See main reference on page 615 for details.

Clinical signs

Vomiting or regurgitation (due to esophagitis) or diarrhea may all be observed, depending on the segment of bowel affected.

Anorexia and dysphagia are more common with esophagitis.

Mild abdominal distention or abdominal pain due to accumulation of gas in the bowel can occur.

Epigastric pain and hypersalivation are due to esophagitis.

Diagnosis

Ileus may be suspected by **palpation of flaccid, dilated loops of bowel**. Gut sounds are decreased or absent.

Survey abdominal radiographs may show dilated, gas- and fluid-filled loops of bowel.

Adynamic ileus can be confirmed by a contrast study using barium-impregnated polyethylene spheres (BIPS), scintigraphy or fluoroscopy to assess motility. Contrast radiographs or endoscopy will be required to identify esophagitis.

Esophagitis may be clinically silent but if regurgitation, hypersalivation and anorexia are present should be considered.

SALMONELLOSIS*

Classical signs

- Most cats have asymptomatic infections.
- In young kittens watery or hemorrhagic diarrhea is the most common sign.
- Vomiting, lethargy and anorexia may also occur, but are uncommon and usually associated with septicemia.

See main reference on page 719 for details (The Cat With Signs of Acute Small Bowel Diarrhea).

Clinical signs

Cats may develop one of **three possible clinical syndromes**: (1) asymptomatic carrier state, (2) gastroenteritis, or (3) fulminant septicemia/bacteremia.

Gastroenteritis is typically characterized by diarrhea that may be watery, mucoid, bloody or all three. Typically, fever, depression and anorexia are first observed, followed by vomiting, abdominal pain and diarrhea.

Cats with septicemia or bacteremia may not have any GI signs, and instead are febrile, lethargic, anorectic and may show signs of septic shock (e.g. hypovolemia, weakness, poor capillary refill time, acute renal failure).

The disease may persist for 3–4 weeks in severely ill cats, and shedding may occur for up to 6 weeks.

Diagnosis

History and physical examination will be important suggestive factors but there are numerous causes of acute diarrhea in young cats.

Routine hematology and serum biochemistry profiles are typically unremarkable in the early phases, but will show evidence of dehydration, electrolyte imbalance and leukocyte abnormalities in the later stages. **Cats with bacteremia/septicemia will have a left shift** (greater than 500 band neutrophils found on hemogram) or **degenerative neutropenia** (neutropenia in the presence of toxic changes and without evidence of band cells) and may have hepatic or renal compromise as a result of the endotoxemia.

Definitive diagnosis depends on the isolation of *Salmonella* spp. from properly cultured fecal samples or from blood cultures in cats with bacteremia.

ETHYLENE GLYCOL*

Classical signs

- Vomiting occurs after ingestion due to the direct toxicity of ethylene glycol to the GI tract.
- 24–36 h later, lethargy, vomiting, anorexia and depression occur secondary to renal failure.

Pathogenesis

Automobile antifreeze is the most common source of this toxin for small animal poisoning.

Other sources of ethylene glycol include household cleaning products, lacquers and cosmetics.

Ethylene glycol itself is not nephrotoxic, but is an alcohol that results in **signs of stupor, vomiting and weakness**. It is the **metabolism of ethylene glycol to glycoaldehyde, glyoxylic acid, glycolate and oxalic acid that result in the development of acute, oliguric to anuric renal failure** and ultimately death due to direct toxic effects on the nephron.

Renal injury is also a result of deposition of calcium oxalate crystals in the tubular lumen that lead to tubular obstruction and back leak, however, this is less a cause of death than the other mechanisms.

Clinical signs

Initial signs occur within the first few hours following ingestion and include **vomiting, hypersalivation, ataxia and depression**, which are associated with alcohol intoxication.

If the cat is not treated at this stage, metabolism of the ethylene glycol leads to formation of severe metabolic acidosis, oxalate crystalluria and renal shutdown (acute anuric renal failure) within 24–48 hours.

Signs of ethylene glycol poisoning at this stage mimic those of all causes of acute, anuric renal failure and include vomiting, depression to obtundation, severe dehydration and hypovolemia due to vomiting, and lack of urine production once dehydration is corrected.

In the end stage of anuric renal failure, cats often become over-hydrated, with the development of pulmonary edema, peripheral edema and ascites.

Once the development of anuric renal failure has begun, the prognosis is grave, and only dialysis and renal transplantation will save the cat.

Diagnosis

The diagnosis is often made based upon a **history of known or suspected exposure** to/ingestion of ethylene glycol (antifreeze). In cats, amounts of less than a teaspoon can be potentially fatal.

When there is no known exposure to ethylene glycol and the animal is presented in acute renal failure, an index of suspicion is required to make the diagnosis. **Presence of oxalate or hippurate crystals** in the urine of a cat in acute renal failure is highly suggestive of ethylene glycol ingestion.

Definitive diagnosis can be made by **toxicologic analysis of serum** for presence of metabolites of ethylene glycol in the blood or by using a commercially available blood test kit for use in clinical practice settings that detects the presence of ethylene glycol in blood. This test is most effective when used within 12–24 hours of ingestion.

Cats with ethylene glycol toxicity will have markedly increased serum osmolality, a profound metabolic acidosis (with increased anion gap) and calcium oxalate crystalluria to support the diagnosis.

Differential diagnosis

Exposure to **poisonous plants**, especially the lily family which cause acute renal failure.

Ketoacidotic diabetes mellitus, acute renal failure due to infectious or other causes, hepatic disease/failure are important extra-intestinal differentials.

In older cats, neoplasia should be considered.

Intussusception or foreign body obstruction should be considered **in young cats**.

Treatment

Immediately **evacuate the stomach** by inducing emesis to prevent further absorption of the toxin.

If the ingestion just occurred, administer activated charcoal to reduce additional absorption of the ingested material from the GI tract. However, absorption of ethylene glycol is within minutes, so once clinical signs are present, this is not indicated.

If the cat has signs of acute toxicity and exposure is > 2–3 hours prior to presentation, administration of 20% ethanol (5 ml/kg IV q 4 h) is recommended to compete with the alcohol dehydrogenase and slow metabolism of the ethylene glycol to its nephrotoxic metabolites.

In acute toxicity, give 4-methylpyrazole (4-MP), an ethylene glycol antagonist, which, if administered within 4 hours of ingestion, will prevent metabolism of the drug to its toxic metabolites. Between 4–12 hours after ingestion, 4-MP will be less effective, but still may help reduce the severity. After 12 hours, the prognosis is grave. In general, 4-MP is less effective in cats than in dogs.

Management of acute renal failure is essential, and includes correction of fluid deficits using isotonic fluids, correction of electrolyte disturbances and correction of metabolic acidosis with cautious use of sodium bicarbonate therapy.

Close assessment of urine output is essential to prevent fluid overload. An indwelling urinary catheter should be placed to measure output, and furosemide and mannitol should be administered to promote increased diuresis and urine flow.

In cats with oliguric or anuric renal failure, hemodialysis may ultimately be required to manage the renal failure.

Prognosis

The prognosis is **guarded** if the intoxication is immediately discovered, the material removed from the GI tract and preventative measures instituted to control metabolism of the poison.

In cats **that are presented greater than 4–6 hours after ingestion** the prognosis is **very guarded to poor**, and in cats already **showing signs of anuric renal failure** the prognosis is **grave**.

FELINE PANLEUKOPENIA VIRUS*

Classical signs

- **Anorexia, vomiting, depression, weakness and dehydration** are commonly observed signs.
- Disease is most severe in kittens, and has a high mortality rate.
- **Diarrhea** is less frequent and occurs later in the course.

Pathogenesis

The disease is caused by a **feline parvovirus which only infects rapidly replicating cells** (e.g. intestinal epithelium, granulocytes, and if infected early in life, granular cells of the cerebellum and developing retina).

In **rapidly dividing cells**, the virus causes cell cytolysis thus destroying the affected cell populations.

- In the **bone marrow**, cells of the white cell series are affected, and lymphoid tissue throughout the body undergoes necrosis, resulting in a rapid and severe decrease in white cell numbers that eventually results in **panleukopenia**.
- In the **GI tract**, the **crypt cells are destroyed** resulting ultimately in the destruction of the intestinal epithelium. This leads to **malabsorption, vomiting and diarrhea, and secondary bacteremia**. The colon is less affected because of the slower mitotic rate of colonocytes.

If the **queen is infected while the kittens are in utero**, the kittens will be **stillborn, aborted, or fetal death will result in resorption**, depending upon the stage of the pregnancy. **Young kittens infected during the neonatal period (< 10 days after birth) will have cerebellar hypoplasia (ataxia, hypermetria) and retinal dysplasia (blindness)**.

In **unvaccinated feline populations**, the disease is associated with **very high morbidity and mortality**, and is highly infectious. However, **vaccination is extremely effective in preventing the disease**, and

cats properly vaccinated against panleukopenia virus are probably immune for life.

Clinical signs

Anorexia, depression and extreme lethargy are very common clinical signs initially. These are followed by **vomiting, diarrhea and dehydration** that can be quite severe. Typically, persistent vomiting, which may be bile-stained, occurs as an early sign in most cats, and can be associated with acute dehydration.

Diarrhea occurs later in the course of the disease and is not present in all cats.

In the **acute form**, most kittens are **febrile**, and may become **septicemic**. In the late stages of the disease, the cat will almost always become hypothermic.

Kittens affected with **cerebellar hypoplasia** will be **ataxic, hypermetric, dysmetric, incoordinated and have a base-wide stance**. These kittens will be otherwise normal both neurologically and physically at birth, and clinical signs will not be apparent until 3–4 weeks post-partum when they begin to walk.

Most affected animals will be kittens that have come from an unvaccinated queen or from a premise with many unvaccinated cats in close proximity. The highest morbidity and mortality is in kittens 3–5 months of age.

Sudden death may be observed in kittens anywhere from 4 weeks to 12 months of age.

Diagnosis

The **history, signalment and physical examination findings** are all suggestive of the disease.

However, in its milder forms, the disease can be difficult to differentiate from many gastrointestinal diseases, including salmonellosis.

The **most consistent hematologic abnormality is panleukopenia**, with leukocyte counts typically ranging between 500–3000 cells/ μ l. The **nadir in the white cell count occurs 4–6 days after infection**. Because the disease is so acute, serum biochemistry values are usually within normal limits. There is a correlation between the degree of leukopenia and severity of the illness.

There is no licensed ELISA test kit for the feline parvovirus, however, the **canine test kit will detect the**

feline parvovirus in feces as well. The test is very sensitive and specific (> 90%) for parvoviruses. **False positives may occur following vaccination with modified live virus vaccines, and false negatives may occur early in the course of disease** (days 1–3 post-infection) before viral shedding is actively occurring.

Serologic testing is still an important diagnostic test for feline panleukopenia, but it **requires paired samples (acute and convalescent) that show a rise in titer to be definitive**, and therefore is the most useful in cat-tery situations to help plan preventative management programs.

Other tests that can be performed include virus isolation on feces or tissues and electron microscopy for detection of virus particles in the feces.

Differential diagnosis

In its severe form, few diseases mimic feline panleukopenia. However, milder clinical forms of the disease must be differentiated from all other infectious causes of gastrointestinal disease.

In particular, **feline leukemia virus** can present in some cats with a **panleukopenia-like syndrome**. The diagnosis is made when the cat is tested for feline leukemia virus and found to be positive. Most FeLV cats are also anemic, which helps in differentiation of the two viruses.

Salmonella infections in cats are **usually subclinical**, but when they are severe, can present with a fulminant gastroenteritis. Non-regenerative hypochromic anemia, lymphopenia, thrombocytopenia, neutropenia with a left shift, and toxic leukocytes are found in cats with systemic disease and endotoxemia. A mature neutrophilic leukocytosis is more characteristic of chronic or localized disease.

Rarely, cats with **griseofulvin toxicity** develop a severe leukopenia and GI signs that resemble panleukopenia. In contrast to the viral disease, the leukopenia caused by griseofulvin toxicity is persistent. Griseofulvin toxicity is more likely to occur in FIV-positive cats.

Treatment

Treatment is supportive, but must be **aggressively administered** if it is to be successful. The key is main-

tenance of **fluid and electrolyte balance and prevention of secondary bacterial infection** until the body is able to neutralize the virus with antibody.

Aggressive fluid therapy is the cornerstone of treatment, to correct the dehydration that occurs from vomiting. Attention to the need for **potassium supplementation**, phosphorus, and other electrolytes, such as magnesium, sodium and chloride are essential.

In cats that are unable to eat for 3–5 days, enteral nutrition via a feeding tube or total parenteral nutrition may be a necessary component of the treatment plan. Once the vomiting is controlled, oral alimentation (via nasoesophageal, esophageal or gastrostomy tubes) can be instituted. It is important to **begin nutritional support as soon as possible**, as the GI tract requires this protein to repair the injured epithelium. In addition, further immunosuppression will occur if protein malnutrition occurs in addition to the leukopenia resulting from the viral attack.

Vomiting should be controlled with **antiemetic therapy**. Either **metoclopramide** (0.1–0.2 mg/kg IV q 8 h) or chlorpromazine (0.01–0.025 mg/kg IV) are effective, but it is important when using any phenothiazine antiemetics that you ensure adequate volume expansion so that hypotension is avoided. If gastritis is suspected histamine-2 blockers should also be considered.

Antibiotic therapy is very important in these kittens, as they are at great risk of development of systemic septicemia due to the loss of intestinal epithelium and leukopenia that ensues as a result of the viral infection.

Four-quadrant therapy (Gram positive, Gram negative, anaerobes and aerobes) is important. Combination therapy using ampicillin (10–20 mg/kg q 8 h)/amoxicillin (5–10 mg/kg q 12 h) and either amikacin (6–8 mg/kg q 24 h) or enrofloxacin (2.5 mg/kg q 12 h) are good choices.

Prognosis

Guarded. The older the kitten is when it is infected, the more likely it is to survive the disease. However, in young kittens, mortality will be very high, despite aggressive therapy.

The more severe the leukopenia, the poorer the prognosis, with white cell counts below 500 cells/ μ l having a grave prognosis.

Kittens with mild cerebellar hypoplasia may make suitable pets, as the condition is not progressive.

Prevention

Vaccination is the key to prevention. Current vaccines are very effective in preventing the disease and have been responsible for reducing the incidence of the disease in cats to a very low level. Further, once a cat has been appropriately vaccinated for this disease, the immunity is likely to be life-long.

Maternal antibodies derived from the queen will be protective, but by 12 weeks of age are waning. Kittens should be vaccinated every 2–3 weeks from 6–7 weeks of age until they are 12 weeks of age.

The virus is extremely hardy, and will persist in the environment for years, unless it is killed by appropriate disinfectants (clorox). Before presenting any new cats to a household that has had a cat with panleukopenia in it, the new cat should be vaccinated appropriately (kittens > 12 weeks should have had two vaccinations 2–3 weeks apart).

In catteries where there are panleukopenia outbreaks, control is achieved by vaccination, isolation of susceptible cats from infected cats, and good hygiene measures to prevent further spread.

HYPERCALCEMIA (HYPERCALCEMIA OF MALIGNANCY, HYPERPARATHYROIDISM/CHOLECALCIFEROL POISONING, IDIOPATHIC)

Classical signs

- Anorexia, vomiting, lethargy or muscle weakness and weight loss may be the only outward signs.
- Other signs include polyuria/polydipsia, muscle wasting and shivering/tremors.

See main references on page 245 (The Cat With Polyuria and Polydipsia for details).

Clinical signs

Cholecalciferol poisoning (e.g. Rampage, Quintox) results in vomiting, lethargy and depression within

3 hours of ingestion. Within 2–3 days of ingestion, diarrhea and acute renal failure occur.

Hypercalcemia occurs in a minority of cats with chronic renal failure. Acute decompensation of renal function may lead to acute onset of vomiting.

Hypercalcemia of malignancy, hypercalcemia secondary to hyperparathyroidism and idiopathic hypocalcemia cause **vague clinical signs of greater than 1 week duration.** These signs include anorexia, vomiting, lethargy or muscle weakness and weight loss as the most common signs observed.

Idiopathic hypercalcemia has been reported in cats where acidifying diets were implicated. Idiopathic hypercalcemia was associated with chronic vomiting, weight loss, dysuria, inappropriate urination, anoxeria, pollakiuria and lethargy.

Diagnosis

Primary hyperparathyroidism (HPT) is much rarer in cats than hypercalcemia of malignancy and hypercalcemia of malignancy is rare in cats compared to dogs.

A history of potential exposure to rodenticides containing cholecalciferol is valuable if hypercalcemia is associated with acute vomiting and depression.

The most common neoplasms associated with hypercalcemia are hematopoietic (lymphoma, multiple myeloma), solid tumors with bony metastasis, e.g. squamous cell carcinoma, and apocrine cell adenocarcinoma of the anal sac, which is rare in cats.

Hematologic abnormalities in HPT and cholecalciferol poisoning are **uncommon**, but non-regenerative anemia is commonly associated with chronic renal failure.

The **serum chemistry abnormalities include hypercalcemia** (serum total and ionized), **hyperphosphatemia (cholecalciferol)**, **renal failure and elevated liver enzyme activities** (hypercalcemia of malignancy, cholecalciferol).

Phosphorus is elevated in renal failure and cholecalciferol toxicity but normal or decreased for all other causes of hypercalcemia.

Azotemia is also common with hypercalcemia due to the development of nephrocalcinosis or other renal damage.

Imaging studies are very important in **ruling out occult neoplastic disease** as the source of the hypercalcemia.

Serum PTH is elevated with HPT and chronic renal failure, but low with neoplastic diseases, idiopathic hypercalcemia and cholecalciferol toxicosis.

PTH-related protein (PTHrP) is decreased with HPT and cholecalciferol toxicity, but increased with neoplasia and chronic renal failure. PTHrP is usually undetectable in idiopathic hypercalcemia.

Ionized calcium levels may be helpful in ruling out renal failure as a cause of hypercalcemia (e.g. ionized calcium is low in renal failure and elevated in all other hypercalcemic diseases).

Idiopathic hypercalcemia is associated with an increased serum total calcium or serum ionized calcium concentration, or both. Serum phosphorus, albumin and 25-hydroxycholecalciferol (vitamin D3) concentrations are normal in cats with idiopathic hypercalcemia.

PHYSALOPTERA

Classical signs

- Vomiting.
- Worms may be present in vomitus.

Pathogenesis

Physaloptera spp. are spirurid worms that **are transmitted to cats by ingestion of infective larvae present in coprophagous beetles, bugs or in transport hosts such as birds, rodents or frogs**. They are **most prevalent in the southern United States**, where conditions are favorable for the intermediate/transport hosts of these parasites to persist.

Physaloptera spp. **are small (2.5–5.0 cm)** worms with cuticular collars and spiraled tails that **cause acute gastritis even when they are present in very small numbers**.

Clinical signs

Vomiting is typically the only clinical sign, and worms may be present in vomitus. In most cases, **cats are otherwise completely healthy**, vomiting is inter-

mittent, and rarely associated with severe bouts of vomiting, dehydration or illness.

Diagnosis

Hematology and serum biochemistry profile are within normal limits.

Fecal examination may expose the ovoid to ellipsoidal, thick-shelled, **larvated eggs** (30–40 × 20 µm), but **this is not a reliable means of making the diagnosis**.

Radiographs will be unremarkable, but **endoscopic examination will allow visualization of the worms**.

Oftentimes, the diagnosis, if not confirmed by direct visualization of worms in stomach via endoscopy, is made by **response to appropriate treatment**.

Differential diagnosis

Other infections with spirurid worms, e.g. *Spiroceri*, will produce similar eggs and occasionally cause vomiting.

Gastritis, gastric trichobezoars and dietary indiscretion or food intolerance should all be considered, because the signs are similar (mild, intermittent).

Treatment

Anthelmintics such as **fenbendazole** (25–50 mg/kg PO q 24 h for 3–5 days) or **pyrantel** which are effective in the stomach will be curative.

Cats that are on **monthly heartworm preventative-containing** ivermectin plus pyrantel (Heartguard) will have effective control of any infection or re-infection. It is not known whether selamectin or milbemycin are effective (at the heartworm-preventative dose) in preventing or treating physaloptera.

Consider **histamine-2 blockers** (e.g. ranitidine or famotidine) or **sucralfate to reduce gastritis**, if the signs are severe.

Prognosis

Good. **Response to treatment is excellent** and because there is no migration of parasites beyond the stomach

wall, re-treatment is unnecessary unless the cat is re-infected.

Prevention

Prevent ingestion of the carrier beetles, bugs or transport hosts (birds, rodents).

ASCARIDS

Classical signs

- Abdominal distention, colicky abdominal pain.
- Poor body condition, not nursing or eating.
- Diarrhea or abnormal feces.

See main reference on page 717 for details (The Cat With Signs of Acute Small Bowel Diarrhea).

Clinical signs

The most common signs of roundworm infection in kittens are **abdominal distention, colicky abdominal pain, poor body condition/hair coat and diarrhea or soft feces.**

Vomiting worms or vomiting due to masses of worms obstructing passage of ingesta is **very uncommon** in cats (compared to dogs), as is the clinical sign of coughing due to larval migration.

Adult cats develop innate immunity and thus, unless they are immunocompromised, rarely have clinical signs of intestinal roundworm infection.

Diagnosis

Fecal flotation will reveal spherical egg (*Toxocara cati*) with pitted outer shell membrane containing a single zygote, and approximately 75 µm in size. *Toxascaris* is also an ovoid egg of similar size but has a smooth shell.

Some cats may have a **peripheral eosinophilia**, suggestive of parasite infestation, but **this is not a consistent finding** nor one that is specific for roundworm infection.

Treatment

Anthelmintics such as **pyrantel** (5–10 mg/kg PO once) or **fenbendazole** (25–50 mg/kg PO q 24 h for 3 days)

must be given to all cats/kittens that are housed together.

Pyrantel is not absorbed from the GI tract to any appreciable amount and thus is **the safest to use in kittens under 4–6 weeks of age.**

Repeat treatment in 3–4 weeks to effectively kill prepatent stages.

Reinfection is prevented by **good sanitation.**

Roundworms have **zoonotic potential** (visceral or ocular larval migrans), although this is not as great a problem as the canine roundworm.

OLLULANUS TRICUSPIS

Classical signs

- Vomiting.

Pathogenesis

Ollulanus tricuspis is a nematode parasite infecting the **gastric glands of cats** resulting in **acute gastritis and vomiting.** The life cycle of the parasite is direct.

The life cycle is completed in the cat with **infection of other cats occurring via ingestion of parasite-containing vomitus.**

The parasite is **found worldwide**, but there have only been sporadic reports of infection in the United States. **Free-roaming and colony cats are more likely to be exposed and infected than are household cats.**

Clinical signs

Vomiting is the most common clinical sign, and occasionally the worms may be found in the vomitus.

Anorexia and weight loss may be observed in severely parasitized cats.

Infection occurs **primarily in adult cats in colonies or high-density environments** (catteries, shelters or homes with many cats living together) that have the opportunity for close intimate contact necessary for parasite transmission.

Diagnosis

Detection of the parasites can be difficult because **no ova are released** and the **larvae and adults are digested during normal passage through the gastrointestinal tract**. **Gastric lavage, examination of vomitus or endoscopic examination** are the recommended procedures for diagnosis of these parasites.

Differential diagnosis

The major differentials are *Physaloptera* spp. and larval forms of *Aelurostrongylus* spp. (the lung worm), which may be coughed up and swallowed.

Treatment and prognosis.

Little is reported about treatment regimes for *Ollulanus* spp. but it is likely that **fenbendazole** (25–50 mg/kg PO q 24 h for 3–5 days) would be effective against these nematodes.

Prevention

Keeping cats from contacting/ingesting infected vomitus by housing cats indoors, or by isolating cats that are known to be infected, is an effective means of prevention.

PERITONITIS

Classical signs

- Abdominal pain, lethargy, ascites, anorexia and fever are common signs.
- Vomiting or diarrhea are less frequent, but often observed in more severe cases.

See main reference on page 467 for details.

Clinical signs

Abdominal discomfort/pain, lethargy and anorexia are common signs and must be differentiated from FIP or other causes of abdominal effusion.

This is a **rare clinical problem in cats**, and occurs **most often secondary to intestinal perforation** (e.g. string foreign body).

Vomiting or diarrhea are not common signs, but when they occur they are often associated with severe disease.

Fever and abdominal distention/effusion may also be present.

Diagnosis

Abdominal radiographs (plain, contrast) and ultrasonography will suggest peritonitis and may pinpoint location or cause (ruptured gallbladder, pancreatitis, bowel rupture). **Radiographic findings** consistent with peritonitis **include loss of abdominal detail** that is often focal, but may include the entire abdomen. **Ultrasound can readily detect any fluid accumulation in the peritoneal space** that is occurring as a result of the inflammatory process.

Definitive diagnosis confirming the presence of peritonitis can be obtained by **abdominocentesis or diagnostic peritoneal lavage and cytologic/bacteriologic examination of fluid**.

Cytology of peritoneal fluids consistent with peritonitis is characterized by **increased cellularity** (primarily neutrophils, with or without intracellular bacteria if the process is septic), and protein and is often described as an exudate. **The key to differentiating peritonitis from FIP or neoplastic causes of abdominal effusion is examination of cell types**, as FIP is typically pyogranulomatous, but with a low to moderate cell count, and neoplastic infiltrates will most commonly be lymphocytes or carcinomatous.

Hematology is non-specific, and usually shows **an inflammatory leukogram**, stress leukogram or sequestration of neutrophils (neutropenia).

SEPTICEMIA/BACTEREMIA/ENDOTOXIC SHOCK

Classical signs

- Generalized depression, fever or hypothermia.
- Tachycardia/tachypnea and signs of shock.
- Vomiting is not consistently present but does occur.

Clinical signs

This is a **rare clinical problem in cats**.

Cats with septicemia are severely depressed, may be febrile or hypothermic (although this is often a poor prognostic sign), and will have **systemic signs of shock** (tachycardia, tachypnea, decreased capillary refill).

Other signs, especially in cats with septic shock, may include **vomiting or bloody diarrhea and anorexia**.

There is **no particular age, breed or sex predilection to development of septicemia or endotoxemia**, but cats with severe infections, immunocompromise (e.g. FeLV or FIV+) or stress may be predisposed.

Diagnosis

Hemogram may reveal neutrophilia progressing to neutropenia and thrombocytopenia. There may be hyperglycemia early, progressing to hypoglycemia later. Hyperkalemia, elevated liver enzymes and azotemia are common, and bacteriuria may be present.

Blood culture is indicated in patients with suspected bacteremia to confirm the infection exists. Blood cultures should be obtained in a sterile manner from multiple venipuncture sites (if possible), and, ideally, samples should be obtained over several hours (every 2–4 hours collect a new sample) to maximize the opportunity to obtain a positive sample. **Urine culture** is also helpful in cases with renal seeding of the infection.

Imaging studies are important in further evaluating the extent of illness and may help identify a focus of infection (radiographs of chest, abdominal ultrasound).

VESTIBULAR DISEASE

Classical signs

- Head tilt, circling, falling.
- Infrequent vomiting and anorexia may occur.

See main reference on page 933 for details.

Clinical signs

Occasionally cats with an acute onset of vestibular disease vomit, but signs of **head tilt** (away from the affected

side with peripheral vestibular disease and towards the affected side with central vestibular disease), circling, falling, ataxia, and horizontal (more typical for peripheral disease) or rotary (more typical of central disease) **nystagmus** are much more prominent than GI signs.

Vomiting or anorexia occur due to disequilibrium effects, **but are not common clinical signs of cats with vestibular disease**. Vomiting is usually only seen in the first 1–2 days after onset and is infrequent (1–2 single episodes in the first 48 hours).

Vomiting is more common with peripheral vestibular disease or idiopathic vestibular syndrome, and is rarely associated with central vestibular disease.

Altered consciousness, postural deficits or other cranial nerve deficits are not typically seen.

Diagnosis

History and physical examination findings are highly suggestive of vestibular disease.

Evaluation of cats with vestibular disease should include a **minimum data base** (hematology, serum chemistry profile and urinalysis), otoscopic examination, radiographs of the tympanic bulla. **CT of the bulla and area of the 8th nerve are also important diagnostic tests.**

Major causes of vestibular signs include: idiopathic vestibular syndrome (diagnosis of exclusion), otitis media/interna (diagnosis by myringotomy, culture, radiographs or CT), middle ear polyps (CT), trauma, neoplasia (radiographs or CT), endocrine diseases causing neuropathies (diabetes mellitus and hyperadrenocorticism) and toxic insults (aminoglycoside antibiotics, topical chlorhexidine or iodophor compounds).

A minor cause of vomiting is **motion sickness** from the vestibular dysfunction during car rides.

PHARMACOLOGIC TOXICITY (NON- STEROIDAL ANTI-INFLAMMATORY DRUG (NSAID) TOXICITY)

Classical signs

- Anorexia.
- Vomiting, with or without hematemesis.
- Abdominal pain.
- Diarrhea, with or without melena.

Pathogenesis

Cats are much more sensitive to the effects of NSAIDs because they have a reduced capacity to metabolize these drugs in their liver (**poor glucuronyl transferase activity**).

The adverse consequences of NSAID ingestion on the gastrointestinal tract are due to multifactorial effects on the tissue, including direct toxicity to the epithelium, increased back diffusion of acid, decreased synthesis of prostaglandins, mucus and bicarbonate, decreased mucosal blood flow and microvascular injury.

Acetaminophen (paracetamol), which is an analgesic, antipyretic drug sometimes included in the NSAID group, does not have the same toxic effects on the gastrointestinal tract. In fact, the **toxicity of acetaminophen in cats is very high**, but the toxic effect is **due to the oxidant effects on red cells causing methemoglobinemia, hemolysis, Heinz body anemia and hepatotoxicity**.

Clinical signs

Cats that have **ingested aspirin, ibuprofen or related NSAIDs** are likely to show **acute signs of GI upset** which may include anorexia, vomiting (with or without hematemesis), or abdominal pain.

Chronic ingestion of these drugs may result in **inappetence, vomiting or diarrhea** (with or without melena).

Acute overdoses of NSAIDs, especially ibuprofen, naproxen, etc., may result in acute oliguric or anuric renal failure.

Cats that have ingested **acetaminophen** (paracetamol) will have **hypersalivation and vomiting early**, followed by development of **cyanosis** (methemoglobinemia) and **facial pruritus** within a few hours. Later, untreated cats may develop **edema of the face and paws**, and will ultimately develop liver failure if they survive the initial toxicity.

Diagnosis

History of ingestion and appropriate clinical signs are usually enough to support NSAID-induced gastritis or ulceration as the cause of the GI signs.

Typically, the **hematology and serum chemistry profile will be normal with NSAIDs other than acetaminophen**, unless the cat has severe erosions or ulcers that have been bleeding. In those cases, **anemia of blood loss** will be present, and in some cases can be quite dramatic.

Cats may present in **acute, oliguric or anuric renal failure**, and in these cats, severe azotemia, hyperphosphatemia, hyperkalemia and severe metabolic acidosis may be present.

Confirmation of gastritis, gastric erosions or ulcers requires imaging studies. The most definitive means of diagnosis is via **endoscopy** whereby through both visualization and histopathology the diagnosis can be confirmed. **Severe ulcers** can also be visualized on **contrast radiographs or via ultrasound**.

Differential diagnosis

Other differentials to consider are acute pancreatitis, mechanical obstructions, infectious agents such as *Helicobacter* that cause acute gastritis and acute gastritis/gastric disease of other causes.

Treatment

Stop further ingestion of NSAIDs, and **remove as much of the drug from the GI tract as possible** (lavage, induce vomiting, administer activated charcoal). This is especially important if the ingestion was an accidental overdose and has occurred within the past 2–4 hours, although gastric lavage is most useful if performed within 1 hour of ingestion.

In cases where the signs of acute gastritis or gastric ulceration are associated with **blood loss, a transfusion may be necessary**. This is especially true if perforation has occurred and immediate surgical intervention is necessary.

Treatment is non-specific, as with any gastritis or ulcer patient: administer **histamine-2 blockers** (ranitidine or famotidine), **mucosal cytoprotectants** (sucralfate), and antiemetics (metoclopramide) if indicated. If the cat is dehydrated from the vomiting episodes, **fluid therapy** and possibly potassium supplementation will also be indicated.

