. Other methods of diagnosis include immunocytochemical staining of muscle endplates, repetitive nerve stimulation, and single-fiber electromyography (Shelton, 1989).

Differential Diagnosis

I. Tick paralysis
II. Acute polyradiculoneuritis
III. Botulism
IV. Acute metabolic or toxic neuropathies

Treatment and Monitoring

I. Anticholinesterase therapy is the primary treatment for acquired MG in dogs.
   A. Pyridostigmine, a long-acting AChE inhibitor, is the most commonly used anticholinesterase drug.
      1. Administer by mouth or a gastric tube at 0.5 to 3.0 mg/kg PO BID to TID.
      2. To avoid a cholinergic crisis, start with the low dose and increase as needed.
   B. If oral treatment is not possible because of severe regurgitation, give neostigmine at 0.04 mg/kg IM QID.
II. Overdosage of anticholinesterase drugs results in a cholinergic crisis that consists of tachypnea and/or dyspnea, bradycardia, hypersalivation, excessive lacrimation, miosis, and generalized weakness.
III. Differentiation between inadequate therapy and overdosage can be made by administration of edrophonium, which should alleviate clinical signs if therapy is inadequate and has little to no effect on clinical signs from overdosage.
IV. Adjunctive immunosuppressive treatment is indicated if limb muscle strength has not returned to normal following anticholinesterase therapy and if there is no evidence of aspiration pneumonia.
   A. Give prednisone initially at an antiinflammatory dosage (0.5 mg/kg PO SID to BID) and increase gradually to immunosuppressive levels (2 to 4 mg/kg PO SID to BID) over 7 to 10 days to avoid initial exacerbation of muscle weakness (Shelton, 1998).
   B. Other immunosuppressive drugs, such as azathioprine 1 to 2 mg/kg PO SID or mycophenolate mofetil 20 mg/kg PO BID can also be tried.
V. In animals with megaesophagus, provide nutritional support via a gastrostomy tube.
VI. In animals with acquired MG secondary to neoplasia, treat the underlying neoplastic condition.
VII. Spontaneous clinical and immunological remission has occurred in >85% of dogs with acquired MG, over an average of 6.4 months (Shelton and Lindstrom, 2001).
   A. Base decisions regarding treatment regimen and duration on clinical signs and periodic testing of AChR antibody titers.
      1. Test AChR antibody titers every 4 to 6 weeks.
      2. Continue treatment as long as AChR antibody titers are positive.
   B. For animals not receiving immunosuppressive agents that become seronegative, consider stopping anticholinesterase therapy .
VIII. Congenital MG requires life-long therapy.
IX. Long-term prognosis for congenital MG is usually considered poor; however, spontaneous remission has occurred in two dachshunds by 6 months of age without medical therapy (Dickinson et al., 2005).

Chronic Inflammatory Demyelinating Neuropathy

Definition and Cause

I. Chronic inflammatory demyelinating polyneuropathy (CIDP) is considered to be an immune-mediated disorder in which the peripheral nerve myelin sheath is the target of an inflammatory reaction.
II. CIDP occurs in dogs and cats of either sex and does not appear to be breed related (Braund et al., 1996; Cummings, 1974; Shores, 1987).
III. CIDP is one of the more common neuropathies in dogs and cats.
IV. An immune-mediated process is suggested by the presence of focal and multifocal endoneural mononuclear cells, such as lymphocytes, macrophages, and plasma cells, and by positive staining for IgG in peripheral nerves.

Pathophysiology

I. CIDP is characterized by multifocal, segmental demyelination, and remyelination.
II. Changes in teased single fibers are dominated by multifocal paranodal demyelination.
III. Axonal loss is not a feature of this disease.

Clinical Signs

I. Onset of signs is usually insidious, and the course is typically chronic, sometimes relapsing, and often slowly progressive.
II. Clinical signs consist of LMN tetraparesis that can progress to tetraplegia with hyporeflexia.

Diagnosis

I. The diagnosis is based in part on history, clinical signs, and exclusion of other disease processes.
II. Electrophysiological testing reveals abnormal NCV, increased latency, and temporal dispersion of the muscle action potential, with minimal EMG abnormalities.
III. Definitive diagnosis requires histopathologic evaluation of nerve biopsies.

Differential Diagnosis

I. Other immune-mediated neuropathies
II. Metabolic or toxic neuropathies
III. Paraneoplastic neuropathies

Treatment and Monitoring

I. Treatment in dogs and cats consists of immunosuppressive dosage of prednisone 1 mg/kg PO BID for 2 weeks, then slowly tapered over 3 to 6 months.
II. Response to treatment is generally good; however, relapses can occur.
III. Adjunctive immunosuppressive treatment (dogs: azathioprine 1 to 2 mg/kg SID PO) is indicated in cases that relapse.

IDIOPATHIC DISORDERS

Distal Denervating Disease

Definition and Cause

I. Distal denervating disease is a common peripheral neuropathy in the United Kingdom that affects the distal segments of peripheral nerves.
II. The etiology is unknown.

Pathophysiology

I. Pathologic changes are confined to the distal branches of motor nerves, with intramuscular nerve fascicles showing marked demyelination (Summers, 1995).
II. There are no pathologic changes in the proximal segments of peripheral nerves.

Clinical Signs

I. There is no apparent age, sex, or breed association.
II. Signs of weakness are usually first observed in the pelvic limbs.
III. Within days to weeks, initial clinical signs progress to LMN tetraplegia accompanied by severe, generalized muscle atrophy.
IV. Sensory function remains intact.

Diagnosis

I. Electrophysiology is consistent with a motor nerve disorder affecting the distal segments.
   A. Abnormal spontaneous EMG activities occur in affected musculature.
   B. Motor nerve studies show decreased amplitude, but normal NCV.
   C. Sensory nerve studies are normal.
II. Muscle and nerve biopsies provide histopathologic confirmation of denervation.

Differential Diagnosis

I. Depending on the rapidity of the onset, distal denervating disease must be differentiated from acute diseases (e.g., acute polyradiculoneuritis, tick paralysis, MG).
II. More chronic and progressive forms must be differentiated from metabolic, toxic, and paraneoplastic disorders.

Treatment and Monitoring

I. There is no treatment.
II. In most dogs, full recovery usually follows spontaneous improvement within 4 to 6 weeks after the onset of clinical signs (Griffiths and Duncan, 1979).

METABOLIC/TOXIC NEUROPATHIES

Diabetes Mellitus–Related Neuropathy

Definition and Cause

I. Poorly controlled diabetes mellitus can be associated with a peripheral neuropathy.
II. Cats are particularly susceptible, whereas dogs are often subclinical.

Pathophysiology

I. Several theories regarding the pathogenesis have been proposed.
II. Activation of the polyol pathway in which aldose reductase reduces free glucose to sorbitol may lead to a depletion of myoinositol, a constituent of the plasma cell membrane important in impulse conduction (Cuddon, 2002).
III. Decreased insulin-like growth factor with diabetes leads to decreased production and axonal transport of microtubules and neurofilaments that are important to axonal health.
IV. Hyperglycemia leads to reduced blood flow and increased oxidative stress through alterations in the microvascular tone, which results in lipid peroxidation.

Clinical Signs

I. In cats, clinical signs are consistent with a sciatic neuropathy that causes a plantigrade posture when standing or walking.
   A. Most commonly, cats display pelvic limb weakness, with reduced to absent patellar and withdrawal reflexes.
   B. Occasionally, tetraparesis is seen.
II. In dog, clinical signs are usually subclinical.

Diagnosis

I. The diagnosis of diabetes mellitus is described in Chapter 44.
II. Electrophysiological findings suggest a sensorimotor neuropathy with conduction deficits, increased F waves, and increased cord dorsum potential latencies, with little or no EMG abnormalities except in the most severely affected animals (Mizisin et al., 2002).
III. Nerve biopsy reveals Schwann cell injury with myelin defects (e.g., splitting, ballooning), and subsequent demyelination, with minimum axonal degeneration (Mizisin et al., 2002).

Differential Diagnosis

I. Other metabolic or toxic neuropathies
II. Inflammatory or immune-mediated neuropathies
III. Vascular neuropathies

Treatment and Monitoring

I. Abatement of neuropathic signs can follow insulin therapy and achievement of a euglycemic state.
II. Clinical signs generally take weeks to months to resolve.
III. Persistent neurological signs are not uncommon despite aggressive management.

Hypothyroid-Related Neuropathy

Definition

I. Hypothyroidism is a relatively common endocrinopathy in older dogs.
II. Primary hypothyroidism has been associated with various nervous system abnormalities in dogs, including neuromyopathy.

Pathophysiology

I. The exact mechanism of hypothyroid-related neuropathies is unknown.
II. Resolution of clinical signs after supplementation is evidence of a causal link between the neuropathy and hypothyroidism.
III. Compression of cranial nerves as they exit their respective foramina in the calvaria may occur from myxedema (Cuddon, 2002).
IV. Axonal flow may also be reduced.

Clinical Signs

I. Clinical signs include generalized LMN signs, as well as cranial nerve dysfunction.
II. Generalized weakness, particularly in the pelvic limbs, exercise intolerance, reduced segmental spinal reflexes, and muscle atrophy are most commonly seen (Cuddon, 2002).
III. Cranial nerve dysfunction include deficits in CNs V, VII, and VIII.
IV. Laryngeal paralysis has been observed, and an association with megaesophagus has been suggested (Jaggy et al., 1994).

Diagnosis

I. The diagnosis is made by identifying hypothyroidism concurrent with clinical signs of LMN disease or cranial nerve dysfunction, followed by resolution of clinical signs with thyroxine supplementation.
II. The diagnosis of hypothyroidism consists of demonstrating a low free T4 with an elevated thyroid-stimulating hormone (TSH) level (see Chapter 42).
III. Electrophysiological findings are nonspecific.
    A. EMG findings include increased insertional activity and abnormal spontaneous activity.
    B. Nerve conduction studies reveal decreased amplitudes and slowed conduction that are evidence of demyelination and axonal loss, respectively.
IV. Peripheral nerve biopsies show demyelination, axonal loss, and evidence of remyelination.

Differential Diagnosis

I. Other metabolic or toxic neuropathies
II. Inflammatory or immune-mediated neuropathies
III. Paraneoplastic neuropathies

Treatment and Monitoring

I. Supplementation with synthetic levothyroxine is started at 0.02 mg/kg PO BID.
II. Dose adjustments are made based on clinical signs and serum thyroxine monitoring (see Chapter 42).
III. Neurological signs may take 1 to 2 months to improve.

Tick Paralysis

Definition and Cause

I. Tick-induced paralysis results from transfer of salivary neurotoxins to the host during parasitic feeding, usually by an adult female tick.
II. The neurotoxin interferes with ACh release, leading to failure of neuromuscular transmission.
III. Various species of tick (mostly *Dermacentor* and *Ixodes* spp.) are incriminated in different parts of the world.

Clinical Signs and Diagnosis

I. Clinical signs of rapidly ascending LMN paralysis are apparent 5 to 9 days after tick attachment (Malik and Farrow, 1991).
II. Weakness begins in the pelvic limbs and rapidly ascends to affect the thoracic limbs.
III. Dogs become recumbent in 24 to 72 hours.
IV. Left untreated, death occurs from paralysis of the respiratory muscles.
V. Presumptive diagnosis is made based on clinical signs and rapid improvement after tick removal.

Differential Diagnosis

I. Acute polyradiculoneuritis
II. Myasthenia gravis
III. Botulism

Treatment and Monitoring

I. After tick removal, clinical improvement is typically seen within 24 hours, with return of normal function by 48 hours.
II. Topical insecticides, such as those containing imidacloprid and permethrin (Advantix) or fipronil (Frontline Plus), are advocated over topical organophosphates.

Botulism

Definition and Cause

I. Botulism occurs following the ingestion of preformed toxin produced by *Clostridium botulinum* in carrion or raw meat.
II. *C. botulinum* is a saprophytic organism found worldwide that requires an anaerobic environment.
III. Botulism is an uncommon disease in dogs.
IV. Domestic cats seem to be remarkably resistant to botulinum toxin.
V. There are several antigenically distinct botulinus toxins (type A, B, C1, C2, D, E, F, and G).
VI. Type C1 is the botulinum toxin most often reported to affect dogs (Inzana, 2000).

Pathophysiology

I. After ingestion, the preformed toxin is absorbed and distributed to cholinergic receptors.
II. The toxin binds to presynaptic receptors at the neuromuscular junction.

III. The toxin diffuses into the axonal terminal and interferes with ACh release, leading to failure of neuromuscular transmission.

Clinical Signs

I. Clinical signs usually develop within a few hours after ingestion but can occasionally take several days to develop.
II. Clinical signs are characterized by progressive, symmetrical weakness to severe tetraplegia, with absent segmental spinal reflexes.
III. Cranial nerve abnormalities, such as facial paralysis, dysphonia, dysphagia, decreased jaw tone, and megaesophagus, may be seen (Coleman, 1998).
IV. Autonomic nervous system imbalance can cause keratoconjunctivitis sicca, constipation, urinary retention, and poorly responsive mydriasis.

Diagnosis

I. Diagnosis is made by the exclusion of other causes of similar clinical signs.
II. Base definitive diagnosis on identification of the toxin in the material ingested, in serum, vomitus or feces.
III. Fecal culture for *C. botulinum* can provide supportive evidence of ingestion of the toxin.

Differential Diagnosis

I. Acute polyradiculoneuritis
II. Myasthenia gravis
III. Tick paralysis

Treatment and Monitoring

I. Treatment primarily consists of supportive care.
   A. Adequate nutrition and hydration are essential.
   B. Provide soft bedding to prevent pressure sores related to recumbency.
   C. Animals with megaesophagus are fed in an upright position to prevent aspiration pneumonia, or alimentation is provided through a gastrotomy tube.
   D. Animals with known or suspected aspiration pneumonia are treated with antibiotics based on culture and susceptibility testing.
II. Antitoxin therapy is available, but must be specific for the particular antigenic type.
   A. A polyvalent antitoxin containing type C is recommended for dogs.
   B. Recommended dosage is 10,000 to 15,000 units IV or IM with two doses administered 4 hours apart.
   C. A test dose of 0.1 mL is given intradermally before administration to identify animals at risk for anaphylaxis.
III. Recovery is usually slow, taking weeks to months to regain function.

Miscellaneous Toxins

Definition

I. Numerous toxins and drugs can cause clinical signs consistent with polyneuropathies.
II. Many also result in central nervous system signs.
III. Systemic signs and clinicopathologic abnormalities are common in toxin-induced neuropathies.

Causes and Pathophysiology

I. Vincristine
   A. Vincristine is a vinca alkaloid that is commonly used in the treatment of hematopoietic neoplasia.
   B. Vincristine causes cessation of microtubule assembly, which causes decreased axonal transport by interfering with neurofilaments.
II. Organophosphates
   A. Organophosphates (OPs) are used as insecticides (see Chapter 125).
   B. OP toxicity can be acute or chronic.
   C. Toxicity results from inhibition of ACh esterase, which leads to overstimulation of AChR by acetylcholine.
   D. With chronic toxicity, axonal degeneration can occur.
III. Heavy metals
   A. Lead is the most common cause of heavy metal intoxication (see Chapter 126).
   B. Lead intoxication is usually the result of ingestion of lead-based products (e.g., paints, fishing weights, lead-based batteries, various plumbing products).
   C. Generally, lead intoxication causes CNS signs; however, peripheral neuropathies can occur.
   D. Lead may cause segmental demyelination by affecting Schwann cells.

Clinical Signs

I. Clinical signs vary with the amount of exposure.
II. Generalized weakness can be acute or chronic.
III. With vincristine, signs range from mild weakness in the pelvic limbs to more severe weakness, intermittent collapse, and loss of pelvic limb reflexes and tone.
IV. Organophosphates may cause signs of muscarinic AChR overstimulation, such as excessive lacrimation, defecation, urination, hypersalivation, drooling, miosis, bradycardia, and dyspnea.
V. Chronic OP toxicity with agents like chlorpyrifos may only cause muscular weakness and fatigue, without signs of muscarinic AChR stimulation (Jaggy and Oliver, 1990).
VI. Neurological signs associated with lead toxicity consist most commonly of seizures; however, abnormal behavior, ataxia, and blindness can also occur.
VII. Gastrointestinal signs (vomiting, anorexia, weight loss, diarrhea) also may occur with lead toxicity.

Diagnosis

I. Presumptive diagnosis is based on history, accessibility to toxic compounds, and concurrent nervous and systemic clinical signs.
II. Occasionally, toxins cause concurrent clinicopathologic abnormalities (see Chapters 125 and 126).
III. Definitive diagnosis is made by toxicological testing.

Differential Diagnosis

I. Metabolic neuropathies
II. Paraneoplastic neuropathies

III. Inflammatory neuropathies
IV. Idiopathic neuropathies

Treatment and Monitoring

I. Nonspecific treatments are directed at eliminating further exposure, reducing further absorption, and alleviating clinical signs.
   A. Oral administration of activated charcoal can reduce gastrointestinal absorption of ingested toxins.
   B. Bathing can eliminate further topical absorption of OP.
II. Some specific treatments are described for the various toxins in Section 18.

VASCULAR DISORDERS

Definition

I. The most common cause of vascular neuropathies is aortic thromboembolism.
II. Thromboembolism occurs at the level of the aortic trifurcation, resulting in dysfunction of the muscles of the pelvic limbs, as well as the sciatic and femoral nerves.

Causes and Pathophysiology

I. In cats, the most common underlying disease is dilated cardiomyopathy.
   A. The origin of the embolus is usually a thrombus attached to an endocardial surface.
   B. Abyssinian, Birman, ragdoll, and male cats were overrepresented in one study (Smith et al., 2003).
II. In dogs, the most common underlying disease is a protein-losing glomerulopathy.
III. Arterial thromboembolism also occurs as a complication of hyperthyroidism and neoplasia (Sykes, 2003).
IV. Ischemia is produced by vasoconstriction of collateral circulation induced by serotonin and thromboxane A_2 released from platelets trapped in the thrombus.

Clinical Signs

I. Clinical signs are typically acute and include paresis and/or paraplegia with cold extremities, weak or absent femoral pulses, firm painful muscles, and loss of nociception.
II. The nail beds are cyanotic and fail to bleed when cut.
III. Occasionally, the same clinical signs can occur in the left thoracic limb as a result of thromboembolism involving the left brachycephalic artery.

Diagnosis

I. The diagnosis of feline cardiomyopathy is discussed in Chapter 10.
II. The diagnosis of protein-losing glomerulopathy is discussed in Chapter 48.
III. Common biochemical abnormalities in the acute phase include hyperglycemia, azotemia, and abnormally high serum concentrations of muscle enzymes (Smith et al., 2003).
IV. Confirm the diagnosis by aortography or Doppler ultrasonography of the aorta and its main branches.

Differential Diagnosis

I. Metabolic or toxic neuropathies
II. Inflammatory or immune-mediated neuropathies
III. Neoplastic polyneuropathies

Treatment and Monitoring

I. Treatment primarily involves supportive care.
II. Thrombolytic therapy is occasionally pursued with a variety of drugs (see Chapters 10 and 68).
III. Thrombolytic therapy can result in acute reperfusion injury.

NEOPLASIA

Paraneoplastic Neuropathies

Definition and Causes

I. A variety of cancers have been associated with both subclinical and clinical polyneuropathies.
II. Subclinical neuropathies have been associated with bronchogenic carcinoma, mammary gland carcinoma, osteosarcoma, thyroid adenocarcinoma, and mast cell tumors (Braund, 1990).
III. Clinical signs have been seen with bronchogenic carcinoma, mammary adenocarcinoma, malignant melanoma, insulinoma, lymphosarcoma, metastatic hemangiosarcoma, and leiomyosarcoma.

Pathophysiology

I. The current hypothesis is that the polyneuropathy results from an immune reaction primarily directed against the cancer that involves antibodies reacting with an antigen common to the nervous system and the tumor.
II. In humans, a variety of antineural, antimyelin basic protein, and antimyelin-associated glycoprotein antibodies, known as *neural onconeuronal antibodies*, have been identified in which there is a common antigen between cancer cells and nervous tissue cells (Cuddon, 2002).

Clinical Signs

I. Neuropathic signs may precede, develop with, or follow the identification of the underlying neoplasia.
II. Clinical signs consist initially of paraparesis, with slow progression to tetraparesis.
III. Clinical signs include hyporeflexia, hypotonia, and varying degrees of muscle atrophy.
IV. A specific syndrome solely involving multiple cranial nerves, particularly CN V, has been reported with lymphoma and leukemias (Carpenter et al., 1987).
   A. Signs include atrophy of the temporalis and masseter muscles, jaw weakness, inability to close the mouth, sensory deficits of the face, and deficits of the palpebral and corneal reflexes.
   B. Other commonly affected nerves are CNs VII and VIII.

Diagnosis

I. Diagnosis is by exclusion of other causes of neuropathies in animals with cancer.

II. Electrophysiology supports the diagnosis of a peripheral neuropathy.
III. Peripheral nerve biopsies show varying degrees of demyelination and axonal loss.

Differential Diagnosis

I. Metabolic or toxic neuropathies
II. Inflammatory neuropathies
III. Idiopathic neuropathies

Treatment and Monitoring

I. Direct treatment at the underlying neoplasia.
II. Successful treatment of the neoplasia may result in resolution of clinical signs (Mariani et al., 1999).
III. Unfortunately, not all clinical signs remit with resolution of the underlying cancer.

Insulinoma-Related Neuropathy

Definition and Cause

I. Clinical signs of generalized weakness can occur as a result of hypoglycemia from a functional insulinoma.
II. Subclinical polyneuropathy also has been reported with insulinomas (Braund et al., 1987).

Pathophysiology

I. Insulinoma is an insulin-secreting neoplasm of the beta islet cells of the pancreas that causes hyperinsulinemia and subsequent hypoglycemia.
II. Unlike neurons of the CNS, the peripheral nervous system can use not only glucose, but also amino acids and fatty acids as energy substrates.
III. Although the exact pathophysiology of the polyneuropathy is unknown, it may be a consequence of decreased energy metabolism secondary to hypoglycemia.
IV. The primary pathology is axonal degeneration affecting the distal axon of motor nerves.
V. Demyelination and remyelination have also been observed.

Clinical Signs

I. Clinical signs occur from both the effects of hypoglycemia and the polyneuropathy.
II. Signs of hypoglycemia include depression, lethargy, and seizures (see Chapters 46 and 73).
III. Signs associated with the polyneuropathy include appendicular weakness, exercise intolerance, collapse, and decreased to absent reflexes.
IV. Occasionally, CN dysfunctions (e.g., facial weakness, atrophy of the musculature of the head) have been seen.

Diagnosis

I. Presumptive diagnosis is made by identifying hypoglycemia and elevated serum insulin levels in dogs with appendicular weakness, and hypo- or areflexia.
II. Electrophysiological findings include fibrillation potentials and positive sharp waves, with mild decreases in NCV.
III. Definitive diagnosis requires histopathologic evaluation of peripheral nerves.
IV. Histopathologic changes include axonal degeneration and secondary demyelination.

Differential Diagnosis

I. Metabolic or toxic polyneuropathies
II. Inflammatory or immune-mediated polyneuropathies
III. Other paraneoplastic polyneuropathies

Treatment and Monitoring

I. Treatment is directed at correcting the hypoglycemia and eliminating the underlying neoplasia.
   A. Surgical removal of the neoplasm is the primary method of treatment (see Chapters 46 and 73).
   B. Hypoglycemia also can be controlled through dietary alterations, including diets high in fiber and low in carbohydrates, frequent feedings, and glucocorticoids (see Chapter 46).
II. Resolution of clinical signs requires weeks to months.
III. Occasionally, clinical signs persist despite euglycemia.

Peripheral Nerve Sheath Tumors

Definition and Cause

I. Peripheral nerve sheath tumors (PNSTs) arise from cells surrounding peripheral nerves.
II. The exact cell of origin is usually unknown.
III. Other terms, such as *neurofibroma, neurofibrosarcoma, schwannoma,* and *malignant schwannoma,* have also been used to describe these tumors.

Clinical Signs

I. Signalment is suggestive.
   A. Dogs are most commonly affected.
   B. Affected dogs range in age from 3 to 13 years, with a median of 9 years (Brehm et al., 1995).
   C. No breed or sex predilection has been reported.
   D. Cats are rarely affected.
II. The most common sign is chronic progressive, unilateral limb lameness.
   A. Thoracic limbs are more commonly affected than pelvic limbs.
   B. The affected limb typically shows signs consistent with LMN disease, such as muscular atrophy, decreased to absent segmental reflexes, and hypotonia.
III. Occasionally, the only clinical sign is pain.
IV. Hemiparesis or tetraparesis can be seen with neoplasia that encroaches on the spinal cord.
V. PNSTs can involve the cranial nerves (Zachary et al., 1986).
   A. The trigeminal nerve is most commonly affected and can result in ipsilateral sensory and motor deficits (atrophy of the muscles of mastication).
   B. Tumors arising from other CNs are rare.

Diagnosis

I. Diagnosis is most commonly made with imaging studies.
   A. Magnetic resonance imaging (MRI) can be used to visualize PNSTs arising from the brachial or lumbar plexus, and from spinal nerves.

B. MRI can also define the extent of the disease (e.g., location in the spinal canal, involvement of the spinal cord) (Platt et al., 1999).
C. Computed tomography (CT) can be used to diagnose a PNST involving the brachial plexus.
D. Ultrasonography can identify tumors involving the brachial plexus.
E. Myelography can identify a PNST within the vertebral canal based on its typical intradural-extramedullary myelographic pattern.

II. Electrophysiological testing defines which nerves are affected but abnormalities are nonspecific.
III. Tumors in the brachial plexus can be palpated occasionally.
IV. Pain at the site of the tumor can often be detected.
V. Tumors involving the thoracic (T)1-T3 spinal nerves or brachial plexus can cause ipsilateral Horner's syndrome.
VI. Surgical biopsy or resection is ultimately needed for a definitive diagnosis.

Differential Diagnosis

I. The most important differential diagnosis is musculoskeletal disease.
II. Lateralized intervertebral disc disease can result in similar clinical signs.
III. Other neoplastic processes compressing a spinal nerve or nerves of the brachial–lumbar plexus must be ruled out.

Treatment

I. Surgical resection via amputation is the treatment of choice.
II. For PNSTs involving the spinal nerves, hemilaminectomy combined with amputation may be needed (Bailey, 1990; Brehm et al., 1995).
III. Adjunctive treatment with postoperative radiation therapy may be beneficial.
IV. Radiation therapy also may be a treatment option for nonresectable PNSTs.

Monitoring of Animal

I. Prognosis varies with extent of disease.
II. Long-term survival can occur with complete resection of PNSTs, which is typically accomplished with tumors located distally on the limb.
III. For PNSTs involving a nerve plexus, the median relapse-free period is 7.5 months and the median survival time is 12 months (Brehm et al., 1995).
IV. For PNSTs involving the spinal nerves, the median relapse-free period is 1 month and the median survival time is 5 months (Brehm et al., 1995).

Secondary Peripheral Nerve Tumors

Definition and Causes

I. Occasionally, tumors of nonneural origin invade or compress peripheral nerves.
II. The most common secondary peripheral nerve tumors are related to hematopoietic neoplasia.
III. Small cell carcinoma of the lung compressing cervical (C) 8 and T1 spinal nerves has been reported (Ferreira et al., 2005).

Clinical Signs

I. Clinical signs relate to the nerves being affected.
II. Hematopoietic neoplasia commonly affects the trigeminal nerve (CN V) resulting in sensory–motor deficits of the head and atrophy of the muscles of mastication.

Diagnosis

I. Definitive diagnosis requires cytological or histopathologic confirmation of neoplastic involvement of nerves.
II. With cranial nerve involvement, CSF analysis may provide a cytological diagnosis of hematopoietic neoplasia.
III. MRI may demonstrate contrast enhancement of peripheral nerves.
IV. In animals with established hematopoietic neoplasia, presumptive diagnosis can be made based on clinical findings of cranial nerve dysfunction, particularly involving the trigeminal nerve.

Differential Diagnosis

I. The most important differential diagnosis is PNST.
II. Musculoskeletal disease can also manifest with clinical signs similar to secondary tumors compressing or invading spinal nerves.

Treatment and Monitoring

I. Treatment is dictated by the histopathologic diagnosis of the secondary tumor.
II. Treatment of hematopoietic tumors is discussed in Chapters 69 and 72.

TRAUMATIC DISORDERS

Brachial Plexus Avulsion

Definition and Causes

I. Common causes of nerve injury include road traffic accidents, gunshot wounds, bites, lacerations, stretching injuries, fractures, and iatrogenic damage from surgical procedures or injections.
II. Avulsion of the nerve roots forming the brachial plexus, as a result of a road traffic accident or falls from a height, is the most common traumatic neuropathy in the dog and cat.
III. Three types of nerve damage can be distinguished, depending on the degree of structural damage.
A. Neurapraxia is a transient, physiologic failure of nerve transmission in the absence of structural damage.
B. Axonotmesis is disruption of the axons, with the endoneurial and Schwann cell sheaths remaining intact.
C. Neurotmesis is complete severance of all structures of the nerve.

Pathophysiology

I. As long as the cell body of the neuron remains intact, damage to the axon results in degeneration of the distal segment, which is known as *Wallerian degeneration.*

II. Regeneration can occur in a proximal to distal direction.
III. Peripheral nerves regenerative at a rate of approximately 1 to 2 mm/day.
IV. The damage most often occurs at the level of the spinal roots where resistance to stretch is less than in peripheral nerves, owing to the lack of perineurium (Summers et al., 1995).

Clinical Signs

I. Clinical signs vary with the severity of the injury and depending on which peripheral nerves are involved.
II. Avulsion of the cranial plexus roots (C6 to C7 nerve roots) causes certain signs.
   A. Avulsion of the cranial plexus results in a loss of shoulder movement and elbow flexion, although the animal can still bear weight on that limb, as the extension of the elbow is spared.
   B. The cutaneous sensation may be lost in the dorsum of the paw and the cranial and lateral antebrachium.
III. Avulsion of the caudal plexus roots (C8 to T2 nerve roots) causes the following:
   A. Avulsion of the caudal plexus results in carriage of the limb with the elbow and shoulder flexed and inability to bear weight because of paralysis of the triceps brachii muscle (elbow extension).
   B. The elbow is dropped and knuckling of the carpus occurs with ambulation.
   C. Cutaneous sensation may be lost distal to the elbow.
IV. Complete avulsion of all plexus roots (C6 to T2 nerve roots) causes a flaccid limb with inability to bear weight and loss of cutaneous sensation in the entire limb.
V. Many dogs with brachial plexus avulsion also have ipsilateral Horner's syndrome, and/or loss of cutaneous trunci reflex.

Diagnosis

I. Diagnosis is made based on history and clinical findings.
II. Identifying specific areas of cutaneous sensation loss (analgesia) in regions of skin innervated by specific nerves (autonomous zones; see Table 21-3) can provide information regarding the involvement of particular nerves (Bailey et al., 1982).
III. EMG helps to document the extent of muscle denervation and confirms the distribution of nerve injury, although changes may not be seen for 7 to 10 days after the injury.

Treatment and Monitoring

I. Treatment for most injuries is conservative and relies mainly on aggressive physiotherapy.
II. Serial evaluation of radial motor NCV may be a useful prognostic indicator, with early decreased conduction velocity indicating a poor prognosis (Faissler, 2002).
III. Carpal arthrodesis may be indicated if triceps function is intact (the animal can extend the elbow and thereby weight support), but the animal is knuckling.
IV. Prognosis varies depending on the degree of dysfunction.
   A. The prognosis is good for animals with cranial brachial plexus avulsion that retain the ability to bear weight and have intact cutaneous sensation.
   B. Animals with complete or caudal brachial plexus avulsion have a guarded to poor prognosis, especially if cutaneous sensation has been lost.
      1. If no improvement occurs during the first 2 months, recovery is unlikely.
      2. Amputation is recommended in these cases, especially if complications such as self mutilation from paresthesia, joint contractures, or trophic ulcers develop.

CHAPTER 26

Introduction

Lisa E. Moore

APPROACH TO CLINICAL PROBLEMS

Gastrointestinal versus Systemic Disease

I. In animals with signs of gastrointestinal (GI) disease, it is important to determine whether the signs are related to a primary GI disease or some other systemic disease.
II. This distinction is sometimes difficult, but usually can be made.
III. The distinction is important so the animal with systemic disease does not undergo unnecessary procedures, such as endoscopy or exploratory laparotomy.
IV. The presence of clinical signs other than those related to the GI tract often indicates a systemic disease.
    A. For example, polyuria and polydipsia do not usually accompany primary GI disease.
    B. Joint swelling may indicate an orthopedic or infectious disease.
V. Once it has been decided that the animal is suffering from primary GI disease, localizing the signs to a specific area of the GI tract is the next step.

Initial Evaluation

I. A complete history and physical examination are the foundation of any diagnostic work-up.
II. Information regarding travel history, environment, and vaccinations is important.
III. Whether any other animals or people in the household have or are affected by similar clinical signs can be important.
IV. Dietary history is especially important when dealing with intestinal problems.
V. Dogs and cats with GI disease may not have any abnormalities on physical examination.
VI. A rectal examination is part of the physical examination of any animal with diarrhea.

Minimum Database

I. Laboratory tests may not be necessary in acute cases, but are imperative in animals with chronic signs.
II. A thorough work-up includes a complete blood count (CBC), serum chemistry profile, urinalysis, fecal examination (both direct and flotation), and abdominal radiography.
III. If systemic disease is present, abnormalities are often found.
    A. Azotemia if the animal is vomiting from renal failure
    B. Electrolyte changes if the animal has hypoadrenocorticism

Further Testing

I. Once a minimum database has been performed, it is usually clear as to whether or not the animal has a primary GI or systemic disease.
II. If it is still unclear, additional tests are appropriate.
    A. Abdominal ultrasonography
    B. Endocrine testing
    C. Contrast radiography

LOCALIZATION AND DEFINITIONS

Vomiting versus Regurgitation

I. It is important to differentiate these signs as the diagnostic work-up for the two problems is quite different.
II. Vomiting is the forceful, reflexive ejection of stomach contents, and it is accomplished by contraction of the muscles of the diaphragm and abdomen.
    A. Vomiting is preceded by signs of nausea, including restlessness, depression, hypersalivation, lip licking, and frequent swallowing.
    B. It is an active process.
III. Regurgitation is the expulsion of ingesta from the esophagus or pharynx.
    A. It is a passive event, with no or little abdominal effort.

B. Generally, few if any prodromal signs are noted, but drooling may be present because of an inability to swallow saliva.
C. Regurgitated food is undigested and may be regurgitated at any time (immediately after eating or many hours later).
D. The ingesta may be tubular in shape, but this is not pathognomonic.

Small versus Large Bowel Diarrhea

I. Small intestinal diarrhea may vary from slightly loose to watery.
   A. The stool may be foul smelling and may contain melena or undigested food.
   B. The volume of stool is increased, and a mild to moderate increase in frequency of bowel movements (2 to 5 times a day) occurs.
   C. Urgency is rare.
   D. Weight loss is common.
   E. Other signs can include flatus, borborygmus, halitosis, vomiting, loss of appetite, or polyphagia.
II. Large intestinal diarrhea may vary from formed to loose.
   A. Mucus and/or fresh blood are common.
   B. Undigested food is rare.
   C. The volume of stool may be normal to increased, and the frequency of bowel movements is increased (5 to 10 times per day), with multiple attempts to defecate each time.
   D. Owners may confuse the attempts to defecate as constipation.
   E. Urgency and tenesmus are common.
   F. Changes in appetite and weight loss are uncommon, but can occur with severe motility changes or with chronic disease.

Melena versus Hematochezia

I. Melena is the presence of digested blood in the stool.
   A. The stool has a black, tarry appearance.
   B. Blood may enter the intestinal tract from numerous sources, such as swallowed blood from dental disease, nasal disease, and hemoptysis or from upper GI bleeding.
   C. Melena does not necessarily indicate primary GI disease, because coagulopathies can also cause GI bleeding.
II. Hematochezia is the presence of fresh, red blood in the stool.
   A. It may occur in the form of streaks on or in the stool, or the entire feces may be bloody and include clots and/or mucus.
   B. Hematochezia suggests involvement of the colon, rectum, or anus.

Other Clinical Signs

I. Halitosis can result from a variety of disorders, including uremia and oral, pharyngeal, esophageal, and gastric diseases.
II. Halitosis can be affected by diet (high protein, poorly digested protein).
III. Other signs of intestinal disease include ptyalism, dysphagia, retching, gagging, difficulty eating, borborygmus, flatulence, ascites, and abdominal pain.

CHAPTER 27

Diseases of the Oral Cavity and Pharynx

Mark E. Hitt | Debra L. Zoran

CONGENITAL/DEVELOPMENTAL DISORDERS

Debra L. Zoran

See Table 27-1.

INFECTIOUS AND INFLAMMATORY DISORDERS

Debra L. Zoran, Mark E. Hitt

Stomatitis, Gingivitis, and Glossitis

Definition

I. These disorders include inflammatory processes of the oral mucosa, tongue, and gingiva that result in ulceration, necrosis, and secondary infection.
   A. Stomatitis: inflammation of the mucous membranes of the mouth
   B. Glossitis: inflammatory lesions of the tongue
   C. Gingivitis: inflammation of the gingiva
   D. Faucitis: inflammatory lesions of the glossopalatine folds or angles of the mouth
   E. Cheilitis: inflammatory lesions of the lips
   F. Periodontitis: lesions of the periodontal membrane, gingiva, and alveolar bone
II. Many oral inflammatory diseases arise secondary to systemic diseases and may involve multiple, oral soft-tissue structures.
III. Progressive involvement and coalescence of multiple sites can occur.
IV. These inflammatory conditions are a frequent problem in cats and are increasing in dogs.
V. Chronic, unrelenting forms of gingivitis or stomatitis have a variety of names, including lymphoplasmacytic stomatitis, plasmacytic stomatitis, chronic ulcerative paradental stomatitis (CUPS), plasma cell gingivitis stomatitis, pharyngitis, and necrotizing stomatitis.
VI. Gingivostomatitis is generalized inflammation of the gingival and oral cavity (Lyon, 2005).

Causes

I. Dental plaque and calculus
II. Immune-mediated diseases
   A. Pemphigus complex: pemphigus foliaceus, pemphigus erythematosus, pemphigus vulgaris
   B. Systemic lupus erythematosus (SLE)
   C. Drug eruptions and/or toxic epidermal necrolysis
   D. Food hypersensitivity
   E. Discoid lupus erythematosus, bullous pemphigoid
   F. Allergic contact dermatitis: plastic materials
   G. Idiopathic vasculitis
   H. Ulcerative gingivitis-stomatitis of Maltese terriers
III. Idiopathic disorders
   A. Feline gingivitis-stomatitis-pharyngitis complex
   B. Feline eosinophilic granuloma complex
   C. Eosinophilic granuloma of Siberian huskies
   D. Ulcerative eosinophilic stomatitis of Cavalier King Charles spaniels
IV. Immunodeficiency disorders
   A. Neutrophil function defects
   B. Neutropenia
   C. Prolonged, immunosuppressive drug therapy
V. Infectious diseases
   A. Bacteria
      1. Major anaerobic species: *Porphyromonas* spp. (formerly *Bacteroides* spp.), *Fusobacterium* spp., *Propionibacterium* spp., *Peptostreptococcus* spp., and *Clostridium* spp.
      2. Gram-positive aerobes: *Streptococcus* spp., *Staphylococcus* spp., *Corynebacterium* spp., *Actinomyces* spp.
      3. Gram-negative aerobes: *Escherichia coli, Pseudomonas* spp., *Proteus* spp., *Pasteurella* spp.
      4. Spirochetes
         a. Acute necrotizing ulcerative gingivitis (ANUG, Vincent's stomatitis, or trench mouth)
         b. Leptospirosis: *Leptospira canicola, Leptospira icterohaemorrhagiae*
      5. Intracellular bacteria: *Bartonella henselae* implicated
   B. Viral diseases
      1. Feline calicivirus: most common
      2. Feline immunodeficiency virus (FIV)
      3. Feline herpesvirus (FHV-1)
      4. Feline leukemia virus (FeLV)
      5. Canine adenovirus (CAV-2)
      6. Canine distemper virus or feline panleukopenia virus
      7. Feline syncytium-forming virus

TABLE 27-1

Congenital and Developmental Disorders

DEFECT	CAUSES	CLINICAL CHARACTERISTICS	DIAGNOSIS	TREATMENT	COMMENTS
Primary cleft palate (lip)	May be secondary to intrauterine trauma or insult Affected pups are born to affected parents	Often associated with secondary cleft palate in the dog May occur unilaterally or bilaterally No signs other than the physical defect	Physical examination	Surgical lip reconstruction	Animals should not be bred Higher incidence in brachycephalic breeds, beagles, cockers, and dachshunds
Secondary cleft palate (hard and soft palate)	Inherited or secondary to developmental insult Occurs in both dogs and cats	Inability to nurse; poor growth; milk drainage from nares; coughing, gagging, and sneezing during nursing Nasal discharge resulting from rhinitis may occur with time Aspiration pneumonia may be fatal	Physical examination of mouth reveals abnormal division of hard/soft palate	Surgical reconstruction of palate when animal is 2-4 months of age; nutritional and medical supportive care until then	Higher incidences in brachycephalic breeds, Shetland sheepdogs, schnauzers, Labrador retrievers, and German shepherd dogs
Malocclusion: prognathism	Genetic factors: normal in brachycephalic dogs and Persian cats Abnormal dentition (position of teeth or retained teeth) Trauma	Clinical appearance: long mandible with short maxilla May predispose to periodontal and gingival disease	Physical examination	Early removal of retained supernumerary or malpositioned deciduous teeth	Maltese terriers are predisposed to retained teeth
Malocclusion: brachygnathism	Genetic factors: long-haired dachshund, shar-pei Abnormal in any breed, but no known cause	Physical finding of shortened mandible with a long maxilla If severe, may prevent normal jaw function and eating	Physical examination	No specific treatment available	
Microcheilia	Unknown cause	Physical finding of a reduced oral fissure	Physical examination	None	Reported in miniature schnauzers
Lip-fold dermatitis	Congenital trait resulting in abnormal conformation of the lip fold in spaniel breeds	Chronic moist, fetid dematitis of lip folds	Physical examination	Resection of skin folds	Affected animals should not be bred Breed with a higher incidence: Brittany spaniel
Elongated soft palate	Brachycephalic breeds are predisposed	Associated with exercise and heat intolerance, and abnormal oropharyngeal function	Physical examination, radiography	Surgical removal of offending tissue	Breeds with a higher incidence: affenpinscher, chow chow, English and French bulldogs, Pekingese, and pugs

Data from Clark RW (ed): Medical Genetic and Behavioral Aspects of Purebred Cats. Forum Publications, Fairway, Kan, 1992; Clark RW (ed): Medical Genetic and Behavioral Aspects of Purebred Dogs. Forum Publications, Fairway, Kan, 1994; Norden DM: Normal development and congenital defects in the cat. p. 1248. In Kirk RW, Bonagura JD (eds): Current Veterinary Therapy XI: Small Animal Practice. WB Saunders, Philadelphia, 1992.

TABLE 27-1

Congenital and Developmental Disorders—*cont'd*

DEFECT	CAUSES	CLINICAL CHARACTERISTICS	DIAGNOSIS	TREATMENT	COMMENTS
Craniomandibular osteopathy	Developmental condition	Proliferation of bones of skull and mandible; painful swelling of mandible Reduced jaw motion results in reluctance to eat and depression	Physical examination and radiographic changes (exostosis of mandible, tympanic bulla, and calvarium)	Corticosteroids and nonsteroidal anti-inflammatory drugs may relieve signs but are not curative Surgery is of limited success in most cases	Breeds affected: West Highland white, Scottish, and Cairn terriers; Labradors; Great Danes; Doberman pinschers
Microglossia	Congenital defect reported in dogs	Excessive drooling, difficulty eating	Physical examination	None	Rare

8. Papovavirus
9. Feline infectious peritonitis (FIP) virus: rare
10. Multiple viral infections: FIV or FeLV and calicivirus or FHV-1

C. Fungal diseases
1. Blastomycosis *(Blastomyces dermatitidis)*
2. Candidiasis *(Candida albicans)*
3. Cryptococcosis *(Cryptococcus neoformans)*
4. Others: histoplasmosis, sporotrichosis, coccidioidomycosis, *Malassezia* spp. (rare)

VI. Metabolic diseases
A. Diabetes mellitus
B. Hypoparathyroidism
C. Uremia: most common cause
D. Hypothyroidism

VII. Neoplasia (see later in this chapter)

VIII. Nutritional disorders
A. Hypervitaminosis A: oral lesions in conjunction with bony exostosis
B. Niacin deficiency (pellagra)
C. Protein-calorie malnutrition
D. Riboflavin deficiency (Roe, 1991)
E. Calcium imbalances: periodontal disease

IX. Physiochemical and traumatic causes
A. Caustic or irritant chemicals
1. Acids, alkalis
2. Phenols
3. Petroleum products
4. Benzalkonium chloride

B. Antineoplastic therapies: chemotherapeutics, radiation therapy
C. Dilantin (diphenylhydantoin)
D. Cyclosporine: gingival hyperplasia that appears as gingivitis
E. Foreign bodies
1. Plant material
2. Fiberglass
3. Bone fragments
4. Quills, claws
5. Rubber bands, string, or Christmas tree tinsel

F. Heavy metals: thallium, mercury
G. Insect bites and stings: bees, spiders, scorpions, ants, etc.
H. Irritant plants: dieffenbachia, poinsettia, philodendron
I. Electric cord burns
J. Persistent overgrooming (cats)
K. Trauma

Pathophysiology

I. A variety of factors influence the pathogenesis of inflammatory oral disease, including the many microorganisms in the mouth and the fact that the oral cavity is subject to trauma, abrasion, and frequent changes in hydration and temperature.

II. Most inflammatory diseases of the oral cavity have an immunological response that is excessive, persistent, or aberrant (Lyon, 2005).

III. Primary defenses against oral disease are the epithelial surface, saliva, and the local (inflammatory) and systemic immune responses (humoral and cell-mediated immunity).

IV. Depression of oral defense mechanisms allows secondary infections by organisms that are not normally pathogenic (Tenorio et al., 1991).
A. Acquired immunodeficiency diseases (e.g., FIV) and chronic corticosteroid use are important causes.
B. Long-term antibiotic treatment can alter the normal microflora, creating resistant species and allowing the overgrowth of bacteria (spirochetes) or *Candida* spp.
C. Chronic systemic diseases alter the replication, exfoliation, and maturation of epithelial cells, predisposing these tissues to disease.
D. The presence or persistence of periodontal disease can also lead to chronic infection and immunological stimulation.

V. Uremia causes oral ulceration by several mechanisms.
   A. Oral microbes degrade urea to ammonia, and the high systemic concentration of urea leads to production of cytotoxic levels of ammonia.
   B. Hyperammonemia results in decreased rates of tissue repair, and reduced platelet (increased bleeding and ulcerations) and immune function.
VI. Animals with diabetes mellitus often develop oral infections from immune compromise, which is exacerbated by the presence of xerostomia (dry mouth) or dehydration.
VII. Immune-mediated diseases cause oral lesions by production of autoantibodies to the normal epithelial components, resulting in destruction of normal mucosa, with concurrent ulcers, erosions, blisters, and inflammation.

Clinical Signs

I. A careful history of the signalment, onset, and duration of clinical signs is important.
II. It is also important to distinguish whether the disease process is either localized to the oral cavity or a manifestation of systemic disease.
III. The most common presenting complaints that may be associated with stomatitis, gingivitis, and glossitis include the following:
   A. Anorexia, reduced appetite, interest in food but refusal to eat
   B. Abnormal or exaggerated chewing motions, "chattering" teeth
   C. Halitosis
   D. Ptyalism (drooling)
   E. Bleeding from the mouth or gums
   F. Dysphagia
   G. Vomiting, retching, gagging, regurgitation
   H. Face rubbing, head shaking
   I. Nasal discharge, sneezing
   J. Fever, depression, regional lymphadenopathy

Diagnosis

I. General anesthesia may be required for a complete examination if the animal is fractious or in pain.
   A. Feline gingivitis-stomatitis-pharyngitis complex
      1. Focal, regional, or diffuse lesions
      2. Generalized hyperemia of mucous membranes and lips
      3. Severe gingival recession around teeth and surrounding bone (teeth may be loose)
      4. Severe oral ulceration
      5. Fever, depression, weight loss from inappetence
      6. Pain when opening the mouth, especially with faucitis
   B. Feline eosinophilic granuloma complex (see later in this chapter)
   C. Eosinophilic granuloma of Siberian huskies, Cavalier King Charles spaniels, and other breeds (rare)
      1. Proliferative eosinophilic lesions of the tongue occurring primarily in young dogs
      2. Other signs: difficult prehension or swallowing, drooling, and oral pain
   D. ANUG
      1. Acute onset of severe halitosis; gingivitis; oral ulceration of tongue, buccal mucosa, and palate
      2. Lesions possibly covered with a gray pseudomembrane of necrotic tissue and purulent exudate
      3. Localized or systemic immunodeficiency probably necessary for development
   E. Leptospirosis
      1. *L. canicola:* severe generalized hyperemia of mucous membranes, oral ulceration and hemorrhage, gingival petechiae, glossitis, lingual necrosis
      2. *L. icterohaemorrhagiae:* severe generalized hyperemia of mucous membranes, oral hemorrhage, gingival petechiae
   F. FHV-1
      1. Acute vesicular to ulcerative, focal to diffuse glossitis and stomatitis
      2. Rhinitis, conjunctivitis, keratitis, pharyngitis
      3. Persistent infections with recrudescence
   G. Calicivirus
      1. Oral vesiculation and ulceration of the tongue, palate, and fauces are the most common clinical manifestations.
      2. Transient fever, limping, and focal interstitial pneumonia occur in some infected cats.
   H. FeLV: chronic proliferative gingivitis, stomatitis, oral ulceration
   I. FIV
      1. Chronic gingivitis, stomatitis, periodontitis
      2. Acute, rapidly progressive gingival necrosis
      3. More severe and persistent with concurrent calicivirus
   J. Candidiasis
      1. Creamy, plaquelike lesions on the tongue, oral mucosa, lips, mucocutaneous junctions
      2. Inflammation and ulceration of mucosa beneath the lesions
   K. Blastomycosis: ulcerative, granulomatous plaques on tongue, gingiva, palate
   L. Cryptococcosis: fleshy, proliferative lesions on the palate, gingiva, lips, or tongue
   M. Phycogranulomatosis
      1. Phycogranulomatosis is a chronic, localized to diffuse glossitis surrounding embedded plant material.
      2. In cats, the lingual frenulum is a common location for awns or burrs to lodge.
   N. Diphenylhydantoin *(Dilantin):* gingival hyperplasia in both cats and dogs
II. Hematology is usually nonspecific.
   A. Anemia: chronic oral hemorrhage, anemia of chronic disease or associated with FIV and FeLV
   B. Leukocytosis: chronic inflammation or infection
   C. Eosinophilia: eosinophilic granuloma complex
III. Other laboratory tests are necessary to differentiate causes.
   A. Biochemical profile
   B. Thyroid function tests (see Chapter 42)
   C. Virological testing for FIV, FeLV, FHV-1, etc.
   D. Immunological testing (see Chapter 76)

E. Cytology
   1. Bacterial agents, especially spirochetes, can be identified.
   2. Fungal elements from *Blastomyces* spp. or *Histoplasma* spp. may be found.
   3. Neoplasia may be detected.

F. Culture
   1. Routine bacterial culture of oral lesions is not recommended, because most cultures reveal normal microbial flora.
   2. If routine antimicrobial therapy is ineffective, culture and sensitivity testing can be used to select antibiotics.

IV. Biopsy is very important in distinguishing a primary cause and appropriate therapy.
   A. Histopathology is essential to differentiate similar-appearing diseases (e.g., squamous cell carcinoma) before initiation of therapy.
   B. Specialized analysis of histopathologic specimens is done for immune-mediated disorders.

Differential Diagnosis

I. Oral neoplasia, especially squamous cell carcinoma (SCC)
II. Eosinophilic granuloma complex

Treatment

I. The primary objective is to identify and remove or treat the underlying cause.
II. The first step is to achieve a clean, healthy periodontium via dental prophylaxis, periodontal debridement, and antibacterial therapy.
III. Bacteria alone may be the primary cause of gingivitis or stomatitis, and it is important to determine if bacteria are a primary or secondary cause.
IV. Because secondary bacterial overgrowth is a common occurrence, symptomatic therapy is indicated.
   A. Amoxicillin 22 mg/kg PO, SC, IM TID
   B. Amoxicillin-clavulanic acid
      1. Dogs: 12.5 to 25 mg/kg PO BID
      2. Cats: 62.5 mg PO BID
   C. Clindamycin 5 to 10 mg/kg PO BID
   D. Cephalexin 22 mg/kg PO, IM, SC TID
   E. Doxycycline 5 mg/kg PO BID
   F. Enrofloxacin 4 mg/kg PO SID (cats) and 5 to 10 mg/kg SID (dogs)
   G. Metronidazole 5 to 15 mg/kg PO BID to TID, then SID to maintain remission
V. Antifungal therapy may be indicated.
   A. Ketoconazole 10 to 15 mg/kg PO BID
   B. Itraconazole 5 to 10 mg/kg PO SID
   C. Fluconazole 2.5 mg/kg PO BID
VI. Antiviral therapy with interferon-γ has been anecdotally beneficial in some cats with retroviral infections.
VII. In cats, corticosteroid therapy is commonly used to treat gingivitis and stomatitis, but other immunosuppressive drugs may be needed in dogs or cats with some forms of immune-mediated or inflammatory diseases or for adverse reactions to corticosteroids therapy (see Lymphoplasmacytic Stomatitis).
VIII. Cyclosporine 1 to 4 mg/kg PO SID or divided BID has been used (anecdotally) with success in some cats, but improvement takes time (4 to 6 weeks) and requires careful monitoring of drug levels.
IX. Nutritional support is important.
   A. Canned diets or soft, blenderized foods may be tolerated best.
   B. Nutritional support in the form of esophagostomy or nasogastric tube feeding may be necessary in cats or dogs with oral pain and prolonged anorexia.
   C. Vitamin supplementation with vitamins C and E may be useful to promote epithelial regeneration, tolerance to inflammation, and healing.
   D. If balanced foods are fed, additional supplementation is generally unnecessary; however, if homemade diets are fed, vitamin and mineral supplements are indicated.
   E. Zinc supplementation in Siberian huskies and other sled dog breeds may be helpful.
X. Oral hygiene is maintained through frequent dental scaling (every 3 to 6 months) and oral cleansing, especially in cats with recurrent or poorly controlled disease.
   A. Oral cleansing to remove necrotic tissue and debris enhances recovery.
   B. Chlorhexidine (0.2%) rinses or gel applications may be used.
XI. Use of various products to enhance or modulate the immune system's response to chronic viral infections (e.g., bovine lactoferrin, interferon) has been reported, but no clear efficacy has been documented.
XII. Laser thermoablation (carbon dioxide laser) is used to reduce chronic proliferative tissue in the oral cavity (especially fauces of cats).

Monitoring of Animal

I. Adequate nutrition and hydration are essential for normal healing and successful management of oral disease.
II. Avoid prolonged antibiotic therapy or frequent changing of antibiotics to prevent development of candidiasis and/or resistant bacterial species.
III. Maintenance of oral hygiene through dental care and oral washes is very important.

Tonsillitis

Definition

I. Tonsillitis is inflammation of the tonsils and surrounding pharyngeal structures, with secondary lymphoid hyperplasia.
II. Primary tonsillitis is rare in dogs and is usually seen in young, small-breed dogs.

Causes

I. Primary tonsillitis may be a manifestation of normal pharyngeal defense mechanisms as the tonsil is exposed to infectious agents.

II. Secondary tonsillitis can be caused by a variety of insults.
  A. Chronic vomiting or regurgitation
  B. Chronic coughing, gagging, or retching
  C. Chronic nasopharyngeal disease or nasal discharge
  D. Foreign body penetration

Pathophysiology

I. Microorganisms that penetrate the tonsillar epithelium are phagocytized and processed by macrophages, presented to B and T lymphocytes, and subsequently stimulate both humoral and cell-mediated immune responses.
II. Lymphoid hyperplasia and reactivity occur when chronic infection overwhelms the tonsillar defense mechanisms.

Clinical Signs

I. Fever, depression
II. Head shaking
III. Dysphagia, repeated attempts to swallow
IV. Anorexia

Diagnosis

I. Clinical signs, history, and direct visualization of enlarged, hyperemic, friable tonsils, and pharyngitis are suggestive; however, the tonsils do not always protrude from the crypts.
II. Cultures are of questionable value because the most common organisms associated with tonsillitis are also the normal microflora of the mouth (*Porphyrmonas* spp., *E. coli, Staphylococcus aureus, Staphylococcus albus*, hemolytic streptococci, diplococci, *Proteus* spp., *Pseudomonas* spp.).
III. Cytology may be useful to rule out neoplasia and other differential diagnoses.
IV. Radiography helps identify penetrating radiopaque foreign bodies (e.g., bone fragments).
V. Anesthesia may be necessary for a complete examination.
VI. Ultrasonography of adjacent lymph nodes and salivary glands may be helpful.

Differential Diagnosis

I. Neoplasia: SCC, lymphosarcoma
II. Underlying disorders that cause chronic vomiting, regurgitation, or coughing

Treatment and Monitoring

I. Where possible, identify and correct the underlying disorder.
II. Broad-spectrum antibiotic treatment for 5 to 7 days is curative in most cases of primary tonsillitis.
  A. Amoxicillin, amoxicillin-clavulanic acid, tetracycline/doxycycline, clindamycin, or metronidazole may be given.
  B. Avoid long-term antibiotic therapy and frequent changes in antibiotics because they promote bacterial resistance and fungal overgrowth.
III. Tonsillectomy is rarely indicated unless the enlarged tonsils interfere with chewing or swallowing, or if tonsillar neoplasia has not been ruled out.

IDIOPATHIC DISEASES

Mark E. Hitt

Lymphoplasmacytic Stomatitis

Definition

I. Lymphoplasmacytic stomatitis is a chronic proliferative inflammatory disorder of the oropharyngeal mucosa variably affecting the gingiva; palatoglossal arches (faucitis); base of the tongue; larynx; and palatine, nasal, and caudal pharynx.
II. Mature cats (>12 months of age) are most frequently affected.
III. Dogs are diagnosed with similar pathology, but less often.
IV. Synonyms include plasma cell gingivitis and stomatitis, lymphoplasmacytic glossopharyngitis, and lymphocytic laryngo-pharyngitis.

Causes and Pathophysiology

I. It is considered an idiopathic condition after chronic viral, bacterial, and mechanical/traumatic factors have been ruled out.
II. Hypersensitivity reactions to oral or dental tissues with bacterial antigens acting as haptens have been hypothesized as the cause.

Clinical Signs

I. Signs are related to inflammation, pain, and proliferation of tissue.
II. Predominant signs include distorted masticatory movements, halitosis, inappetence, bleeding from gums, oral dysphagia, and ptyalism.
III. Oral examination reveals various lesions, including raised, erosive, proliferative, and/or erythematous lesions that may have concurrent ulcerative and proliferative components.
  A. Usually lesions are found at the palatoglossal arches (faucitis), around the teeth (paradental), and along the caudal aspects of the frenulum of the tongue.
  B. Additional affected areas may include the caudal pharynx, nasopharynx, laryngeal mucosa, commissure of the buccal mucosa, and tongue.

Diagnosis

I. Diagnosis is based on biopsy and histopathologic evaluation of the lesions.
  A. Surgical, endoscopic, and rongeur cup-type biopsies are acceptable.
  B. Cytological samples are often nondiagnostic because of the abundant cellular and bacterial debris on the surface of the lesions.
II. Histologic findings include a variable mixture of lymphocytes and plasma cells, with predominance of lymphoid cells under an eroded epithelium.
  A. Additional inflammatory cells (eosinophils, macrophages, neutrophils) can be present.

B. Repeated biopsy of chronic or relapsing cases is advised because of concern for oral neoplasia.

III. Clinical pathologic information is often helpful.
   A. A complete blood count (CBC) may reveal leukocytosis and mild anemia of chronic disease.
   B. Elevation of serum globulins and serum electrophoresis may support a polyclonal gammopathy reflective of a chronic lymphoid inflammatory response.
   C. Bacterial cultures for aerobes and anaerobes and Gram staining are not initially performed because of overlap between normal flora and pathogenic organisms; however, they may be helpful in chronic cases.

Differential Diagnosis

I. Eosinophilic granuloma complex and/or plaques: lesions more localized to the hard palate, philtrum, lips, and tongue
II. Neoplasia: especially SCC, lymphosarcoma
III. Linear foreign body wrapped at the base of the tongue and penetrating foreign bodies lodged in the mucosa (e.g., plant awns, burrs)
IV. Severe pyorrhea associated with bacterial infections and periodontitis
V. Chronic viral infections: FeLV, FIV, caliciviruses, FHV-1
VI. Adverse drug reactions
VII. Immune-mediated diseases: SLE, pemphigus complex, Stevens-Johnson syndrome
VIII. Inflammation from persistent vomiting, reflux of gastric acid and bile
IX. Eosinophilic granuloma of Siberian huskies
X. Eosinophilic stomatitis of Cavalier King Charles spaniels

Treatment

I. Treatment involves aggressive antiinflammatory or immunosuppressive medications.
II. The disorder is a persistent condition requiring long-term control.
III. Formulation of medications into liquids may be preferable.
IV. Oral hygiene is helpful for treating halitosis and removing superficial debris.
V. Antiinflammatory and immunosuppressive drugs include the following:
   A. Prednisone/prednisolone 2 mg/kg PO SID to BID, then tapered to lowest effective dose
   B. Methylprednisolone acetate 2 to 4 mg/kg IM at 2- to 6-week intervals in cats, as tolerated
   C. Megestrol acetate 0.25 mg/kg PO QOD for three doses, then once or twice weekly, as needed in cats only
      1. Do not use in unspayed females, in diabetics, or concurrently with corticosteroids.
      2. Use with caution because of severe potential side effects.
   D. Azathioprine 1 to 2 mg/kg PO SID to QOD in dogs; used concurrently with corticosteroids
   E. Chlorambucil 0.25 to 0.33 mg/kg PO every 72 hours initially in cats and 0.1 to 0.2 mg/kg PO SID to QOD in dogs; used concurrently with corticosteroids
   F. Aurothioglucose 1 mg/kg IM weekly for 10 to 20 weeks, then tapered to once monthly; response possibly delayed for 1 to 3 months
   G. Cyclosporine 2 to 5 mg/kg PO BID initially, then SID or QOD, but anecdotal or literature recommendations inconclusive at this time
VI. Antibiotics are often helpful initially and intermittently as secondary infections recur (see Stomatitis, earlier in this chapter).
VII. Laser fulguration, used carefully in conjunction with immunosuppressive therapy, is reported to help in some cases with marked proliferative lesions.
VIII. Dental extraction is an aggressive treatment.
   A. It is advised only after medications have been tried, or after owner compliance fails and client frustration is high.
   B. It is generally effective.
IX. Response to treatment is variable.
   A. Response to therapy may take weeks to assess.
   B. Lymphoplasmacytic stomatitis is a chronic condition that may be kept in remission, but is not often cured.
   C. Combinations of corticosteroids and immunosuppressive agents have usually provided the most success.

Monitoring of Animal

I. Clients must be advised that initial, frequent reassessments every 2 to 3 weeks to every 1 to 3 months are necessary to safely monitor and guide the use of immunosuppressive drugs.
II. Long-term monitoring of CBC, platelet counts, serum chemistries, and urinalyses are advised at 1- to 3-month intervals to assess for potential adverse effects of medication and chronic inflammation that may include anemia, leukopenia, thrombocytopenia, hepatopathy, and increased risk of bacterial infections.

Oral Feline Eosinophilic Granuloma Complex

Definition and Cause

I. Two forms of eosinophilic granuloma complex affect the oral cavity.
   A. Indolent or "rodent ulcer"–type erosions, often on the upper lip
   B. Eosinophilic granulomas anywhere in the oral cavity
II. These lesions are considered idiopathic because the cause is not well defined.
III. They involve an accumulation of a dense matrix of mixed inflammatory cells, which may have a predominance of eosinophils in fibroproliferative tissue.
IV. They occur as erosions, plaques, or proliferative lesions.

Clinical Signs

I. The clinical signs are the same as those of idiopathic lymphoplasmacytic gingivostomatitis.
II. Lesions are generally more focal than those seen in lymphoplasmacytic disease.

Diagnosis

I. Diagnosis is based on biopsy and histopathologic evaluation.
II. Surgical, endoscopic, and rongeur cup-type biopsies are acceptable.
III. Cytological samples are often nondiagnostic because of the abundant cellular and bacterial debris on the surface of the lesions.

Differential Diagnosis

I. SCC
II. Linear string foreign body
III. Lymphoplasmacytic oropharyngeal disease

Treatment

I. Use corticosteroids (prednisone, prednisolone, dexamethasone, triamcinolone) initially PO and/or intralesionally.
II. Try megestrol acetate at 0.25 to 0.5 mg/kg PO SID for 3 days, then once or twice weekly for several weeks until resolution.
III. Radiation, laser surgery, or cryotherapy can be effective for nonresponsive rodent ulcers.

PHARYNGEAL AND SWALLOWING DISORDERS

Mark E. Hitt

Oropharyngeal Dysphagia Disorders

Definition

I. Dysphagia is defined as difficulty in swallowing.
II. An abnormal oropharyngeal phase of swallowing can occur at several points.
  A. Oral stage: prehension in the oral cavity, bolus formation at the base of the tongue, and initiation of swallowing reflex
  B. Pharyngeal stage: rapid contractions of pharynx to direct the bolus aborally toward the cricopharyngeal passage
  C. Cricopharyngeal stage: coordinated relaxation of the upper esophageal sphincter (UES), propulsion of the bolus by the tightened pharynx into the proximal esophagus, and retightening of the UES and relaxation of the pharynx

Causes and Pathophysiology

I. Dysphagia is clinically difficult to separate into the specific stages.
  A. Visual observation can be difficult to assess.
  B. There are many overlapping causes involving more than one phase of swallowing.
II. Oral and pharyngeal dysphagia may arise from the following:
  A. Hypoglossal nerve dysfunction
    1. Hydrocephalus or other causes of increased intracranial pressure
    2. Trauma to the hypoglossal nerves (central or peripheral)
    3. Neoplasia affecting the cranial nerve nucleus
  B. Systemic neuromuscular disease
    1. Myasthenia gravis: focal or generalized
    2. Endocrine neuropathies
      a. Hypothyroidism
      b. Hyperadrenocorticism
      c. Hypoadrenocorticism
    3. Myopathies
      a. Familial myopathies (see Chapter 82)
      b. Muscular dystrophy-like disease of Bouviers des Flandres
    4. Immune-mediated myositis (inflammatory myopathies)
      a. Masticatory myositis
      b. Eosinophilic myositis
      c. Myositis associated with SLE
  C. Infectious causes
    1. Rabies virus
    2. Submucosal abscess: foreign bodies, bite wounds
    3. Borreliosis (Lyme disease): effects on cranial nerves (rare)
  D. Traumatic and physical obstruction
    1. Skeletal disorders and fractures
    2. Dental disease
    3. Gastroesophageal-pharyngeal reflux: bile or stomach acids
    4. Craniomandibular osteopathy
    5. Tumors of the oropharynx
    6. Pharyngeal mucocele
    7. Inflammatory nasopharyngeal polyps in cats
    8. Retropharyngeal lymphadenopathy from regional infection or metastasis: tonsillar carcinoma, thyroid carcinoma
    9. Pharyngeal mucosal laxity (collagen weakness) associated with hyperadrenocorticism in small and toy breeds of dogs (rare)
    10. Brachycephalic syndrome (see Chapter 15)
    11. Oropharyngeal foreign bodies
III. The etiology of cricopharyngeal dysphagia is variable.
  A. Failure to coordinate (asynchronous) the relaxation of the UES (achalasia) with cricopharyngeal contraction is an idiopathic congenital condition.
  B. Acquired or congenital strictures in the region of the cricopharynx and UES may result from the aforementioned causes.
IV. The mechanism of dysphagia varies and may be a dysfunction of anatomy, an asynchronous coordination of events, or may arise from obstruction.

Clinical Signs

I. Oral dysphagia
  A. Prehensile dysfunction may be noted.
    1. Drooling, dropping food from mouth
    2. Exaggerated efforts to toss food back into the oral cavity

B. Tongue fails to propel material aborally and has poor retractile strength when grasped.
C. Asymmetry of muscular or skeletal anatomy may be noted on examination.

II. Pharyngeal dysphagia
A. Prehension is normal, but there are repeated efforts at swallowing.
B. Gagging and coughing of saliva or a food bolus may occur.
C. Liquids may be swallowed more easily, but a post-swallowing cough or "clearing of the throat" is often reported.
D. Rhinitis and nasal discharge are often noted.
E. Aspiration pneumonia, pneumonitis, and/or tracheobronchitis with associated coughing, fever, or chronic pulmonary disease may be present.
F. Signs of systemic disorders may be present.

III. Cricopharyngeal dysphagia
A. In puppies the time of onset (achalasia) is usually at weaning.
B. Repeated efforts are made to swallow the same bolus of food.
C. Aspiration pneumonia and nasal discharge are common complications.

Diagnosis

I. Complete neurological and musculoskeletal examinations are imperative.
II. Take a careful history and observe any swallowing attempts.
III. Evaluate standard hematological and biochemical tests to identify predisposing disorders.
IV. Serological evaluation of antinuclear antibody, acetylcholine receptor antibody, and masticatory myositis antibodies may identify immune-mediated disorders.
V. Electromyography is helpful in identifying cranial nerve dysfunction but may be difficult to perform and interpret.
VI. Radiography and imaging techniques may be indicated.
A. Swallowing a positive contrast medium under videofluoroscopy is an ideal technique for evaluation of dysphagia.
B. Iohexol mixed with water, barium suspension, or barium mixed with food all have merit as contrast media (different textures).
C. Cervical region soft tissue and musculoskeletal abnormalities may be detected on survey radiographs.
D. Thoracic radiography may identify megaesophagus or detect mass lesions (e.g., thymoma, lymphosarcoma, heart base tumors).
E. Abdominal radiography may identify causes of gastric acid reflux or reveal evidence of more widespread dysautonomic gastrointestinal function.
F. Ultrasonography of the soft tissues of the cervical and ventral pharyngeal region helps identify tumors, cysts, abscesses, and asymmetry in the region.
G. Magnetic resonance imaging and computed tomography may localize tumors.

Differential Diagnosis

I. See causes listed earlier
II. Megaesophagus (see Chapter 30)
III. Retropharyngeal lymphadenopathy or abscess
IV. Meningitis with neck pain
V. Musculoskeletal disorders: temporomandibular joint disease, fractures
VI. Trigeminal neuralgia
VII. Retrobulbar abscess
VIII. Idiopathic polyneuropathy of Dalmatians and other breeds
IX. Laryngeal paralysis

Treatment

I. Treatment for dysphagia relies on determining the underlying cause(s).
II. Symptomatic treatment includes nutritional support.
A. Elevated feeding with trials of various textures of foods is often unrewarding for dysphagia.
B. Percutaneous endoscopic gastrostomy (PEG) tubes are superior to nasoesophageal and pharyngoesophageal tubes.
C. PEG tubes may be replaced for long-term feedings with low-profile gastrostomy (button) tubes.
D. Myotomy of the cricopharyngeal muscle is performed for cricopharyngeal achalasia, but for other dysphagias it may increase the risk of aspiration pneumonia.
III. See Chapter 18 for treatment of aspiration pneumonia.

Monitoring of Animal

I. Spontaneous improvement has been noted in a few cases of cranial nerve neuropathies, but neuropraxias (trauma causing dysfunction of the nerves) and musculoskeletal injuries may require months to improve.
II. Prognosis is guarded to poor if a specific cause cannot be identified because of the risk of aspiration pneumonia and the debilitation that ensues from malnutrition.

NEOPLASIA

Debra L. Zoran

Epulis

Definition and Cause

I. Gingival proliferations of tissue that are benign and do not significantly invade bone are termed *epulides*.
II. Classification of epulides is controversial, but they are most commonly grouped as ossifying epulis, fibromatous epulis, or squamous or acanthomatous epulis.
A. Acanthomatous epulis may be a form of basal cell carcinoma, may be fixed to bone at the gum line, and is considered to be more aggressive than fibromatous or ossifying epulides.
B. Synonyms for acanthomatous epulis are adamantinoma and ameloblastoma.

III. Epulides are common in dogs (20% of oral tumors), but are rare in cats (Withrow, 2001).
IV. No known causes or risk factors have been identified.

Pathophysiology

I. Ossifying and fibromatous epulides are firm or pedunculated, nonulcerating, and noninvasive tumors that can occur as single or multiple growths.
II. An epulis is usually ≤1 to 4 cm and is attached to the gingiva at the gum line, but they do not invade bone in most cases.
III. Acanthomatous epulis is locally aggressive, often associated with marked bony lysis, more commonly affects the rostral mandible, and rarely metastasizes (Withrow, 2001).

Clinical Signs

I. Because of their location, masses are often discovered before signs develop.
II. Dogs may have anorexia, drooling, oral hemorrhage, dysphagia, and halitosis.
III. Epulides are most commonly observed in geriatric dogs but can occur at any age (Diebielzig et al., 1979).

Diagnosis

I. Surgical biopsy is diagnostic, but fine-needle aspirate or a scraping may also be useful to rule out other malignant tumor types.
II. Histologically, acanthomatous epulis may closely resemble SCC.
III. Regional metastasis is more common with SCC, so careful examination of regional lymph nodes (aspirate) is important (Verstraete et al., 1992).

Differential Diagnosis

I. Severe gingival hypertrophy
II. Oral papillomas
III. SCC
IV. Fibrosarcoma
V. Other oral neoplasms: chondroma, osteoma, hemangioma, lipoma
VI. Other dental neoplasms: odontoma, ameloblastoma

Treatment and Monitoring

I. Treat fibromatous and ossifying epulides with surgical excision.
II. Because epulides arise from the periodontal ligament, excision at the level of the gingiva is often incomplete and the tumor may regrow.
III. Partial maxillectomy or mandibulectomy is often necessary to prevent local recurrence of acanthomatous epulis.
   A. The prognosis is guarded to good (Withrow, 2001).
   B. Cryosurgery is not recommended because local recurrence is common.
   C. Radiation therapy is also an effective treatment method.
IV. Successful use of chemotherapy using doxorubicin and cyclophosphamide has been reported, but is not done unless repeated local recurrences develop.
V. Intralesional bleomycin has been successful in a few dogs, but is not recommended as the first therapeutic choice.

Oral Papillomatosis

Definition and Causes

I. Multiple, benign cauliflower-like growths arising from squamous epithelium affect the lips, buccal mucosa, gingiva, tongue, and pharyngeal structures.
II. Papillomas are seen primarily in young dogs (<1 year), with no breed or sex predilection.
III. The tumors are induced by canine oral papillomavirus (papovavirus) and are contagious.
IV. They are not related to nonviral, cutaneous papillomas that are common in geriatric dogs.

Pathophysiology

I. The incubation period following viral infection is approximately 4 to 8 weeks.
II. Tumor growth lasts 1 to 5 months.
III. Spontaneous regression occurs over 6 to 12 weeks (Calvert, 1990).
IV. Regression is accompanied by lifelong immunity.

Clinical Signs

I. Dogs may be asymptomatic, but multiple or large papillomas, dysphagia, ptyalism, halitosis, or other signs of oral disease (e.g., inappetence, face rubbing) may be observed.
II. Lesions vary in appearance from large, gray, pedunculated masses to small, white, smooth nodules.
III. Regressing lesions appear dark and shriveled, and regression may take 1 to 2 weeks.

Diagnosis

I. Clinical signs and gross appearance in a young dog are suggestive.
II. Surgical biopsy and histopathology confirm the diagnosis.

Differential Diagnosis

I. Transmissible venereal tumor (TVT)
   A. Lesions are typically present on external genitalia as well as the mouth.
   B. TVT is usually sessile and more often ulcerated.
   C. Biopsy is diagnostic.
II. SCC: often presents as sessile, ulcerated masses with bony lysis
III. Epulis

Treatment and Monitoring

I. Treatment is usually not recommended if only a few papillomas are present.
II. If large or multiple growths cause persistent clinical signs or do not regress, treatment is indicated.
III. Several methods are effective, including surgical excision, cryotherapy, and electrosurgery.
IV. The efficacy of autologous wart vaccines is questionable, and they are not recommended.

Squamous Cell Carcinoma

Definition

I. SCC is a malignant neoplasm of squamous epithelium.
II. SCC is the most common oral neoplasm of cats (70% of all oral tumors) and the second most common (20% to 30%) oral tumor in dogs (Stebbins et al., 1989; Withrow, 2001).
III. Although tumors of the tongue are rare, SCC of the tongue is the most common lingual cancer.
IV. It is most commonly seen on the ventrolateral surface of the tongue in cats, and is associated with extensive involvement of bone.
V. In dogs, SCC is commonly seen in the tonsillar crypt or gingival mucosa (Withrow, 2001).
VI. Gingival SCC may arise adjacent to the incisors and premolars of the lower jaw; near the molars in the upper jaw; on the hard palate; and on the buccal and labial mucosa (Smith, 2005).

Causes

I. There is no known cause of SCC.
II. Conditions that may be associated with an increased incidence of SCC include the following:
  A. Chronic periodontal disease
  B. Eosinophilic ulcer
  C. Oral papillomatosis
III. Dogs living in an urban environment have a higher incidence (10:1) of tonsillar SCC.

Pathophysiology

I. The biological behavior of SCC varies by the species affected and the location within the oral cavity.
  A. SCCs of the tongue and tonsil are aggressive forms that tend to metastasize early to regional (retropharyngeal or mandibular lymph nodes) and distant (lungs) sites (Withrow, 2001).
  B. SCC of the gingival tissues is locally aggressive (bony invasion in 77%) and superficially ulcerative but is slowly progressive (10% regional metastasis, 3% distant sites) (Smith, 2005).
  C. Small, rostrally located, gingival SCCs tend to have the best prognosis (Ogilvie and Moore, 1995).
II. Generally, SCC tends to occur with greater frequency in white dogs and cats, even though lack of protective pigment may have less effect in the mouth.

Clinical Signs

I. SCC of the tongue
  A. In cats, the tumor arises at the base of the tongue and may initially appear as a small, raised ulcer or erosive lesion.
  B. Canine SCC of the tongue is more likely to arise on the dorsal surface.
  C. The animal may be asymptomatic or show severe dysphagia, difficulty in prehension of food, oral hemorrhage, excessive licking movements, ptyalism, and gagging.
  D. Lingual forms are usually seen in older dogs and cats.
II. SCC of the tonsil (Evans and Shoter, 1988)
  A. It is most often seen in old (mean age, 10 to 12 years), male (2:1) dogs (Spodnick and Page, 1995).
  B. Palpation of enlarged mandibular or retropharyngeal lymph nodes in an older dog indicates the need for a careful examination of the tonsils and caudal oropharynx.
  C. The tumor is typically a unilateral, firm mass deeply attached in the tonsillar crypt and may be associated with subcutaneous swelling, severe dysphagia, and pain.
  D. It rapidly metastasizes to the retropharyngeal lymph nodes, so the disease should be considered systemic at the time of diagnosis.
III. SCC of the gingiva
  A. The mean age of occurrence is slightly younger (7 to 9 years old) than for tonsillar SCC.
  B. Lesions may present as nonhealing ulcers in the gingiva adjacent to teeth or as proliferative, expansile masses without ulceration.
  C. Both single and multiple masses are reported.

Diagnosis

I. Surgical biopsy of the mass and enlarged lymph nodes with histopathology is required for diagnosis.
  A. Cytology is often unrewarding because of the accompanying necrosis and inflammation.
  B. Any nonhealing, ulcerated region in the oral cavity should be biopsied to rule out SCC.
II. Stage all animals with oral masses through blood tests, three radiographic views of the thorax, ± oral radiography, and cytological and histopathological testing.

Differential Diagnosis

I. SCC of the tongue
  A. Sublingual foreign body
  B. Eosinophilic granuloma complex
  C. Other less common neoplasms: granular cell myoblastomas (second most common tongue tumor), fibrosarcoma, malignant melanoma, mast cell tumor, lymphosarcoma
II. SCC of the tonsil
  A. Lymphosarcoma
  B. Salivary gland adenocarcinoma (rare)
  C. Tonsillitis or tonsillar abscess
III. SCC of the gingiva
  A. Chronic gingivitis, periodontitis
  B. Eosinophilic granuloma complex
  C. Epulis
  D. Other neoplasms: fibrosarcoma, osteosarcoma, malignant melanoma
  E. Osteomyelitis (especially in cats)
IV. SCC of the palatine mucosa
  A. Plasmacytic gingivitis-stomatitis complex
  B. Salivary gland adenocarcinoma

Treatment

I. Attempt to rule out metastatic disease first, because some SCCs have metastasized at the time of diagnosis.

II. Surgical excision is the initial treatment of choice, but tumor removal may be difficult because of extensive invasion of underlying tissue and bone.
   A. Hemimandibulectomy or total maxillectomy/mandibulectomy has the greatest success rates for gingival SCC, but when the tumor is large and surgical margins are incomplete, concurrent radiation therapy is indicated (Ogilvie and Moore, 1995; Smith, 2005).
   B. SCC of the tongue is amenable to surgical removal in 40% to 60% of canine cases, but the percentage is lower in cats because of its usual location on the ventral surface of the base of the tongue (Guilford, 1996).
   C. For tonsillar SCC, surgical debulking is only palliative and is typically used in conjunction with radiation therapy.
      1. Radiation therapy and hyperthermia after surgical debulking have provided the best long-term results (Ogilvie and Moore, 1995; Smith, 2005).
      2. Radiation therapy of caudal tumors has a poorer response rate and greater chance of radiation-induced bone necrosis and fistula formation.

III. Cisplatin alone or combined with doxorubicin (dogs), and doxorubicin with cyclophosphamide (cats) may be tried in animals that are not candidates for surgical resection or radiation therapy, or for whom palliation is the treatment choice.

Monitoring of Animal

I. Monitor oral and thoracic radiographs periodically to assess disease progression.
II. Because of the rapid growth of tonsillar SCC, owners must be made aware of the potential for airway obstruction.
III. Nutritional support of the animal is an important part of treatment.
   A. Aggressive forms of nutritional support, such as PEG or esophagostomy tube insertion, may be used for SCC or any oral malignancy.
   B. Special diets, such as soft, blenderized foods, or canned diets may improve food consumption.

Malignant Melanoma

Definition and Cause

I. Malignant melanoma is a neoplasm of melanocytes within the epidermis; however, not all melanomas (up to one third) contain melanin.
II. Melanoma is the most commonly reported oral tumor in dogs; however, it is rare in cats.
III. There is no known cause.
IV. Certain breeds appear to be more susceptible, especially black-coated dogs (e.g., black cocker spaniel, Scottish terrier).
V. The tumor is also common in poodles, dachshunds, and golden retrievers.

Pathophysiology

I. Most oral melanomas are malignant, and melanomas of the mucocutaneous junction are invariably malignant.
II. Major sites are the pigmented gingiva, buccal mucosa, and palate.
III. The tongue is a less common site.
IV. Melanomas are locally aggressive tumors.
   A. Smaller tumors (<2 cm diameter) are associated with longer survival times (Harvey et al., 1981).
   B. Metastasis to regional sites (lymph nodes) occurs early in dogs.
   C. The time to metastasis to distant sites (lungs, brain, kidney) is variable, with lung metastasis most common (Smith, 2005).

Clinical Signs

I. The mean age for melanoma in dogs is 10 to 12 years (Spodnick and Page, 1995).
II. There is no apparent sex predilection for oral melanoma in dogs (Hahn et al., 1994).
III. Female cats may be predisposed, but the numbers reported are small.
IV. Signs depend on location and size of the tumor and include halitosis, dysphagia, difficulty chewing or painful chewing, face rubbing, oral hemorrhage, drooling, and inappetence.
V. Melanomas are typically pigmented, but amelanotic melanomas have a pinkish-white appearance, are friable and necrotic, and bleed very easily.
VI. Tumors may be dome shaped or sessile.
VII. Local invasion of bone is common.

Diagnosis

I. Excisional biopsy with histopathology is diagnostic, although amelanotic melanomas are often reported histologically as anaplastic sarcomas.
II. A complete work-up includes a hemogram, biochemical profile, urinalysis, thoracic and oral radiography, and regional lymph node aspirates or biopsy for staging of the disease.
III. Animals with no evidence of distant metastasis are considered candidates for aggressive therapy.

Differential Diagnosis

I. Fibrosarcoma
II. SCC
III. Hemangiosarcoma
IV. Other anaplastic sarcomas

Treatment and Monitoring

I. Prognosis is guarded to poor, because the tumor may have metastasized by the time of diagnosis (1-year survival is 25%).
II. Radical surgical excision (margins ≥2 cm) via maxillectomy or mandibulectomy is the most common treatment.
III. Cryosurgery may be indicated for lesions <2 cm in diameter that are fixed or minimally invasive into bone.
IV. Radiation therapy may be useful, but large doses may be required.
   A. Concurrent hyperthermia enhances the effectiveness of radiation therapy.

B. Radiation therapy appears to be most effective with small tumors.
C. It is most often used for palliation of inoperable tumors.

V. Chemotherapy for metastatic disease is generally unrewarding.
A. Cisplatin 60 mg/m^2 IV every 3 weeks
B. Carboplatin 300 mg/m^2 IV every 3 weeks (Ogilvie and Moore, 1995)

VI. Immunotherapy may be considered along with chemotherapy for metastatic disease.
A. *Corynebacterium parvum* may be beneficial when used together with surgery.
B. Liposome-encapsulated muramyl tripeptide-phosphatidylethanolamine (L-MTP-PE) immunotherapy has been used but did not improve survival of dogs with in advanced stage (II, III) disease (Withrow, 2001).

VII. Recently a melanoma vaccine has been given limited approval by the U.S. Department of Agriculture.

Oral Fibrosarcoma

Definition and Cause

I. Oral fibrosarcoma is a malignant tumor of fibrocytes.
II. Fibrosarcoma is the second most common tumor of the oral cavity in cats (20%) (Spodnick and Page, 1995).
III. In dogs, oral fibrosarcoma is the third most common malignant tumor (10% to 20%), after melanoma and SCC (Spodnick and Page, 1995).
A. The median age of occurrence is 8 years, with large-breed dogs being overrepresented, especially golden retrievers and Doberman pinschers (Ciekot et al., 1994).
B. Males may be predisposed.
IV. Cats are usually older (mean age, 10 years).
V. There are no known causes or viral associations; it is not related to feline sarcoma virus.

Pathophysiology

I. Oral fibrosarcoma is a solid, fleshy tumor that arises from gingival or periodontal connective tissue, with gingival origin being the most common.
II. The most common sites are the maxillary gingiva and the hard palate in the area between the canine and carnassial teeth.
III. Fibrosarcomas are locally aggressive but only occasionally metastasize to the lungs in cats or old dogs.
IV. In young dogs, the tumor tends to act more aggressively and metastasizes to distant sites.

Clinical Signs

I. The presenting signs depend on the location and size of the tumor and may include dysphagia, ptyalism, anorexia or inappetence, halitosis, exaggerated chewing motions, difficulty chewing, and pawing at the mouth.
II. Fibrosarcomas may grow to be very large (>4 cm in diameter) (Todoroff and Brodey, 1979).

Diagnosis

I. Diagnosis is suggested by the age, breed, sex, and location.
II. Definitive diagnosis is made by excisional biopsy and histopathologic examination.
III. Staging of the tumor is important.
A. Oral radiography often underestimates the tumor margins.
B. Computed tomography is more accurate for determining the extent of bony involvement.

Differential Diagnosis

I. SCC
II. Malignant melanoma
III. Hemangiosarcoma
A. Low incidence of occurrence in the oral cavity
B. Breeds affected: German shepherd dog, golden retriever
IV. Other oral neoplasms
A. Osteosarcoma
B. Salivary gland adenocarcinoma
C. Mast cell tumors
D. Lymphosarcoma
E. Epulis
F. Undifferentiated carcinomas and sarcomas

Treatment

I. Wide surgical excision (partial or complete maxillectomy) is required to prevent local recurrence.
II. Radiation therapy as a single treatment modality is disappointing, unless large doses are used.
A. Megavoltage radiation may be more effective than orthovoltage radiation (Ogilvie and Moore, 1995).
B. Radiation combined with hyperthermia appears to improve local control (Brewer and Turrel, 1982).
III. Fibrosarcoma is unresponsive to cryotherapy.
IV. Combination therapy with surgical debulking, radiation, and/or chemotherapy (e.g., doxorubicin, dacarbazine, carboplatinum, cisplatin) may give the best long-term results.

Monitoring of Animal

I. Local recurrence occurs in 50% of the cases (Withrow, 2001).
II. Some fibrosarcomas are very slow growing, so 6- to 18-month survival times with good quality of life are possible.
III. Metastatic disease is slow to develop, but regional lymph node aspirates and thoracic radiographs are used to monitor disease progression and treatment success.

CHAPTER 28

Dental Diseases

Ellen I. Logan

GENERAL CONSIDERATIONS

I. Primary dental diseases can be subdivided into conditions affecting the tooth or the periodontium.
II. Diseases that affect the tooth structure may cause pathologic conditions in the periodontal apparatus and/or oral mucosa.
III. Diseases affecting the periodontium may result in exfoliation of teeth.
IV. Diseases affecting the tooth (pulpitis) may cause periodontal pathology.
V. Dental diseases have local and systemic ramifications.

CONGENITAL/DEVELOPMENTAL DISORDERS

Absent or Supernumerary Teeth

Definition

I. Dogs and cats are diphyodont, erupting deciduous and permanent teeth, with published dental formulas representing teeth that are normally present in all dogs and cats.
II. Oligodontia (fewer teeth than normal) and polyodontia (supernumerary or excessive teeth) occur sporadically in dogs and cats.
III. Anatomically, the maxillary first premolars and the mandibular first and second premolars are absent in cats.

Causes and Pathophysiology

I. Anomalies of tooth development may be genetic.
II. They may result from primary dysplasias of the enamel organ.
III. They can occur secondary to insults, such as trauma, infection, toxicosis, or metabolic abnormalities.

Clinical Signs

I. Animals may be asymptomatic.
II. Missing teeth may predispose to soft-tissue trauma from occluding teeth and may reduce the self-cleaning mechanism of the oral cavity.
III. Supernumerary teeth may result in malocclusions and abnormal tooth-to-tooth or tooth–to–soft-tissue contacts.
IV. Early onset of periodontal disease (PD) occurs from plaque accumulation and retention.

Diagnosis

I. Oral examination: abnormal dental formula
II. Intraoral radiographs

Differential Diagnosis

I. Unerupted teeth
II. Exfoliation of teeth from spontaneous PD
III. Previous extraction
IV. Retained root
V. Soft-tissue impaction

Treatment and Monitoring

I. No treatment: asymptomatic animal, normal radiographic examination
II. Extraction: overcrowding and/or rotation of the teeth, tissue trauma, plaque retention
III. Periodontal management: daily plaque control, increased frequency of oral examination and professional prophylaxis
IV. Regular oral examinations
  A. Frequency may be quarterly to biannually, depending on severity and home care compliance.
  B. Evaluate for occlusion as well as tooth and periodontal health.

Retained Deciduous Teeth

Definition

I. A primary, or deciduous, tooth is still in place when the permanent tooth has erupted.
II. The condition is also known as *persistent primary teeth* or *pseudopolyodontia*.
III. It is common in small-breed dogs but can occur in all breeds of dogs and cats.

Causes

I. Congenital defect
II. Alterations in eruption of permanent teeth

Pathophysiology

I. Persistent primary (deciduous) tooth forces the permanent tooth to erupt in an abnormal location.
II. Displaced permanent teeth interfere with eruption and occlusion of other permanent teeth.

Clinical Signs

I. Malocclusion results in abnormal tooth-to-tooth and tooth-to-tissue contact.
II. Abnormal tooth wear and increased accumulation and/or retention of microbial plaque and oral debris may occur.

Diagnosis

I. Oral examination reveals erupted primary and permanent teeth in the same location.
II. With respect to incisors, maxillary permanent teeth erupt palatally to primary teeth, and mandibular permanent teeth erupt lingually to primary teeth.
III. For canine teeth, maxillary permanent teeth erupt mesially to primary teeth, and mandibular permanent teeth erupt lingually and distal to primary teeth.
IV. For premolar teeth, maxillary permanent teeth erupt palatally to primary teeth, and mandibular teeth erupt lingually to the primary teeth.
V. The maxillary fourth premolar erupts buccodistally to the last primary premolar.

Treatment and Monitoring

I. Extraction of primary tooth
II. Orthodontic correction if permanent tooth does not move to appropriate position and causes occlusal trauma
III. Biannual to annual oral examinations to evaluate occlusion, tooth, and periodontal health

Malocclusions

Definition

I. Dental occlusion refers to the position of each tooth and its relation to all other teeth.
II. Normal occlusion is classified as a scissors bite.
  A. The mandibular incisors occlude on the cingulum of the maxillary incisors.
  B. The mandibular canine tooth lies between the maxillary third incisor tooth and canine tooth, without touching either tooth.
  C. The maxillary premolar teeth interdigitate with the mandibular premolar teeth, forming a "pinking shears" pattern.
  D. The upper and lower dental arches are symmetrical.
III. Cats have a more uniform skull conformation than dogs, and malocclusions are rare, except in Persians.

Causes and Pathophysiology

I. Congenital or hereditary: breed predilection
II. Delayed eruption of deciduous or permanent teeth
III. Retained deciduous teeth
IV. Trauma affecting jaw growth or tooth eruption

Clinical Signs

I. Tooth malposition or abnormal bite
II. Tooth crowding or rotation
III. Soft-tissue defects from traumatic tooth contact
IV. Fractures or abnormal wear of teeth from improper tooth contact

Diagnosis

I. With Class I malocclusions, generally one or more teeth are malaligned or rotated.
  A. Anterior crossbite
    1. One or more of the mandibular incisors occlude anterior to the maxillary incisors.
    2. Remaining teeth occlude normally.
  B. Base-narrow (lingually displaced) canine teeth
    1. Mandibular canine teeth are displaced lingually.
    2. They occlude against the hard palate.
  C. Lance tooth
    1. The maxillary canine tooth erupts at an angle, creating interference with the mandibular canine tooth.
    2. The condition may be unilateral or bilateral.
II. Class II malocclusions (e.g., mandibular brachygnathism, overjet, retrusive mandible, distal mandibular excursion) occur when the mandibular premolars and molars are positioned distal to the maxillary premolars and molars.
III. Class III malocclusions (e.g., prognathism, undershot, underjet, protrusive mandible, mesial mandibular excursion) occur when the mandibular premolars and molars are positioned rostral to the normal position.
IV. Wry bite is abnormal occlusion caused by a difference in length of the two halves of the mandible and maxilla.

Differential Diagnosis

I. Tooth displacement from trauma, oral masses, or other causes
II. Open bite secondary to jaw fracture, tooth luxation, or trapped foreign body

Treatment

I. A functional, nontraumatic bite does not require treatment.
II. The primary goals of orthodontic treatment are to prevent abnormal wear or trauma to hard or soft tissues from improper contact, and to provide the animal with a comfortable, functional bite.
III. Malocclusions are generally inherited conditions and a signed release informing the owner of legal and ethical considerations should be obtained (Holmstrom et al., 2004c).
IV. Extraction or crown reductions are alternatives to classic orthodontic corrections.
V. The proper orthodontic procedure is determined by the class and severity of the malocclusion (Holmstrom et al., 2004c; Wiggs and Lobprise 1997a).

Monitoring of Animal

I. Instruct the owner to examine the appliance BID and flush the mouth with an oral hygiene solution (e.g., 0.12% chlorhexidine digluconate).
II. Prevent chewing on hard treats and toys, and provide a soft diet while the appliance is in place.
III. Weekly to biweekly oral examinations are used to monitor appliance stability and tooth movement.
IV. Examine at 2 weeks, 2 months, and 6 months after appliance removal to assess occlusal stability.
V. Radiographic evaluation is done 6 months posttreatment to evaluate tooth and root vitality.

Enamel Hypoplasia/Hypocalcification

Definition and Causes

I. Defects in enamel formation may result in pitting and discoloration of the enamel surface of the permanent teeth.
II. Causes include nutritional, metabolic, toxic, or traumatic insults to ameloblasts.

Pathophysiology

I. Injured ameloblasts do not adequately produce or mineralize enamel.
II. Removal of the insult allows subsequent ameloblasts to begin making normal enamel.

Clinical Signs

I. Affected teeth have varying patterns of enamel defects, including isolated opaque spots, pits, and deep horizontal indentations (severe cases).
II. Fractures may occur from weakened tooth structure.

Diagnosis

I. History of illness during gestation, insult, or trauma during tooth development
II. Oral examination: discolored teeth, irregular or pitted teeth, increased plaque or calculus retention on irregular tooth surfaces

Differential Diagnosis

I. Enamel staining
II. Caries
III. Amelogenesis imperfecta: genetic enamel disorder

Treatment

I. Treatment depends on the extent of the lesions.
II. Smooth the tooth surface by removing sharp irregularities and diseased enamel.
III. Restoration of focal defects with composite or glass ionomer may be beneficial, although results are reported to be short-lived (Wiggs and Lobprise, 1997a).
IV. Fluoride application may decrease sensitivity and enhance enamel strength.

Monitoring of Animal

I. Monitor for further degeneration or complications with semiannual to annual examinations.
II. Recommend semiannual to annual professional prophylaxis and daily mechanical plaque control via brushing or feeding a dental food.
III. Do not allow excessive chewing on hard objects.
IV. Inform the owner that enamel degeneration may continue and necessitate future treatment.

Dentigerous Cysts

Definition and Causes

I. These cysts contain part or all of a tooth.
II. Abnormal tooth development or eruption causes epithelial-lined, cystic structures in the bone or tissues of the jaw.

Pathophysiology

I. They are typically benign but cause bony destruction.
II. They may lead to loss of adjacent teeth.
III. Malignant transformation has been reported.

Clinical Signs

I. Animals may be asymptomatic, depending on the size of cyst.
II. Swelling of the gingival tissue or oral mucosa may be detected.
III. Loosening or abnormalities of affected teeth can occur.

Diagnosis

I. History and oral examination: missing (unerupted) tooth, oral swelling
II. Intraoral radiography: embedded tooth or permanent tooth bud, bone loss
III. Histopathology: cystic epithelium

Differential Diagnosis

I. Impacted tooth
II. Oral neoplasia

Treatment and Monitoring

I. Surgical extraction of the affected tooth and thorough removal of the entire epithelial lining of the cyst wall is usually curative.
II. Postoperative evaluation is done at 1 week to evaluate healing.
III. Oral examination and intraoral radiography are repeated 12 months after treatment.

DEGENERATIVE DISORDERS

Attrition and Abrasion

Definition

I. Attrition is physiological wear of tooth surfaces from contact with occluding teeth during mastication.
II. Abrasion is abnormal wear of tooth surfaces from contact with an external object.

Causes

I. Attrition may result from malocclusion and abnormal wear from continuous tooth-to-tooth contact.
II. Abrasion may result from excessive chewing on hard materials, such as rocks or other hard objects.
   A. The incisor teeth in dogs may show marked wear from excessive chewing behaviors and excessive grooming associated with dermatological conditions.
   B. Abrasion may result from inappropriate use of power instrumentation or excessive brushing.

Pathophysiology

I. Excessive wear is not pathologic, unless the wear rate exceeds the rate of reparative dentin formation.
II. As a response to trauma, odontoblasts produce tertiary dentin as a reparative substance.

III. Rapid wear can lead to pulpal exposure and infection as well as compromised tooth strength.

Clinical Signs and Diagnosis

I. Oral examination reveals abnormal tooth wear.
II. Worn teeth have a shortened crown with a discolored occlusal surface and a central dark-brown or black dot.
III. The central occlusal area is probed with a dental explorer.
   A. If the central occlusal area is firm, then adequate reparative dentin is present.
   B. If the probe sinks into the central occlusal cavity, the pulp is exposed.

Treatment and Monitoring

I. No treatment is necessary if adequate tertiary dentin is protecting the pulp and the tooth is not excessively worn.
II. Pulp exposure requires appropriate endodontics or extraction (Niemiec, 2005).
III. Excessive damage may require smoothing of sharp edges, crown prosthesis, or extraction (Wiggs and Lobprise, 1997a).
IV. Prevention of further wear may require avoidance of hard toys or behavior modification to address inappropriate chewing.
V. Regular oral examinations (every 6 to 12 months) are required to monitor further tooth wear and status of dental health.

INFLAMMATORY DISORDERS

Periodontal Disease

Definition

I. Periodontal disease is the most common dental disease in adult dogs and cats.
II. It is pathology that affects the health of the periodontium, which includes the tissues that surround and support the tooth.
   A. The periodontium is composed of the gingiva, cementum, periodontal ligament, and alveolar bone.
   B. PD commonly refers to gingivitis and periodontitis.
      1. Gingivitis is inflammation of the gingiva and is reversible.
      2. Periodontitis includes gingivitis and inflammation and destruction of the remaining periodontal tissues, and is usually irreversible.

Causes

I. Several materials accumulate on tooth surfaces and participate in the pathophysiology of PD.
II. These substances are commonly referred to as *tooth-accumulated materials* or *dental substrates.*
   A. Acquired enamel pellicle is a thin film composed of protein and glycoproteins deposited from saliva and gingival crevicular fluid.
      1. Pellicle initially protects and lubricates the tooth surface.
      2. As pellicle ages, its constituents are modified and provide a framework for initial bacterial colonization.
      3. Within minutes after a dental polishing, approximately 1 million bacterial organisms are deposited per mm^2 of enamel surface.
   B. Microbial plaque is a soft adherent aggregate of bacteria, salivary glycoproteins, extracellular polysaccharides, and epithelial and inflammatory cells.
      1. Dental plaque has a specific composition and texture that changes with time so that a complex biofilm is formed.
      2. Supragingival plaque forms above the gingival margin.
      3. Growth and maturation of supragingival plaque are necessary for subsequent colonization of subgingival surfaces by gingival plaque.
      4. Subgingival plaque is formed entirely within the gingival sulcus.
   C. Calculus is mineralized plaque formed by the interactions of salivary and crevicular calcium, phosphate, and carbonate salts with existing plaque.
      1. Calculus accumulates supra- and subgingivally and thickens over time.
      2. Calculus provides a roughened surface that enhances plaque attachment and accumulation.
   D. Acquired dental stain is discolored pellicle, plaque, or calculus.
      1. Appearance is influenced by various nutritional, chemical, and microbial factors.
      2. Extrinsic staining is not pathologic; however, it is an important aesthetic concern to pet owners and is often the reason veterinary care is sought.
III. PD results from the accumulation and maturation of the dental plaque biofilm.

Pathophysiology

I. Plaque accumulation along the gingival margin induces inflammation in adjacent tissues.
II. Without plaque removal or control, gingivitis progresses in severity and local changes occur that allow subsequent bacterial colonization of subgingival sites.
III. Inflammatory mediators damage the integrity of the gingival margin and sulcular epithelium, allowing infiltration of bacteria.
IV. Bacteria release factors that interfere with normal host cell function or contribute to destruction of cells or cellular components.
V. The host attempts to limit invasion of the periodontal tissues, which may result in further destruction of local tissues from inflammatory cytokines.
VI. PD increases the risk of secondary systemic disorders.
   A. The pathogens associated with PD may cause systemic bacteremia.
   B. Pathogens stimulate an immune and nonimmune host response (e.g., inflammatory cytokines, inflammatory mediators) that may have systemic effects.

Clinical Signs

I. Plaque and calculus accumulation on supra- and subgingival tooth surfaces
II. Oral malodor (halitosis)
III. Gingival redness, swelling, bleeding
IV. Gingival recession
V. Periodontal pocket formation
VI. Increased tooth mobility or exfoliation

Diagnosis

I. Tentative diagnosis is made by a general oral and physical examination.
II. Definitive oral examination under sedation or anesthesia is used to determine the extent of disease and appropriate therapy.
  A. Use a periodontal probe-explorer to evaluate plaque and calculus coverage, gingival inflammation, furcation exposure, tooth mobility, pulp exposure, resorptive lesions, or other tooth abnormalities.
  B. Periodontal probing is done to determine the distance between the free gingival margin and apical extent of any gingival or periodontal pocket.
    1. Normal probe depth in dogs is 1 to 3 mm.
    2. Normal probe depth in cats is 1 mm.
    3. Probe depth may over- or underestimate the extent of periodontitis because of gingival recession or hyperplasia.
  C. Determine attachment loss by measuring the distance between the cemento-enamel junction and the apical extent of the periodontal pocket, as any loss indicates periodontitis.
  D. Dental charting is used to record pathologic findings and therapeutic procedures.
  E. Intraoral radiography identifies lesions that cannot be detected visually or manually, and determines the extent of certain pathologies.
  F. The degree of severity is determined for each tooth because an animal may have teeth in different stages of periodontal disease.
  G. PD may be classified as follows:
    1. PD 0: clinically normal, no gingival inflammation or periodontitis evident
    2. PD 1: gingivitis, inflammatory changes affecting only the gingivae
    3. PD 2: early periodontitis, <25% attachment loss
    4. PD 3: moderate periodontitis, 25% to 50% attachment loss
    5. PD 4: advanced periodontitis, >50% attachment loss

Differential Diagnosis

I. Stomatitis
II. Oral neoplasia
III. Systemic lupus erythematosus
IV. Pemphigus complex

Treatment

I. Removal of supra- and subgingival plaque and tartar
  A. Professional cleaning, hand-scaling, polishing, irrigation, root planing, subgingival curettage, and application of fluoride are done as warranted.
  B. Oral surgery to expose affected roots for treatment may be indicated with advanced periodontitis.
II. Correction of existing attachment loss (Holmstrom et al., 2004d; Wiggs and Lobprise, 1997c)
  A. Application of local antibiotic gel (Doxirobe)
  B. Gingival flap procedures
  C. Bone replacement procedures
  D. Guided tissue regeneration with membrane barriers to promote new bone
  E. Periodontal splinting
III. Tooth extraction
  A. For severe attachment loss
  B. If home care insufficient
IV. Home care
  A. Periodontal health care involves a combination of professional therapy and effective home care.
  B. Home care procedures must be tailored to fit the owner, animal, and pathologic condition.
  C. Mechanical home care is provided by brushing or dietary cleansing.
    1. Tooth brushing is highly effective, but compliance may be low.
    2. Dietary cleansing through proven dental foods is effective in many animals.
  D. Chemical tartar control is provided by oral preparations containing polyphosphates (e.g., hexametaphosphate).
  E. Products formulated with chlorhexidine, zinc, and fluoride provide varying levels of antimicrobial activity.
  F. Barrier agents are placed on the tooth surface to reduce bacterial attachment.
  G. Numerous professional and over-the-counter products are labeled for dental home care.
    1. Product recommendation is based on evidence to support product claims, ability of the owner to apply the product, acceptance by the pet, and the oral pathology present.
    2. The Veterinary Oral Health Council (VOHC) recognizes products that substantiate claims for plaque and/or tartar control.

Monitoring of Animal

I. Intervals for reexaminations are dictated by the degree of periodontal pathology, as well as specific therapies and home care procedures prescribed.
II. Recheck at 1 week to evaluate oral recovery and modify home care.
III. Taper frequency of rechecks to weekly, monthly, or longer intervals to assess oral health and determine appropriate periodontal management protocols.

Caries

Definition and Causes

I. Caries are areas of decay in the tooth structure.
II. They occur occasionally in dogs and rarely in cats.

III. Caries arise from the effects of oral bacteria on fermentable carbohydrates on the tooth surface.
IV. Rarely, they are associated with xerostomia (e.g., Sjögren's syndrome in dogs).

Pathophysiology

I. Fermentation of carbohydrates by oral bacteria produces acids that demineralize the enamel and dentin.
II. Factors that prolong retention of fermentable carbohydrates and bacterial plaque on the tooth surfaces predispose to the development of caries.
III. Caries may affect the tooth crown or root(s).

Clinical Signs

I. Signs of oral pain, such as changes in eating behavior and excessive salivation, may be noticed.
II. Tooth defects (dark spot on enamel, concavity, soft spot) may be noted on oral examination.

Diagnosis

I. Supra- and subgingival oral examination is done with a dental explorer.
   A. Defects and discoloration are carefully probed.
   B. Carious dentin is soft and the explorer sinks into the lesion and sticks slightly as the instrument is retracted.
II. Intraoral radiography is indicated to determine the extent of tooth destruction and define required treatments.
III. Radiolucent defects are seen radiographically, and involvement of the pulp tissue warrants endodontic therapy.

Differential Diagnosis

I. Attrition
II. Abrasion
III. Crown fracture
IV. Enamel hypocalcification
V. Resorptive lesions

Treatment

I. Restore mild to moderate defects with composite or glass ionomer.
II. Endodontic therapy and restoration are indicated if the defect extends into the pulp canal (Holmstrom et al., 2004b).
III. Tooth extraction is done for severe lesions.
IV. Application of a pit-and-fissure sealant on teeth with occlusal surfaces may be considered in high-risk cases (Hale, 1998).

Monitoring of Animal

I. Oral examination and intraoral radiography of treated teeth are performed 6 months postoperatively to evaluate stability of restoration and monitor for lesion progression.
II. Annual oral examination and intraoral radiography are used to detect new lesions.
III. Animals with enamel defects, poorly mineralized enamel, lower salivary pH, and diets high in fermentable carbohydrates are at greater risk for developing caries.

Resorptive Lesions

Definition and Causes

I. Noncarious tooth resorption is frequently diagnosed in cats.
II. The definitive etiology is unknown.
III. Proposed theories include chronic, excessive intake of vitamin D, occlusal stress, and cellular hyperactivity secondary to noxious stimuli that stimulate odontoclastic activity (DuPont, 2005).

Pathophysiology

I. Activated odontoclasts attach to and resorb dental tissues.
II. Lesions begin as a superficial resorption of tooth substance often at or close to the cemento-enamel junction.
III. A grading system for resorptive lesions is as follows:
   A. Stage 1: incipient lesion affecting only enamel
   B. Stage 2: lesion extending into dentin but not involving pulp
   C. Stage 3: lesion extending into the pulp
   D. Stage 4: significant destruction of tooth crown
   E. Stage 5: no remaining tooth crown, gingiva completely covers site
IV. Resorptive lesions may be type 1 or 2.
   A. Type 1 lesions have an identifiable root and periodontal ligament.
   B. Type 2 lesions have root resorption and loss of the periodontal ligament.

Clinical Signs

I. Many cats are asymptomatic.
II. Signs may include anorexia, ptyalism, lethargy, depression, dysphagia, halitosis, and discomfort during eating or an oral examination.

Diagnosis

I. General oral examination may demonstrate suspicious lesions.
   A. Hyperplastic gingival and/or granulomatous tissue may cover the defect.
   B. Surface lesions appear as a concavity in the enamel surface, often at the cemento-enamel junction.
   C. A pink spot may be noticed on the tooth crown.
   D. Advanced lesions located on the crown are readily evident.
II. Definitive oral examination is done under general anesthesia.
   A. Gross deposits of plaque or calculus may cover lesions.
   B. A dental explorer is used to detect resorptive lesions.
III. Intraoral radiography is indicated to determine extent of the lesions and assess the integrity of the periodontal ligament and periapical area.

Differential Diagnosis

I. Furcation (junction of roots) exposure from periodontal disease
II. Stomatitis
III. Caries

Treatment and Monitoring

I. Treatment is controversial because of the progressive nature of the lesions.
   A. Consider the stage and type of lesion.
   B. Discuss treatment options and prognosis with the client.
II. Current recommendations are as follows (DuPont, 2005):
   A. Stage 1 lesions
      1. Debride tissue from defects and etch with acid.
      2. Apply sealant and fluoride.
   B. Stage 2, 3, and 4 lesions
      1. Completely extract type 1 lesions.
      2. Amputate crowns of type 2 lesions when no other disease present
   C. Stage 2 or 3 lesions on canine teeth: restoration until lesion reaches stage 4
   D. Stage 5 lesions
      1. Extract root remnants of type 1 lesions.
      2. Type 2 lesions are monitored visually and radiographically (every 6 to 12 months) for continued resorption or changes requiring further treatment.
III. Perform follow-up oral examinations and intraoral radiography (every 6 to 12 months) to monitor for recurrence or progression.

Apical Abscess

Definition and Causes

I. It is localized infection at or around the tooth apex.
II. Typically it results from endodontic or periodontal disease.

Pathophysiology

I. Trauma or bacterial invasion of the pulp tissue causes pulpitis.
II. Pulpal swelling causes necrosis and extension of infection through the apical delta into surrounding alveolar bone.
III. Sequelae include osteomyelitis, cellulitis, sinusitis, and perforation to a fistulous tract.

Clinical Signs

I. In early stages, the animal may be asymptomatic.
II. Oral examination may reveal a fractured or discolored tooth, a loose tooth, a tooth that is painful on palpation, or purulent discharge in the oral mucosa or facial skin.
III. Advanced stages often demonstrate the following:
   A. Reluctance to chew on the affected side or to chew hard food
   B. Behavior changes associated with discomfort: inappetence, lethargy
   C. Oral malodor (halitosis)
   D. Facial lymphadenitis, localized cellulitis, or swelling
   E. Exophthalmos, pain upon retropulsion of globe or opening mouth with caudal tooth involvement
   F. Sinusitis, nasal discharge
   G. Cutaneous draining fistula over maxillary area or at site of prior enucleation
   H. Fever, occasional regional lymphadenopathy

Diagnosis

I. Tentative diagnosis is based on clinical signs and oral examination findings.
II. Definitive diagnosis is achieved with intraoral radiography.
   A. Thickening of the apical periodontal ligament
   B. Radiolucency surrounding the apical delta
   C. Bone loss and inflammatory changes as the lesion progresses

Differential Diagnosis

I. Resorptive lesions
II. Cysts
III. Neoplasia: squamous cell carcinoma, fibrosarcoma
IV. Other causes of cutaneous fistulas
V. Other causes of exophthalmos (see Chapter 103)

Treatment

I. Perform root canal of the affected tooth for early or mild infections of vital periodontal structures (Niemiec, 2005).
II. Tooth extraction and curettage of the affected area is necessary with large or chronic lesions.
III. Drain and explore any adjacent infection or fistulas (e.g., draining tract ventral to eye in dogs with carnassial tooth abscesses) (Niemiec, 2005).
IV. Systemic antibiotics are indicated in most cases.
V. Postoperative care includes appropriate pain medication and soft foods for several days.

Monitoring of Animal

I. Recheck 7 to 10 days postoperatively to monitor healing.
II. Intraoral radiography 6 to 12 months postoperatively if root canal was performed.
III. Avoid chewing on hard objects with potential to cause tooth fractures (e.g., bones, rocks, hooves).

Oronasal Fistula

Definition and Causes

I. It is a communication between the oral and nasal cavity.
II. Oronasal fistulae can be associated with any of the maxillary teeth.
III. The fistula may be congenital or result from trauma, severe periodontitis, or tooth extraction.
   A. Small-breed dogs are most often affected.
   B. Severe periodontitis of the maxillary canine tooth causes lysis of the bone separating the nasal and oral cavities.
   C. Base-narrow mandibular canine teeth may penetrate the hard palate.
   D. Severe endodontic disease may cause periapical lysis and abscessation.

Clinical Signs

I. Chronic rhinitis and/or sinusitis
II. Sneezing
III. Nasal discharge: possibly putrid or hemorrhagic

Diagnosis

I. Oral examination with a periodontal probe reveals a communication between the oral and nasal cavity.
II. Most fistulae occur in the area of the maxillary canine teeth.
III. Periodontal probing may cause hemorrhage from the ipsilateral nostril.

Differential Diagnosis

I. Periodontal disease
II. Neoplasia
III. Trauma or foreign body penetration

Treatment and Monitoring

I. If the tooth is still present, extracted it and repair the defect.
II. Use a single gingival flap technique when enough gingiva remains to provide a strong anchor for sutures.
III. Use a double gingival flap technique when the fistula is large or chronic in nature (with no remaining attached gingiva).
IV. Use guided tissue regeneration for repair of a deep palatal pocket without fistulation (Harvey and Emily, 1993; Holmstrom et al., 2004a).
V. Give a broad-spectrum antibiotic for 10 days.
VI. Feed a soft-food diet and restrict access to chew toys and hard treats for 2 weeks.

IMMUNE-MEDIATED DISORDERS

Stomatitis

See Chapter 27.

Lymphocytic Plasmacytic Gingivostomatitis

See Chapter 27.

NEOPLASIA

Epulis

See Chapter 27.

TRAUMATIC DISORDERS

Tooth Luxation or Avulsion

Definition and Causes

I. Partial or complete dislocation of a tooth from its alveolus
   A. Vertical luxation (intrusion) occurs when the tooth is pushed apically.
   B. Lateral luxation (extrusion) occurs when the tooth is displaced vertically.
   C. Complete displacement is termed *avulsion.*
II. Potential causes
   A. Trauma
   B. Severe periodontitis: luxation before complete exfoliation

Pathophysiology

I. Trauma causes injury to the periodontium, which results in tooth mobility and movement.
II. Periodontitis causes destruction of the supporting periodontium.

Clinical Signs

I. The animal may be asymptomatic, depending on the degree of luxation.
II. Excessive licking, ptyalism, head shaking, changes in eating behavior, and other signs of discomfort (inappetence, lethargy) may be present.

Diagnosis

I. Oral examination reveals tooth malposition or absence.
II. With intrusion, the tooth appears shorter and is immobile.
III. With extrusion, the tooth appears longer and is mobile.
IV. With avulsion, the owner may find an intact tooth, or a missing tooth may be noted.

Differential Diagnosis

I. Tooth fracture
II. Tooth exfoliation from PD

Treatment

I. Treatment varies depending on the severity of dislocation, health of associated periodontal tissues, time between occurrence and diagnosis, and any handling of an exfoliated tooth.
   A. Optimal results are obtained if the tooth is reimplanted within 30 minutes.
   B. Do not let an avulsed tooth dry out. Placement in saline is the best medium; milk may also be used.
   C. Handle tooth gently by its crown and do not remove periodontal ligament.
   D. Rinse carefully with sterile saline solution, and if severely contaminated, cleanse the tooth gently with sterile gauze moistened with saline.
II. Replacement and splinting in the normal position can be effective with proper cleansing and tooth handling.
   A. Fixation appliances are left in place for 4 to 6 weeks.
   B. Effective oral hygiene through flushing with water or 0.12% chlorhexidine solution is important to remove debris between the teeth and the appliance, and to control plaque accumulation and gingival inflammation.
   C. A broad-spectrum antibiotic is recommended to control infection.

Monitoring of Animal

I. Luxated and avulsed teeth often develop pulpal necrosis, so oral examination and intraoral radiography are performed at the time of appliance removal, and again at 6 and 12 months.
II. Endodontic therapy (root canal) is performed if signs of pulp pathology (tooth discoloration or periapical pathology) are present (Gorrel and Robinson, 1995).

Tooth Fracture

Definition and Causes

I. A break involving part or all of a tooth
II. May involve the enamel, dentin, crown, or root
III. Generally secondary to trauma

Clinical Signs

I. Some animals may be asymptomatic.
II. Increased tongue movement, ptyalism (possibly bloody), head shaking, changes in eating behavior (e.g., reluctance to eat hard foods, frequent trips to food bowl without eating), inability to close mouth, and other signs of discomfort (lethargy, anxiety) may be present.

Diagnosis

I. Oral examination and intraoral radiography
   A. Fractures involving part of the tooth crown (slab fractures) may not be detected until plaque and calculus are removed.
   B. Intraoral radiography is essential to determine extent of the fracture.
II. Crown fractures may affect enamel and/or dentin.
   A. Uncomplicated fractures have not entered the dentin, but pale pink pulp may be visible if the fracture is close to the pulp chamber.
   B. Complicated fractures expose the pulp chamber.
      1. Pulp hemorrhage occurs with a fresh fracture.
      2. An old fracture may have necrotic pulp and the tooth may be discolored.
III. Root fractures may occur at any point along the root surface and may be associated with a crown fracture.

Differential Diagnosis

I. Luxation
II. Caries
III. Enamel defects
IV. Resorptive lesions

Treatment

I. Treatment depends on the tooth and fracture type, age of fracture, and endodontic involvement.
II. Treat uncomplicated crown fractures by smoothing sharp edges and sealing the exposed dentin tubules.
III. Complicated crown fractures require endodontic therapy or tooth extraction.
   A. Treat fresh fractures (pulp still vital) with partial pulpectomy or vital pulpotomy with restoration (Niemiec, 2005).
   B. Old fractures in teeth with necrotic or inflamed pulp require standard root canal therapy and restoration.
IV. Treat root fractures without pulp involvement and extending <5 mm below the gingival margin with restorative dentistry.
V. Treat root fractures with pulp involvement and extending >5 mm below the gingival margin with tooth extraction.
VI. A horizontal root fracture in the coronal part of the root typically requires extraction.
VII. To maintain jaw stability, treat a horizontal root fracture in the coronal part of the mandibular canine tooth by removal of the coronal portion and endodontic therapy.
VIII. A horizontal root fracture located midroot or apically usually heals if the tooth is immobilized.
   A. In a midroot fracture, if the pulp becomes necrotic or the fracture does not heal, endodontic treatment is indicated.
   B. Remove the apical segment if there is radiographic evidence of periapical pathology.

Monitoring of Animal

I. Perform oral examination and intraoral radiography at frequent intervals to monitor healing and pulp health.
II. Perform oral examination and intraoral radiography 6 to 12 months postoperatively for partial pulpectomy and vital pulpotomy procedures; evidence of necrotic pulp with periapical changes requires root canal therapy.
III. Perform oral examination and intraoral radiography 6 to 12 months after standard root canal therapy; any evidence of periapical pathology requires further endodontic therapy (repeating the root canal or surgical endodontics) or tooth extraction.
IV. Oral examination and intraoral radiography are indicated 6 to 12 months postoperatively for root fractures to evaluate healing.

CHAPTER 29

Diseases of Salivary Glands

Jill Lurye

INFLAMMATORY DISORDERS

Ptyalism

Definition

I. Excessive salivary secretion
   A. Typically occurs secondary to an underlying condition
   B. Also referred to as *sialorrhea, hypersialism,* and *hypersialosis*
II. Differentiated from pseudoptyalism in which there is excessive release of saliva that has accumulated within the oral cavity

Causes

I. Conformational disorder of the lips
   A. Most common in giant-breed dogs
   B. May be considered normal in some breeds: bloodhound, Great Dane
II. Salivary gland disorders: see later sections
III. Oral or pharyngeal abnormalities
   A. Neoplasia
   B. Foreign body
   C. Stomatitis, gingivitis: may be viral induced in cats
   D. Functional or neurological disorder of the pharynx
IV. Esophageal or gastrointestinal (GI) abnormalities
   A. Neoplasia
   B. Foreign body
   C. Esophagitis
   D. Esophageal stricture
   E. Megaesophagus
   F. Hiatal hernial
   G. Gastroesophageal reflux
   H. Gastric ulceration
   I. Gastric distension, dilatation, volvulus
V. Metabolic disorders
   A. Hepatic encephalopathy: especially common in cats with portosystemic shunts
   B. Uremia
VI. Drugs and toxins
   A. Caustic plants or chemicals
   B. Organophosphates, cholinergic drugs, pyrethrin, pyrethroids
   C. Oral, otic, or ophthalmic medications with disagreeable taste: especially cats
VII. Neurological and behavioral disorders
   A. Anxiety
   B. Vestibular disease and associated nausea
   C. Disorders of swallowing or decreased jaw tone
   D. Seizures resulting in reduced swallowing or autonomic discharge that stimulates salivation
   E. Clostridial toxins: botulism, tetanus
   F. Certain infections: rabies, pseudorabies

Pathophysiology

I. Anatomical, mechanical, inflammatory, or functional abnormalities can result in dribbling of saliva or prevent normal swallowing, which makes normal saliva production appear excessive.
II. Excess production may occur as a result of primary salivary gland disease or stimulation from other causes.
   A. Excitation of the salivary nuclei in the brainstem or higher centers may lead to increased salivation.
   B. Diseases affecting the oropharyngy, esophagus, or stomach may also stimulate excessive salivation.

Clinical Signs

I. Excessive salivation is the primary sign.
II. Alterations in salivary gland size, shape, or presence of pain may be noted with primary salivary gland diseases.
III. Pawing at the face or facial pain may occur with oral or pharyngeal diseases.
IV. Blood in the saliva is suggestive of oral, pharyngeal, or esophageal abnormalities.
V. Halitosis may occur with oral cavity disease, or less commonly with esophageal and gastric abnormalities.
VI. Anorexia may indicate oral, GI, or systemic causes of the ptyalism.
VII. Dysphagia or changes in eating behavior may occur with oral or neurological diseases.
VIII. Regurgitation may occur with underlying esophageal diseases.
IX. Vomiting is suggestive of GI or systemic illness.
X. Neurological signs can be focal or diffuse.
   A. Signs consistent with vestibular disease or cranial nerve abnormalities may indicate a primary neurologic cause for the ptyalism.
   B. More generalized neurological signs may occur from drug or toxin exposure, or with hepatic encephalopathy.

Diagnosis

I. Physical examination may reveal the following:
   A. Palpation of salivary glands: unilateral or bilateral enlargement, irregular borders, pain, heat
   B. Oral examination: masses, periodontal abnormalities, stomatitis, foreign bodies, pharyngeal abnormalities
   C. Cranial nerve and neurological examination: abnormal jaw tone, abnormal tongue movement, muscle atrophy, abnormal swallowing reflex
   D. Changes consistent with systemic disease: cachexia, abdominal pain, abdominal masses, abnormal behavior

II. Laboratory findings are usually nonspecific.
   A. Complete blood count (CBC) is often normal.
      1. Infections or immune-mediated disease may cause leukocytosis.
      2. Microcytosis may be present with portosystemic shunts.
      3. Cats infected with feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV) may have leukopenia or anemia.
   B. Biochemistry profile is often normal.
      1. Renal disease may be evident with azotemia and hyperphosphatemia if uremia is causing the ptyalism.
      2. Hepatic disease may be evident (e.g., elevated hepatic enzymes; low blood urea nitrogen, albumin and glucose levels; alterations in cholesterol and bilirubin levels).
      3. Severe ptyalism may result in acidosis and hypokalemia from excessive loss of bicarbonate and potassium in saliva.

III. Additional diagnostic tests include the following:
   A. Perform fasting and postprandial bile acids when hepatic encephalopathy is suspected.
   B. Radiographic imaging of dentition, oral cavity, neck, and thorax may be indicated if dental disease, neoplasia, or a foreign body is suspected.
   C. Abdominal ultrasonography is useful if GI, hepatic, or renal diseases are suspected.
   D. Endoscopic evaluation and biopsies may be done if esophageal, gastric, or intestinal diseases are likely.
   E. Fine-needle aspirate and cytology, or biopsy and histopathology of salivary glands, oral lesions, or masses may be helpful.

Differential Diagnosis

I. Determining the cause of ptyalism requires a thorough history and physical examination, including complete oral and neurological evaluations, and certain laboratory tests.

II. History, clinical signs, physical and laboratory findings may differentiate oropharyngeal, GI, neurologic, metabolic, or toxic disorders from primary salivary disease.

Treatment

I. Definitive treatment of the underlying disorder is often required for resolution of ptyalism (see Causes).

II. Symptomatic treatment may help reduce salivation.
   A. Anticholinergic therapy with glycopyrrolate 0.01 mg/kg SC PRN or atropine 0.02 to 0.04 mg/kg SC PRN or 0.04 mg/kg PO TID to QID
   B. Ligation of parotid salivary duct

Monitoring of Animal

I. Monitoring requirements depend on the underlying abnormality (see Causes) and treatment needed.

II. Excessive salivation may result in dehydration, acidosis, or hypokalemia, so monitor hydration status, electrolytes, and acid-base balance.

Sialadenitis

Definition

I. Inflammation of the salivary gland
   A. May be a primary or secondary (extension from surrounding tissues) process
   B. May be infectious or noninfectious in origin

II. Sometimes referred to as, or grouped with, *necrotizing sialometaplasia, salivary gland necrosis*, and *salivary gland infarction*, because of similarities in clinical signs and histopathologic findings

Causes

I. Primary inflammation
   A. Inflammation associated with salivary mucocele
   B. Salivary gland trauma or foreign body penetration
   C. Idiopathic forms

II. Secondary inflammation from surrounding tissues
   A. If no salivary mucocele is present, inflammation is most likely associated with generalized inflammation of the surrounding connective tissues (Spangler and Culbertson, 1991).
   B. Examples include the following:
      1. Abscesses of the head and neck
      2. Viral diseases: canine distemper, rabies, paramyxovirus (Brown, 1989)
      3. Trauma: bite wounds, foreign body penetration
      4. Carnassial tooth root infection
      5. Infarction of local tissue structures

Pathophysiology

I. Typically, lymphoplasmacytic inflammation is present; however, with infectious causes, suppurative or pyogranulomatous inflammation is possible.

II. Inflammation often results in pain and swelling of the involved salivary gland.

Clinical Signs

I. Painful, swollen, warm salivary glands
   A. Mandibular salivary glands are most commonly affected (Spangler and Culbertson, 1991).
   B. Parotid, sublingual or zygomatic glands are affected less often (Spangler and Culbertson, 1991).

C. Early reports suggest the zygomatic rather than mandibular salivary gland is most commonly involved when inflammation is unilateral (Brown, 1989).

II. Mandibular, parotid, or sublingual involvement
  A. Possible dysphagia, anorexia
  B. Ptyalism
  C. Possible fever
  D. Vomiting, nausea, gagging, or retching
  E. Possible fistula formation

III. Zygomatic involvement
  A. Unilateral exophthalmos (see Chapter 103)
  B. Pain upon opening the mouth

Diagnosis

I. Definitive diagnosis often requires histopathologic examination of affected salivary gland or surrounding secondary structures.
II. Clinical signs, history, and cytology of fine-needle aspirates may be suggestive of inflammation.
III. Ultrasonography may identify salivary gland involvement, abnormalities in surrounding tissues, or the presence of foreign material.

Differential Diagnosis

I. Salivary mucocele or fistula
II. Neoplasia
III. Necrotizing sialometaplasia, salivary gland necrosis, sialadenosis

Treatment

I. Surgically remove the affected salivary gland if a mucocele or fistula is present.
II. Start appropriate antibiotic therapy for bacterial infections.
  A. Ideally, choose antibiotics based on culture and sensitivity results.
  B. Choose a broad-spectrum antibiotic if sensitivity results are not available.
    1. Amoxicillin/clavulanate 13.75 mg/kg PO BID
    2. Cephalexin 30 mg/kg PO BID
    3. Clindamycin 5 to 11 mg/kg PO BID
  C. Continue for 1 week past clinical resolution.
III. Treat any primary problem in the surrounding tissues.
  A. Removal of foreign body
  B. Carnassial tooth extraction
IV. Some viral diseases may be self limiting.
V. Prednisone may be helpful.
  A. To reduce inflammation from noninfectious processes (0.5 to 1 mg/kg PO SID to BID)
  B. To treat suspected immune-mediated disease based on histopathology (1.1 to 2.2 mg/kg PO SID to BID)

Monitoring of Animal

I. Monitor until clinical signs resolve and to ensure complications do not develop (e.g., fistula formation).
II. If clinical resolution is not observed, further diagnostic tests, such as histopathologic evaluation and/or surgical removal of the salivary gland, may be required.

Necrotizing Sialometaplasia

Definition

I. Ischemic necrosis of salivary lobules, with metaplastic proliferation of salivary ducts
II. Sometimes referred to as *salivary necrosis*
III. May be an extension or a stage of sialoadenitis

Causes

I. Unknown
II. Numerous theories suggested
  A. Vascular injury, trauma, or infection (dogs) (Schroeder and Berry, 1998)
  B. Immune-mediated (two dogs) (Schroeder and Berry, 1998; Mawby et al., 1991)
  C. Secondary to esophageal or gastric disease (Schroeder and Berry, 1998)
  D. Possible association with limbic seizures (Breitshwerdt et al., 1979; Brooks et al., 1995)
  E. Idiopathic

Pathophysiology

I. Mandibular salivary glands are involved in most cases.
II. Infarction of salivary lobules occurs with subsequent inflammation and metaplasia of salivary ducts.
III. Small terrier breeds may be predisposed.

Clinical Signs

I. Enlarged, painful salivary glands
II. Usually bilateral mandibular salivary gland involvement
III. Nausea, vomiting, inappetence
IV. Dysphagia, retching, gagging, lip smacking
V. Ptyalism

Diagnosis

I. Physical examination: bilateral salivary swelling, pain
II. Laboratory data
  A. CBC is often normal, but, rarely, leukocytosis is seen (Schroeder and Berry, 1998).
  B. Biochemistry profile is typically normal.
III. Additional diagnostic tests
  A. Thoracic radiography to identify underlying diseases
    1. Megaesophagus
    2. Esophageal diverticulum
    3. Mediastinal mass
  B. Endoscopy of esophagus and stomach
    1. Esophageal diverticulum
    2. Gastric infections: *Helicobacter* spp., *Giardia* spp.
    3. *Spirocerca lupi* granuloma and associated neoplasms
    4. Esophagitis or gastritis
  C. Antinuclear antibody assay: positive in some cases
  D. Fine-needle aspirate and cytology: evidence of inflammation
  E. Biopsy of salivary gland
    1. Required for definitive histopathologic diagnosis
    2. Infarction of salivary lobules, with inflammation and metaplasia of salivary ducts

F. Electroencephalography (EEG): abnormal in some dogs and supports a neurological cause

Differential Diagnosis

I. Sialoadenitis
II. Salivary gland infarction
III. Sialadenosis
IV. Neoplasia: usually unilateral
V. Mucocele: usually unilateral

Treatment

I. Institute treatment of any underlying diseases.
   A. Antimicrobials or antiparasiticals as appropriate for *Helicobacter* spp., *Giardia* spp., or *Spirocerca lupi*
   B. Prednisone (1.1 to 2.2 mg/kg PO SID to BID) when immune-mediated disease is suspected
   C. Antiemetics for nausea
II. Surgical removal of the affected salivary gland has not resulted in resolution of dysphagia, retching, and gagging, which suggests that the disease results from neurological or other systemic influences rather than a primary salivary gland abnormality (see Sialadenosis).
III. Phenobarbital (2 mg/kg PO BID) has resulted in improvement in a number of cases, even when a possible underlying etiology was identified (Schroeder and Berry, 1998).

Monitoring of Animal

I. Animals are monitored weekly for resolution of ptyalism, gagging, reduction of salivary gland size, or changes in other clinical signs.
II. In phenobarbital-responsive cases, affected salivary glands may return to their normal size.
   A. Some animals may be weaned off anticonvulsant therapy, whereas others need continuous therapy to prevent recurrences.
   B. Periodically measure liver enzymes, phenobarbital serum levels, and CBCs when using phenobarbital (see Chapter 22).

Sialolithiasis

Definition and Causes

I. Calculus formation within the salivary gland, duct, or mucocele
II. Underlying etiology unknown, but may occur secondary to inflammation
III. Extremely rare

Pathophysiology

I. Precipitation of fibrin and mucin may form soft stones that become mineralized within mucoceles.
II. Sialoliths in the ducts obstruct salivary flow and cause ductal dilation and possible rupture.
III. Salivary gland inflammation may be detected.
IV. Most are composed of calcium carbonate, calcium phosphate, or magnesium carbonate.
V. Over time, glandular atrophy may occur secondary to ductal obstruction.

Clinical Signs

I. Salivary gland swelling and pain are the most common signs initially.
II. Dysphagia and ptyalism may also be observed.
III. The duct may rupture and form a fistula.

Diagnosis

I. Palpation of firm mass in the area of a salivary gland warrants further investigation.
II. Radiography or ultrasonography may identify mineralization.
III. Computed tomography or sialography may be used to locate site of obstruction and identify the sialolith (Trumpatori et al., 2007).
IV. Surgical removal and stone analysis may be needed for definitive diagnosis.

Differential Diagnosis

I. Mucocele with fibrin and mucin precipitates
II. Foreign body
III. Neoplasia
IV. Sialoadenitis
V. Calcinosis circumscripta of the salivary gland (Movassaghi, 1999)

Treatment and Monitoring

I. Surgical removal of sialolith may be attempted if the duct is intact.
   A. Anastomosis of the duct can be difficult.
   B. It is most worthwhile early in the course, before glandular fibrosis and atrophy develop.
II. Presence of a fistula often requires surgical resection of the duct and salivary gland.
III. During the weeks following surgery, monitor for appropriate healing and complications, such as infection or fistula formation.

IDIOPATHIC DISORDERS

Sialadenosis

Definition and Causes

I. Sialadenosis is noninflammatory enlargement of one or more salivary glands.
II. Cause is unknown.
III. Nervous system disorders may play a role.
   A. Limbic epilepsy
   B. Increased parasympathetic tone
   C. Changes in sympathetic innervation to salivary glands

Pathophysiology

I. Mandibular salivary glands are involved in most cases, and the disease is usually bilateral.
II. Alterations in neurological input may result in salivary gland stimulation, with increased salivary size, ptyalism, and clinical signs of retching and vomiting.

Clinical Signs

I. Enlarged salivary glands
   A. Typically, both mandibular salivary glands are involved.

B. Glands are often nonpainful, but possible gulping or retching may occur with palpation.
II. Nausea, vomiting, inappetence
III. Dysphagia, retching, gagging, lip smacking
IV. Ptyalism
V. Exophthalmus with zygomatic gland involvement

Diagnosis

I. Laboratory tests, cytology, and histopathology of salivary glands are usually normal.
II. Abnormal EEG may be detected in some cases and supports a neurological cause.
III. Positive response to anticonvulsant therapy with phenobarbital is suggestive of the diagnosis.

Differential Diagnosis

I. Sialoadenitis
II. Necrotizing sialometaplasia
III. Salivary gland infarction
IV. Neoplasia: usually unilateral
V. Mucocele: usually unilateral

Treatment and Monitoring

I. Phenobarbital (2 mg/kg PO BID) is the primary treatment and is successful in many dogs.
II. Monitor the animal weekly for resolution of ptyalism, gagging, reduction of salivary gland size, or changes in other clinical signs.
III. In phenobarbital-responsive cases, salivary gland size may return to normal.
IV. Some animals may be successfully weaned off phenobarbital once all clinical signs of disease have resolved, whereas others require continuous therapy to prevent recurrences.
V. Monitor phenobarbital serum levels, liver enzymes, and CBC periodically while the animal is on phenobarbital (see Chapter 22).

IMMUNE-MEDIATED DISORDERS

Sjögren Syndrome

Definition and Cause

I. Sjögren syndrome, or Sjögren-like syndrome, is a rare autoimmune disease characterized by keratoconjunctivitis sicca (KCS), xerostomia, and lymphoplasmacytic lacrimal and salivary adenitis.
II. It may be more common in the English bulldog, West Highland white terrier, miniature schnauzer, and Maltese terrier.
III. The exact etiology is unknown.

Pathophysiology

I. Autoantibodies against glandular tissues result in inflammation and destruction of secretory components.
II. It is often associated with other immune-mediated or autoimmune diseases (e.g., thrombocytopenia, glomerulonephritis).
III. A genetic predisposition may be present in certain breeds.
IV. Females are overrepresented.

Clinical Signs

I. Signs related to KCS are commonly reported (see Chapter 97).
II. Gingivitis, stomatitis, dental caries, lack of salivary secretions, anorexia, and dysphagia may be seen.
III. Other signs reflect other immune diseases present (see Chapters 48 and 67).

Diagnosis

I. Physical examination shows evidence of KCS, xerostomia, and additional supporting signs.
A. Schirmer tear <5 mm/min
B. Confirmation of reduced salivary flow following application of topical atropine to the mouth
C. Petechia, ecchymoses, lethargy
II. Laboratory tests
A. CBC, biochemistry profile, and urinalysis are typically normal, unless other body systems are involved.
B. Antinuclear antibody and rheumatoid factor assays, as well as lupus erythematosus cell tests may be positive.
III. Additional diagnostic tests
A. Histopathologic evidence of lymphoplasmacytic salivary gland inflammation is supportive.
B. Indirect fluorescent antibody test for autoantibodies may be positive in glandular tissues.

Differential Diagnosis

I. Other causes of KCS: drug toxicities, trauma, canine distemper, other immune-mediated diseases, dysautonomia
II. Other causes of dental caries, stomatitis
III. Other causes of thrombocytopenia and glomerulonephritis

Treatment

I. Direct treatment at alleviating clinical signs and complications of KCS (see Chapter 97) and xerostomia.
A. Flushing of the mouth with water may be helpful.
B. Provide readily available water source and feed moist diets or diets with water added.
II. Immunosuppressive therapy may be necessary to treat other systemic immune-mediated processes (see Chapters 48 and 67).

Monitoring of Animal

I. Prognosis may be guarded, particularly when other immune-mediated processes are present.
II. Failure to adequately treat KSC may result in severe corneal ulcers that may require enucleation.
III. Clinical signs are difficult to treat and require lifelong therapy.

VASCULAR DISORDERS

Salivary Gland Infarction

Definition and Causes

I. Infarction of the blood supply to the salivary gland leads to tissue necrosis.

II. The cause of primary salivary gland infarction is often idiopathic.
III. In addition to primary infarction, infarction may occur secondary to salivary neoplasia, inflammation, as a component of necrotizing sialometaplasia, or as a result of an underlying systemic disease (e.g., hyperadrenocorticism, disseminated intravascular coagulopathy, sepsis).
IV. It may be confused with necrotizing sialometaplasia.

Pathophysiology

I. Following an ischemic event of unknown etiology, necrosis, regenerative hyperplasia of ductal epithelium, and capsular fibrosis of one or more salivary glands may be observed.
II. Few cases have been reported in dogs and cats, but most have involved the mandibular or sublingual salivary gland (Spangler and Culberston, 1991; Kelly et al., 1979).

Clinical Signs

I. An acute, painful, firm swelling of the salivary gland is the most common clinical sign.
II. Fever, leukocytosis, and anorexia have also been reported.

Diagnosis

I. Clinical signs are often similar to sialadenitis.
II. Histopathologic confirmation of infarction is necessary for a definitive diagnosis.

Differential Diagnosis

I. Sialadenitis
II. Necrotizing sialometaplasia
III. Salivary gland neoplasia
IV. Sialolithiasis with ductal obstruction

Treatment and Monitoring

I. Most signs resolve in 7 to 10 days regardless of treatment (Spangler and Culbertson, 1991).
II. If improvement is not observed, reevaluate the animal for an underlying disease or another etiology.

NEOPLASIA

Definition and Causes

I. Salivary gland tumors are rare in dogs and cats.
II. Overall incidence of salivary neoplasia in dogs and cats is 0.17% (Carberry et al., 1987).
III. Most tumors are malignant, with adenocarcinomas being the most common type.
IV. Other tumor types include squamous cell carcinoma, acinic cell tumor, mixed carcinomas, and other carcinomas.
V. Nonepithelial tumors include the mast cell tumor, melanoma, fibrosarcoma, osteosarcoma, and lymphoma.
VI. Parotid or mandibular glands are most frequently affected.

Pathophysiology

I. Metastasis to regional lymph nodes is common.
II. Distant metastasis may occur, but is slow to develop.

Clinical Signs

I. Spaniel dogs may be at higher risk.
II. Typically a unilateral, firm, painless swelling is detected in the area of the salivary gland.
III. Mass may be in the upper neck (mandibular and sublingual glands), at the base of the ear (parotid gland), in the retrobulbar space or masseter area (zygomatic gland), or within the mucous membranes of the lips (accessory or minor salivary gland tissue).
IV. Signs of exophthalmos, swelling, or pain may occur.
V. A mucocele may also develop.

Diagnosis

I. Cytological examination of a fine-needle aspirate is often diagnostic for neoplasia.
II. Incisional or excisional biopsy provides a definitive diagnosis and tissue of origin.
III. Lymph node aspirate of regional nodes and thoracic radiography are recommended for tumor staging.

Differential Diagnosis

I. Mandibular lymph node neoplasia: lymphoma, metastasis of a nonsalivary tumor
II. Other unilateral salivary diseases: mucocele, abscess
III. Sialoadenitis: often bilateral
IV. Myxoma or myxosarcoma of the head and neck

Treatment

I. Aggressive resection with the associated lymph nodes is recommended.
   A. Because these tumors are typically invasive and are in close proximity to surrounding structures, wide surgical margins are often unobtainable and complete excision is uncommon.
   B. Recurrence is common owing to incomplete resection.
II. Adjunctive radiation therapy may be effective for local control in dogs (Hammer et al., 2001).
III. The use of adjunctive chemotherapy is largely unstudied and is an unproven modality.

Monitoring of Animal

I. Local recurrence is monitored with repeated examinations.
II. Regular evaluation of local lymph nodes via palpation and possibly fine-needle aspiration is done to detect local metastasis.
III. Thoracic radiographs are repeated every few months to monitor for distant metastasis.
IV. Long-term prognosis is typically poor.
V. Reported median survival time of dogs with salivary gland tumors is 550 days and is 516 days in cats (Hammer et al., 2001).

TRAUMA

Salivary Mucocele

Definition

I. It is a swelling in the cervical, oral, sublingual, or pharyngeal region characterized by an accumulation of saliva.

II. It arises as a single or multiloculated cavity that lacks an epithelial lining and is adjacent to a salivary duct or gland.
III. An inflammatory response may occur in surrounding tissues.
IV. It is also referred to as *sialocele*.
V. If the mucocele is sublingual, it is referred to as a *ranula*.

Causes

I. Mucoceles usually result from rupture of a salivary duct.
II. Trauma or foreign body penetration is considered the most likely cause.
III. It may develop secondary to duct occlusion from a sialolith or tumor.
IV. It is rarely a developmental abnormality.
V. Idiopathic forms may also occur.

Pathophysiology

I. A collection of saliva occurs in the subcutaneous tissues of the cervical or intermandibular areas (cervical mucocele), sublingual tissues (ranula), pharyngeal wall (pharyngeal mucocele), or retrobulbar region following damage to the salivary gland or duct.
II. After salivary gland or duct damage, saliva gravitates ventrally and collects in a pocket that is lined by vascularized connective tissue.
III. The sublingual gland is most often involved (especially in cats), followed by the mandibular and zygomatic glands.
IV. Poodles and German shepherd dogs may be predisposed.
V. It is more commonly seen in dogs <3 years of age.

Clinical Signs

I. A nonpainful swelling slowly develops in the ventral or ventrolateral neck region with mandibular gland mucoceles.
II. With ranulas, a sublingual swelling occurs and may result in lingual elevation and dysphagia.
III. Pharyngeal swelling may occur and result in dysphagia, ptyalism, and dyspnea.
IV. Nonpainful, unilateral exophthalmus or cystic periocular swellings may be observed with zygomatic gland involvement.

Diagnosis

I. History, signalment, and physical findings may be suggestive.
II. Fine-needle aspiration of the swelling yields fluid.
   A. A thick, honey-colored fluid may contain small, white, calcified deposits or may be blood tinged.
   B. Cytological examination reveals mucus and red blood cells.
III. Radiography, ultrasonography, and advanced imaging techniques often are not needed for a diagnosis, except for zygomatic gland mucoceles.
   A. May identify presence of salivary calculus (sialolith)
   B. Sialography difficult to perform
   C. Ultrasonography to differentiate fluid-filled structure from solid mass
IV. Histopathologic examination demonstrates a vascularized connective tissue lining.

Differential Diagnosis

I. Cervical abscesses
   A. Usually painful and warm to the touch
   B. Often develop more quickly
II. Other tumors or cysts of the head and neck
   A. Salivary neoplasia, lymphoma, cystadenoma
   B. Branchial cyst (rare)
   C. Thyroglossal duct cysts (rare)
III. Traumatic hematoma or seroma

Treatment

I. Definitive treatment is sialoadenectomy of the involved salivary glands and duct.
   A. Sialoceles are usually unilateral.
   B. For cervical mucoceles when the involved side is not obvious, place the animal in dorsal recumbency and push on the fluid-filled mass; a protrusion near the mandible usually occurs on the affected side.
II. If the sublingual salivary gland is involved, the mandibular salivary gland is also removed because of the intimate relationship of these glands.
III. Drainage of the mucocele is performed in conjunction with sialoadenectomy.
IV. Temporary drainage may occasionally be performed via aspiration to resolve dyspnea associated with pharyngeal swellings or in cases where general anesthesia is considered high risk.

Monitoring of Animal

I. Postoperative monitoring involves the following:
   A. If drains are placed, monitor discharge and remove the drain when discharge subsides.
   B. Monitor the surgical site for infection and seroma formation.
II. Recurrence is rare with complete excision of the correct salivary gland.

Salivary Gland Fistula

Definition and Causes

I. It is a nonhealing wound or tract that continuously drains saliva.
II. It is most commonly associated with penetrating trauma to salivary tissue or ducts.
III. It occasionally results from tissue trauma during ear resection surgery or lancing of a mandibular swelling.
IV. A fistula also may result from infection or necrosis associated with salivary neoplasia, or from extension of disease in surrounding tissues.

Pathophysiology

I. After trauma, saliva leaks through the skin and continuous saliva flow prevents healing of the wound.
II. Necrosis of involved tissues also predisposes to secondary bacterial infections.

Clinical Signs

I. Swelling is observed most commonly in the neck region, or, rarely, on the lateral aspect of the face below the eye.

II. An open, draining lesion is present.
   A. Drainage may increase during eating.
   B. The discharge may be malodorous when secondary infection is present.

Diagnosis

I. History of trauma is supportive.
II. Cytology of fluid may show red blood cells, white blood cells, and mucin consistent with saliva.
III. Oral pilocarpine administration may increase secretions from the fistula.
IV. Sialography, fistulography, or surgical exploration of the tract helps confirm the salivary gland origin.
V. Culture and sensitivity confirms secondary bacterial infection and guides appropriate antibiotic therapy.

Differential Diagnosis

I. Neoplasia with necrosis
II. Soft-tissue foreign bodies
III. Chronic fistulating infection at previous site of ear surgery

Treatment

I. Definitive treatment involves surgical removal of the salivary gland, with wide surgical margins that include the entire fistulous tract.
II. A less desirable option is salivary duct ligation proximal to the fistula, which ceases the flow of saliva through the opening.
III. When secondary infection is present, antibiotic therapy is also indicated.
   A. Broad-spectrum antibiotics may be chosen empirically.
      1. Amoxicillin/clavulanate 13.75 mg/kg PO BID
      2. Cephalexin 30 mg/kg PO BID
      3. Clindamycin 5 to 11 mg/kg PO BID
   B. Therapy based on culture and sensitivity testing is preferred.

Monitoring of Animal

I. Recurrence is possible if the salivary gland, duct, and fistula are not removed in their entirety.
II. If salivary duct ligation is performed, transient salivary gland swelling may occur until secondary atrophy ensues.

CHAPTER 30

Esophageal Diseases

Nolie K. Parnell

MOTILITY DISORDERS

Megaesophagus

Definition

I. Megaesophagus is a diffusely dilated esophagus from decreased or absent motility.
II. It can be either congenital or acquired (adult onset).
III. Adult-onset forms can arise from an underlying primary condition or be idiopathic, with most acquired cases being idiopathic.

Causes

I. Congenital megaesophagus is inherited in the wirehaired fox terrier and miniature schnauzer (Cox et al., 1980; Osborne et al., 1967).
   A. Simple, autosomal recessive trait in wirehaired fox terriers
   B. Simple, autosomal dominant (60% penetrance) or autosomal-recessive trait in miniature schnauzers
II. Congenital megaesophagus has been diagnosed in a litter of Chinese shar-peis (Knowles et al., 1990).
III. Other breeds, such as the German shepherd dog, golden retriever, Irish setter, and possibly the Labrador retriever and Newfoundland are predisposed (Gaynor et al., 1997).
IV. Cats can develop megaesophagus, but it is not as common as in dogs.
V. Siamese cats and Siamese-related breeds are predisposed (Mears and Jenkins, 1997).
VI. Etiopathogenesis of idiopathic, adult-onset megaesophagus is unknown.
VII. Secondary acquired megaesophagus is associated with numerous disorders (Box 30-1).
VIII. Myasthenia gravis (MG) is the most common cause of secondary acquired megaesophagus (Gaynor et al., 1997).

Pathophysiology

I. Congenital megaesophagus probably involves abnormal vagal afferent innervation of the esophagus (Holland et al., 2002).
   A. Vagal efferent innervation is normal, and a primary myopathy is unlikely (Holland et al., 1996).
   B. The exact cause of the abnormal vagal afferent innervation is unknown, but it may be a delay in maturation because some dogs may have improved function with age.
II. Adult-onset, secondary megaesophagus can be caused by any disease that disrupts the central, afferent, or efferent neural pathways.
III. Adult-onset secondary megaesophagus can also be caused by diseases that disrupt esophageal musculature.
IV. Idiopathic adult-onset megaesophagus probably involves an abnormal vagal afferent innervation similar to congenital megaesophagus (Mears and Jenkins, 1997).
V. Absent or severely compromised esophageal motility creates esophageal dysfunction, dilatation, and accumulation of ingesta in the esophagus.

Clinical Signs

I. Regurgitation of food and water is the most common clinical sign.

Box 30-1

Diseases Associated with Megaesophagus

Neuromuscular disorders

- Congenital megaesophagus
- Idiopathic megaesophagus (hereditary?)
- Myasthenia gravis
- Systemic lupus erythematosus
- Polymyositis/polymyopathy
- Tetanus
- Canine distemper
- Dysautonomia

Toxicoses

- Botulism
- Lead
- Organophosphates

Miscellaneous conditions

- Hypoadrenocorticism
- Possible hypothyroidism
- Hiatal hernia
- Gastric dilatation or volvulus
- Esophagitis

Adapted from Washaban RJ: Diseases of the esophagus. p. 1142. In Ettinger SJ, Feldman ED (eds): Textbook of Veterinary Internal Medicine, 5th Ed. Saunders, Philadelphia, 2000.

A. Both frequency of regurgitation and timing with respect to eating varies.
B. Careful historical assessment is needed to distinguish regurgitation from vomiting.
C. Ingesta are generally not bile-stained.

II. Halitosis
III. Weight loss, poor body condition from malnutrition
IV. Ptyalism
V. Respiratory signs from secondary aspiration pneumonia: moist cough, crackles, dyspnea

Diagnosis

I. Physical examination may reveal evidence of causes or complications from megaesophagus.
   A. Neurological deficits, muscle pain, weakness
   B. Fever, crackles, and tachypnea from aspiration pneumonia
   C. Cervical neck swelling secondary to esophageal distension
II. Survey thoracic radiography may reveal a dilated, air-filled esophagus.
   A. Air bronchograms suggest aspiration pneumonia.
   B. Barium esophagram also can be done but is generally not necessary if survey radiography reveals an air-filled esophagus.
   C. If a dilated esophagus is not apparent on plain radiographs, fluoroscopy is performed in conjunction with an esophagram to evaluate esophageal motility, but a risk of aspiration pneumonia exists with the procedure.
III. Laboratory testing is indicated to search for an underlying cause and to assess secondary changes (e.g., infection from aspiration pneumonia).
   A. Complete blood count (CBC), serum biochemical profile, urinalysis
   B. Creatine kinase to evaluate for myopathies
   C. Thyroid function tests to detect hypothyroidism
   D. Adrenocorticotropic hormone (ACTH) stimulation testing to test for hypoadrenocorticism
   E. Acetylcholine receptor antibody titer to diagnose MG
   F. Others: blood lead level, antinuclear antibody assay
IV. Miscellaneous tests to consider include the following:
   A. Esophageal manometry: dynamic measurement of esophageal pressure, transit time, and lower esophageal sphincter pressures
   B. Esophageal scintigraphy: quantitatively evaluates esophageal motility
   C. Advanced neurodiagnostic tests in suspected cases of neuromuscular disease
      1. Electromyography (EMG), nerve conduction velocities (NCV), muscle or nerve biopsy
      2. Imaging of the central nervous system (CNS)
      3. Cerebrospinal fluid (CSF) tap and analysis
   D. Endoscopy
      1. Used to search for underlying etiologies that cause secondary adult-onset megaesophagus
      2. Not a sensitive tool to evaluate esophageal diameter and function

Differential Diagnosis

I. Other causes of regurgitation must be ruled out.
II. Other causes of esophageal dysmotility in young animals include vascular ring anomalies and esophageal foreign bodies and strictures.
III. Other causes of adult-onset dysmotility include esophageal neoplasia, severe esophagitis, esophageal strictures, and foreign bodies.

Treatment

I. If an etiology is identified for the megaesophagus, treatment is aimed at that specific disorder.
II. Resolution of the primary disorder does not guarantee that the megaesophagus will resolve or that normal esophageal function will return.
III. Symptomatic care for megaesophagus includes the following:
   A. Elevated feedings
   B. Frequent, small meals of calorie-dense food
   C. Tailoring of the type of diet to each animal
      1. Variability exists as to the affected animal's ability to swallow different types of foods.
      2. Various consistencies (e.g., gruel, meatballs) should be tried.
      3. Solid boluses of food are more likely to stimulate peristaltic activity.
IV. In severely malnourished animals or if oral feeding is unsuccessful, gastrostomy tube placement may be done.
V. Treatment of aspiration pneumonia includes broad-spectrum antibiotics.
VI. Prokinetic drugs are controversial and are not recommended for animals with idiopathic megaesophagus.

Monitoring of Animal

I. Monitoring is variable based on the severity of the disease.
II. Repeated thoracic radiographs and CBCs are used to monitor response to treatment for aspiration pneumonia.
III. Prognosis is variable.
   A. Congenital megaesophagus recovery rates vary from 20% to 46% (Mears and DeNovo, 2000).
      1. Early recognition carries a better prognosis.
      2. Miniature schnauzers are an exception, as most cases tend to resolve by 12 months of age.
   B. Prognosis is poor for animals with adult-onset idiopathic megaesophagus owing to progression of disease, poor nutrition, or recurrent bouts of aspiration pneumonia.
   C. Prognosis for megaesophagus secondary to MG is reasonably optimistic, because 50% of affected dogs respond to therapy (Shelton et al., 1990).

INFLAMMATORY DISORDERS

Esophagitis

Definition

I. Esophagitis involves inflammation of the esophageal mucosa, although in severe cases transmural involvement can occur.

II. Prevalence of esophagitis is probably underestimated because of variable clinical signs and difficulty in diagnosing the disease with minimally invasive techniques.
III. Both acute and chronic esophagitis occur.

Causes

I. The most common cause is gastroesophageal reflux (GER).
   A. Common causes of iatrogenic GER include the duration of preoperative fasting, preanesthetic and anesthetic agents used, and intraabdominal procedures performed.
   B. Poorly positioned nasoesophageal or esophagostomy tubes that cross the lower esophageal sphincter can also cause GER.
II. Ingestion of caustic agents (e.g., sodium hydroxide, benzalkonium chloride) may cause esophagitis.
   A. The esophagus is more susceptible to alkaline than acidic corrosives (Strombeck and Guilford, 1996).
   B. Drugs may be caustic, especially doxycycline in cats (Melendez et al., 2000).
III. Other causes include acute or persistent vomiting, thermal burns, trauma from esophageal foreign bodies, structural abnormalities (e.g., hiatal hernia), and infectious agents (e.g., pythiosis).

Pathophysiology

I. GER is a normal event in dogs and may also be normal in cats.
II. Esophagitis occurs secondarily to GER by the following:
   A. Refluxed gastric contents contain hydrochloric acid, pepsin, trypsin, bile acids, and lysolecithin that are injurious to the esophageal mucosa.
   B. Hydrochloric acid is the most important component.
   C. The most severe injury occurs when hydrochloric acid is combined with pepsin or bile acids.
   D. Inflammation impairs esophageal motility, which allows subsequent refluxed gastric contents to remain in the esophagus longer, thereby worsening the inflammation.
   E. Esophagitis compromises lower esophageal sphincter tone, allowing refluxed contents to enter the esophagus.
   F. A vicious cycle occurs that perpetuates the problem.
III. Esophagitis secondary to drugs or chemicals is affected by several factors.
   A. Tablets and capsules pass easier when given with water than when given alone (dry) (Westfall et al., 2001).
   B. Retention of drugs causes changes in mucosal pH and hyperosmolarity.
   C. Esophageal damage is usually localized (focal lesion), whereas GER causes more generalized inflammation.
IV. Several factors determine the severity of injury.
   A. Length of time refluxed material remains in the esophagus
   B. Amount of bicarbonate available (via saliva) to buffer refluxed contents
   C. Reduced swallowing and secretion of saliva during sleep and anesthesia
   D. Ability of saliva and submucosal esophageal glands to create a barrier mucus layer
V. Mild esophagitis may heal without fibrosis.
VI. Severe esophageal injury that extends into the muscularis layer can cause stricture formation.

Clinical Signs

I. Historical findings are important because of variable clinical signs.
   A. Differentiate between vomiting and regurgitation.
   B. Note any recent drug administration or anesthetic event.
II. Animals with mild esophagitis may exhibit no clinical signs.
III. Moderate to severe esophagitis may induce one or more of the following:
   A. Regurgitation
   B. Dysphagia, ptyalism
   C. Repeated attempts at swallowing
   D. Refusal to eat despite an interest in food
   E. Anorexia, weight loss

Diagnosis

I. Physical examination is often normal but may show pain on palpation of the neck in severe cases.
II. Minimum laboratory database is usually normal or reveals nonspecific changes.
III. Survey radiographs are usually unremarkable.
   A. Radiography is helpful to rule out other causes of regurgitation (e.g., megaesophagus).
   B. Contrast radiography is preferred (see Chapter 4).
      1. An irregular esophageal mucosa with possible retention of barium is suggestive of esophagitis.
      2. Either liquid barium or barium mixed with food can identify esophageal strictures.
      3. Ideally, fluoroscopy is used to evaluate esophageal motility and potentially identify GER.
IV. Endoscopy is the most sensitive and specific tool to diagnose clinically significant esophagitis.
   A. Normal esophagus is smooth and pale with longitudinal folds that flatten with distension.
   B. The distal third of the feline esophagus is smooth muscle, which creates an appearance of mucosal striations and submucosal vascularity.
   C. Esophageal changes associated with inflammation include hyperemia, increased vascularity, roughened mucosal surface, erosions, and ulcerations.
   D. Distal or multiple abnormalities are suggestive of GER, and focal lesions in the proximal third of the esophagus are suggestive of damage from foreign bodies or caustic agents.
   E. Endoscopy also may be able to document the presence of GER.
V. It is difficult to obtain adequate esophageal biopsy samples with standard endoscopic biopsy instruments.
   A. Biopsy is limited to cases not responding to therapy or if the gross appearance is not typical for benign esophagitis.

B. Abnormalities include squamous hyperplasia or dysplasia, erosions, and ulcers.
C. Acute changes include infiltrates of lymphocytes, plasma cells and neutrophils (Han, 2003).

VI. Manometry of the lower esophageal sphincter and continuous monitoring of esophageal pH can be done in a research setting but is difficult in clinical patients.

Differential Diagnosis

I. Megaesophagus
II. Esophageal stricture
III. Vascular ring anomaly
IV. Hiatal hernia
V. Esophageal foreign body
VI. Esophageal neoplasia

Treatment

I. Immediate treatment of caustic or thermal insults is indicated, and specific recommendations can be obtained from the ASPCA Animal Poison Control Center (888-426-4435).
II. Eliminate predisposing factors, such as a hiatal hernia, foreign body, or administration of a dry or caustic drug.
III. Reduce gastric acid secretion.
A. The volume of acid that is refluxed into the esophagus is subsequently decreased.
B. Histamine $(H)_2$-receptor antagonists inhibit hydrochloric acid secretion.
1. Useful in mild esophagitis, but not as effective in moderate to severe esophagitis (Willard and Weyrauch, 2000)
2. Cimetidine 10 mg/kg PO TID to QID (dogs) and 5 mg/kg PO TID (cats)
3. Ranitidine 1 to 2 mg/kg PO BID; also has some prokinetic activity
4. Famotidine 0.5 mg/kg PO SID to BID
C. Proton-pump inhibitors, such as omeprazole 0.7 mg/kg PO SID, are used in severe cases of esophagitis.
IV. Prokinetic drugs promote gastric emptying, which reduces the amount of gastric fluid that is refluxed, and increase lower esophageal sphincter tone, which decreases the amount and frequency of refluxed fluid.
A. Metoclopramide 0.5 mg/kg PO TID to QID (dogs) and 0.2 mg/kg PO TID (cats)
B. Cisapride 0.5 mg/kg PO BID (dogs) and 2.5 to 5 mg PO BID to TID (cats)
1. Superior to metoclopramide in promoting gastric emptying and increasing lower esophageal sphincter tone
2. Superior to metoclopramide in treating esophagitis (Klinkenberg-Knol et al., 1995)
3. Only available through compounding pharmacies
V. Other drugs that have been tried include the following:
A. Sucralfate 0.5 to 1 g PO TID (dogs) and 250 to 500 mg PO BID to TID (cats)
1. Cytoprotective and used to promote healing of gastric ulcers
2. Needs an acidic environment to work (stomach) and must be carried back into the esophagus as refluxate
3. Little evidence of its efficacy in the treatment of esophagitis (Klinkenberg-Knol et al., 1995)
B. Corticosteroid to prevent stricture formation
1. Questionable efficacy at best
2. Increases risk of infection
VI. Withhold food for 24 to 48 hours in cases of acute esophagitis, especially those secondary to caustic or thermal burns
A. Low-fat diets promote gastric emptying, which reduces the amount of GER.
B. Consider a gastrostomy tube to provide nutritional support in animals with severe esophagitis or those that are debilitated from chronic esophagitis.

Monitoring of Animal

I. Duration of drug therapy is based on the severity of the esophagitis.
A. Mild esophagitis is treated a minimum of 7 days.
B. Severe esophagitis is treated a minimum of 4 weeks.
II. Repeat endoscopy to determine whether esophagitis has resolved before discontinuing drug therapy.
III. If reexamination with endoscopy is not possible, use clinical signs as a guide to determine when to discontinue drug therapy.
IV. Return to a normal, maintenance diet after all medications have been discontinued and no signs have recurred.
V. If clinical signs worsen despite therapy, consider the possibility of esophageal stricture formation.
VI. Prognosis is variable, but generally good.

OBSTRUCTIVE DISORDERS

Esophageal Foreign Body

Definition

I. Foreign material or objects do not move through the esophagus into the stomach.
II. Esophageal foreign bodies are potentially life-threatening and are considered emergencies.
III. Young to middle-aged, small-breed dogs, especially terriers, may be more susceptible (Spielman et al., 1992).

Causes

I. Common esophageal foreign bodies in dogs include bones, fishhooks, sticks, and dental chew products.
II. Common esophageal foreign bodies in cats include needles, bones, fishhooks, and trichobezoars.

Pathophysiology

I. Many esophageal foreign bodies lodge in areas of normal narrowing and less distensibility (Bebchuk, 2002).
A. Pharyngeal esophagus
B. Base of the heart
C. Diaphragmatic hiatal region

II. Depending on the size and shape of the foreign body, the obstruction can be partial or complete.
III. Obstruction creates mural pressure, mucosal ischemia, and eventual necrosis.
IV. Pressure necrosis can lead to mediastinitis and esophageal perforation.
V. Sharp esophageal foreign bodies can also cause lacerations and esophageal perforation.
VI. Pain (often severe) occurs with all types of foreign bodies.

Clinical Signs

I. The duration of clinical signs is shorter in dogs with a foreign body and no perforation compared to dogs with a foreign body and esophageal perforation (Parker et al., 1989).
II. Signs are variable depending on the size of foreign body and its duration in the esophagus.
   A. Lethargy, anorexia
   B. Ptyalism, retching, gagging
   C. Exaggerated swallowing movements
   D. Regurgitation
   E. Evidence of pain: restlessness, distress, tachycardia, tachypnea
III. Signs may also develop from secondary complications, such as respiratory distress from aspiration pneumonia.

Diagnosis

I. Early diagnosis is important to decrease the likelihood of esophageal perforation.
II. History may not be helpful if the owner does not recognize that common chew toys and objects are potential esophageal foreign bodies.
III. Physical examination may be normal in acute cases.
   A. Pain may be detected with cervical esophageal palpation.
   B. In chronic cases, fever and abnormal lung sounds may be present.
IV. Laboratory tests are often normal in acute cases.
   A. Hematology can reveal leukocytosis (from inflammation) and hemoconcentration in chronic cases or in cases with esophageal perforation.
   B. Biochemical parameters are usually normal.
V. It is important to radiograph the entire esophagus.
   A. Survey radiographs are diagnostic if the foreign body is radiopaque.
      1. Identification can be challenging if the foreign body is not radiopaque.
      2. Air or fluid may be visualized proximal to the foreign body.
      3. Segmental esophageal dilatation may occur proximal to the foreign body.
      4. Pneumomediastinum, pneumothorax, or evidence of mediastinitis is suggestive.
      5. A pulmonary alveolar pattern is seen with pneumonia.
   B. Contrast radiography may be helpful.
      1. It is used to diagnose radiolucent foreign bodies.
      2. If esophageal perforation is suspected, barium is contraindicated, and either aqueous iodine or iohexol are used instead (see Chapter 4).
VI. Esophagoscopy allows direct visualization of the foreign body.
   A. It allows identification of perforations and mucosal abnormalities (erythema to severe ulcerations).
   B. If perforation is not suspected, it may allow endoscopic removal of the foreign body.

Differential Diagnosis

I. Other causes of esophageal obstruction: vascular ring anomalies, periesophageal masses
II. Esophagitis from GER, caustic or thermal burns

Treatment

I. An esophageal foreign body is considered an emergency.
II. Endoscopic retrieval is the preferred route of removal.
   A. Flexible or rigid endoscopy can be performed.
   B. Various instruments may be used to move the foreign body.
      1. Long, blunt-ended grasping forceps
      2. Flexible alligator forceps
      3. Foley urethral catheters
   C. Objects that are not sharp and are lodged in the distal esophagus can be pushed into the stomach.
      1. Attempt this only when removal through the mouth is unsuccessful.
      2. Attempt this only when further injury to the mucosa is unlikely.
   D. After removal, evaluate the mucosa for lacerations or perforations.
III. Surgery (lateral thoracotomy) is indicated when endoscopic retrieval is unsuccessful.
   A. Surgery is also indicated if an esophageal perforation is present.
   B. Surgery may be combined with endoscopy to remove fish hooks (Michels et al., 1995).
IV. Following retrieval of the foreign body, medically manage the associated esophagitis (see Esophagitis).
V. Consider insertion of a gastrostomy tube for nutritional support if severe mucosal ulceration or perforation is present.

Monitoring of Animal

I. If no complications occur, postretrieval monitoring is minimal.
II. Complications occur in about 30% of cases (Strombeck and Guilford, 1996).
   A. Esophageal perforation
      1. False-negatives may occur with contrast radiography when a foreign body is still present.
      2. Esophageal perforations up to 12 mm in diameter can be treated conservatively without surgical repair (Killen and Pridgen, 1961).
   B. Esophageal stricture
   C. Esophageal fistulation into the respiratory tract

D. Pneumomediastinum, pneumothorax, pleuritis
E. Pneumonia
F. Segmental dysmotility of the esophagus

III. If signs of esophageal disease begin 7 to 14 days after removal, evaluate for esophageal stricture formation.

Esophageal Stricture

Definition

I. It is a circular band of scar tissue that compromises the esophageal lumen.
II. Esophageal strictures can be singular or multiple and can occur anywhere in the esophagus.

Causes

I. Most esophageal strictures occur secondary to severe esophagitis.
   A. GER that occurs during anesthesia is the most common cause (Sellon and Willard, 2003).
   B. Other causes include chronic vomiting, esophageal surgery, and certain medications (e.g., doxycycline in cats).
II. Esophageal foreign bodies that create mechanical and chemical injury are also common causes.
III. Esophageal neoplasia uncommonly causes strictures.