Prognosis

Good with appropriate therapy and aggressive management unless there is gastric or duodenal perforation, or

acute renal failure has developed before the cat presents to the hospital.

Prevention

NSAIDs should be used cautiously in cats and cats that receive these drugs require frequent careful evaluation.

Accidental exposure to medications not intended for cats should be prevented.

Misoprostil (a prostaglandin agonist) has not been evaluated in cats as a gastric protectant.

TOXICITY (CHEMOTHERAPY DRUG-INDUCED VOMITING)

Classical signs

- Anorexia.
- Vomiting, with or without hematemesis.
- Abdominal pain.
- Diarrhea, with or without melena.

Pathogenesis

Nausea and vomiting are **frequent complications of cancer chemotherapy** drugs. There are many different chemotherapeutic agents and they all vary in their effects; however, **cisplatin, doxorubicin, vincristine and methotrexate commonly cause gastrointestinal side effects.**

The cause of the vomiting may be due to **direct stimulation of the CRTZ or toxicity to the gastrointestinal tract** by inhibiting the rapidly dividing stem cells that populate the GI epithelium. **Vincristine** does not have direct cellular toxicity, but may induce **ileus**, which can result in vomiting, diarrhea or both.

Clinical signs

The **most common GI signs observed with cancer chemotherapy drugs are non-specific**, and include anorexia, vomiting, with or without hematemesis, abdominal pain due to bloating from ileus, diarrhea, pyrexia due to development of secondary infections, or lethargy.

Diagnosis

A history of cancer chemotherapy and appropriate clinical signs are often sufficient to make a presumptive diagnosis. However, it is always important to bear in mind that the **vomiting could be unrelated to the drugs**, and represent an additional problem associated with the disease or a new problem that is unrelated to the disease.

Differential diagnosis

Vomiting may be due to the neoplastic disease itself.

Treatment

Vomiting associated with cancer chemotherapy can be difficult to manage in some situations. The **most effective anti-emetic drugs** for this purpose are the drugs that block the effects on the CRTZ, such as **metoclopramide**. In very severe cases, ondansetron or dolasetron are other alternatives.

In animals that have uncontrollable vomiting, the treatment regimen may have to be altered to allow the cat to have reasonable quality of life.

Prognosis

Guarded, primarily because of the presence of cancer requiring chemotherapy for treatment or control.

ANESTHETIC AGENT (XYLAZINE)

Classical signs

- Lethargy, sedation.
- Vomiting.
- Bradycardia.
- Hypotension.

Pathogenesis

Xylazine is an **alpha-2 adrenergic antagonist** sedative-anesthetic that will induce emesis in cats within minutes of administration due to direct effects on the CRTZ.

Clinical signs

Clinical signs associated with xylazine administration are either associated with the **sedation effects** (which also include some profound cardiovascular effects such as bradycardia and hypotension) or **vomiting**.

Diagnosis

Vomiting is such a common side effect following administration of xylazine that the **drug is used frequently to induce vomiting**.

Treatment

There is no need to treat vomiting associated with xylazine administration since it is self-limiting.

ENCEPHALITIS/MENINGITIS

Classical signs

- Neurologic signs predominate and depend on the location.
- Ataxia, dementia, nerve deficits, or cervical pain may be evident.
- Vomiting is often associated secondary to the systemic illness (fungal, bacterial, protozoal or viral) that is causing the disease.

See main reference on pages 829, 859 for details (The Cat With Seizures, Circling and/or Changed Behavior and The Cat With Tremor or Twitching).

Clinical signs

Neurologic signs predominate and depend on the location in the brain that is affected. If the rostral fossa is affected, seizures, circling, pacing, personality change, and decreased responsiveness are common. If the caudal fossa is affected, depression, head tilt, facial paralysis, incoordination and other brainstem abnormalities are noted.

Vomiting is uncommon, but is often associated with the presence of systemic illness (fungal, bacterial, protozoal or viral) that has also affected the CNS.

Other clinical signs, such as fever, depression, weakness, hypotension or shock may be observed with cats that are systemically ill.

Some cats with only central nervous system disease will have a normal physical examination, with only neurologic deficits or abnormalities found with careful assessment.

Diagnosis

Hematology and serum biochemistry profiles help define **systemic or infectious causes** (e.g. viral, bacterial or fungal causes).

Radiographs of cervical, thoracic and lumbar spine are used to **rule out diskospondylitis** or evidence of **neoplasia**.

Cerebrospinal spinal fluid analysis (cytology and culture) may be essential for the diagnosis, but caution should be exercised during CSF collection due to possible elevated intracranial pressure which could cause tentorial herniation.

Imaging studies (**MRI and CT scanning**) are important means of lesion localization and identification, but are not universally available.

ARSENIC POISONING

Classical signs

- Vomiting, diarrhea, anorexia and depression occur early.
- Arsenic toxicity eventually results in hepatic and renal failure (depression, anorexia, vomiting and diarrhea along with oliguria or anuria, or icterus and ascites).

Pathogenesis

Arsenic may be present in herbicides, insecticides, wood preservatives and treatments used for blood parasites (including heartworm).

Cats appear to be more commonly poisoned than dogs, possibly due to consumption of prey or insects killed by the toxin.

Toxicity may be acute, resulting in immediate and life-threatening illness, **or chronic**, and more insidious.

Clinical signs

Acute arsenic toxicity is associated with vomiting, diarrhea or hematochezia, abdominal pain, weakness

and shock-like signs (e.g. rapid, weak pulses, prostration, subnormal body temperature and collapse).

Chronic, low-grade exposure to arsenic may be impossible to detect clinically, **as anorexia is the only consistent sign**.

Diagnosis

Historical information of exposure to heavy metals is a very important means of getting the diagnosis, however, such information is not always known.

The **hemogram and serum chemistry profile** will be **unremarkable** when the cat presents with signs of gastrointestinal disturbance.

Arsenic poisoning also causes **hepatocellular necrosis**, which will be evidenced by elevations in serum alanine aminotransferase and alkaline phosphatase enzymes. Other abnormalities may include elevations in bilirubin, bile acid values and decreases in albumin (end stage).

Nephrotoxicity associated with arsenic poisoning is also associated with isosthenuria, azotemia and eventually oliguria/anuria.

Definitive diagnosis is made by measurement of **arsenic concentrations in urine (acute), kidney, liver, vomitus or hair (chronic)**.

Differential diagnosis

Other heavy metal toxicoses (e.g. lead), ingestion of caustic agents, or ingestion of poisonous plants should be considered.

Acute renal failure due to other infectious or metabolic causes may mimic arsenical nephrotoxicity.

Treatment

The first step is to **remove the source of arsenic** if possible. If the toxin has been ingested, **lavage the stomach and administer activated charcoal** to minimize further absorption of the agent from the GI tract.

Promote excretion of the toxin from the body by **starting fluid diuresis and administration of BAL** (British anti-Lewisite, dimercaptol) at a dose of 2.5–5 mg/kg in oil, IM, q 4 h for 2 days, then q 12 h up to 10

days. BAL toxicity may occur (e.g. vomiting, tremors or convulsions), which will require cessation of the drug.

DMSA (dimercapto succinic acid) is often used in children, because it is less toxic than BAL, but its effectiveness in cats has not been evaluated.

If the cat is in acute, oliguric or anuric renal failure, dialysis may be necessary.

ANTRAL PYLORIC HYPERTROPHY/STENOSIS

Classical signs

- **Vomiting is the primary sign, and usually is observed several hours after eating.**
- **Projectile vomiting will be observed if the pylorus is obstructed.**

See main reference on page 694 for details of The Cat With Signs of Chronic Vomiting.

Clinical signs

Vomiting is the most common sign. In adult cats, the vomiting occurs as a chronic problem, but in kittens may occur as acute vomiting in a kitten that is just beginning to consume solid foods.

In **congenital pyloric stenosis**, the kittens begin to vomit shortly after they are started on solid food.

Acquired pyloric hypertrophy in adult cats has a more variable presentation, but is usually associated with intermittent vomiting of digested food several hours after consumption.

If the pylorus is completely obstructed the **vomiting may be projectile**.

Chronic intermittent vomiting and gastric distention may lead to **gastroesophageal reflux or esophagitis** which may be associated with regurgitation or inappetence and the resulting weight loss.

Diagnosis

History and signalment are suggestive of a gastric emptying disturbance.

Hemogram, serum chemistries and urinalysis are **typically unremarkable**.

Survey radiographs of the abdomen may be **normal or show gastric distension**. Contrast radiographs may identify **hypertrophic gastric mucosa or a narrow gastric outflow pathway** (“beak sign”).

Ultrasonography may be able to detect a thickened pyloric antrum.

Fluoroscopy or scintigraphy can be used to evaluate gastric peristalsis and emptying, but are not universally available.

Gastric endoscopy may be normal or may reveal thickened folds of mucosa, the pyloric antrum may not insufflate normally, or the pylorus may be too stenotic to allow passage of the endoscope through the orifice.

Definitive diagnosis requires an exploratory laparotomy and histopathologic examination of tissue.

DYSAUTONOMIA

Classical signs

- Vomiting or regurgitation, diarrhea, anorexia and constipation are the primary GI signs.
- Dry eyes, mucous membranes and nose may be observed.
- Bradycardia.
- Dilated pupils.

See main reference on page 792 for details (The Constipated or Straining Cat).

Clinical signs

Dysautonomia is generally seen as an **acute onset of depression, anorexia, constipation, dry external nares and mouth, reduced tear production or dry eye, bradycardia, regurgitation** (due to megaesophagus) and **dilated pupils**.

Other clinical signs that may be present, but are less common, include anal areflexia, fecal incontinence, and dysuria or urinary incontinence.

The disease occurs **primarily in Great Britain**, but sporadic cases have been reported in the United States and elsewhere.

Most affected cats are young (< 3 years old) and have no breed or sex predisposition.

Diagnosis

In general, routine **hemogram, biochemistry tests and urinalysis are within normal limits**.

Megaesophagus may be observed on routine thoracic radiographs.

Constipation or obstipation may also be detected on abdominal radiographs.

Schirmer tear tests will be abnormal (< 5 mm) in most animals.

Ophthalmic pharmacology testing may be helpful, but is not 100% reliable in detecting dysautonomia. However, in dysautonomic cats phospholine iodide will have no miotic effect, and pilocarpine will have an exaggerated miotic effect.

Low plasma or urinary catecholamine concentrations also confirms sympathetic insufficiency.

31. The cat with signs of chronic vomiting

Debra L Zoran

KEY SIGNS

- Active elimination of stomach contents through the mouth.
- ± Preceded by nausea, pacing, and salivation.
- Usually digested food or liquid with acidic or neutral pH.
- ≥ 2 weeks duration.

MECHANISM?

- Vomiting occurs when the vomiting center in the medulla or when afferent impulses from the cerebral cortex, chemoreceptor trigger zone (CRTZ), or receptors in the pharynx or abdominal viscera is stimulated.
- Vomiting is an **active process** that must be distinguished from regurgitation.
- Vomitus may consist of undigested food material (if swallowed whole), partly digested or even liquid, and may be clear, yellow (bile stained) or brown (food colored).
- The **pH of vomitus is usually acidic** (pH < 4), but may be neutral (pH 7) if duodenal content is present (bile reflux).

WHERE?

- Chronic vomiting can be caused by **primary gastrointestinal diseases** or by **extra-intestinal diseases** or disorders that may have no apparent association with the GI tract.
- Vomiting is **rarely associated with primary colonic disease**.
- Extra-intestinal causes of vomiting include:
 - Hepatobiliary disease.
 - Pancreatic disease (e.g. pancreatitis, neoplasia).
 - Renal disease causing acute or chronic renal failure.
 - CNS disease (e.g. vestibular disease, encephalitis, seizure disorders, neoplasia).
 - Metabolic diseases (e.g. hyperthyroidism, ketoacidotic diabetes mellitus or Addison's disease).
 - Cardiomyopathy or congestive heart failure.
 - Systemic illness or infection affecting the CRTZ or cortex (e.g. septicemia).

WHAT?

- Primary gastrointestinal diseases that cause chronic vomiting include:
 - Parasites (e.g. *Physaloptera*).
 - Infectious diseases (e.g. *Helicobacter*).
 - Inflammatory diseases (e.g. IBD, gastritis or gastric ulcer disease).
 - Neoplasia.

- Mechanical (e.g. antral pyloric hypertrophy/stenosis, obstruction, intussusception).
- Dietary disturbances (e.g. food intolerance or food allergy).

The **most common causes of chronic vomiting** are: **inflammatory diseases** (e.g. food allergy or IBD), **dietary** (dietary indiscretion or food intolerance), **neoplastic** diseases and **metabolic or extra-intestinal disturbances** (e.g. renal, hepatic or pancreatic disease).

QUICK REFERENCE SUMMARY

Diseases causing signs of chronic vomiting

ANOMALY

- Dysautonomia (p 695)

This is a disorder of the autonomic nervous system resulting in GI signs due to motility disturbances in the esophagus, stomach, small and large intestine. The esophagus and colon are most dramatically affected and thus regurgitation and constipation are more prevalent than other signs. Chronic vomiting may occur or regurgitation may be reported as vomiting. Acute onset of anorexia, depression, dilated pupils without blindness, prolapsed third eyelids and bradycardia are common.

MECHANICAL

- **Foreign bodies* (p 688)**

Foreign bodies are often associated with an acute onset of vomiting, but string ingestion may cause chronic intermittent vomiting when the obstruction is incomplete or motility disturbances are intermittent.

- **Antral pyloric hypertrophy/stenosis (p 694)**

Acquired or congenital thickening of the pyloric tissue may result in vomiting due to motility disturbances, obstruction of outflow or both. Vomiting usually occurs several hours after eating and may be projectile. Rarely stenosis is functional with no evidence of thickening.

- **Intussusception (p 692)**

Intussusception is usually associated with acute onset of severe vomiting, but sliding, intermittent or incomplete intussusception may have chronic, intermittent vomiting.

METABOLIC

- **Hyperthyroidism** (p 670)**

Intermittent vomiting occurs in conjunction with weight loss, polyphagia and polyuria. Other signs include hyperactivity, irritability, poor grooming habits and large, bulky or mucoid feces.

- **Hepatic diseases (hepatic lipidosis, cholangitis, hepatic cirrhosis, portosystemic anomalies, etc.)** (p 674)**

Vomiting is often associated with hepatic diseases or failure (of any cause). Other signs of hepatic disease include fever, weight loss, icterus, anorexia and lethargy. Cats in severe hepatic failure may show signs of hepatoencephalopathy, including drooling, apparent blindness, stupor, pica or altered behavior.

continued

continued

- **Chronic renal failure* (p 680)**

Intermittent vomiting is due to the effects of azotemia and hypergastrinemia on the gastric mucosa. The most common signs are polyuria, polydipsia, weight loss and decreased appetite.

- **Congestive heart failure* (p 689)**

Intermittent vomiting often occurs in the late stages of the disease, in addition to the signs of cardiovascular and respiratory distress or failure.

- **Diabetes mellitus* (p 681)**

One third of cats with diabetes have a history of vomiting. Cats with severe ketoacidosis secondary to unregulated diabetes mellitus often present with signs of anorexia, weight loss and a sudden onset of vomiting and depression. Polyuria and polydipsia are also present and may have been ongoing for several months prior to the development of the severe signs of illness.

- **Hypercalcemia* (p 683)**

Vomiting often occurs secondary to hypercalcemia. Other clinical signs associated with hypercalcemia include polyuria/polydipsia, anorexia and lethargy. Severe hypercalcemia may cause muscle weakness and dystrophic calcification of tissues (e.g. skin, kidneys, stomach, etc.).

- **CNS diseases (encephalitis, seizure disorders, vestibular disease, neoplasia)* (p 690)**

Vomiting is an uncommon sign of neurologic disease, but chronic intermittent vomiting may be associated with many different diseases of the CNS, and should be considered whenever signs of neurologic disease coexist with vomiting, especially vestibular signs (e.g. head tilt, nystagmus, rolling) or signs suggesting hepatoencephalopathy (e.g. drooling, behavior changes or apparent blindness).

- **Hypoadrenocorticism (Addison's disease) (p 691)**

This is an uncommon endocrine disease in cats that often presents with only vague clinical signs of lethargy, anorexia and weight loss. Vomiting and diarrhea are less common signs in cats, as are changes in the electrocardiogram associated with hyperkalemia.

NEOPLASTIC

- **Intestinal adenocarcinoma** (p 677)**

Anorexia, weight loss and lethargy are the most common signs, but vomiting often occurs when the tumor reaches a size that causes motility disturbances or bowel obstruction. The most common location is the distal small intestine.

- **GI lymphosarcoma** (p 675)**

This tumor tends to be more infiltrative and may involve large segments of small bowel, stomach or colon. Signs range from anorexia and weight loss to vomiting or diarrhea, depending on the location of the tumor.

- **Intestinal mast cell tumor* (p 687)**

These tumors are often solitary and primarily affect the distal small intestine, and may cause no signs, other than weight loss and anorexia, until late in the disease when vomiting develops either secondary to tumor size or presence of metastatic foci.

- **Systemic neoplasia (generalized lymphoma, systemic mast cell tumor)* (p 689)**

Vomiting may occur due to neoplasia involving abdominal organs resulting in direct effects, organ dysfunction or the release of vasoactive substances (e.g. mast cell tumor) that cause gastritis. The most common clinical signs associated with neoplasia include anorexia, weight loss or lethargy and usually occur in older cats.

- Other intestinal neoplasia (fibrosarcoma, carcinoids, plasmacytoma, leiomyosarcoma, etc.) (p 693)

The presence of vomiting as a clinical sign depends on the location and size of the tumor(s) and its effects on the local (abdominal) environment.

- Gastrinoma (p 696)

Gastrinoma may cause chronic vomiting due to gastritis or gastric ulcer disease that is unresponsive to routine therapy.

NUTRITIONAL

- **Food intolerance* (p 669)**

Food intolerance is a non-immune-mediated condition associated with intermittent diarrhea or vomiting, with no pattern or association with eating, and it resolves when the food source is changed to omit the offending substance from diet. The clinical significance of food intolerance is unknown relative to other causes of vomiting because of the difficulty in obtaining a definitive diagnosis.

IMMUNOLOGIC

- **Food allergy (dietary hypersensitivity)* (p 667)**

Chronic vomiting is a common clinical presentation in cats with food allergy, and cutaneous signs may also be present.

- **Idiopathic inflammatory bowel disease (IBD)* (p 671)**

IBD causes chronic, intermittent or recurrent vomiting, anorexia, weight loss and diarrhea in cats. It is a diagnosis of exclusion and requires histopathologic confirmation.

INFLAMMATORY

- **Chronic pancreatitis** (p 673)**

Pancreatitis in cats is often **not** associated with vomiting, especially chronic pancreatitis. The most common signs are anorexia, lethargy and weight loss.

- Gastritis/gastric ulcer disease (p 679)

This is usually associated with an acute onset of vomiting, but low-grade gastritis may result in intermittent signs that do not prompt immediate attention.

INFECTIOUS:

Viral:

- Feline viral diseases (FeLV, FIV, FIP) (p 684)

Vomiting is not a common presenting sign for any of the primary feline viral diseases, but is associated with FeLV or FIV primarily secondary to the systemic disease that is occurring as a result of the infection. In cats with FIP, vomiting may be associated with focal granuloma formation in the GI tract or abdomen or may occur secondary to systemic disease (hepatic, CNS, renal). Other common clinical signs are anorexia, lethargy, fever or dyspnea.

Bacterial:

- **Helicobacter spp.* (p 682)**

The true importance of *Helicobacter* organisms in cats as a cause of chronic gastritis and vomiting is still not known, but there have been increasing numbers of cats with chronic gastritis and presence of these organisms that respond to appropriate therapy.

continued

continued

Protozoal:

- **Toxoplasmosis* (p 686)**

Intermittent vomiting is a common sign in infected cats, but will occur in conjunction with other signs of systemic disease (respiratory, CNS, ocular).

Fungal:

- **Histoplasmosis* (p 685)**

GI histoplasmosis is less common than respiratory or disseminated disease, but vomiting will still often be observed, especially when there is hepatic involvement. The most common signs are respiratory (e.g. coughing or signs of respiratory distress) or lethargy, anorexia and weight loss associated with disseminated disease.

Parasitic:

- **Physaloptera (p 690)**

Chronic intermittent vomiting may be associated with undiagnosed infection with the stomach worm *Physaloptera*.

- **Heartworm disease (*Dirofilaria immitis*) (p 691)**

Dirofilariosis is a disease with primarily regional importance. Cats with heartworm disease may not have signs of respiratory or cardiovascular disease (e.g. coughing or changes in breathing pattern), but instead present with intermittent vomiting, anorexia or weight loss.

Toxin/drug:

- **Pharmacologic (drug-associated vomiting)** (p 678)**

Drugs are a common cause of acute vomiting in cats. However, chronic vomiting may occur in cats that are on long-term drug therapy (e.g. chemotherapy, theophylline, etc.).

- **Lead poisoning (p 692)**

Lead poisoning is an uncommon cause of vomiting in cats, as they are generally more fastidious in their eating habits. In cats ingesting lead-containing materials, both gastrointestinal (vomiting, diarrhea, anorexia) and neurologic (seizures, ataxia, megaesophagus, tremors) signs are typical.

INTRODUCTION

MECHANISM?

Vomiting occurs when the **vomiting center** in the medulla is stimulated, which can occur by several mechanisms:

- Effect of blood-borne toxins or drugs.
- Afferent impulses from the cerebral cortex, chemoreceptor trigger zone (CRTZ), or receptors in the pharynx or abdominal viscera.

The **CRTZ** is stimulated by:

- Blood-borne toxins or drugs.
- Impulses from the vestibular apparatus.

Vomiting is an active process that must be distinguished from regurgitation.

Vomiting in cats is associated with **abdominal muscle contraction, considerable muscular effort and anxiety** prior to the event.

Vomit may consist of undigested food material (if swallowed whole), partly digested or even liquid, and may be clear, yellow (bile stained) or brown (food colored).

Vomit is not typically tubular in form, nor does it contain large amounts of white frothy material.

The pH of vomitus is usually acidic (pH < 4), **but may be neutral** (pH 7) if duodenal content is present (bile reflux).

WHERE?

Vomiting may be associated with **gastrointestinal disease or extra-intestinal tract diseases**.

Gastrointestinal **disease involving the stomach and/or small intestine** causes vomiting.

Vomiting is **rarely associated with primary colonic disease**.

Extra-intestinal causes of vomiting include:

- **Hepatobiliary disease.**
- **Pancreatic disease** (e.g. pancreatitis, neoplasia).
- Renal disease causing acute or chronic **renal failure**.
- CNS disease (e.g. vestibular disease, encephalitis, seizure disorders, neoplasia).
- Metabolic diseases (e.g. **hyperthyroidism**, ketoacidotic diabetes mellitus or Addison's disease).
- Cardiomyopathy or congestive heart failure.
- Systemic illness or infection affecting the CRTZ or cortex (e.g. septicemia).

WHAT?

Primary gastrointestinal diseases that cause chronic vomiting include:

- Parasites (e.g. physaloptera, etc.).
- Infectious diseases (e.g. *Helicobacter*).
- Inflammatory diseases (e.g. IBD, gastritis or gastric ulcer disease).
- Neoplasia.
- Mechanical (e.g. antral pyloric hypertrophy/stenosis, obstruction, intussusception).
- Dietary disturbances (e.g. food intolerance or food allergy).

The most common causes of chronic vomiting are: dietary (indiscretion or food intolerance), **neoplastic diseases, metabolic or extra-intestinal disturbances** (e.g. renal, hepatic or pancreatic disease) and **inflammatory diseases** (e.g. IBD).

Diagnosis is based on the minimum data base, multiple fecal examinations, survey or contrast radiography, radionucleotide or scintigraphic studies (e.g. thyroid disease, motility studies, evaluation for portosystemic shunts, vascular diseases, etc.), ultrasound examination, endocrine testing, evaluation of serum TLI, cobalamin/folate assays, titers for various infectious agents, neurologic examination and diagnostics (e.g. CSF,

computed tomography, etc.), endoscopic examination and biopsy or surgical exploratory with biopsy.

Many diseases that cause chronic vomiting are diseases from which complete recovery is not possible (e.g. IBD, food allergy, motility disturbances, chronic renal disease, etc.) and thus, **long-term therapy including dietary or pharmacologic treatment will be necessary**.

In some cases, the prognosis will be very guarded to poor for long-term survival (e.g. neoplasia, cardiomyopathy), and this should be discussed with the owner.

Occasional vomiting is considered a normal phenomenon in cats, both for removal of ingested hair, but also as a protective mechanism following consumption of new or unusual foods. This should be taken into consideration when evaluating a cat for chronic vomiting.

DISEASES CAUSING SIGNS OF CHRONIC VOMITING (>3 WEEKS DURATION)

FOOD ALLERGY (DIETARY HYPERSENSITIVITY)***

Classical signs

- Chronic vomiting, usually < once per day, immediately to > 12 h after eating.
- Diarrhea is less frequent and more often large bowel in character.
- Weight loss.
- Dermatological signs in some cats (miliary dermatitis, pruritus).

Pathogenesis

Food allergy is an immunologic reaction usually to the protein (or glycoprotein) component of food.

Food allergy may also be associated with dermatological signs.

Approximately 25% of cats with GI signs from food allergy also have dermatologic signs consisting of pruritus, miliary dermatitis and alopecia.

The pathogenesis of food allergy is poorly understood, but is thought to be a combination of two main

mechanisms. Firstly, direct toxicity caused by the ingestion of the food causing **release of histamine and other vasoactive amines**. Secondly, indirect effects are mediated via an amplification system, which responds to the food by releasing mast cell products, the production of **eicosanoids** and other inflammatory mediators, initiation of the kinin cascade, and other events that result in the clinical syndrome.

Clinical signs

Signs associated with food allergy are non-seasonal, affect a wide range of ages, breeds and both sexes, and are present in one or all three of these systems: the gastrointestinal tract, the skin or the respiratory tract.

Cats with food allergy may have vomiting/diarrhea, anorexia and weight loss, but may also have **dermatologic signs**, which may include rodent ulcers, eosinophilic plaques, miliary dermatitis, otitis externa or generalized pruritus, alopecia and erythema. A combination of GI and dermatologic signs should raise the index of suspicion of a food-related problem.

Head and neck pruritus appears to be especially **common in cats with food allergy**.

In some cats, food allergy may be associated with systemic signs such as feline asthma, rhinitis, stomatitis or other respiratory tract signs. However, this is poorly documented.

In a study of cats with documented food sensitivity (food intolerance and food allergy), there was a history of vomiting (56%), diarrhea (25%), or vomiting and diarrhea (19%).

Vomiting usually occurred less than once daily, a few minutes to > 12 h after eating and most commonly consisted of bile.

Large bowel signs (mucus and fresh blood in feces or excessive straining to defecate) were slightly (57%) more common than small bowel signs. Flatulence occurred in 38% of cats.

Weight loss occurred in 70% of cats.

Appetite was variably affected and either normal, increased or decreased.

Some cats were reported as irritable (38%) or lethargic (25%).

Dermatologic signs occurred in 25% of cats and consisted of miliary dermatitis, pruritis and alopecia.

Diagnosis

The **diagnosis of food allergy** is confirmed by performing **elimination/challenge trials**. However, **the diagnosis of food allergy may require a more specific approach to the elimination/challenge trials than is possible with commercially available diets** because of the difficulty in removing all sources of allergy from commercial diets.

The best **elimination diet** for making a definitive diagnosis **in these cases is a home-prepared diet containing novel protein and carbohydrate source**, e.g. lamb, venison, duck, kangaroo, crocodile or ostrich with potato or rice (and added vitamin and mineral supplementation).

Gastrointestinal signs usually resolve within 1–3 weeks but dermatologic signs may require that these diets be **fed a minimum of 6–8 weeks or 2 weeks after all symptoms resolve**.

The cat should then be changed to a **hypoallergenic commercial cat food** (e.g. IVD Limited diets, Hill's d/d diet or z/d diet, Royal Canin's Selected protein diets, or Eukanuba's Response Formula feline) containing food ingredients the cat has been successfully tested with or never exposed to.

Skin tests are inadequate for diagnosis of food allergies because they have a high incidence of false positives and negatives, and are only useful in determining which adverse reactions to foods have an IgE-mediated pathogenesis.

Serum radioallergosorbent (RAST), ELISA, or tests that are variations on the theme, are all available commercially to **test for the presence of antigen-specific IgE in the serum**. However, the difficulties present with skin testing still exist, i.e. non-IgE-mediated and delayed hypersensitivity reactions will also be missed. Not all food allergies cause systemic effects or cause increased systemic levels of IgE and so will be negative using serum IgE testing. Findings of a recent study suggest that type I hypersensitivities account for only 25% of gastrointestinal food sensitivities in cats. Gastroscopic food sensitivity testing has been tested in humans and

dogs, but not in cats, and its utility remains to be established for the routine diagnosis of food hypersensitivity.

Differential diagnosis

The main differential diagnosis for food allergy is food intolerance and they are usually clinically indistinguishable.

Cats with food allergy causing **dermatologic signs** must be differentiated from cats with atopy, flea allergy dermatitis, psychogenic alopecia or insect bite hypersensitivity.

The **gastrointestinal signs** of either syndrome can mimic many other causes of chronic GI disease, including gastritis, pancreatitis, and small bowel diseases such as IBD or colitis. The severity and duration of each event depends on the amount of antigen ingested, the immune response and the sensitivity of the patient. The more severe the presentation, the more differentials that must be included, e.g. neoplasia, extra-intestinal disease, etc.

Treatment

Treatment is initiated during the diagnostic phase by **feeding the elimination diet**. The key to effective therapy is to **find the offending agent(s) and remove them from the diet**.

Corticosteroids may provide partial relief, especially where type I hypersensitivity reactions are involved, but in general are not effective in maintaining remission or symptomatic relief for cats with food allergies.

Antihistamines have not been proved effective in preventing the gastrointestinal symptoms associated with food allergy.

Some animals will eventually develop allergies to components in the elimination diet. In these cases, feeding diets containing protein hydrolysates will be most effective. Unlike regular protein molecules, the molecular size of these hydrolysates is too small to crosslink IgE bound to mast cells.

Prognosis

The prognosis for control of food allergy is excellent if the offending agent(s) can be identified and eliminated from the diet. However, in some cases, that is not

possible and affected animals will have recurrent or persistent clinical signs.

FOOD INTOLERANCE***

Classical signs

- Chronic vomiting, usually < once per day, immediately to >12 h after eating.
- Diarrhea is less frequent and more often large bowel in character.
- Weight loss.
- Dermatological signs in some cats (miliary dermatitis, pruritus).

Pathogenesis

Food intolerance is a non-immunologic reaction to a substance or multiple substances in food. This reaction can occur to proteins or other food components, but it can also be associated with food coloring, additives, preservatives or flavorings. Naturally occurring chemicals such as amines, salicylates and monosodium glutamate are present in food, especially highly flavored rich food.

These distinctions are **difficult to distinguish clinically**.

Food sensitivity may also be associated with dermatological signs.

Approximately 25% of cats with GI signs from food sensitivity also have dermatologic signs consisting of pruritus, miliary dermatitis and alopecia.

The pathogenic mechanisms of food intolerance are poorly understood, but a combination of direct toxicity caused by the ingestion of the food causing **release of histamine and other vasoactive amines**, and indirect effects that are mediated via an amplification system which responds to the food by releasing mast cell products, production of **eicosanoids** and other inflammatory mediators, initiation of the kinin cascade, and other events that result in the clinical syndrome.

Clinical signs

Cats with **food intolerance** traditionally have been thought to have **gastrointestinal tract signs only**, because the syndrome is not an immunologic reaction.

However, humans with food intolerance may have dermatologic signs, mouth ulcers and other systemic signs. In cats, **vomiting, diarrhea, weight loss, poor coat condition and lethargy** are the most frequently observed clinical signs. It is unknown whether dermatologic signs also occur with food intolerance in cats.

The most common clinical signs of food intolerance are the same as food allergy, i.e. vomiting and/or diarrhea. The vomiting is often intermittent and may not necessarily follow any particular pattern in relation to eating. If diarrhea occurs, it is probably more likely to be large bowel in character (mucus and fresh blood in feces or excessive straining to defecate) than small bowel (low frequency, loose to watery feces passed without straining or mucus).