Pathophysiology

I. An esophageal injury initially causes inflammation of the mucosa, submucosa, and muscularis (Weyrauch and Willard, 1998).
II. Secondary formation of fibrous, connective tissue narrows the esophageal lumen.
III. Time from mucosal damage to stricture formation is usually 1 to 2 weeks.

Clinical Signs

I. Dependent on location and severity of esophageal narrowing
II. Dysphagia, regurgitation
III. Refusal to eat despite interest in food
IV. Able to retain liquids better than solids
V. Weight loss
VI. Respiratory distress with proximal strictures

Diagnosis

I. History of recent anesthetic event, esophageal foreign body, vomiting, or oral medication administration
II. Diagnostic imaging
   A. Survey thoracic radiographs are usually unremarkable.
   B. Esophagogram with barium alone or mixed with canned food usually shows esophageal narrowing.
      1. Demonstrates both the number and the location of the stricture(s)
      2. May also demonstrate GER
III. Endoscopy
   A. Direct visualization is the most sensitive diagnostic test.
   B. It allows for both diagnosis and treatment.
      1. If a malignant cause of the stricture is suspected, mucosal biopsy can be performed.
      2. Treatment with balloon catheter dilatation may be undertaken.
   C. Areas at the heart base and near major vessels can be misinterpreted as partial strictures.
   D. Esophagoscopy does not allow identification of extraluminal causes of esophageal narrowing (e.g., vascular ring anomaly, periesophageal masses).

Differential Diagnosis

I. Extraluminal etiologies of esophageal narrowing: lymphadenopathy, granuloma, adhesions from previous trauma or inflammation
II. Vascular ring anomalies in young animals

Treatment

I. Benign strictures are treated with balloon catheter dilatation, esophageal bougienage, intraluminal esophageal stent placement, or surgical resection.
II. Limited experience exists with intraluminal esophageal stents in dogs and cats.
   A. High complication rate
      1. Pressure necrosis at the stent site
      2. Migration of the stent
      3. Tracheoesophageal or bronchoesophageal fistulization
   B. Expensive
   C. Only recommended when medical management fails
III. Surgical resection usually requires thoracic surgery to access the esophagus.
   A. It has a lower success rate than balloon catheter dilatation (Burk et al., 1987).
   B. Iatrogenic stricture formation at the surgery site is common.
   C. It is recommended only when other methods fail.
IV. Esophageal bougienage is the passage of rigid or semirigid dilators of incrementally larger sizes through the stricture.
   A. Greater shear forces are generated than radial forces.
   B. Shear forces increase the likelihood of esophageal perforation.
V. Balloon catheter dilation is the treatment of choice for benign esophageal strictures.
   A. Only radial forces are created because the balloons are stationary within the stricture during dilation.
   B. The balloon catheter is positioned within the stricture using endoscopic guidance and is then inflated to mechanically dilate the strictured site.
   C. Multiple balloon dilation procedures are usually necessary (mean, 2; range, 1 to 5 (Leib et al., 2001).
   D. Intralesional corticosteroids to prevent reformation of fibrous tissue may be indicated for strictures that do not respond to repeated balloon dilation.
   E. Complications include hemorrhage, mucosal tears, and esophageal perforation.
VI. Concurrent medical management is indicated with balloon catheter dilation.
   A. Nutritional support is indicated with severe esophageal strictures or for animals with poor nutritional status.

B. Aggressive treatment of esophagitis is done for at least 14 to 21 days (see Esophagitis).
C. Long-term management of GER may also be indicated.

VII. Malignant esophageal strictures are treated surgically, with adjunctive radiation therapy and chemotherapy.

Monitoring of Animal

I. Prognosis for benign esophageal strictures is good.
   A. *Successful outcome* is defined as diminished or resolved clinical signs and the ability to maintain adequate nutritional status.
   B. A success rate of 88% has been reported with balloon dilation (Leib et al., 2001).
   C. Successful outcome is not defined as a return of normal intraluminal esophageal diameter.

II. Prognosis for malignant causes of esophageal strictures is poor.

MISCELLANEOUS DISORDERS

Hiatal Hernia

Definition

I. It is a protrusion of abdominal contents through the esophageal hiatus of the diaphragm into the thoracic cavity (Callan et al., 1993).
II. Although uncommon, it occurs in both cats and dogs.
III. Two types of hiatal hernias exist.
   A. Sliding hiatal hernia
      1. Cranial displacement of the abdominal esophagus and parts of the stomach through the esophageal hiatus
      2. Most common form in dogs and cats
   B. Paraesophageal hiatal hernia
      1. Abdominal esophagus and lower esophageal sphincter remain in a fixed position.
      2. A portion of the stomach herniates into the mediastinum adjacent to the thoracic esophagus.
IV. Both congenital and acquired forms exist.
   A. Congenital form is the most common.
   B. The congenital form is reported in the Chinese sharpei, English bulldog, and chow chow (Washabau and Hall, 1997).

Causes

I. The cause is not completely understood.
II. Congenital hiatal hernias may occur secondary to incomplete closure of the diaphragmatic hiatus during embryologic development.
III. Acquired hiatal hernia has been associated with chronic vomiting (increased intraabdominal pressure), trauma (via damage to the diaphragmatic nerves), and respiratory distress from airway obstruction (increased negative intrathoracic pressure) (Jergens, 2000).

Pathophysiology

I. Possible loss of contraction of the right crus of the diaphragm around the esophagus occurs during inspiration (Sivacolundhu et al., 2002).
II. Displacement of the gastroesophageal junction leads to increased pressure against the lower esophageal sphincter.
III. Progressive compromise of the lower esophageal sphincter occurs.
IV. Failure of the lower esophageal sphincter allows for GER and secondary esophagitis.
V. Esophageal hypomotility may also contribute to the clinical presentation.

Clinical Signs

I. Some animals are asymptomatic.
II. Signs can be intermittent with sliding hiatal hernia.
III. Regurgitation, hypersalivation, inappetence, and anorexia may be noted.
IV. Respiratory signs can occur secondary to aspiration pneumonia.

Diagnosis

I. Physical examination findings
   A. ± Normal examination or low body condition score
   B. Abnormal lung sounds with pneumonia
II. Laboratory evaluation
   A. Most likely normal
   B. Evidence of inflammation with pneumonia
III. Survey radiography
   A. Caudal, dorsal, gas-filled, intrathoracic, soft-tissue opacity associated with the esophagus
   B. Occasionally megaesophagus
   C. ± Alveolar infiltrates compatible with pneumonia (occasionally)
IV. Contrast radiography
   A. It confirms the presence of a hiatal hernia.
   B. When combined with fluoroscopy, GER and esophageal dysmotility can be documented.
V. Esophagoscopy
   A. It may be helpful if radiography fails to document an intermittent, sliding hiatal hernia.
   B. Changes consistent with esophagitis may be visualized.
   C. An abnormal gastroesophageal junction may be detected.

Differential Diagnosis

I. Congenital megaesophagus
II. Other causes of esophagitis
III. Esophageal foreign body
IV. Esophageal stricture
V. Vascular ring anomaly

Treatment

I. None indicated in asymptomatic animals
II. Medical management
   A. Treat esophagitis secondary to GER for a minimum of 30 days.
   B. Feeding small, frequent meals of a low-fat, softened, or liquefied food may be successful in controlling signs (Lorinson and Bright, 1998).
   C. Antibiotics are indicated if pneumonia is present.
III. Surgical management

A. Indicated for paraesophageal hiatal hernias or if medical therapy of a sliding hiatal hernia fails
B. Many techniques possible
   1. Esophagopexy resolves clinical signs in most animals (Lorinson and Bright, 1998).
   2. Esophagopexy may be combined with hiatal plication and gastropexy.
   3. Fundoplication is not indicated, given the high complication rate and failure to resolve clinical signs (Lorinson and Bright, 1998).

Monitoring of Animal

I. Continue medical therapy for a minimum of 30 days.
II. Prognosis is guarded in animals with concurrent esophageal dysmotility.
III. Prognosis is good in animals that respond to either medical or surgical therapy.

Fistula

Definition

I. A fistula is an abnormal communication between the esophagus and the respiratory tract.
II. Several types of fistula can occur.
   A. Bronchoesophageal: most common
   B. Tracheoesophageal
   C. Pulmonary-esophageal
III. Although uncommon, both congenital and acquired fistulas occur and arise most often in toy and small-breed, terrier-type dogs.

Causes

I. Congenital fistulas may arise from incomplete separation of the esophagus and airways during embryonic development.
II. Cairn terriers may be predisposed to congenital fistulas (Basher et al., 1991).
III. Acquired fistulas arise as complications of esophageal perforations from foreign bodies and neoplasia.

Pathophysiology

I. An intraluminal foreign body (most commonly bones) creates local mucosal ischemia and necrosis.
II. The right caudal lung lobe is frequently affected (van Ee et al., 1986).
III. A fibrous communication with the respiratory tract forms during subsequent healing.
IV. Leakage of esophageal contents causes contamination of the respiratory tract.

Clinical Signs

I. Chronic coughing: frequently associated with drinking and eating
II. Regurgitation, dysphagia
III. Anorexia
IV. Pyrexia and abnormal lung sounds with pneumonia

Diagnosis

I. Crackles may be auscultated over affected lung lobes.
II. Hematology reflects inflammation secondary to pneumonia.
III. On survey radiography a radiopaque esophageal foreign body may be visible.
   A. An alveolar pattern consistent with pneumonia may be seen, especially in areas adjacent to any foreign bodies.
   B. Esophageal diverticula may also be present.
IV. Contrast radiography definitively identifies the communication between esophagus and respiratory tract, but use of hyperosmolar contrast agents should be avoided.
V. Esophagoscopy and bronchoscopy are of limited value.

Differential Diagnosis

I. Aspiration pneumonia
II. Pulmonary abscess
III. Pulmonary granuloma

Treatment

I. Antibiotics are indicated for pneumonia.
II. Lung lobectomy is usually necessary owing to the long-standing pulmonary pathology.
   A. Simple ligation of the fistula is avoided.
   B. Submit excised tissues for culture and histopathology.
III. Nutritional support is indicated for chronic, debilitated animals.

Monitoring of Animal

I. Intensive monitoring is required in the immediate post-operative period.
   A. Frequent monitoring of vital signs
   B. Repeated blood counts and thoracic radiographs
II. Complications include dehiscence, pneumothorax, and pulmonary abcessation.
III. Prognosis is good if the animal successfully recovers from surgery.

Diverticula

Definition

I. A diverticulum is a pouchlike dilatation of the esophageal wall.
II. Diverticula, although rare, may be either congenital or acquired.
III. Acquired forms occur more frequently and are either traction or pulsion in origin.
IV. Diverticula most commonly occur in three areas, namely the pharyngoesophageal, midthoracic, or caudal thoracic (Nawrocki et al., 2003).
V. Cairn terriers and miniature poodles are over-represented (Nawrocki et al., 2003).

Causes

I. Congenital esophageal diverticula result from anomalous separation of the respiratory tract from the foregut (Pearson et al., 1978).

II. Acquired esophageal diverticula arise as follows:
  A. Pulsion diverticula develop from increased intraluminal pressure associated with esophageal strictures, vascular ring anomalies, and esophageal foreign bodies.
  B. Traction diverticula develop secondary to inflammation and periesophageal fibrous tissue, and are most commonly associated with perforating esophageal foreign bodies.

Pathophysiology

I. Pulsion diverticula
  A. Increased esophageal intraluminal pressure compromises a focal area of the esophageal wall.
  B. Mucosal herniation develops.
  C. Accumulation of food in the diverticula leads to inflammation.
  D. Large diverticula compromise motility, cause mechanical obstruction, and induce esophagitis.
  E. With large diverticula, nutritional intake is affected.
II. Traction diverticula
  A. Local inflammation causes fibrous adhesions between the serosal surface of the esophagus and surrounding structures (trachea, lungs, pulmonary hilus).
  B. Adhesions cause chronic esophageal dysmotility, which leads to focal dilatation.

Clinical Signs

I. Small diverticula may be asymptomatic.
II. Regurgitation is common.
III. Halitosis occurs from food accumulation within the diverticulum.
IV. Inappetence, and distress or gasping shortly after eating (odynophagia) may be noted.

Diagnosis

I. Diverticula in the cervical esophagus may be palpated if they contain impacted food.
II. Abnormal lung sounds are auscultated if pneumonia is present.
III. Hematology reflects inflammation if severe, ulcerative esophagitis or aspiration pneumonia is present.
IV. Survey radiography may reveal the following:
  A. Air- or fluid-filled opacity in the area of the esophagus
  B. Alveolar pattern consistent with pneumonia
V. A barium esophagogram shows pooling of contrast medium in the diverticulum.
VI. Esophagoscopy confirms the diagnosis and allows assessment of the severity of food impaction and esophagitis.

Differential Diagnosis

I. Normal esophageal redundancy that is occasionally seen at the thoracic inlet (Strombeck and Guilford, 1996)
II. Esophageal foreign body
III. Periesophageal diseases: abscess, hilar lymphadenopathy, neoplasia
IV. Other causes of esophageal hypomotility: megaesophagus

Treatment

I. Correct the underlying cause of pulsion diverticula.
II. Conservative medical management may be attempted for small diverticula.
  A. Feed in an upright position.
  B. Feed frequent, small meals of a canned, semiliquid, or liquid diet to minimize food impaction.
III. Surgical correction is indicated for large diverticula.
  A. Diverticulectomy is the preferred procedure.
  B. The complication rate is high because of the unique characteristics of the esophagus (Shamir et al., 1999).
    1. Absence of serosal layer and omentum
    2. Inability to rest the esophagus because of continual movement from swallowing and diaphragmatic movement
    3. Poor tolerance to longitudinal stretching and tension
IV. Gastrostomy tube is inserted to provide nutritional support in animals with large diverticula.

Monitoring of Animal

I. Prognosis is guarded owing to the high complication rate associated with surgery.
II. If signs recur 7 to 10 days postoperatively, an esophageal stricture must be considered.
III. Dysmotility may persist following diverticulectomy.

NEOPLASIA

Definition

I. Primary tumors of the esophagus are rare in the dog and cat (<0.5% of all neoplasia) (Rolfe et al., 1994).
II. Metastatic lesions occur more frequently than primary tumors.
III. Both benign and malignant tumors have been identified.
IV. Most tumors occur in middle-aged to older animals.

Causes

I. Leiomyomas are the most common primary benign tumor, and occur most frequently at the lower esophageal sphincter.
II. Fibrosarcoma and osteosarcoma are the most common primary malignant tumors in the dog.
III. Esophageal sarcoma in dogs is associated with *Spirocerca lupi* infection.
IV. Squamous cell carcinoma is the most common primary malignant tumor in the cat.
V. Metastatic tumors or secondary tumors include the following:
  A. Thyroid carcinoma: most common (Ridgway and Suter, 1979)
  B. Other carcinomas: bronchogenic, mammary, gastric
  C. Lymphosarcoma

Pathophysiology

I. Tumors cause obstruction by decreasing intraluminal space.
II. Esophageal hypomotility may arise secondary to infiltration of the tumor into the esophageal wall.

III. Esophagitis may also occur from the tumor or secondary GER.
IV. The exact mechanism for the development of sarcomas associated with *S. lupi* is unknown.
  A. Migrating larvae incite local inflammation, hemorrhage, necrosis, and occasionally, abscesses (Johnson, 1992).
  B. The intense inflammatory reaction may cause an uncontrolled proliferation of fibroblasts (Ranen et al., 2004).
  C. Pathogenesis may be similar to vaccine-associated sarcomas.

Clinical Signs

I. Usually slowly progressive
II. Associated with altered function of the esophagus
  A. Dysphagia, regurgitation, ptyalism
  B. Inappetence, weight loss
III. Hematemesis (rare)
IV. Respiratory signs secondary to aspiration pneumonia

Diagnosis

I. History of middle-aged to older animals with progressive esophageal signs
II. Physical examination findings
  A. Can be normal
  B. May reflect poor nutritional status (low body condition score)
  C. Palpable cervical mass in some cases
  D. Abnormal pulmonary auscultation, if pneumonia present
III. Laboratory evaluation
  A. Normal in most cases
  B. Sarcomas associated with *S. lupi*
    1. Hematology reflecting inflammation (leukocytosis)
    2. Microcytic, hypochromic anemia (Ranen et al., 2004)
IV. Survey radiography
  A. Air may be visualized proximal to the mass.
  B. Segmental esophageal dilatation may be detected proximal to the mass.
  C. Tracheal displacement may be seen.
  D. An intraluminal esophageal soft-tissue structure may be identified.
  E. Pulmonary infiltrates may be present with metastatic disease or aspiration pneumonia.
  F. Hypertrophic osteopathy is reported in dogs with *S. lupi*-associated fibrosarcoma (Ranen et al., 2004).
V. Contrast radiography
  A. It is useful in detecting mucosal irregularities and luminal narrowing.
  B. When used with fluoroscopy, contrast radiography can identify dysmotility.
VI. Computed tomography
  A. Determines extent of disease
  B. May identify metastasis in local lymph nodes
  C. Discriminates between benign esophageal stricture and neoplasia
VII. Esophagoscopy
  A. It allows for direct visualization and biopsy of the mass.
  B. Leiomyomas at the lower esophageal sphincter may be difficult to differentiate from variations in normal mucosa.
  C. Esophageal mucosa can be difficult to biopsy.
  D. Endoscopic biopsies provide small samples that may be inadequate for definitive diagnosis.
VIII. Histopathology
  A. Necessary for definitive diagnosis
  B. May require surgical biopsy if endoscopic samples are inadequate

Differential Diagnosis

I. Esophageal foreign body
II. Esophageal granuloma
III. Esophagitis
IV. Hiatal hernia
V. Compression of esophagus from mediastinal masses

Treatment

I. Dependent on tumor type
II. Leiomyoma: surgical resection usually curative
III. Primary malignant tumors
  A. Most cases have advanced disease at the time of diagnosis.
  B. Partial esophagectomy is indicated but has a significant complication rate.
  C. Adjunctive chemotherapy may be started after recovery from surgery.
IV. Metastatic neoplasia
  A. Surgical resection may be used to relieve any obstruction but is not curative.
  B. Chemotherapy may be attempted.
  C. Most therapy is palliative.
V. Palliative balloon dilatation of the intraluminal obstruction may be considered, but it carries the risk of esophageal perforation.
VI. Nutritional support via a gastrostomy tube may be helpful.

Monitoring of Animal

I. Prognosis for benign tumors is good if the tumor is surgically resectable.
II. Prognosis for malignant and metastatic neoplasia is poor.
III. Palliative measures provide temporary relief from disease, but most animals are euthanized owing to quality of life issues.

CHAPTER 31

Diseases of the Stomach

Lisa E. Moore

CONGENITAL/DEVELOPMENTAL DISORDERS

Pyloric Stenosis

Definition

I. It is a congenital disease of boxers and Boston terriers.
II. Stenosis of the pyloric canal occurs from hypertrophy of the pyloric circular muscle.

Causes

I. The cause is unknown, but an oversecretion of gastrin has been postulated.
II. A functional abnormality has also been proposed, as some animals with pyloric outflow obstruction do not have muscular thickening.

Pathophysiology

I. Stenosis of the pyloric canal causes gastric outflow obstruction.
II. Elevated levels of gastrin can lead to thickening of the pyloric smooth muscle from its trophic effects.
III. Gastrin can also lead to hypertrophy of the mucosa, which can worsen the outflow obstruction.

Clinical Signs

I. Clinical signs are related to delayed gastric emptying.
II. Generally, animals vomit food >12 hours after eating.
  A. The vomiting may be explosive.
  B. The food in the vomitus is usually digested, but may appear undigested.
III. Abdominal distention may be noted.
IV. Weight loss may occur from inability to retain food.
V. Anorexia is uncommon.

Diagnosis

I. Pyloric outflow obstruction is suspected based on the pattern of vomiting.
II. Laboratory findings may show hypokalemia, hypochloremia, and metabolic alkalosis.
III. Plain radiography often shows a stomach distended with gas and fluid.
IV. Contrast radiography may show delayed gastric emptying and a narrowing of the pyloric canal that is referred to as the *beak sign.*
V. Nuclear scintigraphy may also be used to identify delayed gastric emptying.
VI. Abdominal ultrasonography can be used to detect thickening of the pylorus.
VII. Endoscopy may be normal if the mucosa is not thickened.
VIII. At surgery, the pylorus is palpably thickened, and gastrotomy reveals a thickening of the muscular layer.

Differential Diagnosis

I. Other causes of mechanical pyloric outflow obstruction: mucosal hypertrophy, intraluminal masses (e.g., polyps, neoplasia, foreign bodies)
II. Causes of a functional delay in emptying: electrolyte disorders, pain, peritonitis, acute pancreatitis, dysautonomia, gastric ulceration

Treatment and Monitoring

I. After the animal has been stabilized with appropriate fluid and electrolyte therapy, the definitive treatment is surgery.
II. Surgical procedures include pyloromyotomy or various pyloroplasty techniques.
III. Prognosis following adequate surgical correction is good.

INFECTIOUS DISORDERS

Parasitic Gastritis

Definition and Causes

I. Parasites affecting the stomach of cats include *Ollulanus tricuspis* and *Physaloptera* spp. (less common).
II. Gastric parasites of dogs include *Physaloptera* spp.
III. Parasites attach to the gastric mucosa, causing inflammation and gastritis.

Clinical Signs

I. Infections in both dogs and cats may be inapparent.
II. Intermittent vomiting is the most common clinical sign.
III. Variable anorexia may also occur.

Diagnosis

I. *Ollulanus* spp. can be difficult to diagnose.
  A. The parasites and eggs are usually missed on routine parasitologic (usually not passed in the feces) and endoscopic (very small in size) examinations.

B. The best method of diagnosis is microscopic examination of the vomitus.
C. Organisms may also be seen on histopathology.
D. Chronic hypertrophic fibrosing gastritis may also be seen on histopathology.

II. Diagnosis of *Physaloptera* spp. is a little easier.
A. Eggs may be found on fecal flotation, but may not be routinely isolated.
B. The parasites can be seen with endoscopy and appear as 1- to 4-cm–long, white worms attached to the stomach.

Differential Diagnosis

I. Other causes of acute gastritis (see below)
II. Causes of chronic and secondary gastritis

Treatment and Monitoring

I. *Ollulanus* spp.: fenbendazole 10 mg/kg PO SID for 3 days
II. *Physaloptera* spp.: pyrantel pamoate 5 mg/kg PO for two doses, 3 weeks apart
III. Prognosis is excellent for recovery after treatment.

Helicobacter Gastritis

Definition

I. *Helicobacter* gastritis is inflammation of the stomach caused by various species of the genus *Helicobacter*.
II. Many cats and dogs that have colonization of the stomach with these spiral organisms do not have concurrent inflammation.

Causes

I. The organisms are spiral-shaped, gram-negative, motile bacteria.
II. Various species have been isolated from the stomachs of cats, dogs, ferrets, cheetahs, and others.
III. *Helicobacter heilmannii* and *Helicobacter felis* are the most common species that naturally occur in dogs and cats.
IV. *Helicobacter pylori* has been found in laboratory cats, but not in dogs.
V. These bacteria may be normal inhabitants of the stomach.

Pathophysiology

I. The pathophysiology of this disease is unclear.
II. The organisms produce urease (urea $\rightarrow NH_3 + HCO_3$) that buffers acid and allows colonization of the superficial mucus and gastric glands of the stomach.
III. The bacteria have been observed intracellularly.
IV. In infected animals, degeneration of gastric glands, as well as vacuolation and necrosis of parietal cells, has been seen.
A. The inflammation is generally mononuclear (lymphocytes, plasma cells) and can vary in the degree of severity.
B. Lymphoid follicle hyperplasia can be seen.
V. Infected animals may have up-regulation of various cytokines.

Clinical Signs

I. Chronic vomiting is the most common sign.
II. Diarrhea, anorexia, pica, and polyphagia have also been reported.
III. Uncommonly, fever and/or bloody diarrhea may be seen.

Diagnosis

I. Laboratory tests are usually normal, but may show nonspecific changes (e.g., stress leukogram).
II. Abdominal radiography and ultrasonography are usually normal.
III. The best method of diagnosis currently is endoscopic biopsy.
A. Organisms can be visualized on the epithelium or in the mucus layer.
B. Warthin-Starry silver stains enhance visualization of the organisms.
C. Multiple biopsy samples are taken as the colonization can be patchy.
D. Endoscopy also allows evaluation of the mucosa for the type and severity of inflammation and for other changes.
IV. The rapid urease test may be performed and is based on the production of urease by almost all *Helicobacter* spp.
A. The test is also known as the *Campylobacter*-like organism (CLO) test.
B. Gastric tissue is incubated in broth with a pH indicator (phenol red) so that a color change indicates production of ammonia via urease.
C. The degree of color change is proportional to the density of organisms.
D. Results are available in 1 to 24 hours.
E. This test has a sensitivity of 70% to 90% (Happonen et al., 1996).
V. Brush cytology of gastric mucus is a relatively sensitive method of detecting organisms but does not allow determination of whether inflammation is present.
VI. Culture is not usually performed because the organisms are hard to grow in the laboratory.
VII. The C13 urea breath test also has been used in dogs and cats; however, it is not widely available.
VIII. Polymerase chain reaction (PCR) assays of gastric tissue allows diagnosis as well as identification of the species present; however, it is not widely available.
IX. Serological testing is widely used as a screening test in humans, but tests designed for humans should not be used in dogs and cats because the primary organism affecting humans (*H. pylori*) is not generally found in dogs or cats.
X. Serological testing is also difficult in animals because multiple species of *Helicobacter* may occur.

Differential Diagnosis

I. Other causes of chronic vomiting: chronic gastritis, pyloric outflow obstruction
II. Vomiting caused by nongastrointestinal diseases

Treatment

I. The best therapy has yet to be identified in the dog and cat.
II. "Triple therapy" is recommended in symptomatic humans and involves administration of an acid-inhibiting drug, bismuth compounds, and an antibiotic (e.g., clarithromycin, amoxicillin).
III. Most of the therapies tried in dogs and cats have not been 100% successful; many animals, although initially cleared of the organism, become reinfected.
IV. Combinations that have been tried include the following:
   A. Metronidazole, amoxicillin, and famotidine
   B. Azithromycin, tinidazole, bismuth, and ranitidine
   C. Clarithromycin, metronidazole, bismuth, and ranitidine
   D. Amoxicillin, metronidazole, and omeprazole
   E. Amoxicillin, metronidazole, and clarithromycin
V. Therapy is usually given for 2 to 3 weeks.

Monitoring of Animal

I. Monitoring is generally via physical examination and clinical signs.
II. To definitively determine if the organisms have been cleared, invasive testing may need to be repeated, but this is usually not done if the clinical signs resolve.

Gastric Pythiosis

Definition and Cause

I. Gastric pythiosis in dogs is caused by the aquatic oomycete *Pythium insidiosum*.
II. It has been documented only as a cutaneous and subcutaneous infection in cats; however, unpublished information indicates it can occur rarely as a gastrointestinal (GI) infection in cats.
III. The organism may dwell in water or soil.
IV. In the United States, the infection occurs most commonly in the Gulf Coast states, but it has been recognized as far north as New Jersey and Illinois, and as far west as Oklahoma, Missouri, and Kansas.

Pathophysiology

I. Pythiosis occurs most commonly in young, male, large-breed dogs—especially outdoor, working dogs.
   A. Affected dogs are usually exposed to areas of warm, fresh water.
   B. The animals are usually immunocompetent.
II. The infective form is likely the zoospore and may cause infection by encysting in damaged GI mucosa.
III. Infection is characterized by severe transmural thickening of the stomach, and the gastric outflow tract is one of the most common sites of infection.
IV. Inflammation is usually in the submucosa, with variable mucosal ulceration.
V. The disease may extend through to the serosal surface, and associated lymph nodes may be enlarged.

Clinical Signs

I. Severe weight loss and vomiting are common.
II. Lethargy is not usually seen unless obstruction has occurred.
III. Diarrhea and hematochezia may be seen when other parts of the GI tract are involved.

Diagnosis

I. Laboratory abnormalities may include eosinophilia, anemia, hyperglobulinemia, and hypoalbuminemia.
II. Abdominal radiography and ultrasonography reveal thickening of the gastric (usually pyloric) wall.
III. Associated lymphadenopathy also is usually seen on ultrasonography.
IV. Definitive diagnosis requires identification of the organism.
V. Cytology of aspirates of enlarged lymph nodes or thickened stomach wall shows pyogranulomatous, suppurative, or eosinophilic inflammation, but the organism is seen only occasionally.
VI. A presumptive diagnosis can be made based on histopathology.
   A. Findings include granulomatous, eosinophilic to pyogranulomatous inflammation with fibrosis.
   B. Organisms are usually found in the center of granulomas or in areas of necrosis.
   C. The organisms are easier to visualize with Gomori's methamine silver (GMS) staining.
   D. Immunohistochemistry techniques may also be used.
VII. Culture of the organism is difficult unless special sample handling and culture techniques are used.
VIII. A serological enzyme-linked immunosorbent assay (ELISA) has been developed for the detection of antibodies and is highly sensitive and specific in dogs and cats.
IX. Western immunoblot analysis also can be used.

Differential Diagnosis

I. Gastric neoplasia
II. Hypertrophic gastritis
III. Other systemic fungal infections.

Treatment

I. Aggressive surgical resection (3- to 4-cm margins) of the infected area is the treatment of choice.
   A. The organisms may not be present in enlarged lymph nodes, so they are not routinely resected.
   B. Medical therapy for 2 to 3 months (as follows) is recommended following resection because of the possibility of recurrence.
II. If resection is not possible, antifungal therapy can be tried.
   A. Response is often poor, but up to 15% of dogs may respond (Grooters, 2003).
   B. Itraconazole 10 mg/kg PO SID and terbinafine 5 to 10 mg/kg PO are recommended for 6 to 9 months.
   C. Alternatively, amphotericin B lipid complex is given at 2 to 3 mg/kg IV QOD up to a cumulative dose of 24 to 27 mg/kg.

INFLAMMATORY DISORDERS

Acute Gastritis

Definition

I. It is inflammation of the stomach that has an acute onset.
II. It implies that the cause and the inflammation can be eliminated, so that the stomach returns to normal health, with no residual inflammation or fibrosis.

Causes and Pathophysiology

I. Ingestion of pathogenic bacteria rarely cause gastritis because they are usually unable to colonize the stomach.
II. The main exception is the spiral bacteria (*Helicobacter* spp., see *Helicobacter* gastritis).
III. Viruses (e.g., parvovirus, distemper virus, coronavirus) may cause gastritis as part of a more widespread condition.
IV. Bacterial toxins produced by *Clostridium* spp., *Escherichia coli*, and *Klebsiella* spp. have been suggested.
V. Physical damage from foreign bodies and thermal injury can result in gastritis.
VI. Chemicals, such as cleaning agents, floor finishes, and various plant toxins, are also potential causes.
VII. Certain drugs (aspirin) may be directly cytotoxic to the stomach, whereas others exert their toxic effects by indirect mechanisms.
VIII. Garbage ingestion is a common cause of acute gastritis in dogs.
IX. Many metabolic diseases cause gastritis (e.g., renal and hepatic failure, hypoadrenocorticism).

Clinical Signs

I. Acute vomiting is the most common clinical sign, especially after eating or drinking.
II. Blood is occasionally present in vomitus.
III. Varying degrees of anorexia, depression, and abdominal pain may also be noted.

Diagnosis

I. Tentative diagnosis is based on the history and clinical signs.
II. Definitive diagnosis is not commonly made, because animals usually recover rapidly.
III. Laboratory tests are usually unremarkable.
IV. Abdominal radiographs are usually unremarkable, unless an opaque foreign body is present.

Differential Diagnosis

I. Causes of chronic or secondary gastritis: gastrinoma, mast cell tumor, renal failure, hepatic failure
II. Nongastric diseases that cause vomiting: pancreatitis, hypoadrenocorticism

Treatment

I. Administer fluid therapy if needed.
  A. A balanced electrolyte solution is adequate.
  B. Give fluids SC or IV, depending on the severity of the clinical signs.
II. Stop all oral intake (nothing by mouth [NPO]) for 12 to 36 hours.
III. Reintroduce bland food as small, frequent meals.
  A. The food should contain an easily and highly digestible starch, be low in protein, and contain moderate to low fat.
  B. Several commercial canine and feline formulations are on the market and most are labeled as "intestinal formulas."
  C. Homemade diets for dogs include boiled hamburger and rice, low-fat cottage cheese and rice, chicken and rice, cooked egg whites and rice, or tofu and rice, all in ratios of 1:2 or 1:4.
  D. Homemade diets for cats include chicken or turkey, possibly combined with baby rice cereal in a 1:1 ratio.
IV. Antiemetics are used when necessary; they are only symptomatic therapies, so are not to be used in place of adequate diagnostic and specific therapies.
  A. They are reserved for intractable vomiting when the cause of the vomiting is known.
  B. They vary in their site(s) of action.
    1. Alpha$_2$-adrenergic antagonists (phenothiazines)
      a. The sites of action are the chemoreceptor trigger zone (CRTZ) and the vomiting center.
      b. These are potent antiemetics and are effective for most causes of vomiting.
      c. Side effects include sedation and hypotension.
      d. Examples for both dogs and cats include prochlorperazine *(Compazine)* 0.5 mg/kg IM, SC TID and chlorpromazine *(Thorazine)* 0.2 to 0.4 mg/kg SC TID.
    2. Histaminergic (H_1) antagonists (antihistamines)
      a. Sites of action are the CRTZ and the vestibular apparatus.
      b. Side effects include sedation.
      c. These are usually given only for motion sickness.
      d. Examples in the dog include diphenhydramine *(Benadryl)* 2 to 4 mg/kg PO, IM TID and dimenhydrinate *(Dramamine)* 4 to 8 g/kg PO TID.
    3. Dopaminergic ($D_{2)}$ antagonists
      a. Sites of action include the CRTZ and GI smooth muscle.
      b. They are used for vomiting secondary to uremia, delayed gastric emptying, etc.
      c. Side effects include extrapyramidal signs (from metoclopramide) and sedation (from haloperidol).
      d. Examples include metoclopramide *(Reglan)* 0.2 to 0.4 mg/kg PO, SC, IM TID to QID, or 1 to 2 mg/kg/day IV as a constant rate infusion (dog, cat) and haloperidol *(Haldol)* 0.02 mg/kg PO BID (dog).
    4. Serotonergic 5HT$_3$ antagonists
      a. Sites of action are the CRTZ and vagal afferent neurons.
      b. They are used primarily during chemotherapy.
      c. Side effects include sedation.
      d. An example in the dog is ondansetron *(Zofran)* 0.5 to 1.0 mg/kg PO SID to BID or 30 minutes before chemotherapy.

5. Serotonergic $5HT_4$ agonists
   a. Sites of action are the myenteric neurons.
   b. They are used primarily for delayed gastric emptying, rather than as an antiemetic.
   c. An example is cisapride *(Propulsid)* 0.1 to 0.5 mg/kg PO BID to TID (dog, cat).
6. Motilin agonists
   a. Site of action is the GI smooth muscle (motilin receptors).
   b. They are used for delayed gastric emptying, rather than as an antiemetic.
   c. Side effects include vomiting.
   d. An example in the dog is erythromycin 0.5 to 1 mg/kg PO, IV TID.

V. Inhibition of gastric acid secretion is usually not needed; however, H_2 blockers may be used if gastric bleeding is noted (see next section).
VI. Antibiotics are not indicated unless a specific bacterial pathogen is suspected or documented, or disruption of the gastric mucosal barrier is significant.
VII. Locally acting protectants (sucralfate, bismuth subsalicylate) are usually not needed, but may be used safely if desired (see next section).

Gastric Ulceration and Erosion

Definition and Causes

I. Ulceration may be acute and caused by chemicals, gastric dilatation-volvulus, drugs, disseminated intravascular coagulation (DIC), shock, or foreign bodies.
II. Ulcers may arise with chronic disorders, such as inflammatory bowel disease (IBD), neoplasia, renal failure (acute or chronic), and hepatic failure.
III. The most common causes include nonsteroidal anti-inflammatory drugs (NSAIDs), neoplasia, shock, renal and hepatic failure, and hypoadrenocorticism.

Pathophysiology

I. NSAIDs inhibit prostaglandin production, which results in loss of an important part of the gastric mucosal barrier.
   A. Certain drugs (aspirin) can be directly cytotoxic to the epithelial cells.
   B. Risk factors for ulcer formation include higher doses, long-term administration, and concurrent administration with another NSAID or a corticosteroid.
II. Certain neoplasms commonly cause gastric ulceration.
   A. Mast cell tumors release histamine, which causes an increase in H^+ production.
   B. Gastrinomas release gastrin, which also results in increased H^+ production.
III. Shock results in disruption of blood flow to the stomach, leading to ischemia and ulceration.
IV. Renal and hepatic failure causes abnormal metabolism of gastrin (among other substances), with increased production of H^+.
V. In the preceeding situations, reparative mechanisms of the mucosa are overwhelmed and superficial damage (erosions) occurs, or severe lesions that penetrate to the muscularis or deeper (ulcers) develop.

Clinical Signs

I. Clinical signs are variable, with vomiting being the most common.
II. The vomitus may contain fresh or digested blood ("coffee grounds").
III. Anorexia may be noted.
IV. Abdominal pain can occur that may be ameliorated by food (from buffering action of food).
V. Animals may develop acute abdominal pain from gastric perforation and peritonitis, with few or no prior clinical signs.

Diagnosis

I. Laboratory findings may be normal.
II. The cause of ulceration may be detected by laboratory findings (e.g., azotemia, hepatic failure).
III. Acute or chronic microcytic, hypochromic anemia may be seen.
IV. Abdominal ultrasonography reveals changes in the gastric wall consistent with ulceration and focal or diffuse accumulation of peritoneal fluid if a perforation is present.
V. Any free abdominal fluid may be sampled with ultrasound guidance.
VI. Definitive diagnosis requires visualization of the ulceration/erosion via endoscopy.

Differential Diagnosis

I. Other causes of vomiting
II. Other causes of GI bleeding and melena, including thrombocytopenia and other clotting disorders

Treatment

I. Treat any underlying conditions and stabilize the animal with appropriate fluid therapy, electrolyte replacement, and transfusion therapy as necessary.
II. If the animal is receiving a drug that may cause an ulceration, discontinue the drug.
III. Institute specific treatment with antacids.
   A. Acid neutralizers
      1. These agents neutralize acid that has already been produced by the stomach.
      2. They can be very effective, but must be given at least six times per day.
      3. Examples include magnesium hydroxide *(Milk of Magnesia),* aluminum hydroxide *(Amphojel),* and calcium carbonate *(Tums).*
      4. Aluminum-containing antacids decrease absorption of phosphorus and may stimulate mucosal defense mechanisms.
      5. Calcium-containing antacids may cause constipation.
   B. H_2-receptor antagonists
      1. These agents selectively and reversibly bind to H_2 receptors on the oxyntic cell, thus inhibiting the acid secretagogue effect of histamine.

2. Although these drugs only partially inhibit acid secretion, they often allow healing to occur.
3. Cimetidine (5 to 10 mg/kg PO, SC TID to QID in dogs and cats) reversibly inhibits the hepatic microenzyme system (cytochrome P-450), and can interfere with clearance of drugs metabolized by this route.
4. Ranitidine may be six to ten times more potent than cimetidine.
   a. Ranitidine inhibits microsomal enzymes less than cimetidine.
   b. Ranitidine may have gastric prokinetic properties.
   c. Dose is 1 to 4 mg/kg PO, SC, IV BID to TID (dogs and cats).
5. Famotidine has potency similar to ranitidine in dogs, with a longer elimination half-life.
   a. Dose in dogs is 0.5 mg/kg PO, SC, IV SID to BID
   b. Dose is not established for cats.

C. Proton pump antagonist
1. These drugs irreversibly inhibit the hydrogen-potassium-ATPase pump at the apical border of the oxyntic cells.
2. A single daily dose results in virtual antacidity.
3. They also inhibit hepatic microsomal enzymes similar to cimetidine.
4. They are superior to H_2 blockers for treatment of severe reflux esophagitis and indolent gastroduodenal ulceration in dogs.
5. Dose of omeprazole is 0.7 to 2 mg/kg PO SID in dogs; very little experience exists in cats.

IV. Gastric protectants are also useful.
A. Misoprostol is a synthetic prostaglandin E1 analog that inhibits gastric acid secretion and stimulates gastric mucosal defense mechanisms in dogs.
1. Its primary therapeutic use is prophylaxis against gastric mucosal injury caused by NSAIDS.
2. Its main adverse effect is diarrhea.
3. Do *not* use it in pregnant animals, and do *not* allow pregnant women to handle it (can cause abortion).
4. Dose in dogs is 1 to 5 µg/kg PO BID to TID.

B. Sucralfate is a complex salt of sucrose sulfate and aluminum hydroxide.
1. In an acidic environment, sucralfate binds to exposed submucosa and polymerizes.
2. Its primary action is to stimulate mucosal defense and reparative mechanisms, as well as inhibit pepsin activity.
3. Sucralfate stimulates bicarbonate and mucus secretion, increases the viscosity of gastric mucus, and stimulates the release of prostaglandins (facilitates mucosal blood flow and repair).
4. It is not absorbed from the GI tract, but may inhibit absorption of other drugs.
5. It may cause constipation.
6. Dose is 0.25 to 1 g PO BID to QID in dogs and 0.125 to 0.25 g PO BID to TID in cats.

C. Bismuth subsalicylate *(Pepto-Bismol)* has cytoprotective properties by complexing with glycoproteins to retard hydrogen ion diffusion through the mucosa and by decreasing pepsin output.
1. It also has antibacterial activity.
2. Dose in dogs is 0.5 to 1 mL/kg PO every 4 to 8 hours.
3. It must be used with caution in cats because of the salicylate component (0.25 mL/kg PO BID).

V. Antiemetics are used as needed (see Acute Gastritis).
VI. Prokinetic agents enhance GI motility, specifically gastric emptying.
A. Metoclopramide has antiemetic and prokinetic properties.
1. It increases gastroesophageal sphincter (GES) pressure and hastens gastric emptying.
2. Dose in both dogs and cats is 0.2 to 0.4 mg/kg PO, SC, IM TID to QID or 2 mg/kg/day IV as a constant rate infusion.

B. Cisapride has prokinetic and antiemetic effects, but is used primarily as a prokinetic agent.
1. It increases GES pressure, accelerates gastric emptying, enhances colonic propulsive motility, and probably enhances motility of the small intestine.
2. Dose in both dogs and cats is 0.1 to 0.5 mg/kg PO BID to TID.
3. Cisapride is available through a few compounding pharmacies.

C. Erythromycin has an action similar to endogenous motilin, as well as an antiemetic action.
1. It accelerates gastric emptying and has intestinal promotility affects.
2. Dose is 0.5 to 1 mg/kg PO, IV TID in dogs.

D. Ranitidine and nizatidine may stimulate gastric, intestinal, and colonic motility, but their clinical efficacy is unknown.

VII. Uncommonly, gastric ulcers may bleed profusely or may be so deep that perforation is imminent, making partial gastrectomy and resection of the affected area necessary.

Monitoring of Animal

I. Laboratory tests are repeated to ensure that electrolytes have normalized and anemia (if present) is stable or improving.
II. Endoscopy can be repeated to determine definitively if the ulceration has healed, but is not usually done unless clinical signs persist.

Chronic Idiopathic Gastritis

Definition and Causes

I. It is defined as chronic inflammation of the stomach where no cause can be found.
II. The condition may be immune-mediated, and is considered a form of IBD that is localized to the stomach.
III. Postulated causes include food allergy, loss of tolerance to bacterial (normal flora) antigens, genetic susceptibility, or an abnormal immune response (host hypersensitivity).

Pathophysiology

I. The pathophysiology of IBD is complex and poorly understood.
II. Chronic gastritis is a diagnosis of exclusion.
III. Histopathologic findings include occasional microerosions of the epithelium, infiltration of the interstitium with lymphocytes, plasma cells or eosinophils.
  A. Fibrosis of gastric tissue is seen after prolonged, untreated inflammation.
  B. Lesions can be patchy or diffuse.
IV. In cats, eosinophilic gastritis may be seen as part of a more generalized disease (hypereosinophilic syndrome).

Clinical Signs

I. Vomiting is the most common clinical sign.
II. Mild weight loss is seen less commonly.
III. Variable anorexia and depression may occur.

Diagnosis

I. Laboratory tests are usually normal or show nonspecific changes (e.g., stress leukogram, eosinophilia).
II. Abdominal radiographs are usually normal.
III. Abdominal ultrasonography may show a thickened stomach wall and/or enlargement of gastric lymph nodes.
IV. Known causes of gastritis must be excluded.
  A. Negative fecal examination and no response to deworming
  B. No history of NSAID use
V. Gastric biopsy is necessary for definitive diagnosis.
  A. Endoscopic biopsies are often adequate.
  B. Biopsies also may be obtained via exploratory laparotomy.
VI. At endoscopy, the mucosa may appear grossly normal, granular, friable, hyperemic, edematous, or eroded.

Differential Diagnosis

I. Other causes of primary gastritis: food intolerance, parasites, foreign body
II. Other causes of secondary gastritis: renal or hepatic failure, hypoadrenocorticism

Treatment

I. Treatment often involves a combination of dietary changes and/or drug therapy.
II. Feed small, frequent meals of a low-fiber, low-to-moderate–fat diet to hasten gastric emptying.
III. Diets can be of three types.
  A. An easily and highly digestible commercial diet or a home-cooked diet can be prepared.
  B. A novel protein diet can be tried.
  C. A hypoallergenic diet consisting of hydrolyzed protein sources can be tried.
  D. The dietary change may be effective alone, or may be used in combination with drug therapy.
IV. Antiinflammatory or immunosuppressive drugs are indicated if nutritional management alone does not control the clinical signs.
  A. Give prednisone at 2 mg/kg PO SID for dogs and 2 to 4 mg/kg PO SID for cats for 2 to 4 weeks, then gradually tapered over 3 to 6 months.
  B. Some animals may be weaned completely off corticosteroids, whereas others must remain on chronic low doses (usually 0.5 to 1 mg/kg PO QOD).
V. If the animal is refractory to steroid therapy, relapses, or has unacceptable side effects, alternative drugs may be needed.
  A. Metronidazole may be helpful.
  B. Other options include azathioprine or cyclosporine in dogs and chlorambucil or cyclosporine in cats.
VI. Mucosal protectants are used as needed if erosions are present.
VII. Inhibition of gastric acid secretion with H_2 blockers or a proton pump inhibitor may be beneficial.
VIII. Prokinetic agents may be of value if delayed gastric emptying is a concurrent problem.

Monitoring of Animal

I. Repeat laboratory tests to ensure that the animal is stable.
  A. Some animals with severe idiopathic gastritis may have gastric bleeding, so the monitor the packed cell volume (PCV).
  B. Some animals may develop side effects (e.g., diabetes mellitus) secondary to corticosteroid use, so monitor blood glucose as well.
II. Repeat endoscopy and biopsy to definitively determine if the inflammation is under control; however, they are not usually done unless clinical signs persist.

Atrophic Gastritis

Definition and Causes

I. It is a very uncommon condition.
II. The etiology is unknown, but it may be immune-mediated or the terminal stage of idiopathic gastritis.

Pathophysiology

I. The pathophysiology is unknown.
II. Histopathology shows a reduced gastric mucosal parenchyma (loss of glands and cells), some inflammatory cells (lymphocytes and plasma cells), flattened epithelium, shortened gastric pits, metaplastic cells, and fibrosis.
III. Achlorhydria (loss of ability to produce H^+) often results and leads to small intestinal bacterial overgrowth, which in turn may lead to malabsorption.

Clinical Signs

I. Intermittent vomiting is the most common clinical sign.
II. Mild weight loss may be seen, and anorexia and depression may occur.

Diagnosis

I. Laboratory tests are usually normal, but may show nonspecific changes (e.g., stress leukogram).
II. Abdominal radiographs and ultrasonography are usually normal.

III. Endoscopy with biopsy is the method of choice for diagnosis.
IV. The mucosa may appear grossly normal or discolored and thin (more common), with submucosal blood vessels visible under the mucosa.

Differential Diagnosis

I. Other GI causes of vomiting: food intolerance, parasites, foreign body
II. Non-GI causes of vomiting: renal or hepatic failure, hypoadrenocorticism

Treatment

I. Change the diet to small, frequent meals of an easily digested diet, or try a novel protein diet.
II. Use mucosal protectants if erosions are present.
III. Inhibition of gastric acid secretion may make clinical signs worse if achlorhydria is present.
IV. Prokinetic agents are of value if delayed gastric emptying is a problem.
V. Antiinflammatory drugs are indicated if nutritional management alone does not control the clinical signs.
   A. Prednisone is given at 1 to 2 mg/kg PO SID for 2 to 3 weeks then gradually tapered over 3 to 6 months.
   B. Additional antiinflammatory agents are uncommonly needed.

Monitoring of Animal

I. Laboratory monitoring is done for side effects secondary to corticosteroid use (e.g., blood glucose, alkaline phosphatase).
II. Endoscopy and biopsy can be repeated to determine definitively if the inflammation is under control, but are not usually done unless clinical signs persist.

Hypertrophic Gastritis

Definition

I. Hypertrophic gastritis is characterized by focal or diffuse mucosal proliferation along with inflammation.
II. In the focal form, polypoid lesions may occur.
III. Widespread mucosal thickening is less common.

Causes

I. The etiology of this uncommon condition is unknown.
II. Genetics may play a role because it is more common in small-breed dogs (e.g., Lhasa apso, shih tzu, Maltese, basenji).
III. An immune-mediated cause has also been postulated.
IV. Male dogs are predisposed.

Pathophysiology

I. The pathophysiology is unknown, but hypergastrinemia may be involved, as gastrin is trophic to the gastric mucosa.
II. Histopathology shows hypertrophy and hyperplasia of the mucosa, metaplasia of glandular epithelium, and variable amounts of fibrous tissue and inflammatory cells (lymphocytes, plasma cells).

Clinical Signs

I. Intermittent vomiting is the most common clinical sign.
II. Mild weight loss may be seen with variable anorexia and depression.

Diagnosis

I. Laboratory tests and abdominal radiographs are usually normal or show nonspecific changes (e.g., stress leukogram).
II. On endoscopy the mucosa is diffusely or focally thickened, usually in the area of the antrum, and biopsy confirms the diagnosis.
III. Measurement of serum gastrin concentration is done to rule out a gastrin-secreting tumor.

Differential Diagnosis

I. Other GI causes of vomiting: food intolerance, parasites, foreign body.
II. Non-GI causes of vomiting: renal or hepatic failure, hypoadrenocorticism.

Treatment

I. Change the diet to small, frequent meals of an easily digested diet, or try a novel protein diet.
II. Mucosal protectants may be beneficial if erosions are present.
III. Inhibition of gastric acid secretion with H_2 blockers or a proton pump inhibitor may be helpful.
IV. Prokinetic agents are of value if delayed gastric emptying from a motility problem is present, but they are indicated if hypertrophied mucosa causes a physical obstruction.
V. Prednisone may be tried (1 to 2 mg/kg PO SID for 2 to 3 weeks, then gradually tapered over 3 to 6 months) if inflammation is present and nutritional management does not control the signs.
VI. Surgical resection of focal areas of hypertrophy is performed, especially when bleeding polypoid lesions or gastric outflow obstruction are present.

Monitoring of Animal

I. Laboratory monitoring is done for side effects secondary to corticosteroid use (e.g., blood glucose, alkaline phosphatase).
II. Endoscopy and biopsy can be repeated to determine definitively if the inflammation is under control, but they are not usually done unless clinical signs persist.

MISCELLANEOUS DISORDERS

Delayed Gastric Emptying

Definition

I. Food is retained in the stomach for an abnormally long time.
II. The stomach is usually completely empty within 10 to 12 hours after a normal meal.

Causes

I. Various primary intestinal diseases can result in delayed gastric emptying.
   A. Mechanical obstruction from gastric mucosal hypertrophy, pyloric muscular stenosis, foreign bodies, polyps, neoplasia, pythiosis
   B. Functional obstruction or motility disorders from acute or chronic gastritis, acute pancreatitis, gastric ulceration, gastric neoplasia
II. Delayed gastric emptying may also be secondary to non-GI disease.
   A. Metabolic acidosis, electrolyte disorders (hyper- or hypocalcemia, hypokalemia)
   B. Diabetes mellitus, pain, peritonitis, trauma, abdominal surgery
   C. Drugs (narcotics), dysautonomia, hypoadrenocorticism, hepatic failure, uremia

Pathophysiology

I. Pathophysiology depends on the underlying cause.
II. Mechanical obstruction is a physical impedance to outflow of contents from the stomach.
III. Functional obstruction arises from an alteration in normal gastric motility causing defective gastric propulsion, and may be related to an abnormality of neuronal or smooth muscle function or coordination.

Clinical Signs

I. Acute or chronic vomiting is the most common clinical sign.
   A. Whether the vomiting is acute or chronic depends on the underlying condition.
   B. The vomiting often occurs long after ingestion of the meal at a time when the stomach would normally be empty (>10 to 12 hours after eating).
   C. The vomiting may be explosive or projectile.
II. Abdominal discomfort is sometimes noted.
III. Anorexia and depression are uncommon.
IV. Weight loss may be seen with chronic disease.
V. Various other clinical signs are seen depending on the underlying cause, such as polyuria and polydipsia with diabetes mellitus and renal failure.

Diagnosis

I. Regardless of the cause, laboratory tests often shows hypochloremic metabolic alkalosis secondary to loss or pooling of HCl in the stomach.
II. Other laboratory changes depend on the underlying cause (e.g., hyperglycemia with diabetes mellitus, azotemia with renal failure).
III. Contrast radiography is one of the best methods to identify a mechanical outflow obstruction.
IV. Fluoroscopy is also helpful when a functional disorder is suspected.
V. Endoscopy can be used to help determine the cause of a mechanical obstruction, but it is not very helpful if a functional problem is present.

Differential Diagnosis

I. Other causes of acute and chronic vomiting
II. Motility problems of the intestines

Treatment and Monitoring

I. Certain foreign bodies can be removed via endoscopy, while others require surgical removal.
II. Surgery is the treatment of choice for antral pyloric muscular hypertrophy, certain cases of mucosal hypertrophy, pythiosis, and other causes of mechanical obstruction.
III. The underlying cause must be treated in cases of functional obstruction.
   A. Insulin therapy and electrolyte replacement for diabetes mellitus
   B. Antiinflammatory medications for chronic gastritis
IV. Prokinetic agents often are very helpful for functional disorders (see Treatment under Gastric Ulceration and Erosion).
V. Endoscopy and biopsy, ultrasound, or fluoroscopy with contrast media can be repeated to definitively determine if the disease is under control, but these tests are not usually performed unless clinical signs persist.

Bilious Vomiting Syndrome

Definition and Causes

I. Bilious vomiting syndrome is an idiopathic disorder associated with duodenogastric reflux of bile.
II. Duodenogastric reflux stimulates the vomiting reflex.

Clinical Signs

I. Dogs tend to vomit small amounts of bile first thing in the morning on an empty stomach.
II. The physical examination is usually normal.

Diagnosis and Differential Diagnosis

I. Diagnosis is suggested based on the pattern of vomiting and lack of other clinical signs.
II. Laboratory tests are normal.
III. Definitive diagnosis is by exclusion of other causes of chronic vomiting.

Treatment and Monitoring

I. A small meal given just before bed often helps.
II. A prokinetic drug at bedtime may be added if needed.
III. Prognosis is good to excellent for control of the condition.

NEOPLASIA

Definition and Causes

I. Adenocarcinoma is the most common gastric neoplasm of the dog, and lymphoma is the most common tumor of the cat.
II. Other tumors affecting the stomach include the fibrosarcoma, leiomyoma, leiomyosarcoma, and plasmacytoma.

Pathophysiology

I. Neoplastic cells infiltrate the stomach in either a focal (adenocarcinoma) or diffuse (lymphoma) pattern, and may be mucosal or transmural.
II. Mucosal ulceration is common.
III. Lymphoma in cats has been described as large or small cell in type.

Clinical Signs

I. Chronic vomiting, weight loss, and inappetence are the most common clinical signs.
II. Vomitus may include old blood (coffee grounds appearance), and melena may be seen in some cases.

Diagnosis

I. Laboratory tests may be normal or show nonspecific changes (e.g., stress leukogram).
   A. Anemia may be seen with bleeding tumors.
   B. The anemia may be acute and nonregenerative, or chronic (microcytic, hypochromic).
II. Survey abdominal radiographs may reveal a mass effect or gastric wall thickening.
   A. Positive contrast techniques or pneumogastrography may be helpful (see Chapter 4).
   B. Both techniques are performed *after* abdominal ultrasonography, because they interfere with visualization of the stomach and other organs.
III. Abdominal ultrasonography may reveal a gastric mass, enlarged lymph nodes, or evidence of metastasis (liver).
IV. Definitive diagnosis requires biopsy and histopathology.
V. Endoscopy may be performed to obtain a biopsy diagnosis, but does not determine whether metastasis is present.
VI. Surgery can be performed for diagnostic purposes, as well as for therapy.

Differential Diagnosis

I. Other causes of chronic vomiting: GI and non-GI in origin
II. Other neoplasia of the GI track and abdomen

Treatment and Monitoring

I. Treatment depends on the tumor type.
II. The recommended therapy for lymphoma is multi-drug chemotherapy (see Chapter 69).
   A. Remission times are much shorter for dogs than cats.
   B. Small-cell lymphoma in cats is usually treated with prednisone (or prednisolone) and chlorambucil.
      1. Prednisone is started at 5 mg PO BID and chlorambucil at 15 mg/m^2 PO SID for 4 days and repeated every 3 weeks.
      2. An alternative regimen is to give chlorambucil at 6 mg/m^2 PO QOD.
      3. Long-term remissions may be achieved in these cats.
III. Recommended therapy for other types of gastric neoplasia is surgical resection.
   A. The primary mass is resected and >2- to 3-cm margins are included if possible.
   B. With adenocarcinomas, large margins are difficult and metastases are often present at the time of diagnosis.
   C. Prognosis may be better for leiomyosarcoma if the mass is resectable.
   D. Adjunctive chemotherapy has not been shown be beneficial for most gastric tumors, although carboplatin and doxorubicin may be alternated every 3 weeks for three treatments each.
   E. Median survival times are often short (approximately 4 months).

CHAPTER 32

Gastric Dilatation-Volvulus

Emily Soiderer

Definition

I. Gastric dilatation-volvulus (GDV) is an acute, life-threatening condition in dogs characterized by rapid accumulation of gas in the stomach, malposition of the stomach, increased intragastric pressure, and circulatory shock.
II. Gastric dilatation is an acute overdistension of the stomach with gas, fluid, or ingesta.
III. Gastric volvulus is rotation of the stomach around its long axis in a clockwise direction (when viewed from the ventrodorsal perspective), which obstructs outflow of the duodenum and esophagus and compromises the blood supply to the stomach.

Causes

I. The true cause of GDV is unknown and overall prevalence in the general dog population is low.
II. Middle-aged to older, large- and giant-breed, deep-chested dogs are at greatest risk; however, GDV has also been reported in small breeds (e.g., dachshund, basset hound, pug) and the cat (rare).
III. A combination of environmental, anatomical, physiological, and pathologic risk factors include the following (Rasmussen, 2003; Glickman et al., 2000b):
   A. Increased risk in large- and giant-breed dogs, especially Great Danes
   B. Dogs with a first-degree relative with a history of GDV
   C. Large, thoracic, depth-to-width ratio (deep-chested)
   D. Lean body condition
   E. Age
   F. Behaviors that promote aerophagia
   G. Eating from a raised food bowl
   H. Stress and nervous temperament
   I. Feeding a large volume of food per meal (Raghavan et al., 2004)
   J. Feeding of dry foods containing a fat or oil in the first four listed ingredients (Raghavan et al., 2006)
   K. Pyloric outflow obstruction

Pathophysiology

I. Pyloric outflow is compromised (cause usually unknown) and normal methods of removing air are hindered (eructation, vomiting, pyloric emptying), which leads to accumulation of gas, fluid, and/or ingesta.
   A. The source of gas is likely from aerophagia; however, bacterial fermentation may produce some gas.
   B. Fluid accumulates from normal gastric secretion, ingesta, and translocation from venous obstruction, contributing to dilatation.
   C. Progressive dilatation leads to decreased blood flow to the stomach wall, compression of the caudal vena cava, obstruction of venous return to the heart, portal hypertension, and shock.
II. Progressive dilatation of the stomach secondary to gastroesophageal sphincter and pyloric dysfunction is followed by gastric volvulus; alternatively, gastric volvulus occurs first, which leads to gastric dilatation and/or GDV (Brockman et al., 2000).
III. Whether dilatation occurs before or after volvulus is unknown.
IV. Gastric volvulus most commonly occurs in a clockwise direction around the long axis of the esophagus, with the animal in dorsal recumbency and viewed from the caudoventral perspective (Rasmussen, 2003).
   A. The pylorus and duodenum move cranioventrally and to the left.
   B. Gastric distention increases as the pylorus and the gastric body move clockwise.
   C. The pylorus lies along the left body wall, with the fundus on the right.
   D. The degree of volvulus can be from 90 to 360 degrees.
V. The large, overdistended stomach compresses the caudal vena cava and obstructs blood flow from the caudal half of the body returning to the heart.
   A. Decreased cardiac output
      1. From decreased venous return to the heart
      2. Aggravated by endotoxemia
      3. Myocardial ischemia secondary to decreased coronary artery blood flow
      4. Release of cardiodepressant factors
      5. Arrhythmias common
   B. Decreased portal blood flow
      1. Compression of the portal system by the overdistended stomach
      2. Portal hypertension
      3. Interstitial edema and increased tissue hydrostatic pressure within gastrointestinal (GI) tract
      4. Decreased clearance of endotoxins and bacteria
   C. Splanchnic hypoperfusion
      1. From decreased cardiac output
      2. Caudal vena caval and portal hypertension

3. From gastric distention
4. Myocardial ischemia-induced arrhythmias
5. Reperfusion injury

VI. Hypovolemic shock may arise from sequestration of blood volume and from decreases in venous return to the heart, cardiac output, arterial pressure, and coronary artery blood flow, which lead to inadequate delivery of oxygen to the tissues.

VII. Septic shock from gastric perforation, septic peritonitis, or bacterial translocation from compromise of the gastric mucosal barrier can also lead to inadequate delivery and uptake of oxygen by the tissues.

VIII. Gastric dilatation impairs gastric blood flow as small capillaries in the gastric wall are occluded secondary to increased intragastric pressure.
- A. Venous congestion occurs secondary to dilatation and volvulus.
- B. Increased tissue hydrostatic pressure develops.
- C. The short gastric vessels may twist and become thrombosed or avulse, contributing to hemoabdomen.
- D. Thrombosis of the gastric microvasculature may occur.
- E. Fluid and protein shift from the intravascular space into the gastric lumen and become sequestered.
- F. Gastritis, gastric ulceration, necrosis, and perforation may occur as the gastric mucosa is further compromised.

IX. Thoracic and diaphragmatic movements are restricted by the large distended stomach, which results in hypoventilation, decreased tidal volume, ventilation-perfusion mismatch, and hypoxemia.

X. Intestinal ileus and inadequate perfusion of abdominal organs may develop.
- A. Pancreatic edema and congestion predisposing to pancreatitis
- B. Splenic congestion
- C. Renal failure
- D. Liver congestion and necrosis
- E. Intestinal edema, hemorrhage, and mucosal injury

XI. Reperfusion injury occurs when blood flow is returned to tissues that have been deprived and may lead to tissue damage.
- A. Normal waste products and abnormal toxins accumulate when there is inadequate perfusion.
- B. Inflammatory mediators and oxygen free radicals cause local tissue damage as it is reperfused.
- C. Reperfusion injury may lead to multiorgan failure.
- D. Disseminated intravascular coagulation occurs secondary to the intense inflammatory reaction.

Clinical Signs

I. Restlessness
II. Ptyalism, retching
III. Abdominal distention, pain
IV. Weakness, collapse
V. Tachypnea, dyspnea

Diagnosis

I. A presumptive diagnosis of gastric dilatation can be made based on signalment, history, and physical examination.

II. Physical examination findings may include some or all the following:
- A. Distended, painful, tympanic abdomen
- B. Distention not always seen in giant-breed dogs from dilated stomach surrounded by the rib cage (Brockman and Holt, 2000)
- C. Tachycardia, poor peripheral pulse quality
- D. Pale, tacky mucous membranes, prolonged capillary refill time
- E. Tachypnea

III. Radiography of the abdomen is used to assess gastric position and to confirm gastric dilatation and volvulus.
- A. Radiography should be performed *only* after fluid therapy and gastric decompression have been started.
- B. Right lateral abdominal view is the radiographic view of choice and findings may include:
  1. Large, gas-distended stomach
  2. Gas-filled intestines caudally displaced by the stomach
  3. Soft tissue compartmentalization, with a fold of the stomach crossing the dilated stomach, indicating presence of a gastric volvulus
  4. Splenomegaly
  5. Loss of abdominal detail
  6. Free gas from gastric necrosis and rupture or an iatrogenic source (abdominocentesis)
  7. Small caudal vena cava

IV. Hematological and coagulation assays may show the following:
- A. Hemoconcentration
- B. A stress or inflammatory leukogram and possible left shift
- C. Leukopenia suggestive of overwhelming inflammation or endotoxic shock
- D. Thrombocytopenia indicating a hypercoagulable state or blood loss
- E. Prolonged activated clotting time (ACT), prothrombin time (PT), and activated partial thromboplastin time (APTT)

V. Serum chemistry abnormalities may include the following:
- A. Electrolyte abnormalities: most commonly hypokalemia
- B. Hypoalbuminemia
- C. Azotemia
- D. Hepatocellular injury: elevated alanine transferase
- E. Biliary stasis: elevated alkaline phosphatase, bilirubinemia
- F. Pancreatic enzyme elevation
- G. Increased plasma lactate
  1. It is used as a predictor of gastric necrosis and eventual outcome.
  2. If lactate concentration is <6 mmol/L, the dog (99%) is likely to survive.
  3. Median plasma lactate concentration in dogs with gastric necrosis was significantly higher than those without necrosis (de Papp et al., 1999).

VI. Acid–base disorders are common.
- A. Metabolic acidosis occurs secondary to decreased tissue perfusion and a shift by the tissues to anaerobic metabolism resulting in lactic acidosis.

B. Metabolic alkalosis can occur from sequestration of hydrogen ions in the gastric lumen.

Differential Diagnosis

I. Gastric dilatation alone
II. Splenic torsion
III. Mesenteric volvulus
IV. Peritonitis

Medical Treatment

I. Initial emergency treatment is aimed at stabilizing the cardiovascular and respiratory systems; treatment is not delayed by diagnostic tests.
II. Packed cell volume (PCV), total solids (TS), and blood glucose (BG) can be quickly obtained at presentation and are useful for guiding fluid therapy.
III. Aggressive fluid therapy is initiated followed by gastric decompression.
   A. Intravenous access is obtained with two large-bore catheters via the cephalic veins or a jugular catheter.
   B. The saphenous veins are avoided, because venous return to the heart from the caudal half of the body is obstructed by the dilated stomach.
   C. Crystalloids are administered at rates for shock (60 to 90 mL/kg/hr IV).
   D. Colloids are beneficial in raising arterial blood pressure and maintaining plasma oncotic pressure.
      1. Hetastarch is given at 5 to 10 mL/kg IV bolus or at a maintenance rate of 20 mL/kg/day IV.
      2. Colloids can be combined with crystalloids (10 to 40 mL/kg IV).
   E. Hypertonic (7%) saline combined with dextran-70 (6%) has also been used for rapid expansion of intravascular volume (Allen et al., 1991; Schertel et al., 1997).
      1. Dose: 5 mL/kg IV over 5 to 15 minutes
      2. Usually reserved for rapidly deteriorating, hypovolemic animals
IV. Monitor electrocardiography (ECG) and blood pressure during the stabilization period to judge effectiveness of therapy.
   A. Heart rate and blood pressure are improved.
   B. Mucous membrane color, capillary refill time, and pulse quality improve.
   C. Positive inotropes are considered if appropriate fluid therapy does not maintain mean arterial pressures >80 mm Hg.
      1. Dobutamine 5 to 15 μg/kg/min IV (Plumb, 2005)
      2. Dopamine 1 to 3 μg/kg/min IV (Plumb, 2005)
V. Gastric decompression is undertaken immediately.
   A. Orogastric tube decompression
      1. The tube is measured from the tip of the nose to the xiphoid and a piece of tape is placed on the tube at that mark.
      2. A mouth gag is inserted (a roll of 2-inch tape works well) and held by an assistant grasping the dog's muzzle.
      3. Sedation and analgesia are helpful to decrease stress of the dog and ease passage of the tube.
         a. Hydromorphone 0.05 to 0.1 mg/kg IV or buprenorphine 0.005 to 0.01 mg/kg IV combined with diazepam or midazolam 0.2 mg/kg IV
         b. Minimal cardiovascular effects
      4. The orogastric tube is lubricated and inserted into the esophagus.
      5. If resistance is met, the tube can be gently rotated and/or the dog repositioned.
      6. The tube is *never* forced caudally because of the risk of perforating the esophagus.
      7. Once the tube has reached the stomach, gas and fluid should escape.
      8. Water (7 to 10 mL/kg) can be used to lavage the stomach and help remove more solid matter (Rasmussen, 2003).
      9. If water is not recovered, discontinue lavaging, as perforation may be present.
   B. Trocarization
      1. Trocarization is often used when decompression with an orogastric tube fails.
      2. A tympanic area on the dorsolateral abdomen is clipped and aseptically prepared.
      3. A large-bore, over-the-needle IV catheter is inserted through the skin and into the stomach.
         a. The stylet is removed and the catheter hub is checked for an acrid odor and/or bubbling of fluid.
         b. A large-gauge needle can also be used instead of the IV catheter.
      4. Ballottement of the abdomen helps mobilize and release gas after the catheter has been inserted.
   C. Temporary gastrostomy
      1. This technique is reserved for those animals that are too unstable for surgery.
      2. The technique is used if gastric dilatation is severe, and if attempts to decompress via orogastric tube and trocarization have failed.
   D. Adequate decompression essential before surgery
      1. After decompression, the stomach may return to its normal position.
      2. Surgery is still required in these cases to assess gastric viability and prevent recurrence.
VI. Ventricular arrhythmias are common and can occur up to 24 hours later, so continuous ECG monitoring is warranted.
   A. Treatment of arrhythmias is first aimed at normalizing fluid deficits, acid-base and electrolyte abnormalities, and providing adequate analgesia.
   B. For dogs with pulse deficits, multifocal ventricular premature contractions, and a ventricular rate >160 beats per minute, consider antiarrhythmic drugs.
   C. Lidocaine can be given at 2 mg/kg IV bolus and repeated up to a total dose of 8 mg/kg IV (Plumb, 2005).
   D. Lidocaine constant rate infusion (CRI) can be started at 25 to 50 μg/kg/min IV.

E. Other drug choices include procainamide 6 to 8 mg/kg IV bolus over 5 minutes, possibly followed by a CRI of 25 to 50 μg/kg/min IV, and magnesium sulfate 50 mg/kg IV bolus over 5 minutes, possibly followed by CRI of 100 μg/kg/min IV for 6 hours (Rasmussen, 2003).

Surgical Treatment

I. General principles
   A. After adequate cardiovascular stabilization, surgical treatment is pursued.
      1. Surgery must not be delayed, owing to risk of perforation of a necrotic stomach and recurrence of gastric dilation.
      2. Recurrence rates of GDV with medical management alone are 75% to 80% (Meyer-Lindenberg et al., 1993).
   B. The goals of surgery are as follows:
      1. Anatomic repositioning of the stomach
      2. Assessment of gastric and splenic viability
      3. Partial gastrectomy and/or splenectomy, if indicated
      4. Permanent gastropexy to prevent recurrence

II. Anesthesia
   A. Preanesthetics
      1. Hydromorphone 0.05 to 0.1 mg/kg IM, IV (Plumb, 2005)
      2. Diazepam 0.2 to 0.3 mg/kg IV (Plumb, 2005)
   B. Induction agents
      1. Those that do not cause significant cardiovascular disturbances are preferred.
      2. Lower doses than those listed below may be sufficient; give only to effect.
      3. Ketamine 6.6 mg/kg IV is combined with diazepam 0.5 mg/kg IV.
      4. Etomidate is given at 1 mg/kg IV to effect and can be combined with diazepam 0.25 mg/kg IV.
      5. Propofol is titrated to effect.
         a. It is only used in well-hydrated, hemodynamically stable animals.
         b. Similar precautions apply to thiopental (Dodam, 2003).
      6. Mask induction with inhalation agents can be done, but lack of rapid airway access (intubation) is a disadvantage.
   C. Maintenance
      1. Isoflurane or sevoflurane
      2. Combination of inhalation agent and opioid (fentanyl 5 to 15 μg/kg/hr IV CRI (Dodam, 2003)
   D. Assisted ventilation often necessary
   E. Monitoring
      1. Heart rate
      2. Respiratory rate
      3. Arterial blood pressure
      4. Mucous membrane color and capillary refill time
      5. Peripheral pulse quality
      6. End-tidal CO_2
      7. Pulse oximetry
      8. ECG
      9. Blood gases

III. Celiotomy
   A. Make a ventral midline incision beginning at the xiphoid and extending just cranial to the pubis.
   B. Take care when incising the linea alba to avoid puncturing the distended stomach.
   C. Once the abdomen is exposed, identify the distended stomach with the greater omentum stretched over its surface.
   D. Further gastric decompression is performed; either by passage of an orogastric tube by an assistant, or trocarization by the surgeon.
   E. Once the stomach is decompressed, it is returned to its normal position.
      1. With the surgeon standing on the dog's right side, the pylorus is found in the left dorsal abdomen and is gently grasped with the right hand.
      2. The left hand rests on the body of the stomach on the dog's right side.
      3. The pylorus is drawn ventrally and toward the right while at the same time the body of the stomach is pushed dorsally and toward the left.
   F. Once the stomach is in its normal position, an initial assessment of its viability is made.
   G. An abdominal exploratory surgery is then performed.
      1. It allows assessment of the spleen and its vasculature, identification of underlying pathology, and gives the stomach time to reperfuse.
      2. If the splenic vessels are thrombosed, a splenectomy may be indicated.
   H. The stomach is carefully evaluated for areas of necrosis and perforation.
      1. Color and texture are currently the most useful indicators of viability; other characteristics such as tone and peristalsis are also assessed.
      2. Abnormal areas consistent with necrosis are often gray to green, black, or blue-black in color.
      3. Thinning of the abnormal gastric wall can be appreciated upon palpation.
      4. Incising questionable areas in the seromuscular layer may reveal poor perfusion.
      5. Fluorescein dye testing is unreliable (Wheaton et al., 1986).
      6. Assessing capillary blood flow in the stomach wall using laser Doppler flowmetry may be useful (Monnet et al., 2006).
   I. If necrosis is present, determine the extent (usually involves fundus along the greater curvature) and perform a partial gastrectomy.

IV. Gastropexy techniques
   A. The purpose of the gastropexy is to form a permanent adhesion between the stomach and the right body wall to prevent the stomach from becoming malpositioned.
      1. The serosa of the stomach and the peritoneum of the body wall must be disrupted to obtain an adhesion.

2. Multiple gastropexy techniques have been developed, including laparoscopic and laparoscopic-assisted techniques.

B. With an incisional gastropexy, the stomach is drawn to the right body wall to a site that allows the stomach to lie in a normal position once the abdomen is closed and a normal posture is resumed.
   1. This area is usually caudal to the last rib and approximately one third the distance from ventral midline dorsally.
   2. An incision is made through the seromuscular layer of the stomach parallel to its long axis, at the level of the pyloric antrum, midway between the lesser and greater curvatures.
   3. An incision of corresponding length is made in the right abdominal wall just caudal to the last rib through the peritoneum and into the transverse abdominal muscle.
   4. The stomach is brought up to the right abdominal wall and the dorsal incisions are sutured together with monofilament delayed-absorbable (e.g., polydioxanone) or monofilament nonabsorbable (e.g., polypropylene) suture in a simple continuous pattern.
   5. The ventral incisions are then apposed in a similar fashion.
   6. This is a quick and simple gastropexy technique that forms a strong adhesion and has a low recurrence rate (MacCoy et al., 1982).

C. With a belt-loop gastropexy, two parallel incisions (approximately 2 cm apart) are made through the peritoneum and transverse abdominal muscle behind the last rib on the right lateral body wall.
   1. A tunnel is created with blunt dissection between the incisions.
   2. A U-shaped incision is then made through the seromuscular layer of the stomach in the pyloric antrum, including an epiploic branch of the gastroepiploic artery and vein at the base of the flap.
   3. The flap is elevated and then brought through the muscular tunnel created in the abdominal wall and sutured back into place on the stomach.
   4. This technique forms a slightly stronger adhesion than incisional or tube gastropexy; however, it is technically challenging and takes longer to perform (Whitney et al., 1989).

D. A circumcostal gastropexy is very similar to the belt-loop method.
   1. A tunnel is formed under the 11th or 12th ribs at the level of the costochondral junction; the flap is passed under the rib, and sutured back to its original area on the stomach.
   2. This is the strongest of the gastropexies; however, it is technically challenging and potential complications include pneumothorax (if the diaphragm is penetrated) and rib fracture (Woolfson and Kostolich, 1986).

E. A tube gastropexy requires a stab incision through the right abdominal wall, caudal to the last rib, and approximately one third of the way up from the ventral midline.
   1. The stomach should rest at this site without excessive tension or displacement.
   2. The mushroom tip end of a Pezzer tube is brought through the incision in the abdominal wall and into the abdomen.
   3. A purse-string suture is placed in the pyloric antrum halfway between the lesser and greater curvatures in an area where the mushroom tip of the Pezzer tube will not block pyloric outflow.
   4. A stab incision is then made into the stomach in the center of the purse-string, the mushroom tip of the tube is inserted into the stomach, and the purse-string is tied snugly.
   5. Sutures (4 to 5) are preplaced between the pyloric antrum and the body wall surrounding the tube where it exits.
   6. The stomach is brought up to the body wall and the sutures are tied securely and omentum is wrapped around the site.
   7. The tube is secured to the skin using the Chinese finger trap method or with friction sutures, and a bandage is applied to the abdomen.
   8. This is the weakest of the gastropexies and it requires entering the lumen of the stomach.
   9. Advantages include ease of placement, ability to decompress the stomach postoperatively, and provision of an enteral route for nutritional support of anorectic animals (Flanders et al., 1984).

F. Laparoscopic and laparoscopic-assisted gastropexies have been investigated for prophylaxis and may become common as laparoscopy becomes more widely available (Wilson et al., 1996; Rawlings et al., 2002).

V. Perioperative antibiotics
   A. Cefazolin 22 mg/kg IV is given at induction and may be continued postoperatively if the gastric and intestinal mucosal barrier has been damaged.
   B. If sepsis or perforation has occurred, broad-spectrum antibiotics are administered.

Monitoring of Animal

I. IV fluid therapy is continued, and electrolytes and acid–base balance are monitored.
   A. Postoperative hypokalemia may occur and is supplemented appropriately.
   B. IV fluid therapy requirements vary, but are continued until oral fluid intake is adequate to maintain hydration.

II. Food is usually offered 12 to 24 hours postoperatively.

III. Hypoalbuminemia/hypoproteinemia may occur from losses through damaged GI mucosa, and colloidal support may be necessary.

IV. Also monitor for anemia.
   A. For PCVs <20%, consider transfusion of packed red blood cells or whole blood.
   B. For total solids <4.0 gm/dL, initiate colloidal support.

V. Hemodynamic status is monitored through intermittent or continuous measurement of the following:
   A. Blood pressure
   B. Urine output
   C. ECG (see Medical Treatment)
   D. Central venous pressure

VI. Monitor for sepsis via repeated physical examination, complete blood counts, and serum biochemistry abnormalities.
   A. Abdominocentesis or diagnostic peritoneal lavage can identify intracellular bacteria indicating septic peritonitis.
   B. Emergency surgery is indicated if septic peritonitis is confirmed.
   C. Perform blood and urine cultures if septicemia is suspected from bacterial translocation.

VII. Disseminated intravascular coagulation is a potential complication and is suspected with the following:
   A. Petechial and ecchymotic hemorrhages
   B. Unexplained blood loss
   C. Worsening hemodynamic parameters or organ function
   D. Prolonged PT and APTT, decreased fibrinogen, increased fibrinogen degradation products (D-dimers), and thrombocytopenia

VIII. Gastritis secondary to mucosal ischemia is a common postoperative complication and may cause vomiting.
   A. If severe or persistent vomiting occurs, a centrally acting antiemetic is useful.
   B. Secondary gastric ulcers may occur, and H_2-receptor blockers help to reduce acidity.
      1. Famotidine 0.5 mg/kg IV, SC, PO BID
      2. Ranitidine 0.5 mg/kg IV, PO BID
      3. Cimetidine 5 mg/kg IV, IM, PO TID to QID

IX. High mortality rates have been associated with GDV in the past.
   A. More recently, mortality rates of 15% (Brockman et al., 1995), 18% (Brourman et al., 1996), and 24.3% (Glickman et al., 1998) have been reported with surgical intervention.
   B. Dogs with gastric necrosis and perforation had lower survival rates (de Papp et al., 1999).
   C. Recurrence rates of GDV after gastropexy is <10% (Glickman et al., 1998).

X. Prevention involves the following:
   A. Feeding multiple, small meals per day that are low in fat and oil
   B. Feeding from nonraised food bowls
   C. Minimizing stress

XI. Prophylactic gastropexies are recommended in dogs at risk for GDV and can be easily performed at the time of ovariohysterectomy or castration via laparotomy or laparoscopy.

CHAPTER 33

Diseases of the Small Intestines

Debra L. Zoran

CONGENITAL/DEVELOPMENTAL DISORDERS

See Table 33-1.

INFECTIOUS DISEASES

Viral Infections

Definition and Causes

I. A number of viruses are implicated as enteric pathogens in dogs and cats, especially in puppies and kittens <6 months of age.
II. Primary intestinal viruses in dogs include canine parvoviruses (CPV-1, CPV-2), canine coronavirus (CCV), distemper virus, and rotavirus.
   A. Astrovirus, enterovirus, herpesvirus, and parainfluenza viruses have been identified in feces, but their pathogenicity is unknown (Greene, 2006).
   B. Both CPV-2a and CPV-2b are responsible for most illness, with CPV-2b as the most common isolate in the United States and Japan, and CPV-2a as the most common isolate in the Far East (Greene, 2006).
III. The primary intestinal viruses in cats include parvovirus (panleukopenia), coronavirus (enteric or feline infectious peritonitis [FIP] virus), rotavirus, and astrovirus.
   A. Feline immunodeficiency virus (FIV) and feline leukemia virus (FeLV) may cause enteric signs as part of the overall infection.
   B. Other viruses have been identified in feline feces, including torovirus-like particles, reovirus, calicivirus, and picornavirus-like particles, but their significance is unknown (Greene, 2006).

Pathophysiology

I. Viral infections cause disease by invading the enterocytes lining the intestinal villi or crypts, in most instances from oronasal exposure to contaminated feces.
II. CPV-2 is highly contagious, because the organism is extremely resistant in the environment.
   A. It may persist on the dog's hair coat, caretaker clothing, or floors for >5 months; it is resistant to normal disinfectants.
   B. Only sodium hypochlorite (common household bleach) is known to be consistently effective.
III. The severity of clinical signs is highly variable.
   A. Villous cell damage (e.g., coronavirus or rotavirus infection) is well tolerated (less severe clinical signs), because affected enterocytes are soon replaced.
   B. Viral infections causing crypt cell damage or destruction (e.g., CPV-2 infection) result in severe clinical signs.
      1. Normal enterocyte proliferation is completely disrupted from destruction of crypt cells.
      2. Massive loss of villous absorptive and barrier functions occur, predisposing to ascending infections, endotoxemia, and severe fluid and electrolyte losses.

Clinical Signs

I. Canine parvovirus (CPV-2b)
   A. Infection can cause inapparent or subclinical infection or may result in acute, fatal disease.
   B. Lethargy , anorexia, depression, dehydration, vomiting, and diarrhea are the most common signs.
      1. The most severe clinical signs are seen in dogs <4 months of age because of their lack of protective immunity and increased number of rapidly dividing cells.
      2. The clinical course ranges from 4 to 7 days.
   C. Diarrhea is often profuse and hemorrhagic, and vomiting may be intractable.
   D. Fever and leucopenia are common initially, but hypothermia, disseminated intravascular coagulation (DIC), and endotoxic shock occur terminally with septicemia, which may develop within 48 hours in a fulminant infection.
   E. Certain breeds have increased susceptibility, including the rottweiler, Doberman pinscher, American pit bull terrier, German shepherd dog, Labrador retriever, and Alaskan sled dog breeds.
   F. Most adult dogs infected with parvovirus have subclinical disease.
   G. Puppies infected in utero or perinatally (<8 weeks) can develop myocarditis that may progress to cardiomyopathy and sudden death.
   H. Other complications include thrombosis (from DIC), erythema multiforme, hypoglycemia, and septicemia.
II. Canine coronavirus
   A. Infection is via the fecal-oral route, signs are uncommon in adult dogs, and they are generally mild and self-limiting in weanling puppies.

TABLE 33-1

Congenital and Developmental Disorders

DISORDER	DEFINITION AND CAUSE	CLINICAL SIGNS	DIAGNOSIS	TREATMENT
Intestinal atresia	Congenital agenesis of a segment of intestine Occurs in the small intestine in dogs and in the large intestine in cats Three types of atresia have been reported (Guilford et al., 1996): *Membrane atresia:* normal intestine with a luminal membrane that prevents normal flow of ingesta *Cord atresia*: two segments of intestine connected by tissue *Blind end atresia*: two segments of intestine not connected together	High neonatal mortality from inability to digest or process milk or other ingesta Failure to thrive, poor growth, and death are most common in puppies Kittens may develop enlarged abdomens and vomiting owing to colonic obstruction	Clinical signs and signalment are suggestive Definitive diagnosis is by documentation of the anomaly (from imaging studies, at surgery or postmortem)	Treatment is removal of the affected segment of bowel by intestinal resection and anastomosis In kittens, a subtotal colectomy may be required if a significant segment of the large intestine is involved
Intestinal diverticulum	Rare condition in both dogs and cats Most commonly seen in the jejunum in dogs	Many cases are subclinical Clinical signs are nonspecific, including vomiting, diarrhea, weight loss, or inappetence and occur from diverticulitis or diverticular perforation or obstruction	Imaging studies, such as contrast radiographs or ultrasonography, may identify the abnormal structure Definitive diagnosis is made by visualizing the defect (at surgery)	Resection and anastomosis of the affected segment of the intestine are curative In animals not exhibiting any clinical signs, the best approach is often benign neglect
Selective cobalamin malabsorption	Selective inability in the giant schnauzer, border collie, and shar-pei to absorb cobalamin (vitamin B_{12}) (Fyfe et al., 1989; Guilford et al., 1996) Inherited in giant schnauzers as an autosomal recessive trait Results in a defect in the ileal receptor for the cobalamin and intrinsic factor complex, called *cubulin* (Fyfe et al., 1989)	Inappetence and failure to thrive (poor weight gain and lethargy) Clinical signs occur after weaning, at 6-12 weeks of age in giant schnauzers, and often later in border collies and shar-peis	Signalment and history are suggestive Definitive diagnosis is made by finding an extremely low serum cobalamin concentration (normal is 6.7-17.4 µg/L) Dyserythropoiesis is evident by 8-16 weeks of age, with development of a nonregenerative, normochromic normocytic anemia (PCV 27%-31%) by 20-22 weeks of age Abnormal granulopoiesis and low neutrophil numbers may also be seen	Parenteral cyanocobalamin (0.25-1.0 mg SC, IM weekly for 4 weeks, then every 3-6 mo indefinitely) Response is rapid Appetite returns in 24-48 hours, reticulocytosis occurs in 3-4 days, and methylmalonic aciduria stops within 1 week Reevaluate cobalamin levels every 3-6 months Neuter affected dogs

PCV, Packed cell volume.

TABLE 33-1

Congenital and Developmental Disorders—*cont'd*

DISORDER	DEFINITION AND CAUSE	CLINICAL SIGNS	DIAGNOSIS	TREATMENT
	Defect is not defined in either the border collie or shar-pei		Cobalamin deficiency leads to reduced activity of two enzymes important in energy (succinyl CoA) and amino acid synthesis (methionine), which results in the development of methylmalonic aciduria (Fyfe et al., 1989)	
Short bowel syndrome	Rare condition in both dogs and cats Lack of development of a major segment of the small intestine (Guilford et al., 1996; Simpson and Hall, 2000) Acquired short bowel syndrome is more common and is from surgical removal of a large segment of bowel Dogs are able to compensate if 30-40 cm of small intestine are present; cats require 18-20 cm of small bowel for adequate function	Appropriate historical and clinical signs in a young puppy or kitten are suggestive of a congenital defect Clinical signs include a failure to gain weight or weight loss; poor body or coat condition; and chronic, small bowel diarrhea with characteristics of severe malabsorption (steatorrhea, abnormal color, etc.)	Definitive diagnosis is made from imaging studies (e.g., contrast radiographs) showing the abnormally short bowel	There is no specific therapy for short bowel syndrome Compensation can occur if enough of the bowel remains; these animals have soft or semi-formed feces and are able to maintain body weight Feed highly digestible diets to maximize digestion of food and minimize the amount of feces produced
Gluten enteropathy of Irish setter	Autosomal recessive disorder linked to the MHC genes *MQA* and *DQB* in affected dogs (Garden et al., 2000) Disease causes a progressive loss of villous height and increased numbers of goblet cells and intraepithelial lymphocytes Wheat gluten may also have direct toxic effects on the intestinal mucosa of affected dogs	Inappetence, poor growth (stunted or small stature), and chronic diarrhea are the most common signs Diarrhea usually starts in puppies immediately postweaning (4-6 weeks of age) Signs may include semiformed feces or severe, liquid and explosive small bowel diarrhea	Typical history and clinical signs in a young Irish setter are suggestive Affected dogs may have abnormal sugar permeability tests, decreased serum folate (normal serum cobalamin), and negative duodenal juice culture (e.g., no evidence of bacterial overgrowth) Intestinal biopsy reveals vilous atrophy and increased numbers of intraepithelial lymphocytes (distinguish from IBD) A presumptive diagnosis is based on the resolution of clinical signs after the withdrawal of dietary gluten	Only diets that contain no wheat products are fed to Irish setters with this problem Affected dogs will be normal within 4-6 weeks of the diet change Neuter affected dogs

CoA, Coenzyme A; *MHC,* major histocompatibility complex; *IBD*, inflammatory bowel disease.

Continued

TABLE 33-1

Congenital and Developmental Disorders—*cont'd*

DISORDER	DEFINITION AND CAUSE	CLINICAL SIGNS	DIAGNOSIS	TREATMENT
			A definitive diagnosis is confirmed when the clinical signs return on challenge with gluten	
Enteropathy of soft-coated wheaten terriers	Immunological defect that results in a protein-losing enteropathy and nephropathy of unknown cause or inheritance (Vaden et al., 2000) The pathogenic cause of the protein-losing enteropathy is unknown, but wheat gluten does not appear to be the trigger	Typical signs include vomiting, diarrhea, and weight loss (which may be severe) Affected dogs are young, and the most severely affected may die before the age of 5 years In severely hypoproteinemic dogs, ascites and peripheral edema may be observed Dogs that survive the initial insults often develop renal insufficiency secondary to the chronic protein-losing glomerulopathy	This enteropathy is characterized by the presence of IBD with varying morphological characteristics, but lymphocytes and plasma cells often predominate Intestinal protein loss occurs from IBD, lymphangiectasia, or both, and may be detected by measuring fecal α_1-protease inhibitor levels Protein-losing nephropathy occurs secondary to the chronic inflammatory disease in the intestines Intestinal biopsy is necessary to confirm the presence of IBD and lymphangiectasia There is no definitive test for this specific enteropathy other than finding the concurrent GI and renal protein loss in this breed	Treatment of affected dogs is symptomatic, using immunosuppressive doses of prednisolone (2-4 mg/kg/day PO) as for IBD; antibiotics as needed for control of small intestinal bacterial overgrowth; and a low-fat, highly digestible diet to minimize malabsorption and diarrhea Neuter affected dogs
Immunoproliferative small intestinal disease of basenjis	Disease results in the development of chronic diarrhea, gastropathy, and hypergammaglobulinemia in young basenjis (Breitschwerdt et al., 1984) Mode of inheritance is still undetermined	Chronic, intractable diarrhea and emaciation are the most common signs Some dogs will have concurrent vomiting from hypergastrinemia and mucosal hyperplasia Young basenjis may have severe fulminating disease, while adult dogs often have chronic, intermittent diarrhea with acute exacerbations	Confirmation of the diagnosis is by finding lymphoplasmacytic IBD, hypertrophic gastropathy, and concurrent protein-losing enteropathy (hypoalbuminemia, elevated fecal α_1-protease inhibitor levels) in a young basenji	Treatment of basenjis with severe immunoproliferative enteropathy is generally unsuccessful In less severely affected dogs, aggressive treatment of IBD is helpful Novel antigen diets may also be helpful Neuter affected dogs

GI, Gastrointestinal.

B. Neonatal puppies have the most severe clinical signs (vomiting, diarrhea, anorexia), and are often concurrently infected with other viruses, intestinal parasites, or bacteria (e.g., salmonellosis, campylobacteriosis), and are housed in crowded, stressful living conditions, with poor hygiene and nutrition.
C. Fever and bloody diarrhea are very uncommon in puppies with coronavirus enteritis alone, and death from diarrheal disease is very uncommon, except in situations where dehydration or acidosis is untreated.
D. The virus is not as stable in the environment as parvoviruses nor as resistant to disinfectants, so appropriate kennel hygiene is highly beneficial.

III. Canine distemper virus
A. Explosive diarrhea with vomiting, dehydration, and depression may occur before onset of central nervous system signs.
B. The most common clinical signs are lethargy, anorexia, fever, and upper respiratory tract infection, which may be followed by mild gastrointestinal (GI) signs.

IV. Canine rotavirus
A. Rotavirus infections are common enteric pathogens in dogs that are transmitted by the fecal-oral route, but rarely cause more than mild, mucoid to watery diarrhea.
B. Very young puppies (<2 weeks) may develop a fever or more severe signs.

V. Feline panleukopenia virus
A. Fever, anorexia, severe diarrhea, and intractable vomiting are common in young, unvaccinated kittens, with the highest morbidity and mortality occurring between 3 and 5 months of age.
B. In adult cats or in kittens from a well-vaccinated queen, anorexia, lethargy, and mild GI signs may occur, but usually the infection is self-limiting and subclinical.
C. Clinical disease is rare in vaccinated cats and in kittens born to vaccinated queens.
D. Unvaccinated kittens with peracute infection have a high morbidity and mortality rate from severe leukopenia and anemia, and may be found dehydrated, hypothermic, and comatose within 12 hours of onset.

VI. Feline enteric coronavirus (FEC) and FIP virus
A. Infections with enteric coronavirus are most often subclinical, especially in adult cats, but may cause mild, self-limiting diarrhea and fever in young or immunocompromised cats.
B. Clinically apparent FEC infections are most common in kittens 4 to 12 weeks of age.
C. FEC is nearly ubiquitous, especially in colonies, and inapparent infection is common.
D. Clinical signs in cats infected with FIP virus are variable (see Chapter 112).
1. FIP granulomas of the GI tract are known to occur in 10% to 20% of cases and cause chronic, intermittent to persistent small or large bowel diarrhea (Harvey et al., 1996).
2. The lesions may be large enough to be palpable (mass effect), but in many cases are only detected by ultrasonography or exploratory surgery.

VII. Feline leukemia virus
A. In cats that develop alimentary lymphosarcoma, signs of bowel obstruction (anorexia, vomiting, diarrhea, weight loss) or malabsorption (diarrhea, weight loss) may be observed.
B. A panleukopenia-like syndrome (small bowel diarrhea, weight loss) is also occasionally observed.

VIII. Feline immunodeficiency virus
A. The most common GI signs are anorexia, emaciation, and chronic diarrhea, which are secondary to villous atrophy and granulomatous inflammation in the intestinal tract.
B. In some cats, diarrhea may be chronic and intermittent, and not result in weight loss; however, in immunocompromised cats, diarrhea may be very severe and associated with high mortality.

Diagnosis

I. Hematological changes in viral infections
A. Parvoviruses of dogs and cats cause severe leukopenia (primarily neutropenia), and remaining neutrophils may have toxic changes.
1. Cats are also usually anemic (mild, nonregenerative) and thrombocytopenic.
2. Both dogs and cats exhibit a neutrophilia during the recovery phase.
B. Distemper virus in dogs causes leukopenia from lymphopenia.
1. Blood smears may show reactive lymphocytes and occasionally viral inclusion bodies in red blood cells (RBCs) or neutrophils.
2. Thrombocytopenia may also occur, but varies in intensity.
C. CCV, FEC, rotavirus, and other enteric viruses do not usually cause significant changes in the hemogram.
D. FIP is usually associated with a nonregenerative anemia, leukopenia or leukocytosis (with a left shift), and increased serum globulins.

II. Diagnostic tests for viral infection
A. Immunological assays (e.g., commercial enzyme-linked immunosorbent assay [ELISA] for antigen or antibody) are available for detection of parvovirus (antigen), CCV (antibody), FeLV (antigen), rotavirus (antigen, outside of the United States), and FIV (antibody).
1. The tests have a high degree of sensitivity (low false negatives) and specificity (low false positives).
2. Following vaccination with a modified live vaccine for parvovirus, some fecal shedding of virus occurs up to a week and is detected on fecal ELISA assay.
3. The most common reason for a false-negative parvovirus ELISA is testing before active shedding has started or after the brief period of shedding has stopped (10 to 12 days postinfection).
B. Serology for viral infections is useful if the antigen is available for detection (e.g., present in the tissue assayed), and often requires acute and convalescent serum samples.

1. The sensitivity and specificity of serological assays are low or moderate.
2. The presence of large amounts of immunoglobulin M suggests a recent or active infection.
3. A positive hemaglutination titer (HA) present in dog or cat after ≥3 days of clinical illness is diagnostic of CPV-2b or feline panleukopenia infection.
4. FEC can only be confirmed with immunohistochemical or immunofluorescent staining of gut biopsies (Giordano et al., 2005).
5. Definitive diagnosis of FIP requires histopathology, with clinical diagnosis primarily one of exclusion.

C. Viral isolation is rarely used because sample quality is extremely important, and both susceptible cell culture systems and antiserum against the virus must be available.
D. CCV and FEC do not grow well in tissue or cell culture systems.
E. Electron microscopic detection of viral particles in feces rapidly confirms the presence of virus, but requires specialized equipment and a high concentration of virus.
F. Applied molecular diagnostics are increasingly important in the detection of viral infections.
1. The two most common methods are immunoblotting (Western blot) and polymerase chain reaction (PCR) testing.
2. The sensitivity and specificity of these methods are very high and allow detection of preclinical disease.
3. They require only a small quantity of sample for detection of the virus.
4. They require specialized equipment and time and are not yet used for routine diagnosis except in cases where ELISA or virus isolation is not available or diagnostic (e.g., FIP).
5. Detection of FIP messenger ribonucleic acid (mRNA) via PCR in circulating monocytes or in macrophages in effusions is a highly promising new technique.

G. Tissue biopsy, necropsy, and light microscopy are diagnostic in most cases of canine distemper, feline panleukopenia, canine parvovirus, and FIP.

Differential Diagnosis

I. Nonspecific enteritis, including dietary indiscretion or dietary intolerance
II. Bacterial or parasitic enteropathies
III. Toxin-induced intestinal disease
IV. GI obstruction: foreign bodies, intussusception, masses
V. Acute pancreatitis, hepatitis, or other extra-GI inflammatory disease

Treatment

I. In mild cases, supportive care provided on an outpatient basis is adequate.
A. Withhold food for 24 to 48 hours and provide water in small, frequent quantities or as ice cubes.
1. Oral hydration solutions *(Enterolyte, Rebound)* may be given instead of water.
2. The goal of oral fluid therapy is to provide at least 40 to 60 mL/kg/day.

B. Once vomiting resolves, food is reintroduced as small quantities of a bland, highly digestible diet.
1. Examples for dogs include low-fat chicken or turkey with rice or potato, or commercial diets (e.g., Hill's i/d, Purina Veterinary Diets EN, Royal Canin Low Fat, Eukanuba Low Residue).
2. In cats, low-fat intestinal diets may not be palatable enough, so recovery diets (e.g., Hill's a/d) or canned maintenance foods are also offered.
3. Enteral nutrition is essential for recovery of enterocytes (especially in parvoviral infections) and return of normal gut motility patterns, so is reintroduced as soon as possible.
4. In some cases, feeding a liquid diet through a nasoesophageal tube may be necessary.

C. Do not withhold food for >3 days without further nutritional or fluid support, especially in cats (to prevent the risk of hepatic lipidosis) or young kittens and puppies.
D. Once vomiting or diarrhea resolves, reintroduce the regular diet over a period of 3 to 7 days.

II. Parenteral fluid therapy is required for dogs and cats that are dehydrated, have severe vomiting or diarrhea, or are anorectic for >3 days.
A. Lactated Ringer's solution or Normosol-R is given at a rate of 40 to 60 mL/kg/day IV, SC, with additional fluids to correct dehydration and replacing ongoing losses.
B. Potassium chloride (20 to 40 mEq/L) is added to the fluids if anorexia, vomiting, and diarrhea are severe, or if hypokalemia is present.
C. Replacement of magnesium sulfate may also be required if serum concentrations of magnesium are low.
D. In animals with low serum magnesium and hypokalemia, serum potassium does not return to normal until magnesium levels are corrected.
E. Hypoglycemia is a potential complication of severe enteritis in young animals, and requires addition of dextrose to the fluids after the animal is rehydrated.
F. IV nutrition (premade amino acid solutions with dextrose or parenteral solutions formulated by a nutritionist and compounded by a pharmacist) may be indicated in dogs or cats that are unwilling or unable to eat after 3 to 4 days of illness.
G. Anorectic animals, especially cats, become deficient in B vitamins, so add a multiple B-complex solution (5 to 10 mL/L) to the IV fluids or give SC SID.
H. Acid-base disorders are common, but the type and severity vary.
1. Fluid therapy and resolution of vomiting and diarrhea resolve most of these abnormalities.
2. Specific therapy is recommended only in severe, life-threatening cases when blood gas analysis is performed.

I. Hetastarch or plasma therapy is indicated in dogs with severe hypovolemia, endotoxemia, or severe hypoalbuminemia (<1.5 g/dL).

J. SC fluid therapy may be sufficient in animals with only moderate clinical signs.

III. Isolate affected dogs or cats from other animals to prevent spread of infection.
   A. Meticulous hygiene, both of personnel and the hospital cages and runs, is essential to prevent spread of viral infection.
   B. Instruct owners to properly dispose of all fecal material to reduce environmental contamination.
   C. Parvoviruses and coronaviruses are very hardy and can survive for long periods in the environment, but sodium hypochlorite *(Clorox)* and some newer disinfecting agents will kill these viruses.

IV. Antibiotics are rarely necessary in mild cases of viral enteritis.
   A. In animals with severe or hemorrhagic gastroenteritis, especially with leukopenia, use parenteral antibiotics to prevent septicemia.
      1. Some puppies with parvovirus infection have asymptomatic bacteruria, suggesting antibacterial therapy is essential.
      2. Four-quadrant therapy protects against gram-negative and gram-positive aerobic and anaerobic bacterial septicemia.
      3. Utilize ampicillin 11 to 22 mg/kg IV, IM TID to QID and amikacin 6 to 8 mg/kg IV SID, or enrofloxacin 2.5 to 5 mg/kg IV, IM BID.
   B. In dogs with suspected septicemia or endotoxemia, more aggressive antibiotic therapy may be necessary.
      1. Cefoxitin 15 to 30 mg/kg IV, IM TID to QID
      2. Timentin 40 to 50 mg/kg IV TID to QID
      3. Imipenem 2 to 7 mg/kg IV, IM TID

V. Antiemetic therapy is indicated for severe vomiting.
   A. Prochlorperazine 0.25 to 0.5 mg/kg IM BID to TID in the dog and 0.125 mg/kg IM BID in the cat
   B. Metoclopramide 0.2 to 0.5 mg/kg SC, IM, IV BID to QID or as a constant rate infusion of 0.01 to 0.02 mg/kg/hr IV
   C. Chlorpromazine 0.05 mg/kg IV TID to QID or 1 to 2 mg/kg SC TID to QID in the dog
   D. Dolasetron 0.3 to 0.6 mg/kg SC SID to TID
   E. Ondansetron 0.1 to 0.2 mg/kg SC TID in the dog

VI. Other supportive therapy includes the following:
   A. IV immune globulin can be administered to severely neutropenic dogs with parvovirus infection, but it is expensive and difficult to obtain.
   B. Recombinant granulocyte colony-stimulating factor may be given to increased neutrophil counts; however, it may not affect morbidity or survival (Cohn et al., 1999).
   C. Motility-modifying agents or antidiarrheals are not recommended in acute, infectious gastroenteritis, and are given only to dogs with mild diarrhea.
   D. In cats with FIP, corticosteroids are recommended to maintain appetite and reduce the granulomas associated with the dry form of the disease, but their effectiveness has not been proven.
   E. Antiviral therapy has not been shown to improve survival in FIP or CPV infections and may be associated with significant side effects.
   F. Anecdotally, oseltamixir phosphate *(Tomiflu)* may be beneficial in dogs when given at 2 mg/kg PO BID for 5 days, especially if administered within 24 to 48 hours of onset of signs.

Monitoring of Animal

I. Frequently assess hospitalized animals for hydration status, response to therapy, and complications such as septic shock, DIC, or intussusception.

II. Daily monitoring includes determining body weight, performing a complete physical examination, and monitoring packed cell volume (PCV), total solids, blood glucose, and electrolytes.

III. The prognosis for most dogs and cats with viral enteritis is good if aggressive supportive care is initiated early, neutropenia is not associated with sepsis, and secondary complications are mild.

IV. The prognosis is more guarded for very young animals, animals with concurrent infections, or for cats with FeLV, FIV, or FIP infections.

V. All potentially exposed animals are vaccinated or revaccinated if their vaccine status is questionable.

VI. Disinfection of the premises with bleach reduces the risk of transmitting viruses to other animals.

Bacterial Infections

Definition and Causes

I. *Escherichia coli* is part of the normal bacterial flora of the ileum and colon.
   A. Documentation of pathogenic *E. coli* as the cause of intestinal infection is very difficult because many strains are found in clinically healthy dogs and cats (Greene, 2006; Marks and Kather 2003).
   B. Strains of *E. coli* that may cause diarrhea include enteropathogenic, enterotoxigenic, enterohemorrhagic, necrotoxigenic, enteroaggregative, or enteroinvasive (Greene, 2006).
   C. The best way to distinguish pathogenic *E. coli* from nonpathogens is the use of assays for specific toxin genes or molecular typing (Pass et al., 2000).

II. *Salmonella* spp. are frequently isolated from feces of normal dogs (1% to 36%) and cats (1% to 18%); however, their actual prevalence may be much higher in animals fed raw meat diets (Greene, 2006).
   A. *Salmonella typhimurium* is the most important pathogen in small animals (McDonough and Simpson, 1996; Greene, 2006).
   B. The risk factors for clinical disease include age (puppies and kittens <1 year), immunosuppression or stress from hospitalization, malnutrition, neoplasia, coinfection with FeLV or FIV, diabetes mellitus, and immunosuppressive therapy.
   C. Most cats that develop clinical disease are bacteremic, are systemically ill, and also have GI signs.
   D. Most dogs and cats infected with *Salmonella* spp. have transient or subclinical infections, and <10% became severely ill or die (Greene, 2006).

E. "Song bird fever" is caused by *S. typhimurium;* it is a seasonal illness that occurs in outdoor cats that prey on birds in the northeastern United States, and it manifests an acute, febrile, self-limiting gastroenteritis lasting for 2 to 7 days.

III. *Yersinia enterocolitica* and *Yersinia pseudotuberculosis* may cause a relatively mild enterocolitis, but fecal shedding of the organism may persist for weeks.
   A. *Y. enterocolitica* has been isolated from the feces of clinically normal dogs and cats, so it is probably a commensal that only rarely causes clinical disease.
   B. *Y. pseudotuberculosis* causes enteritis during cold, wet, winter months, because it replicates more effectively in cooler temperatures.

IV. *Clostridium* spp. are involved with several different intestinal diseases.
   A. *Clostridium piriformis* (Tyzzer's disease) is a rare disease that causes a chronic hemorrhagic enterocolitis with hepatic necrosis.
   B. *Clostridium difficile* is isolated in both healthy and diarrheic dogs and cats.
      1. *Clostridium* spp. produce three toxins (A, B, and C).
      2. Toxins A (enterotoxin) and B (cytotoxin) have been associated with diarrhea in dogs (Marks and Kather, 2003), but the association in cats is less well defined.
      3. Infection was thought to occur only rarely, was secondary to antibiotic use, and caused pseudomembranous colitis (Weese et al., 2001); however, outbreaks have been reported in dogs without prior antibiotic use.
   C. *C. perfringens* is part of the normal colonic flora in dogs and cats, but under conditions that allow sporulation (e.g., alkaline environment, antibiotic therapy, dietary changes, immunosuppression), enterotoxin is released, causing a watery or hemorrhagic acute to peracute diarrhea.

V. *Campylobacter jejuni* and *Campylobacter upsaliensis* are motile, microaerophilic bacteria that cause enteritis most commonly in puppies or kittens that are housed in kennel situations, or that are stressed or immunocompromised.

VI. *Helicobacter cinaedi* and *Helicobacter fennelliae* have both been cultured in feces from dogs, but whether they are a primary cause of diarrhea in immunocompetent dogs and cats is unknown.

VII. *Shigella* spp. can cause enteritis in dogs that are exposed to feces from infected hosts (primates, humans).

Pathophysiology

I. Diarrhea caused by toxin-producing bacteria occurs from increased chloride secretion and subsequent water and electrolyte loss.
   A. Enteropathogenic *E. coli* adheres to the mucosal cells of the small intestine, causing loss of microvilli.
   B. Enterotoxigenic *E. coli* produces both heat-stable toxins that increase chloride secretion by deregulating guanylyl cyclase activity or stimulating cyclic nucleotide-independent secretion, and heat-labile toxins that alter adenylate cyclase activity, resulting in inhibition of sodium and chloride absorption, and increased secretion of chloride by crypt epithelial cells.
   C. Enterohemorrhagic *E. coli* produces verotoxins (*Shigella*-like toxins) that cause damage to the vascular endothelium, inhibit protein synthesis, and alter fluid secretion.
   D. Necrotoxigenic *E. coli* produces cytotoxic necrotizing factors that attach to the mucosal cells and cause diarrhea by invasion and destruction of the cells.

II. Invasive organisms cause enteritis by invading the bowel epithelium and causing local inflammation and mucosal disruption.
   A. Examples of organisms that are invasive include *Salmonella* spp., *Yersinia* spp., *Campylobacter* spp., and enteroinvasive *E. coli* strains.
   B. Inflammation disrupts the mucosal barrier, resulting in loss of fluids, electrolytes, and in some cases blood.
   C. Mucosal disruption can result in the development of bacteremia.

III. Inappropriate or excessive antibiotic therapy alters the normal intestinal flora and allows invasion of antibiotic-resistant strains of bacterial pathogens.

Clinical Signs

I. Diarrhea caused by toxin-secreting bacteria is less common than that caused by invasive bacteria.
   A. Toxigenic diarrhea is usually watery, with little evidence of an inflammatory response or systemic disease.
   B. Diarrhea of this type leads rapidly to dehydration and electrolyte imbalances, but there is rarely blood, mucus, or cellular debris in the feces.

II. Invasive diarrheas are often acute, hemorrhagic, or mucoid in nature and may cause other clinical signs of illness (e.g., fever, abdominal discomfort, vomiting, anorexia).
   A. Diarrhea may result in severe gastroenteritis and fluid loss, or may affect primarily the large bowel, with signs of colitis.
   B. Animals that develop septicemia may be collapsed, hypothermic, or febrile; hypovolemic; in endotoxic shock; or have signs of DIC.
   C. Organisms that induce severe systemic clinical disease include *Salmonella* spp., enteroinvasive or enterohemorrhagic *E. coli,* and *C. piriformis.*

III. Some bacteria cause clinical syndromes with features of both invasive and toxigenic species.
   A. *Y. enterocolitica* typically causes a mild, self-limiting enterocolitis in dogs.
   B. *C. jejuni* is associated with a hemorrhagic diarrhea, but may also cause chronic colitis.
   C. Enteroadherent *E. coli* may cause a mild to severe enterocolitis with watery to hemorrhagic diarrhea.

Diagnosis

I. Tentative diagnosis is based on typical signalment, history, and clinical signs, and is only rarely based on fecal culture.

II. Definitive diagnosis requires fecal culture, PCR detection of bacterial toxins or DNA, or demonstration of bacterial toxin in the feces.
   A. A positive fecal culture must be interpreted very cautiously, because most of the bacteria implicated in bacterial enteritis are also normal flora (e.g., *E. coli, Salmonella* spp., *Clostridium* spp., and *Campylobacter* spp.) and are found in clinically healthy animals.
   B. When submitting bacterial cultures of fecal material, submit individual samples in media appropriate for each organism suspected.
      1. Diagnosis of campylobacteriosis is best made by culture of the organism from fresh feces placed into anaerobic transport media.
      2. Diagnosis of salmonellosis is best made by culturing the organism; however, caution is advised, as *Salmonella* spp. are isolated from healthy dogs without diarrhea.
   C. The significance of culture results is based on the signalment, history, other test results for viral and parasitic agents, histopathology (if the diarrhea is chronic), and presence of toxin (if it is a toxin-secreting species).
   D. Definitive diagnosis of *C. perfringens* is difficult because detection of endospores (fecal cytology), toxin formation (by ELISA), or the gene for clostridial enterotoxin production (by PCR) are all associated with false-positive and false-negative results.
      1. Presumptive diagnosis is made by increased numbers of spores or a positive fecal enterotoxin in the presence of diarrhea.
      2. The best way to diagnose clostridial diarrhea is finding clostridial enterotoxin in feces by ELISA or PCR, in a dog with acute diarrhea (Marks and Kather, 2003).
   E. Identification of pathogenic *E. coli* requires either specific typing for known pathogenic strains or demonstration of toxin production.
III. Bacterial enteritis may occur secondary to viral infection (e.g., parvovirus).
IV. Toxin assays are available for identification of the presence of toxin in fecal material from *C. difficile, C. perfringens,* and certain *E. coli*, and are used to determine whether these organisms are responsible for the clinical signs.
V. Fecal cytology helps identify the type of enteritis (presence of inflammatory cells, type of cells, number and type of bacteria), determine its severity (presence or absence of RBCs, epithelial cells, leukocytes), and in some cases identifies the cause (e.g., seagull-shaped bacteria characteristic of *Campylobacter* or *Helicobacter* spp.).
   A. Finding *Clostridium* spp. spores (safety pin-shaped organisms) in large numbers (>5 per high-power field) is not an important consideration in the diagnosis of clostridial enterocolitis.
   B. The mere presence of spores does not indicate they are secreting toxin and causing the diarrhea (Marks and Kather, 2003).
VI. Hematological or biochemical changes may be nonspecific; however, significant leukocytosis or leukopenia is suggestive of bacterial causes.
VII. In dogs or cats with diseases of high mortality (e.g., hemorrhagic colibacillosis, salmonellosis, Tyzzer's disease), diagnosis is often based on postmortem examination.

Differential Diagnosis

I. Viral enteritis: especially in puppies and kittens
II. Severe intestinal parasitism in puppies in and kittens
III. Toxin-induced enteritis
IV. Dietary indiscretion and other nonspecific enteritis
V. Extraintestinal causes of diarrhea

Treatment and Monitoring

I. Supportive care is essential to replace lost fluids and electrolytes, and to correct acid-base disturbances from moderate to severe diarrhea.
   A. In animals that are not vomiting and have only mild signs, oral replacement fluid therapy is usually adequate (see Viral Infections earlier in this chapter).
   B. If vomiting is present, institute appropriate IV fluid therapy.
   C. Do not use motility-modifying agents, because removal of the bacterial toxins and inflammatory mediators is enhanced by the diarrhea.
   D. Intestinal protectants are occasionally beneficial in dogs with mild disease to decrease effects of the toxins and reduce inflammation.
      1. Consider bismuth subsalicylate *(Pepto-Bismol)* at 1 to 2 mL/kg PO TID to QID.
      2. *Pepto-Bismol* is not recommended in cats owing to the risk of salicylate toxicity.
II. Antibiotic therapy is indicated, especially if the pathogen is definitively identified; however, antibacterial therapy is controversial for animals with *Campylobacter* spp. or *Salmonella* spp. infections when there are no systemic signs of disease.
   A. Give ampicillin 10 to 22 mg/kg IM, SC, or IV TID to QID for *Salmonella* spp., or *Clostridium* spp. infections.
   B. Administer amikacin 6 to 8 mg/kg IM, IV SID alone for *Salmonella* spp., *Helicobacter* spp., *Yersinia* spp., and *Campylobacter* spp. infections, or in combination with cephalothin for systemic salmonellosis.
   C. Use trimethoprim-sulfadiazine 15 mg/kg SC, PO BID for elimination of salmonella carrier states and treatment of yersiniosis.
   D. Give erythromycin 20 mg/kg PO BID (dogs) and 10 mg/kg PO TID (cats) for *Campylobacter* spp. and *Helicobacter* spp. infections.
   E. Substitute, if necessary, newer generation macrolides, such as azithromycin (5 mg/kg PO SID) for erythromycin (fewer side effects).
   F. Clindamycin 5 to10 mg/kg PO BID may also be effective against *Clostridium* spp.
   G. Metronidazole at 5 to 15 mg/kg PO BID is used for bacterial overgrowth and clostridial enterocolitis.

H. Consider using enrofloxacin 5 to 10 mg/kg PO SID (dogs) or 2.5 to 4 mg/kg PO, SC SID (cats) for gram-negative bacterial infections (*Campylobacter* spp., *Salmonella* spp., and *E. coli*).
I. Tylosin 11 mg/kg PO BID to TID may be used for unidentified bacterial enteritis or antibiotic responsive enteritis.

III. Prevention of infection is achieved by removal of potential sources, such as wild prey or contaminated food products.
IV. Monitoring of animal is similar to that recommended under Viral Infections.

Intestinal Parasitism

See Table 33-2.

Mycotic and Algal Diseases

Definition

I. Mycotic and algal diseases are uncommon in dogs, except in regions where the organism is endemic (e.g., histoplasmosis, phycomycosis), and are rare in cats.
II. They tend to be opportunistic and occur primarily in dogs that are immunocompromised from malnutrition, infection, neoplasia, or drugs, or in dogs with abnormal gut microflora.

Causes

I. *Histoplasma capsulatum*
   A. Infection occurs primarily in the Missouri, Mississippi, and Ohio river valleys; southeastern Texas; and the Gulf Coast region (Greene, 2006).
   B. Dogs are more likely to develop GI histoplasmosis alone.
   C. Cats with GI signs generally have a systemic infection.
II. Miscellaneous infections
   A. These include *Pythium insidiosum, Lagenidium* spp., other Zygomycetes, and *Prototheca zopfii* (Grooters, 2003).
   B. *P. insidiosum* is a water-borne pathogen belonging to the class Oomycetes that causes cutaneous or GI disease in tropical or subtropical regions.
   C. Pythiosis is more common in dogs than in cats and causes only cutaneous infections in cats.
   D. Lagenidiosis is primarily observed in dogs and is associated with cutaneous disease unless it becomes disseminated and systemic signs develop.
   E. The primary zygomycosis associated with GI disease in dogs or cats is mucormycosis caused by *Mucor* spp., *Rhizopus* spp., or *Absidia* spp.
   F. *Prototheca zopfii* is a blue-green algae capable of causing GI and other organ disease in dogs.
III. *Candida albicans:* opportunistic infection
IV. *Aspergillus* spp.
   A. GI involvement is part of disseminated disease.
   B. It is a rare disease and is more common in dogs (especially German shepherd dogs) than in cats.

Pathophysiology

I. *H. capsulatum* is a dimorphic fungus, having both infective and tissue stages.
   A. The free-living mycelial stages (macroconidia and microconidia) live in the soil and are the source of infection.
   B. Once in the body, microconidia are converted into the yeast form in the tissues, are then engulfed by macrophages, and initiate intracellular replication.
II. Pythiosis is the most clinically important miscellaneous organism.
   A. *Pythium* spp. differ from true fungi in producing motile, flagellate zoospores, and having cell walls that contain cellulose, no chitin, and very little ergosterol.
   B. The infective stage is released into warm water environments and likely causes infection by encysting in the GI mucosa.
   C. Pythiosis causes granulomatous inflammatory lesions that may form masses and obstruct the GI tract, or may cause diffuse infiltrative granulomatous enteritis.
   D. Lesions are most frequently observed in the stomach and duodenum, but may involve any segment of the small intestine, with the ileocolic junction another common location.
III. *Lagenidium* spp. infections typically cause cutaneous or subcutaneous draining nodules in dogs, but the disease may disseminate to other body systems.
IV. *Candida* spp. invade and proliferate in the GI tract following prolonged antibiotic therapy, or when the normal GI flora are altered by disease or dysfunction.
V. Disseminated aspergillosis may infiltrate the small intestine, but only when there is severe immunodeficiency or immunosuppression.

Clinical Signs

I. Histoplasmosis
   A. Chronic weight loss, anorexia, and large bowel diarrhea (tenesmus, hematochezia, mucus, urgency) are the most common clinical signs in dogs with primary GI histoplasmosis.
   B. With small intestinal involvement, the diarrhea is either profuse and watery or bloody.
   C. With systemic involvement, fever, lymphadenopathy, hepatomegaly, splenomegaly, icterus, anemia, ascites, cough, and dyspnea are often observed.
   D. Histoplasmosis is more common in young (<4 years) dogs and cats.
II. Miscellaneous fungal/algal infections
   A. Signs include weight loss, anorexia, vomiting, and diarrhea, which are often associated with a palpable abdominal mass.
   B. Infections are more common in male, large-breed dogs living in tropical or subtropical regions.
   C. Cutaneous forms of pythiosis are less common than GI forms in dogs, but skin disease is more common in cats.
   D. Signs of systemic illness can occur with pythiosis, but only after development of intestinal obstruction or perforation.

TABLE 33-2

Small Intestinal Parasitism

PARASITE	CLINICAL FEATURES	DIAGNOSIS	TREATMENT
Nematodes			
Ascarids Dogs: *Toxocara canis* *Toxascaris leonina* Cats: *Toxocara cati* *Toxascaris leonina*	*T. canis* is the most important nematode of public health significance (visceral larval migrans) Clinical signs from migration: coughing, ill thrift, pneumonitis Clinical signs from mucosal dysfunction: malabsorption, weight loss, retarded growth, diarrhea, poor hair coat, enterocolitis Puppies are infected in utero (transplacental), postpartum (transmammary), and by fecal–oral route Feline ascarids do not cross placenta or mammary gland	Fecal flotation with salt or sugar solutions	Pyrantel pamoate Dogs: 1 mL/10 lb (5 kg) PO Cats: 1 mL/5 lb (2.5 kg) PO Fenbendazole 50 mg/kg PO SID × 3 days Milbemycin Drontal Plus: dogs Drontal: cats Selamectin: cats only Puppies are treated prophylactically every 2-3 wk, until >6 wk old, then as needed Prepatent period is 4-6 wk
Hookworms Dogs: *Ancylostoma caninum* *Ancylostoma braziliense* Cats: *Ancylostoma tubeforme* *Ancylostoma braziliense* *Uncinaria stenocephale*	*A. caninum* is the most important hookworm of public health significance (cutaneous larva migrans) Voracious blood-sucking ability causes severe life-threatening anemia in young puppies Diarrhea is the most common sign; may be blood-tinged Iron deficiency anemia in adults	Fecal flotation with salt or sugar solutions	See Ascarids Prepatent period is 2-3 wk
Strongyloides Dogs: *S. stercoralis* Cats: *S. tumefaciens*	Most common in young dogs from kennel or shelter environments Clinical signs include vomiting or diarrhea, coughing, lethargy, and respiratory distress *Strongyloides* spp. are a public health risk as the larvae are infectious	Baermann exam is best to detect larvae Direct visualization of worms in emesis	Fenbendazole 50 mg/kg PO SID × 3 days Ivermectin 200-300 µg/kg PO
Whipworms Dogs: *Trichuris vulpis*	Whipworm infections are most common in urban environments from persistent fecal contamination and reinfection Enterocolitis (large bowel diarrhea)	Fecal flotation with sugar or zinc sulfate solution is best Eggs are shed intermittently, so multiple fecal examinations may be required	Fenbendazole 50 mg/kg PO SID × 3 days Drontal Plus: dogs Milbemycin Ivermectin 200-300 µg/kg PO Prepatent period is 3 mo
Coccidia			
Cystisospora spp. *Cryptosporidium* spp. *Toxoplasma* spp. Others: *Hammondia* spp., *Sarcocystis* spp., *Besnoitia* spp., *etc.*	*Cystisospora* spp. are not highly pathogenic; inapparent infections common; mucoid, foul-smelling diarrhea in young kittens or puppies Cryptosporidia may cause chronic, severe diarrhea and ill thrift in puppies, kittens, and immunocompromised adults	Fecal flotation is best, using salt or sugar solution *Cryptosporidium* spp. are extremely small (3-4 µm) and require both special stains and high-power microscopy for visualization Fecal ELISA is available for detection of cryptosporidia	Animals with asymptomatic *Cystisospora* spp. infections do not require treatment Sulfadimethoxine 55 mg/kg PO once, then 27.5 mg/kg PO SID × 14 days Sulfamethazine 100 mg/kg PO once, then 50 mg/kg PO BID × 14 days

Continued

TABLE 33-2

Small Intestinal Parasitism—*cont'd*

PARASITE	CLINICAL FEATURES	DIAGNOSIS	TREATMENT
	Cryptosporidia are not host specific like most coccidia, thus are zoonotic, especially to immunocompromised humans *Toxoplasma* spp.: see Chapter 116	*Toxoplasma* spp. oocysts are also extremely small and rarely seen on fecal flotation examinations. Toxoplasmosis is diagnosed by measuring serum IgM and IgG levels	For *Cryptosporidium* spp.: paromomycin 125-165 mg/kg PO BID × 5 days For toxoplasmosis: clindamycin 10-25 mg/kg PO BID × 14 days
Protozoa			
Giardia lamblia *Entamoeba histolytica* *Balantidium coli*	*Giardia* spp. infections are characterized by acute or chronic small bowel diarrhea, weight loss, and protein-losing enteropathy Subclinical infections are common Zoonotic, both by direct contact with feces, but also via fomites, as cysts are highly resistant to disruption *Entamoeba* spp. and *Balantidium* spp. are rare, but cause signs of enterocolitis	Zinc sulfate flotation is the most effective concentration method for detection Testing of three separate fecal samples increases the sensitivity from 65% to 96% Trophozoites may be observed on direct saline smears of feces, but the sensitivity is low Fecal ELISA for detection of *Giardia* spp. antigen has a 93% sensitivity, but the specificity is lower than zinc sulfate flotation	Metronidazole 25-50 mg/kg PO SID × 5 days (dogs); 10 mg/kg PO BID (cats) Fenbendazole 50 mg/kg PO × 7 days Furazolidone (cats) 4 mg/kg PO BID × 7 days Drontal Plus: dogs *Giardia* spp. in cats: give Drontal Plus at 2 small dog tablets PO SID × 5 days
Trichomonads			
Pentatrichomonas hominis	Healthy dogs and cats may be carriers Animals with diarrhea found to have *Pentatrichomonas* spp. may have other intestinal diseases or immunodeficiency	Direct examination of feces Special stains may be needed to differentiate from *Giardia* spp.	No effective treatment has been identified
Tritrichomonas foetus	Healthy cats or young kittens with foul, pasty diarrhea Often associated with anal hyperemia No vomiting or anorexia	Direct examination of feces (least sensitive) Culture of organism PCR for organism	Self-elimiting in some cats after several months Ronidazole 10-30 mg/kg PO BID × 14 days; can be neurotoxic
Cestodes			
Tapeworms Dogs: *Dipylidium caninum* *Taenia pisiformis* Cats: *Dipylidium caninum* *Taenia taeniaeformis*	Rarely associated with clinical abnormalities May observe proglottid segments on perineum Severe infestation may result in unthriftiness	Proglottid segments seen on perineum or in litter box Oocysts may occasionally be seen on fecal flotation	Epsiprantel 5 mg/kg PO once (dog); 2.5 mg/kg PO once (cat) Praziquantel 5-7.5 mg/kg PO once (dog); 5 mg/kg PO once (cat)

ELISA, Enzyme-linked immunosorbent assay; *IgM,* immunoglobulin M; *IgG,* immunoglobulin G; *PCR,* polymerase chain reaction.

E. *Lagenidium* spp. and Zygomycetes infections only cause GI signs when they become disseminated.

III. Candidiasis and aspergillosis
   A. They cause chronic, nonhealing ulcerative lesions of the mucosa that result in diarrhea in dogs.
   B. Systemic involvement is more common with aspergillosis, producing clinical signs of anorexia, weight loss, fever, weakness, vomiting, uveitis, and neurological dysfunction.

Diagnosis

I. Histoplasmosis
   A. Definitive diagnosis is made by cytological or histological identification of organisms in macrophages from infected tissues.
   B. Serology is not recommended because of a high percentage of false-positive and false-negative results.

II. *Pythium* spp., *Lagenidium* spp., and others
   A. Definitive diagnosis is made by identification of the organisms (poorly septate and branching fungal hyphae) on histopathologic examination of affected tissues (endoscopic or surgically obtained biopsies).
   B. An ELISA is available for use in dogs and cats, and it has very high sensitivity and specificity.
      1. It can be used before more invasive diagnostics are undertaken.
      2. It is also useful to guide the duration of therapy and detect recurrences (Grooters, 2003).
   C. No consistent laboratory or imaging abnormalities occur.

III. Aspergillosis and candidiasis
   A. Definitive diagnosis is achieved by identification of organisms in cytological or histological specimens from affected tissues.
   B. Serology for aspergillosis includes an agar gel immunodiffusion (AGID) assay or ELISA; however, false negatives are common, and a positive test does not rule out other concurrent diseases, which are common in dogs with aspergillosis.
   C. Both organisms can be cultured from the affected tissue, but must be done with extreme caution as the organisms can be infective to laboratory personnel.

Differential Diagnosis

I. Inflammatory bowel disease (IBD)
II. Intestinal neoplasia
III. Protein-losing enteropathies (PLE)
IV. Obstructive intestinal diseases: intussusception, foreign body
V. Other diffuse enteropathies causing malabsorption

Treatment

I. Histoplasmosis
   A. The drug of choice is itraconazole administered for ≥4 to 6 months or 1 month beyond resolution of clinical signs (Greene, 2006).
      1. Dose in dogs: 10 mg/kg PO SID or divided BID
      2. Dose in cats: 5 to 10 mg/kg PO SID; liquid form preferred as it is well absorbed
   B. Some animals require treatment for 9 to 12 months, and long-term treatment beyond that is occasionally necessary.
   C. If treatment is stopped prematurely, relapses are common.
   D. Alternatives to itraconazole include amphotericin B or fluconazole (see Chapter 111).
   E. Ketoconazole is less effective against histoplasma organisms and has greater toxicity.
   F. Antibiotics or other supportive care may be required in severe cases.
   G. In cats, anorexia may warrant insertion of a feeding tube.

II. Pythiosis and other miscellaneous fungal or algal infections
   A. Wide and complete surgical excision is the only effective treatment and may be curative if the lesion is focal.
   B. Itraconazole, miconazole, and terbinafine have in vitro susceptibility to the organism, but their effectiveness in vivo is questionable.
      1. These drugs may prevent dissemination or local recurrence following surgical excision.
      2. Itraconazole and terbinafine used together appear to be the most effective combination, but the rate of success is still quite low.
   C. Liposome-encapsulated amphotericin B has not been shown to be effective and has greater toxicity.
   D. A new antifungal drug, caspofungin, may be much more effective against pythiosis and other oomycoses, but is extremely expensive, and dosing and safety data have not been reported in dogs.
   E. Supportive care with correction of electrolyte disturbances and dehydration is essential, especially for cases where surgery is to be performed.

III. Aspergillosis and candidiasis
   A. *Candida* spp. are susceptible to itraconazole, fluconazole, and ketoconazole.
   B. Aspergillosis can be effectively treated with itraconazole or one of the newer azoles (voriconazole) or amphotericin B; however, disseminated disease is often unresponsive because of concurrent immunocompromise.
   C. Treatment must be continued for 1 month past the resolution of signs, and correction of the underlying cause is imperative.

IV. Supportive care is very important and may include fluid therapy, nutritional support, antibiotics, control of vomiting, and good husbandry.

Monitoring of Animal

I. The overall prognosis for fungal diseases is fair to poor, depending on the organism involved, the extent of disease, and the response to treatment.
   A. The prognosis is generally better for dogs or cats with pulmonary disease alone than for those with GI or disseminated disease.

B. Dogs with diffuse GI pythiosis or other oomycoses have a very guarded to poor prognosis.

II. Therapy must be given for a long time (≥4 to 6 months) in animals with GI disease, and early withdrawal results in a relapse of the clinical disease.

III. A number of other adverse effects of drug administration must also be monitored (see Chapter 111).

IV. Response to treatment is monitored by assessment of body weight, return of appetite, and resolution of clinical and biochemical abnormalities.

CANINE HEMORRHAGIC GASTROENTERITIS

Definition and Cause

I. Hemorrhagic gastroenteritis (HGE) is a peracute, hemorrhagic diarrhea of dogs that is accompanied by hemoconcentration and an acute onset of vomiting.

II. The etiology is unknown, but it may be an enterotoxemia from *E. coli* or *Clostridium* spp. (Marks and Kather, 2003).

Pathophysiology

I. A dramatic increase in small intestinal vascular and mucosal permeability may be responsible for the rapid loss of blood, protein, and fluids from the GI tract.

II. The syndrome may represent a hypersensitivity or immunological reaction to bacteria or bacterial toxins.

Clinical Signs

I. Signalment is as follows:
   A. HGE is most frequently seen in small-breed dogs, with the miniature schnauzer, poodle, bichon frisé, dachshund, sheltie, and Cavalier King Charles spaniel overrepresented.
   B. HGE is most common in young dogs (2 to 4 years), and there is classically no known exposure to different foods, garbage, or other inciting causes.

II. The clinical signs are peracute and severe, resulting in rapid development of severe hypovolemia and shock.

III. The typical signs include hematochezia, melena, depression, acute onset of anorexia, vomiting (may have hematemesis), abdominal pain, and occasionally fever.

IV. Endotoxic shock occurs in severely affected dogs, as evidenced by hyperemic mucous membranes, slow capillary refill time, hypothermia, generalized weakness, or collapse.

Diagnosis

I. There is no definitive diagnostic test for this syndrome.

II. Presumptive diagnosis is based on the characteristic signalment, history, and clinical signs in a previously healthy dog.

III. Dogs have marked hemoconcentration (PCV=50% to 80%), but the total protein is often normal or low (despite the severe dehydration).
   A. Other hematological and biochemical parameters are usually normal.
   B. The white blood cell count may show a stress leukogram, neutropenia, or neutrophils with toxic changes; however, in most cases the condition is too peracute for these changes to occur.

IV. Tests for viral and bacterial enteric pathogens and fecal evaluations for parasites are negative.

V. Radiography of the abdomen is often unremarkable with the exception of ileus, which may be marked.

VI. Coagulation tests are normal unless the dog is in severe endotoxic shock, and then evidence of DIC may be present.

Differential Diagnosis

I. Parvoviral enteritis

II. Bacterial enteritis, especially *Salmonella* spp., *Clostridium* spp., or hemorrhagic *E. coli*

III. Intestinal obstruction: intussusception, foreign body, volvulus, neoplasia, fungal granuloma

IV. Other causes of hypovolemic or endotoxic shock resulting in hemorrhagic diarrhea

V. Coagulopathies: warfarin toxicity, DIC

Treatment

I. Aggressive treatment of fluid and electrolyte derangements is the most important aspect of initial treatment.
   A. Start IV fluid therapy with isotonic, polyionic crystalloid solutions (Normosol-R, lactated Ringer's) at 60 to 90 mL/kg in the first hour in severely hypovolemic, shocky dogs.
      1. Once the dog is stabilized, fluids are modified to match the ongoing losses.
      2. In many dogs, the best approach is the placement of a central venous catheter to allow measurement of central venous pressure (CVP) during the replacement and maintenance phases of fluid therapy.
   B. In dogs that are severely hypoproteinemic (total protein [TP] <4.0 mg/dL, albumin <2.0 mg/dL), colloid therapy (hetastarch 10 to 20 mL/kg IV) or plasma is preferred to prevent fluid overload, edema formation, and further deteri-oration of the clinical condition.
   C. Electrolyte losses are often severe.
      1. Potassium supplementation (20 to 40 mEq/L) is usually the most critical.
      2. Magnesium and phosphorus (owing to metabolic acidosis and blood loss) must also be monitored.

II. Antibiotic therapy is very important because bacterial translocation via deranged mucosal permeability and shock are common complications.
   A. Four-quadrant therapy is recommended to provide protection against aerobic, anaerobic, gram-positive, and gram-negative bacteria (see doses in Viral Infections).
      1. Ampicillin and amikacin
      2. Ampicillin and enrofloxacin
      3. Cefoxitin or other second- or third-generation cephalosporins
      4. Imipenem or Timentin
   B. Antibiotic therapy is continued for 3 to 5 days beyond the cessation of clinical signs.

III. The use of corticosteroids in dogs with shock is controversial and not recommended for this condition.

IV. Treatment of vomiting is indicated, with drugs such as metoclopramide, prochlorperazine, ondansetron, or dolasetron.
V. Consider ranitidine, famotidine or omeprazole if the vomiting is severe, or blood is present in the vomitus.
VI. Treatment of diarrhea with antidiarrheal agents (loperamide, diphenoxylate, or *Pepto-Bismol*) is not recommended.
VII. A short-term fast (1 to 3 days) is indicated, at least until the vomiting is controlled.
   A. Do not fast dogs for long periods, because the gut requires food to repair itself.
   B. When ready, offer small amounts of a canned, highly digestible, low-fat, low-fiber food.

Monitoring of Animal

I. Monitor serum electrolytes, PCV, and total solids BID to QID initially, depending on the severity of the abnormalities.
II. In very small or toy breeds, blood glucose is also assessed.
III. The rate of fluid administration is monitored by assessing CVP, urine output, PCV, TP, and body weight.
IV. The prognosis is good if the dog is not severely hypoproteinemic and aggressive supportive care is administered.
   A. In most cases, dogs begin to recover in 2 to 3 days.
   B. In dogs with severe hypoproteinemia or with secondary complications, the prognosis is more guarded.
   C. Dogs that do not respond to therapy in 2 to 3 days must be reevaluated, because it is likely that the diagnosis is incorrect or that other complications have developed (e.g., intussusception, endotoxemia, sepsis, DIC).
V. The mortality rate is very high in dogs that are not treated aggressively.

DISORDERS OF MALABSORPTION

Definition

I. Malabsorption or malassimilation is a disorder that results in a primary failure of absorption (e.g., lymphangiectasia, small intestinal disease affecting mucosal transport), and is distinguished from maldigestion caused by failure of digestive processes (e.g., exocrine pancreatic insufficiency, brush border enzyme deficiency).
II. The distinction between maldigestion and malabsorption is artificial because both are inextricably linked; therefore malabsorption is often used as a general term for either defective digestion or absorption.

Causes and Pathophysiology

I. The causes of malabsorption are separated by the site where the primary abnormality occurs.
   A. Examples are luminal, mucosal, or hemolymphatic (postmucosal) disorders (Simpson and Hall, 2000).
   B. No matter the cause or site, the end result is decreased nutrient absorption from the small intestine.
II. Luminal causes of malabsorption include the following:
   A. Motility disorders: hyperthyroidism
   B. Inactivation of enzymes: gastric hyperacidity, Zollinger-Ellison syndrome
   C. Lack of digestive enzymes: exocrine pancreatic insufficiency
   D. Deficiency of bile salts: cholestatic liver disease, obstruction of common bile duct, or loss of bile salts as a result of ileal disease
   E. Bacterial overgrowth in the small intestine resulting in cobalamin deficiency, deconjugation of bile salts, and impairment of intestinal mucosal function
III. Mucosal causes include the following disorders:
   A. Deficiencies of mucosal (brush border) enzymes: trehalase deficiency in cats, lactose deficiency
   B. Disturbances in uptake of luminal substrate across the mucosa from congenital lack of transport protein: intrinsic factor receptor absence
   C. Severe mucosal disease: IBD, neoplasia, etc.
   D. Defects in enterocytes resulting in abnormal transport: villous atrophy, abetalipoproteinemia, inflammatory or infectious diseases affecting enterocytes
IV. There is often considerable overlap between the classes of disorders.
V. Some of the more important individual causes of malabsorption include the following:
   A. Inflammatory bowel diseases: lymphocytic plasmacytic enteritis, eosinophilic enteritis, granulomatous enteritis, etc.
   B. Neoplasia: lymphosarcoma, leiomyosarcoma, adenocarcinoma, etc.
   C. Chronic infectious enteropathies: histoplasmosis, giardiasis, pythiosis, small intestinal bacterial overgrowth
   D. Villous atrophy: idiopathic, secondary to IBD, etc.
   E. Dietary hypersensitivity: dietary allergy, wheat-sensitive enteropathy, dietary intolerance
   F. Short bowel syndrome: congenital or secondary to massive bowel resection
   G. Lymphangiectasia: primary, secondary to other intestinal disease
   H. Idiopathic PLE

Clinical Signs

I. Signs of intestinal malabsorption are varied in both severity and presentation, and range from mild diarrhea or weight loss to severe diarrhea, weight loss, abnormal appetite, and edema or ascites from hypoproteinemia.
II. Diarrhea is the most consistent abnormality.
   A. Occasional soft feces to severe watery diarrhea
   B. Hematochezia and/or melena with severe inflammatory diseases
   C. Light or gray fecal color with maldigestion or a lack of bile salts
III. Weight loss may be the only clinical sign in some cases, and it can be significant.
IV. Other variable clinical signs include alterations in appetite, abdominal discomfort, depression, increased intestinal gas production (borborygmus, belching, flatus), or vomiting.
V. Severe lymphangiectasia may result in edema or ascites from severe hypoproteinemia from PLE, and may rarely be associated with a chylous effusion in the abdomen or thorax.

VI. Protein and fat malnutrition may result in poor skin and hair coat.
VII. Increased risk of bleeding may occur with severe malabsorption and vitamin K deficiency or with loss of clotting proteins secondary to intestinal protein loss.

Diagnosis

I. Rule out extraintestinal causes of diarrhea and weight loss (complete blood count, biochemistry profile, urinalysis), and assess of thyroid, adrenal, and liver function.
   A. Hematological findings are nonspecific, but may include lymphopenia, eosinophilia, neutrophilia, or anemia of chronic disease.
   B. Serum biochemistry profile results are often nonspecific.
      1. With severe malabsorptive disease, hypocholesterolemia, hypoproteinemia, and hypoalbuminemia indicate PLE.
      2. Cats or dogs with IBD may have elevations of liver enzymes and/or hyperglobulinemia.
      3. Electrolyte concentrations are variable, depending on the degree and severity of diarrhea, but hypokalemia is common with severe small bowel diarrhea.
      4. Hypomagnesemia, hypochloremia, and hyponatremia can also occur.
      5. Hypocalcemia (true or pseudo) is a common finding in dogs with PLE from lymphangiectasia (Kimmel et al., 2000).
      6. Serum bile acid concentrations may be increased from concurrent hepatic disease, or may be falsely low owing to deconjugation and loss of bile salts in the GI tract.
II. Fecal examinations are essential.
   A. Perform multiple fecal flotations (more than three) using different flotation media (salt, sugar, zinc sulfate [$ZnSO_4$]), and different methods (direct examination, cytology of fecal smears, Baermann's).
      1. *Giardia* spp. are best detected using a minimum of three $ZnSO_4$ flotations, sugar flotation, or ELISA for giardial antigen.
      2. Diarrhea caused by clostridial overgrowth and enterotoxin production is suggested by finding enterotoxin in the feces using an ELISA assay (Marks and Kather, 2003).
      3. *Cryptosporidia* spp. are difficult to identify because their extremely small oocysts require special microscopy, so an assay for the toxin is the best diagnostic approach.
      4. Fecal cytology may also be useful in identification of *Campylobacter* spp., *Tritrichomonas* spp., *Histoplasma* spp., and other enteric pathogens.
   B. Fecal cultures are important if specific bacterial pathogens are suspected; however, cultures should be followed by PCR assays.
   C. Fecal α_1-protease inhibitor assay detects fecal protein loss in dogs with PLE.
      1. This protein is not affected by intestinal or bacterial degradative processes, but is similar in size to albumin and is lost into the lumen if there is intestinal protein leakage.
      2. The assay has been validated in dogs but not in cats, and requires obtaining three separate, defecated fecal samples.
      3. Send samples directly to the Gastrointestinal Laboratory at Texas A&M University for processing using special collection kits provided.
      4. The assay can be falsely elevated in animals with parasites and other GI disturbances, and from collection problems.
   D. Other fecal tests (fecal fat, proteolytic activity, occult blood) are nonspecific, insensitive, and not recommended.
III. Other serum tests may be helpful in identifying intestinal, pancreatic, or hepatic disease associated with malabsorption.
   A. Trypsin-like immunoreactivity (TLI)
      1. The TLI assay is a species-specific assay for the pancreatic acinar cell enzymes, trypsinogen and trypsin.
      2. Normal serum TLI of dogs is 5.2 to 35 μg/L and of cats is 12 to 82 μg/L.
      3. Serum TLI is unaffected by small intestinal disease, but is markedly low in dogs or cats with exocrine pancreatic insufficiency.
      4. Elevated levels correlate poorly in dogs and only moderately well in cats with acute pancreatitis.
      5. Serum is collected following a fast for 6 to 12 hours.
   B. Serum vitamin concentrations (folate and cobalamin)
      1. Decreased levels of folate occur with severe proximal or diffuse small intestinal disease.
      2. Increased folate levels are observed in animals on parenteral supplementation, and in dogs with exocrine pancreatic insufficiency or with antibiotic responsive enteritis.
      3. Increased levels of folate are also present in hemolyzed blood samples from leakage of the vitamin from RBCs.
      4. A cobalamin deficiency reflects ileal disease, exocrine pancreatic insufficiency, or may occur in the presence of antibiotic responsive enteritis (dogs).
      5. Elevated levels of cobalamin have unknown clinical significance, but may occur with excess parenteral supplementation.
      6. Assays for both cobalamin and folate must be validated and normal values established for each species.
         a. Samples are collected after a 6- to 12-hour fast and stored in darkness, because cobalamin is light sensitive.
         b. Because serum vitamin concentrations can be low in animals with both exocrine pancreatic insufficiency and small intestinal disease, simultaneous serum TLI assay is recommended.
      7. Cats may be more susceptible to cobalamin deficiency because of their increased need for cobalamin.
   C. Measurements of intestinal permeability

1. Tests of intestinal permeability are used to noninvasively determine the presence of intestinal mucosal damage from gluten enteropathy, acute gastroenteritis, IBD, neoplasia, and other diseases.
2. The standard test uses the probe ^{51}Cr-labeled EDTA; however, the marker is not suitable for use in private clinical practice or many referral practices.
3. Other tests use two sugars, one disaccharide (cellobiose, lactulose) and one monosaccharide (mannitol, rhamnose) to determine intestinal permeability by measuring the amount excreted in urine and expression of the results as a ratio.

D. d-Xylose absorption test
1. It has a very low sensitivity for small intestinal disease.
2. It is impractical and cumbersome to perform in most clinical settings and is not recommended.

E. Tests for antibiotic responsive enteritis (previously referred to as *small intestinal bacterial overgrowth*)
1. Increased serum folate and decreased serum cobalamin levels are suggestive but not specific for the problem.
2. Serum unconjugated bile acids increase 10 to 20 times in affected dogs, but an assay is not yet commercially available.
3. At this time, the best diagnostic test is culture of intestinal contents to quantitate bacterial numbers, and isolate known or potential pathogens.
   a. Recent evidence indicates that this method is inadequate for identification of bacterial numbers and species in the intestinal tract (Suchodolski et al., 2005).
   b. DNA technology may be the most reliable and accurate means of identifying and enumerating the wide variety of bacterial species colonizing the intestinal tract, but is only available at research laboratories.

IV. Imaging studies are indicated, but may give nonspecific results and are used to rule out other diseases.
A. Survey abdominal radiography is often normal.
B. Upper GI contrast studies may reveal foreign bodies, masses, intestinal obstruction or intussusception, and gastric or intestinal ulcers (see Chapter 4).
C. Abdominal ultrasonography is used to detect changes in echogenicity of abdominal organs and bowel thickness or irregularities, for identifying lymphadenopathy or other intraabdominal masses, and for obtaining biopsies and aspirates.

V. Endoscopic examination permits direct visualization of the mucosa and provides an opportunity to obtain multiple samples for cytology, biopsy, and culture.
A. In animals with weight loss or chronic diarrhea, samples for biopsy are obtained from multiple sites (stomach, duodenum, ileum, colon).
B. Properly obtained biopsies include submucosa and intact mucosa in the proper orientation (i.e., carefully uncurled and lying flat on a biopsy sponge to maintain orientation).
C. In some cases, endoscopic biopsies may not be sufficient for diagnosis (e.g., focal disease in jejunum unreachable by the endoscope, serosal disease, edematous changes), and full-thickness biopsies may be required.
D. Cytological examination of endoscopically obtained tissue can often be used to make a rapid diagnosis of inflammatory changes present in the mucosa (Jergens, 2003).

VI. Histological examination is essential to document villous atrophy and other architectural changes; verify that lymphatic dilatation is consistent with lymphangiectasia; and confirm neoplastic, inflammatory, or other infiltrative diseases.

VII. Intestinal samples can also be submitted for specialized assays, including analysis for marker enzymes (e.g., lactase, alkaline phosphatase) or cell surface markers cluster differentiation (CD; e.g., CD4, CD8) to help distinguish neoplastic from inflammatory infiltrates.

Differential Diagnosis

I. Exocrine pancreatic insufficiency
II. Hepatopathy resulting in reduced bile production or bile flow
III. Endocrinopathies
A. Hyperthyroidism in cats
B. Diabetes mellitus
C. Hypoadrenocorticism
IV. Dietary intolerance or sensitivity
V. Severe parasitism: heterobilharziasis, giardiasis
VI. Other enteric pathogens: protothecosis, pythiosis

Treatment

I. Specific therapy is directed at correcting or controlling the underlying cause.
A. Exocrine pancreatic insufficiency: see Chapter 36
B. IBD: see the following section
C. PLE and lymphangiectasia: see Protein-Losing Enteropathies
D. Neoplasia: see the following section
E. Parasitic, bacterial, or fungal enteropathies: see earlier
F. Dietary sensitivity: see Chapters 85 and 122
G. Antibiotic responsive enteropathy
1. Antibiotic therapy is most effective if based on culture of intestinal fluid.
2. Antibiotics commonly used for empirical treatment in dogs are as follows:
   a. Tetracycline 10 to 20 mg/kg PO TID for 21 to 28 days
   b. Tylosin 40 to 80 mg/kg PO SID to BID in food
   c. Metronidazole 5 to 15 mg/kg PO BID
   d. Trimethoprim-sulfadiazine 15 mg/kg PO BID
   e. Enrofloxacin 2.5 to 10 mg/kg PO SID to BID

II. General supportive care of malabsorptive diseases involves many options.
A. Feed a highly digestible, low-fat, novel or hydrolyzed protein, low-fiber, or an elemental diet in small quantities.

1. In general, fat is the limiting ingredient, so selection of a diet containing the lowest fat is essential.
2. The lowest fat, highest digestible diet is Royal Canin Low Fat (1.95 g/100 kcal fat).
3. The next lowest diets are Purina Veterinary Diets EN (2.8 g/100 kcal) and Eukanuba Low Residue (2.5 g/100 kcal).
4. In dogs with severe malabsorptive disease, commercially available diets may be inadequate, so homemade novel protein, ultra-low fat diets are needed.

B. Parenteral nutrition is required initially if PLE is severe or until the bowel has time to develop adaptive processes.
C. In dogs with severe PLE and ascites or edema, colloid therapy with hetastarch (5 to 20 mL/kg IV) is helpful.
D. Antibiotic therapy is used to control overgrowth of bacteria.
E. Parenteral vitamin supplementation may be indicated.
1. Cobalamin 250 μg SC, IM weekly or 1 mg SC every 2 weeks for 1 to 3 months
2. Folic acid 1 to 5 mg PO, SC weekly for 1 month
3. Thiamine 10 mg/kg SC, IM SID for 3 to 4 days
4. Tocopherol 100 to 500 IU IM, PO SID with food
5. Vitamin K_1 2 mg/kg PO SID

F. In animals with IBD or lymphangiectasia, antiinflammatory or immunosuppressive therapy with steroids is indicated (see IBD).
G. Histamine$_2$-receptor blockers or proton pump inhibitors are used to control gastric hypersecretion and prevent ulcer development.
1. Ranitidine 0.5 to 1 mg/kg PO, SC SID to BID
2. Famotidine 0.5 to 1 mg/kg PO, SC SID
3. Omeprazole 0.5 mg/kg PO SID

H. Cholestyramine 200 to 300 mg/kg PO BID is administered in dogs to bind bile acids.
I. Loperamide 0.08 mg/kg PO BID to TID is used in dogs for persistent diarrhea not from infectious causes.
J. Special therapy of fungal infection (histoplasmosis) is described earlier.

Monitoring of Animal

I. Warn owners that many cases of malabsorption do not respond immediately to therapy, may require some trial-and-error dietary regimens to achieve a full response, or may not be responsive to therapy at all.
II. Frequent reevaluation is necessary to assess response to therapy, and to make adjustments in the diagnostic and therapeutic approach.
A. Reassessment provides new information when the diagnosis is not apparent on the initial evaluation.
B. Reevaluate serum biochemical and vitamin levels to determine if the therapy has been appropriate.

DIETARY SENSITIVITY AND INTOLERANCE

See Chapters 85 and 122.

INFLAMMATORY BOWEL DISEASES

Definition

I. Eosinophilic enterocolitis is characterized by increased numbers of eosinophils in the stomach, small intestine, or colon.
II. Lymphocytic plasmacytic enteritis (LPE) is characterized by infiltration of the bowel with lymphocytes and plasma cells, and can affect the stomach, small intestine, colon, or all of them.
III. Granulomatous enteritis is characterized by infiltration of macrophages or histiocytes in the lamina propria, and is more common in the distal small intestine and colon of boxers.
IV. Neutrophilic enteritis is characterized by infiltration of neutrophils, may occur at any location in the small or large intestine, and is uncommon in idiopathic IBD.

Causes

I. The etiology of eosinophilic enteritis is unknown, but proposed causes include parasitic infestation, dietary hypersensitivity, and idiopathic disease.
II. Many different causes of intestinal infiltration of lymphocytes and plasma cells exist.
A. Dietary sensitivity
B. Parasitism
C. Bacterial toxins
D. Neoplasia
E. Idiopathic disease

III. Basenjis have a severe, hereditary form of lymphoplasmatic enteropathy (see Table 33-1).
IV. Soft-coated wheaten terriers have a familial PLE that is characterized by severe LPE, lymphangiectasia, and hypoproteinemia; may also be associated with a concurrent PLE; and is most likely an immune-mediated disease with a genetic basis (see Table 33-1).
V. A gluten (wheat)-sensitive enteropathy occurs in Irish setters as an autosomal recessive trait, and is characterized by intestinal infiltration of lymphocytes and plasma cells.
VI. No etiological agent or cause is known for granulomatous or neutrophilic enteritis, or for idiopathic LPE.

Pathophysiology

I. The presence of increased eosinophils, lymphocytes, or plasma cells is likely an immune response to the presence of antigen.
II. If the inflammatory response is significant, it may result in malabsorption owing to changes in the absorptive surface (villous blunting or fusion, crypt abscesses, or fibrosis), lymphatic obstruction, or exudation of protein from the inflammatory effects on epithelial cell function.
III. Eosinophils are chemotactic for other cells, including mast cells, and may result in a local type I hypersensitivity or delayed hypersensitivity reaction to antigens presented to the GI mucosa.
IV. Although the exact etiology of LPE is unknown, an aberrant immune response to luminal antigen (bacterial, parasitic, dietary) is presumed to be the triggering event.

A. Once the mucosa is infiltrated with inflammatory cells, mediators (C-reactive protein, cytokines) are released and trigger the pathogenic effects observed.
B. Intestinal inflammation may be mild or severe, but the effects of the inflammatory changes in the mucosa include malabsorption, vomiting, diarrhea, weight loss, hypoproteinemia, or more widespread effects, such as cholangiohepatitis or pancreatitis.

Clinical Signs

I. Anorexia, weight loss, vomiting, and diarrhea are common signs.
II. Diarrhea may be small bowel, large bowel, or a combination.
III. Enterocolitis is common in cats with eosinophilic IBD.
IV. Melena or hematochezia is observed more frequently with eosinophilic enteritis than with LPE.
V. Doberman pinschers, boxers, and German shepherd dogs may be predisposed to eosinophilic IBD.
VI. Thickened bowel loops may be palpable in cats with severe LPE.
VII. Severe IBD may be associated with concurrent ascites, coagulopathies, cholangiohepatitis, thromboembolic disease, and nephropathies.
VIII. Histiocytic enterocolitis in boxers causes severe hematochezia and large-bowel diarrhea.

Diagnosis

I. See the diagnostic approach for Disorders of Malabsorption.
II. There are no specific hematological or biochemical abnormalities.
   A. Occasionally, neutrophilia or eosinophilia are observed.
   B. In cats, if eosinophilia is significant, hypereosinophilic syndrome (HES) must be considered.
   C. Dogs with severe eosinophilic enteritis are more likely to have significant anemia or hypoproteinemia (from gastroduodenal ulceration or mucosal bleeding).
   D. In LPE, nonregenerative anemia (from chronic inflammation or intestinal blood loss) and mild thrombocytopenia are relatively common changes.
   E. There are no pathognomic changes in serum biochemistries, but abnormalities include hypoproteinemia, hypoalbuminemia, hyperglobulinemia, elevations in liver enzyme concentrations, and electrolyte abnormalities.
III. Fecal examinations are essential for eliminating endoparasites and protozoal infections.
IV. Serum folate and cobalamin concentrations are important indicators of the severity of mucosal disease.
   A. Subnormal folate concentrations occur in proximal disease, whereas low concentrations of cobalamin (vitamin B_{12}) are associated with distal small bowel disease.
   B. Although not diagnostic for IBD, they indicate the need for further evaluation (biopsy) and supplementation.
V. Diagnostic imaging is important to document disease outside the GI tract, further define the extent of intestinal disease, and identify changes compatible IBD, such as mesenteric lymphadenopathy, thickened bowel loops, and concurrent pancreatic inflammation or liver changes (occasionally in cats).
VI. Definitive diagnosis of IBD requires biopsy of the affected bowel.
   A. Biopsy may be obtained via endoscopy or laparotomy.
   B. Surgical biopsies are indicated if there is multiple organ involvement, if endoscopic biopsies are nondiagnostic, or if the disease is distal.
   C. Classic findings in IBD are increased numbers of inflammatory cells infiltrating the lamina propria and submucosal tissues of the intestine in association with changes of mucosal architecture.
   D. Severe IBD is associated with villous blunting, mucosal ulceration, and other severe mucosal irregularities, which may include lymphangiectasia.

Differential Diagnosis

I. Causes of chronic intestinal inflammation: *Giardia* spp., histoplasmosis, protothecosis, pathogenic bacteria, etc.
II. Dietary sensitivity or intolerance
III. Cancers of the small bowel causing LPE-like changes, especially lymphoma
IV. Other primary GI diseases, such as lymphangiectasia
V. HES in cats
   A. Infiltration of eosinophils occurs in multiple organs, including the bone marrow, spleen, liver, intestines, and lymph nodes.
   B. Signs mimic eosinophilic IBD (diarrhea, vomiting, weight loss, anorexia) and may involve other organ systems (splenomegaly, anemia, dermatologic signs).
   C. HES can be distinguished from eosinophilic leukemia by mature eosinophils instead of the immature or blast cells observed with leukemia.
   D. Response to treatment with prednisolone is poor in HES, whereas a good response is expected in eosinophilic IBD.

Treatment

I. Hypoallergenic or novel protein diets, elimination diets, or hydrolyzed protein diets are recommended.
   A. Dietary therapy alone may result in resolution when dietary hypersensitivity is the cause of the inflammatory infiltrates.
   B. Novel, single-antigen or hydrolyzed protein diets reduce the antigenic stimulus and are recommended even when dietary hypersensitivity is ruled out.
   C. Low-residue or highly digestible diets are also alternatives, especially when a low-fat diet is required to prevent further malabsorption.
   D. If homemade diets are used in dogs, well-cooked rice, potatoes, and tapioca are highly digestible, gluten-free carbohydrate sources.
II. Administer appropriate treatment for intestinal parasitism, because it is difficult to identify all parasites with fecal examination.

A. Fenbendazole 50 mg/kg PO SID for 3 to 5 days is appropriate for most intestinal parasites of dogs and cats.
B. Pyrantel pamoate has a narrower spectrum of activity, but is safer in sick dogs or cats.
1. Cats: 10 mg/kg (1 mL/5 lb) PO once
2. Dogs: 5 mg/kg (1 mL/10 lb) PO once

III. Immunosuppressive doses of prednisone reduce the inflammatory and immunological stimulus within the GI tracts once infectious or parasitic causes are ruled out.
A. Give prednisolone 1 to 2 mg/kg PO BID for 3 to 6 weeks in dogs and 2 to 3 mg/kg PO BID in cats, then taper over several months.
B. In cats, methylprednisolone at 1 mg/kg PO BID may be more effective.
C. Some animals require long-term therapy to control the clinical disease, whereas others can be tapered to low QOD doses.
D. A few animals are eventually maintained with diet alone, but these are likely to be animals with a primary dietary sensitivity, not idiopathic eosinophilic IBD.

IV. Antibacterial therapy is generally justified in IBD since secondary overgrowth of bacteria or development of antibiotic responsive enteritis is relatively common, and because bacterial antigens are believed to be of major importance in the development of IBD.
A. Metronidazole is the preferred drug in both dogs and cats for initial therapy.
B. Tylosin may also be effective and has immunomodulatory effects (similar to metronidazole).
C. In severe cases of IBD, fluoroquinolones (enrofloxacin) may be indicated.
D. Bacterial overgrowth is not recognized in cats, but antibiotic therapy with metronidazole is often helpful in the management of IBD.

V. In animals that do not respond to steroid therapy, or have severe steroid-associated side effects, other immunosuppressive drugs may be tried.
A. Dogs: azathioprine 1 to 2.5 mg/kg PO SID to QOD; bone marrow toxicity monitored via frequent CBCs
B. Dogs: cyclosporine 5 mg/kg BID PO; efficacy variable, toxicity problematic, requires blood level monitoring
C. Cats: chlorambucil 1.5 mg/m^2 PO SID to QOD

Monitoring of Animal

I. The prognosis for dogs and cats with eosinophilic IBD is good, and a positive response to therapy can be expected.
A. The more extensive the lesions and severe the disease (e.g., ulcerations, villous atrophy), the more difficult it is to achieve remission.
B. German shepherd dogs are more difficult to control and are more likely to have other concurrent GI abnormalities.

II. The prognosis for LPE varies, depending on the severity of clinical disease, histological changes, and initial response to therapy.
A. In some cases, a single course of drug therapy is all that is required to achieve an apparent cure, whereas others may require lifelong (diet and/or immunosuppressive) therapy.
B. Rarely, cats with LPE develop alimentary lymphoma.

III. In animals with familial or genetic enteropathies, the prognosis is guarded to poor (see Table 33-1).

IV. The prognosis for granulomatous and neutrophilic IBD is unpredictable, but may be guarded depending on the severity and initial response to therapy.

PROTEIN-LOSING ENTEROPATHIES

Definition and Causes

I. PLEs are characterized by increased loss of both small (albumin) and large (globulin) proteins into the GI tract.

II. PLE may be primary or secondary to diseases affecting the bowel (Peterson and Willard, 2003).
A. Examples of inflammatory diseases: IBD, histoplasmosis, other granulomatous diseases
B. Diseases causing villous atrophy: gluten enteropathy, severe viral enteritis, bacterial enteritides
C. Severe parasitic enteropathies in young animals
D. Giardiasis in heavily infested adult dogs
E. Chronic obstructive diseases: intussusception, neoplasia
F. Diseases causing intestinal ulceration or erosion (Table 33-3)
G. Diseases affecting the intestinal lymphatic system
1. Lymphangiectasia is characterized by dilated submucosal, subserosal, and/or mesenteric lymphatics.
2. Primary or congenital lymphangiectasia may occur.
a. Lymphangiectasia is seen in the Norwegian lundehund and small terrier breeds (e.g., Yorkshire, Maltese).
b. Even though the disease is congenital, clinical signs do not occur until lipogranulomatous lymphangitis develops, which is progressive.
3. Acquired or secondary lymphangiectasia may be idiopathic (intestinal lymphatic obstruction from an unknown cause) or may develop secondary to other diseases of the GI tract (e.g., neoplasia, IBD) that cause obstruction of the lymphatics, to thoracic duct obstruction, or to right-sided congestive heart failure.

Pathophysiology

I. It is normal for protein to be lost into the small intestine; however, this protein is usually digested, absorbed, and reused to make new protein.

II. Loss of protein is accelerated in animals with intestinal mucosal or malabsorptive diseases, or lymphatic obstruction.

III. Hypoproteinemia occurs when the rate of GI loss of protein exceeds the liver's ability to synthesize protein.

IV. Hypoproteinemia manifests initially as hypoalbuminemia, with a subsequent reduction in plasma oncotic pressure, but eventually larger proteins are lost and hypoglobulinemia also occurs.

TABLE 33–3

Ulcerogenic Diseases of the Small Intestine

CAUSES	CLINCAL SIGNS	DIAGNOSIS	TREATMENT
Neoplasia Mast cell tumors and mastocytosis Gastrin-secreting tumors (gastrinoma) Hypergastrinemia Secondary to liver disease Secondary to renal disease Drug induced: prolonged use of H_2 blockers or antacids Drug induced NSAIDs Corticosteroids Idiopathic Hypovolemic shock with ischemia	Diarrhea ± gross melena Vomiting with or without hematemesis Weight loss, and anorexia or decreased appetite common Abdominal pain in severe cases Anemia in animals with chronic or severe blood loss	History and appropriate clinical signs are suggestive Lab findings nonspecific but support blood loss (elevated BUN, normal creatinine, decreased total protein and albumin) Liver or renal disease causing hypergastrinemia are supportive. Severe hypergastrinemia from gastrin-secreting tumor is rare, but measurement of serum gastrin is suggestive The definitive diagnosis of ulcerative disease is by visualization of the mucosal defects (endoscopy, specialized imaging studies, or surgery)	Replace blood loss with whole blood if animal is in shock or in respiratory distress Stop all medications that may cause ulcers Decrease gastric acid secretion: Omeprazole 0.5-1.0 mg/kg PO, SC SID Famotidine 0.5-1 mg/kg PO, SC, or IV SID-BID Ranitidine 1-4 mg/kg PO, SC BID-TID Control vomiting Metoclopramide 0.2-0.5 mg/kg PO, SC, or IV TID-QID Prochlorperazine 0.25-0.5 mg/kg IM BID-TID Ondansetron 0.5-1.0 mg/kg IM BID-TID Dolasetron 0.3-0.6 mg/kg SC SID-BID Provide mucosal protection with sucralfate 1 g/25 kg PO TID Withhold food until vomiting is controlled for 24-48 hr Institute specific treatment of primary disease

H_2, Histamine$_2$; *NSAIDs*, nonsteroidal antiinflammatory drugs; *BUN*, blood urea nitrogen.

V. Because coagulation proteins and immunoglobulins are also lost, a dysfunction of the clotting system or abnormal immune responses may arise.

Clinical Signs

I. The most common presenting clinical sign is weight loss.
II. Chronic diarrhea may occur, but is inconsistent and depends on the cause and duration.
III. Diarrhea may be intermittent or continuous, is usually small bowel in character, and may be associated with hematochezia.
IV. Vomiting, anorexia, and lethargy are variable, depending on the cause.
V. Severe PLE may cause peripheral edema, ascites, or pleural effusion, and may be associated with abnormal clotting (increased risk of thromboembolism).

Diagnosis

I. Although signs of diarrhea or vomiting may not occur, most affected animals have weight loss, so an initial assessment must include a work-up for weight loss.
II. Classic abnormalities on hematology and biochemistry profiles include hypoalbuminemia, hypoglobulinemia, hypocholesterolemia, hypocalcemia (true or pseudo), hypomagnesemia, lymphopenia, and mild anemia of chronic disease.
III. Ascites is a pure transudate if it arises from pure loss of albumin, but may be a modified transudate if right heart failure is present, and in rare cases may be chylous if there is a thoracic duct lesion.
IV. Other causes of hypoproteinemia (liver disease, protein-losing nephropathy) must be excluded.
   A. Urinalysis, urine protein: creatinine ratio
   B. Measurement of serum bile acids, other assessments of liver function
   C. Analysis of any ascitic fluid to further identify a cause
   D. Fecal α_1-protease inhibitor assay to assess the presence of GI protein loss (see Disorders of Malabsorption)
V. Also assess for other causes of GI disease (see Disorders of Malabsorption or Inflammatory Bowel Diseases).
VI. Definitive diagnosis of intestinal protein loss is supported by histological evidence of disease(s).

A. Because hypoproteinemia may decrease healing and increase the risk of leakage of biopsy sites or dehiscence of the incisions, endoscopic examination is preferred in animals with severe hypoproteinemia.
B. Some dogs with lipogranulomatous lymphangitis do not have significant mucosal abnormalities in the early stages of the disease; in these dogs, full-thickness biopsies are needed to obtain a definitive diagnosis.
C. Many animals with PLE have a normal-appearing intestinal tract at endoscopy or surgery, so it is imperative that biopsies be taken.
D. Endoscopic evaluation of a classic lymphangiectasia reveals lipid droplets on the surface or prominent, chyle (lipid)-filled villous tips.
E. In dogs with severe edema or ascites from hypoproteinemia, mucosal edema must be corrected with hetastarch before biopsy to assure that diagnostic specimens are obtained.
F. Feeding corn oil (1 tbsp) 6 to 8 hours before the endoscopic or surgical biopsy procedure results in maximum dilation of the lacteals, and may increase the likelihood of obtaining a diagnosis.

Treatment and Monitoring

I. When identified, correct the primary cause of the enteropathy (i.e., administer immunosuppressive therapy for IBD and lipogranulomatous lymphangitis or antifungal therapy for histoplasmosis).
II. The most important aspect of dietary therapy is to feed a low-fat, highly digestible diet to minimize fat malabsorption and lymphatic leakage (Zoran, 2003).
   A. A homemade diet is often the best choice for dogs with severe PLE that have a selective appetite, because it can be formulated to include ultra-low–fat content, novel protein, and highly digestible carbohydrate sources.
      1. One example consists of no-fat cottage cheese, egg whites, or turkey breast as the protein sources, and boiled potatoes (without the skins) or well-cooked white rice as the carbohydrate sources.
      2. Initially, no other fat source is added, but eventually, a small amount of oil (corn oil) must be added to provide essential fatty acids in the diet.
   B. Commercially available, ultra-low–fat (<3 g/100 kcal fat) diets may be adequate in less severe cases.
      1. The lowest fat, commercially available diet that is not also a high-fiber diet is Royal Canin Low Fat.
      2. Hydrolyzed diets also may be well tolerated, but they are not all low in fat.
      3. Purina Veterinary Diets H/A has the lowest fat content of the commercially available hydrolyzed diets.
   C. In dogs that are unable to eat (vomiting, severe diarrhea) nutritional support via total parenteral or partial parenteral nutrition may be needed, especially in dogs that are severely cachetic and edematous.
   D. If hypoproteinemia is severe, but the animal is able to eat, low-fat elemental diets (e.g., *Vivonex*) may be used instead of or in addition to commercial diets.
III. For dogs with severe coagulation protein loss that have a coagulopathy, plasma therapy (10 to 20 mL/kg IV) can be used to provide these proteins, but it is ineffective in increasing serum protein levels.
IV. Following diagnosis and institution of appropriate therapy, reevaluate body weight, serum protein concentrations, and any biochemical abnormalities found on initial presentation.