Weight loss may occur, along with a change in appetite.

Diagnosis

The diagnosis of food intolerance is confirmed by performing elimination/challenge dietary trials.

An elimination trial (either using commercial hypoallergenic diets or premium diets that have reduced food colorings, preservatives, additives, etc.) of 4–6 days should be embarked upon first before proceeding to a more specific food elimination trial requiring controlled food preparation (single novel protein and carbohydrate source). Gastrointestinal signs usually resolve quickly. Vomiting may cease immediately and diarrhea usually within 3 days. Recrudescence of GI signs with challenge usually occurs within 4 days but may take up to 10 days with dermatologic signs.

Differential diagnosis

Food intolerance and food allergy are clinically indistinguishable as they both present with the same clinical signs and are usually highly diet responsive.

Other chronic causes of GI signs include gastritis, pancreatitis and small bowel diseases such as IBD or colitis. As a general rule, more severe clinical presentations require a more thorough clinical workup to eliminate a wider range of differential diagnoses, e.g. neoplasia and extra-intestinal disease.

Treatment

Food intolerance is highly diet-responsive once the offending agent(s) has been identified. This is usually done by using an elimination diet.

Since the condition is not immunologically mediated, drugs that modify or suppress the immune response are unlikely to be beneficial.

Prognosis

Once the inciting food(s) has been eliminated from the diet, food intolerance has an excellent prognosis.

HYPERTHYROIDISM**

Classical signs

- Weight loss.
- Polyphagia.
- Vomiting and/or diarrhea.
- Hyperactivity.
- Poor grooming habits.

See main reference on page 304 for details.

Clinical signs

Weight loss despite a voracious appetite (polyphagia) is the most common owner complaint.

Vomiting and polyuria/polydipsia occur in a third of cats.

Other signs that occur less commonly are restlessness or irritability, poor grooming habits, decreased appetite, lethargy, panting or dyspnea and large bowel diarrhea.

The most prevalent physical exam findings are a palpable thyroid nodule, thin body condition, tachycardia or heart murmur and hyperactivity or irritability.

There is **no breed or sex predilection** for hyperthyroidism, but **most (90%) are old cats (> 10 years)**. Cats < 6 years of age are rarely affected.

Diagnosis

Presumptive diagnosis is often suggested by the **age, history and clinical presentation**.

Hematology changes include **erythrocytosis, and a stress leukogram (leukocytosis, neutrophilia, lymphopenia).**

Serum biochemistry profile changes: **increases in liver enzyme activities (ALT, SAP, GGT, LDH, AST) occur in greater than 50% of cases**, hyperglycemia and pre-renal azotemia are less common. Hyperphosphatemia and hyperbilirubinemia are uncommon (< 10% of cats).

The **urine specific gravity will usually be > 1.035 (>50%)**, but cats with polydipsia/polyuria or underlying renal disease will have unconcentrated urine (urine SG < 1.035).

Definitive diagnosis is made by finding **elevated serum thyroxine (total T_4) levels** in most cats (98%).

In a few cats the total T_4 is in the upper half of the normal range and measurements of **free T_4 , a T_3 suppression test** (useful for diagnosis of mild hyperthyroidism, but takes 3 days), **TRH stimulation test** (performed over 4 hours, side effects common from TRH administration) or **radionuclide (^{99}Tc , pertechnate) imaging** examination (requires special equipment and isolation for 24 hours) **may be required to make the diagnosis.**

Differential diagnosis

Diabetes mellitus, chronic renal failure, liver disease are common extra-intestinal causes of vomiting, weight loss and polyuria/polydipsia that must be differentiated from hyperthyroidism.

Primary GI diseases that may cause similar signs are food intolerance/food allergy, IBD and gastrointestinal neoplasia.

Treatment

Medical therapy with anti-thyroid drugs that inhibit the synthesis of thyroid hormones, such as methimazole or carbimazole (2.5–5 mg/kg q 8–12 h, PO) are commonly used treatments. However, these drugs must be administered daily and have side effects which are potentially problematic. Vomiting and anorexia are relatively common side effects, while hematologic abnormalities are rare.

Calcium ipodate (15 mg/kg PO q 12 h) decreases serum T_3 (but not T_4) concentrations acutely, but the effect is

only short term. Thus, it is not useful in long-term management of the disease.

Adjunctive therapy for hyperthyroid heart disease: beta-adrenergic receptor-blocking agents (propranolol, atenolol for heart rate control, and furosemide, calcium channel antagonists and ACE-inhibitors as needed for heart failure (see page 132).

Surgical thyroidectomy is a highly effective treatment, especially for unilateral disease, but requires an anesthetic procedure and careful technique to preserve the parathyroid glands. If bilateral thyroidectomy is required, the patient will require oral thyroid hormone supplementation. Recurrence of hyperthyroidism in the remaining gland or tissue is common.

Radioiodine therapy is the simplest, safest and most effective therapy for the majority of cats, except cats with chronic progressive renal disease/failure and cats that will not eat in confinement. The major disadvantage is the requirement for special facilities for use of radioisotopes and the cat cannot be handled for 7–21 days. This makes fluid therapy difficult if the cat goes into renal decompensation during that time, or requires other medication.

IDIOPATHIC INFLAMMATORY BOWEL DISEASE (IBD)*

Classical signs

- Vomiting with or without diarrhea.
- Weight loss and anorexia or decreased appetite.

Pathogenesis

Inflammatory bowel disease (IBD) is an **idiopathic inflammatory disease** of the feline GI tract characterized by **infiltration of the lamina propria and mucosa with inflammatory cells** of various types (lymphocytic, plasmacytic, granulocytic, granulomatous, eosinophilic or combinations of these).

A lymphocytic/plasmacytic infiltration is the most common lesion in cats.

The **etiology is unknown** but believed to involve genetic, immunologic, dietary, bacterial and mucosal factors.

Lymphocytes and plasma cells are normal components of the feline GI tract, and increased numbers in the GIT occur in response to many infectious agents. **Differentiation of feline IBD from other diseases requires a complete examination to rule-out other causes for the infiltration.** In IBD, there should also be evidence of **mucosal disease** (e.g. erosion, villous blunting, loss of normal structure in other ways, loss of normal function).

Eosinophilic IBD is rare in cats, and in some cases it is found in association with **hypereosinophilic syndrome** (infiltration of eosinophils in many body tissues including liver, spleen, lymph nodes, etc.).

Other forms of IBD, such as granulomatous and neutrophilic IBD are also rare in cats.

Most forms of IBD involve the small intestine, sparing the stomach and colon, however, enterocolitis and gastritis may also occur.

Recently **an association has been observed between cats with idiopathic IBD and concurrent cholangitis and pancreatitis.** The true relationship between these observations and clinical IBD is not known.

Clinical signs

Vomiting and weight loss are the most common signs, but diarrhea and anorexia are also frequently observed signs.

Middle-aged (> 4 years) cats are most frequently affected, but all ages have been reported to have IBD.

There is **no breed or sex predilection**, but purebred cats may be at increased risk compared to DSH cats.

If there is concurrent cholangitis or pancreatitis, cats may also present with icterus, abdominal pain or fever.

Diagnosis

The diagnosis is based upon several factors: (1) **histologic infiltration** of inflammatory cells, usually lymphocytes and plasma cells in the GI tract; (2) the presence of inflammatory cells is associated with **mucosal abnormalities and functional disturbances**; (3) there are **no other identifiable causes for the infiltration** identified; and (4) the signs of the disease are **chronic** (> 3 weeks in duration).

It is especially important to rule out parasitic, infectious, dietary and extra-intestinal (e.g. hepatic, renal or pancreatic) causes of disease, as these may cause similar lesions to IBD.

The only means of ruling out dietary causes of vomiting is via an elimination trial, which must be conducted using an elimination diet prior to making a diagnosis of IBD.

Endoscopic examination and biopsy is the most common procedure used to obtain the diagnosis. **Multiple (6–8), good-quality** (containing submucosa and properly oriented) **biopsies should be obtained from the small intestine and stomach.** Biopsies should be taken from all regions of the stomach and lymphoid follicles should be avoided when obtaining biopsies from the duodenum. **Full-thickness biopsies obtained surgically are also acceptable** if endoscopy is unavailable, and equal care should be taken to assure biopsy quality (proper handling to minimize artifact and orientation on the biopsy sponge to prevent curling and crush artifacts).

The major difficulty associated with endoscopic diagnosis of IBD is differentiation of IBD from lymphoma, which will not be possible if the biopsy samples are not deep enough (contain submucosa) or if they have significant mucosal artifacts that prevent adequate assessment of mucosal abnormalities. In some cases where histologic differentiation is impossible, immunocytochemistry techniques may have to be employed to distinguish the cell origin (e.g. lymphoma cells tend to be monoclonal, while lymphocytes from cats with IBD will be polyclonal).

Non-specific laboratory abnormalities that may be found in cats with IBD include: hypoproteinemia, hyperglycemia (stress induced), **hypokalemia, elevated liver enzyme activities and a stress leukogram.**

Serum cobalamin and folate levels may be decreased in cats with IBD due to malabsorption.

Radiography and ultrasonography generally do not assist with the diagnosis, but are important in ruling out other causes of the clinical signs, e.g. neoplasia.

Differential diagnosis

Neoplasia (lymphoma is of special mention because it may have a similar histologic appearance to IBD).

Food intolerance or hypersensitivity (food allergy).

Parasitic infections of the GI tract, especially giardia, which are difficult to diagnose.

Infectious diseases such as *Campylobacter*, salmonellosis, *Clostridium*, etc.

Extra-intestinal causes of vomiting such as hyperthyroidism, uncontrolled diabetes, renal failure and pancreatitis.

Treatment

In most cats, a **combination of dietary modification and pharmacologic therapy** (anti-inflammatory, immunosuppressive) is successful in controlling the clinical signs.

Dietary therapy involves three main strategies: (1) low-residue, highly digestible diets; (2) hypoallergenic, elimination diets aimed at controlling food allergies; or (3) high-fiber diets for cats with IBD that primarily involves the large bowel.

The mainstay of **pharmacologic therapy** in cats with IBD is **prednisone (2–4 mg/kg PO q 12–24 h)**. This dose is tapered after the first 2 weeks to the lowest dose that will maintain remission. Some cats can be weaned off prednisone after 3–6 months and maintained on a controlled diet (or diet with metronidazole), while others will require life-long steroid therapy.

In **refractory cases**, dexamethasone (0.25 mg/kg PO q 12–24 h) may be used as well, but is not suitable for alternate day therapy because of the long half life.

Metronidazole is often added (10–15 mg/kg PO q 12 h) to the treatment plan because of the anaerobic, antiprotozoal and immunomodulating effects of the drug.

Other antibiotics that may be useful include tetracycline (20 mg/kg PO q 8 h), doxycycline (5–10 mg/kg PO q 12 h) or **tylosin powder** (10–20 mg/kg PO q 12 h).

In cats that do not completely respond to corticosteroids or that become refractory to standard treatment approach, **chlorambucil** (1 mg PO q 3 days) or **azathioprine** (0.3–0.5 mg/kg PO q 2–3 days) can be added to the regimen. Toxicity (leukopenia) is a major risk with azathioprine use, and should be monitored by hemograms every 2–3 weeks.

Prognosis

Guarded. Cats will frequently respond well to dietary and pharmacologic therapy, but relapses are common and long-term management is required. There is no known cure for IBD and owners should be educated about the nature of the disease to encourage compliance and understanding.

CHRONIC PANCREATITIS*

Classical signs

- Lethargy.
- Anorexia.
- Vomiting is observed in less than 30% of cases.

See main reference on page 639 for details (The Cat With Signs of Acute Vomiting).

Clinical signs

Lethargy and anorexia have been the most commonly observed clinical signs.

In general, **vomiting and anterior abdominal pain occur less frequently.**

Signs may be protracted, with low-grade vomiting occurring in some cats, while others have acute signs.

Diagnosis

A certain **degree of clinical suspicion** is required to make the diagnosis of pancreatitis in cats because the signs are so vague.

Cats with chronic pancreatitis may develop **secondary complications** such as exocrine pancreatic insufficiency, diabetes mellitus, obstruction of the common bile duct or cholangitis.

Hematology and serum chemistry profiles are non-diagnostic, but may show dehydration, electrolyte imbalances, elevated liver enzymes, mild hyperbilirubinemia or a leukocytosis.

Serum lipase and amylase values are not helpful, as they may be elevated, normal or low in normal cats or cats with pancreatic disease.

Imaging studies are the most useful way to obtain a presumptive diagnosis of pancreatitis. **Radiographs of the anterior abdomen** may reveal evidence of local peritonitis, gas in the duodenum or anterior jejunum, or a mass. **Ultrasound examination remains the most reliable technique to evaluate the pancreas** and determine the presence of swelling, abscess or fibrosis. It is important to note that **ultrasonographic changes in chronic pancreatitis persist for months**.

Elevations in serum **trypsin-like immunoreactivity (TLI) assay** have been suggested as a means of detecting pancreatitis, but this **has not been shown to be consistently accurate** either, and is of less use in chronic pancreatitis.

The assay for feline pancreatic lipase (fPLI) has been developed and is a sensitive and highly specific test for acute pancreatitis. However, in cats with chronic pancreatitis, the fPLI may be normal, or mildly increased but below levels diagnostic for pancreatitis, which can make test interpretation difficult.

Differential diagnosis

The list of problems causing anorexia and lethargy in cats is lengthy and includes multiple organ systems and abnormalities.

Treatment

Nothing should be fed for 1–2 days if the cat is vomiting until the vomiting can be controlled. However, a fast of longer than 3 days is to be avoided if at all possible in most cats.

Intravenous fluid therapy should be administered, using a balanced electrolyte solution (either replacement or maintenance fluids) to maintain hydration, correct pancreatic ischemia and reduce the risk of complications of pancreatitis.

Anti-emetics (e.g. metoclopramide 0.1–0.2 mg/kg) may be used if the cat is vomiting.

Cats with severe pancreatitis may be unable to eat for several days (3–5), thus, **parenteral or partial enteral nutrition** will be necessary to prevent development of malnutrition, feline hepatic lipidosis and impaired immunity.

Steroid therapy may be indicated in cats with concurrent IBD or cholangitis.

HEPATIC DISEASES (HEPATIC LIPIDOSIS, CHOLANGITIS, HEPATIC CIRRHOSIS, PORTOSYSTEMIC ANOMALIES)

Classical signs

- Lethargy or depression, vomiting, anorexia and weight loss are common signs.
- Icterus, ascites, hepatomegaly or microhepatica are variable.

See main references on page 421 for details (The Yellow Cat or Cat With Elevated Liver Enzymes).

Clinical signs

Vomiting occurs primarily because of the gastritis that occurs secondary to changes in blood flow and release of GI hormones, and because of mediator release (stimulation of the vomiting center) secondary to presence of toxins from decreased hepatic clearance or function.

Liver diseases often present with the relatively non-specific signs of **anorexia, weight loss, vomiting, and lethargy or depression with or without icterus**.

Other signs include **ascites, edema formation, bleeding disorders due to deficiency of coagulation factors or DIC**, and in cases with severe hepatic failure, signs of **hepatoencephalopathy** (dementia, personality changes, seizures, stupor or coma). Prolongation of clotting times is quite common in cats with hepatopathy.

Diagnosis

Icterus (hyperbilirubinemia) may be caused by **pre-hepatic (hemolysis), hepatic or post-hepatic (bile duct obstruction)** diseases which all must be considered.

The **hemogram** is important in **differentiating hemolysis from hepatic causes of icterus**. **Anemia is a common problem** and may be either regenerative (secondary to blood loss or hemolysis) or non-regenerative (e.g. anemia of chronic disease, bone marrow suppression). Typically the anemia of chronic disease is

less severe (PCV > 20), than that seen with hemolysis or severe blood loss.

Target cells (leptocytes) on the blood smear are also suggestive of liver disease.

Serum biochemical profile results will be supportive of the diagnosis, with the most common findings being **elevated liver enzymes, hyperbilirubinemia**, decreased BUN, decreased albumin and total protein, hypocholesterolemia, and electrolyte disturbances consistent with vomiting (hypokalemia, hypochloridemia, hyponatremia).

A **serum bile acid assay** is the most reliable, easiest to perform and most readily available liver function test. A **pre- and 2-hour post-prandial assay should be submitted** to evaluate liver function. Other function tests include blood ammonia and bromosulfophthalein (BSP) retention.

Measurement of sulfated bile acids in urine is a newly developed test to diagnose liver disease. In many cats that will not eat, obtaining a serum post-prandial bile acid sample is difficult, and this test may provide additional information about the status of liver function in inappetent cats.

Imaging studies (radiographs, **ultrasound**) are used to assess liver size, morphology and structure, and may be used to obtain **aspirates or biopsies** of liver via ultrasound-guided techniques.

In all cases of suspected liver failure, **evaluation of coagulation function is essential**, not only for therapeutic purposes (e.g. determining the presence of DIC, coagulopathies), but also prior to obtaining tissue for biopsy.

The **definitive diagnosis** typically requires **histopathologic examination** of liver tissue, however, in cases of suspected vascular anomalies, a venous portogram or portal scintigraphy is necessary to define the abnormal vascular structures.

Differential diagnosis

Icteric cats: Immune-mediated hemolytic anemia, pancreatic or gastric abscess or tumor obstructing common bile duct, hemolytic anemia secondary to red cell parasites, primary liver diseases (hepatic lipidosis, cholan-

gitis, and hepatic lymphoma or carcinoma) are the most common diseases.

Cats with ascites: Ascites may be caused by pre-hepatic (cardiac), hepatic or post-hepatic (GI lymphatic obstruction, protein-losing enteropathy, severe protein-losing nephropathy or mesenteric hypertension (torsion) or venous thrombosis or vasculitis), and these must be separated. **Ascites due to cardiac failure is very rare in the cat.** Hepatic disease, vasculitis from feline infectious peritonitis or lymphatic obstruction associated with neoplasia are the most common causes of ascites in cats.

Treatment

Treatment is based upon **identifying the primary problem**. The reader is referred to the main reference (page 421) for details.

GI LYMPHOSARCOMA**

Classical signs

- Weight loss.
- Intermittent or persistent vomiting.
- Small or large bowel diarrhea.
- Lethargy or depression.

Pathogenesis

In the United States and other countries where **feline leukemia virus (FeLV) is prevalent, FeLV infection is the most common cause of all types of lymphoma except the alimentary form**, which is only associated with viremia 25–30% of the time. In areas **where FeLV infection is rare** (e.g. east coast of Australia), **most cats with lymphoma are FeLV negative**.

Some evidence suggests that the alimentary form of lymphoma arises from transformed multipotent lymphoid or monocyte precursors or from FeLV-transformed B-lymphocytes, and thus may still be associated with FeLV.

Alimentary lymphoma is the **second most common GI tumor** (adenocarcinoma is first), and occurs in **older cats** (> 8 years).

The **most common site** for lymphoma is the **jejunum or ileum**, with the duodenum being a rare site of occurrence. Lymphoma is the most common tumor found in the feline stomach (although it is still a rare disease), but is found unfrequently in the colon compared to adenocarcinoma.

Lymphoma can occur as a **solitary mass causing an obstructive lesion, or as diffuse disease** affecting many sections of the GI tract and occurring throughout all layers of the bowel wall.

Clinical signs

The **most common clinical signs** associated with intestinal lymphoma in cats are **anorexia, lethargy and weight loss**.

Vomiting and diarrhea are variably observed, depending on the location of the lesion, the nature of disease (diffuse vs. a solitary mass) and duration of disease e.g. fever, hematemesis, icterus, ascites and melena.

Cats that are FeLV positive may also have clinical signs consistent with the disease in other locations (e.g. anemia, leukemia, etc.).

Diagnosis

Hematology may be normal or there may be an anemia of chronic disease (that may be masked by dehydration) in cats that are FeLV negative. **FeLV-positive cats may have a wide variety of hematologic changes**, which should be further investigated with a bone marrow examination.

Serum biochemistry profile values also may be within normal limits, or there may be **increases in liver enzymes, hypercalcemia or hypoproteinemia**. Pre-renal azotemia and electrolyte disturbances may occur in cats with severe vomiting.

The **majority of cats (70–75%) are FeLV antigen negative**.

Radiographs may be normal or may reveal thickened bowel loops or a solitary mass lesion.

Ultrasonography is useful for localizing solitary masses, evaluating mesenteric lymph nodes (which are also typically involved), and for identifying thickened intestinal loops.

The **definitive diagnosis** is made by **histopathologic evaluation** of affected segments of bowel. **Ultrasound-guided aspirates** often will provide sufficient tissue sample for the diagnosis (intestinal wall, mass or lymph nodes).

If the lesion is in a location accessible by **endoscopy**, **biopsies** can be obtained by this method. However, **endoscopic biopsy samples can be easily misread as IBD or visa versa**, and the diagnosis can be missed if the lesion is present only in the submucosa.

If these diagnostic modalities are not available or provide inconclusive results, full-thickness biopsies obtained by surgical exploratory are usually definitive.

Staging the disease requires histologic evaluation of regional (mesenteric) lymph nodes, liver and spleen, radiographic evaluation of lungs and examination of bone marrow aspirates (if indicated) for evidence of metastasis.

Differential diagnosis

The major differential is **lymphocytic plasmacytic IBD**.

Intestinal adenocarcinoma, foreign body, FIP, fungal or algal infections of the GIT, other intestinal tumors (e.g. mast cell tumor) and hyperthyroidism must all be considered.

Treatment

Chemotherapy is provided in stages: induction of remission, intensification, maintenance and rescue. In general, **cats are more difficult to rescue** (compared to dogs) **once the cancer is out of remission**, which is why their survival times are shorter than dogs.

A typical protocol used to induce remission is the COAP protocol: cyclophosphamide (200–300 mg/m² PO q 3 weeks), vincristine (0.5 mg/m² IV q 1 week), cytosine arabinoside (100 mg/m² IV or SC for 2 days only), and prednisolone (50 mg/m² PO q 24 h for 7 days, then EOD). If remission is only partially achieved, intensification with doxorubicin (25 mg/m² IV q 3 weeks) or mitoxantrone (4–6 mg/m² IV q 3 weeks) can be tried.

Maintenance chemotherapy protocols may include continuation of the COAP protocol or use of the LMP protocol (chlorambucil, methotrexate, prednisone).

In cats with small cell (highly differentiated) lymphoma of the GIT, the combination of chlorambucil (20 mg/m² PO every other week) and prednisolone (20 mg/m² PO EOD), with or without methotrexate (2.5 mg/m² PO EOD) is often successfully used.

Other protocols that have been successfully used to treat feline lymphoma include COP (cyclophosphamide, vincristine and prednisone), VCM (vincristine, cyclophosphamide and methotrexate), or VCM plus L-asparaginase.

Nutritional support should be used as needed (especially in cats that are vomiting or not eating enough to maintain normal function).

Control of secondary infections is also sometimes necessary and should be implemented as required. In cats with alimentary lymphosarcoma, metronidazole is often used as the antibiotic choice.

Prognosis

FeLV status does not influence whether or not remission occurs, but is a significant predictor of survival, with FeLV-negative cats having much longer survival times. FeLV-positive cats in stages III–V had no differences in survival than FeLV-negative cats, but in stage I–II, survival is 18 months versus 4 months, respectively, for negative cats and cats with the virus.

The **overall prognosis is guarded to poor** in cats with alimentary lymphoma. Most cats with alimentary lymphoma respond poorly to chemotherapy, but those that do respond may have a survival time of more than one year. Cats with a solitary mass in the GIT that can be resected have a better prognosis.

Most cats with lymphoma treated with multiple agent chemotherapy protocols are expected to live 3–9 months, with 20% living longer than 1 year. **Untreated cats can only be expected to survive 4–8 weeks**. Cats that are **FeLV positive also have shorter survival times**.

Survival does not appear to be influenced by the extent of the disease, anatomic location or clinical stage, which is an important predictor in some types of lymphoma.

INTESTINAL ADENOCARCINOMA**

Classical signs

- **Weight loss and lethargy or depression are the most prevalent signs.**
- **Intermittent to persistent vomiting or hematochezia develop as the tumor obstructs or ulcerates the epithelial surface.**

Pathogenesis

The **most common non-hematopoietic tumor** of the feline GI tract is the adenocarcinoma.

Most intestinal adenocarcinomas occur in the **jejunum and ileum**, with the duodenum rarely affected. Colonic adenocarcinoma is uncommon and usually occurs in **very old cats (e.g. 16 years)**.

Siamese cats represented 70% of 225 reported cases of **intestinal adenocarcinoma** and had a mean age of 10–11 years.

Domestic shorthair cats had the most reported cases of **colonic adenocarcinoma**.

Feline leukemia virus appears to have no role in the pathogenesis of this disease, since all 28 cats in one study that were tested were found to be FeLV negative.

Adenocarcinomas occur either as **annular or intraluminal tumors**.

Metastasis of adenocarcinomas is typically **within the abdominal cavity and not to the lungs**.

Clinical signs

The most commonly observed clinical signs are **anorexia, lethargy, weight loss and vomiting**.

Hematochezia, melena or diarrhea are primarily observed in cats with **colonic disease**.

In cats that are not eating and are vomiting persistently, dehydration may also occur. Fever and abdominal effusion are also late-stage findings associated with metastasis of the tumor.

Diagnosis

Hematologic and serum biochemical profiles are often normal.

Abnormalities may include: hemoconcentration, non-regenerative anemia of chronic disease, electrolyte imbalances or pre-renal azotemia, hypoproteinemia or hypoalbuminemia due to GI protein loss, or elevated liver enzyme activities (metastatic disease).

Radiographs of the thorax rarely reveal metastatic lesions.

Abdominal radiographs may show a mass, enlarged lymph nodes or signs of an intestinal obstruction (e.g. dilated, air-filled bowel segment, abnormal gas patterns, or differences in bowel size or location relative to neighboring bowel). Some cats will have tumors with osseous **metaplasia (mineralization)** or **ascites** that will imply neoplasia. Contrast studies may be very useful in delineating intraluminal or annular lesions.

Ultrasonography is also very helpful in identifying mass lesions and their extent for staging, and can be used to direct **fine-needle aspirates or biopsies** for diagnosis.

In cats with colonic disease, **colonoscopic evaluation and biopsy may also be useful.**

Surgical exploratory is the best way to obtain the definitive diagnosis, get **accurate staging information**, and will also allow **resection of the affected segment** of bowel if that is indicated.

Differential diagnosis

Intestinal foreign body or obstruction, other intestinal neoplasia, inflammatory bowel disease, vomiting and weight loss due to extra-intestinal disease (chronic renal failure, etc.), fungal or algal diseases of the intestine, and FIP granuloma should all be included in the differential list.

Treatment

The **only reported and effective treatment** for intestinal adenocarcinoma in cats is **surgical resection.**

The **role of adjuvant chemotherapy** for feline intestinal adenocarcinoma has not been explored.

Nutritional support may be necessary in cats that do not eat enough to meet at least resting energy requirements ($RER = 30 \times BW \text{ (kg)} + 70$) and cats with cancer may require additional calories ($RER \times 1.5$).

Cats with large colonic resections may require very highly digestible diets to reduce the fecal volume and load on the colon.

Prognosis

The **presence of metastatic disease is not necessarily a poor prognostic sign** in cats with adenocarcinoma, and should not be a disincentive for performing a surgical resection and anastomosis.

The **average survival for cats with the disease is 4–15 months** (with or without metastatic disease), but some cats live several more years following aggressive surgical resection.

PHARMACOLOGIC (DRUG-ASSOCIATED VOMITING) **

Classical signs

- Vomiting observed after administration or ingestion of a drug.

See main reference on page 642 for details.

Clinical signs

In some cases, vomiting is expected following drug administration (e.g. chemotherapy, xylazine), while in others it is not usual (e.g. tetracycline, erythromycin), and in others it represents toxicity or accidental exposure (NSAIDs, narcotics, digitalis).

The **signs observed will depend on the drug that is administered**, e.g. chemotherapy drugs may cause vomiting, anorexia, lethargy, hair loss, etc., while vomiting caused by chloramphenicol or erythromycin may be the only clinical sign.

Diagnosis

Diagnosis is largely dependent upon obtaining an **extensive, accurate history** that includes a complete

history of drugs the cat is taking or has taken, toxins it has been exposed to and the potential for accidental or malicious poisoning.

Some **commonly used drugs known to cause vomiting in cats include** many, if not most, **antibiotics** (e.g. amoxicillin, cephalexin, enrofloxacin, tetracycline, erythromycin, metronidazole, clindamycin), **chemotherapy drugs** (dacarbazine, cisplatin, doxorubicin, methotrexate, cyclophosphamide), **methimazole**, **potassium bromide**, **glipizide**, and **antifungal drugs** (e.g. itraconazole, amphotericin).

In some cases, **determination of blood levels of a specific drug** will confirm the presence of a drug or toxin that was unknown or unexpected. Alternatively, hair and urine samples can also be used in some cases to determine the presence of metabolites of various drugs or chemicals.

If the suspected exposure is recent, evacuation of the stomach and analysis of its contents will also provide a means of determining the presence of drugs or chemicals.

Differential diagnosis

Other acute causes of vomiting such as food intolerance/dietary indiscretion, parasitic diseases, infectious diseases, foreign bodies or gastritis due to other causes should be considered when the history is not helpful in identifying exposure.

Treatment

Choice of treatment depends on whether the vomiting is expected (e.g. chemotherapy) and can be controlled with anti-emetics (e.g. metoclopramide or chlorpromazine), or is due to unexpected toxicity or accidental ingestion.

Supportive care for toxicity or accidental ingestion includes removal of stomach contents and gastric lavage, administration of activated charcoal to reduce absorption of contents, administration of gastric protectants as indicated (NSAID ingestion will cause gastritis), anti-emetics (metoclopramide or chlorpromazine), and fluid support to prevent or treat dehydration.

In cats with vomiting due to intolerance (e.g. tetracycline), changing the drug protocol to another that will be effective is generally all that is indicated.

GASTRITIS/GASTRIC ULCER DISEASE

Classical signs

- Frequent vomiting is typical, but intermittent vomiting will occur in some cats.
- Hematemesis or melena occurs with severe gastritis or bleeding ulcers.

See main reference on page 637 for details (The Cat With Signs of Acute Vomiting).

Clinical signs

Vomiting, either frequently or intermittently, is the primary clinical sign. Severe gastritis and ulcer disease will result in **anorexia**, **abdominal discomfort**, **lethargy** or **weight loss**.

Cats with severe gastritis or ulcer disease may also have **hematemesis** or **melena** from mucosal bleeding.

Diagnosis

Endoscopic examination of the gastric mucosa will often reveal the surface erosions or ulcers, however, **histologic examination** of the tissue is required to make a diagnosis of gastritis. Mild or chronic gastritis lesions may not have an abnormal mucosal appearance.

Gastric or duodenal ulcers can also be identified by **contrast radiography** and by **ultrasonography** in some cases, but these techniques are not as useful as endoscopy.

Most cats with gastritis will have a **normal hemogram and chemistry profile**. Cats with bleeding ulcers may have evidence of **acute** (non-regenerative if peracute, regenerative if recent) or **chronic blood loss** (may be either regenerative or non-regenerative depending on amount of hemorrhage).

Differential diagnosis

Helicobacter spp. infection, parasites (*Physaloptera*, *Ollanus* spp.), IBD, neoplasia, gastritis due to other extra-intestinal diseases.

In cats with ulcers that do not respond to standard therapy, ulcer disease due to a **gastrinoma** should be

ruled out. Diagnosis of a gastrinoma is made histologically by finding a neuroendocrine tumor, usually in the abdomen, and by confirming the presence of **hypergastrinemia** (serum gastrin levels that are extremely elevated) not due to secondary causes.

Treatment

Specific treatment is aimed at identifying and correcting the underlying cause.

Non-specific treatment for gastritis or gastric ulcers involves **reduction of gastric acid secretion, protection of the mucosa** to allow healing and **reduction of gastric retention or vomiting**. This is accomplished by:

Histamine-2 blockers: ranitidine (0.5–1.0 mg/kg PO q 12 h), famotidine (0.5–1.0 mg/kg PO q 12–24 h).