ULCEROGENIC DISEASES

See Table 33-3.

INTESTINAL OBSTRUCTION

Definition

I. Partial or complete obstructions of the small intestine are caused by intraluminal, intramural, or extramural lesions that slow or prevent passage of intestinal contents.
II. Functional obstruction is caused by ileus arising from neurogenic, myogenic, or humoral mechanisms.
III. Obstructions are also classified as to whether they are partial or complete, and whether they are simple or strangulated.
IV. Complete or strangulated obstructions result in a medical and surgical emergency necessitating an immediate response (see Chapter 39).

Causes

I. Intraluminal causes include neoplasia, polyps, foreign bodies (both linear and other), and intussusception.
II. Intramural obstruction is caused by neoplasia, abscesses, granulomas, congenital stenosis and atresia, and inflammatory lesions.
III. Extramural lesions include adhesions, strangulation (mesenteric or organ volvulus), strictures (secondary to surgery), and neoplastic masses incarcerating the bowel or adjacent structures.
IV. Functional obstruction of the bowel is caused by hypomotility and ileus, which may be idiopathic or may occur secondary to infectious or inflammatory diseases (e.g., parvovirus).

Pathophysiology

I. Obstructions in the bowel are also classified according to their location and their relative effects on fluid, electrolyte, and acid-base balance.
   A. High small intestinal obstructions of the duodenum or upper jejunum result in frequent vomiting and a rapid onset of dehydration with severe hypokalemia and metabolic acidosis.
   B. If the high obstruction is a gastric outflow obstruction, hypochloremic metabolic alkalosis is observed.
   C. Lower small intestinal obstructions are often associated with a slower onset of dehydration and vomiting, but diarrhea may be common.
      1. These cases frequently have hypokalemia, hyponatremia, hypochloremia, and metabolic acidosis.

2. Cats are more prone to develop low obstructions.

II. Another effect is alteration in normal GI motility, with subsequent alterations in bacteria and/or bacterial overgrowth, increased bacterial absorption, and development of endotoxemia and septicemia.

III. Intestinal strangulation, intussusception, or incarceration interfere with vascular integrity, resulting in segmental bowel stasis or death, and the animal is often presented in shock or a state of collapse.

IV. Partial, low obstruction or sliding intussusception may be chronic and cause intermittent clinical signs of malabsorption or small intestinal bacterial overgrowth.

Clinical Signs

I. Signs depend on the location, severity, and amount and location of bowel affected.

II. Duration of the process and effects on bowel integrity and function, as well as bacterial translocation, are also important factors in determining the clinical signs.

III. The most common signs are vomiting, anorexia, and lethargy.

IV. Other signs may include diarrhea (especially with lower obstructions), abdominal pain (with bowel strangulation or loss of vascular integrity), and severe dehydration or collapse from hypovolemia, endotoxemia, or septicemia.

Diagnosis

I. Compatible history, signalment, and physical examination findings are suggestive.

II. Palpation may reveal abdominal pain, a mass lesion, intestinal bunching (typical of string foreign bodies) or intussusception.

III. Laboratory findings are variable.
   A. The hemogram is often normal, but neutrophilia or neutropenia, a left shift, evidence of toxic change, and anemia of chronic disease may all be observed.
   B. The biochemical profile is used to rule out other causes of vomiting and anorexia (e.g., pancreatitis, liver disease, renal failure) and to assess electrolyte abnormalities (especially potassium, chloride, sodium, and magnesium).
   C. Prerenal azotemia or hepatic enzyme elevations are common in severely dehydrated or sick animals.

IV. Imaging studies are necessary when palpation is nondiagnostic.
   A. Plain radiography may reveal dilated loops of bowel present proximal to the obstruction, radiopaque foreign objects, intestinal pleating typical of linear foreign bodies, and/or evidence of functional obstruction (ileus of all bowel loops).
   B. Horizontal beam radiography (standing lateral) may show an interface of fluid and gas, with a complete obstruction having gas caps at different levels.
   C. Positive contrast studies can be used to identify obstructions that are partial, low, or intermittent, especially when survey films are inconclusive; however, in vomiting animals aspiration of the material can be life-threatening.
   D. Ultrasonography is used to identify partial or low obstructions, intussusceptions, and mesenteric volvulus or strangulation of bowel.

V. Exploratory laparotomy is necessary if the clinical signs or laboratory data indicate an obstruction, but imaging studies are inconclusive.
   A. Surgery is an acceptable means of confirming the diagnosis, especially if the clinical status is deteriorating in the face of no diagnosis.
   B. Intestinal volvulus, strangulation, and sliding intussusceptions are difficult to diagnose and may only be seen at surgery.

Differential Diagnosis

I. Pancreatitis

II. Hypoadrenocorticism

III. Acute renal or hepatic failure

IV. Severe infectious or inflammatory intestinal diseases

V. Ingestion of toxins

VI. Other causes of acute abdomen (see Chapter 39)

Treatment

I. Stabilize the animal with aggressive fluid therapy and electrolyte supplementation.
   A. Crystalloid therapy (lactated Ringer's solution, Normosol-R) is adequate in most cases, but hetastarch or other colloids are important in severely hypovolemic or shocky animals.
   B. Potassium supplementation (10 to 40 mEq/L) is essential if hypokalemia is present.

II. Parenteral broad-spectrum antibiotic therapy is initiated to combat bacterial overgrowth or translocation, and endotoxemia or septicemia (see Viral or Bacterial Infections).

III. Antiemetics may be considered to control vomiting, but some (metoclopramide) are contraindicated in animals with complete intestinal obstruction or must be used with caution (chlorpromazine) in severe hypovolemia.

IV. Aggressively treat hypoglycemia, systemic inflammatory response syndrome, and DIC arising from endotoxemia.

V. Definitive therapy is surgical intervention.
   A. A variety of surgical remedies are available, including enterotomy, resection and anastomosis, reduction of the intussusception and bowel plication, repair of hernias, and volvulus and mesenteric repair.
   B. Intestinal biopsies are obtained if there is any doubt about the possible cause of the problem.

Monitoring of Animal

I. Careful postoperative monitoring is essential for a successful outcome, especially in those animals that are endotoxemic or septic.
   A. Monitor PCV, TP, vital signs, electrolytes, blood glucose, and fluid status (CVP, capillary refill time, body weight, urine output) closely.
   B. With significant bowel resection or disturbance, oral alimentation is initiated as soon as possible (12 to 18 hours postoperatively) to provide nutrition for the

GI tract, help prevent postoperative ileus, and provide support for recovery and healing.
C. If the animal refuses to eat or is unable to eat because of persistent vomiting, parenteral nutrition must be considered.

II. The prognosis is guarded to good, depending on the severity of the obstruction, the cause, and the presence of any complicating factors (e.g., DIC, endotoxemia, peritonitis).

NEOPLASIA

Definition and Causes

I. The most common malignant tumors of the small intestine in dogs and cats are adenocarcinoma and lymphosarcoma (LSA).
A. Intestinal adenocarcinoma only accounts for 1% of all tumors, so it is relatively rare.
B. Adenocarcinomas appear to be more common in the boxer, collie, poodle, West Highland white terrier, German shepherd dog, Doberman pinscher, and Siamese cats.

II. GI lymphoma is the second most common form of LSA in dogs and the most common form in cats.
A. Intestinal LSA may be of B or T cell origin or a large granular lymphocyte subtype, and the behavior of the tumor is dependent on its type.
B. There is no apparent breed predisposition in cats, but in dogs, the boxer, shar-pei, golden retriever, English springer spaniel, Doberman pinscher, Labrador retriever, and German shepherd dog appear to be predisposed.

III. Other malignant neoplasms affecting the small intestine include mast cell tumors (cats), leiomyosarcomas, and carcinoid tumors.

IV. Leiomyosarcomas are more common in large-breed dogs, especially German shepherd dogs.

V. Benign tumors of the intestinal tract include leiomyomas, polyps, fibromas, lipomas, and adenomas.

VI. The inciting cause of intestinal neoplasia is unknown; however, LSA may be observed in cats with chronic IBD or previous exposure to FeLV (most cats are FeLV negative).

Pathophysiology

I. The etiology of small intestinal adenocarcinoma is unknown, but a genetic predisposition is likely.
A. These tumors typically cause an obstruction of the intestine because they form annular, constrictive lesions.
B. They can form in any segment of the intestine, but are most common in the distal jejunum or ileum in cats and in the colon in dogs.

II. The etiology of LSA is unknown in most cases, but IBD may be a predisposing factor.
A. LSA of the small intestine may occur as a diffuse, infiltrative lesion affecting large segments of bowel with thickening of the bowel wall, as a classic malabsorptive syndrome, or as an obstructive mass.
B. LSA in the cat may arise as a low-grade disease that grows slowly over months or years and may be difficult to distinguish from IBD.
C. LSA may occur in both dogs and cats as a rapidly advancing, high-grade malignancy.

III. Leiomyosarcomas tend to create large masses and have been more often associated with paraneoplastic hypoglycemia.

IV. Mast cell tumors (especially in cats) tend to be infiltrative.

Clinical Signs

I. Clinical signs are dependent on the location of the lesion, the type of lesion (mass effect or infiltrative disease), the rate of development, and other effects initiated by the presence of the tumor.
A. Intestinal adenocarcinoma is often slow growing, so weight loss in the absence of other signs is a frequent finding in the early stages, which may be months.
1. Once an obstructive lesion develops, vomiting or diarrhea (with or without blood) occurs.
2. Metastasis to the liver, mesenteric lymph nodes, peritoneal cavity, other intestinal sites or lungs is common and has usually occurred by the time of diagnosis.
B. Signs of GI LSA are variable.
1. Solitary mass lesions may cause signs of an obstruction, including vomiting or diarrhea, anorexia, and weight loss.
2. Diffuse small-cell LSA may be very insidious, resulting in weight loss, signs of malabsorption or diarrhea (especially in cats), and is easily confused with IBD.
3. Dogs with LSA tend to have a more acute illness and are more likely to develop hypercalcemia.
4. Lymphoblastic LSA may develop very quickly and is often associated with severe malabsorptive disease, melena, and other GI signs.
C. Other intestinal tumors typically cause signs of obstruction (e.g., vomiting, diarrhea, anorexia, weight loss) and may result in a nonregenerative anemia of blood loss.
D. Intestinal mastocytosis of cats is more likely to be associated with intestinal blood loss than other GI tumors.

II. Clinical signs of weight loss or diarrhea in an older animal should warrant an investigation.

III. Physical examination may reveal weight loss or thin body condition (especially cats), but may be otherwise unremarkable.
A. Alternatively, diffuse intestinal thickening or intestinal or abdominal masses may be palpated.
B. In dogs or cats with diffuse abdominal carcinomatosis, ascites or peritonitis may be present.
C. Hepatosplenomegaly is also possible in dogs with diffuse, multicentric LSA.

IV. The most common clinical signs are vomiting, diarrhea, anorexia, and weight loss.

Diagnosis

I. A compatible history, signalment, and physical examination findings are suggestive.

II. Laboratory results are often variable and nonspecific.

A. The hemogram may be normal, or a nonregenerative anemia of chronic disease or iron deficiency may be seen.
B. The biochemistry profile is used to assess albumin levels (intestinal protein loss), electrolytes (loss), or other organ system dysfunction.
C. Specific testing, to rule out pancreatitis (see Chapter 36) may be needed in some cases.
D. Abdominal radiography frequently reveals intestinal abnormalities, masses, abnormal organ position, or abnormal gas patterns.
E. Thoracic radiography is used to rule out metastatic disease.
F. Abdominal ultrasonography is also used to identify masses, abdominal lymphadenopathy, or obstructive lesions in the bowel wall.

III. Definitive diagnosis is made by histopathologic evaluation of biopsies.

Differential Diagnosis

I. Lymphoma: IBD, chronic giardiasis, chronic pancreatitis (cats), cholangiohepatitis (cats), other infiltrative GI diseases or PLE (dogs), severe bacterial overgrowth
II. Adenocarcinoma: foreign body, intussusception, pythiosis granuloma, IBD, LSA, mast cell tumor in the cat, smooth muscle tumors
III. Other intestinal neoplasms: causes of intestinal obstruction, malabsorptive disease

Treatment and Monitoring

I. LSA
A. Focal LSA may be cured with complete surgical resection if margins are clean, but most LSA that is diffuse or has nodal or hepatic involvement requires chemotherapy to provide a good quality of life for a prolonged period.
B. Specific chemotherapy depends on the type and location of LSA (see Treatment and Monitoring under Neoplasia in Chapter 31; see also Chapter 69).

II. Adenocarcinoma
A. Surgical resection is the treatment of choice for intestinal adenocarcinoma.
B. Recurrence is likely even with wide surgical margins, but may provide clinical remission for 6 to 12 months.
C. Chemotherapy is generally unsuccessful.

III. Leiomyosarcoma: surgical resection may provide long-term survival (slow growing).
IV. Intestinal mast cell tumors (cats)
A. Surgical resection is beneficial, but early metastasis is common.
B. Chemotherapy is necessary in diffuse mastocytosis or in cats in which resection is not associated with clean margins.

CHAPTER 34

Diseases of the Large Intestine

Lisa E. Moore | Rhea V. Morgan

CONGENITAL DISORDERS

See Table 34-1.

DEGENERATIVE DISORDERS

Megacolon

Definition

I. Megacolon is flaccid distension and enlargement of the colon and rectum.
II. It usually arises from either mechanical obstruction or functional abnormalities of the distal colon, rectum, or anus.
III. Although congenital forms are rarely recognized, megacolon is usually an acquired disorder.

Causes

I. Mechanical obstructions
  A. Narrowing of the pelvic canal
    1. Pelvic fractures or luxations
    2. Prostatomegaly
    3. Enlargement of the iliac lymph nodes
    4. Neoplasia: bony, prostatic, urogenital
  B. Distal colonic or rectal foreign body
  C. Colonic or rectal neoplasia, granulomas
  D. Strictures
  E. Chronic, recurrent obstipation
II. Functional disorders
  A. Dysautonomia (rare)
  B. Sacral spinal cord or pelvic nerve dysfunction
  C. Autonomic ganglioneuritis in dogs (rare)
III. Idiopathic acquired megacolon of cats

Pathophysiology

I. In acquired megacolon, generalized dysfunction of the colonic smooth muscle occurs.
  A. In some cases, abnormalities of smooth muscle myofilaments cause disruption of colonic motility, which results in constipation and obstipation, and subsequent distension of the colon.
  B. In other cases a permanent functional abnormality may arise after recurrent or chronic constipation and obstipation from varying causes.
  C. The exact pathogenesis of acquired megacolon in cats is not well understood, but may involve both mechanisms.
II. Water continues to be absorbed from retained fecal matter, which results in very hard feces that cannot be passed.

Clinical Signs

I. History of prior pelvic trauma, prostatic diseases, recurrent episodes of constipation or obstipation
II. Unsuccessful attempts to defecate
III. Passage of only small amounts of liquid feces
IV. Possible fresh blood in the fecal material
V. Anorexia, vomiting
VI. Lethargy, dehydration
VII. ± Weight loss in affected cats

Diagnosis

I. On palpation the colon is grossly enlarged and filled with hard feces.
II. Rectal examination is essential to help determine an underlying cause.
  A. Evidence of anal or rectal strictures or masses
  B. Narrowing of the pelvic canal from fractures
  C. Detection of prostatomegaly or lymphadenopathy
  D. Palpable masses of the vagina or urethra
III. Radiography may reveal the following:
  A. Recent or healed pelvic fractures or luxations
  B. Colon distended with dense feces
  C. Possible colonic foreign material (including ingested bones)
  D. Organomegaly of adjacent structures
  E. Fractures, separation of the tail, or other spinal abnormalities
IV. Colonoscopy, biopsy, and histopathology may be required to definitively diagnose neoplasia and other causes.

Differential Diagnosis

I. Other causes of tenesmus, especially colitis and proctitis
II. Causes of stranguria (which is misinterpreted as tenesmus)

Treatment

I. Fluid therapy is indicated for dehydrated animals.
II. Impacted fecal material is removed when the animal is stable.

TABLE 34–1

Uncommon Disorders of the Large Intestine in Dogs and Cats

DISORDERS, SIGNS	DIAGNOSIS	TREATMENT
Disorders That Cause Acute Diarrhea		
Infectious agents		
Giardiasis	Fecal smear, $ZnSO_4$ concentration, antigen test	Fenbendazole
Salmonella spp.	Blood and fecal culture (special media)	Enrofloxacin, amoxicillin, trimethoprim–sulfa
Campylobacter spp.	Fecal smear, culture (special media)	Erythromycin, aminoglycosides
Yersinia enterocolitica	Blood and fecal culture (special media)	Chloramphenicol, aminoglycosides, cephalosporin
Entamoeba histolytica	Fecal smear with methylene blue	Metronidazole
Balantidium coli	$ZnSO_4$ concentration, fecal smear	Metronidazole, tetracycline
Heterobilharzia americana	Fecal smear, biopsy	Fenbendazole ± praziquantel
Cryptosporidium spp.	Fecal smear with special stain*	Controversial—possibly tylosin
Corticosteroid-associated ulceration in dogs with neurological disease	Physical examination, colonoscopy	Discontinue corticosteroid therapy as soon as possible; abdominal surgery may be needed
Secondary to severe pancreatitis	Physical examination, ultrasonography (see Chapter 36)	Manage pancreatitis aggressively (see Chapter 36)
Disorders That Cause Chronic Diarrhea		
Congenital abnormalities		
Vascular ectasia	Colonoscopy, biopsy	Surgical resection of the affected area
Short colon	Colonoscopy, barium enema	Low-residue diet
Enterocyst	Ultrasonography, exploratory surgery	Surgical resection
Histoplasmosis	Rectal scraping for cytology, biopsy	Itraconazole (see Chapter 111)
Protothecosis (dogs)	Rectal biopsy	Itraconazole
Ileocolic intussusception	Ultrasonography, exploratory surgery	Surgical resection
Cecal inversion	Ultrasonography, exploratory surgery	Surgical resection
Extramedullary plasmacytoma	Ultrasonography, exploratory surgery	Melphalan, prednisone
Disorders That Cause Constipation		
Congenital abnormalities		
Atresia, stenosis	Physical examination	Reconstructive surgery
Colonic duplication	Colonoscopy, barium enema	Surgical resection
Dysautonomia	Physical examination, pharmacological ocular function testing, plasma catecholamine levels	Supportive care (see Chapter 105)
Colorectal diverticulum	Rectal examination, barium enema	Surgical resection
Benign colorectal stricture	Colonoscopy, biopsy	Surgical resection; treatment of underlying cause

Modified from Bunch SE, Jergens AE: Diseases of the large intestines. p. 377. In Morgan RV, Bright RN, Swartout MS (eds): Handbook of Small Animal Practice. 4th Ed. WB Saunders, Philadelphia, 2003.
*Carbol-fuchsin, crystal violet.

A. Initially, warm-water enemas may be tried, but these efforts are usually successful only if the fecal mass is relatively soft.
B. General anesthesia, colonic lubrication, and digital evacuation are often needed.
   1. The feces are broken up by a combination of infusion of lubricating liquid (e.g., warm soapy water, diluted water-soluble jelly) and digital manipulation.
   2. Care must be taken to avoid damaging the colonic mucosa and perirectal tissues, especially if forceps are used to extract fecal material.

III. The underlying cause must also be addressed.
IV. Preventative measures are instituted because recurrences are common, especially with functional disorders or when the underlying cause is difficult to rectify.
   A. Add fiber in the form of psyllium, oat bran, or canned pumpkin to the diet.

B. Encourage frequent defecation.
C. Consider laxative therapy.
   1. Lactulose 2 to 10 mL PO TID titrated to maintain soft stools
   2. Docusate sodium (dioctyl sodium sulfosuccinate [DSS]) 50 mg PO SID to BID
D. Administer a smooth-muscle prokinetic agent, such as cisapride (not available commercially).
   1. In vitro studies of normal cats indicate that cisapride effectively stimulates longitudinal contractions.
   2. If given early, cisapride may prevent progression of constipation and dilated colon in cats (Washabau and Holt, 1999).
   3. Cisapride may not be beneficial in severe cases.
   4. Dose in cats is 2.5 to 5 mg PO BID to TID.
   5. Dose in dogs is 0.1 mg/kg PO BID to TID.
E. Erythromycin at 0.5 to 1.0 mg/kg PO TID may stimulate colonic motility in dogs.
F. Nizatidine 2.5 to 5 mg/kg PO SID and ranitidine 1 to 2 mg/kg PO BID may also stimulate colonic motility in cats (Washabau et al., 1996).

V. Surgical subtotal colectomy is indicated for cats with idiopathic megacolon that fail to respond to medical therapy and experience recurrent, severe obstipation.
   A. Many cats have normal enteric function and require minimal continued medical management after surgery.
   B. Soft or diarrheic stools are not common sequelae.
   C. The procedure is done less frequently in dogs, so data on outcomes are lacking.

Monitoring of Animal

I. Clinical signs and consistency of bowel movements are monitored closely to determine efficacy of medical therapy.
II. Aggressive medical management is usually required in cats with idiopathic megacolon and, even with therapy, many affected cats eventually require subtotal colectomy.

ACUTE INFLAMMATORY DISORDERS

Acute Colitis

Definition

I. Acute colitis is the sudden onset of large intestinal diarrhea.
II. It may be a nonspecific disease or arise in association with numerous infections or inflammatory conditions of the cecum, colon, and rectum.

Causes

I. Ingestion of abnormal foodstuffs (e.g., table scraps, garbage) or foreign matter (e.g., bones, rocks)
II. Abrupt exposure to a different diet
III. Certain protozoal and bacterial agents: see Table 34-1, Chapters 31, 33, 116
IV. Parasites: see under Trichuriasis
V. *Clostridium perfringens* type A enterotoxicosis
   A. Overgrowth of normal, anaerobic intestinal bacteria
   B. May be a hospital-acquired infection
   C. Develops soon after discharge from hospital
VI. Stress: hospitalization, travel, boarding, sudden changes in environment, etc.
VII. Drugs: corticosteroids, nonsteroidal antiinflammatory drugs (NSAIDs), etc.
VIII. Other medical conditions: pancreatitis, abdominal surgery or procedures, etc.
IX. More common in dogs than in cats

Pathophysiology

I. Ingestion or exposure to osmotically active material, and bacterial action on that material result in the movement of water in the colon, increased fermentation products, and hypomotility.
II. Spoiled food may contain endotoxins and certain bacteria may generate harmful enterotoxins.
III. Undigested foreign material (e.g., bones, metal particles) can cause direct mucosal injury.
IV. Inflammatory mediators (e.g., kinins, prostaglandins) are released and cause further degradation of the protective mucosal barrier, decreased absorption, and loss of electrolytes.
V. Bleeding and increased production of mucus may occur.
VI. Inflammation stimulates the defecation reflex, which increases the frequency of defecation and often results in tenesmus and dyschezia.

Clinical Signs

I. Acute onset of markedly increased frequency of defecation of a small volume of feces is a hallmark sign.
II. Defecation is often accompanied by tenesmus and/or dyschezia.
III. The feces typically contain mucus and/or fresh blood, and foreign matter may be seen.
IV. A temporal association may occur between feeding a different diet, exposure to some stressful event, hospitalization, administration of an antiprostaglandin drug, and the sudden onset of large intestinal signs.
V. The animal may show signs of discomfort (i.e., pacing, drooling).
VI. Signs of upper gastrointestinal (GI) involvement may also occur, including vomiting, small intestinal diarrhea, and inappetence.
VII. In many cases the physical examination is normal, and the animal is bright and alert.
   A. Mild depression or abdominal discomfort upon palpation may be noted.
   B. Dehydration and vomiting are uncommon unless the upper GI tract is also involved.
   C. The perineum may be stained with fresh blood and/or mucus.
   D. Digital rectal examination may elicit pain or tenesmus, or reveal bloody fluid, mucus, and/or foreign material.

Diagnosis

I. A presumptive diagnosis of large bowel disease is based on tenesmus, dyschezia, fresh blood and mucus in the stool, and an absence of other GI signs.

II. Fecal smears, flotations, or antigen tests are conducted to rule out parasitic and clostridial causes of acute large intestinal diarrhea (see Table 34-1).
   A. Thin fecal smears are made and stained with a Diff-Quik–type stain to identify the presence of high numbers of clostridial spores, which is supportive of the diagnosis.
   B. Gram or Wright-Giemsa stains demonstrate excess numbers of a uniform population of positively stained rods.
   C. Greater than five spores per high-power field is considered abnormal.
III. A positive response to treatment is supportive, as signs usually resolve rapidly after removal of the offending substance and symptomatic care.
IV. Failure to respond to therapy necessitates further diagnostic testing (Figure 34-1).
   A. A complete blood count (CBC) and biochemistry profile to rule out other systemic disease
   B. Bacterial culture, possibly using specialized media
   C. Abdominal radiography ± ultrasonography
   D. Colonoscopy and biopsy
   E. Identification of enterotoxin with reverse passive latex agglutination assays
      1. Only a small volume of fresh feces is needed; it is suspended in buffered saline, and 25 mL of the supernatant is used to detect enterotoxin.
      2. The presence of enterotoxin is not specific for clostridial colitis, because enterotoxin may also be produced in healthy dogs.

Differential Diagnosis

I. Acute, small intestinal diarrhea, especially hemorrhagic gastroenteritis: see Chapter 33
II. Chronic colitis: see Chronic Idiopathic Colitis

Treatment

I. Withhold food for 12 to 24 hours initially.
II. Allow access to water if the animal is not vomiting.
III. Consider subcutaneous fluids for mild dehydration.
IV. After 24 hours, provide small amounts TID to QID of a low-fat, highly digestible diet, such as rice with boiled chicken or low-fat cottage cheese, or prescription diets designed for large intestinal disorders.
V. Fiber may also be added in the form of psyllium or oat bran.
VI. The animal's normal diet may be slowly reinstituted after 3 to 5 days.
VII. Symptomatic medications may be needed to relieve pain, encourage rest, and decrease excess intestinal secretion.
   A. Motility modifiers
      1. Narcotic analgesics may be used for 24 to 48 hours, after GI obstruction has been ruled out.

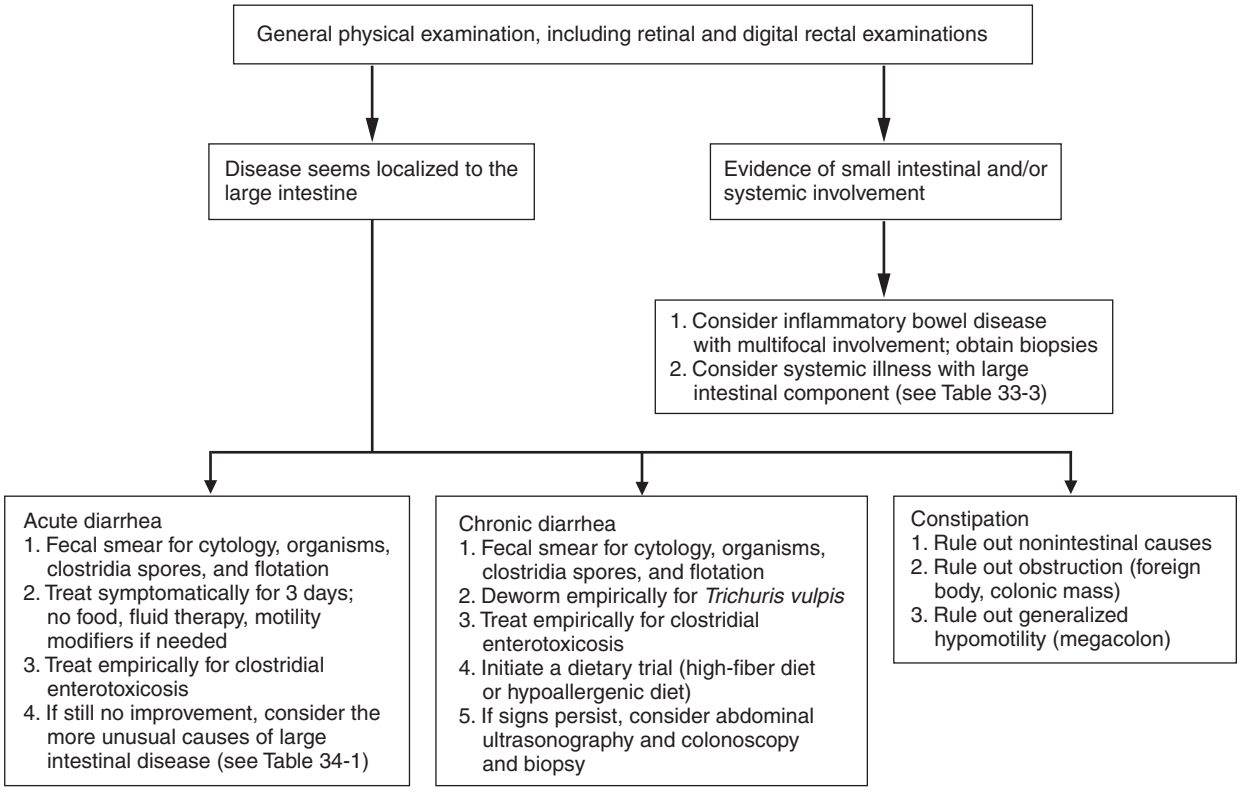

FIGURE 34-1 Diagnostic approach for animals with a history consistent with large intestinal disease. *Reprinted with permission from Bunch SE, Jergens AE: Diseases of the large intestines. p. 377. In Morgan RV, Bright RN, Swartout MS (eds): Handbook of Small Animal Practice. 4th Ed. WB Saunders, Philadelphia, 2003.*

a. Loperamide: 0.08 to 0.2 mg/kg PO TID to QID for dogs, 0.04 mg/kg PO SID to BID *cautiously* for cats
b. Diphenoxylate (with atropine to discourage abuse): 0.05 to 0.1 mg/kg PO TID to QID for dogs, 0.063 mg/kg PO TID for cats

2. They are contraindicated in diarrhea associated with endotoxin or enterotoxin, because they delay evacuation of toxic substances.

B. Antisecretory agents
1. Consider bismuth subsalicylate 1 to 2 mL/kg PO TID for dogs.
2. It causes the feces to appear very dark in color, which does not indicate melena.
3. It must be used cautiously in cats because of their inherent sensitivity to salicylates.

VIII. Specific therapies are instituted for any identified causes.
A. Clostridial enterotoxicosis, salmonellosis, campylobacteriosis, and other bacterial infections
1. Ampicillin or amoxicillin 22 mg/kg PO BID to TID
2. Metronidazole 10 to 15 mg/kg PO BID
3. Tylosin tartrate (2.27 g of tylosin per teaspoon) 10 to 20 mg/kg BID mixed in food

B. Discontinuance of any offending drugs
C. Antiparasitical agents: fenbendazole, praziquantel
D. Manual removal of foreign material, as needed
E. Removal of all identified stressors
F. Appropriate treatment for associated systemic diseases

Monitoring of Animal

I. Most cases of acute colitis resolve within 2 to 3 days with symptomatic or appropriate, specific therapy.
II. Recurrences are possible depending upon the cause, and some cases may become chronic (see Chronic Inflammatory Disorders).

Trichuriasis

Definition and Causes

I. Large bowel diarrhea may be caused by *Trichuris vulpis,* a widespread nematode parasite of dogs in North America.
II. Heavy infestations may involve the ileum, cecum, and colon.

Pathophysiology

I. The nematode burrows into the submucosa and causes varying degrees of mononuclear cell infiltration.
II. Parasite burden and location (focal versus diffuse), as well as the health status of the host, contribute to the degree of illness.
III. Heavy infestations may result in anemia from mucosal bleeding.
IV. The parasite may cause both acute and chronic large bowel diarrhea, owing to the following (Bunch and Jergens, 2003):
A. Hardiness of *Trichuris* spp. ova in the environment and likelihood of reinfection
B. Intermittent shedding of ova
C. Long prepatent period: 70 to 100 days
D. Longevity of the adult organism: months to years
E. Variations in host response and interaction with other parasites

Clinical Signs

I. Infection may be inapparent or signs of systemic illness may occur.
II. Parasite burden does not necessarily correlate with severity of clinical manifestations.
III. Most dogs have signs of large intestinal diarrhea.
IV. Weight loss, weakness, anorexia, polydipsia, and abdominal discomfort may be noted.
V. Dehydration, bradycardia, and hypothermia may be detected in animals with systemic signs.

Diagnosis

I. Ova may be found on fecal flotation, but infection cannot be ruled out with a single negative fecal flotation, as the nematode may only shed ova intermittently.
II. Rectal examination, performed to rule out other causes of hematochezia, is usually normal.
III. Response to empirical treatment in animals with a typical history, signs, and environmental risk for trichuriasis may also be diagnostic.
IV. Adult parasites can be visualized incidentally during colonoscopy.
V. Animals with systemic signs may have findings on a biochemistry profile similar to mineralocorticoid deficiency.
A. These include hypochloremia, hyponatremia, hyperkalemia, azotemia, poor urine concentrating ability, and metabolic acidosis.
B. Infected animals have normal adrenal responsiveness (both cortisol and aldosterone) after adrenocorticotropic hormone stimulation testing, however.

Differential Diagnosis

I. Other causes of acute and chronic colitis
II. Other intestinal parasites
III. Hypoadrenocorticism
IV. Cecal inversion
V. Colonic polyps or neoplasia
VI. Colonic motility disorders

Treatment

I. Fenbendazole is given at 50 mg/kg PO SID for 3 consecutive days.
II. Treatment is repeated in 3 weeks if other common GI parasites are present, and again 3 months later for *T. vulpis.*
III. Other supportive care (e.g., fluid therapy for dehydration) is provided as needed.

Monitoring of Animal

I. Because of intermittent shedding of ova, posttreatment fecal flotation cannot be used to judge treatment efficacy.
II. Retreatment is recommended if signs return, with or without a positive fecal flotation result.

III. For recurrences, or if reinfection is likely, heartworm preventive products that also include agents active against *T. vulpis* are recommended.
   A. Milbemycin oxime *(Interceptor)* 0.5 mg/kg PO once monthly
   B. Diethylcarbamazine with oxibendazole *(Filaribits Plus)* 6 mg/kg PO SID; possible adverse hepatic idiosyncratic reactions to this combination of drugs

CHRONIC INFLAMMATORY DISORDERS

Chronic Idiopathic Colitis

Definition

I. Chronic idiopathic colitis is also referred to as *inflammatory bowel disease* (IBD) and may be composed of three different forms of disease.
   A. In dogs and cats, lymphocytic-plasmacytic colitis is the most common form.
      1. Histologically, the lamina propria has inflammatory infiltrates of predominantly plasma cells and lymphocytes, with lesser numbers of neutrophils and eosinophils.
      2. Crypt dilatation and loss of epithelium are also common.
   B. Eosinophilic and histiocytic ulcerative colitis occur less frequently.
      1. Eosinophilic colitis is characterized by infiltration of the lamina propria with eosinophils.
      2. In cats, eosinophilic colitis may occur as a single entity or be a component of hypereosinophilic syndrome.
      3. Histiocytic, ulcerative colitis is an uncommon disease characterized by colonic mucosal ulceration and inflammation with periodic acid-Schiff (PAS)-positive histiocytes (macrophages).
      4. Histiocytic colitis of the boxer may also be referred to as *granulomatous colitis of boxers.*
   C. Granulomatous and suppurative colitis are uncommon entities.

II. Familial tendencies have been noted in some of these diseases.
   A. Basenji: lymphocytic-plasmacytic colitis (immunoproliferative enteropathy)
   B. Purebred cats: lymphocytic-plasmacytic colitis
   C. Boxer and French bulldog: histiocytic, ulcerative colitis
   D. Sporadic reports of ulcerative colitis: bull mastiff, Alaskan malamute, English bulldog, Doberman pinscher, a cat

Causes and Pathophysiology

I. The pathogenesis of idiopathic colitis or IBD may be immunologic because of the character of the most common cellular infiltrates and the positive response to treatment with immunosuppressive drugs or hypoallergenic diets.

II. Infection with adherent, invasive *Escherichia coli* may be associated with granulomatous colitis of boxers (Simpson et al., 2006; Van Kruiningen et al., 2005).

III. Regardless of the inciting cause, goblet cell hyperplasia with excess mucus production, mucosal inflammation and erosion, and hematochezia are common features.

IV. Inflammatory cell infiltrates can occur only in the large intestine or may involve the stomach and small intestine (see Chapters 31 and 33).

V. The degree and type of cellular infiltrate do not seem to correlate with severity of clinical signs.

Clinical Signs

I. Episodes of or prolonged (weeks) large bowel diarrhea occur.

II. Most affected dogs and cats are middle-aged.

III. Boxers with ulcerative colitis are often <2 years of age.

IV. Anorexia, vomiting, dehydration, and weight loss may occur if the large intestinal disease is severe or if the upper GI tract is involved.

V. Systemic signs (weight loss, debilitation) may be evident in boxers with histiocytic ulcerative colitis.

Diagnosis

I. Physical examination is often normal, except for digital rectal examination.
   A. Rectal examination may reveal thickened, irregular mucosa, mucus and fresh blood, and may precipitate tenesmus.
   B. It is also helpful to rule out other causes of large intestinal signs, such as masses, strictures, foreign bodies, perineal hernias, anal sac disease, and perianal fistulas.

II. A CBC, biochemistry profile, urinalysis, fecal flotation, and rectal cytology are indicated (see Figure 34-1).
   A. Laboratory test results are usually unremarkable.
   B. Eosinophilia may be seen with trichuriasis, eosinophilic colitis of dogs, and disseminated hypereosinophilic syndrome of cats.
   C. Neutrophilia, mild anemia, and hypoalbuminemia may be seen in some dogs with ulcerative colitis.
   D. Monoclonal or polyclonal gammopathy may accompany eosinophilic or plasmacytic enterocolitis.
   E. High serum alanine transaminase activity is often seen in cats.
   F. Rectal cytology may identify another causative agent (e.g., *Histoplasma* spp., *Prototheca* spp., *Cryptosporidium* spp.).

III. Cats are tested for feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV).

IV. A more aggressive diagnostic approach is undertaken in animals that do not respond to empirical treatment (see Treatment).
   A. Survey abdominal radiographs are usually unremarkable.
   B. Abdominal ultrasonography may show thickening of the walls of the large and small intestines and regional lymphadenopathy.
   C. Colonoscopy allows direct visualization of the mucosa, identification of masses, and biopsy of any identified lesions.
      1. The animal must be prepared adequately before colonoscopy.

a. Withhold food for 24 to 36 hours.
b. Administer an oral lavage solution (20 to 30 mL/kg divided in two doses 2 to 4 hours apart) the afternoon before the procedure.
c. Give 1 to 2 warm-water enemas the morning of the procedure.

2. Position the animal in left lateral recumbency.
3. Use a flexible fiberoptic endoscope to permit the most complete examination.
4. Take multiple biopsy specimens from several locations.
5. With lymphocytic-plasmacytic colitis, the colon may grossly appear normal or the mucosa may be hyperemic, with pale areas (cellular infiltrates).
6. With ulcerative colitis, colonoscopy reveals patchy red foci (pinpoint ulcerations), overt ulceration, thick mucosal folds, areas of granulation tissue, and strictures.

D. See additional tests described under Acute Colitis.

Differential Diagnosis

I. Acute colitis and its various causes
II. Trichuriasis: dogs
III. Infectious causes of chronic colitis (see Table 34-1)
  A. *Tritrichomonas foetus*: cat
  B. Histoplasmosis: dog, cat
  C. Protothecosis: dog
  D. FeLV, FIV: cat
IV. Antibiotic-responsive colitis: bacterial adherence or overgrowth
V. Dietary intolerance or allergy
VI. Cecal inversion or ileocolic intussusception
VII. Colonic polyps and neoplasms
VIII. Colonic strictures
IX. Irritable bowel syndrome
X. Small intestinal diarrhea and its causes: see Chapter 33
XI. Perianal fistulas in dogs
XII. Complication of pelvic irradiation

Treatment

I. Empirical treatment can be tried and helps to rule out other causes of chronic colitis.
  A. Dogs are dewormed for trichuriasis.
  B. Dogs (and perhaps cats) may also be treated empirically for clostridial enterotoxicosis (see Acute Colitis).
  C. Cats may be treated with metronidazole or fenbendazole for tritrichomoniasis.
  D. Dogs and cats are changed to a different, high-quality, easily digestible diet for 4 to 6 weeks.
    1. Several commercial products are available and marketed as large intestinal diets.
    2. Fiber is added to the diet in the form of soluble fiber, such as oat bran or psyllium,
      a. Add $^1/_4$ to 3 tablespoons/day PO.
      b. Some commercial diets already contain a soluble fiber.
  E. Novel protein diets that contain protein and carbohydrate sources not commonly found in commercial foods (e.g., duck, venison, rabbit) may also be tried.
  F. Hypoallergenic diets that contain hydrolysated protein may be tried.
II. Drugs that contain 5-aminosalicylic acid (5-ASA) are considered the preferred treatment for dogs with lymphocytic-plasmacytic and suppurative colitis.
  A. Sulfasalazine is initially given at 15 to 20 mg/kg PO TID and requires monitoring for side effects (e.g., keratoconjunctivitis sicca, polyarthritis, thrombocytopenia).
  B. Olsalazine does not contain a sulfa component, so there are fewer side effects, but the drug is more expensive.
    1. Initial dosage in dog is 5 to 10 mg/kg PO BID.
    2. The dosage may be tapered after signs are controlled for at least 1 to 2 weeks (usually after 3 to 4 weeks of treatment), and then decreased to the lowest effective dose.
  C. These drugs must be used very cautiously, and at reduced dosages and frequencies in cats because of their sensitivity to salicylates.
III. Other drugs can be added or tried for lymphocytic-plasmacytic colitis if clinical signs persist.
  A. Prednisone 2 mg/kg PO SID or divided BID in dogs and 2 to 4 mg/kg PO SID or divided BID in cats.
    1. It is the preferred drug in cats.
    2. It may allow the sulfasalazine dosage to be reduced further in dogs.
  B. Metronidazole may also be used at 10 to 15 mg/kg PO BID, then tapered to the lowest effective dose for long-term use.
  C. Tylosin tartrate (2.27 g of tylosin per teaspoon) may be used at 10 to 20 mg/kg PO BID mixed in food.
    1. It is safe for long-term use (weeks to months).
    2. Cats generally do not like the taste, so the powder may be compounded into a capsule.
  D. Probiotic bacteria (e.g., *FortiFlora*) may be tried SID in dogs and can be given long-term.
IV. Prednisone (see doses, discussed previously) is the drug of choice for eosinophilic and granulomatous (regional) colitis in dogs and cats.
V. Treatment for histiocytic ulcerative colitis in dogs initially involves adding soluble fiber to the diet and starting antimicrobial therapy.
  A. Supplement the existing diet with psyllium $^1/_2$ to 3 tablespoons/day PO, or change to a specially formulated diet containing soluble fiber.
  B. First choice antibiotics include the following:
    1. Enrofloxacin 5 to 15 mg/kg PO BID alone or with metronidazole and amoxicillin
    2. Metronidazole 15 mg/kg PO BID
    3. Tylosin 45 mg/kg PO SID to BID
  C. Antiinflammatory and/or immunosuppressive drugs may be tried if antimicrobials are ineffective.
    1. Prednisone 2 mg/kg PO SID or divided BID until clinical remission, then tapered slowly over 4 to 6 months
    2. Sulfasalazine 25 to 40 mg/kg PO TID

3. Azathioprine 2 mg/kg PO SID for 2 weeks then QOD

D. Anticholinergics are avoided, as they may worsen the clinical signs.

Monitoring of Animal

I. Drug therapy (5-ASA drugs and/or prednisone) may be tapered after signs have been resolved for at least 2 weeks.
II. Some animals require drug therapy for life, whereas in others the disease is controlled with diet alone (after drug discontinuation).
III. Keratoconjunctivitis sicca is a common adverse reaction to sulfonamide use, but may be reversible if detected early.
   A. Baseline Schirmer tear testing is performed before initiating therapy with sulfasalazine.
   B. Tear production is then assessed every 2 to 4 weeks in dogs receiving long-term sulfasalazine.

Fiber-Responsive Colitis

Definition and Causes

I. This term is used for cases of chronic colitis that respond well to only soluble fiber supplementation.
II. The cause is unknown.

Pathophysiology

I. Fiber administration has several beneficial effects on the colon.
II. Soluble fiber traps water and delays intestinal transit time, allowing excess water to be absorbed and fermented by intestinal bacteria, yielding more bacterial by-products.
III. Together with insoluble fiber, which is not digested, these effects increase fecal bulk.
IV. Increased fecal bulk stimulates rhythmic segmental contractions, further prolonging fecal transit time.
V. Both types of fiber bind bile acids, some of which are injurious to colonic mucosa.
VI. Anaerobic bacteria in the colon metabolize fiber, yielding short-chain fatty acids, such as butyric acid.

Clinical Signs

I. Clinical signs are generally intermittent.
II. Increased frequency of defecation of small amounts of feces mixed with fresh blood and/or mucus is the primary sign.
III. Signs of systemic illness are very uncommon.
IV. Results of the general physical examination are normal.
V. Digital rectal examination may be normal or reveal mild pain, fresh blood, or excessive mucus.

Diagnosis

I. The diagnosis is one of exclusion.
II. Affected animals usually do not respond to deworming for *Trichuris* spp., treatment for *Clostridium* enterotoxicosis, or use of a bland or hypoallergenic diet.
III. All diagnostic testing, including colonoscopy and biopsy, is unremarkable.

Differential Diagnosis

I. Other causes of chronic colitis: see Idiopathic Chronic Colitis
II. Other causes of acute colitis
III. Systemic illnesses that may affect the colon: histoplasmosis, protothecosis, etc.

Treatment and Monitoring

I. Add soluble fiber to the diet.
II. Supplement the existing diet with psyllium 1/2 to 3 tablespoons/day PO.
III. Alternatively, change to a specially formulated diet containing soluble fiber.
IV. Most signs resolve within a few days.

Irritable Bowel Syndrome

Definition and Causes

I. The disease resembles irritable bowel syndrome in humans, but dogs and cats do not have constipation as part of the disease.
II. It is not known whether the disorder represents undiagnosed clostridial enterotoxicosis or if it is a true motility disorder.

Clinical Signs

I. Signs of large bowel diarrhea occur intermittently.
II. A relationship with stressful events (e.g., boarding, travel, grooming, new members in the household, separation from the owner, or visits to the veterinarian) may be elucidated by careful questioning of the owner.
III. Affected animals may not outwardly appear excitable or overly anxious.
IV. There is no evidence of systemic illness, and results of a general physical examination are usually normal.
V. Digital rectal examination may be normal or reveal fresh blood or excessive mucus.

Diagnosis

I. The diagnosis is one of exclusion.
II. Affected animals usually do not respond to deworming for *Trichuris* spp., treatment for *Clostridium* enterotoxicosis, or use of a bland or hypoallergenic diet.
III. All diagnostic testing, including colonoscopy and biopsy, is unremarkable.

Differential Diagnosis

I. Other causes of chronic colitis: see Idiopathic Chronic Colitis
II. Other causes of acute colitis

Treatment and Monitoring

I. Soluble fiber is added to the diet.
   A. Supplement the existing diet with psyllium 1/2 to 3 tablespoons/day PO.
   B. Alternatively, change to a specially formulated diet containing soluble fiber.

II. If necessary, motility-modifying agents can be given to control acute episodes (see Acute Colitis).
III. An antianxiety agent may be tried in dogs.
  A. A combination of 5 mg chlordiazepoxide hydrochloride and 2.5 mg clidinium bromide *(Librax)* is available.
  B. Dosage is 0.10 to 0.25 mg/kg of clidinium PO BID to TID.
IV. The disorder is not life-threatening, but may be challenging to control.

NEOPLASIA

Definition

I. Many colonic tumors are malignant in dogs, and virtually all are malignant in cats.
II. Most primary tumors are solitary.
III. Mucosal adenomas (polyps) are the most common benign tumors.
  A. Small polyps are unlikely to represent premalignant lesions, although they can be multiple.
  B. Leiomyomas and other tumors have been reported sporadically.
IV. Adenocarcinoma is the most common malignant, primary tumor of dogs and often occurs in pedunculated or annular intraluminal forms in the rectum.
V. GI lymphoma may involve the small and/or large intestine and is the most common malignant tumor of cats.
  A. The large intestine may also be affected in multicentric lymphoma.
  B. Lesions may be focal and nodular or diffuse and infiltrative.
VI. Other primary tumors include leiomyosarcoma (especially cecal), carcinoid, extramedullary plasmacytoma, and mast cell tumor.

Causes and Pathophysiology

I. No causative factors have been identified in large intestinal cancer of dogs and cats.
II. Most cats with GI lymphoma are FeLV negative.
III. Most benign tumors are slow growing and cause intermittent signs for up to 12 months before diagnosis.
IV. Malignant tumors are usually detected within 3 months.

Clinical Signs

I. Male, medium- to large-breed dogs or domestic shorthair cats >9 years of age are most likely to have malignant tumors.
II. Hematochezia is the most common sign (82% of cases) (Valerius et al., 1997).
III. GI signs are those of chronic large intestinal diarrhea.
IV. Annular adenocarcinoma often causes tenesmus and constipation.
V. Persistent tenesmus can cause rectal prolapse.
VI. Occasionally prolapsed polypoid tumors may protrude from the anus.
VII. Some tumors (cecum) result in perforation and signs of septic peritonitis.
VIII. Upon abdominal palpation, large colonic tumors or general thickening (lymphoma) of the colon may be detected.
IX. On digital rectal examination a rectal adenocarcinoma often forms an annular constrictive lesion, which must be differentiated from inflammatory strictures from proctitis or colitis.
X. Systemic signs are variable and may include vomiting, dehydration, anemia, anorexia, and weight loss.

Diagnosis

I. Results of a CBC, biochemistry profile, and urinalysis are usually normal.
II. Extreme neutrophilia has been reported in a dog with a rectal adenomatous polyp (Thompson, 1992).
III. Survey radiographs are often normal.
IV. Abdominal ultrasonography may differentiate focal from diffuse lesions, and identify regional lymphadenopathy or involvement of the liver.
V. The most common malignant large intestinal tumors do not often disseminate to the lungs, but thoracic radiography is still recommended.
VI. Colonoscopy is useful to visualize tumors and to obtain multiple biopsies.
VII. Not all tumors are identified from endoscopic biopsy, so exploratory laparotomy and full-thickness biopsies may be required to achieve a diagnosis.

Treatment

I. Some tumors can be treated with surgical resection.
  A. Rectal adenoma (polyp)
  B. Distal rectal polypoid adenocarcinoma
  C. Solitary cecal or colonic tumor of any cell type (with wide margins)
II. Large intestinal lymphoma is not as responsive as the multicentric form, but chemotherapy may be tried (see Chapter 69).
  A. Small-cell lymphoma in cats is usually treated with prednisone (or prednisolone) and chlorambucil, and long-term remissions may be achieved in these cats.
  B. Start prednisone at 5 mg PO BID and chlorambucil at 15 mg/m^2 PO SID for 4 days then and repeated every 3 weeks.
  C. Alternatively, give chlorambucil at 6 mg/m^2 PO QOD.
III. Annular rectal adenocarcinoma is difficult to treat.
  A. Local resection and cryosurgery may offer longer survival times than radical resection.
  B. Radiation therapy has been successful in a small number of dogs (Straw, 1996).
  C. Palliative therapy with stool softeners or a colostomy may be tried because distant metastasis is unusual.
  D. Local recurrence is the most common cause of euthanasia.

Monitoring of Animal

I. Recurrence is common (41% of cases) (Valerius et al., 1997), with signs of hematochezia, dyschezia, tenesmus, and mucoid stools.

II. Recurrence is higher in dogs with multiple masses, diffuse disease, or carcinoma in situ (Valerius et al., 1997).
III. Increased survival times are seen in dogs with adenomas, carcinoma in situ, noninvasive carcinomas, and wide, clean margins after surgical excision (Wolf et al., 1997).

CHAPTER 35

Diseases of the Anus and Perianal Region

Eric R. Pope

CONGENITAL DISORDERS

Imperforate Anus

Definition and Causes

I. *Imperforate anus* is the general term used to describe a group of abnormalities that result in either a reduced ability or inability to pass feces from the rectal tube.
II. Four types have been documents (Vianna and Tobias, 2005).
  A. Congenital anal stenosis
  B. Imperforate anus alone
  C. Imperforate anus with termination of rectum as a blind pouch
  D. Discontinuity of the proximal rectum with normal anal and terminal rectal development (atresia ani)
III. Atresia ani occurs as a failure of the cloacal membrane that separates the anal invagination and rectum to resorb.
IV. All types usually have an intact external anal sphincter and associated nerve supply, as well as normally developed anal sacs.

Pathophysiology

I. The inability or reduced ability to pass feces results in abdominal distention and ultimately signs of a lower intestinal obstruction.
II. As the abdominal distention worsens, the puppy or kitten becomes restless and anorexic.

Clinical Signs

I. Congenital anal stenosis
  A. Clinical signs may not become apparent before weaning.
  B. Tenesmus and constipation develop.
II. Atresia ani
  A. Tenesmus
  B. A bulging anal dimple in the absence of an anal orifice
  C. Absence of feces
  D. Abdominal distention and/or discomfort
  E. Restlessness, decreased vigor

Diagnosis

I. Signalment
  A. Females at greater risk
  B. Breed predisposition: poodle, Boston terrier
II. Suspicious history and clinical signs
III. Compatible physical examination findings
  A. Bulging perineum and anal dimple with atresia ani
  B. Possibly abdominal distention
IV. Horizontal-beam radiography
  A. It aids in determining point of termination of the rectum.
  B. Elevate hind end.
  C. Migration of gas to distal colon and rectum helps to define the limits of the rectal pouch.
  D. The reliability of the technique depends on the following:
    1. Amount of gas used: air introduced into stomach by tube can migrate caudally
    2. Consistency of feces in terminal rectum: possible decreased migration of gas

Differential Diagnosis

I. Congenital rectal stricture
II. Congenital anal stenosis

Treatment

I. For atresia ani, incise skin over the anus with a cruciate incision.
II. Identify and avoid the external anal sphincter and anal sac openings.
III. Mobilize the rectal pouch and incise in a cruciate pattern over the imperforate rectum.
IV. Suture the rectum to subcutaneous tissues and skin with interrupted sutures.

Monitoring of Animal

I. Fecal incontinence may be a sequela.
  A. Normal anal sphincter function may be absent depending on the amount of damage caused by the surgical reconstruction.
  B. Incontinence can also result from lack of normal sensation in the rectal segment.
II. Small and debilitated animals may not survive the surgical correction.

DEGENERATIVE DISORDERS

Fecal Incontinence

Definition

Fecal incontinence is the inability of the animal to retain feces until defecation is appropriate.

Causes

I. Sphincter mechanism dysfunction
   A. Neurological dysfunction from damage to the lower sacral (S) spinal cord (S1 through S3 cord segments) or to local innervation of the anorectal area
      1. External anal sphincter damage
         a. Fractures of the lower lumbar and/or sacral vertebrae
         b. Sacrococcygeal luxations
         c. Spinal cord disease: fibrocartilaginous emboli, neoplasia
         d. Surgical trauma: perineal hernia repair in dogs, perineal urethrostomy in cats
         e. Penetrating wounds: bite wounds, gunshots
      2. Internal anal sphincter damage
         a. Most causes of internal anal sphincter dysfunction are ill defined.
         b. It is occasionally encountered as an isolated disorder in aged dogs.
   B. Sensory incontinence
      1. Sensory receptors in the wall of the rectum and pararectal musculature respond to dilatation of the rectum by feces.
      2. Interruption of interplay between these receptors results in inappropriate defecation, because an increase in the tone of the external anal sphincter does not occur.
   C. Nonneurogenic causes
      1. Inflammatory diseases of the perianal and anorectal area
      2. Surgical trauma to sphincter musculature
      3. Neoplasia
II. Loss of reservoir function following resection of proximal two thirds or more of the colon

Pathophysiology

I. The internal anal sphincter is controlled by the autonomic nervous system and maintains a high level of tone that is primarily responsible for continence at rest.
II. The external anal sphincter is tonically active, with contraction occurring during peristaltic activity to prevent inappropriate defecation.
III. Dysfunction or loss of sensory receptors in the rectal muscularis and pararectal muscles or their afferent nerve fibers interrupts the coordination between the internal and external anal sphincters.
IV. Dysfunction of the spinal cord segments S1 through S3 or their somatic efferents destroys function of the external anal sphincter.
   A. Unilateral damage of peripheral efferents causes only transient incontinence.
   B. Incontinence is transient because of decussation of muscle fibers and cross-innervation.
V. Dysfunction or disruption of the hypogastric nerves or pelvic plexus interferes with internal anal sphincter function.

Clinical Signs

I. Sphincter mechanism dysfunction
   A. Flatulence with usually normal stool consistency
   B. Involuntary or inappropriate defecation
      1. It occurs with exercising, barking, or becoming excited.
      2. Animal is unaware that feces are being passed and does not posture normally.
   C. Soiling of perineal region between defecations
II. Loss of reservoir function: frequent passage of abnormally soft, unformed, or liquid feces

Diagnosis

I. History
   A. Owner complaint of unconscious defecation by the animal
   B. Known spinal cord disease, previous lumbar or sacrococcygeal trauma
   C. Inflammatory disease of the colon or rectum
   D. Perianal fistulas
   E. Previous surgery to anorectal or perineal region: congenital anorectal disease, perineal hernia, perianal fistulas, anal or rectal neoplasia
II. Physical examination
   A. Sphincter mechanism incontinence
      1. Anus is dilated on visual inspection.
      2. Soiling of the perineal region is common, especially if the tail is flaccid.
      3. Decreased or absent anal sphincter tone is detected on rectal examination.
      4. Decreased or absent perianal reflex is noted.
      5. With nonneurogenic causes, the perianal reflex may be intact, but anal constriction is impaired mechanically.
      6. A thorough neurological examination may reveal sensory and motor deficits to other perineal structures, such as the tail, pelvic limbs, and urinary bladder.
   B. Sensory incontinence
      1. Normal external anal sphincter tone
      2. Soiling of perineal region, indiscriminate passage of feces
III. Other tests
   A. Radiography is indicated to investigate possible spinal cord disease and musculoskeletal injuries.
   B. Electromyographic studies may be helpful for demonstrating denervation, as suggested by positive sharp waves and fibrillation potentials.

Treatment

I. Denervation of the external anal sphincter is often a permanent, untreatable condition.

II. Reinnervation may be possible if the neurolemmal sheath and nerve cell bodies are intact.
III. If other neurological deficits exist, the animal may no longer be a functional pet.
IV. Symptomatic care for mild or nonneurogenic incontinence includes the following measures:
   A. Give multiple feedings per day of a low-bulk diet.
   B. Exercise the dog immediately after eating to encourage elimination.
   C. Walk frequently during the day.
   D. Do not feed the animal near bedtime.
   E. Tail amputation may make husbandry easier if the tail is paralyzed.
V. A silicone elastomer sling is effective in restoring continence in normal dogs with experimentally created fecal incontinence, but results in clinical cases have been mixed (Dean et al., 1988).
VI. Sensory incontinence is permanent.
VII. Intestinal adaptation generally results in significant improvement of clinical signs over time in animals with reservoir incontinence.

Monitoring of Animal

I. Incontinence may be transient or permanent, depending on the etiology (e.g., inflammatory, postsurgical).
II. Prognosis is guarded to poor regardless of cause.
III. Most causes of incontinence related to surgery can be avoided with careful dissection by an experienced surgeon.

Rectal Deviation and Sacculation

Definition

I. Rectal deviation is an S-shape or similar curve in the rectal tube.
II. Rectal sacculation is a dilatation of the lateral rectum, usually at its terminal extent.

Causes and Pathophysiology

I. Rectal deviation and sacculation are most commonly associated with perineal hernia (see later in this chapter)
II. The muscles of the pelvic diaphragm normally provide the support that prevents the rectum from deviating laterally or bulging out as peristaltic contractions push feces caudally.

Clinical Signs

I. Tenesmus and dyschezia may be present.
II. A large bulge occurs lateral and cranial to the anorectal junction, especially when defecating.

Diagnosis

I. History of tenesmus
II. Physical examination findings
   A. Bulging rectum
   B. Palpation of a feces-filled pouch in the rectum just proximal to the anus
   C. ± Palpable hernial ring
III. Barium enema demonstrating an outpouching
IV. Proctoscopy and/or colonoscopy to confirm the diagnosis

Differential Diagnosis

I. Perineal hernia with retroflexed urinary bladder
II. Prostatic disease with perineal location of a prostatic or paraprostatic cyst
III. Prior trauma
IV. Neoplasia, especially tumors of the perineum or pelvic canal

Treatment

I. Correct the underlying cause.
II. Correcting a perineal hernia restores the lateral support of the rectal wall, facilitating defecation.
III. Low-residue diets and stool softeners may alleviate symptoms in some dogs.
IV. A colopexy performed with cranial traction on the rectum helps palliate signs of rectal deviation and sacculation if perineal herniorrhaphy is unsuccessful.

Monitoring of Animal

I. Deviation and/or sacculation may recur if associated with a perineal hernia and the repair fails.
II. Imbrication or excision of affected tissue is seldom indicated and carries an additional risk of infection caused by subcutaneous exposure to colonic contents.

Anorectal Stenosis and Stricture

Definition

I. Anorectal stenosis is a partial obstruction of the anal or rectal lumen by intraluminal or extraluminal lesions.
II. Anorectal stricture is diminution in size of the anal or rectal lumen, either from cicatricial contracture or deposition of abnormal tissue.

Causes

I. Secondary to underlying diseases
   A. Anorectal abscesses
   B. Perianal fistulas, chronic anusitis, or proctitis
   C. Neoplasia
II. Trauma
   A. Accidental injuries
   B. Surgical complication, especially after perianal fistula surgery and rectal resection for prolapse or neoplasia
   C. Ingestion or malicious placement of a foreign object

Pathophysiology

I. Diseases affecting >50% of the circumference of the anus or rectum result in partial or complete obstruction.
II. Any disease or trauma evoking an inflammatory response in the anorectal region can cause a constricting ring of scar tissue to form.
III. Rectal adenocarcinomas often involve the rectal wall circumferentially as they increase in size.

Clinical Signs

I. Thin, ribbon-type stools
II. Tenesmus, dyschezia, hematochezia
III. Megacolon with constipation
IV. Incontinence

Diagnosis

I. History and clinical signs are helpful.
II. Rectal palpation reveals a mass obstructing part of the rectal lumen.
III. A constricting ring that does not relax when the animal is under anesthesia is found on rectal palpation.
IV. If the obstruction or stricture is more cranial, contrast radiography (barium enema) aids in the diagnosis.
    A. It helps delineate the extent of the stricture.
    B. It may also demonstrate megacolon rostral to the stricture.
V. Proctoscopy allows direct visualization of intraluminal lesions.
    A. It helps in determining the exact location and extent of the lesion.
    B. It aids in obtaining a biopsy specimen to rule out neoplasia.
VI. Computed tomography (CT) can be used to assess the extent of involvement of extraluminal disease processes.

Differential Diagnosis

I. Spastic rectum (functional stricture) associated with proctitis or anal sac disease that disappears with a surgical plane of anesthesia
II. Extraluminal masses within the pelvic canal
    A. Urogenital tract
    B. Pelvis
    C. Pelvic musculature
    D. Soft tissues: sarcomas

Treatment

I. Dietary management includes stool softeners and a low-residue diet.
II. If tumor is suspected, a biopsy is performed before any surgical intervention.
III. If malignancy is diagnosed, a work-up for metastasis is indicated with thoracic and abdominal radiographs, ultrasonography, and CT scan.
IV. Simple circular rectal strictures may respond to repeated balloon dilatation with concurrent use of prednisone 1 mg/kg PO BID for 14 days and then tapered.
V. Surgery is indicated if dietary management and balloon dilatation are unsuccessful in alleviating the signs or if neoplasia is diagnosed; however, the risk of causing damage to the external anal sphincter must always be considered when deciding to do surgery in this region.
VI. Surgical techniques include the following:
    A. Anal stricture
        1. If the stricture is not too severe, two to four longitudinal incisions made through the stricture site are sutured transversely to enlarge the anal opening.
        2. With more extensive lesions, excise the fibrotic ring and suture the rectal mucosa to the anal skin (modified rectal pull-through) in an effort to preserve anal sphincter function.
    B. Rectal stricture
        1. Longitudinal incisions made through the stricture at the 12, 3, 6, and 9 o'clock positions are closed transversely.
        2. With more severe lesions, excise the stricture completely and anastomose the rectum with simple interrupted appositional sutures.
            a. Strictures located near the anorectal junction may be accessible through the anus.
            b. More cranial lesions are exposed using the dorsal approach to the anus (Holt et al., 1991).
        3. Treat rectal and colonic strictures secondary to neoplasia palliatively by inserting an intraluminal stent (Hume et al., 2006).

Monitoring of Animal

I. Simple circular strictures often respond to balloon dilation, but it may be necessary to repeat this procedure several times.
II. If surgery is performed, recurrence of the stricture is possible regardless of the procedure used.
III. Tenesmus and rectal prolapse may occur postoperatively secondary to the inflammation of surgery and the presence of suture material in the rectum.
IV. Incontinence may be a sequela to any corrective surgery.
V. Prognosis is guarded to poor if the underlying cause is rectal carcinoma.
VI. High-risk patients and those with inoperable disease may be managed successfully with dietary changes, including stool softeners, low-residue foods, or laxatives.

Perineal Hernia

Definition

A perineal hernia is a disruption of the pelvic diaphragm musculature that allows contents of the pelvic canal and/or abdominal cavity to herniate into the perineal subcutaneous tissues.

Causes

I. The exact etiology is unknown.
II. Degenerative changes of the muscles of the pelvic diaphragm occur, especially the levator ani muscle.
III. Imbalance of androgenic and estrogenic hormone levels or alteration in their receptors in the pelvic diaphragm musculature may be present.
IV. The levator ani is thinner and narrower and has a weaker fascial attachment to the external anal sphincter and rectal wall in the male dog, which may be a contributing factor.
V. Prostatic disease (e.g., benign prostatic hyperplasia) causing tenesmus can lead to a hernia.
VI. Tenesmus secondary to chronic constipation and obstipation from various causes also lead to pelvic musculature weakness.

VII. It is a rare but potential surgical complication after perineal urethrostomy in cats.

Pathophysiology

I. Partial or total rupture of the muscles forming the pelvic diaphragm is likely, especially the levator ani muscle.
II. Four types of hernia have been described, namely the caudal, dorsal, ventral, and sciatic.
III. The caudal type is most common and occurs between the external anal sphincter and the levator ani.
IV. Loss of support of the rectal wall allows the rectum to deviate, interfering with normal defecation.
V. Retroflexion of the urinary bladder into the hernia results in urinary obstruction that can lead to a life-threatening nephropathy.

Clinical Signs

I. Soft, reducible, nonpainful swelling in the ventrolateral perineum on one or both sides of the anus
II. Constipation, tenesmus
III. Dyschezia, fecal incontinence
IV. Dysuria if bladder is retroflexed into the ischiorectal space
V. Systemic signs associated with organ entrapment (e.g., uremia) or concurrent disease (e.g., prostatitis)

Diagnosis

I. Signalment and history
   A. Intact middle-aged to older male dog
   B. Constipation, straining to defecate, or bulge in perineum
II. Compatible clinical signs
III. Palpation of a defect in the pelvic diaphragm externally, after manual reduction of the hernial contents
IV. Palpable defect of the pelvic diaphragm musculature on rectal examination
V. The presence of impacted feces in a rectal sacculation
VI. Nonreducible, painful, fluid-filled perineal mass with signs of uremia and the inability to pass a urinary catheter (urinary bladder retroflexion)
VII. Discoloration of the skin overlying a retroflexed bladder
VIII. Radiography
   A. Survey radiographs show a soft-tissue mass or fecal material in the perineal area.
   B. Barium enema demonstrates a rectal deviation or sacculation.
   C. Urethrocystogram sometimes demonstrates a misplaced bladder or prostate.

Differential Diagnosis

I. Rectal diverticulum without a perineal hernia
II. Neoplasia
III. Caudally located paraprostatic cyst

Treatment

I. Dietary management
   A. Low-residue food
   B. Stool softeners
   C. May be tried as primary management in dogs with minimal signs or in those instances in which the anesthetic risk is too great for surgical correction
   D. As an adjunct to surgical therapy
II. Digital removal of feces and enemas during episodes of obstipation or tenesmus
III. Castration to help decrease the size of the prostate
IV. Treatment of choice: herniorrhaphy
   A. Reduce the hernia using blunt dissection.
   B. Remove the hernial sac and excessive fat.
   C. Protect the pudendal nerve and internal pudendal artery and vein, located in the ischiorectal fossa on the ventrolateral surface of the coccygeus muscle.
   D. Be aware of the location of the caudal rectal nerves and anal sacs during placement of sutures in the external anal sphincter.
   E. Use the thick perineal subcutaneous tissue (perineal fascia) to provide additional support to the primary repair technique.
   F. Standard suture reconstruction consists of suturing together muscles that normally form the pelvic diaphragm, including the external anal sphincter, lateral coccygeus, and internal obturator muscles.
   G. Internal obturator muscle flap transposition is the most reliable surgical technique, particularly for large and bilateral hernias, and is associated with a low rate of recurrence.
   H. Implants can be used to augment the previously mentioned repairs or when other techniques fail.
      1. Synthetic materials, such as polypropylene mesh
      2. Biological implant (processed swine intestinal submucosa) (Stoll et al., 2001)
   I. Salvage procedures are used when primary repair is not indicated or has failed.
      1. Semitendinosus muscle flap for ventrally located hernias (Mann and Constantinescu, 1998)
      2. Colopexy and cystopexy
         a. Colopexy eliminates or reduces severity of rectal deviation or sacculation, thereby facilitating defecation.
         b. Cystopexy prevents retroflexion of urinary bladder.
   J. Retroflexion of the urinary bladder into the ischiorectal fossa is an emergency and is managed as follows:
      1. Attempt catheterization of the bladder and, if unsuccessful, perform cystocentesis percutaneously to reduce size of the bladder, and then repeat catheterization attempt.
      2. Stabilize animal and treat for uremia before performing definitive repair of the hernia.
      3. If the urinary bladder is incarcerated and cannot be catheterized or repositioned, perform perineal herniorrhaphy on an emergency basis.

Monitoring of Animal

I. Animals exhibiting excessive pain or signs of sciatic nerve paralysis should be evaluated for potential nerve entrapment by sutures.

II. Withhold food and water for 1 day postoperatively.
III. Place on a low-residue diet and stool softeners for 2 to 4 weeks.
IV. Recurrence is possible and is affected by the technique used and the experience of the surgeon.
V. Fecal incontinence is more likely if the repair is bilateral.
VI. Rectal prolapse can be a transient problem, particularly if sutures penetrate the rectal lumen.
VII. Wound infection may occur.
   A. Because infection may be related to sutures being placed in the colon, suture removal and exploration of the infected wound is necessary.
   B. Antibiotics help prevent a postoperative infection caused by contamination at the time of surgery.
   C. Give cefoxitin 30 mg/kg IV 30 minutes before surgery, and two more injections IM at 1.5-hour intervals thereafter.

INFLAMMATORY AND INFECTIOUS DISEASES

Proctitis

Definition and Causes

I. Inflammation of the rectum
II. Arises with infectious or inflammatory diseases involving the colon and other portions of the intestinal tract
III. Occurs secondary to foreign bodies, such as sharp objects
IV. May follow surgical trauma involving the rectum

Clinical Signs

I. Unproductive tenesmus
II. Assuming the posture for defecation for prolonged periods of time
III. Hematochezia, dyschezia

Diagnosis

I. History of ingesting a foreign body, concurrent intestinal disease, or recent surgery to the region
II. Thickening of the rectal mucosa on digital rectal examination
III. Fresh hemorrhage following digital examination
IV. Proctoscopy revealing inflamed, swollen, or ulcerated rectal mucosa
V. Colonoscopy and fecal cultures to identify more diffuse involvement
VI. Plain radiography revealing a foreign body if it is radiopaque
VII. Biopsy and histopathology necessary to confirm the diagnosis

Differential Diagnosis

I. Lower bowel disease
II. Rectal neoplasia
III. Anorectal stricture
IV. Masses in the pelvic canal
V. Prostatomegaly

Treatment

I. Treat or eliminate the underlying cause.
II. Hydrocortisone retention enemas may decrease inflammation.
III. Local anesthetic gel in the rectum may help reduce tenesmus.
IV. Feed low-residue foods and stool softeners for 7 to 10 days.

Monitoring of Animal

I. A good prognosis is expected if stricture is not a sequela.
II. Proctitis is often a self-limiting disease if the cause is removed (e.g., foreign body).

Rectal Prolapse

Definition

I. Eversion of one or more layers of the rectal wall through the anus
II. Complete: all layers involved
III. Incomplete: only rectal mucosa everted

Causes

I. Persistent straining caused by intestinal or urogenital disease
   A. Severe enteritis, including that caused by endoparasites
   B. Foreign bodies
   C. Neoplasia of rectum or distal colon
   D. Rectal deviation
   E. Dystocia
   F. Feline urologic syndrome
   G. Prostatic disease
II. Breed predisposition: Boston terrier, Manx cats
III. Prior rectal or perineal surgery

Clinical Signs

I. Incomplete prolapse
   A. Only a slight protrusion of mucosa
   B. Worsens immediately after defecation
II. Complete prolapse
   A. Prolapsed tubular mass with a depression in the end
   B. Everted rectal tissue swollen, edematous, and reddened
   C. Possible areas of ulceration or necrosis secondary to chronic exposure or vascular compromise
   D. Most commonly occurs in kittens and puppies <4 months of age
III. Possible tenesmus or pain

Diagnosis

I. Based on history and clinical signs
II. Confirmed by physical examination findings

Differential Diagnosis

I. Prolapsed ileocolic or colonic intussusception must be considered.
II. Grossly, rectal prolapse and prolapsed intussusception appear similar, but signs of partial or complete obstruction usually accompany the latter.

III. With rectal prolapse, a lubricated probe does not pass between the rectal wall and the prolapsed mass.
IV. With prolapsed ileocolic or colonic intussusception, the probe passes freely between the protruding mass and the rectal wall.

Treatment

I. Treat or remove any underlying cause.
II. Conservative management of rectal prolapse is attempted if the prolapse is viable and reducible.
  A. Apply a warm isotonic or hypertonic solution to the mucosa.
  B. Gently massage prolapsed mucosa to remove edema.
  C. Reduce the prolapse and place a loose, purse-string suture in the anus using 2-0 monofilament nonabsorbable suture material.
  D. A thermometer or syringe casing of appropriate size is used to avoid overtightening of the purse-string suture.
  E. Feed a low-residue diet and give stool softeners.
  F. Remove purse-string suture in 7 to 10 days.
  G. Continue dietary management and stool softeners until the underlying cause is corrected.
III. Surgical correction is indicated if the prolapse recurs, or if it is nonviable or irreducible.
  A. Use colopexy to treat and prevent recurrent rectal prolapse.
  B. Amputation of the prolapsed rectum may be indicated.
    1. Amputation is the treatment of choice if the rectal mucosa is necrotic, lacerated, or irreducible.
    2. Perform amputation if more conservative methods fail (purse-string or colopexy).
    3. Administer cefoxitin 30 mg/kg IV 30 minutes before surgery, followed by 30 mg/kg IM at 1.5-hour intervals for two more doses.

Monitoring of Animal

I. Recurrence is likely with more conservative methods, especially if the underlying cause is not addressed concomitantly.
II. Stenosis or incontinence is not uncommon after rectal surgery; therefore, more conservative methods of treatment are tried first whenever possible.

Anal Sac Disease

Definition

I. Anal sac impaction: retention of anal gland secretions
II. Anal sacculitis: inflammation and/or infection within the anal sac
III. Anal sac abscess formation: rupture of the anal sac secondary to obstruction of the duct or stasis of secretions and secondary infection

Causes

I. Not fully understood, but related to changes in the ability to empty anal sacs normally
II. Environmental and dietary factors (e.g., a high-fat diet leading to loose stools)
III. Breed predisposition: more common in small breeds, especially the poodle and Chihuahua
IV. Abnormally small duct system leading to obstruction
V. External anal sphincter dysfunction
VI. Hypersecretion of anal glands, possibly related to seborrhea
VII. Change in character of the secretions
VIII. Chronic diarrhea

Pathophysiology

I. Retained secretions evoke an inflammatory response within the anal sac.
II. Bacteria proliferate in the trapped secretions.
III. Severe cellulitis ensues, followed by potential abscess formation.
IV. Anal sacculitis and abscessation can be extremely painful, causing reluctance to defecate and constipation.

Clinical Signs

I. Licking and biting at tailhead region or tail chasing
II. Rubbing anus on ground or "scooting"
III. Discomfort when sitting or reluctance to sit
IV. Tenesmus, pain, or reluctance to defecate
V. Redness and/or swelling over anal sac region
VI. Perianal draining tract from abscessation

Diagnosis

I. Clinical signs often localize the disorder to the perianal area or specifically to the anal sacs.
II. Physical examination reveals one of the following:
  A. Impaction
    1. Firm, swollen anal sac
    2. Difficult or impossible to express contents
    3. Secretions thick and pasty
  B. Hypersecretion: voluminous secretion that is more liquid than normal
  C. Sacculitis
    1. Foul, purulent, and/or bloody material expressed from sac
    2. Overlying skin possibly reddened and painful on palpation
  D. Abscess formation
    1. Presence of an open wound or draining tract that communicates with the sac
    2. Usually unilateral

Differential Diagnosis

I. Anal sac neoplasia
II. Perianal gland neoplasia
III. Perianal fistulas
IV. Perianal trauma, especially bite wounds
V. Urinary tract or perivulvar infections in the female

Treatment

I. Anal sac impaction
  A. Express anal sacs by squeezing the skin overlying the anal sac or by internal compression applied by a finger inserted into the rectum.

B. If unsuccessful, consider sedation to facilitate further treatment.
C. If secretions are inspissated, instill saline or mineral oil to soften them before expression.
D. Flush out sacs with saline or antiseptic solution (0.1% povidone-iodine, 0.05% to 0.1% chlorhexidine).
E. Repeat manual expression weekly for 3 to 4 weeks.
F. If secretions remain thick or impaction is recurrent, anal sacculectomy may be necessary.

II. Anal sacculitis
A. Manually express the anal sacs every 5 to 7 days for three to four treatments.
B. Sedation is usually necessary because of pain.
C. Irrigate with antiseptic solution as for anal sac impaction, but only after samples for culture and sensitivity testing are taken, especially if the infection is recurrent.
D. Antibiotic solutions can be instilled into the anal sacs after irrigation.
E. Institute oral antibiotics for 10 to 14 days.
F. Instruct owner to apply hot compresses BID for 5 to 7 days.
G. Anal sacculectomy may be necessary, especially if repeated expressions, flushes, and antibiotic instillations are unsuccessful in controlling either anal sac impaction or infection.

III. Abscess formation
A. Heavily sedate or anesthetize the animal to allow thorough inspection and treatment.
B. Lance abscess and express anal sac rectally if eruption and drainage has not occurred spontaneously.
C. If already ruptured, cannulate duct and flush area well with antiseptic solution.
D. Submission of specimens for culture and sensitivity is ideal, but empirical treatment with broad-spectrum antibiotics can also be performed, particularly if it is a first occurrence.
E. Instruct owner to apply hot compresses BID for 5 to 7 days.
F. Irrigate abscess cavity with antiseptic solution BID for 3 to 5 days (longer if wound remains open or discharge persists).
G. If abscessation is recurrent, consider anal sacculectomy after abscess has healed.
H. Bilateral anal sacculectomy is recommended even if only one side appears to be involved.

Monitoring of Animal

I. Anal sac impaction and inflammation often recur.
II. It is important to maintain a regular schedule of anal sac expression if the animal is prone to recurrence (e.g., every 4 to 6 weeks).
III. In some instances, the owner can be taught how to express the anal sacs.
IV. A change in diet that allows more normal stool consistency may help control impaction (e.g., changing from a canned food diet to a dry ration, lowering fat content, etc.).
V. Draining tracts that develop after anal sacculectomy are usually the result of incomplete removal and may require exploratory surgery with excision of any remaining tissue to achieve complete resolution.
VI. Fecal incontinence is a potential complication of anal sacculectomy, especially when done bilaterally.

Perianal Fistula

Definition

I. Chronic, painful, inflammatory condition involving the perianal tissues
II. Results in ulcerative lesions in the skin and deeper draining tracts with a malodorous discharge

Causes

I. Genetic predisposition
A. It is reported in many breeds, but the German shepherd dog and Irish setter are most commonly affected.
B. Although conformation may contribute (broad, flat tailhead resulting in a fecal film over the perineal area), only a small percentage of dogs with this conformation are affected.

II. Immunological defect (Wyatt, 1998)
III. Concurrent colitis, especially in German shepherd dogs (Harkin et al., 1996)

Pathophysiology

I. Lesions begin as periappendageal inflammation in the dermis, with infiltration of lymphocytes, plasma cells, and eosinophils.
II. Progression of the inflammation leads to the development of ulcerative lesions and draining tracts (sinuses) of variable depth.
III. True rectal-cutaneous fistulas are uncommon.
IV. The fibrosis that develops with chronic lesions may lead to anal stenosis and stricture.

Clinical Signs

I. Onset often insidious and may go unnoticed
II. Excessive licking of the perianal region
III. Single or multiple draining tracts with thick, malodorous discharge
IV. Perianal hemorrhage
V. Dyschezia
VI. Tenesmus or constipation
VII. Personality change
VIII. Pain on raising tail and with rectal palpation

Diagnosis

I. Breed of dog is suggestive.
II. Physical examination shows typical lesions, and removal of hair often reveals a greater extent of involvement.
III. Proctoscopy and colonoscopy are performed to identify concurrent colonic involvement.

Differential Diagnosis

I. Anal sac abscesses with fistulas directly overlying the anal sac

II. Perianal tumors, especially squamous cell carcinoma and adenocarcinoma
III. Autoimmune skin disease
IV. Anusitis
V. Perianal irritation from caustic or thermal injury and trauma

Treatment

I. Medical management is recommended as the initial treatment for most cases.
   A. Immunosuppressive drugs
      1. Cyclosporine
         a. Dosage is 4 to 8 mg/kg PO BID initially (6 to 12 weeks) and then tapered, for a total of 18 to 20 weeks of treatment (Patterson and Campbell, 2005).
         b. Treating with the higher initial dose and then tapering over a longer time period may provide a faster resolution and fewer relapses.
      2. Prednisone
         a. Give 3 to 4 mg/kg PO SID for 3 to 6 weeks, then slowly taper to 1 mg/kg SID to QOD.
         b. Monitor for relapses as the dose is tapered (Patterson and Campbell, 2005).
         c. Prednisone is recommended primarily for dogs with mild lesions.
      3. Azathioprine
         a. Dose is 50 mg PO SID (Tisdall et al., 1999).
         b. Treat for 4 to 6 weeks or until no further improvement is seen.
         c. Complete resolution is unlikely, but the drug simplifies the surgery needed to eliminate residual disease.
         d. It can be used with prednisone at a dose of 1.5 to 2.2 mg/kg PO SID for 2 to 4 weeks then QOD. (Patterson and Campbell, 2005).
      4. Topical tacrolimus (0.1%)
         a. Primary treatment for mild lesions (Patterson and Campbell, 2005)
         b. Adjunct to cyclosporine therapy so induction dose of cyclosporine can be reduced
   B. Antibiotics
      1. Secondary infection of the fistulas is common.
      2. They reduce odor and amount of discharge.
      3. Consider metronidazole 15 mg/kg PO BID for 7 to 10 days.
      4. Consider cephalexin 20 mg/kg PO BID for 7 to 10 days.
   C. Dietary modification (hypoallergenic diets) for evidence of colitis
II. Surgical management is indicated when medical management fails.
   A. Anal sacculectomy is recommended in all cases, because the sacs often become secondarily involved.
   B. Excise all diseased tissue via surgical dissection, electrosurgery, or carbon dioxide laser.
   C. Perform primary closure unless excessive tension is present.
   D. Tail amputation may alter the local environment if there is a recurrence (van Ee, 1993).

Monitoring of Animal

I. Monitor for complications of immunosuppressive therapy.
II. Fecal incontinence is a possible sequela to surgery depending on the severity of the fistulas and depth of involvement.
III. Recurrence of the fistulas is possible.

NEOPLASIA

Perianal Adenoma

Definition and Causes

I. A benign, androgen-dependent tumor arising from circumanal hepatoid glands
II. Most common in older, intact male dogs
III. Can arise from a number of sites around the anus, tailhead, and genitalia
IV. Occasionally occurs in older spayed females

Pathophysiology

I. It is a benign neoplasm of primarily hepatoid glandular tissue, with a sebaceous component, in the dermis of the perianal skin.
II. Continued growth results in raised masses that often ulcerate and become secondarily infected.

Clinical Signs

I. Excessive licking of the perianal area
II. Single or multiple firm mass(es) in the perianal dermis
III. Possible masses around the anus, tailhead, inguinal region, and prepuce
IV. Ulceration leading to bleeding and secondary infection with larger masses
V. Sometimes an incidental finding

Diagnosis

I. Physical appearance and location of the mass is usually diagnostic.
II. Rectal examination rules out anal sac neoplasia.
III. Cytological examination of fine-needle aspirates reveals typical hepatoid cells.
IV. Histopathologic examination of the excised mass is necessary to differentiate benign lesions from malignant ones.
V. The testicles should be carefully evaluated for evidence of accompanying neoplasia.