Proton pump inhibition: omeprazole (0.5–1.0 mg/kg PO q 24 h), note: this drug is difficult to dose in cats as it must be recompounded, but is the most effective acid suppression drug.

Mucosal protection: sucralfate (250–500 mg PO q 8–12 h) note: give at least 2 hours before giving H₂ blockers.

Anti-emetics: metoclopramide (0.1–0.2 mg/kg PO q 8–12 h) as needed to control vomiting, promote gastric emptying and reduce gastroesophageal reflux.

Feed only highly digestible, low-fat foods (e.g. Hill's i/d diet, Purina EN, Iams low-residue diet, etc.) **in small amounts**. In some cats, it is best to give them nothing per os until the gastritis/ulcer healing has begun and the vomiting is under control (1–3 days).

Hydration should be maintained with **IV or SQ fluids as needed**, if the cat is unable to eat or has severe vomiting.

CHRONIC RENAL FAILURE*

Classical signs

- Polyuria/polydipsia.
- Weight loss.
- Anorexia.
- Lethargy.
- Poor/hair coat/unkempt appearance.
- Vomiting.

See main reference on page 235 for details (The Cat With Polyuria/Polydipsia).

Clinical signs

Polyuria/polydipsia, anorexia or decreased appetite, and **weight loss** are the most common clinical signs of chronic renal failure.

An unkempt hair coat, decreased grooming and reduced overall activity level are also often observed.

Intermittent vomiting or diarrhea due to hypergastrinemia and uremia and uremic ulcers or stomatitis occur in severe cases.

Polyuria is profound until the late stages of the disease, when oliguria gradually develops with the progression to end-stage kidney disease.

Diagnosis

History and physical examination findings are suggestive of the diagnosis in a geriatric cat.

Hematology, serum biochemistry profile and urinalysis will confirm the presence of **azotemia, isosthenuria** or poorly concentrated urine (1.015–1.035), **mild to moderate non-regenerative anemia**, dehydration may also be present, along with **hypokalemia, hyperphosphatemia**, and evidence of chronic metabolic acidosis (low total CO₂).

Differential diagnosis

Hyperthyroidism, diabetes mellitus, hepatic disease (hepatic lipidosis if cat is/was obese) and neoplasia (lymphoma, adenocarcinoma, etc.) are important differentials in an old cat with polyuria/polydipsia and weight loss.

Treatment

Supportive. Fluid therapy as needed. **Sub-cutaneous fluids may be very important adjunctive therapy** in cats that do not drink enough or are vomiting, and have severe polyuria that results in dehydration and worsening azotemia.

Dietary manipulation. Feeding a diet that has a **moderate or low quantity of high-quality protein, reduced phosphorus, and relatively high in calories**, to maintain weight, decrease azotemia and reduce the effects of renal secondary hyperparathyroidism.

Phosphorus binders (e.g. amphoteg) may be needed when dietary manipulation no longer is effective in reducing serum phosphorus levels.

Potassium supplementation (potassium gluconate) is needed in most cats with chronic renal failure due to potassium wasting and total body potassium depletion that occurs.

In cats with frequent vomiting, histamine-2 blockers (famotidine 0.5–1.0 mg/kg PO q 24 h, ranitidine 0.5–1.0 mg/kg) may be helpful in reducing hyperacidity and gastritis that occurs secondary to azotemia and hypergastrinemia.

Cats in more advanced stages of renal disease may have a significant **non-regenerative anemia (PCV < 20)** due to the lack of erythropoietin production from the failing kidney, which may respond, for a limited period of time, to treatment with **recombinant human erythropoietin**.

DIABETES MELLITUS*

Classical signs

- Polyuria/polydipsia.
- Weight loss.
- Polyphagia or anorexia.
- Lethargy, weakness and/or depression.
- Vomiting.

See main reference on page 236 for details (The Cat With Polyuria and Polydipsia).

Clinical signs

Signs of **polydipsia, polyuria, polyphagia and weight loss** may be **present for months prior to diagnosis**.

Approximately **one-third of cats with diabetes mellitus have a history of vomiting**. An **acute onset of vomiting** may occur with **ketoacidosis**.

The **classical signs of ketoacidosis** include **polyuria, polydipsia, anorexia, weight loss, dehydration, vomiting, weakness and depression**.

In some cats, other clinical signs may include **peripheral nerve dysfunction (plantigrade stance), dementia or stupor/coma**.

Diagnosis

The **clinical signs and history** of polyuria/polydipsia suggest that diabetes mellitus should be considered.

The **hemogram is non-specific**, hemoconcentration and a stress leukogram are common, however, some cats have an inflammatory leukogram secondary to infection (a common sequelae of unregulated diabetes mellitus).

A **serum biochemistry profile and urinalysis** will be **diagnostic**. The finding of **hyperglycemia with glucosuria with or without ketonuria, and in some cases bacteriuria/pyuria is typical**. Other abnormalities likely to be observed include elevated liver enzymes, hypokalemia (may be severe), hypophosphatemia (may be severe), hypomagnesemia, low total CO₂ values (supportive of acidosis), and azotemia (may be pre-renal or renal in origin).

Other studies, such as imaging, blood gas analysis, etc. are used to further characterize the disease relative to severity and cause (e.g. pancreatitis, etc.), but **should not be done at the expense of initiating appropriate and immediate therapy**.

Differential diagnosis

The **differentials are numerous, based upon the history and clinical signs** (e.g. renal failure, hepatic disease, poisoning, neoplasia and inflammatory bowel disease) but a minimum data base will serve to confirm the presence of diabetes mellitus.

Treatment

Ketoacidotic diabetes mellitus can be a medical emergency, as many cats will have severe metabolic acidosis, dehydration and electrolyte disturbances that are life threatening unless addressed.

Fluid therapy (0.9% NaCl or Normosol) is the essential, but must be used judiciously in conjunction with **replacement of potassium, phosphorus and magnesium**, which are often severely depleted. Serum potassium may rapidly decrease during initial therapy and should be monitored very closely (q 2–4 h).

Insulin replacement is instituted with a short-acting insulin (e.g. regular insulin, 0.1–0.2 U/kg, IV or IM q

2–6 h or as a constant rate infusion). **Frequent monitoring (q 1–2 h) of blood glucose concentrations is necessary** so that when the blood glucose level drops below 16.8 mmol/L SI (300 mg/dl), 5% dextrose is added to the fluids.

In cats that are not severely acidotic, and are still eating and not vomiting, insulin treatment may be instituted with NPH insulin (0.25–0.5 U/kg, SQ q 12 h), or where available PZI or glargine, with monitoring of blood glucose levels (q 2–3 h).

Cats that have urinary tract or other infections should be treated with appropriate **antibiotics**.

Vomiting is controlled with metoclopramide (0.1–0.2 mg/kg q 12 h) as needed.

Cats that are able to eat without vomiting should be fed a **highly palatable diet** (see page 238). **High-protein, reduced-carbohydrate diets** are advantageous in both thin and obese diabetic cats unless they have concurrent renal disease and need to eat a lower-protein diet.

HELICOBACTER SPP.*

Classical signs

- The classical sign is vomiting.

Pathogenesis

Helicobacter organisms known to **colonize the feline stomach** include: *H. pylori*, *H. felis*, and *H. bizzozeronii*. Other *Helicobacter* spp. that have been identified in the small intestine and liver of cats include *H. cinaedi* and *H. fennelliae*. The significance of these organisms and their ability to cause clinical disease is unknown.

H. felis is commonly found in the stomach of cats and may not be a feline pathogen, but *H. pylori*, which causes peptic disease in humans, is believed to also be associated with **gastritis in cats**, especially cats in **colonies or catteries**. *H. bizzozeronii* is the most common gastric colonizer in cats, and has experimentally produced chronic gastritis in kittens.

Infection is primarily transmitted via the **oral–oral route**. **Organisms are present in vomitus, oral secretions and saliva**, and may be transmitted via improperly disinfected dental equipment, endoscopes and

other instruments, or via contact with oral secretions directly.

Infection with *Helicobacter* organisms results in **increased infiltration of the mucosa with polymorphonuclear cells and mononuclear cells**, and is classified as **chronic gastritis**.

Persistent infection is associated with increased development of gastric lymphoid follicles, especially in the antrum, the location of heaviest concentration of organisms in most cats.

At this time, there does not appear to be a breed or sex predilection for infection or development of signs.

The classical sign is chronic vomiting due to gastritis, but **the incidence and true importance of *Helicobacter* spp. in gastritis in cats is not known**.

Clinical signs

Chronic vomiting, weight loss and in some cases, pica are reported in clinically affected cats.

However, **these organisms will be present in clinically healthy animals**, so a direct cause-and-effect relationship cannot be established.

Diagnosis

The diagnosis is **made by histologic examination of gastric mucosal tissue** (usually obtained via endoscopy). Either a **special silver stain or modified Giemsa stain** must be used to identify the organisms.

Culture and organism identification is also required to make a definitive diagnosis, since not all spiral organisms are pathogens or *Helicobacter* spp. *Helicobacter* spp. require **special media and handling for successful culture in vitro**.

***Helicobacter* spp. produce urease** that can be used to provisionally diagnose their presence, by placing biopsy samples in urea broth or by using the **commercially available test** (CloTest). However, **this test is neither sensitive nor specific for *Helicobacter* infection**.

Serologic assays used in humans are not reliable for testing in cats because of the cross-reactivity between other spiral organisms (commonly present in normal cats) and *H. pylori* (the suspected pathogen).

Differential diagnosis

Chronic gastritis due to other causes such as hepatic disease, pancreatitis, chronic renal failure or IBD may result in a similar clinical presentation.

Treatment

There have been various treatment regimens recommended for cats with *Helicobacter* infection, but none have been well substantiated.

The triple therapy regimen has been the mainstay of treatment for *Helicobacter* infection. This is bismuth (0.5–2 ml/kg PO q 4–6 h), metronidazole (62.5 mg PO q 24 h), and amoxicillin (15–20 mg/kg PO q 12 h). This regimen with the addition of famotidine (0.5–1.0 mg/kg PO q 24 h) has been recommended in refractory or severe cases.

Famotidine (0.5–1 mg/kg PO q 24 h), ranitidine (1–2 mg/kg PO q 12 h), or omeprazole (0.5–1.0 mg/kg PO q 24 h), in addition to antibiotic therapy have more recently been recommended.

Other antibiotics that may be used include tetracycline (22 mg/kg PO q 8 h), clarithromycin (7.5 mg/kg PO q 12 h), or azithromycin (5 mg/kg PO q 24–48 h).

Pepto-bismol can be used (1 ml/kg PO q 24 h) to control gastritis due to *Helicobacter* infection, but salicylate toxicity has occasionally been observed in individual cats.

The **duration of treatment for infected cats** has also not been well substantiated, but **14–28 days** has been the standard recommendation.

Prevention

Unknown, but careful attention to cleanliness of endoscopes and dental equipment is advised.

Public health

H. felis and *H. heilmannii* both are capable of colonization of humans and cats, but are not particularly pathogenic. *H. pylori* has not been isolated reliably from pet cats, so the zoonotic potential of *Helicobacter* in pet cats as a cause of human gastritis (a significant problem) has not been shown.

Most epidemiologic studies do not incriminate pet contact with human infection, and only contact with commercially reared cats has been shown to have any potential for risk, suggesting the possibility of a reverse zoonotic infection.

HYPERCALCEMIA* (MALIGNANCY, CHOLECALCIFEROL TOXICITY, CHRONIC RENAL FAILURE, HYPERPARATHYROIDISM, IDIOPATHIC HYPERCALCEMIA)

Classical signs

- Signs vary with the cause of hypercalcemia.
- Anorexia, vomiting and weight loss are typical.
- Polyuria and polydipsia are late signs, due to renal failure.
- Muscle weakness or tremors may occur acutely.

See main reference on page 245 (The Cat With Polyuria and Polydipsia) for details.

Clinical signs

Vomiting may be due to the disease causing the increased serum calcium or to the direct effects of elevated calcium stimulating vomiting receptors both peripherally or centrally.

The signs are dependent upon the cause of hypercalcemia, which can be due to the presence of malignancy, ingestion of cholecalciferol-containing rodenticides, endocrinopathies (primarily primary hyperparathyroidism) or idiopathic.

Signs associated with large elevations in serum calcium include **anorexia, vomiting, muscle weakness, polyuria and polydipsia, shaking/tremors and weight loss**.

Hypercalcemia has also been associated with the **development of calcium-containing nephroliths or uroliths**, which may cause signs of renal or bladder dysfunction.

Generally, **in cats, hypercalcemia is rare**, but if present is most commonly caused by renal failure or is secondary to malignancy. In some cats, the cause cannot

be identified. Other rarer causes include vitamin D toxicosis, primary hyperparathyroidism, hyperthyroidism, hypoadrenocorticoism and granulomatous disease.

Diagnosis

Hypercalcemia of malignancy is most often secondary to lymphoma, but may be due to multiple myeloma, adenocarcinoma and squamous cell carcinoma. Diagnosis of this disorder is based upon finding the primary tumor, an elevation of PTH-rP but not of iPTH in serum, and a response to therapy.

Primary hyperparathyroidism is rare in cats, but will be associated with an increased iPTH assay, a decrease in serum phosphorus and lack of other primary abnormalities.

Cholecalciferol poisoning is associated with a decrease in both the iPTH assay and PTH-rP assay, hyperphosphatemia and often evidence of mineralization of abdominal and other soft tissues.

Chronic renal failure (renal secondary hyperparathyroidism) is associated with an elevated iPTH and PTH-rP assay, but normal or decreased ionized calcium. Ionized calcium will be elevated with all other causes of hypercalcemia.

Recently, idiopathic hypercalcemia has been reported in cats and acidifying diets were implicated. This is associated with an increased serum total calcium or serum ionized calcium concentration, or both. Serum iPTH concentrations are low or in the low-normal range, while serum PTHrP is usually undetectable. Serum 25-hydroxycholecalciferol (vitamin D3) concentrations are normal in affected cats, as are serum phosphorus and albumin levels.

Phosphorous concentrations are normal or low-normal in all causes of hypercalcemia except cholecalciferol toxicity or renal failure, unless renal failure develops secondary to hypercalcemia.

Treatment

Specific treatment of hypercalcemia is directed at correcting the underlying cause if possible.

Supportive therapy measures to control or reduce hypercalcemia include **correction of fluid deficits and**

fluid diuresis with physiologic saline (60–180 ml/kg/day) and **administration of drugs that induce calciuresis** (furosemide 2–4 mg/kg PO q 12 h, or prednisolone 1–2 mg/kg PO q 12 h).

In severe, life-threatening hypercalcemia, where the above measures are inadequate, **sodium bicarbonate** (0.5–2 mEq/kg in IV fluids over 6 hours), **salmon calcitonin** (4 U/kg IV q 12–24 h) and **dialysis** (peritoneal or hemodialysis) **may be necessary**.

Other long-term therapeutic measures include feeding **a low-calcium diet** (Hill's k/d, u/d).

FELINE VIRAL DISEASES (FeLV, FIV, FIP)

Classical signs

- Weight loss, anorexia and lethargy are the most common signs.
- Vomiting is less common.
- ± Fever

See main reference on pages 540, 339, 372 for details.

Clinical signs

Specific signs depend upon the effect of the infection on the individual cat, e.g. development of neoplastic disease, bone marrow involvement, secondary infections and local (granuloma formation in FIP) or systemic disease (CNS, respiratory, hepatic, effusions).

The **most common signs** are **weight loss, anorexia and lethargy or depression**.

Feline leukemia virus (FeLV) is often associated with **neoplastic disease** (lymphoma, bone marrow infiltration) or **bone marrow dyscrasias** (cytopenias, myelodysplasias, etc.). Vomiting may occur associated with lymphoma.

Feline immunodeficiency virus (FIV) results in immunodeficiency disease that often results in **secondary infections** being the cause of significant morbidity and mortality. The skin, respiratory system and the gastrointestinal tract are most often affected.

The **classical presentation of effusive feline infections peritonitis (FIP)** is anorexia, lethargy, fever, weight loss, abdominal enlargement and dyspnea due to the **pleural and peritoneal effusion** of fluid.

Non-effusive FIP may present with a **wide variety of clinical signs depending on the system involved**, including chorioretinitis, fever, vomiting and/or diarrhea, abdominal pain (renal, liver), anorexia, lethargy and weight loss.

Diagnosis

Diagnosis of FeLV is by **ELISA antigen testing** and confirmation with serum or bone marrow IFA if the diagnosis is in doubt. PCR testing can also be performed in FeLV-suspect cats for confirmation.

FIV infection is detected by an **antibody test** and confirmed either via western blot analysis or **PCR testing** for the presence of viral proteins. (Note: vaccinated cats will test positive on the antibody test.)

Diagnosis of FIP is a very difficult process because of the lack of a definitive test that is sensitive and specific enough to differentiate enteric corona viral infections from FIP (a mutant of enteric corona virus).

Antibody titers are available, but detect the presence of any corona virus (feline enteric, canine enteric, FIP, etc.). Most cats from catteries, shelter situations or large, multi-cat populations will be exposed to enteric corona virus because of the ubiquitous nature of the virus in these settings (up to 85–90%). Thus, antibody testing of cats from these environments will be quite difficult to interpret. **Specific ELISA tests for the 7B protein in FIP have not proved to be reliable in the field.**

Serum PCR testing for FIP shows great promise for becoming a definitive diagnostic test, but the currently available serum tests still are not reliable tests for distinguishing FIP versus enteric corona virus. **The PCR test is an excellent means of ruling out FIP (negative test means the cat does not have FIP).** However, **a positive serum PCR test does not prove the cat has FIP.**

The **definitive diagnosis of FIP** still requires **histologic examination of tissues** for the classical changes or virus isolation. This is not usually necessary in cats with effusive FIP, but non-effusive FIP has such variable clinical signs and progression that the diagnosis is quite challenging.

PCR on tissue samples which have classic changes is also a good diagnostic test for FIP.

HISTOPLASMOSIS*

Classical signs

- **Dyspnea, wheezing or coughing are classical signs.**
- **Signs of gastrointestinal, CNS, or hemolymphatic system disturbances occur with systemic involvement.**

See main reference on page 755 for details.

Clinical signs

The **classical presenting signs are respiratory: dyspnea, wheezing or coughing.**

In cats with systemic histoplasmosis, the gastrointestinal tract, CNS or the skeletal system may be involved. The **GI tract signs are typically associated with diarrhea**, but in some cases, vomiting is observed, along with anorexia, weight loss and lethargy.

In generalized histoplasmosis, more non-specific signs may occur, such as anorexia, weight loss, fever, lymphadenopathy and lethargy.

Nervous system signs are rare and typically associated with seizures, changes in mentation or meningitis (neck or back pain, other neurologic signs such as ataxia, cranial nerve signs or weakness).

The **hemolymphatic system** involvement is manifest primarily as **bone marrow infiltration** with the fungus, which crowds out the red cell, white cell and/or platelet precursors, so the clinical signs are variable depending on the extent of marrow destruction.

Diagnosis

This disease has a **regional occurrence**, so a supportive history in a cat from an endemic area is suggestive.

In cats with **pulmonary histoplasmosis**, there may be very few hematologic or serum biochemical changes (e.g. leukocytosis, mild anemia, hyperproteinemia due to increased gamma globulins).

Disseminated histoplasmosis will often be associated with increases in liver enzyme activities, abnormal hemogram (bone marrow involvement causing anemia, thrombocytopenia, etc.), or changes associated with

protein losing enteropathy (hypoproteinemia, hypoalbuminemia, hypocholesterolemia, altered serum electrolytes).

Radiographs will be useful in cats with pulmonary disease, but less helpful with evaluation of other organs. Cats with intestinal histoplasmosis often have thickened loops of bowel that can be seen radiographically or via ultrasound imaging. **Ultrasound** may be useful in assessing liver and GI tract involvement.

Serology is available for detection of systemic fungal infections, including histoplasmosis, but the tests have a **high percentage of false negatives** in cats.

The **definitive diagnosis is obtained by finding organisms** in the affected tissues.

Endoscopic or surgical biopsy, fine-needle aspirates by ultrasound guidance, bone marrow examination or bronchial washing are necessary to obtain the diagnosis. In cats with signs of GI disease, especially diarrhea, rectal scrapings may also reveal the organism.

TOXOPLASMOSIS*

Classical signs

- Toxoplasmosis is a systemic disease involving multiple organs systems.
- Respiratory tract signs (dyspnea, coughing, rhinitis).
- CNS signs (ataxia, behavioral changes, seizures, circling).
- Hepatic disease signs (vomiting, diarrhea, icterus, anorexia, lethargy, weight loss, abdominal effusion, or discomfort).
- Cardiac signs (arrhythmias, sudden death).
- Ocular signs (chorioretinitis, anterior uveitis, optic neuritis, blindness, anisocoria, glaucoma or retinal detachment).
- Rarely GIT granuloma causing vomiting.

See main reference on page 375 for details.

Clinical signs

Toxoplasmosis is a systemic, multi-organ disease that often affects young kittens, but adult cats are also

infected, especially those with FIV or feline leukemia virus infection.

Infected cats most frequently have respiratory tract disease (dyspnea, coughing, rhinitis), **CNS disease** (ataxia, behavioral changes, seizures, circling), **hepatic disease** (vomiting, diarrhea, icterus, anorexia, lethargy, weight loss, abdominal effusion or discomfort), **cardiac disease** (arrhythmias, sudden death) or **ocular disease** (chorioretinitis, anterior uveitis, optic neuritis, blindness, anisocoria, glaucoma or retinal detachment).

Adult cats with FIV have more multi-systemic signs, while cats without FIV often have ocular or neurologic signs only.

Occasionally, toxoplasma granulomas (tissue cysts) form in the GIT or pancreas, rather than encysting in muscle, and result in chronic vomiting. The encysted organisms cause immune complex formation that is responsible for the granuloma formation and the chronic, but sublethal clinical disease.

Diagnosis

Hemogram abnormalities: non-regenerative anemia, neutrophilic leukocytosis, lymphocytosis and eosinophilia are most commonly observed.

Lymphopenia may be present in cats with FIV or end-stage disease.

Biochemical abnormalities are common with systemic disease and include: hypoproteinemia, hypoalbuminemia, hyperglobulinemia, elevated liver enzyme activities (hepatic involvement), increased creatine kinase (muscle involvement), hyperbilirubinemia (cats with cholangitis), proteinuria is also relatively common.

In focal GIT *Toxoplasma* granuloma, biochemical abnormalities may be minimal.

Diagnosis is based on finding the organism in tissues (cytology or histopathology) or by serologic testing.

Thoracic radiographs in cats with acute disease will reveal a diffuse interstitial pattern with a mottled lobar distribution.

Fecal examination for oocysts in cats is usually not helpful since less than 1% of infected cats shed the oocysts on any given day.

Serologic testing is currently the best method of detection, but because of the presence of antibodies in both healthy and diseased cats, titers must be used cautiously. **No single serologic test can definitively confirm toxoplasmosis.**

Serum ELISA tests for IgM, IgG and IgA are readily available and have been used to try to distinguish acute from chronic infections in cats. Finding of a **high IgM titer, along with a four-fold increase over 2–3 weeks (or decrease) in IgG titer** (in the presence of appropriate clinical signs, and response to anti-toxoplasma drugs, e.g. clindamycin) is suggestive of recent or active toxoplasmosis.

Other tests of serum IgG supportive of toxoplasma infection are the **modified agglutination test (MAT)** and the latex agglutination test (LAT). The MAT is the most sensitive test of IgG antibody, but is not uniformly available. The LAT cannot distinguish antibody classes, thus is less useful.

Aqueous humor and CSF titers are also useful, but should be compared with serum titers to determine if local immunoglobulin production is occurring.

INTESTINAL MAST CELL TUMOR*

Classical signs

- Weight loss and anorexia are the most common early signs.
- Intermittent or persistent vomiting, diarrhea and lethargy or depression become more prevalent with advancing disease.

Pathogenesis

Mast cell tumors of the intestine are the **third most common GI tract neoplasm** in cats behind lymphoma and intestinal adenocarcinoma.

These are tumors of **old (mean age = 13 years) cats**, with **no breed or sex predilection**. They occur with about the same frequency as mast cell tumors of the lymphoreticular system (e.g. spleen, lymph nodes and bone marrow), but **cats with intestinal mast cell tumors typically do not have circulating mast cells.**

Intestinal mast cell tumors are usually solitary, and affect the **distal small intestine**, but multiple masses can occur. Typically, they appear as a **segmented nodular thickening in the small intestine.**

Mast cell tumors of the GI tract are usually **poorly differentiated** (thus cytologic examination is difficult) and **highly malignant**, with metastasis to the mesenteric lymph nodes, liver and spleen. They are generally not functional tumors and are **not typically associated with gastrointestinal ulcer disease**. However, there may be chronic bleeding from the tumor into the GIT.

No association with FeLV, FIV or FIP has been reported.

Clinical signs

The **most common clinical signs** in cats with an intestinal mast cell tumor are **weight loss, lethargy and anorexia.**

Intermittent or persistent **vomiting, diarrhea and lethargy** or depression become **more prevalent with advancing disease.**

Vomiting and/or diarrhea may also be observed, but often not until late in the disease.

Other signs include ascites, splenic enlargement (metastasis), and rarely, mast cells in circulation (bone marrow involvement).

Diagnosis

Palpation of an intestinal mass in an older cat is suggestive of neoplasia, but **these tumors may be very small.**

Abnormalities of the hemogram or serum chemistry profile are uncommon, but may include anemia (non-regenerative), hypoproteinemia and elevated liver enzyme activities.

Survey radiographs may identify a mass, evidence of intestinal obstruction, or mild peritoneal effusion, but contrast radiography will be required to identify the location and extent of many of these tumors.

Ultrasonography is a useful tool in identifying the location, extent and presence of metastatic lesions. **Fine-needle aspiration or biopsy** of these masses by

ultrasound guidance may be useful, but because of the poorly differentiated nature of the tumor they may also be non-diagnostic.

Analysis of peritoneal effusion fluid may be helpful if mast cells are present, but as with fine-needle aspirates, the effusion may be suggestive of neoplasia, but not necessarily give a definitive diagnosis.

Definitive diagnosis requires histopathologic examination of the tissue, which is usually best achieved by wide surgical resection and anastomosis.

Staging of the tumor is achieved by biopsy of mesenteric lymph nodes, spleen, liver and bone marrow aspiration (if indicated). **The tumor rarely metastasizes out of the abdomen.**

Differential diagnosis

Other intestinal neoplasia, foreign body, fungal or algal disease, inflammatory bowel disease, and extra-intestinal causes of anorexia, weight loss and vomiting (chronic renal failure, hyperthyroidism, etc.) are all differentials that should be considered.

Treatment

Surgical resection is the only known treatment. Surgical margins must be > 5 cm beyond the visible edge of the lesion because of the cellular invasion that occurs along the tumor mass.

Metastasis occurs early in the course of the disease to the spleen, liver and regional lymph nodes.

Other forms of therapy (**chemotherapy, radiation, etc.**) **have either been ineffective or not evaluated.** **Adjunct therapy with cimetidine, anti-histamines and prednisone** may be tried to control signs associated with mast cell degranulation, but are **often not helpful** because these tumors are typically poorly differentiated and **do not produce granules or GI ulcer disease.**

Nutritional support (enteral or parenteral nutrition) may be required for cats that do not want to eat or are vomiting.

Prognosis

The **prognosis is poor** for cats with this disease.

Despite surgical removal, **cats with intestinal mast cell tumors rarely live longer than 4 months.**

FOREIGN BODIES*

Classical signs

- The classical sign is an acute onset of frequent vomiting.
- Intermittent vomiting will occur in some cats with foreign bodies that are causing an intermittent or incomplete obstruction (e.g. string).

See main reference on page 636 for details.

Clinical signs

The **classical sign is an acute onset of frequent vomiting**, but intermittent vomiting will occur in some cats with foreign bodies that are causing an **intermittent or incomplete obstruction** (e.g. string).

There may or may not be palpable abnormalities in the intestinal tract, and most cats will be clinically normal otherwise.

Diagnosis

The **definitive diagnosis** is usually made by **contrast radiography**, however, survey radiographs or **ultrasound examination** may also reveal abnormalities that are consistent with a GI foreign body.

String foreign bodies often are found attached to the base of the tongue, thus a **thorough oral exam is always essential in cats with a suspected GI foreign body.**

Some foreign bodies can be found and retrieved by **gastrointestinal or colonic endoscopy**. In many cases, these foreign objects are metallic and will be visible on survey radiographs.

Differential diagnosis

Gastric parasites, heartworm disease, *Helicobacter* spp. gastritis, food intolerance, food allergy, and antral pyloric hypertrophy or stenosis are primary differentials

because they all may cause vomiting in the absence of other signs of disease.

Treatment

Surgical removal of the foreign body is required if it is not able to be retrieved and removed via an endoscopic procedure.

CONGESTIVE HEART FAILURE*

Classical signs

- Coughing or dyspnea.
- Lethargy.
- Anorexia.
- Exercise intolerance.
- Weight loss.

See main reference on page 124 for details (The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

Clinical signs

Classical signs of congestive heart failure include **dyspnea, coughing, cyanosis, pale mucous membranes**, poor pulse quality, inappetence, exercise intolerance/weakness and lethargy. Cats are usually presented with acute dyspnea and cyanosis.

The **signs may be quite variable** depending on the cause of heart failure. **Valvular disease** is often associated with an **audible murmur**, while **heart muscle diseases** often are associated with **tachycardia, gallop rhythm and weak pulses**.

Other signs that may be observed in cats with heart failure include collapse, vomiting, weight loss, limb paresis/paralysis due to thromboembolic disease, and rarely, abdominal distention.

Other cats may develop pleural effusion that increases respiratory effort but is not associated with coughing or increased lung sounds (decreased or absent lung sounds are present).

Vomiting episodes are typically chronic, but infrequent and more commonly associated with heart muscle disease (myopathy) rather than valvular disease.

Diagnosis

History and physical examination findings will be suggestive of congestive heart failure, especially if the cat has a murmur, gallop rhythm or other signs referable to primary heart disease.

Hematology and serum biochemical profile data may reveal **mild, non-specific changes**, such as anemia of chronic disease, prerenal azotemia, elevations in liver enzyme activities secondary to congestion, and changes in electrolytes and proteins consistent with dehydration. If myositis is a differential for the cause of heart failure, elevated creatine kinase values may be useful additional information.

Imaging studies are necessary to make a **definitive diagnosis**. In particular, **thoracic radiographs** will be helpful in assessing **cardiac size and pulmonary involvement** (edema vs. pleural effusion, etc.). **Cardiac ultrasound examination** is the best diagnostic test for evaluating cardiac muscle function, size and presence of valvular or other defects.

Electrocardiography may also be useful to detect or document any **arrhythmias**.

SYSTEMIC NEOPLASIA*(GENERALIZED LYMPHOMA, SYSTEMIC MASTOCYTOSIS)

Classical signs

- Weight loss.
- Lethargy or depression.
- Anorexia.
- Enlarged spleen or liver, lymph nodes or bone marrow involvement.

Clinical signs

The **most common clinical finding** is marked **hepatomegaly or splenomegaly** along with **enlarged lymph nodes** (mesenteric).

Other common signs are **vomiting and anorexia**.

In some cases, **peritoneal effusion** will be present, which along with the hepatomegaly or splenomegaly will be observed as **profound abdominal enlargement**.

Diagnosis

Definitive diagnosis is obtained by **fine-needle aspiration of the enlarged liver, spleen or lymph nodes**.

Mast cells or lymphoblasts/cytes may also be found in the systemic circulation on routine hematology, and will also be found on examination of **bone marrow aspirates**. In addition, **anemia and cytopenias are also common findings** on hematologic exams.

Ultrasound or radiographic evaluation will reveal the extreme size of the liver and spleen and ultrasound guidance can be used in obtaining fine-needle aspirates (especially of lymph nodes or sections of the liver that have obvious structural abnormalities).

CNS DISEASES* (ENCEPHALITIS, VESTIBULAR DISEASE, SEIZURE DISORDERS, NEOPLASIA)

Classical signs

- Neurologic signs localized to the region of the CNS that is affected (e.g. vestibular disease is associated with loss of balance, ataxia, falling to one side, head tilt, nystagmus, etc.).
- Vomiting is infrequent.

Clinical signs

The predominant clinical signs will be **neurologic signs that are localized to the region of the CNS that is affected**. Vestibular disease can be associated with vomiting, but typical signs include loss of balance, ataxia, falling to one side, head tilt and nystagmus. **Most neurologic diseases that cause vomiting affect the CNS**, not the spinal cord or peripheral nervous system, except for the peripheral parts of cranial nerve VIII located in the inner ear.

Vomiting is an infrequent but still important sign of CNS disturbance most often associated with involvement of the **peripheral vestibular system**.

Cats with signs of **hepatoencephalopathy** (changes in behavior, stupor, drooling or ataxia) may vomit from the effects on the CNS or the GIT.

Diagnosis

A thorough **neurologic examination** is the first step in determining if neurologic disease is present and in attempting to determine if the disease is affecting the central, spinal or peripheral nervous system.

Other important diagnostic tests for diseases in the CNS include CSF analysis, including culture and serology (FIP, toxoplasmosis, fungal disease), computed tomography or MRI imaging, electroencephalogram, and brainstem auditory-evoked response (middle/inner ear).

Radiographs of the middle/inner ear areas are non-specific and very difficult to evaluate, and have **largely been replaced by CT** as a means of assessing this region. However, **middle and inner ear infections** can also be diagnosed via **myringotomy and culture of fluid** from the middle ear.

Unless a systemic disease process is the cause of the CNS signs, the **minimum data base is likely to be normal**.

PHYSALOPTERA

Classical signs

- The classical sign is frequent vomiting, but intermittent vomiting will occur in some cats.

See main reference on page 653 for details (The Cat With Signs of Acute Vomiting).

Clinical signs

The **predominant clinical sign is vomiting**. Most cats will present with an acute onset of vomiting, but others may have intermittent, chronic vomiting.

Diagnosis

Fecal floatation and finding of the **larvated eggs** in the feces (**shedding is intermittent**, so multiple feces are required) is diagnostic, but unrewarding.

Finding of **small worms in vomitus or on endoscopic examination**.

Response to a **therapeutic trial with fenbendazole** (25 mg/kg PO q 24 h for 3–5 days).

HEARTWORM DISEASE (*DIROFILARIA IMMITIS*)

Classical signs

- Signs are variable.
- No signs may be present.
- Signs of respiratory disease (tachypnea, dyspnea).
- Intermittent vomiting.
- Signs of cardiovascular disease (lethargy, anorexia, coughing, weakness).
- Sudden death.

See main reference on page 139 for details.

Clinical signs

Anorexia and weight loss are the **most common signs** observed in cats with dirofilariasis.

Respiratory signs such as wheezing, dyspnea, and occasionally coughing are less common than in dogs, and often **mimic feline asthma**.

Intermittent vomiting is a relatively frequent sign associated with feline heartworm disease that may occur in the absence of other clinical signs.

Sudden death is a complication of heartworm disease in cats, and may occur in 20–30% of infected cats.

Diagnosis

A history of **living in a heartworm endemic area** along with the **appropriate clinical signs** in the absence of heartworm preventative use should arouse clinical suspicion.

Hematology may reveal an **eosinophilia or basophilia**.

Unless cats have developed heart failure, the chemistry profile and urinalysis are usually normal. Cats that are in right congestive heart failure may have elevated liver enzyme activities or azotemia.

Radiographs of the thorax will reveal the **classic changes associated with heartworm disease**, which are enlarged pulmonary arteries, arterial tortuosity or blunting, pulmonary interstitial pattern and right-sided cardiac enlargement.

Ultrasound can also be used to identify worms in the main pulmonary artery or right ventricle, but the sensitivity of this test is highly dependent on operator experience.

A **heartworm antibody test** is the recommended **screening test** for cats, and while it does not confirm infection, it is an accurate means of confirming exposure. However, **it may remain positive for 18 months or more after resolution of infection, and also may be positive if arrested larval infection has occurred**.

Because cats generally have only 1–2 worms present, the **standard heartworm antigen tests used in dogs are often not sensitive enough to detect the disease in cats**.

A feline antigen test has been developed, and detects the presence of a single male worm, but false-negative tests still occur. Antigen tests should not be the sole means of evaluating cats for heartworm infection.

HYPOADRENOCORTICISM (ADDISON'S DISEASE)

Classical signs

- Lethargy, anorexia and weight loss are most common.
- Vomiting.
- Polyuria, polydipsia.
- Clinical signs may wax and wane.

See main reference on page 252 for details.

Clinical signs

This is a very rare disease in cats.

The classical signs are **lethargy, anorexia and weight loss**. Other signs that may be seen are vomiting, polyuria/polydipsia, weakness and waxing/waning signs.

Most cats (> 50%) will be **hypothermic, dehydrated or depressed on physical examination**, but other signs such as weak pulses, bradycardia and collapse are less common.

Diagnosis

The **history and clinical signs will be vague in early cases**, so that a degree of clinical suspicion is required to make the diagnosis.

Anemia, lymphocytosis and eosinophilia are relatively uncommon (< 20%) findings in cats.

Serum biochemistries and urinalysis show **hyponatremia, azotemia (pre-renal or renal), and hyperphosphatemia** in the majority of cats. Hyperkalemia and hypochloridemia are also common, but not seen in every case.

Other less common (< 30% cases reported) abnormalities include metabolic acidosis, increased liver enzyme activities, hypercalcemia and hyperbilirubinemia.

Slightly more than 50% of affected cats will have an **unconcentrated urine sample (SG < 1.030)**, supporting renal azotemia.

The **definitive diagnostic test** for hypoadrenocorticism is an **ACTH stimulation test**, which will reveal a low resting cortisol concentration, and no response (no increase in cortisol levels) following administration of ACTH (Cosyntropin 0.125 mg/cat, IM), at either the 30 or 60 min post-administration sampling times. Administration of steroids by any route (oral, parenteral or topically) or progestins (e.g. megestrol acetate) will suppress cortisol response to ACTH. This suppression may persist for weeks after the last time of administration, especially if administration was chronic.

Radiographic changes include microcardia and hypoperfusion of the lungs due to hypovolemia. **ECG changes classically observed in dogs**, such as peaked T waves, reduced or absent P waves, or atrial standstill are not seen in cats.

If serum electrolyte concentrations are normal, but a subnormal response to ACTH administration is observed, the cat may have: (1) residual mineralocorticoid secretion; (2) secondary hypoadrenocorticism from pituitary or hypothalamic disease causing only glucocorticoid deficiency but this has not yet been reported in cats; or (3) **secondary hypoadrenocorticism due to exogenous administration of glucocorticoids or progestogens**. Although this is the most common cause of secondary hypoadrenocorticism and suppressed adrenal response to ACTH, it rarely causes sufficient lethargy for veterinary attention to be sought. If clinical signs consistent with hypoadrenocorticism are present in a cat with a suppressed ACTH stimulation test secondary to steroid administration, the signs are most likely caused by another disease.

To differentiate pituitary or hypothalamic disease from exogenous drug administration as the cause of secondary hypoadrenocorticism, **plasma ACTH concentration** is measured.

INTUSSUSCEPTION

Classical signs

- The classical sign is an acute onset of frequent vomiting.
- Intermittent vomiting will occur in some cats.

See main reference on page 643 for details.

Clinical signs

An **acute onset of vomiting, abdominal pain or anorexia is the most common sign**. However, in some cats with **sliding, intermittent or incomplete intussusception**, the signs may be intermittent. **Weight loss and vomiting** will be more prevalent in these cats.

Diagnosis

A palpable abdominal mass may help direct the diagnostic approach if it is present.

Contrast radiographs or ultrasound examination of the GI tract are the most definitive means of making the diagnosis.

Intussusception rarely presents as a chronic problem, so in these cases, abnormalities associated with chronic GI dysfunction (e.g. hypoproteinemia, hypoalbuminemia) may be present.

LEAD POISONING

Classical signs

- Gastrointestinal signs include anorexia, vomiting, diarrhea and abdominal pain.
- Neurologic signs include aggression, nervousness, tremors, seizures, blindness and dementia.

See main reference on page 596 for details.

Clinical signs

Gastrointestinal signs include anorexia, vomiting, diarrhea and abdominal pain. Weight loss is common.

Neurologic signs include aggression, nervousness, tremors, seizures, blindness and dementia.

GI signs tend to occur **acutely** and **before neurologic signs**. **CNS signs** are associated with **severe toxicity or chronicity**.

Diagnosis

There may be a history of exposure to lead-containing materials in the environment (paints, roofing materials, batteries, used motor oil, lead shot, etc.).

Characteristic clinical signs (the **combination of gastrointestinal and neurologic signs**) are suggestive.

There are **typical hemogram changes** including basophilic stippling of RBCs, and increased numbers of nucleated RBCs, although these are not as common in the cat as in the dog.

Radiographs may reveal radiopaque material in the GIT.

The **definitive diagnosis** is made by measurement of a **blood lead level** (> 0.5 ppm is diagnostic).

Treatment

Gastric lavage or **induction of emesis** should be performed to remove the offending materials from the stomach, **if ingestion was recent**. If the material can be retrieved by endoscopy or surgical removal (e.g. it is a large object) it should be done.

Oral activated charcoal should be administered to reduce the absorption of the material from the GIT.

An IV catheter should be placed and **supportive fluid therapy** (Normosol or LRS, 40–60 ml/kg IV) should be commenced.

Calcium EDTA to chelate lead and hasten excretion can also be used (25 mg/kg q 6 h IV as 10 mg Ca EDTA/ml in dextrose, maximum 2–5 days).

If seizures or other severe neurologic signs are present, **appropriate seizure control** (e.g. IV valium 2.5–5 mg or phenobarbital 1–4 mg/kg IM) should be used.

If the cat is debilitated and anorectic, **nutritional support** may also have to be instituted.

OTHER INTESTINAL NEOPLASIA (FIBROSARCOMA, CARCINOMAS, PLASMACYTOMA, LEIOMYOSARCOMA, ETC.)

Classical signs

- Weight loss.
- Lethargy or depression.
- Anorexia.
- Vomiting and/or diarrhea.

Clinical signs

The **clinical signs observed** will depend upon the **tumor location** in the GI tract.

In cats, **anorexia, weight loss and lethargy** are the **most common clinical signs** of any gastrointestinal neoplastic disease.

Vomiting and/or diarrhea may be observed, but will be **variable** depending on whether the tumor is in the small intestine or colon, and whether it is diffuse or solitary in extent.

Diagnosis

Palpation of an intestinal mass is an important **diagnostic tool**, since many of these tumors are solitary and produce strictures or obstructions.

Hematology and serum biochemistry profiles may be **within normal limits** in cats with intestinal neoplasia.

Abnormalities associated with secondary effects of the tumor include dehydration, electrolyte imbalances, anemia of chronic disease, etc.

Radiographs of both the thorax and abdomen are an important, but sometimes non-diagnostic, tool. Radiographs are best for assessment of **pulmonary metastasis**.

Ultrasound is an invaluable tool for lesion localization, determination of lesion extent and in some cases, obtaining a fine-needle aspirate or biopsy of the lesion.

Definitive diagnosis is by histopathologic evaluation of a biopsy or tissue obtained after surgical resection.

ANTRAL PYLORIC HYPERTROPHY/STENOSIS

Classical signs

- Vomiting several hours after eating.
- Projectile vomiting will be observed if the pylorus is obstructed.
- Abdominal distention or pain may be observed due to gastric distention.

Pathogenesis

Antral pyloric hypertrophy is a condition that involves hyperplasia of the pyloric musculature, pyloric mucosa or both, which results in narrowing or complete obstruction of the gastric outflow tract.

The condition can be congenital or acquired, but in either case, the exact cause is unknown.

Both neural dysfunction and endocrinopathies (hypergastrinemia) have been proposed to be involved in the disease.

The obstruction of gastric outflow results in gastric retention and subsequent gastric distention. Gastric distention stimulates gastrin secretion which is trophic to antral tissues and may further contribute to mucosal hypertrophy.

In some cases of congenital pyloric stenosis there is no antral hypertrophy. The gastric retention is believed to be due to a motility disturbance that results in a functional obstruction.

For reasons that are yet unknown, the disorder has been observed primarily in Siamese cats.

Clinical signs

Vomiting is the most common sign.

In congenital pyloric stenosis, kittens begin to vomit shortly after they commence solid food.

Acquired pyloric hypertrophy has a more variable presentation, but is usually associated with intermittent vomiting of digested food several hours after consumption. If the pylorus is completely obstructed the vomiting may be projectile.

Chronic intermittent vomiting and gastric distention may lead to gastroesophageal reflux or esophagitis which may be associated with regurgitation or inappetence and weight loss.

Diagnosis

History and signalment will be suggestive of a gastric emptying disturbance.

Hemogram, serum chemistries and urinalysis are typically unremarkable.

Survey radiographs of the abdomen may be normal, show gastric distention, or pyloric abnormalities. Contrast radiographs may identify hypertrophic gastric mucosa or a narrow gastric outflow pathway ("beak sign").

Ultrasonography may detect a thickened pyloric antrum if it is present.

Fluoroscopy or scintigraphy can be used to evaluate gastric peristalsis and emptying, but are not universally available.

Gastric endoscopy may be normal or may reveal thickened folds of mucosa, the pyloric antrum may not insufflate normally, or the pylorus may be too stenotic to allow passage of the endoscope through the orifice.

Definitive diagnosis requires an exploratory laparotomy and histopathologic examination of tissue for antral pyloric hypertrophy, but motility disturbances can only be diagnosed via fluoroscopy/scintigraphy, and hypergastrinemia can be detected by measurement of serum gastrin levels.

Differential diagnosis

Neoplasia (gastric adenocarcinoma, leiomyosarcoma, lymphosarcoma) of the gastric, pancreatic or duodenal tissues resulting in pyloric thickening and obstruction should be considered, especially in older cats.

Neoplasia of surrounding tissues resulting in gastric outflow obstruction from an external source, or a gastric

foreign body resulting in obstruction or decreased outflow may also result in similar clinical signs.

Gastric ulcer disease may result in chronic vomiting and abnormal motility.

Extra-gastrointestinal causes of vomiting include hepatic, renal, metabolic, inflammatory (pancreatitis) or endocrine causes.

Treatment

Definitive treatment for pyloric antral hypertrophy/stenosis is **surgical correction of the outflow obstruction**.

In cats with **motility disturbances**, **gastric prokinetic therapy** (metoclopramide 0.1–0.2 mg/kg PO q 12 h, or cisapride 5 mg/cat PO q 8–12 h) may improve movement of ingesta and reduce clinical signs.

However, **in early cases**, medical management with **feeding of small meals consisting of highly digestible foods** (low residue, low fat, low fiber) may also be helpful.

Following surgical correction of the outflow obstruction, some animals will still require medical therapy with gastric prokinetics because of residual motility disturbances.

Prognosis

The prognosis is **guarded to good with surgical management**, as some animals may still require life-long medical management following surgery to control the clinical signs.

Cats that develop **esophagitis due to reflux disease** may have a **more guarded prognosis** because of the problems associated with esophagitis (stricture development).

DYSAUTONOMIA

Classical signs

- Depression and anorexia.
- Mydriasis, reduced pupillary light reflex, protruding nictitans, normal vision.
- Xerostomia (dry mouth and mucous membranes) and keratoconjunctivitis sicca.
- Retching, regurgitation or vomiting.
- Fecal incontinence or constipation.

See main reference on page 792 for details (The Constipated or Straining Cat).

Clinical signs

Lethargy and anorexia are present in almost all cats and usually develop over a **48-hour period**.

The classical signs are associated with **the dysfunction of both sympathetic and parasympathetic nervous system**. **Ocular signs include** dilated pupils, decreased or absent pupillary light reflex and protruding nictitans, but have **normal vision**.

Gastrointestinal signs are present in about 95% of cats and include constipation, regurgitation (secondary to megaesophagus) and dry mouth. Vomiting may occur or regurgitation may be reported as vomiting.

Less commonly observed signs are bradycardia, hypotension, urinary incontinence or a distended, easily compressed bladder, proprioceptive deficits and transient syncopal episodes.

Diagnosis

There is **no definitive, antemortem diagnostic test for dysautonomia**.

Diagnosis is made by using the **clinical presentation** along with **radiographic evidence of megaesophagus** and its associated complications, and use of **pharmacologic testing** to evaluate the function of the sympathetic and parasympathetic nervous system.

Direct-acting parasympathomimetic and sympathomimetics produce an effect in diseased cats but not in normal cats because of post-ganglionic denervation hypersensitivity in affected cats. **Indirect (preganglionic) acting agents produce an ocular effect in normal cats but not diseased cats**.

Ocular testing with sympathomimetic agents, e.g. 1% hydroxyamphetamine (indirect acting) produces no mydriasis, and 1% phenylephrine (direct acting) produces rapid mydriasis in affected cats.

Ocular testing with parasympathomimetic agents, e.g. 0.5% physostigmine (indirect acting) produces no miosis, and 0.1% pilocarpine (direct acting) produces rapid miosis in affected cats.

Systemic testing using 0.04 mg/kg atropine, subcutaneously, will increase the heart rate if the sympathetic nervous system is normal. Note: Do not use ephedrine, epinephrine or other sympathomimetics, because fatal arrhythmias can be induced.

Failure to demonstrate a wheal and flare response following intradermal injection of histamine (1:1000) indicates a defect in the sympathetic innervation of cutaneous blood vessels.

GASTRINOMA

Classical signs

- **Chronic vomiting unresponsive to routine therapy for gastritis and gastric ulcer disease.**

Pathogenesis

Chronic gastritis and gastric ulcer disease are produced secondary to a **gastrin-secreting tumor** that arises from the **pancreatic islet cells** (called Zollinger–Ellison syndrome).

This is a **rare disease** that has only been described in three older cats.

The pancreatic tumor may occur as a solitary lesion, or there may be multiple lesions on the liver due to metastasis.

Clinical signs

Typical signs include **chronic vomiting, weight loss and anorexia** in a cat previously diagnosed with gastritis or gastric ulcers on histopathologic examination of the stomach, but **unresponsive to routine therapy**.

Diagnosis

The gastritis and gastric ulcer disease are diagnosed by **endoscopy and histologic examination of the stomach and duodenum**.

However, to make a definitive diagnosis of Zollinger–Ellison syndrome, a **serum gastrin level** must be obtained along with the finding of a **discrete tumor on the pancreatic islets**. **Very high levels of serum gastrin** are obtained in cats with gastrinoma.

Differential diagnosis

These are rare tumors of the GI tract, so **even finding elevated serum gastrin levels is not sufficient**, since there are other causes for elevations in serum gastrin levels (e.g. chronic renal failure, etc.).

Other causes of chronic gastritis, including *Helicobacter* spp., liver disease and pancreatitis should be explored.

Treatment

Surgical removal of the tumor, if possible, is the treatment of choice. Management of the gastritis and gastric ulcer disease is as for other primary causes of this problem (see section on gastritis for details, page 680).

32. The cat with signs of acute small bowel diarrhea

Debra L Zoran

KEY SIGNS

- Loose to watery feces.
- \pm Melena.
- No mucus or fresh blood.
- < 3 weeks duration.

MECHANISM?

- There are four recognized pathophysiologic mechanisms of diarrhea include osmotic, secretory, increased permeability and altered motility.

Small bowel diarrhea is characterized by:

- Loose to watery feces.
- Increased volume of feces.
- Normal to increased frequency of defecation.
- No straining or tenesmus associated with defecation.
- If blood is present in feces it occurs as melena.
- Increased mucus is not present in the feces.
- Weight loss and vomiting are commonly observed concurrently.

WHERE?

- Small intestinal tract (duodenum, jejunum and ileum).

WHAT?

- Mild, acute small bowel diarrhea is a common problem that may be caused by a variety of self-limiting factors, including dietary, infectious, parasitic or toxic agents. However, severe small bowel diarrhea may be life-threatening and associated with severe systemic or GI disease. Some diseases typically produce chronic diarrhea, but in the early stages are perceived as producing acute diarrhea.

QUICK REFERENCE SUMMARY

Diseases causing signs of acute small bowel diarrhea

MECHANICAL

- **Foreign bodies* (p 713)**

Diarrhea commonly occurs either due to motility disturbances or irritating effects of the foreign object that may cause increased secretion.

- **Intussusception* (p 712)**

Acute onset of diarrhea may occur due to alterations in gut motility, however, vomiting is a more prominent clinical sign.

- **Motility disturbances**

Primary motility disturbances are rare, but secondary causes of abnormal GI motility such as post-operative ileus, post-obstructive disease or metabolic or endocrine causes of ileus are more important causes of diarrhea.

- **Short bowel syndrome (p 730)**

Spontaneous short bowel syndrome occurs acutely with intussusception, bowel strangulation and intestinal volvulus. Iatrogenic syndrome associated with resection of 75–90% of the small intestine results in severe diarrhea and weight loss. Congenital forms of short bowel syndrome are reported, but are rare.

METABOLIC

- **Hyperthyroidism* (p 711)**

Intermittent diarrhea, vomiting or voluminous stools in an older cat with a good to ravenous appetite, obvious weight loss and poorly groomed coat are characteristic of this disease.

- **Inflammatory hepatobiliary disease (cholangitis)* (p 710)**

The clinical presentation of cholangitis is non-specific: anorexia, lethargy, weight loss, vomiting, diarrhea, dehydration, hepatomegaly and icterus. The disease primarily affects male cats greater than 4 years of age.

- **Shock (hypovolemic, septic, endotoxic)* (p 722)**

Acute diarrhea occurs secondary to gastrointestinal ischemia from severe hypovolemia or sepsis and may contribute to patient morbidity.

- **Exocrine pancreatic insufficiency (p 730)**

A rare disease in cats, but is typically associated with small bowel diarrhea, weight loss and a ravenous appetite. Diarrhea is typically chronic but may be perceived as acute onset.

NUTRITIONAL

- **Food intolerance*** (p 704)**

Indiscretion is associated with an acute onset of diarrhea due to overeating, eating too quickly or ingesting a foreign substance (food or non-food). Intolerance presents with intermittent diarrhea or vomiting, with no pattern or association with eating, and resolves when the food source is changed to omit offending substance from diet.

- **Food allergy (dietary hypersensitivity)* (p 709)**

Vomiting appears to be more common than diarrhea in cats with food allergy, but it is more likely to occur when the disturbance affects more distal aspects of the GI tract.

NEOPLASTIC

● Tumors of the small intestine* (p 715)

The most common tumor of the feline digestive system is alimentary lymphoma. Other tumors that occur in the small intestine are adenocarcinomas (second), and mast cell tumors (third), with fibrosarcomas, leiomyosarcomas and carcinoids occurring rarely. With the exception of lymphoma, which can occur at any age, most tumors occur in old cats. The clinical signs most often observed are anorexia and weight loss, with vomiting or diarrhea less common. The diarrhea is often chronic, but the onset may be acute.

IMMUNOLOGIC

● Idiopathic inflammatory bowel disease (IBD) (p 714)

Generally considered to be a disorder associated with chronic, intermittent vomiting, diarrhea or weight loss, but acute exacerbations of diarrhea may occur. IBD is described primarily by the predominant inflammatory cell type infiltrating the mucosa. Lymphocytic plasmacytic enteritis is the most common form of IBD, but eosinophilic and suppurative forms of the disease occur as well.

INFECTIOUS

● Coccidiosis (isosporosis, cryptosporidiosis, toxoplasmosis)** (p 705)

Infections that result in mild to moderate diarrhea are most common in neonates and immunosuppressed adults. Most adults have asymptomatic infestations. The species of coccidia most commonly associated with disease in cats are *Isospora* spp., *Cryptosporidium parvum* and occasionally *Toxoplasma gondii*.

● Giardiasis** (p 707)

Acute or chronic small bowel diarrhea is the most common clinical presentation, however in some cats large bowel diarrhea also may occur.

● Nematode parasites (roundworms, hookworms)* (p 717)

Common signs occurring in kittens with roundworms (*Toxocara cati*, *Toxascaris leonina*) include unthriftiness, diarrhea and pot-bellied appearance, however, vomiting may also occur.

● Salmonellosis* (p 719)

Diarrhea, weight loss and systemic illness are primarily problems in young or debilitated cats, as most cats are asymptomatic carriers. The disease is most important clinically in young kittens or geriatric cats that develop septicemia due to *Salmonella* spp., and may die acutely. Salmonellosis is a zoonotic disease.

● *Clostridium perfringens* enterocolitis* (p 721)

Diarrhea occurs due to sporulation of clostridial organisms and release of enterotoxin resulting in a secretory diarrhea that is usually small bowel in character, but can also have a large bowel component.

● Feline coronavirus infections (feline enteric coronavirus/feline infectious peritonitis* (p 718)

Feline enteric coronavirus causes mild, transient diarrhea in young kittens, and is the source of feline infectious peritonitis virus (FIPV). Systemic infectious disease by FIPV is characterized by vasculitis and granulomatous lesions in affected organs. Since FIPV rarely affects the GI tract singularly, vomiting is often associated with the disease effects on the liver, kidneys or other organs. Rarely FIPV causes intestinal granulomas that obstruct the GI tract and cause vomiting or diarrhea that is usually chronic, but may have an acute onset.

continued

continued

- **Feline panleukopenia virus (p 722)**

Infectious viral enteritis of young cats that is often fatal in unvaccinated populations. Typically, there is a sudden onset of depression and anorexia. Vomiting is followed by diarrhea, varying from mild to severe. Panleukopenia may result in systemic septicemia and rapid death. A relatively rare problem in vaccinated cats due to the vaccine efficacy.

- **Peritonitis (p 729)**

Abdominal pain, distention, fever, decreased appetite and lethargy are the most common presenting signs. Vomiting or diarrhea may occur, but is not a consistent problem.

- **Feline leukemia virus (p 725)**

Systemic retroviral disease associated with neoplasia and bone marrow disease in cats. Diarrhea occurs most commonly secondary to development of GI lymphoma.

- **Feline immunodeficiency virus (p 726)**

Diarrhea is not a common presenting sign of cats with FIV, but diarrhea can occur secondary to the immunodeficiency disease or result from a purulent form of colitis that can occur in a small number of cats that are infected with FIV.

- **Campylobacteriosis (p 726)**

An uncommon cause of diarrhea in cats, but will cause mucoid, bloody diarrhea, weight loss, anorexia and fever in affected kittens or young cats. Most affected cats are from shelters or catteries that have crowded conditions and poor hygiene. In adult cats, the disease is usually self-limiting, but it is an important zoonosis.

- ***Bacillus piliformis* (Tyzzer's disease) (p 732)**

Produces clinical signs that are identical to panleukopenia.

IDIOPATHIC

- **Acute gastroenteritis*** (p 702)**

This acute, mild small bowel diarrhea may be caused by a number of dietary, bacterial, parasitic or toxic agents that are usually self-limiting.

- **Hypereosinophilic syndrome (p 729)**

Rare disorder that is associated with eosinophilic IBD and systemic eosinophilia (increased circulating eosinophils and increased eosinophils in lymph nodes, etc.). It is usually associated with chronic vomiting, diarrhea and weight loss, and is poorly responsive to treatment.

- **Idiopathic juvenile diarrhea (p 727)**

This is a condition of kittens and young cats less than one year of age. It causes chronic small bowel diarrhea, which is self-limiting once the kitten reaches adulthood.

Toxic:

- **Pharmacologic (antibiotic-induced diarrhea)** (p 705)**

Acute onset of diarrhea or vomiting after initiating antibiotic therapy. Antibiotics often associated with inducing diarrhea: ampicillin, cephalosporins, clindamycin, metronidazole, tetracycline, etc.

- **Pyrethrins/pyrethroids/permethrins/organophosphates* (p 718)**

Vomiting, diarrhea, hypersalivation, contact dermatitis, ataxia, excitation, seizures and dyspnea are all reported signs of toxicity to these insecticides.

- Heavy metals (lead, arsenic) (p 724)

The two most common heavy metal intoxications are ingestion of lead and arsenic. Both cause severe GI signs: vomiting, diarrhea, anorexia, and depression, but lead poisoning will progress to neurologic signs (e.g. ataxia, tremors and seizures), while arsenic is nephrotoxic and hepatotoxic.

- Plant ingestion/toxicity (p 728)

Plants may irritate mucous membranes and cause acute drooling, vomiting or diarrhea. Plant toxins that result in renal or hepatic failure may cause more severe and prolonged vomiting, diarrhea, depression and anorexia.

INTRODUCTION

MECHANISM?

Acute small intestinal diarrhea is a common clinical problem that is often **mild or self-limiting**.

In general, small bowel diarrhea tends to be **milder in cats than in dogs** because of the **capacity of the feline GI tract to absorb water**.

Some diseases which typically produce chronic diarrhea may present as acute diarrhea.

In some cats, **life-threatening illness** develops due to the severity of fluid loss or as a result of the primary problem causing the small bowel diarrhea (endotoxemia, neoplasia, etc.).

There are **many different causes** of diarrhea, which literally is the presence of increased water in the feces.

The increase in fecal water may be due to a physical, functional or physiologic disturbance in the small intestine, the colon, or both.

Characteristics of small bowel diarrhea include:

- A **large volume of watery or very soft feces**.
- **No mucus or hematochezia**, if blood is present it occurs as **melena**.
- There is little or **no straining or tenesmus**.
- **Weight loss and vomiting** are commonly observed.
- The **frequency of defecation** is **normal to increased**.

Diarrhea may be due to increased **osmotically active substances** present in the lumen. The **most common causes of this type of diarrhea** are **dietary overload/indiscretion** and **malabsorption**, which can be due to deficiency of pancreatic (e.g. EPI) or intestinal brush border enzymes, or upper small bowel diseases (e.g. mucosal or intramural), such as IBD or lymphoma.

Increased secretion of water and electrolytes is another cause of diarrhea which occurs primarily as a result of activation of cellular second messenger pathways (cAMP, cGMP, etc). The **causes of secretory diarrhea in cats** include *Salmonella*, *Clostridium*, *Campylobacter*, *E. coli*, and *Staphylococcus*. Diarrhea due to hyperthyroidism may also be due to a secretory mechanism, but this is unproven.

The presence of **increased intestinal permeability due to inflammation, erosion/ulceration or necrosis** is also an important cause of diarrhea. A major cause of increased permeability diarrhea in cats is IBD, but lymphoma or other causes of intestinal inflammation, such as the enteroinvasive bacteria (e.g. *E. coli*) can also cause diarrhea by this mechanism.

Altered intestinal motility, either increased or decreased segmentation or propulsion movements will cause diarrhea. While it is difficult to prove that altered motility is the primary cause of diarrhea in many cases, it may occur in hyperthyroidism, dysautonomia, some infectious enteropathies and in GI neoplasia.

The **main consequences of acute small bowel diarrhea** are **dehydration and development of metabolic acidosis** as a result of **fluid and electrolyte losses**.

Infectious and parasitic causes of small intestinal diarrhea may be either **self-limiting or severe**, depending on the pathogenicity of the organism.

Inflammatory bowel disease, neoplasia and other more severe diseases that cause small bowel diarrhea are often associated with other signs of systemic or GI disease, such as **weight loss, anorexia, vomiting or depression**.

WHERE?

Small bowel diarrhea can be the result of **disease in the small intestine** (duodenum, jejunum, ileum) or occur

secondary to **systemic illness** (peritonitis, septicemia), **organ failure** (hepatic, renal or pancreatic disease) or **other miscellaneous causes** such as hyperthyroidism.

A careful **history and physical examination** will determine whether the problem is likely related to the GI tract or a systemic problem.

In **otherwise healthy cats with acute diarrhea** that is likely due to dietary indiscretion, mild infectious enteritis or exposure to a self-limiting toxin, a **minimal diagnostic approach is needed**.

In **cats that are dehydrated, clinically depressed, anorectic or vomiting**, a more aggressive approach that includes a **hemogram, chemistry profile, fecal analysis, and radiographs or ultrasound** is indicated.

WHAT?

The **most common causes of mild, self-limiting small bowel diarrhea include food intolerance or dietary indiscretion, and some infectious or parasitic agents**.

Cats with **small bowel diarrhea of a more serious nature** often have **systemic illness/organ failure** (e.g. hepatitis, renal failure, or pancreatic disease such as pancreatitis), or **severe intestinal disease** such as neoplasia or inflammatory bowel disease, which must be carefully evaluated.

Diagnosis is based upon history and physical examination findings, radiography, hematology and serum chemistry profiles, serology if indicated for FeLV/FIV, serum TLI, fecal analysis, fecal cytology or alpha-1 protease inhibitor testing, serum cobalamin/folate assays and histopathology.