Differential Diagnosis

I. Perianal adenocarcinomas
   A. Much less common, but often clinically indistinguishable from benign tumors
   B. Carry a poor prognosis and commonly metastasize to regional lymph nodes, especially sublumbar nodes
II. Anal sac adenocarcinoma
III. Diffuse hypertrophy of circumanal hepatoid glands in older male dogs

IV. Perianal fistulas
V. Anal sac abscess
VI. Other benign perirectal neoplasms: lipoma, fibroma, trichoepithelioma, leiomyoma

Treatment

I. Castration is the therapy of choice, whether alone or in combination with excision.
II. Submit testicles for histopathology to rule out androgen-secreting tumors (Leydig cell tumor).
III. Surgical excision is indicated under certain conditions.
   A. The tumor is ulcerated, necrotic, hemorrhaging, or getting progressively larger.
   B. The tumor occurs in a female dog.
   C. Excision is typically performed at the time of castration.
IV. Estrogen therapy is not recommended because of its myelosuppressive effects.
V. Radiation therapy is effective, but expensive.
VI. Cryosurgery is effective, but not commonly used.

Monitoring of Animal

I. Most dogs respond well to castration alone, especially if the tumors are small.
II. Surgical excision and cryotherapy may have some complications.
   A. Wound dehiscence and wound infection
   B. Anal stricture with extensive dissection or freezing
   C. Fecal incontinence unlikely unless the lesions are very deep
III. Anusitis, proctitis, or anal stricture may arise after radiation therapy.
IV. Perianal adenocarcinoma is suspected if the tumors fail to regress or continue to grow.

Perianal Adenocarcinoma

Definition and Cause

I. Malignant tumor of the circumanal hepatoid glands
II. Growth not androgen dependent

Pathophysiology

I. Locally invasive malignant tumor of the circumanal hepatoid glands
II. Metastasis to regional lymphatic and lymph nodes common

Clinical Signs

I. Signs are similar to those of perianal adenoma.
II. Males are most commonly affected.
III. Enlarged sublumbar lymph nodes may be palpable by abdominal or rectal palpation.
IV. Interference with defecation occurs with severe regional lymph node enlargement.

Diagnosis

I. Histopathologic evaluation of biopsy specimens (core biopsy specimen)
II. Abdominal radiography and ultrasonography to detect metastases
III. CT scan to search for metastases

Differential Diagnosis

I. Perianal adenoma
II. Anal sac adenocarcinoma
III. Other perirectal masses

Treatment

I. Wide surgical excision of primary tumor if small and metastasis not detected
II. Excision of enlarged lymph nodes (for palliation)
III. Radiation therapy
IV. Chemotherapy with cisplatin or doxorubicin possibly helpful (Withrow, 2001)

Monitoring of Animal

I. Warn owner of the potential for recurrence and metastasis.
II. Reexamine every 3 months for new tumor formation or perianal ulceration.
III. Metastasis occurs to regional lymph nodes, liver, and numerous subcutaneous sites, usually within 6 months.
IV. Complete excision of small lesions may be curative.

Anal Carcinoma

Definition and Cause

I. Aggressive form of squamous cell carcinoma in the intermediate cutaneous zone around the anus
II. A highly malignant and metastatic tumor that initially may appear like perianal fistulas

Pathophysiology

I. Ulcerative or proliferative-ulcerative lesions in the skin around the anus
II. Rapidly progressive lesions resulting in pain, tenesmus, and bleeding

Clinical Signs

I. Flat, ulcerative lesions in the perianal skin
II. Tenesmus, dyschezia
III. Perianal bleeding
IV. Extension into the pelvic cavity on rectal palpation

Differential Diagnosis

I. Anusitis, proctitis
II. Perianal fistulas
III. Other perianal neoplasia

Treatment

I. Wide excision of early lesions
II. Radiation therapy

Monitoring of Animal

I. Aggressive surgery may result in fecal incontinence.
II. Prognosis is poor.

Anal Sac Neoplasia

Definition and Causes

I. These are aggressive tumors that originate from the apocrine glands of the anal sac.
II. The cause is unknown.
III. Early studies indicated higher incidence in females, but more recent studies showed no gender predisposition (Turek et al., 2003).

Pathophysiology

I. The tumors originate in glandular epithelium of the anal sac and are initially confined to this structure.
II. Extension to local tissues occurs as the mass enlarges.
III. Early metastasis to the regional lymph nodes (especially pelvic canal and sublumbar nodes) is common.
IV. Distant metastasis to liver, spleen, and other organs occurs.
V. Hypercalcemia from production of parathyroid hormone-related protein (PTH-RP) is not uncommon.
VI. Metastatic lesions are often functional and produce PTH-RP.

Clinical Signs

I. Small masses asymptomatic and discovered on physical examination
II. Bulging ventrolateral to anus with larger masses
III. Usually unilateral
IV. Licking at the anal area
V. Dyschezia, tenesmus
VI. Constipation
VII. Systemic signs caused by hypercalcemia (see Chapter 43)

Diagnosis

I. Signalment and history often increase the index of suspicion.
II. Palpable mass is present in anal sac or a visible mass is seen in the perineum.
III. Sublumbar lymph node enlargement raises suspicion that the mass is malignant.
IV. Hypercalcemia, hypophosphatemia, and secondary renal insufficiency may be documented on biochemical profile.
V. Increased PTH-RP may be detected.
VI. Obtain chest and abdominal radiographs to check for metastasis.
VII. Abdominal ultrasonography and CT scan are used to assess the extent of metastasis.
VIII. Excision followed by histopathologic evaluation is necessary to confirm the diagnosis.

Differential Diagnosis

I. Anal sac impaction and infection
II. Perianal gland adenoma and adenocarcinoma
   A. Usually more superficial
   B. Anal sac still palpable
III. Other tumors of the perineum

Treatment

I. Surgical excision is the treatment of choice, including sublumbar lymph node removal.
II. Adjunctive radiation therapy of the primary site and regional lymph nodes can be effective (Withrow, 2001).
III. Chemotherapy can be attempted, but efficacy is not established.
IV. Mitoxantrone combined with radiation therapy has improved overall survival time compared with surgery alone (Turek et al., 2003).
V. Treat hypercalcemia and renal insufficiency.

Monitoring of Animal

I. Asymptomatic dogs with complete excision and no evidence of local invasion or metastasis have a good to guarded prognosis (DeNovo and Bright, 2000).
II. If metastatic disease is identified, the long-term prognosis is poor.
III. Hypercalcemia should resolve following complete excision.
IV. Recurrence of hypercalcemia is indicative of either recurrence of the primary tumor or metastatic disease.
V. Acute and chronic complications are common after radiation therapy

Rectal Neoplasia

CHAPTER 36

Diseases of the Exocrine Pancreas

Craig G. Ruaux

INFLAMMATORY DISEASES

Acute Pancreatitis

Definition

I. It is an inflammatory condition of the exocrine pancreatic tissue, with infiltration by inflammatory cells and interstitial damage by pancreatic enzymes.
   A. Several mechanisms exist to prevent damage to pancreatic tissue from digestive enzymes, and defects in any of these mechanisms can potentially lead to pancreatitis.
      1. Proteolytic enzymes are synthesized as inactive precursors (zymogens).
      2. Zymogens are isolated in secretory granules before secretion.
      3. Local proteins inhibit or inactivate any zymogens that become activated within the secretory granules.
      4. Secretion of the secretory granules is localized, usually only through the apex of the acinar cell into the acinus.
   B. With excessive stimulation of the pancreas, ischemia, or excess hydrostatic pressure in the pancreatic duct, enzyme/proenzyme transport is disturbed.
      1. Excretion of zymogen granules into the intercellular space and interstitium exposes pancreatic tissue to damaging effects from these enzymes.
      2. Damage to the pancreatic interstitium by digestive enzymes causes release of cytokines that attract inflammatory cells to the pancreas.
   C. The pancreas is a source of cytokines released during pancreatitis.
      1. Tumor necrosis factor-α, interleukin 6, and interleukin 10 are produced by inflamed pancreatic acinar tissue (Brivet et al., 1999).
      2. Pancreatic production of proinflammatory cytokines may lead to systemic inflammatory response and distant organ failure (Ruaux, 2000).

II. Acute pancreatitis can range from a mild, self-limiting disease to fulminant, rapidly lethal disease.
   A. Complications are common in severe, acute pancreatitis.
   B. Acute pancreatitis is diagnosed in both dogs and cats.
      1. Cats often present with more subtle signs of disease, possibly only inappetence or occasional vomiting.
      2. Cats are more commonly affected with chronic, relapsing pancreatitis rather than single bouts of severe, acute pancreatitis.

Causes

I. Nutritional factors
   A. Obese dogs are at greater risk of developing acute pancreatitis.
   B. Lower fat diets reduce the risk of relapse in recovering animals.
   C. History of consumption of a high-fat meal is common in dogs with acute pancreatitis.

II. Hyperlipidemia
   A. There is a high frequency of pancreatitis in miniature schnauzers, which commonly have marked hyperlipoproteinemia.
   B. Very high concentrations of triglycerides may lead to lipid thrombi in the pancreatic circulation, thereby causing or worsening pancreatic ischemic injury.
   C. Hyperlipidemia may also result from abdominal fat necrosis.

III. Trauma
   A. Surgical or blunt abdominal trauma may precipitate pancreatic inflammation.
   B. Hypovolemia, ischemia, and reperfusion injury are most likely responsible.
   C. Pancreatic biopsy alone is rarely associated with significant pancreatic inflammation in hemodynamically stable animals.

IV. Hepatobiliary disease: possible extension of inflammatory disease to pancreas

V. Small intestinal disease: extension of inflammatory disease to pancreas

VI. Pancreatic duct reflux
   A. It is considered rare.
   B. It is only likely with high intraduodenal pressure (e.g., during vomiting).
   C. As vomiting is a common sequela of pancreatitis, the role of ductal reflux in initiation of the disease is difficult to assess.

VII. Pancreatic duct obstruction
   A. It may arise with neoplasia, trauma, surgery, and parasite migration.
   B. Compression of the duct and resultant back pressure damages pancreatic acinar tissue.

C. Frequency of pancreatitis from duct obstruction is low.

VIII. Drugs
- A. Many drugs have been implicated, mainly in limited observational studies.
- B. Glucocorticoids are commonly considered to cause pancreatitis, but no experimental evidence is available.
  1. High-dose glucocorticoids are often given to animals with hemodynamic compromise (e.g., shock, intervertebral disc disease).
  2. Ischemia and reperfusion injury of the pancreas from the concurrent condition is a more likely cause of pancreatitis.
- C. Hyperadrenocorticism may increase the risk of acute pancreatitis by increasing food intake and dietary indiscretion.

IX. Babesiosis: possible ischemia and reperfusion injury (Mohr et al., 2000)

X. Conditions associated with acute pancreatitis in cats
- A. Inflammatory bowel disease (IBD)
- B. Cholangitis, cholangiohepatitis (Mansfield and Jones, 2001)
- C. Infections: *Toxoplasma gondii,* parvovirus, feline infectious peritonitis (FIP)
- D. Hepatic lipidosis: 59% of acute cases (Hill and Van Winkle, 1993)
- E. Organophosphates, drug toxicities
- F. Abdominal trauma: high-rise syndrome

Pathophysiology

I. Within the pancreatic parenchyma, ischemia/reperfusion injury or excessive stimulation lead to abnormal release of zymogen granules.

II. Lipase and elastase-mediated damage to the pancreatic interstitium triggers inflammation within the gland.

III. Release of pancreatic enzymes into the interstitium and peritoneal space establishes a chemical peritonitis.

IV. Up-regulation of inflammatory cells occurs from pancreatic cytokine release, leading to a state of systemic inflammation.

V. Fluid losses from vomiting, ileus, and severe systemic inflammatory changes can lead to organ failure.

VI. There is no experimental evidence that circulating pancreatic enzymes contribute to organ failure in naturally occurring acute pancreatitis.

VII. Secondary hepatic injury is common in acute pancreatitis.
- A. Pancreatic swelling can obstruct the common bile duct, leading to extrahepatic cholestasis.
- B. Local release of pancreatic enzymes and cytokines, and degranulation of neutrophils can lead to hepatocellular injury.
- C. Splanchnic congestion and circulatory compromise also occur.

Clinical Signs

I. The clinical signs of pancreatitis are variable and nonspecific.

II. The following are common signs observed in dogs:
- A. Acute vomiting, often following a high-fat meal
- B. Cranial abdominal pain
  1. Splinting on palpation of the abdomen, particularly in the right cranial quadrant
  2. Restlessness, pacing, adoption of the "prayer position"
- C. Fever
- D. Obtundation

III. Less common signs in dogs are as follows:
- A. Diarrhea
- B. Abdominal mass or distension, hepatomegaly
- C. Icterus, petechiation, coagulopathy
- D. Weakness, tachycardia, tachypnea, pulmonary edema
- E. Injected mucous membranes

IV. Clinical signs in cats are often more subtle, but commonly include the following:
- A. Vomiting, inappetence, weight loss, diarrhea, icterus, lethargy, dehydration, hypothermia, dyspnea
- B. ± Palpable abdominal masses and cardiovascular shock
- C. Diarrhea with intestinal disease

Diagnosis

I. No diagnostic test is 100% sensitive and specific for acute pancreatitis.

II. Pancreatic inflammation often has a patchy distribution and varying severity within the gland (Newman et al., 2004).

III. A presumptive diagnosis can be made from physical findings, history, presence of predisposing factors, laboratory results, and/or imaging findings.

IV. Laboratory investigation may show the following changes:
- A. Complete blood count (CBC)
  1. Neutrophilia, with or without a left shift
  2. Neutropenia and degenerative left shift from severe systemic inflammation, sepsis, peritonitis, pancreatic necrosis
  3. Decreased platelets and red blood cell fragments with disseminated intravascular coagulopathy (DIC)
  4. Increased packed cell volume (PCV) and total protein from dehydration
- B. Routine biochemistry assays
  1. Elevated total bilirubin with secondary hepatopathy or cholestasis
  2. Azotemia: prerenal (dehydration), acute renal failure
  3. Hyperglycemia
     - a. It is common and may be secondary to increased glucagon secretion, insulin resistance, and stress-related cortisol and catecholamine release.
     - b. Cats are particularly susceptible to stress-induced hyperglycemia.
  4. ± Elevated alkaline phosphatase and alanine transaminase
     - a. Secondary hepatitis, hepatic ischemia, local peritonitis
     - b. Cholestasis or cholangiohepatitis

5. Hypercholesterolemia, hypertriglyceridemia, gross lipemia common
6. Possible hypocalcemia
   a. Calcium consumption
   b. Low serum albumin concentrations with systemic endothelial dysfunction
   c. Intracellular shifts of calcium

C. Digestive enzyme activities
1. Amylase and lipase may be elevated in dogs.
2. Amylase and lipase are of no clinical value in cats.
3. Elevations of amylase or lipase and compatible clinical signs support the diagnosis, but sensitivity and specificity are low.
4. The diagnosis cannot be ruled out in the presence of normal amylase and lipase.
5. Renal failure may cause a three-fold elevation in serum lipase.

D. Trypsin-like immunoreactivity (TLI)
1. Trypsin/trypsinogen is exclusively pancreatic in origin, and there is no significant reabsorption from the intestinal tract.
   a. Elevations are consistent with increased pancreatic acinar cell permeability as occurs with pancreatitis.
   b. They are markedly elevated in the early stages of experimental acute pancreatitis, but return to normal or are subnormal within the first 24 hours (Williams et al., 1996).
   c. Trypsinogen is cleared by renal mechanisms, and active trypsin is cleared extremely rapidly by plasma anti-proteinases and the reticuloendothelial system.
2. TLI is cleared by renal mechanisms, so renal insufficiency may lead to elevated serum TLI in the absence of pancreatic disease.
3. Serum TLI has poor diagnostic accuracy in both dogs and cats, and it is not recommended for this disease (Ruaux and Atwell, 1999; Swift et al., 2000).
4. The reference range (normal values) for serum TLI in dogs is 5 to 35 μg/L, and in cats it is 12 to 82 μg/L.
5. Values >50 μg/L in dogs and >200 μg/L in cats are recommended for the diagnosis of acute pancreatitis.

E. Pancreatic lipase immunoreactivity (PLI)
1. The pancreas produces a structurally distinct lipase.
2. PLI assays are available for both dogs and cats.
3. Pancreatic lipase is cleared from the circulation slower than TLI, which increases the sensitivity of this test for acute pancreatitis (Williams et al., 2003).
4. The normal values for PLI are 0 to 200 μg/L in dogs (using the IDEXX specPL assay) and 2.0 to 6.8 μg/L in cats.
5. Values >400 μg/L in dogs and >12 μg/L in cats support a diagnosis of pancreatitis.

V. Abdominal radiography is indicated when acute pancreatitis is suspected and may show the following signs:
   A. Diminished contrast and increased soft-tissue density in the cranial abdomen, often with a granular appearance ("ground glass" appearance)
   B. A widening of the angle between the pylorus and descending duodenum, or the presence of a mass medial to the descending duodenum
   C. Gas distension of the stomach
   D. Presence of a static gas pattern in the descending duodenum and/or transverse colon
   E. Caudal displacement of the transverse colon

VI. Abdominal ultrasonography has become increasingly useful in the diagnosis of pancreatitis, and the following findings are suggestive:
   A. Loss of echodensity or mottled echogenicity in the area of the pancreas
      1. Hypoechoic areas are commonly seen in hemorrhagic forms of the disease, with surrounding hyperechoic regions representing pancreatic edema.
      2. Peripancreatic fat is often hyperechoic.
   B. Mass effect in the area of the pancreas
   C. Localized peritoneal effusion
   D. Biliary obstruction secondary to pancreatic inflammation
   E. Pancreatic pseudocysts or abscesses
      1. Cystic masses may contain necrotic pancreatic tissue, pancreatic secretions, and inflammatory exudates.
      2. Pseudocysts and abscesses may be seen distant from the body of the pancreas.

VII. Computed tomography (CT) is of limited value (Gerhardt et al., 2001; Jaeger et al., 2003).

VIII. Abdominocentesis, exploratory laparotomy and laparoscopy may all be considered if the diagnosis is unclear.
   A. Therapeutic actions should not be delayed by these diagnostic steps.
   B. The pancreas can be viewed laparoscopically via a ventral or right lateral approach.
   C. The pancreas can be biopsied with punch-type biopsy forceps, avoiding the center of the gland.
   D. Complications of laparoscopic biopsy are rare.

Differential Diagnosis

I. Other causes of acute abdomen syndrome: see Chapter 39

II. Other gastrointestinal (GI) diseases
   A. Intestinal obstruction, foreign bodies, intussusception, volvulus
   B. Intestinal infarction
   C. Viral infections: parvovirus, canine distemper, infectious canine hepatitis
   D. Systemic infections: leptospirosis, salmonellosis, sepsis
   E. Acute cholecystitis
   F. Hemorrhagic gastroenteritis
   G. Hepatic infarction

III. Other nongastrointestinal diseases
   A. Acute pyelonephritis
   B. Acute renal failure (possible complication of pancreatitis)

C. Rupture of the urinary bladder, post-renal obstruction from feline urologic syndrome, ureteral calculi
D. Prostatitis
E. Ketoacidotic diabetes mellitus (possible complication of pancreatitis)
F. Peritonitis
G. Hypoadrenocorticism
H. Pyometra, acute metritis
I. Testicular torsion

Treatment

I. The major goals of therapy are as follows:
   A. To correct and maintain normal fluid balance and electrolytes
   B. To control vomiting
   C. To control abdominal pain
   D. To maintain the integrity of the pancreatic microcirculation
   E. To anticipate and manage complications
II. Therapeutic planning begins with rational determination of the severity of the condition.
   A. Loss of all exocrine pancreatic function is not acutely life-threatening.
   B. Death from acute pancreatitis is secondary to distant organ failure rather than exocrine pancreatic gland failure.
      1. Assessment of the CBC and biochemistry panel allows detection of other organ problems.
      2. Compromise of multiple organs is associated with more severe disease and a worse prognosis.
III. Medical management of mild acute pancreatitis involves the following:
   A. Attempt to eliminate any predisposing factors (see Causes).
   B. Assess state of hydration.
   C. Fluid losses in pancreatitis are often greater than anticipated because of ileus.
   D. Institute fluid replacement therapy with a balanced electrolyte solution (e.g., lactated Ringer's, Normosol) at a rate calculated to replace deficits and meet maintenance requirements.
      1. Consider potential for ongoing losses if vomiting or diarrhea continues.
      2. Subcutaneous fluids may be used in some very mild cases treated as outpatients, but hospitalized animals should receive parenteral fluids.
      3. Addition of 20 mEq KCl/L of fluids is recommended because of potassium loss with vomiting.
      4. Mild acidosis resolves with fluid therapy, rehydration, and increased renal perfusion in most uncomplicated cases.
   E. If vomiting continues, consider antiemetics.
      1. Metoclopramide may be given at 0.2 to 0.5 mg/kg SC TID to QID, or as a constant rate infusion of 1 to 2 mg/kg /24 hours IV (preferred).
      2. If vomiting is not controlled with metoclopramide, ondansetron *(Zofran)* or dolasetron *(Anzemet)* is given at 0.6 mg/kg IV SID.
   F. Give nothing per os (NPO) for 48 to 96 hours.
      1. Maintain hydration with fluid therapy.
      2. Offer water 24 hours after vomiting stops.
      3. If water is tolerated, gradual reintroduction of a high-carbohydrate, low-fat diet is indicated.
      4. Initial diets may be either homemade or commercially available low-fat products.
      5. Feed small amounts often.
      6. If food is tolerated while hospitalized, discharge with instructions to avoid high-fat foods.
      7. Table scraps must be diligently avoided.
   G. Institute effective pain control.
      1. Butorphanol 0.2 to 0.4 mg/kg SC every 4 to 6 hours
      2. Oxymorphone 0.05 to 0.1 mg/kg SC, IM, IV every 4 to 6 hours (use low dose in cats)
      3. Avoid nonsteroidal antiinflammatory drugs (NSAIDs) because of risk for GI ulceration
   H. Manage complications.
      1. There is little evidence of bacterial infection in most cases of mild acute pancreatitis, so antibiotics are not recommended in routine cases.
      2. Any decline in PCV and total protein warrants further investigation.
IV. Medical management of severe, acute pancreatitis can be challenging.
   A. It often involves failure or compromise of multiple organ systems and is a medical emergency.
   B. Treatment requires 24-hour care and intensive monitoring.
   C. The major causes of death are hypovolemia and cardiovascular shock.
      1. Following resuscitation for cardiovascular shock, affected animals are at high risk for renal, pulmonary, and hepatic insufficiency, as well as DIC.
      2. Initial resuscitation therapy must be aggressive, so administer crystalloid fluids at shock rates (up to 90 mL/kg/hr IV) for the first hour.
      3. Monitor PCV and total protein.
      4. If total protein is declining, consider a plasma transfusion or colloidal fluids (hetastarch, dextrans) for support of plasma oncotic pressure (see Chapter 71).
         a. They may reduce pancreatic edema, help maintain pancreatic microcirculation, and reduce or mitigate pulmonary edema and pleural effusion.
         b. Plasma replenishes coagulation proteins and reduces the risk of DIC.
      5. Whole blood transfusion may be indicated for severe intraabdominal hemorrhage (see Chapter 71).
      6. Proteinase inhibitors (e.g., aprotinin) have provided no benefit in spontaneous acute pancreatitis and are not recommended.
   D. Administer effective analgesia.
      1. Butorphanol 0.2 to 0.4 mg/kg SC every 4 to 6 hours
      2. Oxymorphone 0.05 to 0.1 mg/kg SC, IM, IV every 4 to 6 hours (use low dose in cats)
      3. NSAIDs avoided because of the risk for GI ulceration
   E. Most animals are inappetent for several days.

1. Maintain NPO for 48 hours after cessation of vomiting.
2. If NPO >5 days, or if >10% body weight is lost while receiving adequate fluid therapy, nutritional support is indicated.
   a. Enteral feeding is preferred, to maintain gut function.
   b. Feeding of an elemental diet by jejunostomy catheter may be considered.
   c. Total parenteral nutrition may be necessary in some cases.

F. Control vomiting as described previously.

V. Surgical intervention may be indicated for management of peritonitis, with open peritoneal drainage and lavage.
   A. Surgical management of complications following pancreatitis has been described elsewhere (Bellenger et al., 1989; Barnhart and Smeak, 1998; Marchevsky et al., 2000).
   B. Ultrasound-guided percutaneous drainage of pseudocysts may be attempted (Smith and Biller, 1998).

Monitoring of Animal

I. The following complications are anticipated with severe pancreatitis, and early recognition is important for their successful management:
   A. Acute renal failure
   B. DIC
   C. Pancreatic abscessation, pseudocyst development
   D. Sepsis
      1. Ileus, circulatory compromise, and GI inflammation compromise the gut's barrier function.
      2. Devitalized pancreatic tissue may become infected following bacterial translocation or pancreatic duct reflux (during vomiting).
   E. Pulmonary insufficiency and thromboembolism
   F. Cardiac arrhythmias
   G. Diabetes mellitus, ketoacidosis
      1. They are relatively common, transient phenomena.
      2. Hyperglycemia and acidosis often resolve with fluid therapy.
      3. Institute insulin for diabetic ketoacidosis.
   H. Jaundice
      1. It may arise from direct hepatic injury, secondary inflammation, obstruction of extrahepatic biliary duct, or hemolysis.
      2. Persistent jaundice despite aggressive therapy indicates a need for exploratory laparotomy.
   I. Exocrine pancreatic insufficiency
      1. It is uncommon in dogs after a single episode of severe, acute pancreatitis.
      2. It may develop after recurrent bouts of mild to severe, acute pancreatitis.

II. Mild, edematous pancreatitis has a fair to good prognosis.

III. Severe, hemorrhagic, or necrotizing pancreatitis has a poorer prognosis.

Chronic Pancreatitis

Definition and Causes

I. Chronic pancreatitis is characterized by either recurrent episodes of inflammation or persistent clinical signs.

II. Chronic pancreatitis may occur with improper dietary management following acute pancreatitis.

III. Chronic, subclinical pancreatitis is the most common form of pancreatitis in the domestic cat.

IV. Chronic pancreatitis may accompany other systemic illnesses.
   A. Dogs: hyperadrenocorticism, diabetes mellitus, hyperlipidemia
   B. Cats: toxoplasmosis, FIP, panleukopenia, IBD, cholangiohepatitis

Pathophysiology

I. Recurrent inflammatory episodes may lead to progressive destruction of pancreatic parenchyma, with fibrosis and loss of acinar cellular mass.
   A. Progressive loss of pancreatic tissue may cause permanent impairment of pancreatic or hepatic function.
   B. Subclinical chronic pancreatitis is the main cause of exocrine pancreatic insufficiency in cats.
   C. Diabetes mellitus may develop with loss of islet cells.
   D. Extrahepatic bile duct obstruction may lead to obstructive cholestasis.

II. In cats, chronic pancreatitis and cholangiohepatitis or hepatic lipidosis may coexist because of the connection between the pancreatic and common bile ducts.

III. Miniature schnauzers are at increased risk for development of chronic pancreatitis and often have hyperlipidemia.
   A. Marked breed predisposition suggests a genetic component in these dogs.
   B. No mutations have yet been detected in trypsinogen or lipoprotein lipases in affected dogs (Bishop and Steiner, 2002).

Clinical Signs

I. Anorexia, chronic intermittent vomiting

II. Intermittent pyrexia, abdominal pain

III. Weight loss, diarrhea

Diagnosis

I. Clinical signs are often vague and nonspecific.

II. History usually indicates a waxing and waning general malaise.

III. Clinical pathologic results are highly variable and often unremarkable.
   A. The serum PLI test is often useful in confirming the diagnosis, with elevations persisting for several days following episodes of pancreatic inflammation (Williams et al., 2003).
   B. Mildly elevated PLI in animals with consistent clinical signs is supportive of the diagnosis.
   C. Traditional serum lipase assays are of no value.

D. Rule out toxoplasmosis and FIP in cats.

IV. Abdominal ultrasonography may show changes similar to those described for acute pancreatitis, and the pancreatic duct may be dilated (>1 mm) in cats (Leveille et al., 1996).

Differential Diagnosis

I. Other causes of chronic vomiting: chronic gastritis, renal failure, GI foreign body, or gastric neoplasia

II. Other causes of chronic intestinal signs: IBD, hypoadrenocorticism, intestinal neoplasia

III. Other causes of chronic inappetence: cholangiohepatitis (cats)

Treatment and Monitoring

I. During episodes of acute signs, treatment is similar to that for acute pancreatitis, as described earlier.
   A. Many cases recover rapidly with outpatient therapy (pain control, pancreatic rest).
   B. Persistence of vomiting or presence of dehydration warrants hospitalization and treatment as for acute pancreatitis.

II. Long-term management revolves around dietary changes.
   A. For dogs, higher carbohydrate and fat-restricted diets are recommended.
   B. Cats may benefit from a novel protein source and moderate fat restriction.
   C. Requirements for dietary arachidonic acid limit the long-term use of very low-fat diets in cats.

III. In some cases where dietary management is not effective, oral prednisone at antiinflammatory doses (0.5 to 1.0 mg/kg PO SID to QOD) may be considered.

IV. There is no objective evidence of benefit from oral supplementation with pancreatic enzymes in these cases.

V. Prognosis is fair to good if dietary management is successful and other predisposing factors (e.g., hyperlipoproteinemia) can be controlled.

NONINFLAMMATORY DISEASES

Exocrine Pancreatic Insufficiency

Definition

I. Loss of pancreatic acinar tissue results in a syndrome of malabsorption, maldigestion, malassimilation, and small intestinal diarrhea.

II. Clinical signs do not develop until approximately 85% to 90% of the exocrine pancreatic secretory function is lost (Westermarck et al., 1993; Wiberg and Westermarck, 2002).

III. Exocrine pancreatic insufficiency (EPI) occurs in both dogs and cats, but the frequency in cats is lower.

Causes

I. The most common cause in young dogs is pancreatic acinar atrophy.
   A. Numerous breeds are affected; large breeds are affected most often.
   B. The German shepherd dog has a high prevalence, and the disease is most likely inherited in an autosomal recessive manner (Moeller et al., 2002).
   C. Lymphocytic infiltration of the pancreas precedes pancreatic acinar atrophy in German shepherd dogs and rough-coated collies (Wiberg et al., 1999; Wiberg et al., 2000; Wiberg, 2004).

II. Chronic pancreatitis is the most common cause of EPI in the cat, because the end stage of chronic pancreatitis is fibrosis and acinar atrophy.

III. Pancreatic neoplasia, congenital pancreatic hypoplasia or aplasia, and pancreatic duct obstruction, although rare, can all lead to exocrine insufficiency.

IV. EPI can occur with some nonpancreatic diseases (e.g., duodenal hyperacidity, severe protein-calorie malnutrition).

Pathophysiology

I. Loss of pancreatic acinar tissue results in reduced secretion of digestive enzymes into the small intestine.

II. Failure of small intestinal digestion results in nutrient malabsorption.
   A. Concomitant changes occur in small intestinal mucosal function and morphology, contributing to malabsorption.
   B. Mucosal enzyme defects lead to abnormal transport of sugars, amino acids, and fatty acids.
   C. Loss of trophic factors in pancreatic secretions may result in villous atrophy and inflammatory infiltration.
   D. Bacterial overgrowth may occur, leading to nutrient competition.
   E. Global malnutrition has an adverse effect on the GI mucosa.

III. With EPI secondary to chronic pancreatitis (typically cats), diabetes mellitus may occur from islet cell loss.

Clinical Signs

I. Signalment
   A. In dogs, signs are usually seen in young adults, typically <2 years of age.
   B. Pancreatitis-induced EPI in dogs can occur at any age, but is more common in middle-aged to older dogs and in smaller breeds.
   C. In cats, signs usually develop in middle-aged to older cats, reflecting the more chronic etiology.
   D. There is no sex predilection.

II. Common clinical signs and physical examination findings
   A. Young adult dogs are usually bright, alert, and active, but underweight for their age.
   B. Cats typically have chronic weight loss as well as a waxing and waning appetite, which reflect underlying chronic pancreatitis.
   C. Mild to moderate weight loss is noted.
      1. Weight loss occurs despite a good to ravenous appetite and polyphagia.
      2. Pica and coprophagia may occur in dogs.
      3. Some dogs are emaciated, with muscle wasting and severely reduced body fat.

D. Diarrhea is a common clinical sign.
   1. Decreased digestion and malabsorption result in an increased osmotic gradient into the GI lumen.
   2. Protein and carbohydrates in the lumen undergo bacterial fermentation with production of diarrheagenic products.
   3. The diarrhea is typically voluminous, poorly formed, and may have a rancid odor.
   4. As fatty acids are a major osmotic agent, the diarrhea may show some improvement with a low-fat diet.
   5. With indoor–outdoor cats, diarrhea may not be observed.
E. Vomiting is an occasional clinical sign in dogs, but it is more common in cats.
F. Borborygmus and flatulence may be noted.
G. The hair coat is often of poor quality.
H. Oily staining of the perineum is common in cats and may be noted in dogs.
I. Polydipsia and polyuria may occur with diabetes mellitus.

Diagnosis

I. Typical history and clinical signs, particularly in young large-breed dogs, are suggestive.
   A. Clinical signs are nonspecific, and the diagnosis must be confirmed.
   B. Confirmation is important because treatment is expensive in large-breed dogs.
II. Many laboratory tests have been used to diagnose EPI in dogs and cats.
   A. Clinical biochemistries are usually unremarkable.
   B. Traditional diagnostic tests, such as the oral N-benzoyl-L-tyrosyl-para-amino-benzoic acid (BT-PABA) test, fecal fat determination, and fecal proteolytic activity, are of poor sensitivity and specificity and are not recommended.
III. The most reliable test in both dogs and cats is serum TLI concentration.
   A. Reduced TLI concentration is highly sensitive and specific for EPI.
   B. Prior administration of pancreatic extracts does not interfere with the assay.
   C. Canine TLI assays are widely available.
   D. Feline TLI assay is only available from the Gastrointestinal Laboratory at the College of Veterinary Medicine and Biomedical Sciences, Texas A&M University.
   E. Interpretation of TLI results is straightforward in most cases.
      1. Serum TLI is markedly decreased in dogs (<2 μg/L) and cats (<8 μg/L) with EPI.
      2. Dogs with small intestinal disease usually have normal serum TLI concentrations (5 to 35 μg/L).
      3. Cats with small intestinal disease often have mild elevations in serum TLI concentrations (100 to 200 μg/L).
      4. Subclinical EPI in dogs is diagnosed with persistent serum TLI concentrations <5 μg/L in the absence of clinical signs (Wiberg and Westermarck, 2002; Westermarck and Wiberg, 2003).
IV. Serum PLI is inferior for the diagnosis of EPI (Steiner et al., 2001).
V. Measurement of serum folate and cobalamin concentrations is indicated.
   A. Serum folate may be elevated from increased bacterial biomass.
   B. Serum cobalamin may be reduced owing to ileal mucosal disease and intrinsic factor deficiency.
   C. In the cat, the pancreas is the sole source of intrinsic factor, so essentially all cats with EPI have marked cobalamin deficiency (Ruaux et al., 2001, 2005).
   D. Fecal elastase enzyme-linked immunosorbent assay has lower sensitivity and specificity than serum TLI and is not recommended for the diagnosis of EPI.

Differential Diagnosis

I. The major differential diagnoses for EPI are diffuse, infiltrative small intestinal diseases (see Chapter 33).
II. Many cats with clinical signs suggestive of EPI have normal to elevated serum TLI concentrations and significant small intestinal disease.

Treatment

I. Goals
   A. Replacement of pancreatic digestive enzymes
   B. Restoration of an adequate nutritional state
      1. Replacement of fat-soluble vitamins
      2. Replacement of water-soluble vitamins, such as cobalamin
II. Digestive enzyme replacement
   A. Pancreatic enzyme supplements are commercially available and are usually extracts from porcine pancreata.
   B. Enteric-coated preparations are less effective in dogs and cats.
   C. Preincubation of food with enzymes does not increase effectiveness and may lead to food aversion in cats.
   D. Addition of bile salts, antacids, or sodium bicarbonate to the meal has no benefit.
   E. Dosages of powdered pancreatic enzymes are as follows:
      1. In dogs, start with 2 tsp/20 kg body weight with each meal.
      2. In cats, start with $^1/_2$ tsp/5 kg.
   F. Mix enzymes with a maintenance diet immediately before feeding.
   G. Two meals a day are usually adequate to promote rapid weight gain in affected dogs.
      1. Diarrhea usually resolves within 2 to 3 days.
      2. Once improvement is seen, determine minimal effective dose via slow tapering.
      3. Strict maintenance of dietary routines is critical.
   H. High doses of pancreatic enzymes may lead to periodontal bleeding and ulceration in dogs, necessitating dosage reduction (Rutz et al., 2002).
III. Restoration of nutritional state

A. Maintenance dog and cat foods are usually adequate with appropriate enzyme replacement therapy.
B. Higher fiber diets are not recommended as they may adversely impact the activity of supplemented digestive enzymes.
C. A low-fat, highly digestible diet may be beneficial for initial stabilization, but the utility of these diets is not universally accepted (Simpson et al., 1994; Westermarck et al., 1995).
D. Consider supplementation with fat-soluble vitamins in severely affected animals.
   1. Coagulopathy from vitamin K deficiency has been documented in a cat (Perry et al., 1991).
   2. Deficiency of fat-soluble vitamins is common in affected German shepherd dogs (Rutz et al., 2001).
E. In cats with cobalamin deficiency (<300 pg/L), parenteral supplementation is instituted at 250 μg SC every 7 days for 6 weeks, then 250 μg SC every 14 days for 6 weeks, then 250 μg SC every 28 days thereafter (Ruaux et al., 2002, 2005).
F. Medium-chain triglyceride (MCT) oil, 1 to 2 mL/kg/day PO in combination with a severely fat restricted diet may be used in dogs if steatorrhea continues.
G. Severe fat restriction is done with caution in cats because of their obligate requirement for dietary arachidonic acid.
H. Reduction of gastric acid secretion is not recommended in most cases.
I. Antibiotic therapy may be considered for dogs.
   1. If there is evidence of intestinal bacterial overgrowth, antibiotic therapy may be indicated.
   2. Tylosin (25 mg/kg PO BID) or metronidazole (10 to 15 mg/kg PO BID) are reasonable choices.
J. If there is poor response to therapy, prednisone at 1 to 2 mg/kg PO SID for 14 days, then tapered, may be beneficial because lymphocytic-plasmacytic enteritis often coexists with EPI.

Monitoring of Animal

I. Monitor body weight
   A. Rapid weight gain is expected with adequate enzyme replacement therapy.
   B. Some dogs fail to regain full body weight even if steatorrhea and polyphagia resolve.
II. Lifelong treatment is usually required.
III. Prognosis is generally good for dogs with EPI.
   A. Response to therapy is variable, but >50% show improvement (Wiberg et al., 1998).
      1. Poor responses are seen in 20% of affected dogs.
      2. Dermatological disorders are common.
   B. Because EPI requires lifelong therapy and is more common in large-breed dogs, financial constraints may be an issue for some owners.
   C. A high prevalence (10%) of fatal mesenteric torsion has been seen in German shepherd dogs with EPI in Finland (Westermarck and Rimaila-Parnanen, 1989).
IV. Prognosis is more guarded for cats with EPI.
   A. Food aversion may occur when mixed with digestive enzymes.
   B. Cats may also develop diabetes mellitus, which is more difficult to manage than usual because of poor nutrient uptake.
   C. Owner compliance and administration of enzymes, antibiotics, etc. is often poorer than with dogs.

PARASITIC DISEASES

Definition and Causes

I. Parasitic infestation is an uncommon cause of pancreatic disease in cats.
II. Cats may contract a pancreatic fluke, *Eurytrema procyonis*.
   A. It is normally found in the pancreatic ducts of raccoons and foxes.
   B. Infection is most likely through consumption of an infected intermediate host.
III. Cats may also develop pancreatic duct parasitism by the hepatic fluke, *Amphimerus pseudofelinus.*

Pathophysiology

I. Chronic infestation of the pancreatic duct system may lead to enlargement and fibrosis of the pancreatic ducts.
II. Duct obstruction may produce chronic pancreatitis through increased back pressure on the pancreatic acinar tissue.
III. Chronic inflammation and fibrosis may lead to pancreatic atrophy and decreased pancreatic secretory capacity.

Clinical Signs

I. Infection may be clinically silent or signs may be vague and nonspecific.
II. See discussion of clinical signs under Chronic Pancreatitis.
III. Signs consistent with pancreatitis have been described in a cat infected with *E. procyonis* (Anderson et al., 1987), and rare case reports describe pancreatitis in cats with *A. pseudofelinus* infections (Rothenbacher and Lindquist, 1963; Lewis et al., 1991).

Diagnosis

I. Without a high index of suspicion, these infections remain undiagnosed.
II. Diagnosis is made by demonstration of characteristic parasite ova in fecal flotation preparations.
III. The ova of *A. pseudofelinus* are destroyed on routine fecal flotation and require formalin-ethyl acetate sedimentation.
IV. Histopathologic examination of pancreatic tissue may show evidence of trematodes.

Differential Diagnosis

I. Chronic pancreatitis
II. Exocrine pancreatic insufficiency

Treatment and Monitoring

I. Treatment with fenbendazole 30 mg/kg/day PO for 6 days is effective for *E. procyonis*.

II. Praziquantel 40 mg/kg PO for 3 days is a reasonable alternative and has been recommended for *A. pseudofelinus* (Lewis et al., 1991).
III. Infected cats do not represent a zoonotic risk.

EXOCRINE PANCREATIC NEOPLASIA

Definition and Causes

I. Tumors of the exocrine pancreas are relatively rare in cats and dogs (approximately 0.6% of all neoplasms).
II. Benign pancreatic masses include nodular pancreatic hyperplasia and pancreatic adenomas.
III. Malignant tumors are usually adenocarcinomas.
  A. Typically arise from ductal cells
  B. Acinar cellular origin more common in cats
  C. Metastasis of other malignancies occasionally detected

Pathophysiology

I. Malignant pancreatic tumors are often very aggressive.
II. Metastasis to the duodenum, liver, regional lymph nodes, mesentry, stomach, and (less commonly) pulmonary tissues has usually occurred by the time of diagnosis.
III. Rapid, local growth of the neoplasm may cause gastric outflow, intestinal, obstruction or common bile duct obstruction.
IV. Abnormalities in liver enzyme activities and jaundice are common.

Clinical Signs

I. Pancreatic neoplasms are typically diagnosed in older dogs and cats.
II. Signs are often nonspecific and include obtundation, fever, weight loss, anorexia, abdominal pain, and dehydration.
  A. Vomiting is uncommon.
  B. A palpable mass may be detected in the right cranial abdomen.
  C. Jaundice may be present with bile duct involvement.
  D. Steatitis, panniculitis, and progressive alopecic dermatitis have occasionally been reported (Godfrey, 1998; Fabbrini et al., 2005).
III. Occasionally, concurrent signs of diabetes mellitus or EPI may be noted.
IV. Benign neoplasms of the pancreas typically do not cause clinical signs and are an incidental finding.

Diagnosis

I. Clinical signs and history are often vague.
II. Clinical biochemistry results may resemble acute pancreatitis and often indicate hepatic disease.
III. Serum lipase activity may be extremely elevated, but this finding is nonspecific.
IV. Ultrasonography of the abdomen may identify masses within the pancreas.
  A. Small pancreatic masses may be obscured by overlying gas-filled intestinal loops.
  B. Liver, duodenal, gastric, and mesenteric metastases may be detected.
  C. Ultrasound- or fluoroscopic-guided aspirates are useful in establishing a diagnosis (Bennett et al., 2001).
V. Thoracic radiography may detect pulmonary metastasis.
VI. Detection of neoplastic cells in abdominal effusions is uncommon.
VII. Exploratory laparotomy and histopathologic examination are required for definitive diagnosis.

Differential Diagnosis

I. Acute pancreatitis
II. Chronic pancreatitis
III. Cholangitis/cholangiohepatitis with jaundice
IV. Pancreatic paraneoplastic partial alopecia: see Table 73-1

Treatment and Monitoring

I. Surgical removal of isolated masses is indicated.
II. Palliative and salvage procedures may be performed in selected cases.
  A. Cholecystojejunostomy bypasses a common bile duct obstruction.
  B. Gastrojejunostomy bypasses a duodenal obstruction.
  C. These procedures have high morbidity and mortality rates, but may improve quality of life for short periods.
III. Successful chemotherapy for pancreatic carcinoma has not been reported in dogs and cats.
IV. The prognosis for most dogs and cats with pancreatic carcinomas is extremely poor.
V. Resolution of pancreatic paraneoplastic alopecia has been reported in a cat following resection of the associated mass (Tasker et al., 1999).

CHAPTER 37

Diseases of the Hepatobiliary System

Kenneth Harkin

CONGENITAL/DEVELOPMENTAL DISEASES

Congenital Portosystemic Shunts

Definition and Causes

I. Congenital portosystemic shunt (PSS) is a vascular anomaly resulting in direct communication between the portal and systemic circulation.
II. Extrahepatic shunts are the most common type in small breeds of dogs and cats.
III. Intrahepatic shunts are the most common shunt in large breed dogs with a patent ductus venosus being the most frequent anomaly.
IV. Prevalence is unknown, but it is relatively common in the dog (0.5%) (Tobias and Rohrbach, 2002).
V. Commonly affected breeds include the Havanese, Yorkshire terrier, Maltese, Dandie Dinmont terrier, pug, miniature schnauzer, Irish wolfhound, and Cairn terrier.
VI. PSS is uncommon in cats.

Pathophysiology

I. Diversion of portal blood from the liver to the systemic circulation deprives the liver of trophic factors, resulting in hepatic atrophy.
II. Shunting of portal blood prevents normal clearance of toxins and bacteria by the liver.
III. Bacteremia is rarely significant, but toxins result in hepatic encephalopathy (see Hepatic Encephalopathy).

Clinical Signs

I. Hepatic encephalopathy
  A. Most commonly occurs after a meal
  B. Depression, stupor, or coma
  C. Circling, head pressing, amaurosis (blindness)
  D. Pica, personality changes, ptyalism (cats)
  E. Seizures (more common in cats)
II. Intermittent vomiting
III. Polyuria, polydipsia: may resolve with antibiotics
IV. Pollakiuria, stranguria, or hematuria associated with urate urolithiasis
V. Growth retardation

Diagnosis

I. Screening laboratory tests
  A. Complete blood count (CBC)
    1. Mild anemia: hypochromic, microcytic
    2. Poikilocytosis in cats
  B. Serum biochemistry profile
    1. Hypoalbuminemia, hypocholesterolemia, hypoglycemia
    2. Low blood urea nitrogen (BUN)
    3. Normal or mildly elevated serum alanine transaminase (ALT) and alkaline phosphatase (ALP)
    4. Often normal in cats
  C. Urinalysis
    1. Ammonium biurate crystalluria
    2. Hyposthenuria or isosthenuria
    3. Active sediment with urate cystic calculi
  D. Postprandial serum bile acids: significantly elevated
II. Imaging techniques
  A. Abdominal radiographs usually document microhepatica.
  B. Abdominal ultrasonography may reveal microhepatica with homogenous echogenicity.
    1. Visualization of the shunting vessel is often possible (d'Anjou et al., 2004).
    2. Renomegaly and urolithiasis may be identified.
  C. Rectal portal scintigraphy
    1. ^{99m}Technetium-pertechnetate placed in the rectum eventually enters the portal circulation.
    2. Radioactivity occurs in the liver before the heart in normal animals.
    3. Radioactivity is seen in the heart and lungs before the liver with PSS.
  D. Intraoperative portography
    1. Catheterization of mesenteric vein at laparotomy
    2. Radiographs or fluoroscopic images obtained during injection of contrast
    3. Often unnecessary, as the shunting vessel usually visible during laparotomy

Differential Diagnosis

I. Hypoglycemia in puppies (toy breeds)
II. Cobalamin deficiency in the border collie

III. Cirrhosis
IV. Intrahepatic arteriovenous fistula, acquired PSS
V. Hydrocephalus, idiopathic epilepsy, other causes of encephalopathy

Treatment

I. Medical management: see treatment of Hepatic Encephalopathy
II. Surgical correction of PSS
  A. The preferred treatment method
  B. Surgical options
    1. Silk ligation: partial or complete
    2. Ameroid constrictor
      a. Most popular technique
      b. Shorter surgery time than silk ligation (Hurn and Edwards, 2003)
    3. Cellophane banding
    4. Transvenous coil embolization
  C. Liver biopsy for histopathology
III. Surgical complications
  A. Portal hypertension occurs with a rapid onset of congestive enteropathy and ascites.
    1. Most common with complete silk ligation
    2. May require emergency surgery to remove the ligature
    3. Possible acquired shunts in some dogs
  B. Generalized motor seizures may develop 12 to 72 hours after ligation and are accompanied by a high mortality rate.
  C. Persistent clinical signs may be explained by the following:
    1. Concurrent presence of portal vein hypoplasia
    2. Development of acquired shunts from portal hypertension
    3. Incomplete ligation or failure to ligate additional PSSs
  D. Persistent signs may need long-term medical management or repeated ligation.

Monitoring of Animal

I. Monitoring after surgical ligation
  A. With partial ligation, rectal portal scintigraphy is repeated in 3 months to evaluate the need for additional ligation.
  B. With complete ligation or ameroid constrictor placement, follow-up is dependent on the presence of clinical signs.
    1. Asymptomatic animals are rechecked at 3 to 6 months, with evaluation of serum biochemistry profile and serum bile acids.
    2. In symptomatic animals, rectal portal scintigraphy, abdominal ultrasonography, biochemistries, and bile acids are repeated.
II. Monitoring during chronic medical therapy
  A. Serial serum bile acids are not very helpful, as the degree of dysfunction cannot be predicted by comparing levels from various times.
  B. Asymptomatic animals are reevaluated every 6 to 12 months.
  C. Animals that remain symptomatic require frequent evaluation to optimize therapy and monitor nutritional status.

Portal Vein Hypoplasia

Definition and Cause

I. It is abnormal microscopic circulation of the hepatic portal system that is poorly understood.
II. It is also termed *hepatic microvascular dysplasia,* although the term *portal vein hypoplasia* is preferred.
III. Despite the general acceptance of this condition as a disease, the histological changes identified can be seen in healthy dogs with normal serum bile acids.
IV. Although some liver disease is likely to be present in these dogs, portal vein hypoplasia has not been definitively proven.

Pathophysiology

I. Decreased portal vein circulation results in hepatic arterial overcirculation that maintains sinusoidal perfusion.
II. Sinusoidal pressure increases, resulting in dilation of portal lymphatics and hepatic venules.
III. Embryological sinusoidal vessels reopen from the hypertension, shunting blood away from sinusoids.
IV. These shunting vessels have a variable effect on the development of clinical signs.

Clinical Signs

I. No apparent clinical signs: most common
II. Signs of hepatic encephalopathy

Diagnosis

I. Screening laboratory tests
  A. CBC: usually normal in most cases; rarely, changes similar to PSS
  B. Serum biochemistry profile: usually normal; mild elevations in liver enzymes; changes similar to PSS (rare)
  C. Urinalysis: ammonium biurate crystals possible
  D. Serum bile acids: postprandial levels not as high as with PSS (median = 41 mmol/L) (Allen et al., 1999)
II. Imaging tests
  A. Liver size is usually normal on radiography.
  B. Ultrasonography and transcolonic scintigraphy are usually normal.
  C. Intraoperative contrast portography is usually normal.
III. Histopathologic findings
  A. Hepatic arteriolar tortuosity (duplication), portal venule hypoplasia
  B. Iron granuloma formation
  C. Also identified in dogs with PSS

Differential Diagnosis

I. Portosystemic shunt
II. Lysosomal storage diseases
III. Urea cycle enzyme deficiency

Treatment

I. Most dogs require no therapy.
II. Symptomatic dogs are treated with medical therapy as for PSS.

Urea Cycle Enzyme Defects

See Table 37-1.

INFECTIOUS DISEASES

Hepatic Abscess

Definition

I. Abscesses are variably sized, focal or multifocal, localized collections of purulent material that form from necrosis of hepatic tissue.
II. They may be infected (primary or secondary) or sterile.

Causes

I. Unknown in most cases
II. Hematogenous spread from infections of the skin, heart, gastrointestinal (GI) tract, etc.
III. Secondary to immunosuppressive conditions: diabetes mellitus, hyperadrenocorticism, exogenous corticosteroids
IV. Ascending biliary tract infection, pancreatitis
V. Hepatic neoplasia or infarcts

Pathophysiology

I. Inflammation from necrosis or infection results in fever and pain.
II. Release of toxins from bacteria cause systemic signs of sepsis.
III. Abscess rupture may result in peritonitis.

Clinical Signs

I. Lethargy, fever
II. Vomiting, diarrhea
III. Weight loss

Diagnosis

I. CBC
   A. Leukocytosis, often with a left shift
   B. Thrombocytopenia, possible evidence of disseminated intravascular coagulation (DIC)

TABLE 37-1

Miscellaneous Hepatobiliary Diseases

DISORDER	CAUSE(S)	CLINICAL FINDINGS	DIAGNOSIS	TREATMENT/PROGNOSIS
Urea cycle enzyme deficiency	Congenital defect	Hyperammonemia, HE	Biopsy and measurement of enzyme levels	Supportive therapy for HE Poor prognosis
Vacuolar hepatopathy	Cortisol excess Idiopathic Hyperlipidemia	Asymptomatic, polyuria/polydipsia, elevated ALP	Biopsy, tests for hyperadrenocorticism	Treat underlying disease Good prognosis
Idiopathic hepatic fibrosis	Unknown	Ascites, weight loss, polyuria/polydipsia, HE	Biopsy	Colchicine, diuretics, others as for chronic hepatitis Poor prognosis
Intrahepatic arteriovenous fistula	Congenital defect	Ascites, HE, GI signs, hypoalbuminemia	Ultrasonography, laparotomy, arteriography	Surgical resection of affected liver lobe Guarded prognosis
Granulomatous hepatitis	Bacterial and fungal infection Immune disorders Neoplasia Idiopathic forms	Anorexia, fever, hepatomegaly	Biopsy with special stains for fungi, culture, antinuclear antibody assay	Underlying etiology determines therapy and prognosis
Cholecystitis/cholangitis	Mucocele Cholelithiasis Pancreatitis Immune suppression	Abdominal pain, fever, vomiting, icterus, leukocytosis	Ultrasonography, bacterial culture of bile	Antibiotics, supportive care, ± cholecystectomy Good prognosis
Scottish terrier hepatopathy	Idiopathic	Asymptomatic, elevated ALP	Biopsy	No treatment needed Prognosis excellent
Biliary flukes (cat)	*Platynosomum* spp. *Amphimerus* spp.	GI signs, icterus	Fecal flotation	Praziquantel 20-40 mg/kg SC, PO SID for 3 days Variable prognosis

HE, Hepatic encephalopathy; *ALP,* alkaline phosphatase; *GI,* gastrointestinal.

C. Mild anemia
II. Serum biochemistry profile
A. Elevated ALP and ALT
B. Hypoalbuminemia
C. Hyperbilirubinemia (less common)
D. Hyperglobulinemia with chronicity
III. Coagulation profile: abnormal prothrombin time and partial thromboplastin time consistent with DIC
IV. Abdominal radiography
A. ± Hepatomegaly
B. ± Focal gas accumulation
C. ± Poor abdominal detail
V. Ultrasonography
A. Hyperechoic, mixed-echoic, or anechoic masses
B. ± Localized peritoneal effusion
VI. Definitive diagnosis
A. Laparotomy or laparoscopy with biopsy, aerobic and anaerobic bacterial culture
B. Ultrasound-guided aspiration with cytology and culture

Differential Diagnosis

I. Hepatic neoplasia: primary, metastatic
II. Nodular regeneration of the liver
III. Extramedullary hematopoiesis

Treatment

I. Antibiotic treatment is optimally guided by culture and sensitivity.
A. Good first choices in dogs pending culture results include the following:
1. Ampicillin 22 mg/kg IV, PO TID and enrofloxacin 5 mg/kg IV, PO BID
2. Cefoxitin 30 mg/kg IV TID to QID
3. Metronidazole 20 to 30 mg/kg IV, PO SID, cefazolin 22 mg/kg IV TID or cephalexin 22 mg/kg PO TID, and enrofloxacin or marbofloxacin 5 mg/kg PO BID
B. Long-term antibiotic therapy (4 to 6 months) is recommended.
II. Surgery is indicated for large abscesses, when the abscess has ruptured and septic peritonitis has occurred, and for abscesses localized to a single lobe.
III. Ultrasound-guided drainage and alcoholization is effective for confined lesions.

Monitoring of Animal

I. Underlying or predisposing conditions are identified and managed to prevent recurrence.
II. For animals that are managed medically, perform an ultrasound examination monthly until resolution or reduction in size is noted, and then every 3 months for 6 to 12 months after completing antibiotics.

Other Infectious Causes of Hepatitis

See Section 15.

Feline Acute Cholangiohepatitis

Definition and Causes

I. It is an acute bacterial infection of the liver and biliary tract.
II. It may result from an ascending infection with enteric bacteria.
III. The most common organisms isolated include *Escherichia coli*, *Enterobacter* spp., *Streptococcus* spp., *Klebsiella* spp., *Clostridia* spp., and *Bacteroides* spp.

Pathophysiology

I. The predominant finding on histopathology is a neutrophilic infiltration.
II. Although some degree of biliary stasis may be necessary for this to occur, diseases that cause biliary stasis (cholelithiasis, pancreatitis) are not often identified.

Clinical Signs

I. It typically affects young to middle-aged cats; males may be predisposed.
II. Duration of clinical signs is usually short (<5 days).
III. Jaundice, vomiting, diarrhea, and fever are common.

Diagnosis

I. Laboratory findings
A. Increased ALT: fivefold to tenfold increase
B. Increased ALP: twofold to fourfold increase
C. Elevated bilirubin (mean total bilirubin 5.0, range 0.1 to 20)
D. Leukocytosis with a left shift in 30% to 50% of cases
II. Imaging tests
A. Liver may be enlarged or normal in size on radiographs.
B. Liver may appear hypoechoic, and the biliary tree may appear thickened and dilated on ultrasonography.
C. Evidence of cholelithiasis may occasionally be found.
III. Definitive diagnosis by hepatic biopsy
A. Periductal and periportal suppurative inflammation and edema
B. Accumulation of suppurative exudate in intrahepatic bile ducts
C. Piecemeal necrosis with local extension of inflammation
D. Dilation of intrahepatic bile ducts

Differential Diagnosis

I. Acute pancreatitis
II. Feline infectious peritonitis (FIP)
III. Toxoplasmosis
IV. Tularemia
V. Cytauxzoonosis
VI. Salmonellosis

Treatment

I. Intravenous fluid therapy is usually required, with fluid deficits corrected over 8 to 12 hours and potassium supplemented as needed.

II. Antibiotic therapy is started pending the results of culture.
  A. Ampicillin 22 mg/kg IV, PO TID and enrofloxacin 5 mg/kg IV, PO SID
  B. Cefazolin 22 mg/kg IV TID and enrofloxacin
  C. Ticarcillin/clavulanic at acid 33 to 50 mg/kg of ticarcillin IV QID
  D. Amoxicillin/clavulanic acid 13.75 mg/kg PO BID
  E. Cefoxitin 30 mg/kg IV TID
III. Long-term, antibiotic therapy (3 to 6 months) is recommended.
IV. Cats rarely require surgery to relieve an extrahepatic bile duct obstruction or obstruction from inspissated bile.

Monitoring of Animal

I. Reevaluate liver enzymes every 1 to 2 weeks until antibiotic therapy is discontinued.
II. If liver enzymes are not normal after completing therapy, further evaluation (repeat biopsy) may be indicated.

INFLAMMATORY DISEASES

Canine Chronic Hepatitis and Cirrhosis

Definition

I. Chronic hepatitis is an inflammatory disease of the liver that is characterized by bridging fibrosis, hepatocellular necrosis, piecemeal necrosis, and predominantly nonsuppurative inflammation.
II. Most dogs are identified only when the disease is advanced.
III. Cirrhosis is the end result, with bridging fibrosis, nodular regeneration, and permanent distortion of the hepatic architecture.
IV. The term *chronic active hepatitis* has often been used previously for this disease.

Causes

I. In some cases the etiology may be identified; however, in most dogs the underlying cause is never defined.
II. Possible etiologies include canine adenovirus 1 (CAV-1), leptospirosis, and long-term administration of medications (e.g., phenobarbital, primidone, phenytoin, carprofen).
III. See also Copper Storage Hepatopathies.

Pathophysiology

I. The predominant inflammatory cells are lymphocytes and plasma cells.
II. Nonspecific, immunological response leads to chronic hepatic injury.
III. Antibodies are directed against liver-specific antigens and perpetuate hepatic injury.

Clinical Signs

I. Commonly affected breeds include the Doberman pinscher, American and English cocker spaniels, Labrador retriever, and German shepherd dog.
II. Typical age is 4 to 7 years.
III. Lethargy, anorexia, vomiting, and weight loss are common.
IV. Small bowel diarrhea, polyuria, and polydipsia are seen occasionally.
V. Ascites, icterus, and hepatic encephalopathy occur in severe cases.
VI. In some dogs the disease is subclinical and identified on routine laboratory testing.

Diagnosis

I. Serum biochemistry results
  A. Increased ALT and ALP occur in most affected dogs.
  B. Hypoalbuminemia is seen in many affected dogs.
  C. BUN is usually subnormal.
  D. Hyperbilirubinemia occurs early in the course of disease when the primary lesion is periportal.
    1. Clinical jaundice is not seen until bilirubin >2.0 mg/dL.
    2. Jaundice may not be apparent until bilirubin >4.0 mg/dL.
  E. Hyperglobulinemia is uncommon and occurs from chronic inflammation.
  F. Serum cholesterol may be increased, normal, or decreased.
  G. Hypoglycemia is rarely seen except in end-stage cirrhosis.
II. Coagulation profile results
  A. Variable, depending on the stage of chronic hepatitis
  B. Uncommonly associated with vitamin K deficiency
III. Bile acids concentrations: postprandial levels almost always abnormal
IV. Radiographic findings
  A. Survey radiography: small or normal sized liver
  B. Ultrasonography: normal or diffuse hyperechogenicity, microhepatica, irregular margins, cirrhotic nodules
V. Histopathologic examination of liver biopsy
  A. It provides the definitive diagnosis.
  B. Also submit samples for culture and mineral analysis.
  C. Samples obtained at laparotomy and laparoscopy are preferred.
    1. Tru-cut biopsies may not always provide the diagnosis.
    2. Fine-needle aspirate cytology often is not accurate enough to make the diagnosis.
VI. Recommendations for biopsy
  A. Persistently elevated liver enzymes without an obvious cause
  B. Not precluded by absence of clinical signs

Differential Diagnosis

I. Hepatic neoplasia
II. Protein-losing enteropathy
III. Systemic lupus erythematosus
IV. Right-sided congestive heart failure
V. Hypoadrenocorticism

Treatment

I. The goals of therapy are to control inflammation, arrest fibrosis, resolve infection, improve bile flow and decrease toxic bile acids, provide antioxidants, decrease absorption

of hepatic encephalopathic toxins, support hepatic regeneration, and manage or prevent GI complications.

II. Various drugs are used to control inflammation.
  A. Give prednisone at 1 mg/kg PO SID for 2 to 3 weeks, then taper.
    1. Do not give if cultures are positive.
    2. Dexamethasone (0.2 to 0.4 mg/kg PO SID) is an alternative in dogs with ascites, as it has less mineralocorticoid activity.
  B. Use azathioprine in combination with corticosteroids to reduce their dosage.
    1. Dose is 2 mg/kg PO SID for 10 to 14 days, then QOD for 3 to 6 months, then 1 mg/kg PO QOD indefinitely.
    2. Side effects include GI upset, myelosuppression, and pancreatitis.
  C. D-penicillamine is principally used as a copper chelator.
    1. Dose is 10 to 15 mg/kg PO BID.
    2. It may cause persistent vomiting.
  D. Metronidazole is given at 15 mg/kg PO SID or divided BID for its possible immunomodulatory and antioxidant effects.

III. Colchicine may be given to combat fibrosis.
  A. Recommended dose is 0.03 mg/kg PO SID (do not use the probenecid/colchicine combination).
  B. Side effects include hemorrhagic gastroenteritis, myelosuppression, nephrotoxicity, and neuromyopathies.

IV. Resolve or control infections.
  A. Antibiotics are recommended in the following situations:
    1. Positive culture results
    2. Significant suppurative component on biopsy
    3. To reduce any bacterial contribution to hepatic encephalopathy
    4. Prophylaxis after liver biopsy or episodes of gastroenteritis
  B. Antibiotic choices include the following:
    1. Ampicillin 22 mg/kg IV TID, amoxicillin 22 mg/kg PO TID, or amoxicillin-clavulanic acid 13.75 mg/kg PO BID
    2. Cephalexin 22 mg/kg PO TID or cefadroxil 22 mg/kg PO BID
    3. Enrofloxacin 5 mg/kg PO BID
    4. Metronidazole 15 mg/kg PO SID for anaerobic infections

V. Ursodeoxycholate 10 to 15 mg/kg PO SID is used to improve bile flow and reduce toxic bile acids.

VI. Antioxidant therapy helps protect against ischemic, hypoxic, oxidative, or free radical damage.
  A. Zinc acetate or gluconate
    1. Prescribed for copper hepatopathy
    2. May also have antifibrotic activity
  B. D-Alpha-tocopheryl-1000-polyethylene glycol succinate (*Liqui-E;* TwinLab, New York, N.Y.)
    1. It is a water-soluble form of vitamin E that accumulates in hepatocytes to a greater degree than does the acetate form.
    2. Dose is 25 IU/kg PO BID.
    3. The sweet taste may be objectionable to some dogs.
  C. S-adenosyl-L-methionine (SAMe)
    1. It is normally produced in the liver from dietary methionine, but in cirrhosis, SAMe synthetase is reduced.
    2. Administer SAMe on an empty stomach at a dose of 20 mg/kg PO SID.

VII. Decrease absorption of hepatic encephalopathic toxins.
  A. Give antibiotics to reduce production of toxins by enteric bacteria.
  B. Give lactulose at 0.5 mL/kg PO TID.

VIII. Institute dietary changes that support hepatic regeneration.
  A. Protein requirements are at least as high as those of healthy individuals.
  B. Protein is necessary to maintain a positive nitrogen balance and stimulate hepatic regeneration.
  C. In the animal without encephalopathy, give a diet that contains between 25% and 32% protein in a highly digestible source.
  D. Protein-restricted diets are given only to treat hepatic encephalopathy, which most commonly occurs in dogs with PSS and severe hepatic dysfunction.

IX. Prevent or treat GI complications.
  A. GI ulcers and subsequent hemorrhage can complicate hepatic encephalopathy, precipitate an encephalopathic crisis, and cause anorexia.
  B. Famotidine is given at 0.5 to 1.0 mg/kg PO SID to BID to decrease gastric acid production.
  C. Consider sucralfate as a GI protectant at 250 to 1000 mg PO TID.

X. Recommendations for managing ascites include the following:
  A. Furosemide is given at 1.0 mg/kg PO BID.
  B. Spironolactone may be tried at 1 to 2 mg/kg PO BID, alone or in combination with furosemide.
  C. Restricted exercise and decreased salt intake are rarely effective.
  D. Abdominocentesis is performed in dogs with significant ascites or compromised cardiac or respiratory functions or anorexia, and it is followed with diuretics.

Monitoring of Animal

I. Evaluate body weight, liver enzymes, serum albumin and bilirubin monthly until they are stable, then every 3 to 6 months.

II. Monitor serum bile acids every 6 to 12 months.
  A. Changes in degree of elevation do not correlate well with changes in hepatic function.
  B. Return to normal signals normalization of hepatic function (rare).

III. Any dog that suddenly decompensates with ascites, hepatic encephalopathy, or vomiting requires immediate reevaluation.

IV. Ascites is a poor prognostic sign.

V. For dogs that are receiving azathioprine, check a CBC at 2 and 4 weeks initially, then monthly while on 2 mg/kg QOD, and every 3 months when on the lowest dose.

Feline Chronic Cholangiohepatitis

Definition and Causes

I. It is also referred to as *nonsuppurative cholangitis*, *lymphoplasmacytic cholangitis,* or *cholangiohepatitis*.
II. It is presumed to be immune-mediated.
III. It often occurs as a component of other inflammatory diseases of the intestine or pancreas.

Pathophysiology

I. Predominant infiltrating cells are lymphocytes and plasma cells.
II. Nonspecific, immune-mediated destruction of the liver may arise from an unknown insult and be self perpetuating.
III. It may be a component of lymphoplasmacytic inflammatory diseases of the cat.
   A. In one study, 15 of 18 cats with chronic cholangiohepatitis had inflammatory bowel disease (IBD), 9 of 18 had pancreatitis, and 7 of 18 had both pancreatitis and IBD (Weiss et al., 1996).
   B. Other disorders associated with chronic cholangiohepatitis include toxoplasmosis, feline immunodeficiency virus (FIV) infection, and idiosyncratic reactions to chronic medications.

Clinical Signs

I. It is less severe than acute cholangiohepatitis, but cats are usually ill for longer periods.
II. Most are middle-aged cats.
III. Duration of illness is typically ≥3 weeks.
IV. No sex or breed predilection has been found.
V. Vomiting, diarrhea, and jaundice are common.
VI. Most cats have good appetites.

Diagnosis

I. ALT and bilirubin are mildly to moderately increased.
II. Abdominal radiography is usually unremarkable, but ultrasonography may reveal a diffuse to patchy hyperechogenicity of the hepatic parenchyma.
III. Definitive diagnosis is by biopsy.
   A. Mixed lymphoplasmacytic periportal inflammation
   B. Piecemeal necrosis and extension of lymphoplasmacytic inflammation into surrounding parenchyma
   C. Focal invasion of bile duct epithelium with lymphocytes
   D. Reduction in number of bile ducts
   E. Bridging portal fibrosis in later stages

Differential Diagnosis

I. Idiopathic hepatic lipidosis
II. Hepatobiliary neoplasia
III. Chronic pancreatitis
IV. Acute cholangiohepatitis
V. Toxoplasmosis
VI. Lymphocytic portal hepatitis
   A. It is a waxing and waning disease similar to chronic cholangiohepatitis.
   B. Affected cats are older (≥11 years) and have intermittent vomiting and jaundice for months to years.
   C. Hepatomegaly, marked leukocytosis, mild elevations in ALT and ALP, and hyperglobulinemia are common.
   D. A biopsy is required for diagnosis and demonstrates periportal lymphocytic infiltrates.
   E. Treatment is similar to chronic cholangiohepatitis, although some cats require no therapy if the disease is waning.

Treatment

I. Give prednisolone (which may be superior to prednisone in cats, as it needs no conversion to an active form) at 2 to 4 mg/kg PO SID for 4 to 8 weeks, and taper gradually to a dose that controls clinical signs.
II. Ursodeoxycholate acid may be tried at 10 to 15 mg/kg PO SID, but its efficacy is unproven.
III. Start antibiotics if there is evidence of infection based on culture of bile or hepatic tissue.
IV. Antioxidant therapy may be helpful.
   A. Give D-alpha-tocopheryl-1000-polyethylene glycol succinate *(Liqui-E)* at 25 IU/kg PO BID.
   B. Give SAMe at 20 mg/kg PO SID on an empty stomach.
V. Use cyclosporine at 5 mg/kg PO SID to BID in cats that have a poor response to prednisone or develop diabetes mellitus from chronic prednisone administration.

Monitoring of Animal

I. Monitor body weight and serum liver enzymes, bilirubin, and albumin every 2 to 4 weeks for several months.
II. If response to therapy is poor, perform a complete re-evaluation, including liver biopsy.
III. Prognosis is variable, although most affected cats have good long-term survival.

Copper Storage Hepatopathies

Definition

I. It is a chronic progressive hepatitis of dogs associated with the accumulation of copper in hepatocytes.
II. It is well characterized in the Bedlington terrier and West Highland white terrier.
III. It also occurs in the Dalmatian, Labrador retriever, Doberman pinscher, keeshond, and Skye terrier.

Causes

I. It is often a hereditary disease.
II. Cholestasis can also result in copper accumulation in hepatocytes.

Pathophysiology

I. In the Bedlington terrier, an autosomal trait leads to expression of an abnormal hepatic metallothionein, with resultant reduced biliary copper excretion.
II. As hepatic copper concentration increases progressively over time, hepatic injury increases.
III. Above a critical concentration, acute hepatic necrosis develops.

Clinical Signs

I. Many dogs are asymptomatic.
II. Acute episodes of anorexia, vomiting, weakness, lethargy, and dehydration may occur.
III. In chronic cases, anorexia or inappetence, poor body condition, and intermittent vomiting and diarrhea may occur weeks to months before onset of liver failure, and these dogs eventually develop jaundice, ascites, cachexia, and hepatic encephalopathy.
IV. Peracute episodes of hemolytic anemia and jaundice may occur.

Diagnosis

I. ALT is consistently elevated; ALP values are variable.
II. Bile acid assays indicate presence of liver disease.
III. Radiographic and ultrasonographic findings are variable.
IV. The measurement of serum or plasma copper or ceruloplasmin is not diagnostic.
V. Definitive diagnosis requires hepatic biopsy with quantitative measurement of hepatic copper.
   A. Dry matter copper >400 ppm is abnormal.
   B. Clinical disease usually occurs with copper levels >2000 ppm (dry matter).
VI. Affected Bedlington terriers accumulate copper as they age, so biopsies of the liver are performed at 6 months, and at 14 to 15 months of age.
   A. Normal dogs have normal liver copper content on both biopsies.
   B. Affected homozygotes have increased hepatic copper on both biopsies.
   C. Heterozygotes have elevated copper at 6 months but normal values at 14 to 15 months.
VII. In the West Highland white terrier, copper accumulation is not progressive with age.
   A. After 2 years, they do not appear to accumulate more copper.
   B. Maximum documented hepatic copper is much lower than in Bedlingtons.

Treatment

I. Zinc acetate or gluconate stimulates the production of intestinal metallothionein, which preferentially binds intestinal copper.
   A. Dose is 5 to 10 mg/kg PO SID of elemental zinc, or alternatively, give 50 to 100 mg SID to medium- and large-breed dogs.
   B. Some dietary constituents inhibit absorption, so zinc must be administered 1 hour before or 2 hours after a meal; however, it can be mixed with meat (tuna fish, ground beef) to prevent GI upset.
   C. The goal is to double baseline plasma zinc levels.
II. D-Penicillamine is a copper chelator that results in urinary excretion of copper.
   A. Dose is 10 to 15 mg/kg PO BID.
   B. Side effects include GI upset, renal disease, proteinuria, and cutaneous eruptions.
III. Trientine (2,2,2 tetramine, *Syprine*) is a copper chelator with no serious side effects.
   A. It is given at 10 to 15 mg/kg PO BID.
   B. It has substantially greater copper chelation ability than D-penicillamine.
   C. 2,3,2 Tetramine has greater than fourfold to ninefold potency compared to trientine, but is not commercially available.

Monitoring of Animal

I. Hepatic biopsy may be obtained every 1 to 6 months to monitor success of copper chelation.
II. Monitor serum liver enzymes, bilirubin, albumin, and cholesterol every 3 to 6 months.
III. The prognosis is good if the disease is identified before the onset of liver failure.

PARASITIC DISORDERS

See Table 37-1.

IDIOPATHIC DISEASES

Feline Idiopathic Hepatic Lipidosis

Definition

I. It is characterized by the accumulation of fat (triglycerides) in vacuoles within hepatocytes.
II. It is a syndrome of cyclic anorexia or inappetence that exacerbates the lipidosis, which in turn worsens the anorexia.

Causes

I. The exact etiology remains a mystery.
II. It usually occurs secondary to some stressful illness or event (e.g., upper respiratory infection, boarding, addition of new cats to the household, recent diet change), although an initiating event may not be identified.
III. It can occur secondary to other diseases.
   A. Examples include diabetes mellitus, other hepatic diseases, renal failure, hyperthyroidism, pancreatitis, neoplasia, small intestinal diseases, and starvation.
   B. Resolution of the primary disease may result in resolution of the lipidosis once the cat starts eating.
   C. Chronic pancreatitis is associated with a worse prognosis in cats with hepatic lipidosis.

Pathophysiology

I. Mechanisms for hepatic lipidosis include the following:
   A. Excess delivery of triglycerides to the liver during anorexia and insulin-deficient or insulin-resistant states
   B. Impaired formation and release of very low density lipoprotein
   C. Impaired oxidation of fatty acids
II. Acute hepatic failure is a consequence when treatment is delayed.
   A. Lipid vacuoles cause peripheral displacement of hepatocyte organelles and disruption of normal hepatocyte function.

B. The prognosis for recovery worsens with progressive hepatic failure, because hepatic encephalopathy may develop.
C. Coagulopathy may occur from decreased synthesis of clotting factors in the liver and decreased absorption of vitamin K.

Clinical Signs

I. No breed, age, or sex predilection
II. Indoor cats more often affected
III. Many cats initially obese
IV. Anorexia or decreased appetite for several days to weeks
V. Early signs: weight loss, dehydration, ptyalism, vomiting
VI. Late signs: severe wasting, icterus, hepatic encephalopathy (e.g., depression, head pressing, circling)

Diagnosis

I. CBC
  A. Mild, nonregenerative anemia
  B. Stress leukogram
II. Serum biochemistry profile
  A. ALP: often the most significantly elevated liver enzyme
  B. ALT also elevated
  C. Hyperbilirubinemia
  D. Evidence of liver failure: hypoalbuminemia, hypoglycemia, low BUN, hypocholesterolemia (bad prognostic indicator)
  E. Elevated creatine kinase: associated with anorexia, not muscle damage
III. Bilirubinuria: always abnormal in cats
IV. Serum bile acids: usually abnormal in both fasting and postprandial samples
V. Other tests to consider: feline leukemia virus (FeLV), FIV, toxoplasmosis, serum thyroxine
VI. Abdominal radiography
  A. It may reveal no significant findings.
  B. Many previously obese cats still have abundant falciform fat.
  C. The liver may be normal in size or slightly enlarged, with rounded edges.
VII. Abdominal ultrasonography: diffuse hyperechogenicity of liver parenchyma
VIII. Cytological and histopathologic examinations
  A. They are usually diagnostic.
  B. Fine-needle aspirate (FNA) reveals multiple hepatocytes packed with small and large vacuoles.
  C. Liver biopsy is superior to FNA, but may not be necessary.
    1. Obtaining a biopsy allows identification of other diseases (e.g., cholangiohepatitis).
    2. It may be obtained via ultrasound guidance, laparoscopy, or laparotomy.
    3. A coagulation profile is usually performed before biopsy.

Differential Diagnosis

I. Acute or chronic cholangiohepatitis
II. Hepatic neoplasia: lymphoma
III. Gastrointestinal diseases: IBD, lymphoma
IV. Pancreatitis

Treatment

I. Enteral feedings are the most critical component of therapy.
  A. Force feeding or appetite stimulants usually do not result in adequate food intake.
  B. Insert a feeding tube in all affected cats.
    1. Nasoesophageal tube
      a. A 5-French infant feeding tube is placed through the nose and into the esophagus.
      b. It allows for temporary nutritional support (2 to 4 days) and is a good option for initial stabilization of the cat in the hospital.
    2. Esophagostomy tube: preferred if there is no esophageal disease
    3. Gastrostomy tube options
      a. Percutaneous endoscopic gastrostomy (PEG) tube
      b. Many blind percutaneous gastrostomy tube techniques
      c. Major problems: splenic entrapment, pressure necrosis of the skin
  C. Provide a diet that has adequate calories and good quantities of protein, carbohydrates, and fat.
    1. Canned cat food can be blended and strained.
    2. On the first day, give $^1/_3$ the daily requirement, followed by $^2/_3$ on the second day, and then the full requirement thereafter.
    3. Divide food into 6 to 8 meals for the first 1 to 2 weeks, then gradually reduce the number of feedings to TID to QID.
    4. Some cats require nutritional support for ≥60 to 90 days, although most start eating on their own within 2 to 4 weeks.
    5. Let the cats eat on their own for 4 to 7 days (without nutritional supplementation) to evaluate whether they are eating enough before the tube is pulled.
II. Antiemetics may help reduce any associated vomiting, especially when tube feeding is started.
  A. Metoclopramide 0.2 to 0.4 mg/kg PO TID
  B. Cisapride 0.5 mg/kg PO BID
  C. Ondansetron 0.1 to 0.3 mg/kg IV BID to TID or dolasetron 0.5 mg/kg IV SID for refractory, severe vomiting
III. Give antacid therapy for GI hemorrhage (hematemesis, melena).
  A. Not routinely required
  B. Famotidine 0.5 mg/kg IV, PO SID to BID
  C. Sucralfate 250 mg PO BID to TID

Monitoring of Animal

I. Evaluate hepatic biochemistries and body weight every 1 to 2 weeks during therapy and recovery.
II. Do not discontinue tube feeding or remove tube too early.

Gallbladder Mucocele

Definition and Causes

I. It is a pathologic collection of mucus in the gallbladder.
II. It is one of the most common causes of extrahepatic biliary disease in the dog.
III. There is no known etiology.
IV. An infectious cause has been suggested, but cultures from bile or gallbladder wall are usually sterile.

Pathophysiology

I. Mucus accumulation admixed with bile can extend into the biliary tree, resulting in bile duct obstruction.
II. Progressive distension of the gallbladder may result in necrosis of the gallbladder wall.

Clinical Signs

I. Most dogs are older (≈10 years), although dogs as young as 3 years may be affected.
II. Dogs may be asymptomatic.
III. Acute to subacute onset of vomiting, anorexia, lethargy, and icterus may occur.
IV. Polyuria/polydipsia and abdominal discomfort may be noted.

Diagnosis

I. CBC
  A. Leukocytosis is common, often with a mature neutrophilia.
  B. Mild anemia may be present but is uncommon.
II. Serum biochemistry profile
  A. ALP is significantly elevated (as high as 11,100 U/L) (Pike et al., 2004).
  B. Moderate to significant elevations occur in ALT (as high as 4827 U/L).
  C. Hyperbilirubinemia (as high as 17.5 mg/dL) is common.
III. Abdominal radiography: normal, hepatomegaly
IV. Ultrasonography
  A. It is the definitive diagnostic test.
  B. Echogenic material in the gallbladder can appear striated, stellate, or amorphous.
  C. Dilated common bile ducts may be identified.
  D. Gallbladder wall rupture may appear as a loss of continuity in the wall.
  E. Echogenic peritoneal effusion is often seen but not diagnostic for rupture.

Differential Diagnosis

I. Acute pancreatitis
II. Leptospirosis
III. Gallbladder neoplasia
IV. Acute hepatitis
V. Cholelithiasis

Treatment

I. Asymptomatic animal
  A. Medical therapy may be attempted, but is not often successful.
    1. Antibiotics: amoxicillin-clavulanic acid, cephalosporins, fluoroquinolones, metronidazole
    2. Ursodeoxycholate 10 to 15 mg/kg PO SID
  B. Surgical therapy is often required.
II. Symptomatic animal
  A. Surgical treatment is required.
  B. Cholecystectomy is the treatment of choice.
  C. Obtain bile and gallbladder wall samples for aerobic and anaerobic bacterial culture.
  D. Adhesions to liver, omentum, stomach, and diaphragm may complicate removal.
  E. Gallbladder rupture requires copious lavage to remove contents from the abdomen.
  F. Assess patency of the common bile duct.
  G. Intraoperative hemorrhage from the hepatic fossa may occur after cholecystectomy, but is often readily controlled.
  H. Necrosis of the common bile duct may necessitate euthanasia.

Monitoring of Animal

I. Prognosis is dependent on the severity of signs, but is good for most dogs.
II. Ultrasonography and hepatic biochemistries are repeated every 2 to 4 weeks while on medical therapy.
III. Immediate postoperative therapy includes IV fluid therapy, IV antibiotics (e.g., ampicillin, cefazolin, cefoxitin), and pain control (e.g., buprenorphine, fentanyl, morphine).
IV. Complications after surgery include pancreatitis, bile peritonitis from bile duct leakage, pulmonary thromboembolism, and aspiration pneumonia.

Vacuolar Hepatopathies

See Table 37-1.

Idiopathic Hepatic Fibrosis in Young Dogs

See Table 37-1.

Hepatocutaneous Syndrome

Definition and Causes

I. It is also known as superficial necrolytic dermatitis and necrolytic migratory erythema.
II. Although a hepatopathy is recognized in most cases, the etiology is unknown except for those with a glucagonoma (rare).
III. A classic triad of findings occurs.
  A. Ulcerative and crusting lesions of foot pads, mucocutaneous junctions, ears, pressure points
  B. Vacuolar hepatopathy
  C. Late onset glucose intolerance: diabetes mellitus

Pathophysiology

I. There are two theories for the development of the cutaneous lesions.
  A. Increased portal glucagon with increased hepatic gluconeogenesis, decreased plasma amino acids, and protein depletion of the epidermis

B. Hyperglucagonemia with increased arachidonic acid synthesis in keratinocytes, inflammation, and necrosis
II. Dermatohistopathology reveals the following:
A. Epidermal parakeratotic hyperkeratosis
B. Severe intercellular and intracellular edema
C. Clefts and subcorneal vesicles
D. Foci of epidermal necrosis
E. Hyperplasia of the basal layers of the epidermis
III. Liver histopathology is characterized by the following:
A. Large, nodular areas of normal hepatic parenchyma are isolated by areas of parenchymal collapse.
B. Collapsed areas contain severely vacuolated hepatocytes (lipid), numerous small bile ductules, and a network of reticulin and fine collagen fibrils.
C. There is no evidence of cirrhosis.