DISEASES CAUSING SIGNS OF ACUTE SMALL BOWEL DIARRHEA (<3 WEEKS DURATION)

ACUTE GASTROENTERITIS***

Classical signs

- Vomiting, anorexia or reduced appetite are common.
- Acute gastroenteritis is more common in young cats or kittens, but can occur in any age, breed or sex.
- Mild to severe small bowel diarrhea may also be observed.

Pathogenesis

Mild, acute small bowel diarrhea is a **common presenting complaint**, and may be **caused by a variety of self-limiting disturbances**, including dietary, parasitic, infectious or toxic agents.

Small bowel diarrhea can be caused by **osmotic** (increased unabsorbed substances present in the lumen, such as occurs in overeating or malabsorption), **secretory** (increased secretion of ions and water into the lumen, which is mediated by second messengers such as cAMP or cGMP and often stimulated by bacterial or viral agents), **increased permeability** (increased intestinal permeability occurs from diseases that cause increased inflammation, erosion, ulceration or necrosis), and **altered intestinal motility** (increased or decreased intestinal motility can result in diarrhea, especially when it affects segmentation contractions in the colon).

Cats with self-limiting gastroenteritis require **minimal diagnostic testing** and will respond to **symptomatic treatment**.

Certain strains of *E. coli* may behave as gastrointestinal pathogens. Very little is known about diarrheagenic *E. coli* in cats and further epidemiological investigations on this subject are needed. One recent study showed no difference in the strains of *E. coli* isolated from a group of cats with diarrhea and a control group of cats that did not have diarrhea.

Clinical signs

Acute onset of **vomiting, diarrhea, anorexia or lethargy** in an **otherwise healthy cat**.

Dehydration may occur if the signs are severe.

Rarely associated with hematemesis, hematochezia or melena.

Diagnosis

Acute idiopathic gastroenteritis is a pathological description and not a diagnosis. One of the many etiologies listed in this chapter is the likely cause. However in cats that are otherwise healthy, but have mild signs of gastroenteritis and no clinical evidence of dehydration, an extensive diagnostic work-up is rarely indicated or performed so the cause of the signs remains unknown.

A **PCV, TP** and **fecal examination** are simple, inexpensive tests that should be used in cats that seem lethargic or dehydrated.

In cats with **more persistent or severe clinical signs, a dietary change**, more extensive **fecal analysis** (zinc sulfate flotations, culture or cytology) and additional evaluation of the **hemogram or chemistry profile** is indicated.

Differential diagnosis

Food intolerance (ingestion of substances that cause an adverse response that is not immunologically mediated, e.g. not food allergy) or **dietary indiscretion** (ingestion of foreign or usual foods or non-food substances that cause GI disturbance) is a common cause of acute gastroenteritis.

Bacterial or viral infections of the GI tract may be mild and self-limiting, or severe and life-threatening, so the clinical presentation must be carefully evaluated.

Other causes of acute, mild gastroenteritis are ingestion of **toxic substances** (plant material, oil or other materials attached to hair coat, etc.).

Treatment

Fluid therapy is indicated if there are clinical signs of dehydration, or if the cat is unable to drink.

Balanced isotonic replacement electrolyte solutions are the best fluid choices for cats with mild to moderate metabolic acidosis and dehydration secondary to acute diarrhea.

Fluids may be given **subcutaneously** in cats that are only mildly dehydrated.

In cats with severe dehydration or who are intolerant of subcutaneous fluid administration, **intravenous** replacement of fluid deficits is necessary.

Oral rehydration therapy is effective in patients that are mildly dehydrated and can ingest oral fluids.

The maintenance rate for fluid therapy is **40–60 ml/kg/day**, and replacement of fluid deficits is calculated by:

$$\text{BW (kg)} \times \% \text{ dehydration} = \text{fluid deficit (liters)}$$

Deficits should be replaced over 4–6 hours or more, and ongoing losses estimated and additional fluid amounts added to the maintenance fluid rate calculated.

Potassium supplementation of intravenous fluids should be initiated once the cat is rehydrated and should be **monitored and adjusted based upon serum potassium levels**.

Antimicrobial therapy is not routinely indicated for treatment of acute, mild forms of gastroenteritis.

The **choice of antibiotic** should be **based on the suspected or known causative organism** (*Campylobacter*, *Clostridium* spp., etc.).

Cats with severe mucosal injury as evidenced by blood loss or hypoproteinemia have the potential to develop septicemia, or signs of systemic sepsis (fever, depression, leukocytosis, hypoglycemia, etc.). These cats should receive **broad-spectrum, parenteral antibiotics** effective against enteral pathogens (e.g. either alone or in combination: ampicillin, enrofloxacin, trimethoprim-sulfadimethoxine, metronidazole or cephalexin).

The **most effective motility-modifying drugs** for treatment of diarrhea are the **opioids** (loperamide 0.08–0.16 mg/kg q 12 h or diphenoxylate 0.05–0.1 mg/kg q 12 h). **Opioids should be used with care** in cats because safe, effective dosages have not been established.

Anticholinergic drugs have no useful role in the symptomatic treatment of diarrhea in cats with gastroenteritis, because they reduce both peristaltic and segmental intestinal motility contractions.

Intestinal protectants and absorbent agents (kaolin, pectin, activated charcoal, barium, bismuth subsalicylate) may or may not be clinically effective, but are not harmful and are likely most beneficial when used in acute, non-specific enteritis.

Bismuth subsalicylate, 0.25 ml/kg q 4–6 h, has been shown to be most effective in acute small-intestinal diarrhea, but should be used cautiously in cats to decrease the **possibility of salicylate toxicity**.

If **vomiting** is a concurrent problem, **anti-emetic therapy** should also be initiated. Metoclopramide, 0.2–0.5 mg/kg q 6–8 h, or prochlorperazine, 0.1–0.5 mg/kg q 8 h, are two commonly used anti-emetics. **Anti-emetic therapy should not be used if a gastric outflow obstruction is suspected**.

Withhold food for 24–48 hours in cats with acute small bowel diarrhea, and only offer water or oral isotonic glucose, amino acid and electrolyte solutions.

Because **most diarrheas in cats are osmotic rather than secretory**, feeding through an acute diarrhea will worsen the signs and may exacerbate the condition. This is in contrast to humans with secretory diarrhea, where feeding is advantageous.

Prognosis

In general, for the majority of cats with acute, non-specific gastroenteritis, the prognosis is excellent.

The prognosis is guarded for cats with severe diarrhea or diarrhea occurring secondary to problems in other body systems.

Prevention

Reduce opportunities for ingestion of toxic or irritating substances.

FOOD INTOLERANCE***

Classical signs

- Intermittent vomiting or diarrhea.
- Inappetence.

Pathogenesis

Food intolerance is a non-immunologic, adverse reaction to a substance(s) present in food. This reaction may be to a food component such as the type of protein or carbohydrate, a particular component (e.g. wheat gluten) or it may be to food colorings, preservatives, flavorings, etc.

Food intolerances may result from an **inability to adequately digest a dietary constituent** (e.g. lactose) or from **metabolic, toxic or pharmacological responses to food components** such as histamine in foods, lectins or from the metabolism of dietary residues by the large intestinal microflora.

The precise **mechanism** associated with vomiting or diarrhea due to food intolerance is **unknown**.

The **mucosa (formerly gut) associated lymphoid tissue is believed to be a major component in the devel-**

opment of food intolerance, as it is this tissue that is responsible for promoting tolerance and hyporesponsiveness to harmless dietary antigens.

Intolerance may develop as a result of **abnormal mucosal barrier function**, disturbances in immunoregulation (**decreased tolerance**) or simply an **abnormal recognition or response to certain dietary antigens**.

Clinical signs

Intermittent but persistent vomiting or diarrhea are the most common signs.

Poor hair coat, pruritus, inappetence or failure to thrive may also be noted but these are less common.

Presence of concurrent dermatologic and gastrointestinal signs should prompt consideration of a food allergy.

Diagnosis

There is **no diagnostic test** for this problem other than to **observe a beneficial response to an appropriate dietary trial**. This should be carried out for a minimum of 3 weeks.

Use a highly digestible diet or an elimination diet, either a commercial diet containing a single novel protein source, or a homemade diet of **boiled white rice and a novel meat source** such as duck, venison, rabbit, kangaroo, tofu, horsemeat, etc.

Differential diagnosis

Acute, intermittent diarrhea in an otherwise healthy cat suggests early inflammatory bowel disease, GI parasites, dietary indiscretion, or acute gastroenteritis due to infectious causes.

In some cats, this may be a sign of early renal or liver disease, hyperthyroidism and other primary GI abnormalities such as neoplasia.

Treatment

The **diet should be changed so that it does not contain the offending substance**. This may be as simple as changing from a grocery store brand to a premium brand food (or vice versa), but also may require changing

to a hypoallergenic food product (e.g. IVD's Limited diets, Hill's d/d, Eukanuba Response formula, Royal Canin, etc.) or in unresponsive cases, formulating a novel homemade diet that is complete and nutritionally balanced.

In food intolerance, the abnormal gastrointestinal response is non-immunologic, thus the **use of oral prednisolone is not indicated and is unlikely to be beneficial.**

Prognosis

Good if the appropriate diet can be found, which is usually not a difficult problem. However, the cat may have to remain on the diet indefinitely.

Prevention

There is no known method to predict which cats are susceptible to food intolerance, and further, no way to prevent the development of food intolerance.

PHARMACOLOGIC** (ANTIBIOTIC-INDUCED DIARRHEA)

Classical signs

- Anorexia, vomiting or diarrhea may all occur following administration of antibiotics.

Pathogenesis

Vomiting or diarrhea associated with antibiotics is a **common occurrence** and can occur with almost all of the popular antibiotics, including: **amoxicillin, cephalixin, erythromycin, lincomycin, sulfasoxazole, tetracycline, trimethoprim-sulfadiazine, metronidazole** and clindamycin.

The **mechanism for induction of nausea, vomiting or diarrhea varies** for each drug.

Diarrhea often occurs due to a disruption of the enteric microflora that results in overgrowth of pathogenic species or sporulation of normal flora resulting in release of toxins that cause diarrhea.

Clinical signs

Anorexia or a decrease in appetite and vomiting are common occurrences following antibiotic use.

Diarrhea may be liquid and explosive (consistent with **small bowel diarrhea**) or unformed, soft feces with increased mucus (**large bowel character**).

There are **no age, breed or sex predispositions to adverse effects**, but in many cats, once an adverse effect occurs due to one antibiotic, **other closely related antibiotics may cause similar problems.**

Diagnosis

The diagnosis is not difficult because it is **based upon an appropriate history and physical examination findings** (e.g. no other abnormalities are found). A fecal exam and appropriate dietary history will rule out the other potential causes of acute diarrhea.

Treatment

The best approach is to **stop the use of the antibiotic in question**, and if antibiotic therapy is still required, **switch to an appropriate antibiotic of another class.**

Prevention

There is no known way to predict a cat's response to antibiotic therapy, but certain antibiotics (e.g. **clindamycin, cephalosporins, and amoxicillin**) are the **most common culprits.**

COCCIDIOSIS** (ISOSPOROSIS, CRYPTOSPORIDIOSIS, TOXOPLASMOSIS)

Classical signs

- Acute small bowel diarrhea is most common in young cats or kittens.
- In severely infected kittens, weight loss, anorexia and dehydration may also occur.
- Most adult cats will be asymptomatic or have subclinical infections.

Pathogenesis

Coccidian parasites (*Isospora*, *Cryptosporidia*, etc.) are **common intestinal inhabitants** that may occur as

commensals or pathogens, depending on the circumstances.

Isospora felis and *I. rivolta* are the two *Isospora* species (also called *Cystoisospora*) that infect cats.

Cryptosporidium parvum is generally accepted to be the cause of feline cryptosporidiosis.

Immunocompetent cats will only develop *Cryptosporidia* infections in the GI tract, but immunocompromised cats can have infections of the liver, pancreas, gall bladder and respiratory tract in addition to the GI disease.

Cryptosporidiosis has been primarily reported in cats with immunosuppressive or immune-mediated diseases such as FeLV, IBD and intestinal lymphosarcoma.

Unlike most coccidian parasites, the life cycle of *Cryptosporidium* occurs **entirely within one host**.

In other coccidian parasites infection occurs by **ingestion of infective (sporulated) oocysts or tissues from an infected paratenic host (wildlife, large animals, etc.)**.

Concurrent disease, malnutrition, stress and immunosuppression appear to be important contributing factors in the development of clinical disease.

Clinical disease is most common in **young kittens from crowded, unsanitary, high-stress conditions**.

Natural infections of **healthy kittens and cats** result in **asymptomatic infections** in almost all cases.

Diarrhea is present in about 10% of cats with the enteroepithelial form of toxoplasmosis but is more common in kittens infected before weaning. Acute diarrhea is most common in neonatal kittens.

Clinical signs

The principal clinical sign of coccidiosis is diarrhea, which may be bloody, mucoid or watery.

Other signs that may be observed include **vomiting, weight loss, lethargy and dehydration**.

Adult cats that are infected with coccidian parasites (including cryptosporidia) are typically **asymptomatic**.

Young or immunocompromised cats with cryptosporidiosis will have profuse, watery diarrhea and

mesenteric lymphadenopathy due to intestinal hypersecretion and malabsorption.

Diagnosis

Diagnosis is made by identification of isosporoid oocysts in fresh feces.

The oocysts of cryptosporidia are smaller than RBCs, 1/10th the size of isospora, and 1/16th the size of a *Toxocara* oocyst.

- **Special flotation media** (Sheather's sugar or zinc sulfate flotation) is required along with **special staining** (Kinyoun's carbol-fuchsin negative) or **phase contrast microscopy, to identify *Cryptosporidia***.
- Because of their small size, the operator needs to focus up and down on the sample to be able to identify the oocysts.

Other methods of identification of **fecal *Cryptosporidia*** include an **ELISA test**, however, its effectiveness in identifying feline species of *Cryptosporidia* is unknown, a **PCR test for *Cryptosporidium* DNA** in the feces, or **electron microscopy of intestinal biopsy samples**.

Fecal samples submitted to the laboratory should be **preserved in formalin** to minimize the risk of human infection.

Differential diagnosis

The primary differentials are other intestinal parasites or protozoa (giardiasis), infectious diarrhea, toxin-induced diarrhea or dietary disturbances, which are common in young cats adjusting to new foods.

Treatment

Sulfonamides are the drugs of choice for *Isospora*, however they are **coccidiostatic**, not curative. Sulfadimethoxine (15 mg/kg q 12 h \times 14 days) alone, or in combination with trimethoprim, is the drug of first choice.

Other drugs that may be considered if treatment failure occurs are nitrofurazone, tetracycline, quinacrine, spiramycin or roxithromycin.

Treatment of subclinical infections of isospora or cryptosporidiosis is **not indicated or necessary**, as full recovery will occur.

Cats or kittens with clinically significant cryptosporidiosis may be treated with **tylosin, clindamycin or azithromycin**, however, the clinical effectiveness of these drugs is not well tested.

Cats or kittens that are **dehydrated and anorectic** will require supportive care in the form of **fluid replacement therapy** or **nutritional support** or both.

Prognosis

The prognosis for complete recovery in immunocompetent cats and kittens is excellent.

Any adult cat with coccidiosis or cryptosporidiosis should be carefully evaluated for the presence of other immunodeficiency (e.g. FIV) or immune-compromising diseases (e.g. neoplasia, IBD, etc.).

Prevention

Coccidiosis is primarily a problem of **poor sanitation, and over-crowded, high-stress conditions** that occur in catteries, shelters and other **population-dense situations**.

Because the **oocysts** (both *Isospora* and *Cryptosporidia*) are **environmentally resistant**, only **aggressive sanitation measures** (daily fecal removal, disinfection of cages, runs and food utensils with steam cleaning or 10% ammonia solutions) will prevent contamination.

Public health

Cryptosporidiosis is a significant zoonosis, and thus, careful precautions must be taken in handling infected animals, their feces and their environments.

Even though the association between human infection and feline cryptosporidiosis is weak, this problem should not be taken lightly, especially in cases of cats owned by **immunocompromised humans**.

GIARDIASIS**

Classical signs

- The most common sign is liquid, to semiformed, diarrhea with increased frequency and urgency.
- Some animals are asymptomatic, and most remain bright, alert and afebrile.

Pathogenesis

Giardia intestinalis is a commonly encountered **flagellate protozoan parasite**, with a **direct life cycle**.

Giardia cysts are ingested from contaminated water, or directly from **animal to animal** (e.g. in kennels or catteries).

Excystation of the ingested cysts releases two motile trophozoites in the small intestine.

Cysts are approximately 9–13 microns in size but are not routinely identified in flotation solutions because they are **not shed consistently and are small**.

Sugar flotation solutions will cause the cysts to shrivel.

Trophozoites are slightly **larger, tear-drop-shaped, have four pairs of flagella and are binucleated**. The trophozoites attach to the mucosal brush border to absorb nutrients. Little is known about encystation and what triggers it.

Cysts are susceptible to desiccation, but **can exist for months in a cool, moist environment**.

The **pathogenesis** of *Giardia* infection is not well understood but is believed to involve **malabsorption, disturbances in brush border enzyme function and possible enterotoxin production**.

Severe clinical disease is **more common in young cats**, but adults can become infected and symptomatic.

Protective immunity appears to protect cats from the development of clinical signs, but may not protect from shedding, since **some animals will continue to shed organisms despite treatment**.

Clinical signs

Most adult cats infected with *Giardia* spp. remain asymptomatic.

The **most common sign observed is the presence of liquid to semiformed diarrhea**, associated with increased frequency and quantity of defecation, in an otherwise healthy cat.

Vomiting, dehydration, lethargy and anorexia may be observed in severe cases, but are uncommon.

Occasionally, chronic small bowel diarrhea with weight loss and poor body condition are observed.

Cats are more likely to also have evidence of acute or chronic large bowel diarrhea (with hematochezia, increased mucus and tenesmus) than are other species affected.

Diagnosis

The diagnosis is made by appropriate fecal examination techniques. **Zinc sulfate flotation is considered to be the most accurate** and practical test. **Three consecutive zinc sulfate flotations will identify 95% of infected animals.**

Other methods include **examination of fresh fecal saline smears** (1 drop saline with a small amount of feces that is spread thin enough to read a newspaper through) for trophozoites (only 40% of infected animals will be identified), **duodenal aspiration** (e.g. instill 10 ml of saline into the duodenum, either through the accessory channel of the endoscope or injected directly during laparotomy, and then aspirate the fluid for examination) **of fluid looking for trophozoites** (requires endoscopy or laparotomy, but is 88% effective), **or fecal ELISA testing for *Giardia* specific antigens** (95% sensitivity, but low specificity).

At this time, the zinc sulfate flotation test appears to be the easiest, most reliable and most accurate method of identifying *Giardia* infections.

Because of the **small size of the cysts (1/8 the size of a *Toxocara* oocyst)**, the operator needs to scan the slide carefully and focus up and down through the different planes to identify the cysts in the preparation.

Differential diagnosis

Other infectious, parasitic, dietary, toxic and idiopathic causes of small bowel diarrhea must be considered since many cats have only mild signs.

Treatment

Metronidazole (50 mg/kg/day PO for 5 days) continues to be recommended for treatment of giardiasis in cats. However, **resistant strains of the protozoan are increasingly being reported**, and thus this therapy may not be effective in all cases.

Side effects associated with metronidazole therapy include gastrointestinal upset and neurologic signs,

such as seizures, coma and behavioral changes. All of these are less common in cats than in dogs and are reversible with discontinuation of treatment.

Other drugs that have been recommended for treatment of giardiasis are **quinacrine and furazolidine**, but **these drugs may not eliminate the infection**, only improve the clinical signs.

Albendazole and fenbendazole have been recently shown to be effective in treatment of dogs and cats with giardiasis. Albendazole (25 mg/kg q 12 h × 2 days) is **not approved** for use in cats in the United States and is teratogenic, hepatotoxic and causes bone marrow suppression, and thus is **not recommended**. **Fenbendazole (50 mg/kg/day × 3 days) has been recommended for treatment of giardiasis in cats.**

Proper disposal of feces and good sanitation is essential to remove any environmental contamination.

Prognosis

With proper diagnosis, treatment and sanitation procedures, *Giardia* infections can be completely controlled.

Prevention

Since the cysts are susceptible to drying and many common disinfectants, **good sanitation** can prevent a once contaminated area from being a source of additional infections.

Avoid allowing cats access to drinking water that may have fecal contamination.

A **vaccine** is now available that purports to reduce shedding of *Giardia* cysts, however, immune system activation has been shown to decrease shedding without having an effect on the infection itself. The vaccine does not prevent infection or reduce severity, and in a study in cats made no significant difference overall.

Public health

Giardia cysts should be considered **potentially zoonotic**.

The infectivity of different strains of *Giardia* for different species is quite variable, but this fact should not preclude the need to take adequate precautions when handling feces.

FOOD ALLERGY (DIETARY HYPERSENSITIVITY)*

Classical signs

- Gastrointestinal signs are variable, but can include vomiting, diarrhea, weight loss or anorexia.
- Food allergy may also produce dermatologic signs usually in the absence of GI signs.

See main reference on page 667 for details.

Clinical signs

Gastrointestinal signs are more variable, but can include vomiting, diarrhea, weight loss or anorexia.

- In cats, vomiting is more common than diarrhea.
- Generally, signs of hypersensitivity involve either the GI tract or skin.
- Clinical signs can occur at any age.

Most common signs are **dermatologic in origin** (pruritus, alopecia, miliary dermatitis, seborrhea), affect the **head, face, ears and inner thigh** especially, and are **non-seasonal** in occurrence.

There are no known breed or sex predispositions for food allergy.

Diagnosis

The **definitive diagnosis of food allergy** is only obtained by **feeding an elimination diet**. The signs usually start to resolve after 4–7 days but may require 6–8 weeks for complete resolution, then reintroduction of the offending diet results in the reappearance of signs.

- The elimination diet chosen depends on the cat's preferences for food, the owner's willingness to make homemade foods, and the clinical situation; however, the **best elimination diet is a diet containing a single, novel protein source** (turkey, venison, duck, kangaroo, etc.) **and a single, novel carbohydrate source** (rice, potato, etc.), **with no other additives except a pet vitamin**.
- A **homemade diet** (1/3 cup protein, 2/3 cup carbohydrate) can be used as a diagnostic trial, but is **not a balanced diet for long-term maintenance**. In

most cats, choosing a commercial diet that contains a single, novel protein source will work best for long-term management of these cats.

- Diets that contain **protein hydrolysates** are less antigenic than intact proteins because their molecular structure is too short to bridge IgE receptors on the cell membrane. The usefulness of these diets in cats with food allergy is unknown. Type I (IgE-mediated) hypersensitivity is thought to be involved in only about 25% of food allergy cases. However, these diets give another option for both diagnosis and treatment of cats with food allergy.

Other diagnostic tests, including intradermal skin testing, ELISA testing, RAST testing, and gastroscopic food testing have all been tried in an attempt to find easier methods of making the diagnosis. However, the **only reliable test currently available is the food elimination trial** (which is also what is used in humans).

In most cats, the **hemogram and chemistry profile will be completely normal** or have mild non-specific changes associated with inflammation.

Differential diagnosis

Other differentials such as food intolerance, parasites, and metabolic or neoplastic diseases should be considered. **Inflammatory bowel disease** is also a disease that mimics food allergy and is very difficult to differentiate from it.

Flea allergy is the most common cause of dermatologic signs of allergy, but atopy and food allergy must be considered.

Treatment

Once an elimination diet has been identified that successfully relieves the clinical signs, the cat should remain on that diet indefinitely. However, it is best in most cases to try to **identify a commercial diet that most closely resembles the elimination diet** so that the cat receives a nutritionally complete and balanced diet.

After a period on one diet, **cats may develop hypersensitivity to that new diet**, so new (even more novel) diets will be necessary.

Most cats with food allergy respond only partially or not at all to prednisolone.

INFLAMMATORY HEPATOBILIARY DISEASE (CHOLANGITIS)*

Classical signs

- Weight loss, anorexia and depression.
- Vomiting.
- Icterus.

See main reference on page 427 for details.

Clinical signs

Weight loss (often dramatic), anorexia, vomiting, icterus and depression are the most common signs.

Other signs may include ascites, diarrhea or fever.

Most affected cats are middle-aged or older.

Diagnosis

The presence of **icterus** helps to narrow the differentials list to **hepatic, pre-hepatic and post-hepatic diseases**.

The **hemogram** in cats with hepatic disease is **often abnormal** (e.g. mild, non-regenerative anemia, with abnormal RBC morphology including schistocytes, leptocytes or target cells), but the changes are **not specific** for liver disease. However, it does help **rule out pre-hepatic causes of icterus** which are **rare in cats**.

Serum chemistry abnormalities may include **elevated liver enzyme activities** (sometimes dramatically), **hyperbilirubinemia**, **hypocholesterolemia**, **hypoalbuminemia**, **decreased BUN and electrolyte alterations** (consistent with vomiting or dehydration, e.g. hypokalemia, hypernatremia).

Bilirubinuria is common, but some cats may have urate crystalluria if the liver failure is severe.

Bile acid assay (pre- and 2 hours post-prandial) will show mild to moderate elevations.

Urine sulfated bile acids are a new test of liver function that may be useful in situations where obtaining post-prandial bile acids is impossible, for example in inappetent cats.

Coagulation function (platelet numbers and function, and coagulation factors) should be evaluated since liver disease often adversely affects these functions.

Ultrasonography is the most **useful imaging modality**, and it can also be used to obtain **fine needle aspirates or biopsies**. In cats with cholangitis the liver may be normal, decreased or increased in size, but typically will have a **hyperechoic pattern due to the presence of inflammatory infiltrates**.

The results of tru-cut biopsies do not always reflect the histopathologic diagnosis of surgically obtained wedge biopsies. This was illustrated in a recent study of 189 biopsies, where > 60% of the cats had tru-cut biopsies that failed to confirm the presence of cholangitis, which was confirmed by wedge biopsies.

Liver biopsies taken via surgical exploratory are more diagnostic, and will also allow **placement of a feeding tube** (gastrostomy or jejunostomy tube) during the procedure, which is **essential for any cat that has not eaten for 3–5 days**.

In addition to liver histopathology, samples of hepatic tissue should also be submitted for **aerobic and anaerobic culture**.

Differential diagnosis

Cats that have vomiting, diarrhea, and weight loss in addition to icterus, the list of differentials is narrowed to **pre-hepatic** causes (hemolysis), **hepatic causes** (hepatic lipidosis, hepatic necrosis, hepatic failure, etc.), and **post-hepatic** causes (pancreatitis, neoplasia of stomach, pancreas, duodenum or bile duct, and common bile duct obstruction).

In **cats that are not icteric**, the list of potential causes broadens extensively to include the spectrum of metabolic, neoplastic, toxic and infectious causes of both systemic and primary gastrointestinal origin.

Treatment

Therapy for cats with cholangitis is **largely supportive**, but the histopathologic findings are crucial in **determining severity, the type of inflammatory infiltrate** (which is essential to choosing appropriate therapy), and the overall **prognosis** for the disease.

Most cats with severe liver disease will require fluid therapy to replace deficits, provide maintenance fluid support during the recovery period, and induce diuresis

to assist removal of hepatotoxins and prevent tubular sludging from bilirubinuria and casts.

The fluids should be **isotonic, balanced electrolyte solutions**, but **preferably not containing lactate**, which is not converted to bicarbonate in cats with liver failure and thus serves as an additional source of acid. Ringers solution and Normosol-R are replacement electrolyte solutions without lactate.

Vomiting should be controlled with a combination of **anti-emetic therapy** (e.g. metoclopramide or dolasetron) and **acid-blocking therapy** (H_2 antagonists such as famotidine), since **cats with liver disease are prone to development of hypergastrinemic gastritis**.

Diarrhea is rarely severe enough to require therapy and often resolves as the anorexia worsens.

Cholorectic agents (Actigall) should be used to **reduce bile sludging and improve bile salt flow**.

Cats with neutrophilic cholangitis should be given **broad-spectrum parenteral antibiotics**. A penicillin combined with a fluorinated quinolone provides a good spectrum of activity for enteric pathogens. Ideally, the **antibiotic choice should be based upon culture results**, but if the culture is negative or the cat is systemically ill, broad-spectrum antimicrobial chemotherapy should be initiated.

Lymphoplasmacytic cholangitis is believed to be an **immune-mediated** disease and has recently been shown to occur in association with inflammatory bowel disease and pancreatitis. **Prednisolone therapy** (2–4 mg/kg/day) is indicated in cats with lymphocytic plasmacytic hepatic infiltrates.

Nutritional support is often overlooked in cats that do not have hepatic lipidosis, but is crucial for all sick cats due to their requirement for essential amino acids and fatty acids to be provided in the daily diet. Nutrition can be provided in the **short term (1–3 days) via nasoesophageal feeding tubes**, but for longer periods, **esophageal feeding tubes** or a **percutaneous endoscopic gastrostomy (PEG) tube** should be placed to allow larger amounts of food per feeding as well as feeding a blenderized cat food rather than liquid enteral diets.

When initiating enteral feeding in sick cats, **the volume of food must be gradually increased over 3–5 days**, to reduce vomiting and gastric retention of food. A con-

stant rate infusion of food over 24 hours is less labor intensive than using initial 1–2 hour feedings of small volumes of food. After the initial introductory period, **the goal is to achieve a daily caloric intake near the resting energy requirement (RER)**, calculated as $BER = [70 + \text{body wt (kg)} \times 30]$.

Most anorectic or ill cats will benefit from addition of **B vitamins** to the fluids, however, **fat-soluble vitamin deficiency may also develop** in cats that are anorectic or have malabsorption. **Supplementation with vitamin K and in some cases, vitamin E** should be considered in those cats. Supplementation with **L-carnitine** may also be beneficial.

Potassium and phosphorus should be supplemented in cats with low serum levels using potassium chloride and potassium phosphate.

Antioxidant therapy with S-adenosylmethionine (S-AdoMet) (20 mg/kg/day PO) is indicated in all cats with cholangitis.

HYPERTHYROIDISM*

Classical signs

- Weight loss despite a good to ravenous appetite.
- Polyuria/polydipsia.
- Vomiting, diarrhea or voluminous feces.
- Hyperactivity or irritability.
- Poor coat condition.

See main reference on page 304 for details.

Clinical signs

Typical signs include weight loss despite a good to ravenous appetite, **hyperactivity, polyuria/polydipsia**, and a poor coat condition.

Vomiting, diarrhea or voluminous feces are common, and may be observed as an acute problem.

Most cats will have **tachycardia, a gallop rhythm** or other signs associated with congestive heart failure (coughing, increased respiratory rate, weakness) secondary to **thyrotoxic heart disease**.

Gastrointestinal signs associated with hyperthyroidism are often intermittent or relatively mild, with the exception of weight loss and appetite changes.

Diagnosis

The **definitive diagnosis** is an **elevated serum total thyroxine concentration (T_4)**.

Other **non-specific abnormalities of the hemogram or chemistry profile** may include hemoconcentration, mild anemia, increased liver enzyme concentrations, including elevated serum alanine aminotransferase activity, or hyperglycemia.

A **thorough assessment of renal function** should be undertaken (BUN, creatinine, UA) before initiating treatment of hyperthyroidism in cats since the **increased renal blood flow associated with hyperthyroidism may result in acute renal decompensation when the thyroid disease is treated** (especially with surgical or radioactive iodine therapy).

Most cats will have a **palpable thyroid nodule**.

Cats with signs of hyperthyroidism but serum total T_4 in the upper half of the normal range should be tested using **free T_4 levels**, as false lowering of the T_4 level may occur due to non-thyroidal illness.

In cats with suspected hyperthyroidism, but normal serum total or free T_4 levels, a T_3 suppression test or radioactive thyroid scan can be performed to confirm the diagnosis.

Cats with signs of cardiovascular disease should also have **thoracic radiographs and an echocardiogram** performed to determine the extent of thyrotoxic heart disease and need for therapy.

Differential diagnosis

The major differentials for an older cat with weight loss, vomiting or diarrhea include neoplasia, exocrine pancreatic insufficiency, hepatic or renal disease and inflammatory bowel disease. However, the presence of cardiovascular signs, a ravenous appetite or hyperactive behavior with the GI signs should point to hyperthyroidism first.

Treatment

Treatment for hyperthyroidism includes **both control of the over-secretion of thyroid hormone as well as its effects on the remainder of the body** (e.g. thyrotoxic heart disease).

There are **three commonly used therapeutic approaches** to treatment of the hyperthyroid condition in cats: (1) **medical management** with methimazole; (2) **surgical removal** of the adenomatous thyroid; and (3) **radioactive iodine treatment** of the cat to obliterate the hyperactive gland(s).

The **treatment method chosen depends on several factors**: (1) the **condition of the cat** (requires assessment of anesthetic and surgical risks, renal function, cardiovascular function); (2) the **availability of radioactive therapy**; (3) the **owner's wishes** (financial and other considerations), and the **clinical judgment of the attending veterinarian**.

Prior to surgical or radioiodine therapy, evaluation of renal function and cardiovascular status is extremely important. **Cats with marginal renal function may not be good candidates for thyroidectomy or radioiodine therapy** which will reduce renal blood flow and metabolism dramatically and may induce an acute exacerbation of renal failure.

Some cats with thyrotoxic heart disease may require calcium channel or beta-blocker therapy, furosemide if they are in heart failure, or aspirin (efficacy unproven) to reduce the risk of thromboembolism. **Many cats with thyrotoxic heart disease respond to treatment of hyperthyroidism alone.**

INTUSSUSCEPTION*

Classical signs

- Anorexia, inappetence or normal appetite are all possible, depending on the location and severity of the obstruction.
- Weight loss.

Clinical signs

Intussusceptions are **rare in cats compared to dogs**. When they occur, they tend to be in the jejunum.

With **high intussusceptions**, vomiting, abdominal discomfort, anorexia, lethargy, dehydration and hypovolemia leading to shock are the most common clinical signs.

Low intussusceptions (at the ileocolic junction) typically present with bloody, mucoid diarrhea, tenesmus,

intermittent vomiting and weight loss. In many of these cases, the intussusception can be palpated.

Depending on the location and severity of the obstruction, there may be **anorexia or inappetence and vomiting**.

Diagnosis

Hemogram and serum biochemistry profiles are variable depending on the severity and location of the intussusception, however, **dehydration, electrolyte abnormalities, anemia and leukocyte changes** have all been observed depending on the cause of the intussusception.

Radiographs and/or ultrasound examination of the gastrointestinal tract are the **best means of confirming the diagnosis**. Contrast studies may be used but should not be done at the expense of delaying treatment in severely ill cases.

Endoscopic examination or colonoscopy can also be used to obtain a diagnosis, especially with low intussusceptions.

Differential diagnosis

Many **diseases that can precipitate an intussusception** (viral enteritis, foreign bodies, gastroenteritis, intestinal parasitism, etc.) also have clinical signs that **mimic it**. Therefore, a thorough physical examination, diagnostic evaluation, and close patient monitoring are essential. **Mesenteric volvulus** is a very difficult condition to differentiate from intussusception both clinically and radiographically, but fortunately is very rare in the cat.

Treatment

Intussusception must be considered a **surgical emergency**. Cats with signs of **shock or endotoxemia** should be prepared for surgery by **correcting fluid and electrolyte imbalances**, administration of **broad-spectrum, parenteral antibiotics** (combinations such as ampicillin/amoxicillin or cefazolin and enrofloxacin, amikacin, cefoxitin or imipenam), and use of **histamine-2 blockers** (ranitidine or famotidine) or **protecs** if gastric erosions or ulceration is suspected.

Motility-enhancing drugs, such as metoclopramide, are contraindicated in patients with GI obstruction and should not be used.

After surgical correction, if **gastric ulceration is not a complicating factor, oral alimentation should be instituted in the first 24 hours**, to enhance the return of normal motility and reduce the possibility of post-operative ileus.

FOREIGN BODIES*

Classical signs

- Weight loss, anorexia or inappetence
- Acute onset of vomiting or gagging, occasionally diarrhea is observed.

See main reference on page 636 for details.

Clinical signs

The signs **depend upon the location** of the foreign object.

With gastric or upper small intestinal obstructions, acute onset of frequent vomiting or gagging is common.

Dehydration, lethargy and anorexia are common in these cats, and they may show evidence of **abdominal discomfort** (either on palpation or by posture).

In cats **with a lower intestinal obstruction, diarrhea will be more prevalent** and vomiting less frequent.

If the foreign body is of significant size or if intestinal plication from a linear foreign body is present, these **abnormalities may be palpable**.

Cats that develop an **intestinal perforation** as a result of the foreign body may be quite ill (**depression, fever, hypovolemia/shock**).

Depending on the location and severity of the obstruction, there may be an **acute onset of anorexia or inappetence**.

Diagnosis

History and physical examination findings are very important. Always examine under the tongue of vomiting cats for evidence of a string or thread foreign body.

Hemogram and serum biochemistry profile findings will likely be **normal if the condition is acute**.

Long-standing or severe linear foreign bodies or GI perforation will show an **inflammatory response**, evidence of dehydration (hemoconcentration or elevated proteins) and **electrolyte abnormalities** consistent with vomiting (hypokalemia is most common).

The **diagnosis is obtained by imaging studies**, including **radiography** (plain or contrast studies looking for evidence of an obstructive gas pattern), **ultrasonography or upper GI endoscopy**. In some cases, endoscopy will allow retrieval of the foreign object, and is a useful means of assessing other damage (e.g. erosions, ulcers, or tears in the mucosa).

Differential diagnosis

Acute diarrhea is not the classic clinical sign of a foreign body, but may occur **in combination with vomiting or anorexia**, and can occur without these signs if the obstruction is more distal.

Some cats with linear foreign bodies have a waxing/waning course of vomiting, diarrhea or anorexia that may not suggest the diagnosis immediately.

Other differentials in those cases would include infectious, dietary or inflammatory gastrointestinal diseases.

Treatment

In cases where the object is still in the stomach, it is sometimes possible to safely **retrieve the object** (needle, small toy, etc.) via an **endoscopic** procedure.

Most GI foreign bodies however, will require **surgical removal**, and some may be a **surgical emergency when GI perforation has occurred**.

Cats that are severely dehydrated from persistent vomiting, or have suspected intestinal perforation and leakage should be stabilized as much as possible with **aggressive fluid therapy** and **broad-spectrum antibiotics** prior to surgery (e.g. combination of ampicillin/amoxicillin or cefazolin and enrofloxacin, amikacin or cefoxitin). Some cats with a protracted history of vomiting will benefit from **histamine-2 blockers** or **GI protectants** if gastritis or gastric erosions are suspected.

Motility-modifying agents, such as metoclopramide, should not be used until the obstruction is relieved.

IDIOPATHIC INFLAMMATORY BOWEL DISEASE (IBD) (LYMPHOPLASMACYTIC ENTERITIS, EOSINOPHILIC ENTEROCOLITIS)

Classical signs

- Vomiting, anorexia and weight loss are the most common signs of upper GI IBD.
- Diarrhea can occur.
- Affected cats are usually middle aged or older, with no particular sex or breed predisposition.

See main reference on page 768 for details.

Clinical signs

Typically, IBD is associated with upper GI signs of chronic intermittent **vomiting, weight loss and anorexia**.

Diarrhea is also observed in some cats, when the disease affects the colon or distal small intestine. This occurs less often in cats than in dogs. Acute exacerbation of diarrhea may occur.

Most cats with IBD have chronic signs of GI disease.

The disease is most prevalent in **middle-aged to older cats**, but the range is from **6 months to 17 years**.

There appears to be **no breed or sex predisposition** to IBD in most studies, but purebred cats and males appear to be over-represented in some studies.

Diagnosis

IBD is a diagnosis of exclusion, that requires two steps: (1) the **histopathologic confirmation** of an excessive inflammatory response, and (2) the **elimination of the multitude of potential causes** for GI inflammation.

The majority of cats with IBD will have a **normal hemogram and serum chemistry profile**, however, a few **abnormalities are not uncommon, but they are not specific for IBD**. These include leukocytosis, mild

non-regenerative anemia, increases in liver enzyme concentrations, mild hypoalbuminemia and mild hyperglycemia.

Fecal examination (flotation, direct exam, cytology) is **essential** to rule out parasitism.

Ultrasound examination is very important, not only in evaluation of the abdomen for structural abnormalities, but especially for **assessing bowel wall thickness and lymph node enlargement**, which have been shown to correlate well with the severity of IBD. Ultrasound is also important, as it may allow **fine-needle aspiration** of abnormalities which facilitate diagnosis, but also will help determine the best approach to take when obtaining the biopsies (**full thickness vs. endoscopic**).

Radiography, including contrast studies, **has not been shown to be helpful** in differentiating cats with IBD and those with other diseases.

Ultimately, endoscopic examination or a surgical exploratory will be necessary to obtain biopsies of the GI tract. Endoscopy is less invasive and allows visualization of the mucosal surface, which may assist in the evaluation of the cat. **Multiple (6–8) biopsies should be taken from multiple sites** (stomach, duodenum, ileum and colon), even if there is no visible evidence of disease.

Since there are no simple, easy tests for food intolerance or food allergy, **dietary elimination trials** should be conducted in all cats with signs of IBD or that have inflammatory infiltrates of the GI tract.

Differential diagnosis

The list of diseases that may mimic, cause or complicate IBD (e.g. cause GI inflammation and similar clinical signs) is extensive: systemic diseases (**hyperthyroidism, pancreatic disease, liver disease**, feline viral diseases, **toxoplasmosis**), parasitic diseases (nematodes, *Giardia*, *Cryptosporidia*, other parasites such as coccidia, entamoeba), **bacterial infection** (*Helicobacter*, *Campylobacter*, *Salmonella*, *Clostridia*, etc.), metabolic diseases (exocrine pancreatic insufficiency, serum cobalamin or folate deficiency), nutritional disorders (**food intolerance**), immunological conditions (food allergy) and **neoplasia (lymphoma, adenocarcinoma, mast cell tumor)**.

Treatment

The key to successful treatment of IBD is to have a **correct diagnosis** (and that is a **real challenge**).

Even if food allergy/intolerance has been ruled out, a **highly digestible, hypoallergenic or elimination diet** is important in the treatment of IBD. Cats with IBD have an abnormal gut immune system, **thus the presence of additional dietary antigens will only serve to exacerbate the inflammatory response**.

The mainstay of treatment of IBD in cats is **immunosuppressive doses of prednisolone (2–4 mg/kg/day PO)**.

Metronidazole (10–15 mg/kg q 12 h PO) is also **very effective**, and in some cats, may be as effective as steroid therapy. Many clinicians start with metronidazole and dietary therapy, and then add prednisolone if the response to treatment is incomplete.

In cats with **severe IBD** that is not responsive to metronidazole, prednisolone and dietary therapy, **cytotoxic drugs may be considered**. However, **most cats with IBD do not require additional cytotoxic drug therapy**, to manage their disease. Drugs that may be considered include chlorambucil (2 mg/m²), azathioprine (0.3 mg/kg EOD) and cyclosporine (5 mg/cat/day). **CBCs should be monitored every 2–3 weeks** to detect myelosuppression early.

Cats with a poor response to treatment or recurrent disease should be carefully re-evaluated (including multiple GI biopsies) to be sure that the diagnosis is correct. Lymphoplasmacytic enteritis can be mistaken for intestinal lymphoma in the early stages or a new problem may have developed.

TUMORS OF THE SMALL INTESTINE*

Classical signs

- Chronic, progressive vomiting that may include hematemesis.
- Weight loss and anorexia may be the earliest, and most consistent signs.
- Lethargy or depression are also common, especially later in the course.
- Diarrhea is more common with infiltrative neoplasms.

See main reference on page 675 for details.

Clinical signs

Weight loss and anorexia are the earliest and most common clinical signs.

Lethargy or depression are also common.

Diarrhea is most common with infiltrative neoplasms, such as alimentary lymphoma, which is the most common neoplasm in the feline small intestine.

Vomiting is a common presenting complaint and may be associated with hematemesis.

In the USA there is **no breed predilection** for lymphoma, but **Siamese cats appear to be predisposed to adenocarcinoma**.

Signs typically occur in **older cats**, however, **alimentary lymphoma occurs in cats of all ages**.

Intestinal forms of lymphoma are usually found in FeLV-negative cats, however, the **multicentric form of lymphoma can involve the GI tract and is often associated with FeLV-positive antigenemia** where FeLV is frequent in the feline population.

Both **adenocarcinoma and mast cell tumors of the GI tract** are often associated more with **vomiting and weight loss due to their mass-like, obstructive behavior**.

Diagnosis

Palpation of the abdomen may reveal a mass or thickened intestinal loops.

Hematology and serum chemistry profiles are usually non-specific, but help to rule out other causes of vomiting. **The most frequent hematologic abnormality is anemia of chronic disease** (normocytic, normochromic), but blood loss anemia is also observed. **The abnormalities found in the chemistry profile depend on the extent of the disease and severity of vomiting**, and are **non-specific** as well.

The most helpful diagnostic procedures are imaging techniques: radiography, ultrasonography or possibly endoscopy. There are no specific radiographic features of neoplasia, since it may be infiltrative or obstructive in nature. Ultrasound may be more helpful in identification of thickened loops of bowel or mass lesions.

Depending on the location and size of the mass, **ultrasonography will allow visualization of the lesion**, and

may also facilitate diagnosis via **fine-needle aspiration or biopsy**.

Ultimately, **histopathologic examination of the tissue is necessary for a definitive diagnosis**.

In **cats with obstructive or mass lesions**, lesions unreachable by the endoscope, or when ultrasound-guided fine-needle aspirates are non-diagnostic, **surgically obtained biopsies and resection are the best approach**.

Differential diagnosis

Alimentary lymphoma is easily (and often) mistaken, especially in the early stages of disease, for **lymphoplasmacytic enteritis (inflammatory bowel disease)**.

Many other severe GI or systemic diseases may resemble intestinal neoplasia, including hyperthyroidism, chronic renal failure or liver disease, pancreatitis, severe food intolerance or sensitivity, and severe forms of infectious enteritis. Differentiation of these diseases is based on **blood testing, exploratory laparotomy and intestinal biopsy**.

In cats with **mass-like or obstructive lesions**, other diseases to consider are **intussusception or foreign bodies, FIP or fungal granulomas, and focal abscesses**. Differentiation often requires exploratory laparotomy or biopsy.

Treatment

For **adenocarcinoma, mast cell tumors** and other tumors that tend to occur as solitary mass lesions, **surgical removal via intestinal resection is the primary approach**. **Biopsies should be obtained of liver, regional lymph nodes and mesenteric tissues** to determine if metastasis has occurred and its extent.

Chemotherapy has not been proven effective for adenocarcinoma or intestinal mast cell tumors.

Lymphoma of the alimentary tract is generally an infiltrative neoplasm and chemotherapy using combination protocols (COAP, etc.) are the treatments of choice. See main reference on page 676 for details.

NEMATODE PARASITES* (ROUNDWORMS, HOOKWORMS)

Classical signs

- Abdominal distention, colicky abdominal pain.
- Poor body condition, not nursing or eating.
- Diarrhea or abnormal feces.

Pathogenesis

Toxocara cati and *Toxascaris leonina* are the **primary roundworms of cats**. *T. cati* can be transmitted via milk, and by ingestion of the ova or hosts (e.g. rodents) containing the ova. Adult roundworms live in the small intestine.

Ancylostoma tubaeforme is the **most common hookworm of cats**, but is **less pathogenic than the primary hookworm of dogs** (*A. caninum*). Infections occur by ingestion of larvae, migration of larvae through the skin, via paratenic hosts, or prenatally. However, **hookworms are much less of a problem in cats than in dogs**.

Clinical signs

Kittens are most likely to have clinical signs associated with infestation with helminths.

The clinical signs may include **abdominal distention**, **colicky abdominal pain**, **poor body condition/hair coat**, **poor or reduced appetite**, **diarrhea or abnormal feces**, and **vomiting worms or vomiting due to masses of worms obstructing passage of ingesta**.

Ascarids of cats do not pass through the placenta, so kittens will not develop prenatal infections like puppies do.

Diagnosis

Fecal flotation will reveal **spherical egg** (*Toxocara cati*) with **pitted outer shell membrane** containing a single zygote, and approximately $75 \times 45 \mu\text{m}$ in size. *Toxascaris* is also an ovoid egg of similar size but has a smooth shell.

Ancylostoma tubaeforme ($60 \times 40 \mu\text{m}$) is the most common hookworm of cats, and is most prevalent in tropical regions. The eggs are elliptical and slightly smaller than roundworm eggs, but still readily identified on saline fecal flotation.

Infection may be associated with **peripheral eosinophilia**, **hypoproteinemia**, and mild to severe regenerative anemia (blood loss).

Kittens with severe intestinal parasitism may develop a bowel obstruction or intussusception resulting from the motility disturbance, in these kittens, **radiography, contrast studies or ultrasound examination** will be necessary to identify the problem.

Differential diagnosis

The age and clinical signs are usually supportive of the diagnosis, but other protozoal, infectious or dietary causes of gastroenteritis should be considered.

Treatment

Anthelmintics such as pyrantel (5–10 mg/kg PO once) or fenbendazole (25–50 mg/kg PO q 24 h for 3 days) are effective and can be used for treatment of both kittens and adult cats.

Selemectin (oral monthly heartworm preventative, flea adulticide and nematocide) **may be used to treat or prevent intestinal parasites**.

Repeat treatment in 2–3 weeks (hookworms) and 4–6 weeks (roundworms) to effectively **kill prepatent stages**.

Re-infection is prevented by good sanitation. Feces must be removed from the litter box or collected if outside, and incinerated.

Prognosis

Excellent, except in cats with intestinal obstruction, etc., which have a more guarded prognosis until the problem is surgically corrected.

Public health

Both roundworms (visceral larval migrans) and hookworms (cutaneous larval migrans) have

zoonotic potential, but are not as prone to cause larval migrans as canine parasites.

PYRETRINS/PYRETHROIDS/ PERMETHRINS/ORGANOPHOSPHATES*

Classical signs

- Acute onset of vomiting, diarrhea, hypersalivation and agitation.
- Contact dermatitis.
- Ataxia and possibly seizures.

See main reference on page 644 for details.

CLINICAL SIGNS

Signs associated with contact exposure or ingestion of pyrethrin/pyrethroid-containing pesticides is **generally mild**.

Vomiting, diarrhea, hypersalivation and agitation are the most common signs of organophosphate toxicity.

Permethrins are very toxic to cats, resulting in **central nervous system signs**, which include muscle tremors, ataxia, excitation or seizures. Cats may also become **hyperthermic secondary to prolonged muscle activity** or seizures.

Contact dermatitis is not common, but may be observed in cats with the topical preparations.

Diagnosis

History of exposure to or ingestion of products containing permethrin (most common) or pyrethroids.

There is generally no need for further diagnostic testing since **signs will abate with removal of the product** from the skin or GI tract and supportive care.

Differential diagnosis

The history of recent application of a product containing these chemicals is usually definitive.

Treatment

The first and most important step, if the cat is not seizing, is to **bath the cat to remove any remaining chemical**.

Cats that have **muscle tremors, seizures or other neurologic dysfunction** may need specific therapy such as phenobarbital or valium for seizure control. **Methocarbamol** (a muscle relaxant) may be helpful in decreasing excessive muscle activity.

Organophosphate toxicity is treated with **2-PAM and/or atropine** (0.2–0.4 mg/kg) to control the excessive salivation and defecation.

The signs will be self-limiting once the chemical is removed from the body, so **supportive care** is all that is required. However, some cats may require **1–3 days to recover**.

Since cats will not drink or eat, **fluid therapy may be needed**. In some cats, muscle tremors may be so severe to increase body temperature, so **monitoring (and controlling) body temperature is important**.

FELINE CORONAVIRUS INFECTIONS* (FELINE ENTERIC CORONAVIRUS/FELINE INFECTIONS PERITONITIS)

Classical signs

- Mild to moderately severe diarrhea for 2–5 days, usually in kittens (enteric form).
- Signs of FIP are vague and variable and include weight loss, fever and anorexia.
- Occasionally vomiting and chronic diarrhea are observed in cats with FIP.

Clinical signs

Enteric coronavirus infection causes a mild to moderate, self-limiting diarrhea, usually seen in kittens.

Diarrhea is uncommon in adults, but occasionally can be a peracute, severe hemorrhagic diarrhea.

- **Feline enteric coronavirus is important because this virus is the source** of feline infectious peritonitis (FIP). **This occurs by mutation of the enteric virus to the pathogenic, virulent FIP coronavirus that infects and replicates in macrophages.**

The clinical signs associated with feline infectious peritonitis (**FIP**) **virus** infection are quite **variable** and depend a great deal upon the stage when the cat presents to the veterinarian for evaluation.

Cats with **fulminant FIP** will likely be severely **depressed, anorectic and have significant weight loss**. Respiratory distress from **pleural effusion** is also common, as is the presence of **ascites**. Some of these cats will have **gastrointestinal tract signs**, such as vomiting or diarrhea, if there is significant **intestinal, liver or renal dysfunction**.

Cats with the so-called **non-effusive or “dry” FIP**, will have much more **vague clinical signs**, including reduced appetite, fever, mild weight loss and general malaise. Some cats will have mild abdominal **discomfort, respiratory signs, neurological signs and granulomatous retinal lesions**.

In some cats, **FIP granulomas** will cause more **focal signs associated with the body system that is affected**. Vomiting and/or chronic diarrhea from granulomas in the GI tract have been reported, as have central nervous system signs ranging from ataxia to seizures.

Diagnosis

The definitive diagnosis of FIP in cats antemortem is quite difficult, especially in cases of focal or non-fulminant FIP.

Interpretation of serologic tests can be difficult, because most test for antibodies to FECV, rather than for the FIPV form of the virus. While the **negative predictive index is relatively good**, false-negative tests can occur in cats with FIP. **Polymerase chain reaction (PCR) testing** is the best current test, but at present is only definitive for confirmation that a cat **does not have FIP**. The PCR test still has false positives that prevent it from being a good screening/diagnostic test. The 7B ELISA test detects antibody to 7B protein, but both false-positive and false-negative results are common with this test.

Currently, **the definitive test for FIP remains histopathologic examination or immunohistochemistry and virus isolation**.

SALMONELLOSIS*

Classical signs

- Abdominal distention, colicky abdominal pain.
- Poor body condition, not nursing or eating.
- Diarrhea or abnormal feces.

Pathogenesis

Salmonella are motile, Gram-negative bacilli that are **ubiquitous pathogens** able to infect many mammals, birds and reptiles.

Virulence of different strains varies and this is determined by the ability to invade tissues.

Salmonella **localize in the lymph nodes and intestinal tract**, and **shedding of organisms occurs for 3–6 weeks**. **Reactivation of shedding or clinical illness may occur after stress**, immunosuppression, other viral infections or crowded environmental conditions.

Salmonella produce enterotoxins which **increase secretions and fluid loss** in addition to the **entero-invasive effects**.

Endotoxemia or bacteremia may occur concurrently with intestinal infection or in the absence of GI signs.

Endotoxemia due to *Salmonella* is believed to only occur in cats with severe immunocompromise.

Clinical signs

There are **several clinical syndromes** that occur: **gastro-enteritis, bacteremia/septicemia, organ localization and the persistent asymptomatic carrier state**.

Acute episodes occur 3–5 days after exposure, with the most severe signs in kittens or old cats.

Cats will present with **fever, malaise, vomiting, abdominal pain and diarrhea**.

The **diarrhea** varies from watery to mucoid and may have hematochezia.

Weight loss, dehydration, shock and death will ensue if the cat is not treated aggressively.

Other organ systems may be affected with the systemic illness, including the CNS (seizures) and respiratory tract (pneumonia).

Cats that are presented with **endotoxemia or bacteremia** often have a **subclinical gastrointestinal infection**.

Very young kittens, less than 7 weeks old, **will not have fever despite bacteremia**. **Hypothermia**, weakness and collapse may occur without the onset of GI signs.

Organ localization occurs after clinical or subclinical bacteremia and is less common in cats than it is in humans.

The most common sites of organ localization include pyothorax, meningitis, osteomyelitis and focal abscesses of organs or skin.

Songbird fever is a clinical syndrome of **acute febrile illness** in cats associated with seasonal migrations of birds in the **northeastern United States**. The disease is characterized by **fever, depression, diarrhea** and **anorexia** in young, roaming (outdoor) cats that lasts for 2–7 days and may be self-limiting or very severe.

The vast **majority of cats with salmonellosis (>90%) have transient or no clinical illness**. Occasionally chronic diarrhea will occur for up to 8 weeks. **Recovered cats will shed for up to 6 weeks**.

Diagnosis

History (acute onset) and physical examination (fever, depression, diarrhea) will be important suggestive factors but there are numerous causes of acute diarrhea in young cats.

Routine **hematology and serum biochemistry profiles are typically unremarkable in the early phases**, but will show evidence of **dehydration, electrolyte imbalance and leukocyte abnormalities in the later stages**. Cats with bacteremia/septicemia will have a left shift or degenerative neutropenia, hypoglycemia, and may have hepatic or renal compromise as a result of the endotoxemia.

Definitive diagnosis depends on the culture of *Salmonella* spp. from fecal samples, or from urine, CSF, synovial fluid or blood in cats with bacteremia.

Serology can be used, but **many subclinically infected cats will have titers**, thus this method is **not an accurate means of diagnosis**. It is also not useful in acutely ill cats to aid treatment decisions because of the **time delay in seroconversion**.

Fecal cytologic exam will reveal **large number of fecal leukocytes**, thus suggesting an **infectious organism that disrupts the mucosal barrier**.

Differential diagnosis

Other acute, GI infectious diseases, such as feline panleukopenia virus, *Campylobacter* and *Clostridium*

should be considered, in addition to *Giardia*, *Cryptosporidia*, dietary indiscretion and toxicity.

Treatment

Acute gastroenteritis, without systemic septicemia, is best treated with **parenteral isotonic replacement fluids**. Maintenance fluid therapy is 40–60 ml/kg/day and replacement includes maintenance plus correction of dehydration, i.e. $BW \times \% \text{ dehydration}$ plus additional fluids to replace any ongoing losses. **The replacement fluids are to be given over 12–24 hours**, then the fluid rates can be adjusted to meet the patient's needs for maintenance and ongoing losses.

Cats with **severe hypoproteinemia** due to GI protein loss or septicemia and endotoxemia may benefit from **plasma transfusions or colloid (Hetastarch) therapy**.

Antibiotic therapy is not indicated in treating cats with uncomplicated gastroenteritis, but is **recommended in cats with sepsis or endotoxemia**. Antibiotics that may be effective against salmonellosis include the fluorinated quinolones, aminoglycosides and trimethoprim-sulfonamide combinations.

Antibiotic therapy may prolong the period of shedding, and is associated with **development of resistant populations of *Salmonella* spp.**

The presence of neutrophils on a rectal cytology swab justifies antibiotic therapy.

Prognosis

Excellent for cats with mild or subclinical infections, which comprise the majority of the cases.

In cats with septicemia or endotoxemia, the mortality rate is high due to cardiovascular collapse, renal failure and DIC.

Prevention

Enforcement of **strict hygiene** (litter box) and **proper cleaning of cages** (phenolic compounds or bleach) will reduce the risk of subclinical carriers creating disease problems in large population groups or hospitals.

Public health

Salmonellosis should be considered a zoonotic disease.

CLOSTRIDIUM PERFRINGENS* ENTEROCOLITIS

Classical signs

- Acute small bowel diarrhea with or without anorexia or lethargy.

Pathogenesis

Clostridium perfringens is an **anaerobic, Gram-positive, spore-forming rod** that is a **normal inhabitant of the colon** in animals and people.

Enterotoxin formation by *Clostridium* spp. causes **increased membrane permeability** and results in fluid and ion loss. Eventually, the epithelial cells will die and slough.

Most clostridia **exist in the GI tract in their vegetative state**, but under certain conditions (alkaline environment, other concurrent infections, antibiotic therapy or stress) the bacterium will undergo **sporulation and release of enterotoxin**.

Following an infection, the organism can be shed for weeks to months, and because of its stability in the environment, has the potential to infect many other susceptible animals.

Clinical signs

The most common clinical sign is **severe, watery to mucohemorrhagic diarrhea**.

In most cats, the diarrhea only lasts a few days, but in some, it may persist and become chronic. Animals that have severe diarrhea will become dehydrated, lethargic and may be anorexic.

There is **no breed, sex or age predisposition**, but cats from **catteries or in stressed environments** are at increased risk.

Diagnosis

The **history (acute onset, predisposing conditions) and physical examination findings (character of the diarrhea)** help to focus the diagnostic approach toward infectious, parasitic and dietary causes of diarrhea.

The presence of the organism can be confirmed by **culture of fresh fecal specimens**, however, **because this is part of the normal flora, this approach is not definitive**.

Similar to the dog, there appears to be a **poor correlation between the presence of fecal endospores and the presence of enterotoxin**.

Reverse passive latex agglutination (RPLA) tests for clostridial enterotoxin are available and have been used in dogs and humans, but have **not been evaluated in cats**. In dogs, the test does not differentiate dogs with clostridial diarrhea from normal dogs, as **> 25% of normal dogs are positive**. An enzyme immunoassay (Techlab, Inc., Blacksburg, VA) appears to be more specific in dogs. A **positive enterotoxin assay determined by ELISA** (regardless of endospore numbers) in the context of clinical signs consistent with clostridial infection is **strongly supportive of clostridial-associated diarrhea**.

PCR tests are also utilized for testing feces for enterotoxin, but are not universally available.

Differential diagnosis

Other enteric bacterial infections, parasitic and protozoal infections, dietary disturbances and toxin exposure should all be ruled out first.

Because this disease can occur in any age of cat, other considerations are **metabolic disease (hyperthyroidism), liver disease and neoplasia**.

Treatment

In severely ill cats, parenteral fluid therapy and introduction of a **bland, highly digestible diet** is necessary.

The primary treatment is the use of **antimicrobial drugs that have a good spectrum against anaerobic bacteria**: metronidazole, tylosin, ampicillin/amoxicillin and clindamycin have all been successfully used.

Addition of dietary fiber (1 tbsp psyllium/cat), or changing to a diet with increased dietary fiber may greatly **reduce the proliferation of clostridial organisms in the large bowel**.

Prognosis

Good with appropriate antibiotic therapy in most cats.

Some cats will have recurrent bouts of diarrhea that require repeated treatment with antibiotics or may benefit from lactulose, which reduces the luminal pH and thus will decrease sporulation.

SHOCK (HYPOVOLEMIC, SEPTIC, ENDOTOXIC)*

Classical signs

- Acute onset of generalized depression, fever or hypothermia.
- Tachycardia/tachypnea and signs of shock.
- Vomiting is not consistently present but does occur, and bloody diarrhea is also occasionally observed.

See main reference on page 269 for details.

Clinical signs

Cats with endotoxemia or sepsis are **depressed, usually febrile (but may be hypothermic)**, and show signs of **shock**.

Vomiting or bloody diarrhea may occur in the **later stages** of illness.

Other signs include respiratory distress, weakness, obtundation and seizures.

Diagnosis

Hemogram, serum chemistry and urinalysis show neutrophilia if there has been time for neutrophilia to develop, or neutropenia, thrombocytopenia, hyperglycemia early, progressing to hypoglycemia later. Hyperkalemia, and elevated liver enzymes and BUN are common, as is bacteriuria.

Blood culture is indicated in patients with suspected bacteremia to confirm the infection exists. **Urine culture** is also helpful in cases with **renal seeding of the infection**.

Imaging studies are important in further evaluating the extent of illness and **may help identify a focus of**

infection (e.g. radiographs of chest, abdominal ultrasound).

FELINE PANLEUKOPENIA VIRUS

Classical signs

- Acute onset of anorexia, vomiting, pyrexia, depression, weakness and dehydration.
- The disease is most severe in kittens, and has a high mortality rate.
- Diarrhea occurs late in the course of the disease.

Pathogenesis

Feline panleukopenia is a **parvovirus** that requires **rapidly dividing cells** for successful infection (lymphoid tissue, bone marrow and intestinal mucosal crypts).