Clinical Signs

I. Typically older dogs (6.5 to 16 years)
II. GI signs: diarrhea, vomiting, inappetence
III. Hyperkeratosis of footpads with severe crusting
IV. Reluctance to walk
V. Mucocutaneous ulcerations, ear crusting, pressure point ulcers, deformed nails
VI. Polyuria and polydipsia with diabetes mellitus

Diagnosis

I. Laboratory test results
A. ALP is elevated (often >1000 U/L) in all dogs.
B. ALT is mildly elevated in many dogs.
C. Low BUN and cholesterol are common.
D. Variable hyperglycemia is present.
E. Mild, normocytic, normochromic, nonregenerative anemia may be detected.
II. Abdominal ultrasonography
A. Liver can be small, normal (most common), or large in size.
B. Surface of liver is often slightly irregular.
C. A distinctive "honeycomb" pattern is present in the parenchyma, with variably sized hypoechoic regions surrounded by highly echogenic areas.
III. Specialized testing
A. Hypoaminoacidemia, especially low glutamine and proline (<10% of normal)
B. Serum glucagon levels
1. Normal in all dogs with vacuolar hepatopathy
2. Elevated with glucagonoma
IV. Histopathology of skin and liver: definitive

Differential Diagnosis

I. Diseases with similar gross cutaneous lesions
A. Pemphigus foliaceous
B. Lupus erythematosus
C. Zinc-responsive dermatosis
D. Generic dog-food dermatosis
II. Differentiated by skin biopsy

Treatment

I. Goals of treatment
A. Resolution of the cutaneous lesions
B. Prevention of deterioration of hepatic dysfunction
C. Effective management of diabetes mellitus
II. Short-term amino acid infusions for dogs with severe cutaneous lesions
III. Long-term treatment nutritional therapy
A. Do not feed a protein-restricted diet.
B. Attempt to correct hypoaminoacidemia.
C. Feed a high-quality, easily digestible protein.
1. Minimum of 28% to 35% protein (dry matter basis)
2. High-protein, low-fat diets (approximately 50% protein) preferred
D. Supplement diet to provide additional amino acids.
1. Egg yolks and cottage cheese
2. Amino acids (variety of products high in branched chain amino acids are available over the counter) at 1 to 2 g/5 to 10 kg body weight PO TID
3. Whey protein supplement at 1 to 2 g/kg/day PO (unflavored or vanilla preferred)
4. Powders mixed with yogurt or broth
IV. Zinc therapy is given as for copper hepatopathy.
V. Water-soluble vitamin E is given as for chronic hepatitis.
VI. Essential fatty acid therapy is also helpful
A. Dose: 30 to 90 mg/kg PO SID
B. Side effects: lethargy, vomiting, diarrhea
VII. Ursodeoxycholate is not a critical component of therapy, but is used as for chronic hepatitis.

Monitoring of Animal

I. Skin lesions
A. They improve within 4 to 6 weeks with successful therapy.
B. Monitor for secondary bacterial and fungal pododermatitis.
II. Hepatic lesions
A. Monitor liver enzymes, bilirubin, albumin, glucose, and cholesterol every 1 to 3 months.
B. Values improve within 2 to 4 months with successful therapy, but ALP may never normalize.
III. Diabetes mellitus
A. Develops in most dogs
B. Requires insulin therapy (see Chapter 44)

METABOLIC AND TOXIC DISEASES

Hepatic Encephalopathy

Definition and Causes

I. Hepatic encephalopathy (HE) is a complex neurological syndrome associated with acquired and congenital liver disease.
II. Causes include the following:
A. Portal vascular anomalies
B. Idiopathic feline hepatic lipidosis
C. Fulminant hepatic failure
D. End-stage chronic hepatitis/cirrhosis
E. Urea cycle enzyme deficiencies
III. Contributing factors include the following:
A. Anesthesia, surgery

B. High protein meal
C. GI bleeding: ulceration, intestinal parasites
D. Hypokalemia: enhances renal ammonia production
E. Bacterial infections or septicemia
F. Alkalosis: enhances transfer of ammonia into central nervous system (CNS)
G. Constipation, dehydration
H. Transfusions of stored blood
I. Diuretics

Pathophysiology

I. HE involves the accumulation of neurotoxins.
II. Ammonia is converted to glutamine in the brain, and this pathway can be rapidly overwhelmed.
  A. Serum glutamine levels are increased in dogs with HE.
  B. Blood ammonia is typically high in advanced liver failure.
    1. The level correlates poorly with severity of HE.
    2. Blood levels are not very useful in the diagnosis of HE.
  C. In the CNS, chronic hyperammonemia impairs the glutamate-nitric oxide-cGMP pathway (neurostimulatory pathway), which contributes to the neurological impairment.
III. False neurotransmitters are formed from excessive delivery of aromatic amino acids to the CNS.
  A. Tryptophan and phenylalanine are converted to false neurotransmitters, such as octopamine and phenylethanolamine.
  B. The false neurotransmitters are depressive in their action.
IV. Activation of central gamma-amino butyric acid (GABA)-benzodiazepine receptors also produces a depressive effect on the CNS.
V. Manganese intoxication produces clinical signs similar to HE (Schenker and Bay, 1997).
VI. Serum levels of tumor necrosis factor-α are increased in acute and chronic liver disease, and increase peripheral-type benzodiazepine receptors in the cerebral cortex.
VII. Other factors that may play a minor role include short-chain fatty acids, mercaptans, phenols, brain lactate, and zinc deficiency.

Clinical Signs

I. Grading scheme for HE
  A. Grade 0: normal
  B. Grade 1: irritability, restlessness, altered sleep, agitation
  C. Grade 2: lethargy, sluggishness, decreased inhibitions
  D. Grade 3: somnolent, but can be roused
  E. Grade 4: comatose
II. Common signs
  A. Depression, lethargy, stupor, coma
  B. Ataxia, circling, compulsive pacing
  C. Head pressing, disorientation, amaurosis
  D. Hysteria, aggression
  E. Excessive panting
  F. Ptyalism in cats
  G. Seizures (more common in cats)
  H. Polyuria, polydipsia
  I. Vomiting, diarrhea

Diagnosis

I. High index of suspicion in certain breeds
  A. Yorkshire terriers and other breeds known to have a high prevalence of PSS
  B. Doberman pinschers or other breeds with a high prevalence of chronic hepatitis
  C. Bedlington terrier or other breeds with a high prevalence of copper toxicosis
II. Compatible physical examination findings
  A. The presence of icterus
    1. Unexpected in dogs with PSS
    2. Common in dogs with acute hepatic failure
  B. Copper-colored irises in cats with PSS
  C. Hypersalivation in cats
  D. Microhepatica
III. Supportive laboratory results
  A. Hypoalbuminemia, hyperbilirubinemia, hypocholesterolemia, hypoglycemia, and elevated liver enzymes
  B. Abnormal serum bile acids
  C. Elevated blood ammonia levels
    1. Only accurate if assayed immediately and against a control sample
    2. Not elevated in every animal with HE
  D. Presence of PSS on ultrasonography

Differential Diagnosis

I. Hypoglycemia: see Chapter 46
II. Diabetic ketoacidosis
III. Azotemia
IV. Cerebral infarction
V. Meningitis or encephalitis: see Chapter 23
VI. Epilepsy
VII. Distemper encephalitis
VIII. Propane inhalation, carbon monoxide intoxication
IX. Inherited cobalamin deficiency: giant schnauzer, border collie

Treatment

I. Emergency therapy
  A. Lactulose can be given as an enema for grade 3 to 4 disease.
    1. Dose is 100 mL in 200 mL water, given at 5 to 15 mL/kg QID.
    2. The stool pH will be <6 if therapy is effective.
  B. Povidone iodine enema
    1. A 1:10 dilution of povidone iodine with water is given at 20 mL/kg QID.
    2. It acidifies the colon and decreases bacterial numbers.
  C. IV fluid therapy is started with crystalloid solutions that do not contain lactate.
  D. Give supplemental dextrose to animals with acute or fulminant hepatic failure.
II. Long-term management
  A. Surgically correct any PSS, if possible.

B. Institute therapy specific for any underlying, acquired liver disease.
C. Restrict dietary protein.
   1. Establish the protein tolerance of the animal and feed the highest amount tolerated.
   2. Supplementation of vegetable protein-based diets may allow a higher protein content to be fed.
   3. When restricting protein in cats, make sure the diet is high in arginine to prevent deficiency.
D. Lactulose is a nonabsorbable disaccharide that is metabolized in the colon by certain bacteria.
   1. Lactulose is converted to lactic acid, acetic acid, formic acid, and carbon dioxide, which decrease the breakdown of amino acids, protein, and blood, and minimize the formation of short-chain fatty acids.
   2. Acidification of the colon draws ammonia out of the blood into the gut, where it is trapped for excretion.
   3. Low pH decreases the survival of urease-producing bacteria and promotes growth of non–urease-producing bacteria.
   4. Cathartic action decreases the retention of nitrogenous waste.
   5. Give lactulose at 0.5 to 1.0 mL/kg PO TID and titrate to produce a soft stool.
E. Antibiotics kill the bacteria that produce ammonia and may have a synergistic effect with lactulose.
   1. Neomycin 20 mg/kg PO BID to TID for 10 to 14 days
   2. Metronidazole 15 mg/kg PO SID
   3. Ampicillin 20 mg/kg PO TID
F. Zinc may be given, as for Copper Hepatopathy.

Monitoring of Animal

I. See specific monitoring advice for the primary disease conditions.
II. Monitoring blood ammonia levels is not indicated because they correlate poorly with therapeutic success.
III. Regular evaluation of serum albumin is indicated for animals on low-protein diets.
IV. Avoidance of ulcerogenic medications (e.g., nonsteroidal antiinflammatory drugs) is warranted.

Hepatic Necrosis and Failure

Definition

I. Fulminant hepatic failure is characterized by hypoalbuminemia, hypoglycemia, hypocholesterolemia, decreased coagulation factors, and cholestasis of short (<2 weeks) duration, with the potential for complete recovery.
II. Not all forms of necrosis and failure are toxic in origin.

Causes

I. Blunt abdominal trauma with liver lobe rupture
II. Liver lobe torsion
   A. With or without diaphragmatic hernia
   B. Can lead to ischemic necrosis, endotoxic shock, and death
III. Postcaval syndromes: right-sided congestive heart failure (CHF), pericardial disease, Budd-Chiari-like syndrome from occlusion of the caudal vena cava between the heart and liver
IV. DIC with thromboembolic disease and infarction
V. Acute pancreatitis: shock, DIC, bacteremia, extrahepatic bile duct obstruction
VI. Gastric dilatation-volvulus: disrupted portal and vena caval blood flow
VII. Immune-mediated hemolytic anemia: hypoxia, damage from unconjugated bilirubin and hemoglobin, thromboembolism from autoagglutination
VIII. Vasculitis: infectious, noninfectious causes
IX. IBD: absorption of inflammatory mediators, endotoxin, and enteric bacteria
X. Hyperthermia: direct thermal injury, shock, DIC
XI. Neoplasia: tumor invasion (especially lymphoma), impaired perfusion, release of vasoactive substances
XII. Infections
   A. Viral: infectious canine hepatitis, canine herpesvirus
   B. Bacterial
      1. Bacteremia: *Staphylococcus* spp. or *Streptococcus* spp.
      2. Anaerobic bacteria of enteric origin
      3. *Bacillus piliformis* (Tyzzer's disease), salmonellosis
      4. Bacterial cholangiohepatitis
      5. Leptospirosis
      6. Tularemia
   C. Rickettsial
      1. *Ehrlichia canis*: liver disease uncommon, vasculitis-induced necrosis
      2. Rocky Mountain spotted fever: necrosis from vasculitis
   D. Protozoal
      1. Toxoplasmosis: hepatic necrosis from host response to tachyzoites
      2. Neosporosis: hepatic infiltration, necrosis
   E. Fungal: histoplasmosis, blastomycosis, coccidioidomycosis, aspergillosis
   F. Toxins
      1. Uncommon in dogs and cats
      2. Amanita mushroom poisoning: rare
      3. Drugs
         a. Thiacetarsamide, metofane, halothane, ketoconazole
         b. Cats: oral diazepam, griseofulvin
         c. Dogs: carprofen, trimethoprim-sulfa, amiodarone, methotrexate
      4. Blue-green algae

Pathophysiology

I. Distribution of necrosis
   A. Widespread: CAV-1, trimethoprim-sulfa, oral diazepam
   B. Focal: any insult, hypotension and local hypoxia during anesthesia, often seen in surgical biopsies
   C. Centrilobular: hypoxemia, hypoperfusion, chronic passive congestion, certain toxins (thiacetarsamide, aflatoxins, amanita mushrooms)

D. Midzonal: rare and usually associated with centrilobular necrosis
E. Periportal: uncommon; associated with some hepatotoxins, endotoxins, IBD, chronic pancreatitis
F. Paracentral: involves an entire hepatic acinus, occurs secondary to ischemia from thromboembolism

II. Consequences of fulminant hepatic failure
A. Hepatic encephalopathy
B. Cerebral edema
1. Major cause of death
2. Occurs from vasogenic edema, cytotoxic edema, cerebral ischemia
C. Coagulopathies
D. Hypotension: from endotoxemia, retention of vasogenic amines, etc.
E. Cardiac dysfunction and arrhythmias
F. Pulmonary edema
G. Acid-base and electrolyte disturbances: hyponatremia, hypokalemia, metabolic acidosis
H. Pancreatitis, renal failure
I. Hypoglycemia: develops rapidly
J. Secondary infections
K. Portal hypertension: grave prognostic sign
L. Cholestasis

Clinical Signs

I. Signs may be absent or vague.
II. Nonspecific signs occur in animals with focal, mild, or moderate hepatic necrosis.
III. Signs may relate to another organ system that is affected (e.g., CHF, pyometra, severe shock).
IV. With severe or massive acute hepatic necrosis, signs are often severe, but rarely specific.
A. Anorexia, depression, fever
B. Vomiting, possibly GI hemorrhage with melena, hematemesis
C. Jaundice, hepatic encephalopathy

Diagnosis

I. ALT and AST are consistently elevated within hours of the insult.
A. May reach levels 30 to 50 times the reference range
B. Often fall to lower levels with a few days
C. Poor correlation of elevation with severity of injury
II. Changes in ALP are dependent on the type of injury.
A. More severe elevations with cholestatic processes
B. Mild elevations typical in first days of hepatic necrosis
C. Often elevated longer than ALT
D. Persistent elevations from continued cholestasis, reactive biliary hyperplasia, or hepatic regeneration
III. Hyperbilirubinemia: more severe with periportal necrosis
IV. Hepatic biopsy to identify primary hepatic diseases

Treatment

I. Treat any primary disease.
II. The need for IV fluid therapy is dependent on the underlying condition and the severity of clinical signs and dehydration.
A. Crystalloid solutions that do not contain lactate are recommended.
B. Supplement with dextrose to provide a 2.5% or 5% solution, depending on serum glucose levels.
C. Potassium chloride supplementation is instituted.
1. Give 0.3 to 0.5 mEq/kg/hr in IV fluids to animals with severe hypokalemia.
2. Give 16 to 36 mEq/L in IV fluids to animals with normokalemia and on a maintenance rate of fluids (40 to 60 mL/kg/day).

III. Antioxidants may be beneficial.
A. D-Alpha-tocopheryl-1000-polyethylene glycol succinate (*Liqui-E;* TwinLab, New York N.Y.) is given at 25 IU/kg PO BID.
B. SAMe *(Denosyl)* is given at 20 mg/kg PO SID on an empty stomach.
C. Silymarin
1. Drug of choice for amanita mushroom poisoning
2. Dose: 25 to 50 mg/kg PO SID for dogs and cats

IV. Supportive care for complications of acute hepatic failure includes the following:
A. Treat hepatic encephalopathy, as discussed earlier.
B. Treat cerebral edema with mannitol (0.5 to 1 g/kg IV BID to TID) and with elevation of the head, but treatment is rarely successful.
C. Treat coagulopathies with fresh frozen plasma (5 to 10 mL/kg IV, repeated as needed to normalize coagulation profile) or fresh whole blood if anemic (10 to 20 mL/kg IV).
D. Treat hypotension initially with IV crystalloid fluid therapy, but severe hypotension that fails to respond may be treated with the following:
1. Hydroxyethyl starch 10 to 20 mL/kg IV bolus followed by 1 mL/kg/hr IV
2. Dopamine 2 to 10 µg/kg/min IV constant rate infusion (CRI)
3. Dobutamine 5 to 20 µg/kg/min IV as CRI (dog) or 0.5 to 2 µg/kg/min IV as CRI (cat)
E. Pulmonary edema is poorly responsive to therapy.
1. Furosemide 2 to 4 mg/kg IV TID to QID may be tried.
2. Supplement with oxygen via nasal cannula or oxygen cage.
F. Use antibiotics (e.g., ampicillin, ampicillin, enrofloxacin, cefoxitin) to prevent secondary infections.
G. Manage GI hemorrhage with famotidine.

V. Traumatic rupture rarely requires surgical intervention.
A. Stabilize the animal, providing blood products as needed.
B. Only intervene surgically if bleeding seems uncontrollable.

Monitoring of Animal

I. Prognosis is good with acute hepatic injury (e.g., toxin, trauma, brief hypoxia) if fulminant hepatic failure does not develop.
II. The development of cerebral edema, pulmonary edema, profound coagulopathy (prothrombin time and partial

thromboplastin time exceeding test limits), portal hypertension, and refractory hypotension are grave prognostic indicators.
III. The prognosis for survival is dependent on the primary disease condition or etiology.
1. Blue-green algae poisoning is routinely fatal.
2. Most infectious causes have a good prognosis with early treatment.

VASCULAR DISEASES

Acquired Portosystemic Shunt

Definition

I. Various vascular communications can develop near the kidneys that connect the portal and systemic circulation.
II. They may develop from preexisting but nonfunctional communications.
III. They are associated with any disease that causes portal hypertension.

Causes

I. Hepatic arteriovenous fistula
II. Noncirrhotic portal hypertension
III. Cirrhosis
IV. Hepatic fibrosis
V. Postligation of congenital PSS
VI. Any disease resulting in portal hypertension: cirrhosis, idiopathic hepatic fibrosis, portal vein thrombosis

Pathophysiology

I. Portal hypertension stimulates the opening of alternative vascular communications.
II. Development of HE is the same as for congenital PSS.

Clinical Signs

I. Dependent on underlying disease condition
II. Signs of HE

Diagnosis

I. Diagnostic tests are typically directed toward the primary hepatic disease.
II. Multiple tortuous vessels are identified near the kidney on ultrasonography.
III. Rectal portal scintigraphy confirms the presence of a shunt and is usually suggestive of acquired PSS.
IV. Direct visualization during laparotomy is needed in some cases.

Treatment

I. Treat the underlying disease condition.
II. Treat HE, if present.
III. Ligation of an acquired PSS is not recommended
A. An acquired PSS is a necessary adaptive process (in portal hypertension) to prevent congestive enteropathy and ascites.
B. Ligation results in immediate postoperative death.

NEOPLASIA

See Table 37-2.

TRAUMA

Extrahepatic Biliary Tract Rupture

Definition

It is a tear in the gallbladder, cystic duct, hepatic ducts, or common bile duct with secondary leakage of bile into the abdomen.

Causes

I. Blunt force trauma (e.g., automobile crash, cow kick)
II. Penetrating abdominal injury (e.g., gunshot)
III. Infectious cholecystitis
IV. Gallbladder mucocele
V. Cholelithiasis

Pathophysiology

I. Bile duct ruptures almost always arise from blunt force trauma.
A. Most common site of rupture is the common bile duct distal to the last hepatic duct.
B. Second most common site is at the junction of the common bile duct and duodenum.
C. The cystic duct is rarely ruptured by trauma.
II. Gallbladder rupture almost always occurs from nontraumatic causes.
III. Leakage of bile results in focal or diffuse peritonitis.

Clinical Signs

I. Abdominal pain
II. Abdominal distension
III. Vomiting, anorexia
IV. Icterus

Diagnosis

I. Hyperbilirubinemia and elevated liver enzymes occur.
II. Abdominal radiographs may show focal or diffuse loss of detail consistent with free abdominal fluid.
III. Abdominal ultrasonography may identify the etiology (e.g., mucocele), and the gallbladder may appear empty in cases of ductal rupture.
IV. Evaluation of fluid obtained on abdominocentesis or diagnostic peritoneal lavage documents the presence of bile.

Differential Diagnosis

I. Acute hepatitis
II. Ruptured splenic mass
III. Gastric perforation
IV. Pancreatitis
V. Peritonitis from other causes: see Chapter 38

Treatment and Monitoring

I. Surgical correction is required.
A. Ruptured common bile duct: duct repair, cholecystojejunostomy

TABLE 37-2

Hepatic Neoplasia

TUMOR TYPE	ULTRASONOGRAPHIC FEATURES	TREATMENT AND PROGNOSIS
Hepatocellular carcinoma or adenoma	Inhomogeneous echogenicity, either diffuse or circumscribed	Surgical resection if restricted to a single lobe Poor prognosis for carcinoma
Bile duct carcinoma	Multifocal with mixed echogenicity	Surgical resection if restricted to a single lobe Poor prognosis
Lymphoma	Generalized hyper- or hypoechogenicity Focal or multifocal nodules of varying echogenicity	Treatment same as for generalized lymphoma Fair prognosis for 1 year survival Grave prognosis if animal in liver failure Poor prognosis if cat is FeLV positive
Biliary cystadenoma (cats only)	Focal or multifocal cystic lesions within the liver	Excellent prognosis if surgically resectable Fair prognosis for 1-2 year survival if not resected
Hemangiosarcoma (primary and metastatic)	Solitary, circumscribed mass with cavitary lesions or multiple hypoechoic nodules	Surgical resection of solitary mass, followed by chemotherapy Poor prognosis for 6-month survival
Metastatic carcinoma	Multifocal hypoechoic nodules or diffuse inhomogeneity, target lesions	No therapy Grave prognosis
Insulinoma (metastatic)	Not routinely identified	Surgical removal of visible metastatic lesions Management of primary tumor Good prognosis for 1 year survival
Mast cell disease (metastatic)	Diffuse hyperechogenicity, hypoechoic nodules	Chemotherapy Fair prognosis for 1 year survival

FeLV, Feline leukemia virus.

B. Ligation of ruptured hepatic ducts
C. Cholecystectomy for gallbladder rupture

II. See treatment of peritonitis is Chapter 38.

III. Prognosis is dependent on the site of rupture.
A. Excellent for rupture of gallbladder and common bile duct distal to cystic duct
B. Variable depending on ease of repair for ruptures of common bile duct proximal to cystic duct
C. Fair to good when bile peritonitis is present

CHAPTER 38

Diseases of the Peritoneum

Rhea V. Morgan

INFLAMMATORY DISORDERS

Peritonitis

Definition

I. Peritonitis is inflammation of the serous membranes of the abdomen and may involve the omentum.
II. Peritonitis can be categorized as primary or secondary, infectious or noninfectious, aseptic or septic, and focal or diffuse.
III. Secondary peritonitis is the most common form, and usually arises from some underlying abdominal disease or condition.

Causes and Classification

I. Primary peritonitis
  A. Feline infectious peritonitis (FIP) is the most common primary disease.
  B. Pansteatitis from vitamin E deficiency or excessive dietary polyunsaturated fats occurs rarely in the cat.
  C. Apparent spontaneous bacterial peritonitis has been reported rarely in immunocompromised animals (Kirby, 2003).
II. Septic peritonitis
  A. It is usually associated with compromise of the gastrointestinal (GI) tract and is bacterial in origin.
    1. GI necrosis, perforation, rupture, infarction, dehiscence, torsion, intussusception
    2. Pancreatic abcessation
    3. Hepatobiliary diseases
    4. Avulsion of the mesentery
  B. Contaminated or infected urogenital lesions may lead to septic peritonitis.
    1. Pyometra, uterine rupture or torsion
    2. Rupture of an infected bladder or an infected prostatic cyst
    3. Renal and prostatic abcessation
    4. Iatrogenic from cystocentesis of an infected bladder (rare) (Specht et al., 2002)
  C. Other causes include penetrating wounds, evisceration of the abdomen, contaminated peritoneal dialysis, splenic abscess, surgical contamination, umbilical abscess, among others.
  D. The most common bacterial pathogens are *Escherichia coli, Clostridium* spp., *Streptococcus faecalis,* and *Enterococcus* spp. (Swann and Hughes, 2000).
  E. *Actinomyces* and *Nocardia* spp. infections may occur, with and without known penetrating injuries.
  F. Viruses that may cause focal peritonitis in dogs include parvovirus and infectious hepatitis virus.
  G. Protozoal causes are rare, but include toxoplasmosis in cats and neosporosis in dogs (Holmberg et al., 2006).
III. Bile peritonitis develops from rupture of the gallbladder or bile duct(s) and leakage of bile into the abdomen.
  A. Causes include blunt trauma to the abdomen, necrotizing cholecystitis, bile duct obstruction (from calculi, parasites, neoplasia), and surgery (e.g., bile diversion procedures, gastric dilatation-volvulus correction).
  B. The peritonitis may be septic (most common agent is *E. coli)* or aseptic (Swann and Hughes, 2000).
  C. Bile causes a chemical peritonitis that may be lethal if untreated.
IV. Other causes of chemical peritonitis include aseptic pancreatitis, uroabdomen, and exposure to surgical glove powder, antibiotics, barium, povidone-iodine, or other agents.
  A. Urine does not usually cause serious peritonitis unless it is infected.
  B. Severe, sterile enzymatic peritonitis may accompany acute pancreatitis.
V. Parasitic peritonitis is uncommon, but may occur in dogs from abnormal nymphal pentastomiasis with *Porocephalus crotali* and infections with *Mesocestoides* spp. (Kirby, 2003).
VI. Mechanical peritonitis may arise from exposure of the abdomen to air (e.g., laparoscopy) or sterile foreign bodies (e.g., surgical gauze or other materials), rough handling of abdominal tissues, and other sources of trauma.
VII. Sclerosing encapsulating peritonitis is a rare disorder that results in encasement of the abdominal organs in a thick, collagenous connective tissue.
  A. It has been reported in dogs and one cat (Bellenger and Rothwell, 1991; Boothe et al., 1991; Hardie et al., 1994).
  B. Many of the dogs were young, large-breed dogs.
  C. In most cases the cause is unknown, but the cat had steatitis and, in three dogs, the condition was associated with ingestion of fiberglass, bacterial peritonitis

(Hardie et al., 1994), and leishmaniasis (Adamama-Moraitou et al., 2004).

Pathophysiology

I. Inflammation of peritoneal surfaces may lead to vasodilation, increased permeability, and loss of fluid and protein into the abdominal cavity (effusion).
II. Infection, necrosis, and decreased blood flow to abdominal organs generate inflammatory mediators and cytokines, with development of systemic inflammatory response syndrome (SIRS).
III. SIRS tends to be worse with septic, bacterial (especially bile) peritonitis and peritonitis associated with pancreatitis (Swann and Hughes, 2000).

Clinical Signs

I. History and clinical signs may be nonspecific (depression, anorexia, vomiting, diarrhea) or misleading in some animals.
   A. Onset of signs is acute in many cases of septic and traumatic peritonitis.
   B. Onset may be slower in animals with mesenteric avulsions (5 to 7 days) or aseptic, bile peritonitis (days to weeks) (Fossum, 2002a).
II. A history of recent abdominal surgery, abdominal trauma, and penetrating wounds is suggestive.
III. Abdominal enlargement, tachypnea, or dyspnea may occur with large volumes of abdominal effusion.
IV. Abdominal pain is variable in most animals, with septic or traumatic peritonitis being painful.
   A. Fewer cats (62%) than dogs with septic peritonitis exhibit abdominal pain (Costello et al., 2004).
   B. Most cats with FIP are not painful.
V. Signs of SIRS include injected mucous membranes, rapid capillary refill time, tachycardia, bounding pulses, and fever.
VI. Untreated SIRS may lead to dehydration, hypovolemia, cardiovascular collapse, and shock.
VII. Other signs relate to the underlying causes.
   A. Icterus: hepatobiliary disease
   B. Polyuria, polydipsia: pyometra, urinary tract disease
   C. Stranguria, dysuria: prostatic or other lower urinary tract diseases
   D. Fever, chorioretinitis, weight loss: FIP
   E. Abdominal bruising, puncture wounds, pelvic fractures: trauma

Diagnosis

I. Laboratory testing is indicated in all cases of suspected peritonitis.
   A. Significant leukocytosis and neutrophilia with a left shift are common in many cases of septic or chemical peritonitis.
   B. Anemia and evidence of dehydration may be detected.
   C. Biochemistry changes are variable and reflect the underlying cause or type of peritonitis.
      1. FIP: hyperglobulinemia from a polyclonal gammopathy, hyponatremia, hyperkalemia (Chastain and Panciera, 2002)
      2. Hepatobiliary disease, bile duct rupture: bilirubinemia, liver enzyme elevations, hyponatremia, hypoalbuminemia
      3. Uroabdomen: elevated blood urea nitrogen (BUN), creatinine, potassium
      4. Septic peritonitis: possible panhypoproteinemia, electrolyte abnormalities, hypoglycemia
      5. Pancreatitis: see Chapter 36
II. Abdominal radiography reveals a loss of abdominal detail that may be focal or generalized.
   A. Early signs of fluid accumulation are a patchy or mottled appearance to the abdominal organs and loss of discrete edges.
   B. With large amounts of effusion, the abdomen has a "ground-glass" appearance.
   C. The GI tract may contain excessive fluid, air, or both.
   D. Free abdominal air may be seen with penetrating wounds, rupture of hollow organs, gas-producing anaerobic bacterial infections, and after abdominal surgery, laparoscopy, or pneumoperitoneography.
   E. Other abnormalities may be detected (e.g., organomegaly, foreign body, emphysematous changes in the gallbladder or liver, distension of hollow organs, gallstones, pelvic or spinal fractures) depending on the underlying cause.
III. Ultrasonography may identify small volumes (<6 mL/kg) of effusion or localized effusions, and it often helps to determine the cause (Negrini et al., 2003).
   A. In early cases of peritonitis, little or no effusion may occur.
   B. Rupture of the GI tract may be difficult to identify with ultrasonography.
IV. Other imaging procedures to consider include thoracic radiography, positive-contrast radiography of the GI (using water-soluble iodinated contrast medium) or urinary tracts (see Chapter 4), and pneumoperitoneography.
V. Abdominocentesis and fluid analysis are indicated in cases with abdominal effusion.
   A. Contraindications are few (coagulopathies, gastric dilatation, uterine enlargement).
   B. It may be performed with or without ultrasound guidance.
   C. Techniques include a single paracentesis, four-quadrant paracentesis, or diagnostic peritoneal lavage.
   D. Submit samples for bacterial cultures, cytology, and fluid analysis.
VI. If abdominocentesis fails to yield a diagnostic sample, perform diagnostic peritoneal lavage.
   A. Insert a peritoneal lavage catheter into the abdomen via a 2-cm skin incision caudal to the umbilicus.
   B. If gentle suction yields no fluid, infuse 20 mL/kg of warm, sterile saline into the abdomen.
   C. Roll the animal from side to side, then collect fluid by gravity drainage.
   D. The volume retrieved is usually less than that infused, particularly in dehydrated animals.
VII. Results of fluid analysis may help determine the cause.

A. Normal fluid in abdomen: <1 mL/kg, <3000 nucleated cells/μL, <2.5 g/dL protein (mostly albumin) (Swann and Hughes, 2000)
B. Aseptic peritonitis (Kirby, 2003)
   1. Serosanguineous, turbid, cloudy fluid
   2. Nondegenerate neutrophils, absence of bacteria
   3. Protein > 3.0 g/dL, >5000 cells/μL
C. Septic peritonitis
   1. Serosanguineous, hemorrhagic, turbid, or cloudy fluid
   2. Toxic, degenerate neutrophils with intra- or extracellular bacteria
   3. Nucleated cell count 5000 to 100,000/μL, protein > 3.0 g/dL
   4. Low fluid glucose: <50 mg/dL or blood-to-fluid glucose difference >20 mg/dL
   5. Fluid-to-blood lactate difference >2 mmol/L (dogs)
D. Pancreatitis
   1. High numbers of degenerate neutrophils
   2. Possible fluid amylase and lipase concentrations higher than serum levels (Guija de Arespacochaga et al., 2006)
E. Uroabdomen
   1. Clear or slightly turbid fluid that may be yellow tinged
   2. Low cell counts early
   3. Transient fluid BUN concentration higher than serum levels, and persistent fluid creatinine and potassium concentrations higher than serum levels
F. Bile peritonitis (Moore and Andreasen, 2002; Fossum, 2002b)
   1. Dull green or purulent fluid, bile pigment in macrophages
   2. Fluid bilirubin concentration that is often >2 times greater than that of serum
   3. Fibrillar mucinous material occasionally identified in fluid (Owens et al., 2003)
G. FIP
   1. Clear, straw-colored fluid; rarely appears chylous (Savary et al., 2001)
   2. Viscous consistency, with possible clots
   3. Cell count 3000 to 15,000/μL, protein >3.5 g/dL
H. *Mesocestoides* spp. infection (Caruso et al., 2003; Bonfanti et al., 2004)
   1. Exudative, suppurative hemorrhagic fluid
   2. Calcareous corpuscles (remnants of cestodes), acephalic metacestodes visible on cytology

VIII. In some cases, peritonitis and its underlying cause are only diagnosed by laparoscopy or exploratory laparotomy, and histopathology (Figure 38-1).

Differential Diagnosis

I. Ascites
   A. Fluid is usually clear and colorless, but may be blood tinged after repeated paracenteses.
   B. Mononuclear cells and nondegenerate neutrophils are common.
   C. Fluid often contains <500 to 1500 cells/μL and <2.5 g/L protein (Kirby, 2003; Moore and Andreasen, 2002).
II. Chylous ascites or effusion
   A. Rare presence of chyle in the peritoneal cavity
   B. In cats, associated with intraabdominal neoplasia (hemangiosarcoma), biliary cirrhosis, extrahepatic portal shunts, cardiomyopathy (Gores et al., 1994; Nelson, 2001)
   C. In dogs, associated with rupture or thrombosis of mesenteric lymphatics, lymphatic obstruction, thoracic duct ligation, lymphangiectasia, chylothorax (Kirby, 2003; Moore and Andreasen, 2002)
   D. Characterized by a cloudy, white, or pinkish effusion that contains very high concentrations of triglyceride compared with serum triglyceride (Fossum et al., 1992) and stains positive with Sudan stain
III. Hemoabdomen: see Hemoabdomen
IV. Other causes of acute abdominal pain: see Chapter 39
V. Neoplastic effusions: see Neoplasia

Treatment

I. In critically ill animals, IV crystalloid and colloid fluids, and therapy for shock (see Chapter 132) are instituted.
   A. Provide glucose and potassium supplementation as needed.
   B. Consider sodium bicarbonate therapy.
   C. Low-dose heparin (50 to 100 U/kg SC BID) has been associated with higher survival rates in experimental septic peritonitis (Fossum, 2002a) and disseminated intravascular coagulopathy (DIC).
II. Administer parenteral antibiotics for septic peritonitis.
   A. Ampicillin 20 to 40 mg/kg IV TID to QID or cephazolin 20 mg/kg IV TID, possibly combined with amikacin 30 mg/kg IV SID (dogs) or 10 mg/kg IV SID (cats)
   B. Ampicillin or cefazolin combined with gentamicin 6 mg/kg SC SID
   C. Metronidazole 10 mg/kg IV BID added for anaerobic infections
   D. Third-generation cephalosporins
      1. Cefoxitin 30 mg/kg IV TID to QID
      2. Cefotaxime 30 to 40 mg/kg IV TID to QID (dogs)
      3. Ceftazidime 20 to 50 mg/kg IV TID (dogs)
   E. Imipenem 3 to 10 mg/kg IM TID to QID (dogs)
   F. Modified based on culture results
III. It is imperative to remove the underlying cause, which usually requires a celiotomy (see Figure 38-1).
   A. Perform corrective procedures (e.g., repair of bile ducts, gallbladder removal, biliary diversion, resuturing of dehiscences, intestinal anastomosis, repair of urinary tract ruptures, removal of ruptured uterus, omentalization of prostatic abscesses and cysts) and serosal patching of sutured sites.
      1. Serosal patching is used to decrease the incidence of dehiscence that is associated with peritonitis (Kirby, 2003).
      2. Use of suture materials that do not degrade quickly is also recommended.
   B. Obtain samples for culture and histopathology.

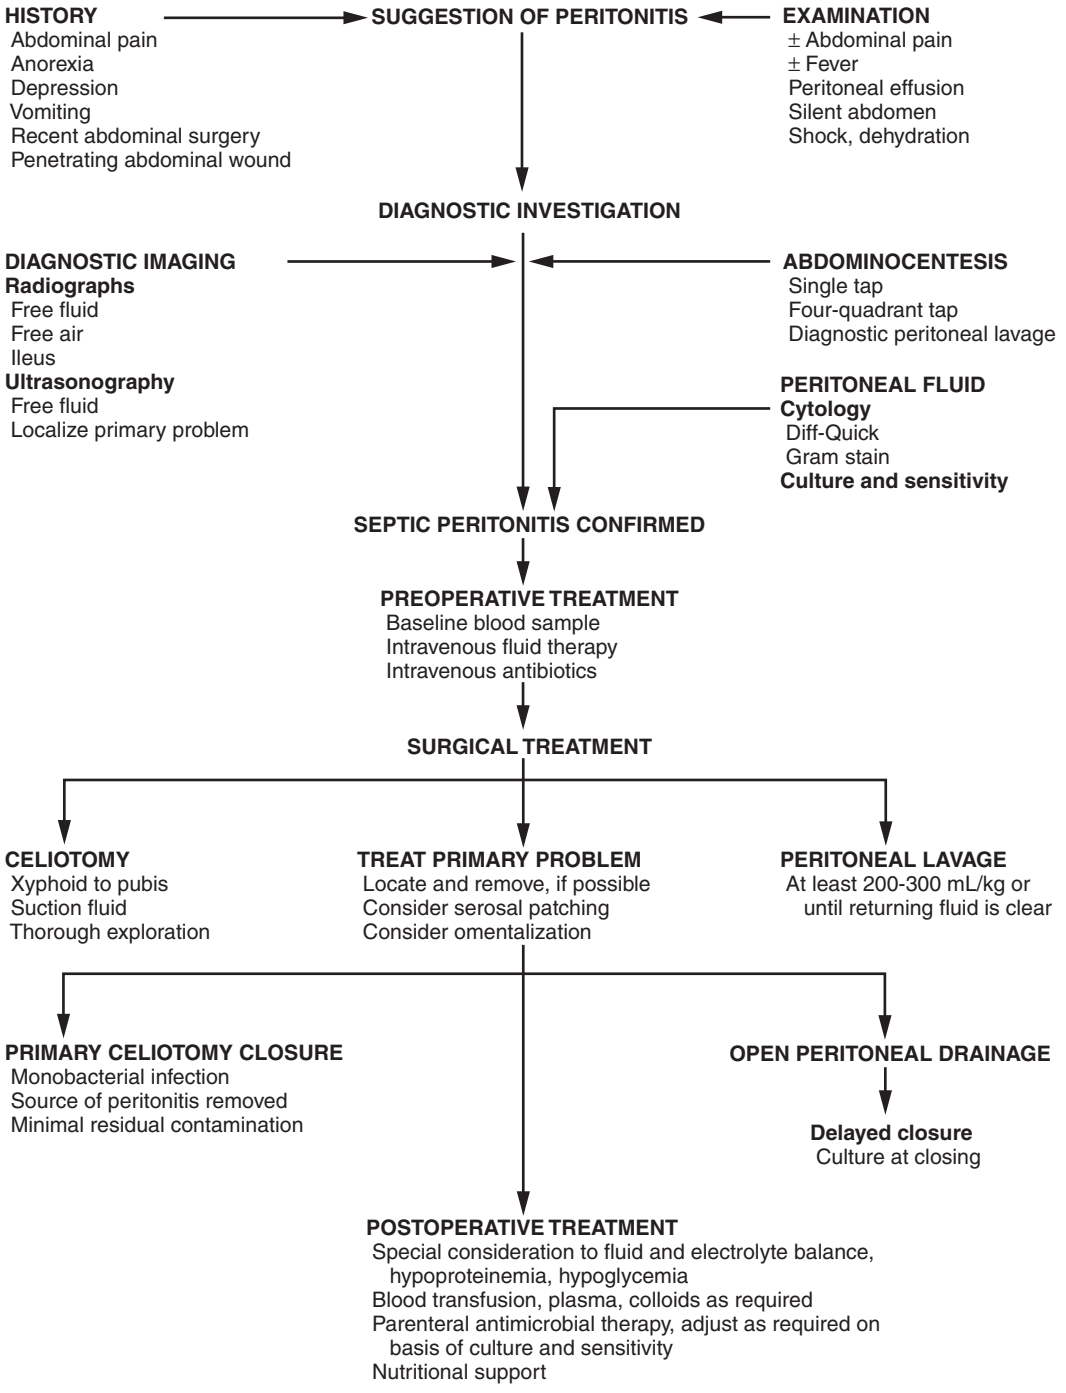

FIGURE 38-1 Algorithm for investigation and treatment of septic peritonitis. *Modified from Kirby BM. Peritoneum and peritoneal cavity. p. 414. In Slatter D (ed): Textbook of Small Animal Surgery. 3rd Ed. WB Saunders, Philadelphia, 2003, with permission.*

C. For diffuse peritonitis, the abdomen is usually lavaged with warm, sterile saline.
   1. A minimum of 200 to 300 mL is initially infused, and lavage with suction is continued until the abdominal fluid becomes clear.
   2. Addition of antibiotics to the fluid is not recommended because of the risk of chemical peritonitis.

D. After exploration, perform primary abdominal closure or leave the abdomen open for continued drainage.
   1. Closure may be done with or without drainage tubes and suction, and is usually performed for localized peritonitis.
   2. Open-abdominal drainage is often preferred for generalized or severe peritonitis (Kirby, 2003; Fossum, 2002a), although some cases may be managed with closed-suction drains (Mueller et al., 2001).

E. Open drainage involves removal of the falciform fat and partial closure of the abdominal wall (2- to 6-mm

gap, 8 to 10 cm in length) with monofilament nylon suture.
1. Cover the opening with a sterile bandage, changed BID initially.
2. The abdomen is usually closed in 3 to 5 days, once much of the drainage has subsided, and hematological and biochemistry parameters are improving or normal.

F. *Mesocestoides* spp. infections in dogs have been treated with fenbendazole 100 mg PO BID for 4 to 12 weeks, and abdominal drainage and lavage, with variable success (Caruso et al., 2003).
G. Specific therapies for sclerosing, encapsulating peritonitis have not been defined, although antibiotics and corticosteroids have been tried with mixed success.

Monitoring of Animal

I. Postoperatively, intensive monitoring is usually required (Lipowitz et al., 1996).
   A. Vital signs are monitored continuously for evidence of SIRS and sepsis.
   B. Electrolyte abnormalities are common and monitored SID to TID.
   C. Continuous electrocardiography is used to monitor for arrhythmias.
   D. Acid-base status and serum protein levels are monitored SID, as needed.
II. Postoperative treatment includes continued IV fluid therapy, plasma transfusions for hypoproteinemia, and blood transfusions for blood loss or anemia (see Chapter 71).
   A. Continue parenteral antibiotics until the animal is stable, then convert to oral forms.
   B. Change abdominal bandages using aseptic technique until the abdomen can be closed, taking special care to avoid contamination of the bandage with urine.
   C. Analgesia with oxymorphone, fentanyl, morphine, or butorphanol is recommended postoperatively (see Chapter 39).
   D. Consider low-dose heparin for animals with DIC (see Treatment under Peritonitis).
   E. Maintaining normal body temperature and providing adequate padding and nursing care are important in recumbent animals.
III. Prognosis is variable, depending on the severity and origin of the peritonitis.
   A. Mortality for animals with severe, generalized peritonitis that requires open abdominal drainage is 20% to 48% (Fossum, 2002a).
   B. Bile peritonitis is associated with an overall survival rate of 50%, but the prognosis for sterile bile peritonitis is much better (approaches 100%) than for septic bile peritonitis (27%) (Ludwig et al., 1997).
   C. Postoperative sepsis (complicated by hypoalbuminemia, hypo- or hyperglycemia), respiratory complications, or DIC are associated with higher mortality.
   D. Sclerosing, encapsulating peritonitis has a poor prognosis.

Hemoabdomen

Definition and Causes

I. Hemoabdomen or hemoperitoneum is free, nonclotting blood within the abdominal cavity.
II. Causes include ruptured neoplasia, trauma (blunt or penetrating), liver lobe torsion, splenic torsion, coagulopathies, and iatrogenic injury to abdominal organs (Figure 38-2).

Pathophysiology

I. Trauma to the abdomen is common following automobile injuries, with the spleen, liver, and kidneys being the most common sources of intraabdominal bleeding.
II. Hemangiosarcomas of the spleen and liver are the most common tumors associated with hemoabdomen.
III. Rapid loss of blood into the abdominal cavity causes circulatory compromise similar to external blood loss, with decreased blood pressure, tachycardia, pallor, weakness, and collapse (see Shock in Chapter 132).
IV. At least 40 mL/kg of blood must be present in the abdomen before abdominal distension can be detected (Vinayak and Krahwinkel, 2004).

Clinical Signs and Diagnosis

I. Signalment and history may be suggestive of hemoabdomen and its cause.
   A. Young, male, mixed-breed dogs are the most likely victims of abdominal trauma.
   B. Bleeding neoplasms occur most commonly in older, large-breed dogs.
   C. Recent abdominal surgery, ultrasound-guided or blind biopsies, or abdominocentesis may indicate iatrogenic injury.
   D. Hemoabdomen following minor trauma is suspicious of a coagulopathy.
II. Onset of signs is often acute and dramatic, but signs may be delayed for up to 3 hours after trauma (Vinayak and Krahwinkel, 2004) or originally be intermittent (e.g., recurrent mild bleeding from hemangiosarcomas).
III. Physical examination may reveal the following:
   A. Evidence of circulatory shock: pallor, weak and thready pulses, tachycardia, weakness, collapse
   B. Evidence of abdominal trauma: cutaneous bruising, lacerations, inability to walk from concurrent musculoskeletal injuries, hematuria
   C. Evidence of clotting problems: petechiae and/or ecchymoses elsewhere on the body, hematuria, pallor
   D. Abdominal distension, tenderness, and/or presence of a fluid wave with ballottement
   E. Palpable abdominal mass, especially in the spleen or liver
IV. Diagnostic imaging involves abdominal radiography and ultrasonography, and thoracic radiography.
   A. Abdominal radiography usually shows free fluid in the abdomen and loss of abdominal detail.
   B. Evidence of masses, abnormal organ contours, or peritonitis may also be detected.

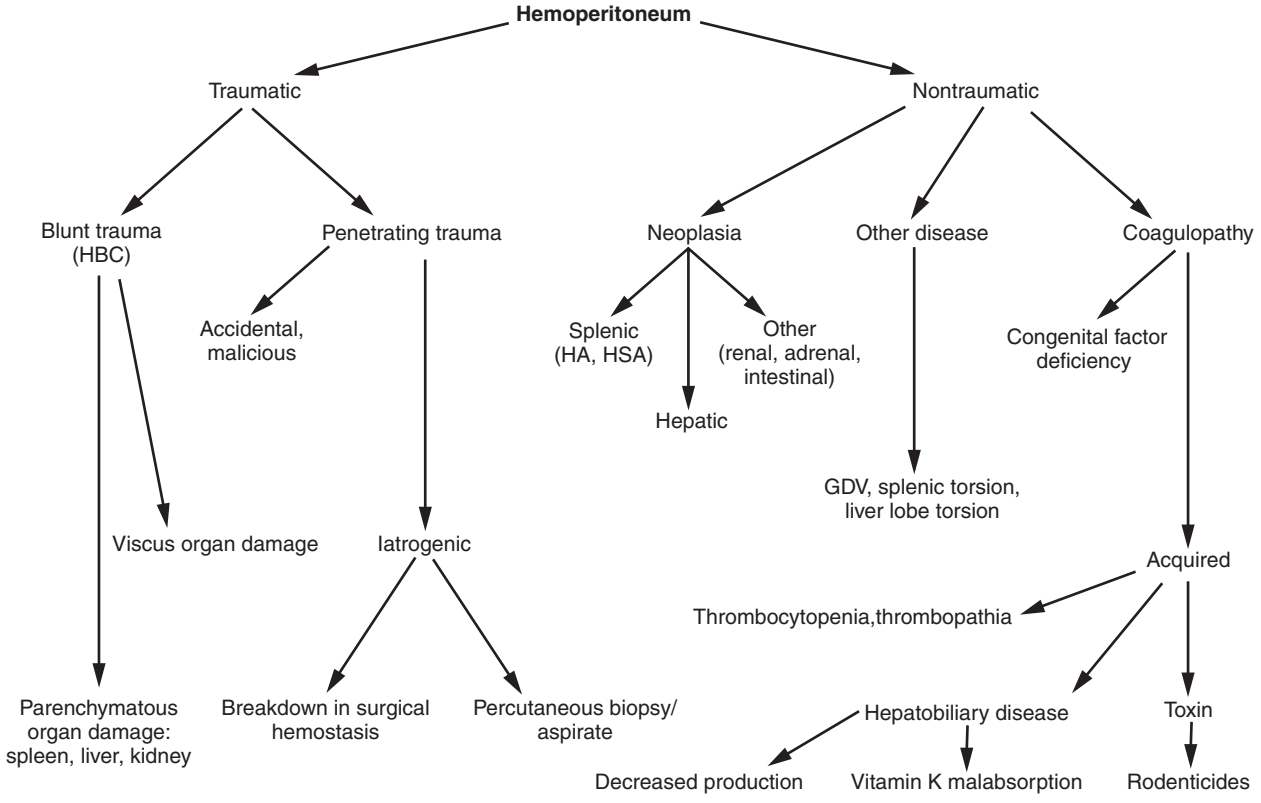

FIGURE 38-2 Causes of hemoabdomen. *HBC,* Hit by car; *HA*, hematoma; *HAS*, hemangiosarcoma; *GDV*, gastric dilatation-volvulus. *Modified from Brockman DJ, Mongil CM, Aronson LR et al: A practical approach to hemoperitoneum in the dog and cat. Vet Clin North Am Small Anim Pract 30:657, 2000, with permission.*

C. Ultrasonography is performed after the animal is stabilized to help identify the source of bleeding, any abdominal masses, sites of potential trauma, and torsion of the liver or spleen, as well as to guide paracentesis.
D. Thoracic radiographs are done to search for metastasis with suspected neoplasia and to rule out pulmonary trauma in cases of abdominal trauma.

V. Hemoabdomen is confirmed with abdominocentesis (50% to 62% accuracy) or diagnostic peritoneal lavage (~100% accuracy) (Mongil et al., 1995; Kirby, 2003).
A. Blood that has been present in the abdomen for >45 minutes and does not contain platelets will not clot (Crowe, 1980).
B. If the sample clots, then iatrogenic aspiration of the liver or spleen is likely.
C. The packed cell volume (PCV) and total solids (TS) of the fluid are measured and compared to peripheral blood.
1. PCV and TS >peripheral blood may occur with splenic aspiration.
2. PCV >2% to 5% in peritoneal lavage fluid indicates hemorrhage (Dye, 2003).
D. Cytology, biochemical assays, and cultures may also be performed on the fluid, especially if peritonitis is suspected.
1. Neoplastic cells are rarely seen and are a poor prognostic sign.
2. Red blood cells (RBCs) are the predominant cell with hemoabdomen.

VI. A complete blood count (CBC), biochemistry profile, and coagulation studies are indicated to help identify the underlying cause and evaluate the status of the animal before surgery.
A. Anemia (initially unresponsive) and hypoproteinemia are common if bleeding has been prolonged or profound.
B. The presence of nucleated RBCs in the CBC is suggestive of hemangiosarcoma.
C. Thrombocytopenia and other coagulation abnormalities may indicate primary bleeding problems or secondary changes (e.g., DIC).
D. Elevated liver enzymes may occur with hepatic contusion, torsion, or neoplasia.

VII. Cross-matching, blood typing, or both are indicated if transfusion therapy is anticipated.

Differential Diagnosis

I. Chronic or recurrent ascites
II. Hemorrhagic effusion associated with peritonitis

Treatment

I. Direct initial measures at stabilization of the animal, including rapid IV fluid therapy with crystalloids and/or colloids, oxygen supplementation, etc. (see Chapter 132).
II. Autotransfusion may be done in animals with traumatic hemoabdomen (Crowe, 1980) and transfusion of whole

blood may be considered in all cases with serious bleeding (see Chapter 71).

III. Replacement of clotting factors with cryoprecipitate, administration of platelet-rich plasma, and institution of vitamin K therapy may be indicated for certain coagulopathies (see Chapters 67 and 68).

IV. Once the animal is stable, further diagnostic tests are performed to better differentiate whether the source of the bleeding is neoplastic or nonneoplastic, and to stage (e.g., thoracic radiographs, abdominal ultrasonography, echocardiography with hemangiosarcomas) the animal with obvious neoplasia.

V. Mild cases of abdominal bleeding associated with trauma (blunt or iatrogenic) or bleeding from coagulopathies often subside with only medical therapy and strict rest.

VI. Exploratory laparotomy is indicated for suspected or confirmed neoplasia, persistent or uncontrolled bleeding (unassociated with coagulopathy), torsion of the spleen or liver, hemorrhage associated with rupture of the urinary tract or hollow organs, penetrating trauma, and if all other tests fail to reach a diagnosis.
   A. It is preferable to delay surgery until the animal is hemodynamically stable.
   B. Upon entering the abdomen, manually control hemorrhage and evacuate blood to allow thorough examination of the entire abdomen.
   C. Perform corrective surgical procedures and thoroughly lavage the abdomen before closure (see Peritonitis).

Monitoring of the Animal

I. Postoperative monitoring is similar to that for peritonitis.

II. Prognosis is variable, depending upon the underlying cause.
   A. Prognosis associated with nonneoplastic diseases is generally good.
   B. Most cases of mild external or iatrogenic trauma are self-limiting and cause no long-term consequences.
   C. Many (57%) cases of serious, traumatic hemoabdomen survive, and response improves (67% to 75%) with aggressive medical and/or surgical therapy (Mongil et al., 1995).
   D. Splenectomy and liver lobectomy are usually curative for torsions of the spleen and liver.
   E. Coagulopathies can vary in their severity and response to treatment (see Chapters 67 and 68).
   F. Hemangiosarcoma that has metastasized to the thorax, cardiac tissues, or multiple abdominal organs may warrant immediate euthanasia without further therapy.
   G. Hemangiosarcoma that has not metastasized at the time of surgery may be followed by chemotherapy in an attempt to prolong survival.

NEOPLASIA

Definition and Causes

I. The most common, primary neoplasm of the peritoneum is malignant mesothelioma, which can arise from the mesothelial cells of all coelomic cavities.

II. Secondary tumors often originate in adjacent abdominal organs and invade or metastasize to the peritoneum.

III. Examples of secondary tumors include hemangiosarcoma, visceral mast cell tumor, carcinomatosis of the omentum, and adenocarcinomas of the intestines and urogenital tract (Bertazzolo et al., 2003; de Souza et al., 2001).

IV. The following discussion pertains primarily to mesotheliomas (See Hemoabdomen for information on abdominal hemangiosarcomas).

Pathophysiology

I. Exposure to asbestos has been incriminated in the development of mesotheliomas in both people and dogs (Harbison and Godleski, 1983).

II. Mesothelioma is very rare in the cat and no predisposing factors have been identified.

III. Three histological types exist in cats and dogs: epithelioid, sarcomatoid, and biphasic (contains both epithelioid and sarcomatoid cells).

IV. A deciduoid form, which cytologically resembles endometrium of pregnancy, has been reported in one dog (Morini et al., 2006).

Clinical Signs

I. Most affected animals are middle-aged to older, but mesothelioma has been reported in dogs as young as 3 years (Geninet et al., 2003).

II. Weight loss, anorexia, lethargy, and abdominal distension are common signs, because most mesotheliomas cause peritoneal effusion.

III. Respiratory distress may be noted from abdominal effusion pressing on the diaphragm.

Diagnosis

I. Diagnostic work-up is similar to that described for peritonitis (see Figure 38-1).

II. Fluid retrieved by paracentesis may reveal malignant cells, but cells from mesotheliomas are difficult to differentiate from reactive mesothelial cells, which are common in many types of effusions.

III. Histopathology and immunohistochemistry are usually required to make a definitive diagnosis of mesothelioma and to determine the type (Geninet et al., 2003; Bacci et al., 2006; Morini et al., 2006).

Differential Diagnosis

I. Other causes of peritoneal effusion: see Peritonitis and Hemoabdomen

II. Causes of ascites and chylous effusions

Treatment and Monitoring

I. Because of its wide dissemination within the abdomen, surgical excision is usually impossible, but exploratory laparotomy may be needed to confirm the diagnosis.

II. The efficacy of chemotherapy for mesothelioma has not been well studied because of the relative rarity of the tumor.

III. Even with repeated abdominal drainage, most dogs are dead within 2 months, although one dog with a cystic form of the disease survived 3 years (DiPinto et al., 1995).

CHAPTER 39

Acute Abdomen Syndrome

Daniel Z. Hume

Definition and Causes

I. Acute abdomen syndrome is the acute onset of abdominal pain.
II. Pain may arise from sites within or outside of the abdominal cavity.
III. General categories or types of acute abdomen syndrome include the following:
  A. Inflammatory
  B. Mechanical
  C. Neoplastic
  D. Vascular
  E. Associated with congenital defects
  F. Traumatic

Pathophysiology

I. Nociceptive pain is transient pain in response to a noxious stimulus.
II. A primary afferent nociceptor is a sensory neuron capable of reception and transmission of a stimulus following tissue damage.
  A. The peripheral terminals of the primary afferent neuron are located within the mesentery, within or on peritoneal surfaces, and within the mucosa and muscularis of hollow organs.
  B. Nociceptors have unmyelinated (C fibers) or thinly myelinated (Aδ fibers) axon fibers, and respond to various stimuli.
    1. Mechanical: stretch, distension, torsion, contraction
    2. Chemical: hydrogen ions, substance P, serotonin, prostaglandins, lipid metabolites, bradykinins
    3. Heat, cold
III. Three types of abdominal pain exist.
  A. Visceral pain
    1. Typically caused by mechanical stimulation of abdominal organs
    2. Transmitted by slow conducting C fibers
    3. Often described as a dull, achy, poor-localized pain
  B. Parietal pain
    1. Typically caused by inflammatory mediators and byproducts interacting with nociceptors within the parietal surface of the abdomen
    2. Transmitted by rapidly conducting Aδ fibers
    3. Often described as sharp, well-localized, shooting pain
  C. Referred pain
    1. Afferent signals from an extraabdominal region that enter the spinal cord at or near the same location as a visceral afferent neuron arising from an intra-abdominal region
    2. Shared nociceptive segment within a central pathway

Clinical Signs

I. Significant medical or historical information
  A. Previous medical problems
  B. Previous surgical procedures
  C. Last known estrus or breeding
  D. Access to toxins or garbage
  E. History of known foreign material ingestion
  F. Administration of prescribed, over-the-counter, or homeopathic medications
  G. Previous, similar episodes
II. Clinical signs
  A. Vomiting, diarrhea
  B. Abdominal pain, "prayer" position
  C. Anorexia, inappetence
  D. Lethargy, depression
  E. Vulvar or preputial discharge
  F. Abdominal distention
  G. Fever

Diagnosis

I. Physical examination
  A. Findings consistent with poor perfusion include increased capillary refill time, pale mucous membranes, weak to absent peripheral pulses, increased heart rate, decreased rectal temperature, and cool extremities.
  B. Findings consistent with dehydration include increased skin turgor, tacky mucous membranes, and recessed globes.
  C. The abdomen is palpated and evaluated for the following:
    1. Presence of abdominal pain
    2. Organomegaly, mass lesions
    3. Increased intestinal wall thickness, foreign bodies, intussusceptions, etc.
    4. Urogenital abnormalities
      a. Renal size, shape, architecture, presence of pain

b. Bladder size, compressibility, uroliths, presence of pain
5. Palpable fluid wave
6. External bruising, penetrating wounds, ulcerative lesions, petechiae, ecchymoses

D. Neurological status is accessed.
1. Mentation, level of alertness
2. Cranial nerve function
3. Movement, gait, postural reflexes, postural reactions

E. Assessment of respiration involves auscultation, with evaluation of respiratory rate, rhythm, effort, and synchrony.

F. Assessment of cardiovascular system includes the following:
1. Cardiac auscultation
2. Pulse quality and strength
3. Capillary refill time
4. Jugular pulse

G. Evaluate the vulva or penis and prepuce for discharge, bleeding, petechiae, etc.

H. Rectal examination is important.
1. Digital palpation for fractures or step defects of the pelvis
2. Digital palpation for prostate abnormalities
3. Fecal examination for digested or frank blood pigments, foreign material, mucous, etc.

II. Laboratory data

A. Initial tests
1. Packed cell volume (PCV) and total solids (TS)
a. Increased PCV and TS: hemoconcentration
b. Decreased PCV and normal to increased TS: hemolysis, decreased red blood cell production
c. Normal to increased PCV, decreased TS: decreased protein production or loss
d. Decreased PCV and TS: blood loss
2. Blood smear
a. Red blood cell morphology
b. Platelet estimate: 1 platelet per high power field (100 ×) = 10,000 to 15,000 platelets/μL
c. White blood cell (WBC) morphology and estimate
(1) Mean WBC in 10 fields (40 ×) × 1500 = leukocytes/μL
(2) Differential count
(3) Toxic or degenerative leukocyte changes
3. Serum color: icterus, hemolysis, lipemia
4. Urine: urine specific gravity, sediment examination
5. Electrolytes or venous blood gas analysis

B. Comprehensive database
1. Complete blood count
2. Serum chemistry
3. Urinalysis
4. Coagulation panel
5. Serum lactate
a. Indication of anaerobic metabolism
b. May be a measure of tissue perfusion

III. Survey abdominal radiography

A. Decreased abdominal serosal detail may be noted with abdominal effusion or peritonitis.

B. Moderate to severe enlargement of small intestines with gas or fluid may be seen with small intestinal mechanical obstruction.
1. In dogs, normal bowel diameter does not exceed the height of the central part of the body of a lumber vertebra and is not larger than twice the width of a rib.
2. In cats, diameter of the bowel is ≤12 mm.

C. A soft-tissue tubular structure may be seen in animals with intussusceptions, pyometra, and uterine enlargement.

D. Intestinal plication and teardrop-shaped luminal gas bubbles may be seen with a linear foreign body.

E. Compartmentalization of the stomach and pyloric displacement occur with a gastric dilation-volvulus (right lateral projection).

F. Animals with pancreatitis may have increased opacity, granularity, and decreased detail in the right cranial quadrant, along with an increase in the gastroduodenal angle.

G. Loss of distinct diaphragmatic borders or presence intrathoracic abdominal viscera may be seen with a diaphragmatic hernia.

H. Loss of retroperitoneal detail and increased size of retroperitoneal space may be seen with renal or ureteral urine leakage or hemorrhage.

I. The urinary bladder may be visualized when ruptured, and concomitant pelvic fractures may be seen.

J. Prostatic disease resulting in prostatic enlargement may cause cranial displacement of the bladder and increased soft-tissue density in the caudal abdomen.

K. Splenomegaly, displacement of adjacent abdominal organs, abnormal splenic location or shape, loss of abdominal detail, and intrasplenic gas may detected with a splenic torsion.

L. Increased renal size may occur with pyelonephritis, acute renal failure, neoplasia, feline infectious peritonitis, subcapsular cysts, compensatory hypertrophy, or ureteral obstruction with hydronephrosis.
1. In dogs, a normal kidney is approximately 2.5 to 3.5 times the length of the second lumbar (L2) vertebral body.
2. In cats, a normal kidney is approximately 1.9 to 2.4 times the length of the L2 vertebral body.

IV. Contrast radiography

A. Indications for upper gastrointestinal (GI) study (see Chapter 4)
1. Survey radiographs not definitive
2. A partial intestinal obstruction suspected
3. To evaluate GI transit time
4. Abdominal ultrasonography not definitive or available

B. Pneumocolonography
1. It may be used to discriminate between normal gas or feces-filled large intestine and a small intestine dilated with gas.
2. Survey radiographs are taken immediately before the procedure.

C. Peritoneography
1. It may be used in the diagnosis of a diaphragmatic or body wall hernia.
2. Barium is never used for this study.
3. Take survey radiographs immediately before the procedure.
4. Clip and aseptically prepare the abdomen, then insert a needle or over-the-needle catheter into the peritoneal cavity near the umbilicus.
5. Slowly inject an iodinated contrast agent (1.1 mL/kg or 2.2 mL/kg if ascites present) into the peritoneal cavity.
6. Elevate the pelvic area for 5 minutes to increase distribution to the cranial abdomen.
7. Orthogonal-view radiographs are obtained, focusing over the area of interest.

V. Abdominal ultrasonography
A. A complete or partial abdominal ultrasound may be used to evaluate the architecture and size of the abdominal viscera, identify and procure samples of abdominal effusate, and aid in the diagnosis of many abdominal diseases.
B. Focused assessment with sonography for trauma (FAST screening) involves the following (Boysen et al., 2004):
1. Uses standardized technique to assess free abdominal fluid
2. Involves transverse and longitudinal views of four abdominal quadrants (cranial abdomen, caudal abdomen, dependent flank, and nondependent flank)

VI. Simple abdominal paracentesis
A. Indicated in any animal with an abdominal effusion of unknown etiology
B. May be contraindicated with a suspected bleeding problem
C. Successful procedure: >5 mL/kg retrieved using a single-hole needle or catheter
D. Increased yield with ultrasound guidance
E. Procedure
1. Place animal in lateral recumbency; clip and aseptically prepare area.
2. Use a 20- to 22-gauge needle or catheter.
3. Gently insert the needle or catheter near the umbilicus.
4. Allow fluid to drip into sample tubes or evacuate via gentle aspiration.
5. Increase yield with side-hole or a peritoneal dialysis.

VII. Four-quadrant paracentesis
A. Four quadrants are sampled, as described previously, for simple abdominocentesis.
B. Samples are taken from an imaginary square centered over the umbilicus, with the corners of the square being approximately 4 to 6 cm from the umbilicus.
1. Right cranial and caudal quadrants
2. Left cranial and caudal quadrants

VIII. Diagnostic peritoneal lavage
A. Indications
1. Indicated in animals with suspected abdominal disease in which simple abdominal or four-quadrant paracentesis has been unsuccessful
2. More sensitive than paracentesis
B. Procedure
1. Local and systemic analgesia are indicated.
2. Clip and aseptically prepare an area approximately 10×10 cm that is centered around the umbilicus.
3. Place animal in lateral recumbency.
4. Gently insert an 18- to 22-gauge IV or peritoneal dialysis catheter into the abdominal cavity near the umbilicus and direct the catheter caudally.
5. If no fluid is detected after removal of the stylet, infuse sterile, warmed crystalloid fluid (20 to 22 mL/kg) over approximately 5 minutes and remove the catheter.
6. Roll the animal from side to side and massage the abdomen to help distribute the fluids.
7. Repeat a simple or four-quadrant paracentesis.

IX Abdominal fluid analysis
A. Assess PCV, total protein (TP), and total nucleated cell count (TNCC).
1. Transudate: TNCC <1500 cells/μL, TP < 2.5 g/dL
2. Modified transudate: TNCC 1000 to 7000 cells/μL, TP 2.5 to 5.5 g/dL
3. Exudate: TNCC >5000 cells/μL, TP > 3.0 g/dL
B. Cytological evaluation involves a subjective description of the fluid.
1. Determination of the type of inflammatory infiltrate
2. Presence and degree of nuclear degeneration, microorganisms, plant or food material, or bile
3. Evidence of malignancy.
C. Perform aerobic and anaerobic bacterial culture.
D. Supportive evidence of a septic effusion includes the following:
1. Glucose levels < 50 mg/dL
2. Blood-to-peritoneal glucose difference >20 mg/dL
3. Peritoneal-to-blood lactate difference >2 mmol/L
4. Effusion lactate levels >2.5mmol/L
5. Effusion pH <7.2
E. Changes supportive of uroabdomen include the following:
1. Abdominal fluid creatinine >2 times serum creatinine
2. In dogs: potassium in the fluid >1.4 times serum potassium
3. In cats: potassium in the fluid >1.9 times serum potassium
F. Bilirubin is also assessed.
1. Fluid bilirubin concentration >2.0 times serum bilirubin is supportive of bile peritonitis.
2. Bile pigment may also be seen on cytological evaluation.

Differential Diagnosis

I. Hepatobiliary system lesions
A. Acute hepatitis

B. Liver lobe torsion
C. Gall bladder rupture
D. Biliary mucocele
E. Extrahepatic bile duct obstruction
F. Cholecystitis
G. Hepatic abscess
H. Neoplasia
I. Cholangiohepatitis
J. Cholelithiasis

II. GI disorders
A. GI erosion and/or ulceration
B. Mechanical obstruction or intussusception
C. Neoplasia
D. Mesenteric volvulus or torsion
E. Gastric dilation, with or without volvulus
F. Mesenteric infarction
G. Severe gastritis, enteritis, and/or colitis
H. Gastroesophageal intussusception

III. Pancreatic lesions
A. Pancreatitis
B. Pancreatic abscess
C. Neoplasia
D. Necrosis

IV. Reproductive tract disorders
A. Pyometra, metritis, uterine torsion
B. Prostatic infection, abscess, neoplasia, cyst
C. Testicular infection, torsion, abscess, neoplasia
D. Dystocia

V. Urinary tract diseases
A. Pyelonephritis, nephroliths, infarction, swelling, acute nephritis, renal failure
B. Ureteral obstruction, avulsion
C. Urinary bladder infection, inflammation, rupture, cystoliths
D. Urethral obstruction
E. Neoplasia

VI. Peritoneal cavity disorders
A. Peritonitis
1. Septic or bile peritonitis
2. Pneumoperitoneum, uroperitoneum, hemoperitoneum
B. Steatitis
C. Hernias: abdominal wall, inguinal hernia, umbilical hernia, diaphragmatic hernia
D. Myositis of abdominal musculature

VII. Spleen: splenic torsion, neoplasia, splenitis

VIII. Other causes of periabdominal pain
A. Intervertebral disk disease
B. Diskospondylitis
C. Fractures, luxations, subluxations

Treatment

I. Every attempt is made to aggressively enhance and maintain peripheral tissue perfusion in animals with poor perfusion.

II. Results of thorough physical examination, minimum laboratory tests, and blood pressure measurements are considered before initiation of fluid therapy.

III. Fluids therapy involves the following:
A. Crystalloid fluid therapy: see Chapter 132
B. Hypertonic (7%) saline: 4 to 5 mL/kg IV over 10 to 15 minutes
C. Colloid fluid therapy: see Chapter 132
D. Plasma and blood product therapy: see Chapter 71

IV. Careful attention is paid to making the animal as comfortable as possible during hospitalization or until definitive therapy can be attempted.
A. Opioids are preferred, with the following being typical dosages in dogs:
1. Morphine 0.5 to 1.0 mg/kg IM, IV every 4 to 6 hours
2. Fentanyl 3 to 10 μg/kg IV initial bolus, followed by a constant rate infusion (CRI) of 0.5 to 1.0 μg/kg/min IV
3. Hydromorphone: 0.1 to 0.2 mg/kg IM, IV every 4 to 6 hours
4. Buprenorphine: 6 to 15 μg/kg SC, IM, IV TID to QID
5. Butorphanol: 0.1 to 0.5 mg/kg SC, IM, IV every 4 to 6 hours or as a CRI of 0.1 to 0.4 mg/kg/hr IV
B. Nonsteroidal anti inflammatory drugs (NSAIDs) are avoided until a definitive diagnosis is established and the animal is stabilized.

V. A significant number of the cases of acute abdomen require exploratory laparotomy for definitive diagnosis and treatment, and surgical indications include the following:
A. Lack of positive response to appropriate medical therapy
B. Intracellular bacteria visualized on cytology of the peritoneal effusion
C. Free peritoneal gas or penetrating wound(s)
D. Intestinal obstruction
E. Evidence of pyometra
F. Hemoabdomen
G. Suspected abscessation of an abdominal organ
H. Torsion, volvulus, rupture of an abdominal organ
I. Procurement of a biopsy
J. Evidence of intraabdominal leakage or urine, bile, GI contents

VI. Adjunctive medical therapy is usually required.
A. Antiemetics (dosages for dogs)
1. Metoclopramide 0.2 to 0.4 mg/kg IM, IV, PO, SC TID to QID or CRI of 1 to 2 mg/kg/day IV
2. Dolasetron 0.5 to 1.0 mg/kg IV SID
3. Ondansetron 0.1 to 0.2 mg/kg IV, PO BID to QID
4. Prochlorperazine 0.1 to 0.5 mg/kg IM, SC TID to QID; may cause hypotension
5. Chlorpromazine 0.1 to 0.5 mg/kg IM, SC TID; may cause hypotension
B. Gastrointestinal protectants (dosages for dogs)
1. Famotidine 0.5 mg/kg IV SID to BID
2. Ranitidine
a. May not be effective at acid suppression in the dog (Bersenas et al., 2005)
b. Dose: 0.5 to 2.0 mg/kg PO, IV BID to TID
3. Cimetidine 5 to 10 mg/kg IV, PO TID to QID

TABLE 39-1

Antimicrobials Useful for Acute Abdominal Syndrome

ANTIMICROBIAL	DOSE IN DOGS	DOSE IN CATS
Ampicillin sodium	22 mg/kg IV TID	22 mg/kg IV TID
Enrofloxacin	5-20 mg/kg IV SID	5 mg/kg IV SID
Amikacin sulfate	15 mg/kg IV SID	15 mg/kg IV SID
Metronidazole	10-15 mg/kg IV BID	10-15 mg/kg IV BID
Clindamycin	10 mg/kg IV TID	10 mg/kg IV TID
Ticarcillin/ clavulanate	50 mg/kg IV QID	50 mg/kg IV QID
Cefoxitin sodium	15-30 mg/kg IV QID	15-30 mg/kg IV QID

4. Omeprazole 1 mg/kg PO SID to BID
5. Esomeprazole 0.5 to 1 mg/kg PO SID to BID
6. Pantoprazole: 1 mg/kg PO SID to BID
7. Sucralfate: 250 mg/15kg PO TID to QID
8. Misoprostol: 2 to 5 μg/kg PO TID to QID

C. Antimicrobial therapy (Table 39-1)
1. Broad-spectrum antimicrobials are considered in all animals with septic foci (identified or suspected).
2. Critically ill animals may be at increased risk for bacterial translocation and secondary sepsis.
3. Ideally, appropriate samples for aerobic and anaerobic cultures are procured before the commencement of therapy.

D. Glycemic control
1. Blood or serum glucose is monitored frequently.
2. Ideal range is 80 to 140 mg/dL.
3. For blood glucose concentrations <80 mg/dL, consider a CRI of dextrose 2.5% to 5.0% in isotonic fluids.
4. If blood glucose is <50 mg/dL, consider a bolus of dextrose 0.25 to 0.5 g/kg IV, diluted to a 10% solution if given via a peripheral catheter.
5. If blood glucose is persistently >250 mg/dL, consider regular insulin 0.1 U/kg IM.

VII. Early implementation of nutrition may improve outcome (see Chapter 122).

Monitoring of Animal

I. Animals with an acute abdomen are often critically ill and very dynamic.
II. Diligent and frequent monitoring is paramount.
III. Monitoring parameters include the following:
A. Vital parameters (temperature, heart rate, pulse quality, respiratory rate and effort, capillary refill time) every 2 to 4 hours
B. Systemic blood pressure every 2 to 4 hours
C. Blood glucose every 2 to 6 hours
D. Pulse oximetry every 4 to 6 hours
E. Mentation every 4 to 6 hours
F. Pain scoring (see Chapter 1) every 4 to 6 hours
G. PCV/TS and electrolytes every 4 to 6 hours

CHAPTER 40

Introduction

Rita H. Miller

GENERAL CONSIDERATIONS

I. Hormones are chemical messengers that are secreted from endocrine glands and interact with specific receptors of target cells to regulate cellular activity in the body.
   A. Hormones are transported in blood as free hormone or bound to specific carrier proteins.
   B. The free hormone is the biologically active form.

II. Hormones can be classified according to their biochemical structure.
   A. Peptides
   B. Steroids
   C. Amines
   D. Fatty acids

III. Hormones interact with specific receptors located on a membrane surface or within the nucleus of a cell.
   A. The hormone-receptor interaction leads to activation of second messengers, such as cyclic adenosine monophosphate (AMP) and cyclic guanosine monophosphate (GMP), which subsequently initiate cellular events.
   B. The message transmitted by the hormone generates a specific biological response.

IV. Hormone production is regulated by homeostatic mechanisms to maintain concentrations within a narrow range according to a physiological "set-point."
   A. Most hormones are secreted continuously throughout the day.
      1. Basal secretion is minimal in the absence of stimulatory signals.
      2. Concentrations of some hormones fluctuate in a rhythmic fashion throughout the day.
   B. Hormone production is influenced by biological needs.
   C. Feedback loops exist that sense the circulating concentration of a hormone, and subsequently down-regulate or up-regulate hormone production.
      1. Feedback control of hormonal secretion is determined by the concentration of free hormone.
      2. Feedback loops may involve the central nervous system and hypothalamus via electrical and chemical signals.
      3. A direct feedback may exist whereby the response generated by the hormone directly affects the gland of origin.
   D. Feedback loops are dysfunctional in endocrine diseases, leading to loss of regulation of hormone production.

V. Hormones are rapidly inactivated to prevent a continuous cellular response.
   A. Hormone degradation takes place in target tissues or nontarget tissues, such as the liver and kidney.
   B. Hormones may be degraded into metabolically active or inactive metabolites.
   C. Some hormones are excreted unchanged into the urine or bile.

VI. Secretory tissues and their associated endocrine hormones are as follows:
   A. Hypothalamus
      1. Corticotropin-releasing hormone
      2. Thyrotropin-releasing hormone
      3. Growth hormone-releasing hormone
      4. Somatostatin
      5. Antidiuretic hormone
   B. Pituitary gland
      1. Thyroid-stimulating hormone
      2. Adrenocorticotropic hormone
      3. Growth hormone
   C. Thyroid gland
      1. Thyroxine
      2. Triiodothyronine
      3. Calcitonin
   D. Adrenal gland
      1. Cortisol
      2. Aldosterone
      3. Epinephrine
      4. Norepinephrine

E. Pancreas
   1. Insulin
   2. Glucagon
   3. Somatostatin
F. Parathyroid gland: parathyroid hormone
G. Skin, liver: vitamin D_3
H. Kidney
   1. Vitamin D_3
   2. Erythropoietin
I. Heart: atrial natriuretic factor

DISORDERS OF THE ENDOCRINE GLANDS

I. Primary injury to an endocrine gland leads to a decrease in function.
   A. Immune-mediated disease
   B. Neoplasia
   C. Surgical manipulation
   D. Drug-induced damage
II. Secondary or tertiary disease causes inappropriate stimulation of the gland.
III. Excessive hormone production results from several mechanisms.
   A. Primary hypersecretion of the hormone can develop in a diseased endocrine gland.
      1. Hyperplasia of endocrine gland
      2. Neoplasia of endocrine gland
   B. Hyperstimulation of the endocrine gland may result from secondary or tertiary disease.
   C. Ectopic hormone production can result from tumors of nonendocrine glands.
   D. Iatrogenic disease arises from drug administration, leading to excessive systemic hormone concentrations.
IV. A hormone defect may be present, which is often of genetic origin.
V. Hormone resistance can develop when the sensitivity of the target tissue to the hormone is reduced.
   A. Antibody production against a hormone or hormone receptor
   B. Defect in hormone receptor or postreceptor mechanisms
VI. Abnormal hormone transport is possible.
   A. Decrease in plasma concentration of carrier protein
   B. Competition for carrier proteins by certain medications

DIAGNOSTIC APPROACH TO ENDOCRINE DISEASES

I. Breed predilection is present in several endocrine diseases.
II. Sex predilection is noted for most endocrine diseases.
III. Most endocrine diseases develop in middle-aged adult and geriatric patients.
IV. Diagnostic evaluation often provides early clues to the diagnosis.
   A. Collect baseline laboratory data, including a complete blood count, serum biochemistry profile, and urinalysis.
   B. Hormone concentration is measured using radioimmunoassay, enzyme assay, or dialysis techniques.
      1. Total hormone concentration in serum
      2. Free hormone concentration in serum
      3. Total hormone concentration in urine
   C. Dynamic tests measure the response of a hormone to a stimulatory or suppressive agent.
      1. Stimulation test to assess response to a normal stimulatory hormone
      2. Suppression test to diagnose disorders of hypersecretion
   D. Measurement of the primary stimulatory or suppressive hormone in serum is possible for some diseases.
   E. Measurement of antibodies against the hormone supports an immune-mediated pathogenesis in endocrine disease.
   F. Radioisotope studies are used to study physiological and biochemical responses of a gland.
   G. Diagnosis is best made when the signalment, history, clinical signs, and test results are consistent with the disease condition.
V. Dilemmas exist in the diagnosis of endocrine diseases.
   A. A normal or abnormal hormone concentration or dynamic test result does not always rule in or rule out the endocrine disease.
   B. Hormone secretions are often pulsatile in nature, so concentrations vary throughout the day.
   C. Antibodies produced against a particular hormone may interfere with the radioimmunoassay test.
   D. Blood concentrations of some hormones, such as catecholamines, cannot be accurately measured.
   E. Hormone concentrations are affected by multiple factors.
      1. Age of the animal
      2. Overall health of the animal
      3. Sexual cycle
      4. Serum protein concentration, which influences the plasma concentrations of protein-bound hormones
      5. Drug administration, which can alter the affinity of carrier proteins to bind hormone, resulting in changes in total hormone concentration
      6. Instability of hormone during transport and processing, leading to inaccurate test results

CHAPTER 41

Diseases of the Pituitary Gland

Kate E. Hill | Clinton D. Lothrop, Jr.

PITUITARY HYPOFUNCTION: PITUITARY DWARFISM

Definition

I. Hypopituitarism is a deficiency of one, several, or all pituitary hormones.
II. In young dogs, the term *hypopituitarism* is used to describe growth hormone (GH) deficiency, with or without loss of other pituitary hormones (pituitary or endocrine dwarfism).

Causes

I. Certain factors contribute to the development of congenital hypopituitarism.
   A. Failure of oropharyngeal ectoderm of Rathke's pouch to differentiate into trophic hormone-secreting cells of the anterior pituitary gland
   B. Progressive formation of enlarging pituitary cysts that exert pressure on adjacent structures
   C. Benign tumor of Rathke's pouch (craniopharyngioma): uncommon
II. Pituitary or endocrine dwarfism is an inherited autosomal recessive disease.
III. Adult-onset hypopituitarism is frequently associated with primary pituitary neoplasia or head trauma.

Pathophysiology

I. Deficiency of pituitary hormones arises.
   A. Growth hormone
   B. Adrenocorticotropic hormone (ACTH)
   C. Luteinizing hormone
   D. Follicle-stimulating hormone
   E. Thyroid-stimulating hormone (TSH)
II. Synthesis and secretion of target organ hormones, including cortisol, thyroid hormone, and/or insulin-like growth factors (IGFs) are decreased.
III. Normal growth requires the presence of IGFs and other factors, as well as the ability of target tissues to respond to them.
   A. IGFs (somatomedins)
      1. Somatomedins have marked growth-promoting effects on bone, cartilage, connective tissue, and skeletal and cardiac muscle.
      2. Their production is GH dependent.
   B. Fibroblast growth factor, nerve growth factor, epidermal growth factor
IV. Normal body maturation and growth also depend on normal concentrations of thyroid hormone.
V. The absence of GH, IGFs, or thyroid hormone results in dwarfism.

Clinical Signs

I. Short stature compared to litter mates
II. Hair coat abnormalities
   A. Retention of puppy hair coat
   B. Gradual bilateral alopecia sparing the head and extremities
III. Progressive hyperpigmentation of skin
IV. Delayed or absent permanent dentition
V. Infantile external genitalia, variable reproductive function
VI. With advancing age
   A. Obesity, weakness, lethargy
   B. Thickening and peeling of skin
VII. Water consumption and urination usually normal
VIII. German shepherd and carnelian bear dogs overrepresented

Diagnosis

I. Presumptive diagnosis of pituitary dwarfism: typical breed, history, and clinical signs
II. Laboratory evaluation
   A. Complete blood count: occasional decreased packed cell volume
   B. Biochemistry profile
      1. Slightly decreased phosphorus, albumin
      2. Possibly increased blood urea nitrogen (BUN)
   C. Urinalysis: to rule out kidney disease
III. Definitive diagnosis: GH stimulation test or measurement of serum IGFs
   A. Insulin response test (Nichols et al., 1997)
      1. In animals with GH deficiency, insulin-induced hypoglycemia is more severe than in normal animals.
      2. Problems with the test include serious hypoglycemia and difficulty in the interpretation of results.
      3. The test is rarely performed.
   B. GH stimulation test with clonidine or xylazine: GH analysis currently unavailable

C. Serum IGF-I (somatomedin C) assay from Michigan State University Animal Health Diagnostic Laboratory, East Lansing, Mich.
1. Indirect measurement of pituitary function
2. Decreased serum concentrations diagnostic of GH deficiency (normal IGF-I = 5 to 45 nmol/L)

IV. Assessment of thyroid and adrenal function (see Chapters 42 and 45)
A. Uncomplicated hypopituitarism: results usually normal
B. Secondary hypothyroidism, hypoadrenocorticism possible
1. Low thyroxine (T_4), free T_4, cortisol concentrations
2. Low resting ACTH, TSH values
3. Poor response to stimulation with TSH or ACTH

Differential Diagnosis

I. Malnutrition-induced short stature
A. Decreased caloric intake
B. Maldigestion and/or malabsorption syndromes
II. Hypothyroidism of thyroid origin
III. Congenital heart disease
IV. Congenital gastrointestinal, liver, or kidney diseases
V. Chondrodystrophic dwarfism
VI. Mucopolysaccharidosis
VII. Hydrocephalus

Treatment

I. Growth hormone replacement
A. Give dogs porcine GH 0.1 IU/kg SC three times per week for 1 to 2 months.
B. Human GH may cause antibody formation.
II. Progesterone therapy
A. Successful in a small number of cases
B. Medroxyprogesterone acetate 2.5 to 5.0 mg/kg PO initially every 3 weeks and then every 6 weeks (Kooistra et al., 1998)
C. Proligestone 10 mg/kg SC every 3 weeks (Knottenbelt and Herrtage, 2002)
III. Thyroid replacement therapy
A. Most pituitary dwarfs have secondary hypothyroidism.
B. Give L-thyroxine 20 µg/kg PO SID for life.
IV. Glucocorticoid replacement therapy
A. Glucocorticoid replacement is not clinically beneficial in cases of pituitary dwarfism, despite low-normal baseline cortisol levels and sluggish responses to ACTH stimulation.
B. In animals with grossly abnormal ACTH response tests, administer prednisone or prednisolone 0.2 to 0.4 mg/kg/day PO.

Monitoring of Animal

I. Most pituitary dwarfs are presented for hair coat abnormalities (alopecia) that improve with replacement therapy.
A. Monitor the animal every 60 to 90 days after initial GH administration for signs of recurrent alopecia.
B. The goal of therapy is to have a plasma IGF-1 concentration within the reference range.
C. If hair coat abnormalities recur, resume GH therapy for an additional 1 to 2 months.
II. Some dogs become refractory to GH replacement therapy.
A. They develop antibodies to GH, thereby diminishing the biological activity of GH.
B. Consider changing to a different species-type of GH.
C. Porcine GH has the same antigenicity as canine GH, so antibody formation is not usually a problem.
III. Instruct owners to monitor urine glucose concentrations on a daily basis, and to measure blood glucose weekly during GH treatment.
A. Stop GH administration if hyperglycemia occurs.
B. Transient and even permanent diabetes mellitus is a potential side effect, especially with older dogs.
IV. Because most pituitary dwarfs receive a diagnosis when their long bone growth plates are near or past closure, a significant increase in stature is not expected.

Acromegaly

Definition

I. Acromegaly is a disease characterized by an overgrowth of connective tissue, increased appositional bone growth, coarsening of facial features, and enlargement of viscera.
II. It arises from excessive secretion of GH.

Causes and Pathophysiology

I. In the dog, acromegaly is primarily associated with administration of progestational agents or with increased endogenous progesterone levels (diestrus).
A. Canine acromegaly: progesterone stimulation of GH production in ductular epithelia cells in the mammary gland (diestrus)
B. Rarely from pituitary neoplasia
II. Feline acromegaly is commonly associated with pituitary neoplasia.
III. GH has both anabolic and catabolic effects.
A. Anabolic effects are mediated by IGFs.
B. GH has antiinsulin effects, so excessive levels may induce diabetes mellitus.

Clinical Signs

I. Prominent skinfolds of face and neck
II. Blunt, broad facial features
III. Enlarged interdental spaces from increased connective tissue growth
IV. Inspiratory stridor from enlargement of orolingual, oropharyngeal, and orolaryngeal tissues
V. Abdominal enlargement
VI. Panting, fatigue
VII. Diabetes mellitus
A. Diabetes is often difficult to control or regulate.
B. Weight gain occurs in an insulin-resistant, diabetic animal.
VIII. Central nervous system (CNS) signs in animals with pituitary tumors

A. Head pressing, dull behavior
B. Inappetence in older dogs and cats

IX. Cats: cardiomyopathy, arthropathy, renal failure

Diagnosis

I. History of progesterone use for estrus or behavioral control in dogs
II. Common laboratory abnormalities
  A. Elevated serum alkaline phosphatase
  B. Increased blood glucose
  C. Persistent hyperphosphatemia without azotemia
  D. Renal failure: late stages of feline acromegaly
III. Radiographic abnormalities
  A. Diffuse increase in soft-tissue structures of the lingual, oropharyngeal, and laryngeal regions
  B. Degenerative arthropathy with periosteal reactions
IV. High circulating somatomedin C: IGF-I >100 nmol/L
  A. Serum IGF-1 concentrations between 70 and 100 nmol/L are considered nondiagnostic and should be repeated in 3 months.
  B. Some insulin-resistant, diabetic cats can have IGF-1 concentrations in the nondiagnostic range.
  C. Cats with acromegaly show an increase in the IGF-1 concentration over this 3-month period.
V. Computed tomography or magnetic resonance imaging of the brain
  A. For suspected pituitary tumor
  B. A consideration for diabetics with high insulin requirements not associated with other diseases
    1. Rule out hyperadrenocorticism and corticosteroid overdose.
    2. Rule out systemic infections.
  C. Often normal in dogs
  D. May identify a pituitary mass in cats
VI. GH suppression test
  A. GH analysis has limited availability in the United States; the University of Florida veterinary endocrinology laboratory can perform the assay.
  B. GH analysis is available at Utrecht University, The Netherlands.

Differential Diagnosis

I. Inspiratory stridor: other causes of upper airway obstruction
  A. Elongated soft palate
  B. Laryngeal paralysis
  C. Foreign body
  D. Neoplasia: thyroid adenocarcinoma, intratracheal ring carcinoma
II. Other causes of insulin-resistant diabetes mellitus
III. Hyperadrenocorticism

Treatment

I. Following exogenous progesterone withdrawal, GH levels dramatically decline, soft-tissue abnormalities reverse, and glucose intolerance improves.
II. Perform ovariohysterectomy to eliminate the estrous cycle.
III. Spontaneous acromegaly in cats associated with neoplasia of the pituitary gland may respond to external-beam cobalt therapy.
IV. Somatostatin therapy has been ineffective.
V. Dogs with acromegaly induced by medroxyprogesterone acetate injections have been successfully treated with aglépristone, a progesterone receptor blocker.

Monitoring of Animal

I. Reversal of soft-tissue abnormalities occurs in about 6 to 8 weeks.
II. GH-induced diabetes mellitus may be permanent or reversible.
  A. Prognostic factors for reversibility of GH-induced diabetes include the following:
    1. High-fasting serum insulin concentrations: pancreatic beta cell reserves present with adequate chance for recovery
    2. Low or undetectable serum insulin concentrations: pancreatic beta cell reserves exhausted, so poor chance for recovery
    3. Dose or duration of progestational agents or progesterone phase of estrous: higher dose and duration decrease reversibility
  B. Carefully monitor blood glucose after progesterone withdrawal, because insulin requirements usually diminish.
III. Prognosis for feline acromegalics is guarded because most develop serious renal, cardiac, and other complications.

Diabetes Insipidus

Definition

I. Central diabetes insipidus (CDI) is a partial or absolute deficiency of antidiuretic hormone (ADH) or vasopressin.
II. Nephrogenic diabetes insipidus (NDI) is a congenital or acquired disease in which the kidneys are unresponsive to ADH.
III. Acquired NDI is the most common form of diabetes insipidus (DI).

Causes

I. Causes of CDI
  A. Congenital defects
  B. Infection, inflammation
  C. Trauma: accidental or surgical
  D. Neoplasia
II. Causes of NDI (Nichols, 2004; Feldman and Nelson, 2004b)
  A. Congenital, end-organ unresponsiveness to ADH: rare
  B. Acquired defects of distal tubules and collecting ducts following infections: pyelonephritis, chronic renal failure, pyometra
  C. Secondary to metabolic disorders: hypokalemia, hypercalcemia, hyperadrenocorticism, pyometra, hyperthyroidism, hypoadrenocorticism
  D. Secondary to drugs: lithium, demeclocycline, methoxyflurane

Pathophysiology

I. ADH is produced by the hypothalamus.
II. Production and release of ADH are controlled by a variety of factors.
  A. Elevations in serum osmolality, primarily sodium
  B. Elevated blood volume or blood pressure
  C. Fear, body temperature
  D. Pharmacologic agents: barbiturates, nicotine, morphine
III. ADH primarily acts on the distal convoluted tubules and collecting ducts of the kidney.
  A. ADH attachment to receptor sites increases permeability of the renal tubular epithelial cells.
  B. Water moves across the epithelial cells from the tubular lumen to the interstitium (gradient present in renal medulla).
  C. The final concentration (urine specific gravity [USG], osmolality) of the urine is dependent on ADH action and the renal medullary concentration gradient.
IV. Absent ADH activity or renal medullary washout results in an extremely dilute urine (USG <1.008).
V. Partial ADH deficiency results in urine with a specific gravity of 1.00 to 1.016.

Clinical Signs

I. Profound polyuria and polydipsia (PU/PD) are present, often with an acute onset.
II. Although the frequency of urination may decrease with time from stretching of the urinary bladder, the volume of urine remains the same.
III. Severe, rapid dehydration may occur in animals with complete DI if water is unavailable for as little as 4 to 6 hours.
IV. Occasionally anorexia, weight loss, and CNS signs occur.

Diagnosis

I. Physical examination: often unremarkable
II. Complete blood count and serum biochemistry profile
  A. Occasional hypernatremia
  B. Important in ruling out other causes of PU/PD
III. Urine specific gravity
  A. It is usually 1.001 to 1.007 in complete DI.
  B. With severe dehydration in partial DI, USG may approach isotonicity or be slightly hypertonic (rare).
IV. Specific testing for diagnosis and definition of DI requires thorough assessment of urine concentrating capacity before and after exposure to exogenous vasopressin.
  A. Modified water deprivation test
  B. Exogenous vasopressin test
  C. Repositol vasopressin test, ADH trial
  D. 1-Deamino-8-D-arginine vasopressin (DDAVP) trial
V. Modified water deprivation test
  A. Cautions
    1. Perform only after ruling out other causes of PU/PD.
    2. Allow gradual water restriction to 100 mL/kg/day for 3 to 4 days before the test to restore the renal medullary interstitial gradient and correct concentration abnormalities from medullary washout.
  B. Test protocol
    1. Obtain baseline data, including body weight, USG, BUN, estimated skin elasticity, and urine and serum osmolality.
    2. Urine osmolarity can be roughly calculated by multiplying the last two digits of the USG by 36 (NOTE: not accurate with severe proteinuria or glycosuria).
    3. Remove all water and food.
    4. Empty the urinary bladder every 60 to 120 minutes either by catheterization or walking the dog; cats require an indwelling urinary catheter.
    5. Monitor USG, urine osmolarity, body weight, hydration, BUN, serum electrolytes, and serum osmolarity every 60 to 120 minutes.
    6. Stop test when any of the following occurs:
      a. USG = 1.025 (900 mOsm/L)
      b. Increased BUN
      c. Loss in body weight >3% to 5%
      d. Dehydration: decreased skin elasticity, significant increases in hematocrit or total solids
  C. Interpretation
    1. USG ≤ 1.008: complete central DI or NDI
    2. USG of 1.010 to 1.020: partial central DI
    3. USG >1.025: psychogenic DI
VI. Response to exogenous vasopressin
  A. Indications
    1. If the water deprivation test suggests nonpsychogenic DI (USG <1.025)
    2. Characterization of the disorder as central or nephrogenic in origin (CDI versus NDI)
    3. As a continuation of the modified water deprivation test
  B. Test protocol
    1. Administer aqueous vasopressin 2 to 5 U IM.
    2. Empty the bladder at 30, 60, and 90 minutes; check urine osmolarity, USG, BUN, serum electrolytes, hydration, and CNS status.
    3. Alternatively, give desmopressin acetate (DDAVP) 4 drops into the conjunctival sac or 10 to 20 μg/kg of the intranasal preparation IV, SC.
      a. Use a bacteriostatic filter if administering IV.
      b. Collect urine samples every 1 to 2 hours for 8 hours and possibly at 12 and 24 hours.
    4. End the test and introduce small amounts of water (10 to 20 mL/kg PO every 30 minutes for 1 to 2 hours).
  C. Interpretation
    1. USG increases <10% (USG <1.015): nephrogenic DI or medullary washout
    2. USG increases 10% to 50%: partial CDI
    3. USG increases 50% to 800%: CDI
VII. Response to desmopressin as a diagnostic trial
  A. Use
    1. Demopressin helps to diagnose CDI when the differential considerations are CDI, NDI, or psychogenic polydipsia.
    2. It can overcome medullary washout within 2 to 4 days.

B. Test protocol
   1. Owner monitors water intake for 2 to 3 days before and throughout the trial.
   2. Owner administers DDAVP nasal spray into conjunctival sac, 4 drops BID for 5 to 7 days.
   3. Owner collects a urine sample for urine osmolarity and USG at the predetermined times each day, with urine samples collected between days 5 and 7.

C. Interpretation
   1. A dramatic reduction in water intake and an increase in USG >50% is consistent with central DI.
   2. Dogs with NDI are not helped by DDAVP.
   3. Dogs with psychogenic polydipsia may have a slight decrease in water intake and urine output; however, some dogs have increased urine output.
   4. Dogs with early hyperadrenocorticism (PU/PD, but no other signs) may have a mild to moderate increase in urine concentration, but DDAVP eventually becomes ineffective as hyperadrenocorticism continues to suppress vasopressin activity.

Differential Diagnosis

I. Most disease processes causing PU/PD are characterized by other systemic signs, which help differentiate them from DI.
II. Rule out other causes of PU/PD.
   A. Diabetes mellitus
   B. Renal disease, pyelonephritis
   C. Liver disease, portosystemic shunt
   D. Pyometra
   E. Hyperadrenocorticism, hypoadrenocorticism
   F. Defect in renal glucose resorption (Fanconi's syndrome)
   G. Hyperviscosity syndrome
   H. Psychogenic polydipsia
   I. Hyperthyroidism (cats)
   J. Hypercalcemia, potassium depletion

Treatment

I. Treatment of CDI involves the use of exogenous ADH.
   A. Repositol vasopressin (pitressin tannate) has been discontinued.
   B. Desmopressin acetate (DDAVP) is commercially available.
      1. Intranasal form: 0.1 mL (2 to 4 drops) in each nostril or conjunctival sac SID to BID, with frequency titrated to control PU/PD
      2. Alternate route of intranasal form: 2 to 5 μg SC
         a. Administered through a bacteriostatic filter (Nichols, 2004).
         b. Intranasal form is significantly cheaper than parenteral form.
      3. Oral tablets (0.1 or 0.2 mg size)
         a. Give 0.1 mg PO TID, then increase to effect.
         b. Some dogs can have the dose decreased to BID.
      4. Parenteral DDAVP (4 μg/mL): 0.5 to 2 μg SC SID to BID
   C. Lysine-8-vasopressin (*Diapid* nasal spray)
      1. Dose to effect: often 1 to 2 sprays in a nostril SID to TID
      2. Less expensive, also less effective in some animals
      3. Administration not as well tolerated
II. Ancillary therapy may be tried in certain cases.
   A. Thiazide diuretics
      1. Probably work by decreasing resorption of sodium, consequently decreasing urine volume
      2. Useful in CDI, especially in association with low-sodium diets
   B. Chlorpropamide *(Diabinese)* 125 to 250 mg/day PO to decrease PU/PD (Nichols, 2000; Nichols, 2004)
III. Partial forms of CDI may require no specific therapy other than unlimited access to water.
IV. NDI is usually difficult to treat.
   A. Treat any underlying cause of acquired NDI.
   B. No specific therapy exists for primary NDI, but palliative measures include the following:
      1. Hydrochlorothiazide 0.5 to 1.0 mg/kg PO BID
      2. Chlorothiazide 10 to 40 mg/kg PO BID (Nichols, 2004)
      3. Avoidance of excessive salt (rawhide toys, salty foods)
   C. Allow unlimited access to water.

Monitoring of Animal

I. During the initial course of therapy, monitor for overhydration and, if it occurs, reduce the availability of water until the animal acclimates.
II. Long term, the owner can be taught to judge the optimal dosage and frequency of medication to be administered based on water intake and behavior.
III. DI is generally irreversible, except when caused by head trauma or hypophysectomy.
IV. Prognosis is variable.
   A. Prognosis is generally good with treatment, depending on the underlying disorder.
   B. If not treated, affected animals are prone to severe dehydration during illness or with water restriction.

Adult-Onset Growth Hormone Deficiency

Definition

I. Selective GH deficiency in the adult dog, with normal concentrations of other pituitary hormones, results in dermatological manifestations (see Chapter 87).
II. This disease is also called *hair cycle arrest* (previously known as *Alopecia X*), and the pathogenesis is poorly understood (Frank, 2005).

Clinical Signs

I. Normal stature
II. Bilateral, symmetrical hair loss with secondary hyperpigmentation that spares the head and distal extremities
III. No systemic clinical signs
IV. Breeds affected: chow chow, samoyed, poodle, Pomeranian (primarily males)

Diagnosis

I. Low GH levels, no response to provocative stimulation
   A. Normal GH response test in 30% of affected animals

   B. Thyroid and adrenal function tests normal
II. Possibly normal somatomedin C serum concentrations

Differential Diagnosis

I. Rule out other causes of endocrine dermatoses, including hyperadrenocorticism, hypothyroidism, and sex hormone abnormalities.
II. See Differential Diagnoses for Symmetrical Alopecia in Chapter 87.

Treatment and Monitoring

I. GH replacement therapy may be tried (see Pituitary Hypofunction, above).
II. Mitotane therapy is controversial (see Chapter 87).
   A. For adrenal hyperplasia-like syndrome
   B. Requires monitoring with ACTH stimulation testing to avoid secondary adrenal insufficiency
   C. Variable regrowth of hair
III. Intact male dogs are usually castrated before GH or mitotane treatment.
IV. Melatonin (3 to 6 mg PO BID) may help hair growth.
V. Trilostane has resulted in regrowth of hair.
   A. Dogs <2.5 kg: 20 mg PO SID
   B. Dogs 2.5 to 5.0 kg: 30 mg PO SID
   C. Dogs 5 to 10 kg: 60 mg PO SID

CHAPTER 42

Diseases of the Thyroid

Cynthia R. Ward

HYPOTHYROID DISEASES

Canine Hypothyroidism

Definition

I. Clinical hypothyroidism results from lack of circulating thyroid hormone.
II. It is the most commonly diagnosed endocrinopathy in the dog owing to a significant incidence of false-positive diagnoses.

Causes

I. The most common cause is destruction of both thyroid glands, resulting in lack of production of thyroid hormone.
II. The initiating insult is unknown.
III. A genetic component is suggested, with a polygenic mode of inheritance in colony-raised beagles and an autosomal recessive mode of inheritance in borzois.
IV. It is associated with a rare major histocompatibility complex class II haplotype (Kennedy et al., 2006).

Pathophysiology

I. Primary disease (most common)
  A. Lymphocytic thyroiditis
    1. Probably immune-mediated
    2. Antibodies (Abs) against triiodothyronine (T_3), thyroxine (T_4), and thyroglobulin found in hypothyroid dogs
    3. Thyroid gland infiltrate: lymphocytes, plasma cells, and macrophages
    4. Slowly progressive follicle destruction over years
    5. Clinical signs when 75% of gland destroyed
    6. Increased prevalence of antithyroid hormone Abs in certain breeds, females, and larger dogs (Nachreiner et al., 2002)
    7. Association between recent vaccination and increased anticanine thyroglobulin antibodies (Scott-Moncrieff et al., 2002)
  B. Thyroid atrophy
    1. Adipose tissue replaces thyroid parenchyma.
    2. No inflammatory cells are seen, and the cause is unknown.
    3. It may reflect end-stage lymphocytic thyroiditis.
  C. Neoplastic destruction
    1. Bilateral primary thyroid neoplasia
    2. Metastatic thyroid neoplasia
    3. Most animals euthyroid, but may be hypothyroid with significant thyroid gland destruction
  D. Parasitic destruction: *Leishmania* spp.
II. Secondary disease
  A. Lack of thyroid-stimulating hormone (TSH) synthesis or secretion
  B. Rare in dogs
  C. Pituitary malformations and neoplasia
III. Congenital
  A. Also known as cretinism, congenital hypothyroidism is rare in dogs.
  B. Thyrotropin-releasing hormone (TRH) or TSH deficiency has been identified in giant schnauzers and boxers (Greco et al., 1991).
  C. Thyroid peroxidase deficiency and goiter occur as an autosomal recessive disease in toy fox terriers (Fyfe et al., 2003).
IV. Iatrogenic disease
  A. Following surgery, radiation, or ^{131}I treatment for thyroid adenocarcinoma
  B. Trimethoprim-sulfa antibacterials: trimethoprim-sulfadiazine, trimethoprim-sulfamethoxazole (Gookin et al., 1999)
    1. Dose and duration dependent: high end of dosage range for >4 weeks
    2. Resolution of clinical signs and normalization of thyroid function after treatment cessation
    3. Postulated interference with thyroid peroxidase activity and inhibition of thyroid hormone synthesis

Clinical Signs

I. Signalment
  A. Middle-aged dogs: range = 0.5 to 15 years
  B. Golden retrievers and Doberman pinschers overrepresented
  C. Spayed females and castrated male dogs may be at increased risk
II. Signs often subtle with gradual onset
III. Metabolic signs from decreased cellular metabolism
  A. Lethargy, exercise intolerance
  B. Heat seeking
  C. Weight gain, obesity
  D. Mental dullness

E. Decreased appetite, constipation
F. Bradycardia, hypothermia

IV. Dermatological signs (see Chapter 87)
V. Neuromuscular signs
A. Muscle weakness, muscle atrophy
B. Ataxia, tetraparesis, decreased spinal reflexes
C. Cranial nerve paralysis
D. Lameness: one or more limbs
E. Peripheral vestibular disease
F. Subclinical myopathy
G. Myasthenia gravis (Dewey et al., 1995)
H. Possibly laryngeal paralysis
1. No causal relationship established
2. Minimal or no resolution following thyroxine supplementation (Jaggy et al., 1994)
I. Rare cerebral disorders
1. Myxedema coma with severe mental dullness, facial myxedema, bradycardia, and hypothermia
2. Atherosclerosis and severe lipidemia with seizures, disorientation, and circling
J. Cricopharyngeal achalasia (Bruchim et al., 2005)

VI. Reproductive signs
A. Prolonged interestrous intervals
B. Failure to cycle
C. Lack of libido in the bitch
D. Hyperprolactinemia and inappropriate galactorrhea
E. Normal fertility in male dogs (Johnson et al., 1999)

VII. Cardiovascular signs
A. Sinus bradycardia
B. Low-voltage R waves on electrocardiography
C. Thromboembolic disease from atherosclerosis
D. Possible association with dilated cardiomyopathy (Phillips and Harkin, 2003)

VIII. Congenital hypothyroidism (cretinism)
A. Growth, mental retardation
B. Disproportionately large heads
C. Retention of puppy coat
D. Disproportionate dwarfism: retarded epiphyseal growth

IX. Concurrent endocrine diseases
A. Immune-mediated, polyglandular endocrine gland destruction
B. Possible concurrent hypoadrenocorticism, diabetes mellitus, and hypoparathyroidism

X. Behavioral changes
A. Aggression (Fatjo et al., 2002)
B. Cognitive dysfunction

Diagnosis

I. Hematological abnormalities: mild to moderate normocytic, normochromic, nonregenerative anemia
II. Serum chemistry abnormalities
A. Fasting hypercholesterolemia: possibly severe
B. Fasting hypertriglyceridemia
C. Possible mild elevations in liver enzymes
D. Increased creatine kinase (rare)

III. Baseline thyroid hormone assays
A. T_4 and free thyroxine (fT_4) are commonly measured.
B. Basal T_4 is a useful screening assay.
1. Values in the mid to high end of the reference range usually signify euthyroidism.
2. Values in the low-normal or below-normal range are not diagnostic of hypothyroidism.
3. Antibodies against T_4 may cause spurious results (low or high).
4. Measurement is affected by many physiological and pharmacologic factors.
5. Greyhounds and Scottish deerhounds have lower T_4 levels (Gaughan and Bruyette, 2001).
6. Conditions that may decrease T_4 in euthyroid animals include concurrent illnesses and certain drugs.
a. Any critical illness
b. Hypoadrenocorticism or hyperadrenocorticism
c. Diabetes mellitus
d. Heart and renal failure
e. Liver disease
f. Weight loss
g. Infections
h. Endurance conditioning (Evason et al., 2004; Panciera et al., 2003)
7. Common drugs that may decrease T_4 in euthyroid animals include the following:
a. Phenobarbital
b. Glucocorticoids
c. Trimethoprim-sulfa antibiotics
d. Clomipramine

C. Basal T_3 measurement is less accurate than T_4 for diagnosing hypothyroidism and is also affected by serum anti-T_3 Abs.
D. The fT_4 assay involves separating serum T_4 from its binding proteins.
1. Effects of drugs or illness on serum T_4 transport protein concentration or affinity are eliminated.
2. The free hormone (separated by equilibrium dialysis) offers several diagnostic advantages over T_4 measurement alone.
a. Unaffected by anti-T_4 Abs
b. Superior sensitivity, specificity, and accuracy
c. Recommended test when nonthyroidal illness present
3. Results must be interpreted with caution in animals on phenobarbital therapy because a falsely lowered fT_4 may occur, even though the animal is euthyroid (Kantrowitz et al., 1999).

E. Basal thyrotropin or canine thyroid-stimulating hormone (cTSH) concentrations are usually elevated in hypothyroid dogs.
1. Measurement of TSH in dogs has been hampered by lack of a readily available sensitive assay for cTSH.
2. Sensitivity and specificity are less than that of the T_4 or fT_4 measurement, so cTSH is not recommended as a single test.
3. Between 13% and 38% of hypothyroid dogs have a cTSH value within the reference range (Peterson et al., 1997; Scott-Moncrieff et al., 1998).

4. Approximately 8% to 18% of euthyroid dogs with concurrent illness have elevated cTSH concentrations (Scott-Moncrief et al., 1998; Dixon and Mooney, 1999).
5. When combined with low T_4 or fT_4, cTSH measurement is very specific.
6. Animals on treatment with phenobarbital may have a falsely increased cTSH (and lowered fT_4), even though they are euthyroid.

IV. Circulating Abs to T_3, T_4, and thyroglobulin can be measured with a specific enzyme-linked immunosorbent assay.
   A. Elevations of these Ab concentrations, especially antithyroglobulin Ab, may indicate early immune-mediated destruction of the gland.
      1. Approximately 50% of hypothyroid dogs have Abs against thyroglobulin, which indicates the presence of lymphocytic thyroiditis (Young et al., 1991; Refsal and Nachreiner, 1997; Vajner, 1997).
      2. Anti-T_3 and -T_4 antibodies are much less prevalent (6% and 2% of samples, respectively), and are not well correlated with hypothyroidism.
      3. Anti-T_3 and -T_4 antibodies are measured to determine if spurious interference has occurred in basal T_3 and T_4 measurements.
   B. Euthyroid dogs also may have positive antithyroglobulin Ab titers (Nachreiner et al., 1998).
   C. Measurement of antithyroglobulin Ab may be useful in breeding animals to help identify potential carriers of hypothyroidism.

V. Scintigraphy with ^{99m}technetium pertechnetate (TcO_4^-) is used to assess thyroid function.
   A. TcO_4^- is taken up by the thyroid gland in proportion to thyroid activity.
   B. Though useful when thyroid function testing is equivocal, expense and lack of availability limits its usefulness in the diagnosis of hypothyroidism.

VI. Thyroid glands may be imaged with ultrasonography; in hypothyroid dogs, they are usually smaller and have decreased volume compared with glands in euthyroid dogs (Bromel et al., 2005; Reese et al., 2005).

VII. TSH response test assesses thyroid gland reserve, but it is limited by expense and inconsistent availability of medical-grade bovine TSH.

VIII. Therapeutic trials (response to treatment) are used as a last resort when no other means of testing is diagnostic.
   A. Results are evaluated with caution because euthyroid animals may show clinical improvement with thyroid supplementation.
   B. Challenge by withdrawal of thyroid supplementation and observation of recurrence of clinical signs is desirable when diagnosis is made by a therapeutic trial.

Differential Diagnosis

I. Hyperadrenocorticism
II. Sex hormone abnormalities
III. Other causes of obesity and lethargy
IV. Other causes of cranial and peripheral neuropathies
V. Other causes of infertility in the bitch

Treatment

I. Emergency therapy of myxedema stupor or coma
   A. Administer sodium levothyroxine (L-thyroxine) 1 to 5 μg/kg IV BID.
   B. Maintain hydration with IV crystalloid fluid therapy.
   C. Combat hypothermia.

II. Thyroid supplementation with sodium L-thyroxine
   A. Brand-name products are recommended because generic replacements may have limited or variable bioavailability.
   B. Dosages are adjusted for each individual animal and can be very variable.
      1. The initial dose is 0.02 mg/kg PO BID.
      2. Increase to 0.04 mg/kg PO BID if necessary.
      3. Use BID initially, then possibly reduce to SID when clinical signs improve (Greco et al., 1998).
   C. Use lower initial dosages in dogs with cardiac illness or severe debilitation or in geriatric animals.

Monitoring of Animal

I. Improvement in clinical signs
   A. Improvement in activity and appetite usually occurs in 1 to 3 weeks.
   B. Improvement in skin and hair coat generally takes 4 to 6 weeks.
   C. Neurological abnormalities may take several months to improve.

II. Thyroid hormone measurements
   A. Begin monitoring serum hormone concentrations 2 to 4 weeks after instituting therapy.
   B. T_4 levels measured 4 to 6 hours post pill should be in the high-normal or slightly above the reference range.
   C. T_4 levels measured just before the next dose are ideally in the normal range.
   D. fT_4 is measured in animals with T_4 autoantibodies and should be in the middle-upper normal range 6 hours post-pill.
   E. Continue monitoring every 4 to 8 weeks for the first 8 to 10 months because, as metabolism changes, thyroid hormone replacement requirements vary.

Feline Hypothyroidism

Definition and Causes

I. It is a rare disease in cats.
II. It can be congenital or acquired.
III. The most common cause is iatrogenic disease following treatment of hyperthyroidism.

Clinical Signs

I. Severe lethargy
II. Constipation
III. Inappetence
IV. Obesity

V. Seborrhea sicca
VI. Stunted growth

Diagnosis

I. Appropriate history and clinical signs
II. Baseline serum T_4 measurement usually diagnostic
III. Measurement of feline TSH
  A. Canine assay is validated for cats.
  B. High TSH along with a low T_4 supports a diagnosis of hypothyroidism.
IV. TRH stimulation test
  A. TRH 0.1 mg/kg IV (Relefact by Ferring; Thypinone by Abbott) is administered.
  B. Serum samples are submitted before and 6 hours after TRH injection.
  C. Normal cats demonstrate a 50% increase in T_4, whereas hypothyroid cats do not show an appropriate increase.
  D. Transient side effects of TRH administration in cats include salivation, vomiting, tachypnea, and defecation.

Differential Diagnosis

I. Other causes of obesity, poor hair coat quality, and constipation
II. Other causes of severe lethargy
III. Other endocrinopathies: acromegaly, hyperadrenocorticism
IV. Unrelated illnesses arising after treatment of hyperthyroidism

Treatment and Monitoring

I. L-thyroxine is started at 0.05 to 0.1 mg (per cat) PO SID to BID.
II. Dosage is adjusted based on resolution of clinical signs and serum T_4 measurements, as in dogs.
III. Clinical signs and T_4 measurements usually improve within 4 to 6 weeks.

HYPERTHYROID DISEASES AND NEOPLASIA

Feline Hyperthyroidism

Definition

I. Hyperthyroidism results from an excess of circulating thyroid hormone.
II. The disease first appeared in the United States in the late 1970s.
III. It is now the most common endocrinopathy diagnosed in cats.

Causes

I. Hyperplastic or neoplastic thyroid cells overproduce thyroid hormone independent of any negative regulatory signals from the hypothalamic-pituitary-thyroid axis.
II. Etiology is unknown, but may be related to environmental (cat litter), nutritional (canned food), or abnormal cellular factors (Kass et al., 1999, Edinboro et al., 2004, Ward et al., 2005).

Pathophysiology

I. Adenomatous hyperplasia
  A. Small, multifocal functional nodules throughout the thyroid gland or generalized hyperplasia
  B. Most common cause
  C. Bilateral in approximately 70% of affected cats (Holzworth et al., 1980)
II. Solitary adenoma
  A. Circumscribed adenoma involving much of the gland
  B. Much less common: approximately 10% of hyperthyroid cats
  C. Bilateral or unilateral
III. Carcinoma
  A. Accounts for 1% to 2% of cases (Turrel et al., 1988)
  B. May be functional or nonfunctional

Clinical Signs

I. Signalment
  A. Middle-aged to older cats: average age at time of onset, 12 to 13 years; range, 4 to 21 years
  B. No reported breed or gender predilection
  C. Siamese and Himalayan cats potentially at decreased risk
II. Clinical signs (Broussard et al., 1995)
  A. Often less severe when diagnosed early
  B. Weight loss
    1. Most common clinical sign: 87% of affected cats
    2. From increased metabolic rate
  C. Polyphagia (49%)
  D. Vomiting (44%)
    1. Undigested food, often following rapid ingestion
    2. Acute gastric distention
    3. Worsened by overgrooming and hairball formation
  E. Polyuria/polydipsia (36%)
    1. Increased medullary blood flow and solute washout, decreased urine concentration
    2. Potential psychogenic polydipsia
  F. Behavioral changes (31%)
    1. Nervousness, hyperactivity, aggression
    2. Increased vocalization
    3. Shivering, tremors
  G. Diarrhea (15%)
    1. Loose and bulky stools, increased fecal volume
    2. Malabsorption and increased fecal fat content
  H. Weakness, lethargy: less common, variable
  I. Heat or stress intolerance: seeks cool places
  J. Panting, respiratory distress: sometimes attributable to cardiac disease
  K. Sudden-onset blindness from hypertension-induced retinal detachment
  L. Anorexia (7%) interspersed with polyphagia
III. Physical examination findings (Broussard et al., 1995)
  A. Enlarged palpable thyroid gland (83%)
    1. Discovery dependent on palpation skill
    2. Unilateral or bilateral enlargement
    3. Possible extension into the thoracic inlet
  B. Thin or cachectic (65%)

C. Cardiovascular signs
   1. Cardiac murmurs (54%)
   2. Tachycardia (42%)
   3. Gallop rhythm
   4. Atrial and ventricular arrhythmias
   5. Congestive heart failure
   6. Pleural effusion with muffled heart sounds
   7. Systemic hypertension
D. Dermatological signs
   1. Excessive shedding, matting of hair coat
   2. Greasy or dry skin, seborrhea
   3. Increased rate of claw growth
   4. Truncal alopecia from hair pulling, thin skin
E. Neuromuscular signs
   1. Muscle weakness, ventriflexion of the neck
   2. Muscle tremors, gait abnormalities
   3. Collapse, seizures
   4. Inability to jump to high places
F. Respiratory signs: tachypnea, dyspnea
G. Ocular abnormalities
   1. Retinal hemorrhages, dilated retinal vessels
   2. Detached retina
H. Dehydration
I. Apathetic hyperthyroidism
   1. Occurs infrequently: approximately 10% of hyperthyroid cats
   2. Severely ill
   3. Lethargy, anorexia

Diagnosis

I. Complete blood count (CBC)
   A. Mild elevation in packed cell volume
   B. Increased mean cell volume
   C. Stress leukogram: mature neutrophilia, lymphopenia, eosinopenia
   D. Increased platelet size
   E. Possible anemia
II. Serum biochemistry results
   A. Mild to moderate elevation of serum liver enzyme concentrations
   B. Mild hyperphosphatemia, hypokalemia
   C. Hyperglycemia from stress or concurrent diabetes mellitus
   D. Increased urea nitrogen and creatinine with concurrent renal disease or dehydration
   E. Decreased ionized calcium
III. Urinalysis
   A. Possible isosthenuria if renal insufficiency or polyuria present
   B. Possible glucosuria from stress hyperglycemia or concurrent diabetes mellitus
IV. Thoracic radiography
   A. Mild to severe cardiomegaly
   B. Signs of heart failure: pleural effusion and/or pulmonary edema
V. Basal serum total T_4 concentration
   A. It is increased in >95% of hyperthyroid cats (Broussard et al., 1995).
   B. It is the primary test used to diagnose hyperthyroidism.
   C. If T_4 is normal in a cat suspected to be hyperthyroid, repeat the test in 1 to 2 weeks, because hormone levels are known to fluctuate.
   D. It is affected by nonthyroidal illnesses (McLoughlin et al., 1993).
      1. Nonthyroidal illness artificially decreases serum T_4 to low-normal or below the reference range in euthyroid cats.
      2. Hyperthyroid cats with concurrent nonthyroid disease may have T_4 concentrations within or even below the normal range, making the diagnosis of hyperthyroidism difficult.
VI. Serum fT_4 concentration measured by equilibrium dialysis
   A. It is increased in hyperthyroid cats.
   B. It is useful in early hyperthyroidism when T_4 is normal.
   C. It may be misleading as a sole diagnostic test because 6% to 12% of euthyroid cats with nonthyroidal illness have elevated fT_4 (Mooney et al., 1996; Peterson et al., 2001).
   D. It is evaluated concurrently with a T_4.
   E. It is less accurate as a single test than a serum T_4.
VII. Serum T_3 or free T_3 measurements
   A. More baseline fluctuation than T_4 measurements
   B. No increased benefit over T_4 and fT_4
VIII. T_3 suppression test (Refsal et al., 1991)
   A. T_3 inhibits TSH secretion from the pituitary gland, so T_4 secretion decreases in a normal animal (T_4 half-life = 6 to 8 hours).
   B. Protocol is as follows:
      1. Day 1: obtain serum for basal T_3 and T_4 levels, and freeze or refrigerate separated serum.
      2. Day 2 to 3: give 25 μg T_3 (liothyronine) PO TID for seven treatments.
      3. Day 4: 2 to 4 hours after the seventh treatment, obtain samples for T_3 and T_4 measurement.
   C. Interpretation is as follows:
      1. Normal animal: T_4 values <1.5 μg/dL (20 nmol/L) or suppression of T_4 to ≤50% of pretreatment values
      2. Hyperthyroid animal: T_4 >1.5 μg/dL (20 nmol/L)
      3. Serum T_3 values
         a. Not useful in the diagnosis of hyperthyroidism
         b. Helpful to determine whether the owner gave the medication as instructed and that it was properly absorbed from the gastrointestinal (GI) tract
         c. Should increase after liothyronine treatment
   D. It is an excellent test to diagnose hyperthyroidism, especially in animals with nonthyroidal illness.
   E. Problems with the test include owner compliance with pill administration, low GI absorption, and the need to return the cat at the proper sampling times.
IX. TSH stimulation test
   A. TSH stimulates T_3 and T_4 release in normal animals.

B. In hyperthyroid cats, TSH administration should result in decreased release of T_4 and T_3.
C. T_4 levels following TSH are often normal in hyperthyroid cats, so the test is difficult to interpret and not useful.

X. TRH stimulation test (Peterson et al., 1994)
A. TRH stimulates TSH, T_3, and T_4 release in normal cats.
B. In hyperthyroid cats, TRH should induce no changes in T_4 and T_3.
C. The test involves obtaining blood for basal T_3 and T_4 levels, then giving TRH (*Relefact* or *Thypinone*) 0.1 mg/kg IV and collecting samples for T_3 and T_4 4 hours post-TRH.
D. Immediate side effects of TRH administration include salivation, vomiting, tachypnea, and defecation, but these are transient.
E. Interpretation is difficult and the test has limited diagnostic utility.

XI. Thyroid imaging with ^{131}I, ^{125}I, or pertechnetate ($^{99m}TCO_4^-$)
A. Identifies functional thyroid tissue
B. Determines extent of thyroid gland involvement and localizes ectopic thyroid tissue
C. Identifies metastatic tissue in cats with functional thyroid carcinoma
D. Pertechnetate faster, and comparison with salivary gland uptake helps quantify functional activity (Daniel et al., 2002)
E. Expensive, with limited availability

Differential Diagnosis

I. Diabetes mellitus
II. Chronic renal failure
III. Intestinal malabsorptive disease
A. Inflammatory bowel disease
B. Intestinal lymphosarcoma
C. Exocrine pancreatic insufficiency
D. Other GI diseases resulting in malabsorption and/or maldigestion

Treatment

I. Medical therapy with antithyroid thiourelene compounds
A. Mechanism of action
1. Prevention of iodine incorporation into tyrosyl groups
2. Prevention of coupling of monoiodotyrosine and diiodotyrosine into T_3 and T_4
3. Direct interaction with the thyroglobulin molecule
B. Examples
1. Methimazole *(Tapazole):* medical treatment of choice
2. Propylthiouracil: not recommended owing to side effects
C. Advantages of methimazole therapy
1. Less initial financial outlay
2. Allows for partial control of disease in animals with renal compromise
3. Stabilization of animals for surgery or ^{131}I treatment
4. Trial use to determine presence of renal compromise (i.e., worsening of renal function tests as hyperthyroidism is controlled)
D. Disadvantages of methimazole therapy
1. Daily pilling
2. Side effects common within the first 3 months or as dosages increase
a. Transient anorexia, vomiting, lethargy
b. Facial excoriations
c. Hepatic toxicity
d. Hemolytic anemia
e. Leukopenia, thrombocytopenia
f. Positive antinuclear antibody titers
g. Bleeding tendencies: increased proteins induced by vitamin K absence or antagonists
h. Usually resolve with discontinuation of the drug
E. Methimazole treatment regimen
1. Should be given BID for maximal control (Trepanier et al., 2003)
2. If renal function is normal, give 2.5 to 5 mg PO BID, depending on severity of clinical signs and thyroid hormone serum levels.
3. If renal insufficiency or failure is present, give 1.25 to 2.5 mg PO BID.
4. Transdermal gel forms can be compounded and are used on the ear pinna at the same dose and frequency as oral methimazole (Sartor et al., 2004); owners must wear gloves during application.

II. Medical therapy with oral cholecystographic contrast agents
A. Mechanism of action is via inhibition of outer-ring 5′ deiodination of T_4 to T_3, and direct inhibition of thyroid hormone secretion.
B. They are used in methimazole-intolerant cats to stabilize them for surgery or ^{131}I therapy.
C. Optimal results are obtained in cats with mild or moderate disease, and most cats become refractory to the drug after approximately 3 months.
D. Ipodate is administered at 100 mg PO SID or divided BID, but has limited availability.
E. Telepaque, iopanoic acid, another cholecystographic agent may be used at similar doses, although there are no direct studies in cats.

III. Stable iodine therapy
A. Large doses of iodine decrease thyroid hormone synthesis by an unknown mechanism.
B. Effects are usually transient, so iodine is only used to stabilize animals before surgery.
C. It is used in combination with a β-adrenergic blocking agent 10 to 14 days before surgery (Foster and Thoday, 1999).
D. Dose is 30 to 100 mg PO SID or divided BID.
E. Available preparations include the following:
1. Potassium iodide (*Thyroshield;* Fleming Laboratories, Mumbai, India) is available as a 65-mg/mL solution of potassium iodide.

2. Lugol's solution (5 g iodine with 10 g potassium iodide per 100 mL solution) yields 6 mg iodine/drop.
3. Taste is unpleasant, but the drug can be placed in a gelatin capsule immediately before administration.

IV. Surgical therapy: thyroidectomy
- A. Optimal to remove both glands; can operate one side at a time
- B. Presurgical methimazole administered through the morning of surgery
- C. Beta-blocking agents possibly administered before and after surgery
- D. Curative in most cases
- E. Postsurgical hypoparathyroidism and hypocalcemia: common, often resolves in several days
- F. May unmask renal failure

V. Iodine-131 treatment
- A. Treatment of choice in cats with normal renal function
- B. Mechanism of action
  1. Iodine-131 is concentrated in the hyperfunctioning follicles of the thyroid glands.
  2. Iodine-131 is primarily a beta radiation emitter that causes local tissue damage and kills hyperfunctional follicle cells.
  3. Radioactive half-life is 8 days.
- C. Advantages
  1. One subcutaneous injection is curative in 95% of cats, and a second treatment is necessary in only 2.5% of cases (Peterson and Becker, 1995).
  2. Side effects are negligible, with hypothyroidism occurring in 2.5% of treated cases (Peterson and Becker, 1995).
  3. It is not invasive.
  4. Destruction of ectopic thyroid tissue is accomplished.
  5. Destruction of malignant cells is possible at high doses.
- D. Disadvantages
  1. Hospitalized throughout the time of radioactive clearance, usually for 3 to 10 days
  2. Expensive
  3. May precipitate onset of renal failure

VI. Percutaneous ethanol injection
- A. It involves ultrasound-guided injection of ethanol into the thyroid gland.
- B. Its major complication is laryngeal paralysis, and large-scale studies are lacking in cats.

VII. β-Adrenoreceptor blocking agents
- A. Used to control tachycardia, hypertension, hyperexcitability, and arrhythmias associated with hyperthyroidism
- B. Used in cats awaiting surgery or ^{131}I therapy, or during initial therapy with methimazole
- C. Used during methimazole withdrawal to prevent signs of acute thyrotoxicosis (thyroid storm)
- D. Atenolol 6.25 mg PO SID to BID; contraindicated if congestive heart failure present

VIII. Therapy of combined hyperthyroidism and renal failure
- A. These diseases often coexist.
- B. Thyroid hormone increases cardiac output, decreases peripheral vascular resistance, increases renal plasma flow, and increases glomerular filtration rate (GFR) (Graves et al., 1994).
- C. With successful treatment of hyperthyroidism and subsequent GFR reduction, renal disease may become apparent.
- D. Careful management is required of cats with overt renal failure at the time of diagnosis.
  1. Methimazole is the treatment of choice, because serum T_4 concentrations can be kept slightly above the normal range if renal parameters worsen.
  2. Methimazole is instituted at a lower dose (see earlier discussion).
  3. Beta-blockers, such as propranolol or atenolol, are used for tachycardia and arrhythmias in those animals with renal failure in which serum T_4 normalization is contraindicated.

Monitoring of Animal

I. Methimazole therapy
- A. Monitor CBC, platelet count, blood urea nitrogen, creatinine, and serum T_4 2 to 3 weeks after starting therapy.
  1. Decrease dosage or discontinue if T_4 is low, hematological abnormalities are noted, or renal function has deteriorated.
  2. Institute beta-blockade therapy if methimazole is severely reduced or withdrawn to prevent acute thyrotoxicosis (thyroid storm).
  3. Increase dosage if T_4 remains elevated and other parameters are normal.
- B. Recheck every 2 to 3 weeks for first 3 months; then every 3 to 6 months, as necessary.

II. Iopanoic acid therapy
- A. Monitor for resolution of clinical signs.
- B. T_3 levels usually return to normal.
- C. T_4 levels usually not helpful for monitoring.

III. Surgical therapy
- A. Monitor serum calcium for 4 to 5 days after bilateral thyroidectomy because hypoparathyroidism may develop with damage or inadvertent removal of the parathyroid glands at the time of surgery.
- B. See treatment of Hypocalcemia in Chapter 43.
- C. Following surgery, hypothyroidism may develop and become clinically significant in some cats, requiring supplementation with L-thyroxine (see Feline Hypothyroidism).

IV. Radioactive iodine therapy
- A. Measure serum T_4 and renal parameters 2 weeks after ^{131}I treatment.
- B. Repeat measurements monthly until T_4 levels are normal or stabilize.
- C. Transient hypothyroidism is possible, but T_4 values usually normalize within 6 to 8 weeks, and these cats

usually show no clinical signs and do not require thyroid supplementation.
D. Cats may take 6 months before T_4 levels normalize.
E. Cats with low serum T_4 levels do not require treatment unless clinical signs of hypothyroidism are present.

Thyroid Tumors in Dogs

Definition and Cause

I. Relatively common tumors: 1% to 4% of all canine neoplasms (Harari et al., 1986)
II. Usually large, nonfunctional masses in the neck
III. Most malignant (>90%), with metastasis by the time of detection
IV. Cause unknown

Pathophysiology

I. Malignant carcinoma
  A. Most common (>70%) of all canine thyroid tumors
  B. Most unilateral; bilateral possible
  C. Develop in normal thyroid area or ectopic locations
  D. Locally invasive to esophagus, cervical musculature, surrounding vasculature and nerves, and trachea
  E. Possible metastasis to local lymph nodes at time of diagnosis
  F. Variable thyroid function
    1. Most animals are euthyroid because the tumor is nonfunctional.
    2. Rarely (<5%) tumors are functional and hyperthyroidism occurs.
    3. Some animals (possibly up to 30%) become hypothyroid when normal thyroid tissue is destroyed by the tumor.
II. Benign adenomas
  A. Much less common
  B. Usually small and found incidentally on necropsy
  C. Usually nonfunctional

Clinical Signs

I. Signalment
  A. Middle-aged or older (>5 years) dogs
  B. No sex predilection
  C. Boxers, beagles, and golden retrievers at increased risk
II. Clinical signs
  A. Large palpable cervical mass
  B. Signs related to local tissue compression and invasion by the mass
    1. Dyspnea, cough
    2. Dysphagia, hoarseness of bark
    3. Anorexia, weight loss
  C. Signs associated with functional thyroid tumors
    1. Signs of overproduction of thyroid hormone include polyuria/polydipsia, polyphagia, weight loss, restlessness, nervousness, and frequent defecation.
    2. Fewer signs of local tissue compression are noted, because the mass is often detected earlier, while it is still small.

Diagnosis

I. Palpable mass in ventral cervical region
II. Possibly enlarged regional lymph nodes
III. Imaging studies
  A. Plain cervical radiography identifies a soft tissue mass.
  B. Computed tomography or magnetic resonance imaging determines extent of invasion.
  C. Pertechnetate ($^{99m}TCO_4^-$) imaging identifies both metastatic disease and local invasion (Marks et al., 1994).
  D. Chest radiography is used to detect metastatic disease.
IV. Fine-needle aspirate
  A. Samples are often nondiagnostic and diluted with blood.
  B. Thyroid tumors do not exfoliate well.
  C. Malignant thyroid tumors may appear benign on cytological examination.
V. Biopsy
  A. Surgical wedge biopsies are often necessary.
  B. Percutaneous Tru-Cut biopsies are difficult to obtain, and significant bleeding may occur after the biopsy.
VI. Thyroid function testing
  A. Baseline hormone assays reveal increased serum T_4 or fT_4 with functional thyroid tumors.
  B. Endogenous TSH concentrations are low or low-normal with functional thyroid tumors.
  C. Rule out the presence of T_3 and T_4 autoantibodies that artificially elevate baseline T_4 concentrations (see Canine Hypothyroidism).

Differential Diagnosis

I. Nonthyroid neoplasia: lymphoma, regional soft tissue sarcoma, chemodectoma (carotid body tumors), metastatic oral tumors
II. Infectious or inflammatory conditions: abscess, granuloma
III. Salivary mucocele

Treatment

I. Thyroid tumors in dogs are highly malignant and have often metastasized by the time of diagnosis, so treatment is often palliative.
II. Surgical excision is the treatment of choice (Klein et al., 1995; Brearley et al., 1999).
  A. Excision is possible with small, encapsulated tumors.
  B. Many tumors are large and invasive, rendering them difficult to completely remove.
  C. If complete removal is impossible, debulking facilitates further treatment or is palliative.
  D. Tumors are very vascular, and intraoperative hemorrhage is common.
III. Chemotherapy produces variable results.
  A. Doxorubicin may reduce tumor size, but remission is not usually achieved.
  B. Cisplatin may be tried.
  C. Combination chemotherapy with cyclophosphamide and vincristine can also be attempted.
  D. Combination therapy with surgical debulking may be more effective.

IV. Different types of radiation therapy are available (Theon et al., 2000).
   A. External beam (cobalt) irradiation
      1. Important modality for control of invasive thyroid carcinoma
      2. Also used for large, nonresectable tumors as adjunctive therapy postsurgery
      3. Potential side effects: pharyngitis, laryngitis, esophagitis
      4. Considered even if metastatic disease is present, because the disease is often slowly progressive
      5. Median survival time: 2 years (Pack et al., 2001)
   B. Iodine-131 therapy
      1. Used most successfully in dogs with functional tumors
      2. High doses necessary
      3. Reversal of clinical signs possible, but treatment not curative (Adams et al., 1995)
      4. Adjunctive therapy to surgery (Worth et al., 2005)
      5. Shown to reduce size of mediastinal metastases
      6. Methimazole and beta-blocker agents to control signs of hyperthyroidism

Monitoring of Animal

I. Histologically evaluate all surgical margins.
II. Assess the animal every month for return of clinical signs, tumor regrowth, lymph node metastasis, and pulmonary metastasis.
III. If a functional tumor was present, measure thyroid function (T_4, fT_4, and/or endogenous TSH concentrations) every 1 to 3 months.

CHAPTER 43

Disorders of the Parathyroid Gland

Rita H. Miller | Dennis J. Chew

PRIMARY HYPOPARATHYROIDISM

Definition and Causes

I. Diffuse lymphocytic parathyroiditis (immune-mediated origin suspected) is the most common histological finding.
II. Parathyroid agenesis is rare.
III. Iatrogenic hypoparathyroidism is possible following surgical manipulation, removal of the parathyroid glands, or trauma.
IV. Both hypomagnesemia and hypermagnesemia can reduce secretion of parathormone (PTH) and impair PTH action on its receptors.
V. Signalment is as follows:
   A. Dogs from 6 weeks to 13 years of age
   B. Cats ranging in age from 5 months to 6.7 years
   C. Females more common than males
   D. Most common breeds: toy poodle, miniature schnauzer, Labrador retriever, German shepherd dog, terriers

Pathophysiology

I. The normal response of the body to decreased ionized calcium is increased production of PTH.
II. The lack of PTH secretion leads to hypocalcemia as a result of the following mechanisms:
   A. Inability to mobilize calcium and phosphorus from bone
   B. Failure to reabsorb calcium in the urine and to increase 1,25-dihydroxyvitamin D_3 (calcitriol) synthesis in the kidney
   C. Decrease in urinary phosphorus excretion, which can result in mild hyperphosphatemia
   D. Failure to reabsorb calcium and phosphorus from the intestine

Clinical Signs

I. Common clinical signs of hypocalcemia include the following:
   A. Seizures and/or tetany
   B. Twitching, muscle tremors, and fasciculations
   C. Stiff gait, ataxia
   D. Disorientation, abnormal behavior
   E. Weakness
II. Other clinical signs are possible in dogs.
   A. Facial rubbing, pruritus
   B. Anorexia
   C. Panting
   D. Fever
   E. Weakness
   F. Polyuria/polydipsia (PU/PD)
III. Signs are often intermittent and most obvious after exercise or stress, possibly owing to blood pH changes and a shift of ionized calcium to bound fractions.
IV. Cats exhibit facial rubbing, ptyalism, dysphagia, and sometimes prolapse of the third eyelid.
V. Physical examination reveals other possible abnormalities, such as cataracts, bradycardia in cats, hyperthermia, and hypothermia.
VI. Electrocardiographic abnormalities include sinus bradycardia, prolonged ST segment duration, and prolonged Q-T interval.

Diagnosis

I. Serum biochemistry profile reveals hypocalcemia (<6.5 mg/dL) and hyperphosphatemia (>6 mg/dL).
II. Serum PTH concentration is evaluated concurrently with serum calcium concentration.
   A. Serum PTH is often undetectable.
   B. Low or low-normal PTH in the face of ionized hypocalcemia is abnormal.
   C. Normal parathyroid glands synthesize and secrete high levels of PTH when challenged by ionized hypocalcemia.

Differential Diagnosis

I. Other common causes of hypocalcemia
   A. Hypoalbuminemia, which leads to decreased binding stores for calcium
      1. Ionized calcium (Ca^{2+}) may be normal or low.
      2. So-called calcium-correction formulas that use serum albumin cannot accurately predict ionized Ca^{2+}.
   B. Chronic renal failure
   C. Eclampsia
   D. Acute renal failure
   E. Acute pancreatitis
II. Occasional causes of hypocalcemia
   A. Ethylene glycol toxicity
   B. Phosphate enema
   C. Sodium bicarbonate administration
III. Rare causes of hypocalcemia

A. Acute tumor lysis syndrome
B. Vitamin D deficiency
C. Laboratory error
D. Intestinal malabsorption
E. Transfusion of citrate anticoagulant-containing blood
F. Nutritional secondary hyperparathyroidism

IV. Prioritization and elimination of most differential diagnoses
A. History and physical examination findings
B. Laboratory database

Treatment

I. Intravenous calcium administration
A. Infuse 5 to 15 mg elemental calcium/kg (0.5 to 1.5 mL/kg of 10% calcium gluconate) slowly IV to effect over 10 to 15 minutes.
B. Monitor heart rate and electrocardiogram (ECG) during calcium infusion.
C. Stop calcium infusion if signs of cardiotoxicity occur, including bradycardia, elevated ST segment, or short Q-T interval.

II. Parenteral calcium administration following cessation of seizures/tetany
A. Constant-rate infusion of calcium is provided in fluids free of lactate, bicarbonate, phosphates, or acetates.
B. Subcutaneous administration of diluted calcium salts is no longer recommended because of the possible development of calcinosis cutis and sterile abscesses in the region of injection sites.

III. Maintenance therapy
A. Oral vitamin D
1. Ergocalciferol (vitamin D_2; *Drisdol*)
a. Low cost
b. High doses required: 1000 to 2000 U/kg PO SID, tapered to once a week
c. Maximum effect not achieved for several weeks
d. Chronic problems with hypercalcemia associated with the drug's long half-life
2. Dihydrotachysterol USP (DHT tablets)
a. Long half-life
b. Dosage extremely variable: 0.01 to 0.02 mg/kg PO SID to QOD
c. Recently removed from the market in North America
3. Calcitriol *(Rocaltrol):* the vitamin D metabolite of choice
a. Rapid onset of action
b. Short half-life, allowing frequent dosing adjustments
c. Induction dose: 20 to 30 ng/kg/day PO for 3 to 4 days
d. Maintenance dose: 5 to 15 ng/kg/day PO
B. Oral calcium therapy
1. Necessary acutely to ensure gastrointestinal (GI) calcium absorption
2. Tapered and usually discontinued over time because dietary calcium intake is adequate
3. Calcium carbonate: preferred form
4. Dosage: 25 to 50 mg/kg/day PO of elemental calcium in divided doses

Monitoring of Animal

I. Goal of chronic therapy is to maintain serum calcium in the low-normal range.
II. Monitor for hypercalcemia or hypocalcemia via serum calcium concentration.
A. Monitor daily while animal is hospitalized.
B. Monitor weekly until it has stabilized in low-normal range.
C. Recheck every 3 months thereafter.

HYPERPARATHYROIDISM

Definition and Causes

I. The most common cause is a solitary adenoma of one of the four parathyroid glands.
II. Malignant parathyroid tumors are rare.
III. Benign hyperplasia of the parathyroid glands has been reported.
IV. Typical signalment is as follows:
A. Older animal with a mean age of 11.2 years (range 6 to 17 years) in dogs and 12.9 years (range 8 to 15 years) in cats (Feldman et al., 2005)
B. No sex predilection in either species
C. Keeshonds and Siamese cats overrepresented

Pathophysiology

I. The normal parathyroid gland synthesizes and secretes PTH at a rate that is inversely proportional to the concentration of extracellular ionized Ca^{2+}.
II. The function of PTH is to increase serum calcium concentration; major sites of action are the kidneys, bones, and intestines.
A. PTH increases calcium reabsorption from the renal tubules and increases urinary phosphorus excretion.
B. PTH increases the release of calcium from bone.
C. PTH stimulates the absorption of calcium in the intestines indirectly via increased synthesis of calcitriol.
III. PTH synthesis is inhibited by hypercalcemia, hypophosphatemia, and by calcitriol (in the face of normal serum calcium concentration) through a negative feedback loop.
IV. The normal, negative feedback control of serum calcium concentration is lost in cases of primary hyperparathyroidism, with increased production of PTH and subsequent hypercalcemia.

Clinical Signs

I. The clinical signs in dogs are often insidious in onset, and hypercalcemia is sometimes an incidental finding on routine or preanesthetic laboratory tests.
A. Urinary effects
1. PU/PD is most common and is sometimes accompanied by urinary incontinence with increased volume of urine production.
2. Urolithiasis is present in one third of canine cases.

B. Gastrointestinal signs
   1. Anorexia
   2. Vomiting
   3. Constipation
C. Neuromuscular signs
   1. Lethargy, exercise intolerance
   2. Muscle weakness or wasting in dogs
   3. Shivering and muscle twitching, seizures with severe hypercalcemia
D. Stiffness, apparent limb pain

II. Clinical signs in cats are nonspecific.
A. Anorexia, vomiting, weight loss
B. Weakness
C. Polyuria/polydipsia

III. Physical examination is often unremarkable or may reveal the following:
A. Muscle atrophy, weakness, or tremor occurs in dogs.
B. Pain may be elicited on orthopedic examination.
C. Parathyroid gland adenomas are usually too small to palpate in dogs.
D. Most cats have a palpable cervical mass, usually from adenoma-associated cystic changes.

Diagnosis

I. Hemogram is usually unremarkable.

II. Biochemistry profile demonstrates several abnormalities.
A. Persistent hypercalcemia, and low or low-normal serum phosphorus concentration occur in dogs with normal renal function.
   1. Serum phosphorus increases with renal failure.
   2. Mean total calcium concentration in dogs is 14.5 mg/dL (range 12.1 to 23.0 mg/dL) (Feldman et al., 2005).
   3. Mean plasma ionized Ca^{2+} concentrations in dogs is 1.71 mg/dL (range 1.22 to 2.41 mg/dL) (Feldman et al., 2005).
   4. Hypercalcemia is the only consistent finding in cats and usually ranges from 11 to 22.8 mg/dL (Kallet et al., 1991).
B. Prerenal or renal azotemia is uncommon.
C. Serum alkaline phosphatase is sometimes mildly increased in dogs.
D. Ca^{2+} concentration is increased, often before total serum calcium exceeds the normal range.
E. Urinalysis in both species may reveal dilute urine (urine specific gravity <1.030), with or without red blood cells, white blood cells, bacteria, or crystals.

III. Serum intact PTH concentration is increased or mid- to high-normal.
A. There is no correlation between PTH and serum calcium concentrations.
B. The "two-site" PTH immunoradiometric assay is validated for dogs and cats.
   1. Reference ranges at the Endocrine Diagnostic Section, Animal Health Diagnostic Laboratory, East Lansing, Mich., are as follows:
      a. Normal canine serum PTH: 2 to 13 pmol/L
      b. Normal feline serum PTH: 0 to 4 pmol/L
   2. Proper sample handling is very important.
      a. PTH degrades during transit to a commercial laboratory, especially with high prevailing temperatures.
      b. Serum proteases, responsible for much of PTH degradation, are inhibited by submitting ethylenediamine tetraacetic acid (EDTA)-treated plasma rather than serum, or by using special tubes containing aprotinin.
      c. Chilled samples retard degradation of PTH.
      d. EDTA-treated plasma samples arriving at refrigerated temperatures (4° C) are preferred.
C. Evaluate elevated serum PTH in light of serum total or ionized Ca^{2+} concentration.
   1. Hypercalcemia reduces PTH concentrations in animals with normal parathyroid glands.
   2. A normal PTH may be inappropriately high in hypercalcemic dogs, especially if it is in the upper half of the normal range.
   3. Very low PTH values in cats are expected; it is not possible to inhibit PTH to below-normal range.
D. Serum parathyroid hormone-related peptide (PTHrP) is undetectable in dogs with primary hyperparathyroidism.

IV. Radiography and ultrasonography are recommended.
A. Thoracic and abdominal radiographs may be normal.
   1. Calcium-containing cystic calculi are possible in dogs and cats.
   2. A generalized decrease in long bone cortical density is noted with long-standing hyperparathyroidism.
B. Ultrasonography of the neck using a high-frequency transducer may identify parathyroid gland masses.
   1. Parathyroid glands are <3 mm in diameter in normal dogs (Wisner, 1998).
   2. The median greatest diameter was 6 mm (range 3 to 23 mm) in hyperparathyroid dogs, and almost all parathyroid masses were >4 mm in diameter (Feldman et al., 2005).
   3. False negative scans can occur in hyperparathyroid dogs.

Differential Diagnosis

I. Hypercalcemia of malignancy
A. Physical examination findings: lymphadenopathy, organomegaly, bone pain, or an anal gland mass (dogs)
B. Radiography (chest, abdomen, and bone) and abdominal ultrasonography: possible identification of masses
C. Lymph node and/or bone marrow aspirate: possible detection of lymphosarcoma
D. PTH: low or undetectable
E. PTHrP increased in some malignancies, especially carcinomas
F. Serum phosphorus concentration: normal to low in the absence of azotemia

II. Renal failure
A. Serum phosphorus increased
B. Serum PTH normal or increased
C. Ca^{2+} decreased or normal

III. Vitamin D toxicosis: serum phosphorus possibly increased
IV. Hypoadrenocorticism
V. Osteolytic disease
VI. Nonpathologic causes
  A. Laboratory error
  B. Lipemia
  C. Young, growing animal
  D. Postprandial sample
VII. Idiopathic hypercalcemia (cats): the most common cause of hypercalcemia in cats
VIII. Other causes of cranial cervical masses, especially in cats

Treatment

I. Each hyperparathyroid case must be evaluated individually to determine preoperative therapy.
  A. Those with the greatest degree of presurgical hypercalcemia need the most supportive care before and after surgery.
  B. Animals with a calcium × phosphorus (Ca × Phos) of >60 require aggressive therapy to prevent soft-tissue mineralization.
    1. Most hyperparathyroid animals have low serum phosphorus and a Ca × Phos of <60.
    2. Animals with primary hyperparathyroidism usually do not need emergency therapy.
II. Medical therapy for hypercalcemia is instituted.
  A. Correct fluid deficits with IV fluids.
  B. Give diuretics with 0.9% saline at 100 to 125 mL/kg/day IV to promote calciuresis.
  C. Diuretics are sometimes given to reduce serum calcium concentration following rehydration.
    1. Furosemide 2 mg/kg IV, SC, or PO BID to TID
    2. Thiazide diuretics: contraindicated as they increase renal tubular reabsorption of calcium
  D. Sodium bicarbonate infusion (1 mEq/kg IV slow bolus) is used only for a hypercalcemic crisis to transiently lower ionized Ca^{2+} and total calcium.
  E. Prednisone 1 to 2.2 mg/kg PO BID or dexamethasone 0.1 to 0.22 mg/kg IV, SC BID is given to promote calciuresis and for other nonspecific effects on the GI tract and bone.
    1. Give only if a diagnosis has been confirmed.
    2. Lymphosarcoma is difficult or impossible to diagnose once glucocorticoids have been administered.
  F. Other options to reduce hypercalcemia are as follows:
    1. Bisphosphonates may be tried in dogs.
      a. Etidronate *(Didronel)* 10 to 40 mg/kg/day PO divided BID
      b. Pamidronate *(Aredia)* 1 to 2 mg/kg diluted in 0.9% NaCl and infused IV over 2 to 4 hours
        (1) Effects last 2 to 4 weeks.
        (2) Repeat treatment if needed.
    2. Calcitonin provides quick-acting adjunctive treatment to further decrease ionized Ca^{2+} in those with severe hypercalcemia.
      a. It can be tried while waiting for other treatment to become effective.
      b. Its effects are short-lived, and dogs may develop anorexia and vomiting during treatment.
III. Surgical removal of all enlarged or grossly abnormal parathyroid tissue is recommended.
IV. Ultrasound-guided ethanol chemical ablation or radiofrequency heat ablation is the treatment of choice at select institutions if concurrent surgery for cystic calculi is not necessary.

Monitoring of Animal

I. Hypocalcemia is possible within 2 to 6 days of surgery as a result of atrophy of the remaining parathyroid glands.
  A. It is most likely to develop in animals with the highest presurgical hypercalcemia.
  B. Hospitalize animals with severe presurgical hypercalcemia for at least 5 to 7 days postoperatively.
  C. Monitor calcium concentrations once or twice daily.
  D. Cats infrequently develop hypocalcemia postoperatively.
II. Prophylactic vitamin D metabolite therapy is started before surgery to prevent hypocalcemia, especially in dogs with severe hypercalcemia.
  A. Dihydrotachysterol (DHT) is prescribed at 0.02 mg/kg/day PO for 3 days, followed by 0.01 mg/kg/day PO for 1 week, but the product is currently not available in North America.
  B. Calcitriol *(Rocaltrol)* 5 to 10 ng/kg PO BID is the preferred fast-acting vitamin D metabolite; it also has a short half-life.
  C. The dose of vitamin D metabolite is gradually reduced weekly by 25% to 50%, as long as serum calcium concentration remains >8 mg/dL.
  D. Vitamin D metabolite therapy is usually discontinued by weeks 12 to 16.
  E. The goal of vitamin D and calcium therapy is to maintain serum calcium in the low-normal range to allow continued stimulation of the remaining parathyroid glands so they may recover from atrophy.
III. Vitamin D metabolite therapy can cause hypercalcemia and subsequent renal toxicity.
  A. If hypercalcemia develops, discontinue vitamin D therapy.
  B. Reinstitute vitamin D only if hypocalcemia recurs.
IV. Prognosis for dogs and cats is excellent if surgery is successfully performed and animals are monitored closely postoperatively.
  A. Hypercalcemia may recur if an adenoma develops in one of the remaining parathyroid glands.
  B. If hypercalcemia persists following the removal of one gland, consider that either an adenomatous gland has been missed or multiple endocrine neoplasia exists.
  C. Renal failure can develop before or after surgery.

CHAPTER 44

Diseases of the Endocrine Pancreas (Islet Cells)

Rebecka S. Hess

DIABETES MELLITUS

Definition

I. Derivation of name: diabetes = polyuria; mellitus = sweet
II. Type I diabetes mellitus (DM)
  A. Most common form of DM in dogs and cats
  B. Develops from beta cell destruction and impaired insulin secretion, (hypoinsulinemia)
  C. Usually insulin-dependent diabetes mellitus (IDDM)
  D. Possible progression from non–insulin-dependent diabetes mellitus (NIDDM) to IDDM
III. Type II DM
  A. Uncommon in cats and rare in dogs
  B. Characterized by insulin resistance and impaired insulin secretion, with or without beta cell destruction
  C. Serum insulin concentration normal, high, or low
IV. Secondary DM
  A. Secondary to diestrus or pregnancy in the dog
  B. Secondary to megestrol acetate treatment in the cat
V. Transient DM
  A. Occurs mainly in cats
  B. Theorized to develop in animals with subclinical DM and a concurrent disorder or exposure to an insulin-antagonistic drug

Causes

I. Type I DM
  A. Genetic: autosomal recessive inheritance in Keeshonds
  B. Immune-mediated following precipitating events: infections, toxins, unknown causes
II. Type II DM
  A. Obesity
  B. Islet-specific amyloid deposition
  C. Genetic
  D. Unknown

Pathophysiology

I. The Islets of Langerhans represent the endocrine pancreas and contain four types of cells.
  A. Alpha cells contain glucagon.
  B. Beta cells contain insulin.
  C. Delta cells contain somatostatin.
  D. F cells contain pancreatic polypeptide.
II. Insulin affects carbohydrate, protein, and fat metabolism.
  A. Insulin is anabolic, and its principal effects on carbohydrate metabolism are as follows:
    1. Increase glucose entry to muscle and adipose tissue
    2. Increase glycogen synthesis in the liver
    3. Decrease gluconeogenesis in the liver
  B. Insulin's principal anabolic effects on protein metabolism are the following:
    1. Increase amino acid uptake in muscle
    2. Increase protein synthesis in muscle and liver
    3. Decrease protein catabolism in muscle
  C. Insulin's principal anabolic effects on fat metabolism include the following:
    1. Increase lipid synthesis in adipose tissue and liver
    2. Decrease ketogenesis
    3. Activate lipoprotein lipase
    4. Inhibit hormone-sensitive lipase
  D. Lack of insulin or decreased action of insulin leads to the following:
    1. Hyperglycemia
    2. Catabolism of glycogen, protein, and fat stores
    3. Ketogenesis
    4. Lipemia
III. Other actions of insulin include increasing cell growth and increasing intracellular uptake of potassium and phosphorous.
IV. Insulin secretion is stimulated by various agents.
  A. Glucose
  B. Mannose, fructose
  C. Amino acids
  D. Glucagon
  E. Intestinal hormones: gastrin, secretin, cholecystokinin
V. Insulin-induced hypoglycemia can be reversed by four counterregulatory or diabetogenic hormones.
  A. Glucagon
  B. Catecholamines
  C. Glucocorticoids
  D. Growth hormone

Clinical Signs

I. Signalment
  A. Dogs
    1. Mean age of onset is 7 to 9 years.
    2. Samoyeds, miniature schnauzers, miniature and toy poodles, and pugs are at increased risk.

3. German shepherd dogs, golden retrievers, and American pit bull terriers are at decreased risk.
4. Intact and neutered females may have an increased risk of developing DM.

B. Cats
1. Mean age of onset is 10 years.
2. Burmese cats are at increased risk in Australia.
3. Neutered males may be at increased risk.

II. History and clinical signs
A. Polyuria and polydipsia (PU/PD)
B. Weight loss
C. Polyphagia
D. Blindness (dogs)
E. Plantigrade stance (cats)

III. Physical examination findings
A. Animals may be normal to severely compromised.
B. Signs are often nonspecific.
1. Underweight, normal, or obese body condition
2. Variable hydration status: normal or dehydrated
3. Hepatomegaly
4. Cataracts (dogs)
5. Plantigrade stance (cats)
6. Lethargy, weakness

Diagnosis

I. Appropriate history, clinical signs, and physical examination findings along with persistent hyperglycemia and glucosuria are sufficient for a diagnosis of DM.

II. Affected animals frequently have concurrent diseases that may influence clinical signs and physical exam findings.
A. Hyperadrenocorticism (dogs)
B. Urinary tract infection (UTI; dogs)
C. Hypothyroidism (dogs)
D. Acute pancreatitis (dogs and cats)
E. Neoplasia (dogs and cats)
F. Hepatic lipidosis (cats)
G. Chronic renal failure (cats)
H. Bacterial and viral infection (cats)

III. Because diabetics are usually middle-aged to older animals with concurrent disorders, further diagnostics are warranted.
A. Complete blood count (CBC)
1. The CBC is often normal.
2. Hematocrit may be normal, low, or high.
3. "Stress leukogram" may be present and is characterized by mature neutrophilia, monocytosis, lymphopenia, and eosinopenia.
4. Neutrophilia with a left shift may occur with infection.

B. Serum biochemistry profile
1. Alanine aminotransferase (ALT), aspartate aminotransferase (AST), and alkaline phosphatase (SAP) activity may be increased.
2. Lipemia and hypercholesterolemia are common.
3. Total bilirubin concentration may be increased.
4. Azotemia may be present.

C. Urinalysis (UA)
1. Specific gravity is variable, although it is usually >1.025.
2. Glucosuria is present.
3. Proteinuria, bacteruria, or ketonuria may be present.

D. Urine culture and sensitivity (C & S)
1. They are always performed in diabetic animals even if white blood cells (WBCs) are not apparent in the urine sediment.
2. Animals with DM are often immunocompromised; therefore, they may have a UTI with few or no WBCs in the urine sediment.
3. Glucosuria also increases the risk of UTIs.

E. Serum insulin or C-peptide concentration
1. Expected to be low in type I DM
2. Variable in type II DM

Differential Diagnosis

I. PU/PD
A. Renal disease
B. Liver disease
C. Hyperadrenocorticism
D. Hypoadrenocorticism
E. Hyperthyroidism
F. Hypercalcemia
G. Hypokalemia
H. Drugs, iatrogenic: glucocorticoids, diuretics, anticonvulsants, fluid overload
I. Pyometra
J. Diabetes insipidus
K. Psychogenic
L. Polycythemia

II. Weight loss despite polyphagia
A. Hyperthyroidism
B. Gastrointestinal parasites
C. Exocrine pancreatic insufficiency
D. Protein-losing enteropathy or nephropathy

III. Hyperglycemia
A. Stress
B. Hyperadrenocorticism
C. Drugs: glucocorticoids, progesterone, megestrol acetate
D. Total parenteral nutrition or other intravenous fluids
E. Postprandial
F. Diestrus
G. Pheochromocytoma
H. Acromegaly
I. Acute pancreatitis
J. Factitious measurement

IV. Glucosuria: primary renal glucosuria

Treatment

I. Insulin (Table 44-1)
A. Sources of insulins
1. Human insulin or human insulin analogue produced in bacteria by recombinant DNA techniques
2. Porcine or porcine–bovine mixture insulin

B. Types of insulin and durations of action
1. Short-acting insulins
a. Regular insulin
b. Identical to human insulin

TABLE 44-1

Insulin Products Used in Dogs or Cats

BRAND NAME	GENERIC NAME	SPECIES SOURCE	DURATION	MANUFACTURER	CONCENTRATION*	VOLUME, CONCENTRATION, APPROXIMATE COST
Humulin R, Novolin R	Regular insulin	HA[†]	Short	Eli Lilly[‡] Novo Nordisk[§]	U-100	10 mL, 1 vial = 1000 units, $25-$35
Humulin N, Novolin N	Neutral protamine Hagedon (NPH)	HA[†]	Intermediate	Eli Lilly Novo Nordisk	U-100	10 mL, 1 vial = 1000 units, $20-$30
Vetsulin (United States), *Caninsulin* (Europe, Australia)	Lente	Porcine	Intermediate	Intervet[‖]	U-40	10 mL, 1 vial = 400 units, $16-$30
PZI Vet	Protamine zinc insulin (PZI)	90% beef, 10% pork	Intermediate	Idexx[¶]	U-40	10 mL, 1 vial = 400 units, $86-$100
Lantus	Glargine	HA[†]	Intermediate to long	Aventis[#]	U-100	10 mL, 1 vial = 1000 units, $60-$74

*U-100 = 100 U/mL; U-40 = 40 U/mL.

[†]Human insulin analogue produced in bacteria by recombinant DNA techniques.

[‡]Indianapolis, Ind.

[§]Princeton, N.J.

[‖]Hillsboro, Del.

[¶]Westbrook, Me.

[#]Bridgewater, N.J.

c. Currently the only short-acting insulin that has been well characterized in dogs and cats

2. Intermediate acting insulins
   a. Neutral protamine Hagedorn (NPH) isophane insulin suspension: identical to human insulin
   b. Purified porcine lente insulin
   c. Protamine zinc insulin (PZI): mixture of 90% beef and 10% pork insulin
3. Long-acting insulin
   a. Glargine insulin
   b. Human insulin analogue
   c. Currently the only long-acting insulin characterized in dogs and cats

C. Frequency of insulin therapy
1. Twice-daily insulin is usually required in dogs and cats.
2. Occasionally, once-daily insulin treatment is sufficient.
3. Successful, once-daily treatment is observed more commonly with glargine insulin and in cats

D. Initial dosage
1. A safe initial dose for all insulin products in both dogs and cats is 0.5 U/kg subcutaneously.
2. The dose is adjusted based on clinical signs and glucose curves (see Monitoring of Animal).

II. Diet
A. Dog
1. Diet components: high insoluble fiber, complex carbohydrates, fixed protein, restricted fat
2. Examples: Canine w/d by Hill's (Topeka, Kan.), Glucose-Control by IAMS (Dayton, Ohio)

B. Cat
1. Diet components: high protein, low carbohydrate
2. Examples: Feline m/d by Hill's, Feline DM by Purina (St. Louis, Mo.)

C. Feeding schedule
1. Twice daily, at a fixed time
2. Before insulin administration to ensure dietary intake before onset of insulin action

III. Exercise
A. Promotes weight loss
B. May increase glucose transport and glycogen synthesis in dogs and cats

IV. Oral hypoglycemics
A. Sulfonylureas (glipizide)
1. Mode of action
   a. Stimulates insulin secretion from pancreatic beta cells
   b. Increases peripheral glucose uptake
2. Adverse effects in cats
   a. Vomiting shortly after drug administration
   b. Increased hepatic enzyme activities, icterus
   c. Hypoglycemia
3. Candidates for glipizide therapy
   a. Cats with type II DM are more likely to respond than cats with type I DM.
   b. Treat only clinically stable, uncomplicated diabetics.

c. Do not use in cats with profound hyperglycemia or diabetic ketoacidosis.

4. Dosage
   a. Give 2.5 mg/cat PO BID for first 2 weeks.
   b. If no adverse effects occur and the cat is still hyperglycemic, increase to 5 mg PO BID after 2 weeks.
   c. If the cat is still hyperglycemic at 4 weeks, discontinue glipizide and begin insulin treatment.

B. Vanadium
1. Mode of action is to increase insulin sensitivity in skeletal tissue and liver.
2. Candidates for treatment are the same as for glipizide.
3. Cats treated with insulin and vanadium may require less insulin and have better resolution of clinical signs than cats treated with insulin alone.
4. Dose is 45 mg/cat PO SID.
5. Adverse effects include vomiting, diarrhea, and anorexia.

C. Chromium
1. Proposed mode of action in rodents and humans is to increase insulin sensitivity.
2. Currently there are no studies to suggest that chromium improves glycemic control in cats or dogs with naturally occurring diabetes mellitus.
3. Chromium supplementation in cats does not affect glucose tolerance in obese and nonobese cats.

D. Acarbose
1. Mode of action is to competitively inhibit alpha glucosidase enzymes, resulting in reduced postprandial hyperglycemia.
2. Candidates for treatment are diabetics on appropriate insulin and dietary therapy that exhibit postprandial hyperglycemia.
3. Acarbose is administered at the time of a meal.
4. Acarbose is used in conjunction with insulin.
5. Doses in dogs are as follows:
   a. Dogs weighing <10 kg: 25 mg PO BID for 2 weeks, then 50 mg PO BID
   b. Dogs weighing ≥10 kg: 50 mg PO BID for 2 weeks, then 100 mg PO BID
6. Dose in cats is 12.5 mg PO BID
7. Adverse effects (observed more commonly with higher dosages) include diarrhea and flatulence, and usually subside with time.

V. Suspected insulin resistance
A. Insulin resistance is suspected when clinical signs and hyperglycemia persist with insulin dosages >1.5 U/kg per dose.
B. Reasons for perceived insulin resistance are as follows:
1. Improper handling or administration of insulin
2. Outdated, inactive insulin
3. Improper dosage or frequency of insulin injection
4. Poor absorption of insulin
5. Antiinsulin antibodies
6. Somogyi effect

C. Presence of concurrent disorders listed in the preceding Diagnosis section can cause true insulin resistance.

Monitoring of Animal

I. Owners must monitor the following parameters.
A. Changes in clinical signs: PU/PD, polyphagia, body weight
B. Urine glucose BID: before feeding
C. Ketonuria BID: emergency situation if present
D. Appetite BID

II. Adjust the insulin dose and seek veterinary advice in the following instances:
A. If vomiting or anorexia occur, administer half the insulin dose.
B. If the animal does not eat its meal, administer half the insulin dose.
C. If seizures, weakness, or signs of insulin-induced hypoglycemia are observed, rub corn syrup onto gums and seek emergency veterinary care.

III. Monitoring of cats is similar to dogs, but can be more difficult.
A. Cats often reject fixed BID meals and require free-choice food.
B. Cats may refuse appropriate diets.
C. Sampling urine at fixed times can be difficult.

IV. Veterinary monitoring involves the following:
A. Clinical signs: PU/PD, polyphagia, body weight
B. Monitoring for glucosuria or ketonuria
C. Glucose curves
1. Measure glucose every 2 hours for at least 12 hours in animals receiving BID insulin, and for 24 hours in animals receiving SID insulin.
2. Insulin duration is defined as the number of hours after insulin administration that blood glucose remains below 200 to 250 mg/dL.
   a. If insulin duration is approximately 12 hours, give insulin BID.
   b. If insulin duration is approximately 24 hours, give insulin SID.
3. Adequate glycemic control is achieved when glucose concentrations over 12 to 24 hours are 100 to 250 mg/dL in dogs and 100 to 300 mg/dL in cats.
   a. If the animal is persistently hyperglycemic, increase the insulin dosage.
   b. If the animal is persistently hypoglycemic, decrease the insulin dosage.
4. Initially, perform glucose curves every 1 to 2 weeks until adequate glycemic control is achieved.
5. Perform follow-up glucose curves every 1 to 6 months, depending upon clinical signs and trends in monitoring at home.
6. Measurement of a single blood glucose concentration is not a useful monitoring tool owing to the Somogyi effect.
   a. The Somogyi effect is characterized by increased secretion of glucagon, catecholamines, glucocorticoids, and growth hormone in response to severe insulin-induced hypoglycemia.
   b. Pronounced compensatory hyperglycemia can occur as a result of an insulin overdose.

D. Glycosylated hemoglobin

1. Formed from an irreversible bond of glucose to hemoglobin
2. Reflects serum glucose concentrations during the prior 3 to 4 months

E. Fructosamine
1. Formed from an irreversible bond of glucose to various serum proteins
2. Reflects serum glucose concentrations during the preceding 1 to 3 weeks

F. Possible long-term complications: cataracts, uveitis, retinopathy, neuropathy, nephropathy

DIABETIC KETOACIDOSIS

Definition

I. Diabetic ketoacidosis (DKA) is a severe form of complicated DM that is a medical emergency.
II. DKA is characterized by acidosis and ketosis in animals with DM.

Causes and Pathophysiology

I. Ketones are synthesized from fatty acids as a substitute form of energy, because inadequate amounts of glucose enter into cells.
II. Concurrent diseases may contribute to development of DKA.
III. Excess ketoacids results in potentially life-threatening acidosis and electrolyte abnormalities.
A. Hypokalemia is common.
1. Acidosis results in a potassium shift out of the cell to electrically compensate for hydrogen movement into the cell.
2. Hypokalemia is further aggravated by diuresis, vomiting, potassium binding of ketoacids, and diffusion of potassium into the cells after insulin therapy.
3. Hypokalemia can lead to profound muscle weakness that may cause respiratory paralysis in extreme cases.

B. Hypophosphatemia is also common.
1. Hypophosphatemia develops when phosphate shifts from the intracellular space to the extracellular space as a result of hyperglycemia, acidosis, and hypoinsulinemia.
2. Osmotic diuresis or fluid therapy, along with insulin administration, causes extracellular phosphate depletion, leading to whole-body phosphate depletion.
3. Hypophosphatemia is associated with hemolysis and seizures.

C. Hyponatremia can occur from diuresis, vomiting, and sodium binding to ketoacids.
D. Hypomagnesemia occurs in cats, but is uncommon in dogs.

Clinical Signs

I. History and clinical signs
A. Similar to an uncomplicated diabetic