Infections of kittens in utero, or in the immediate postnatal period, results in **infection of the cerebellum, cerebrum, retina and optic nerves** which may result in seizures, behavioral changes, cerebellar dysfunction and retinal degeneration.

Damage to the intestinal crypt cells results in shortening and eventually loss of the villous (absorptive) cells. Diarrhea is caused by malabsorption and increased permeability.

Kittens infected with panleukopenia are **highly susceptible to secondary bacterial infections** with enteric microflora.

Gram-negative endotoxemia is a common complication and cause of death in kittens.

Infection of the queen early in the pregnancy can result in a wide variety of **reproductive disorders**, including early fetal death, infertility, abortions or fetal mummification. **Late-stage gestation infections** result in the birth of **live kittens with varying degrees of neurologic dysfunction**.

As with canine parvovirus, the feline virus is **highly contagious, and is very persistent** in the environment.

Panleukopenia is **transmitted by direct contact** of susceptible animals with infected cats or their secretions

(feces contains the largest amount of virus). However, **fomites** are an important aspect of transmission because of the prolonged survival of the virus in the environment.

Feline panleukopenia can be **inactivated by bleach and formaldehyde**, but is **resistant to other common disinfectants**.

Clinical signs

The majority of cases of clinical panleukopenia are observed in **kittens or young cats under 1 year age**.

Clinical signs vary from **mild to very severe**.

Anorexia, depression and extreme lethargy are very common clinical signs in the early stages.

Vomiting usually occurs but varies in severity and is associated with dehydration.

Diarrhea occurs 24–48 hours after the onset of depression, and may be mild or marked with severe blood-streaked or hemorrhagic diarrhea.

In the **peracute form**, death may occur before diarrhea develops.

- The cat often sits sternally with its head down (flexed).
- **Abdominal palpation** may reveal evidence of pain, enlarged abdominal (mesenteric) lymph nodes and increased gas or fluid in the intestines.

The cat **may or may not be febrile**, but may become febrile if there is sepsis. In the late stages of fatal disease, the cat will almost always become hypothermic. **Hypothermia indicates a grave prognosis**.

Kittens affected in late gestation, or in the first 9 days after birth, are often **ataxic, hypermetric, dysmetric, incoordinated** and have a base-wide stance when they begin to walk at 2–3 weeks of age.

Other neurologic abnormalities include **seizures, behavioral changes and retinal degeneration**.

Prenatally infected kittens may be stillborn or die as fading kittens in the first few days of life.

Many susceptible cats will be infected, but have **subclinical or mild GI signs** associated with depression and anorexia for 1–3 days.

Secondary upper respiratory tract infections may occur, especially calici- or herpesvirus infections.

Diagnosis

The **history (acute onset of depression and vomiting)**, **signalment (cat less than 1 year of age)** and **physical examination findings (fluid- and gas-filled intestines)** are all suggestive of the disease.

The milder forms of the disease that occur in adult cats can be difficult to differentiate from many other gastrointestinal diseases.

The most consistent hematologic abnormality is panleukopenia, with leukocyte counts typically ranging between 500 and 3000 cell/ μ l. **Because the disease is so acute, serum biochemistry values are usually within normal limits**. Hypoglycemia and elevated liver enzyme concentrations may be detected in cats with endotoxemia.

There is no licensed ELISA test kit for the feline parvovirus, however, the **canine test kit will detect the feline parvovirus in feces** as well. **False-positive and false-negative test results can occur**.

- **False-positive test results can occur following recent vaccination** with a modified live panleukopenia vaccine, and **false-negative results occur if the kitten is tested before shedding starts**, if there is **low virus burden or late in the course** when shedding becomes more intermittent.

Serologic testing is still an important diagnostic test for feline panleukopenia, but it **requires paired samples (acute and convalescent)** that show a rise in titer to be definitive. **Serology is usually only indicated in a multi-cat facility** so appropriate preventative vaccination programs can be implemented.

Other tests that can be performed include virus isolation on feces or tissues and electron microscopy for detection of virus particles in the feces.

Differential diagnosis

In its severe form, which is typically present in kittens, **few diseases mimic feline panleukopenia**.

Milder clinical forms of the disease in adult cats must be differentiated from **all other infectious causes of gastrointestinal disease** (e.g. campylobacteriosis, giardiasis, etc.).

Feline leukemia virus can present in some cats with a panleukopenia-like syndrome, but is easily distinguished from feline panleukopenia by the presence of FeLV antigenemia, persistent leukopenia and anemia in a well, vaccinated cat.

Salmonella infections in cats are **usually subclinical**, but can present with a **fulminant gastroenteritis similar to panleukopenia**. In acute salmonellosis, leukopenia may be present.

Treatment

Treatment is supportive, but must be **aggressively administered** if it is to be successful.

The key is **maintenance of fluid** (40–60 ml/kg/day plus correction of dehydration and treatment of ongoing losses) and **electrolyte balance** (add potassium chloride to fluids) and **prevention of secondary bacterial infection** until the body is able to neutralize the virus with antibody.

Antibiotics effective against enteric pathogens (Gram-negative and anaerobic bacteria) must be given to control secondary bacterial infections. Combination therapy with ampicillin (10–20 mg/kg q 8 h) or cephalexin (20–30 mg/kg q 8 h) and amikacin (8 mg/kg q 24 h) or enrofloxacin (5 mg/kg q 24 h) is necessary for broad-spectrum coverage.

Control of vomiting can usually be achieved with metoclopramide (0.2–0.5 mg/kg q 6–8 h) or prochlorperazine (0.1–0.5 mg/kg q 6–8 h) therapy.

Plasma or blood transfusion therapy (up to 20 ml/kg for plasma therapy, or calculate transfusion to increase the PCV to approximately 20%) are indicated in kittens with severe anemia, hypoproteinemia or hypotension.

Young kittens also need nutritional support to prevent the development of hypoglycemia and assist the immune response. **B vitamin supplementation** is also especially important.

- **Nutritional support may include tube feeding** (orogastric, nasogastric) with liquid enteral supplements, **force feeding** of canned or blenderized foods, or **intraosseous/intravenous feeding** (total or partial parenteral nutrition). **If the kitten is not vomiting, the enteral route is preferred**, but in vomiting patients, parenteral routes of feeding will be necessary. The most important nutrients to

include are **amino acids and glucose**, which can be given via a peripheral vein or intraosseously.

As with other parvovirus infections, **aggressive supportive care** (fluids, antibiotics, warmth, control of emesis, and nutrition, including gamma globulins if available) is the key to success.

Treatment of adult cats is supportive, but depends on the severity of the clinical signs.

There is **no treatment for the neurologic signs**.

Prognosis

The **prognosis for kittens or very young cats** with severe signs of feline panleukopenia is **guarded to grave**, as many die. **Kittens infected before 10 days of age** that survive have **life-long neurologic dysfunction**, which is **not progressive**, and may be acceptable to the owners.

Adult cats are likely to survive without significant disability, and will have **life-long immunity**.

Prevention

The currently **available vaccines for feline panleukopenia are excellent**. Kittens should be vaccinated at 8–9 weeks and then boosted at 12–14 weeks.

Adults have traditionally been revaccinated annually, but this is not necessary. In a recent study, **protective immunity from a killed feline panleukopenia vaccine was found to persist for at least 7 years**, and modified live vaccines are believed to impart life-long immunity.

In young kittens, it is also important to **reduce their risk of exposure by isolation from unvaccinated or ill cats**.

HEAVY METALS (LEAD, ARSENIC)

Classical signs

- Vomiting, diarrhea, anorexia and depression occur early.
- Chronic signs of lead toxicity involve the central nervous system, e.g. seizures, tremors and ataxia are most common.

(continued)

Classical signs—Cont'd

- **Arsenic toxicity eventually results in hepatic and renal failure presenting as depression, anorexia, vomiting and diarrhea, along with oliguria or anuria, or icterus and ascites.**

See main reference on pages 596, 659 for details.

Clinical signs

There are **two major categories of clinical signs with lead poisoning**: (1) **gastrointestinal signs**, which occur **early in the course of the disease**, and (2) **central nervous system signs**, which are manifest **late in the disease**.

GI tract signs occur early with lead toxicity and may include **vomiting, diarrhea, salivation, inappetence and lethargy**.

Chronic signs of lead toxicity involve the central nervous system, and include **seizures, tremors and ataxia**.

Arsenic causes GI signs early, but is **hepatotoxic and nephrotoxic**, resulting in depression, anorexia, vomiting and diarrhea along with oliguria or anuria, or icterus and ascites.

Lead is commonly found in older paints, while **arsenic is primarily obtained from snail baits**.

Diagnosis

Historical information of exposure to heavy metals is a very important means of getting the diagnosis, however, such information is not always known.

The **hemogram and serum chemistry profile will be unremarkable** when the cat presents with signs of **gastrointestinal disturbance**.

The most **common hematologic abnormality associated with lead poisoning is basophilic stippling** of red cells, which occurs in 30% of cats with lead exposure, and the presence of **nucleated red blood cells** (also 30%). However, these tests are **not pathognomonic for lead poisoning**.

Heavy metals also cause hepatocellular necrosis, which will be evidenced by **elevations in serum ala-**

nine aminotransferase and alkaline phosphatase enzymes. Other abnormalities may include elevations in bilirubin, bile acid values and decreases in albumin (in end stage hepatic failure).

Nephrotoxicity associated with arsenic poisoning is also associated with **isosthenuria, azotemia and eventually oliguria/anuria**.

FELINE LEUKEMIA VIRUS

Classical signs

- **Clinical signs are incredibly variable and depend on which organ(s) are affected.**
- **Weight loss, inappetence.**
- **Occasionally vomiting or chronic diarrhea.**
- **Diarrhea is rarely observed as an acute onset.**
- **Anemia may be observed.**

See main reference on page 540 for details.

Clinical signs

Inappetence, weight loss, and lethargy are typical non-specific signs.

The **clinical signs** observed in cats infected with feline leukemia virus will be quite **variable and depend upon which body system(s) is affected**.

Neoplasia, immunosuppression and bone marrow disease (especially of the red cell series causing anemia) **are the most common clinical manifestations** of the disease.

Generalized lymphosarcoma is a manifestation of FeLV in cats, and **involvement of liver and mesenteric lymph nodes results in gastrointestinal tract signs**, such as vomiting, anorexia, chronic diarrhea and weight loss. While the diarrhea is generally chronic in nature, the owner may perceive that it is acute in onset. Occasionally, the diarrhea occurs in cats with a good to increased appetite.

Diagnosis

Any ill cat should be tested for infection with feline leukemia virus, due to its many **clinical manifestations**

and the **poor prognosis** that exists for cats that are infected with the virus.

The **hemogram and serum chemistry profile** will likely be **abnormal, especially in cats with systemic illness**. The changes may be mild or subtle (**mild anemia of chronic disease, mild changes in white blood count, liver enzymes, etc.**) in the early stages of the disease, and dramatic (**severe non-regenerative anemia, leukopenia, elevation of liver enzymes, etc.**) when the disease finally progresses to end-stage.

Radiographs and ultrasound examination are useful in detecting lymphosarcoma involving the GI tract.

Biopsy of the GI lesions via fine-needle, tru-cut or wedge resection of tissue will be necessary to **confirm the diagnosis of lymphosarcoma**.

The **definitive diagnostic test** for detection of feline leukemia virus infection in cats is a **serum ELISA test which detects viral antigen**. A positive test should be confirmed using a follow-up ELISA test 8–12 weeks later, or by using an immunofluorescent antibody (IFA) test on whole blood or bone marrow, as the sensitivity and specificity of serological tests such as these are affected by the incidence of disease in the local population and the individual cat's risk factors for infection.

FELINE IMMUNODEFICIENCY VIRUS

Classical signs

- Chronic disease of middle-aged to older cats.
- Most common clinical signs are weight loss, chronic infections and development of neoplastic disease.
- Acute or chronic diarrhea is an uncommon problem but occasionally occurs as the only sign.

See main reference on page 339 for details.

Clinical signs

Clinical signs may be **due to direct effects of the virus or occur secondary to the development of immunodeficiency**, but in either case, occur in **middle-aged to older, male cats that are outdoor or occasionally fight**.

Acute signs include **fever, lymphadenopathy and inappetence**. Other signs include weight loss and non-specific lethargy.

Chronic small bowel diarrhea is one clinical syndrome associated with FIV infection. Other syndromes include non-regenerative anemia, neutropenia, anterior uveitis, glomerulonephritis and central nervous system signs ranging from behavioral changes to seizures.

Diagnosis

History (middle-aged, male, outdoor cat) and **physical examination** (non-specific signs of weight loss, with possible multi-system involvement) findings are suggestive.

Antibodies to FIV are detected in serum by an ELISA test commercially available.

Cats vaccinated for FIV will be positive to the antibody test and cannot be distinguished from infected cats.

Confirmation of the test is not usually necessary in ill cats, but **in healthy cats, confirmation of the positive antibody test by western blot or PCR analysis is suggested**.

Kittens may obtain antibody from milk and not be infected, so **a positive antibody test in kittens under 16 weeks of age should be re-evaluated in 1–2 months** to determine whether the antibody was maternal or infectious.

CAMPYLOBACTERIOSIS

Classical signs

- Abdominal distention, colicky abdominal pain, and diarrhea are the most common signs.
- Kittens are generally in poor body condition, or have other concurrent infections.

Pathogenesis

Campylobacter spp. are **Gram-negative, motile rods** associated with diarrheal disease in many species.

The disease is spread by **fecal–oral mechanisms**, with food and water being primary sources of infection.

The disease is **most prevalent, and clinically significant, in kittens from catteries, shelters or laboratories.**

Most adult cats have asymptomatic infections, and those with diarrhea often have other **concurrent enteric pathogens** present that exacerbate the severity of the disease.

Exposure to *Campylobacter* results in the development of protective immunity which may explain why kittens are more prone than adults to the development of clinical disease.

Clinical signs

In cats, **clinical signs of campylobacteriosis are uncommon in the absence of other pathogens.** Most infections are asymptomatic.

Affected cats are usually **less than 6 months** of age.

The primary clinical sign of infection is diarrhea, which may be watery, bloody, mucoid or a combination.

Some kittens will become systemically ill with lethargy, dehydration and anorexia observed.

Diagnosis

History and physical examination findings are important, but **may be unremarkable.**

Routine hematology, chemistry profiles and imaging studies are typically unremarkable.

Diagnosis can be confirmed by culturing freshly obtained fecal samples. Samples can be **transported at room temperature without special handling,** but must be **cultured in a microaerophilic atmosphere.**

***Campylobacter* are often cultured from the feces of normal cats** (up to 40%), so it is important to correlate the presence of the organism with the history and clinical signs.

Dark-field or phase contrast microscopy can also be used to identify the motile, curved bacteria on fresh fecal samples. **Gram-stained samples** can also be used to identify the **gull wing-shaped rods in the feces.** However, these approaches are less sensitive and require more technical skill.

Differential diagnosis

Infectious (*Salmonella*, *Clostridium*), parasitic (*Giardia*, *Cryptosporidia*, etc.), and dietary (intolerance or discoloration) agents should all be considered.

Treatment

Since most cats with *Campylobacter* infections are asymptomatic or associated with other infections, the **effectiveness of antibiotics for treatment of this disease is unknown.**

Several antibiotics appear to be effective in eliminating the organism, including erythromycin (10 mg/kg q 8 h PO), metronidazole (5–10 mg/kg q 12 h, PO), cephalosporins (20 mg/kg q 12 h PO), and fluorinated quinolones (5 mg/kg q 24 h PO).

Prognosis

Excellent, especially in adult cats.

Public health

Enteric campylobacters are known to be human pathogens, and kittens can be a source of human infection.

Usually kittens with diarrhea are incriminated as causes of human infection, however, because humans can be infected with extremely small amounts of the bacteria, **asymptomatic cats and kittens that are shedding can also be a source of infection.**

The best way to prevent human zoonosis is to stress the importance of exercising appropriate personal **hygiene when handling pet feces or litter boxes.**

IDIOPATHIC JUVENILE DIARRHEA

Classical signs

- The only presenting sign is chronic diarrhea.

Pathogenesis

The **pathogenesis** of idiopathic juvenile diarrhea is **unknown.**

Clinical signs

The disorder occurs **in kittens and young cats under a year of age**.

The only clinical sign is presence of **chronic small bowel diarrhea**.

Kittens are otherwise healthy, active and gain weight

Diagnosis

The diagnosis is one of exclusion. Thus, infectious, parasitic, dietary and mechanical disorders must all be ruled out.

Cats with this syndrome are **often purebred cats**, and the **diarrhea is self-limiting once they reach adulthood**.

Differential diagnosis

Because this is a disease of kittens, bacterial, viral, parasitic, protozoal, dietary and toxic causes of diarrhea must all be carefully considered.

Treatment

There is **no known effective treatment** for this condition. But, since it is self-limiting, owners should be instructed not to give up prematurely.

Prognosis

The prognosis is good once the kitten reaches adulthood.

PLANT INGESTION/TOXICITY

Classical signs

- **Acute onset of drooling, vomiting or diarrhea due to the irritant effects on mucous membranes.**
- **More severe and prolonged vomiting, diarrhea, depression or anorexia may occur if hepatic or renal failure occurs as a result of the toxicity.**

See main references on page 646 for details.

Clinical signs

Vomiting is the most common sign following ingestion of plant material, whether or not it is poisonous/toxic to the gastrointestinal tract or not.

Other signs may include anorexia, **drooling, dysphagia or diarrhea**.

Diagnosis

History of exposure or ingestion is essential in many cases, because **there is so much variability in presentation**.

Plants that cause vomiting due to irritation or direct GI upset include *Philodendron*, *Dieffenbachia* (dumb cane), *Euphorbia* (poinsettia), *Caladium*, *Ricinus* (castor bean), *Robinia* and *Solanum* (tomato, eggplant or nightshade) spp. to name a few of the more common plants.

Plants that cause vomiting secondary to nephrotoxicity include *Lilium* (lily), *Rheum* (rhubarb) and *Oxalis* spp.

Differential diagnosis

Consider dietary indiscretion, foreign body or ingestion of other toxins if there is an **acute onset of vomiting or diarrhea in an otherwise healthy cat**.

Cats ingesting plants that are **nephrotoxic** will have signs that are indistinguishable from other causes of vomiting due to systemic metabolic, infectious or inflammatory diseases.

Treatment

In most cases, the vomiting is self-limiting after the offending plant is removed from the GI tract.

Gastric protectants (e.g. sucralfate 0.5–1 g/cat PO) or **histamine-2 antagonists** (e.g. famotidine, 0.5 mg/kg PO or SQ q 24 h) may be indicated if severe gastritis develops.

Gastric lavage may be helpful if large amounts of irritant plants are consumed and is important following ingestion of toxic plants to reduce further absorption of toxic substrates.

Other treatments that may be necessary include **fluid therapy**, **anti-emetics** such as metoclopramide (0.2–0.5 mg/kg PO or SQ q 8 h), and **offering food that is bland or highly digestible**.

Once signs of nephrotoxicity are observed following lily plant ingestion, progression to anuric renal failure and death is unavoidable. Supportive care with fluid therapy may slow the onset of signs, but there is no effective treatment.

HYPEREOSINOPHILIC SYNDROME

Classical signs

- Severe, small bowel diarrhea that may be unresponsive to treatment.
- The hemogram is characterized by peripheral eosinophilia and there is infiltration of eosinophils in the bone marrow, spleen, liver, lymph nodes and other organs.

See main reference on page 758 for details.

Clinical signs

The **clinical signs** are similar to those of cats with IBD except the **intestinal wall thickening** is more pronounced, **hepatosplenomegaly** is common, and **bloody diarrhea is common**. The diarrhea is usually chronic rather than acute.

Some cats will **cough**, have **skin lesions** (miliary dermatitis) and have **peripheral lymphadenopathy**, but these clinical signs are less common.

Diagnosis

Histopathologic examination of liver, spleen, lymph node or intestinal biopsies provides the definitive diagnosis. There is infiltration of these organs by large numbers of normal eosinophils.

Treatment

The cornerstone of treatment is **high-dose prednisolone therapy** (3–6 mg/kg/day PO), but **relapses are common**, even if the high doses of steroids are maintained.

Hydroxyurea (7.5 mg/kg q 12 h PO) may also be used to reduce eosinophil production. It is administered for 3–14-day courses, as required to maintain the cat in remission.

Nutritional or fluid support is often required until the disease is brought under control.

Prognosis

The prognosis is guarded to poor.

PERITONITIS

Classical signs

- Abdominal pain, lethargy, ascites, anorexia and fever are common signs.
- Vomiting or diarrhea are less frequent, but often observed in more severe cases.

See main reference on page 467 for details.

Clinical signs

Intestinal perforation secondary to string or other foreign bodies, is the **most common cause of peritonitis**. **Other causes** include penetrating wounds and chemical peritonitis (due to bile duct rupture).

Abdominal discomfort/pain, lethargy and anorexia are common signs.

Vomiting or diarrhea are not common signs, but when they occur are often associated with severe disease.

Fever and abdominal distention/effusion may also be present.

Diagnosis

Abdominal radiographs (plain, contrast) and ultrasonography will suggest peritonitis and **may pinpoint location or cause** (ruptured gallbladder, pancreatitis, bowel rupture).

Definitive diagnosis confirming the presence of peritonitis is with **abdominocentesis or diagnostic peritoneal lavage and cytologic/bacteriologic examination of fluid**.

Hematology is non-specific: inflammatory leukogram, stress leukogram or sequestration of neutrophils.

SHORT BOWEL SYNDROME

Classical signs

- Severe, and in some cases intractable, small bowel diarrhea.
- Peracute onset of vomiting, depression and anorexia if associated with ischemic intestinal disease.

Pathogenesis

Short bowel syndrome is classically **due to surgical resection of a large segment (75–90%) of the small intestine** that results in **fluid overload to the colon** and resultant diarrhea.

Other causes include ischemic intestinal diseases such as intussusception, bowel strangulation and intestinal volvulus, which are very rare in the cat.

Intestinal adaptation occurs in the large bowel, which ultimately results in a return to a soft or semi-formed fecal specimen.

If greater than 85% of the small intestine has been removed the chance for adaptation is poor.

Congenital forms of short bowel syndrome are also rare, and will be seen in kittens with intractable diarrhea.

Clinical signs

Diarrhea, dehydration and weight loss all occur as a result of short bowel syndrome.

Other signs are related to **intestinal malabsorption: deficiency of proteins, vitamins or clotting factors.**

Small intestinal bacterial overgrowth may also occur resulting in **vomiting or anorexia** as well.

If associated with ischemic intestinal diseases, evidence of endotoxemia and shock may be present.

Depression, anorexia and vomiting are the most common signs. The acuteness and severity of the signs depend on the **extent of the bowel compromise.**

Diagnosis

The diagnosis is **presumptive if surgical resection is the cause.**

Cats are often **hypoproteinemic**, may be **hypcholesterolemic**, and have other **non-specific hemogram or chemistry abnormalities.**

Imaging studies can be used to confirm the diagnosis.

Differential diagnosis

Other diseases that may cause similar signs include severe infectious enteropathies, inflammatory bowel disease or alimentary neoplasia.

Treatment

If the disease is spontaneous in the adult cat, stabilization and prompt surgery is required.

Tincture of thyme will allow the bowel to adapt when the syndrome is iatrogenic in origin.

Broad-spectrum antibiotics may be needed.

Low-fat, highly digestible diets are necessary to maximize absorption of nutrients.

Fat-soluble vitamins should be administered as needed. Cobalamin 125–250 µg SQ once per week until serum concentrations are normalized, then every 1–2 months to maintain levels. **Folate** 0.5 mg PO daily until serum levels normalized then as required. **Vitamin E** supplementation may also be needed.

Parenteral nutrition may be required in some cats in the early stages to support them until bowel function returns.

Prognosis

Guarded; in cats where diarrhea persists for longer than 2 months after the resection, the prognosis for a return to function is poor.

EXOCRINE PANCREATIC INSUFFICIENCY

Classical signs

- Weight loss despite a vigorous appetite, which may include pica and coprophagy.

Classical signs—Cont'd

- Fecal characteristics may be normal, soft and voluminous or watery diarrhea.
- Poor haircoat and greasy, flaky seborrhea are also common.

Pathogenesis

Exocrine pancreatic insufficiency (EPI) is **very rare in the cat compared to the dog**.

The **most common cause of EPI** in the cat is **chronic pancreatitis**.

A **less common cause of EPI** is infestation with the **feline pancreatic fluke**, *Eurytrema procyonis*.

Other, possible causes of EPI in cats include **pancreatic adenocarcinoma** and congenital pancreatic acinar hypoplasia or aplasia.

Idiopathic pancreatic acinar atrophy, the most common cause of EPI in dogs, has **not been reported in cats**.

In humans with EPI caused by chronic pancreatitis, diabetes mellitus occurs concurrently. It is **unknown whether cats with chronic pancreatitis and EPI will also progress to develop diabetes mellitus** as well.

EPI is believed to develop when **> 90% of the enzymes of the exocrine pancreas are destroyed**. These enzymes play an integral role in assimilating the major food components: proteins, lipids and carbohydrates.

Pancreatic enzymes increase the efficiency of breakdown of macromolecules in the digestive tract and enhance the transport mechanisms for sugars, amino acids and fatty acids. Thus, **food substances are inefficiently broken down and cannot be readily transported across the intestinal lumen without pancreatic enzymes**.

Diarrhea occurs due to the presence of **large quantities of fats, protein and carbohydrates**, which are **osmotic**.

Maldigestion of these important nutrients leads to **weight loss** and may also cause **deficiencies of vitamins, fatty acids or other essential nutrients**.

Clinical signs

The **most common clinical signs** are **polyphagia, diarrhea and weight loss**.

Vomiting and anorexia are also occasionally reported.

The feces are typically **pale, loose, voluminous**, and they may be quite **malodorous**.

Cats often have a **greasy, flaky haircoat** due to the **fat malabsorption**.

Deficiencies of fat-soluble vitamins can result in a bleeding disorder (**vitamin K-responsive coagulopathy**), which may present as **excessive bleeding from venepuncture sites or spontaneous hemorrhage** (nose bleeds, hematuria, melena, etc.).

Diagnosis

Results from routine **hematology and chemistry profiles** will be **normal in most cats**. Occasionally, **elevations in hepatic enzymes or neutrophilia** will be observed.

Routine **abdominal radiography and ultrasonography** is usually normal, and is **not diagnostic**.

Fecal proteolytic activity testing will reveal **undetectable levels of enzymes**, which is diagnostic for EPI, but the test is very labile, so **false-positive tests occur to improper sample handling**.

A recently validated radioimmunoassay for **feline trypsin-like immunoreactivity (fTLI)** is available, much like the TLI test available for use in dogs.

Severely decreased fTLI concentrations are diagnostic for EPI in cats.

All cats with EPI should have a serum cobalamin and folate assay, since many cats with EPI are cobalamin deficient or have concurrent small bowel disease, causing folate levels to be low.

Differential diagnosis

The **clinical signs are so non-specific** that many other diseases that cause polyphagia, weight loss and diarrhea must be considered: **hyperthyroidism**, diabetes mellitus, corticosteroid treatment or hyperadrenocorticism, **chronic renal failure**, heart failure, liver disease, dental disease, neoplasia, and **chronic intestinal diseases such as inflammatory bowel disease and alimentary lymphoma**.

Treatment

Most cats with EPI can be successfully treated by **dietary supplementation with pancreatic enzymes**. The **powder products** (1 tsp per meal) appear to be **more clinically effective than tablets**.

If the cat refuses to eat the food with pancreatic extract, **raw pancreas can be offered, but it is essential to use bovine pancreas to prevent transmission of Aujeszky's disease in porcine pancreas** in areas where the disease occurs.

A diet that contains low amounts of insoluble fiber should be fed, since insoluble fibers may interfere with pancreatic enzyme activity.

Some cats will not respond to enzyme supplementation alone, and this may be due to **concurrent cobalamin deficiency or small intestinal disease**. Cobalamin supplementation should be given **parenterally (100–250 µg SC once weekly** for 6–8 weeks, then monthly or bimonthly as needed).

In cats with suspected vitamin K deficiency, supplementation should also be initiated (vitamin K₁ 1 mg/kg/day PO).

Other supplements that should be given include: **tocopherol** (30 IU orally, once daily with food for the first month until levels are normalized), and **folate** (0.5 mg orally, once daily).

It is **unknown whether or not cats develop small intestinal bacterial overgrowth as a complication of EPI** as is common in dogs. However, **in cats that do not respond as anticipated** to pancreatic enzyme supplementation, **addition of metronidazole or tetracycline to the treatment regime** is indicated.

Prognosis

Because EPI is associated with the **irreversible loss of pancreatic acinar tissue, complete recovery is not possible**.

However, with appropriate management, cats with EPI will gain weight, pass normal feces and can live a normal life.

Prevention

There is no known way to prevent the development of EPI, however, if cats with chronic pancreatitis can be

recognized and appropriately managed, it may be possible to prevent the consequences of chronic pancreatitis-EPI.

TYZZER'S DISEASE (*BACILLUS PILIFORMIS*)

Classical signs

- The disease occurs primarily in kittens at weaning age, but is rare.
- Rapid onset of depression, abdominal discomfort.
- Death within 24–48 hours is common, but some may have signs several days before death.

Pathogenesis

Disease is caused by *Bacillus piliformis*, a spore-forming, Gram-negative, intracellular bacillus.

This is primarily a disease of laboratory rodents, and is very rare in cats and dogs, but may be seen in kittens and especially weanlings.

The source of the infection is believed to be rodent feces.

The organism proliferates in the intestinal epithelium producing enterocolitis and then spreads to the liver and systemic circulation.

Clinical signs

The most common signs are an **acute onset of depression and abdominal discomfort**.

Death usually occurs within 24–48 hours, although weight loss and recurrent or chronic diarrhea can occur in older cats.

The **diarrhea is typically infrequent, scant and pasty**.

Diagnosis

There is **no ante-mortem test for Tyzzer's disease**, and most frequently, the diagnosis is made by necropsy.

The lesions are most severe in the ileum, colon and liver, with the ileum and colon being severely thickened.

Special stains (**Giemsa**) will reveal the filamentous organisms in the histopathologic specimens.

The organism is difficult to culture because of its intracellular, microaerophilic nature.

Differential diagnosis

The disease is so peracute that panleukopenia must be considered, as well as other infectious agents that cause severe enteritis and systemic disease.

Treatment

There is no known effective therapy.

Supportive care with antibiotics, fluids and maintenance of body functions (temperature, nutrition) are essential.

Prognosis

Poor.

33. The cat with signs of chronic small bowel diarrhea

Debra L Zoran

KEY SIGNS

- Loose to watery feces.
- \pm Melena.
- No mucus or fresh blood.
- > 3 weeks duration.

MECHANISM?

- Diarrhea may be defined as a **change in the frequency, consistency or volume** of bowel movements.
- The **four recognized pathophysiologic mechanisms** that cause diarrhea include osmotic, secretory, increased permeability and altered motility.
- **Osmotic diarrhea** and conditions causing **increased permeability** are believed to be the **most common causes of diarrhea**.
- **Classification of diarrhea** by characteristics that tend to be more prevalent in **small vs. large intestinal disease** is a helpful way to develop an appropriate diagnostic and treatment regimen. **Small bowel diarrhea is characterized by:**
 - Loose to watery feces.
 - **Increased volume** of feces.
 - **Normal to increased frequency** of defecation.
 - **No or little straining or tenesmus** associated with defecation.
 - If blood is present in feces it occurs as **melena**.
 - No increase in mucus on the feces.
 - **Weight loss and vomiting** are commonly observed concurrently.

WHERE?

- The **small intestinal tract** (duodenum, jejunum and ileum) is the site of origin of the diarrhea. However, **diseases in other body systems may cause diarrhea** in an otherwise normal intestinal tract (e.g. liver disease, hyperthyroidism, etc.).

WHAT?

- Chronic small bowel diarrhea is a clinical sign that should be **aggressively evaluated** to determine its cause.
- Cats with chronic diarrhea of small intestinal origin may have any of a number of GI or systemic diseases or disorders, but **metabolic** (hyperthyroidism, renal or liver disease, etc.), **idiopathic** (inflammatory bowel disease), **neoplastic** (lymphoma), and **nutritional** (food allergy or intolerance) are **common causes**.

QUICK REFERENCE SUMMARY

Diseases causing signs of chronic small bowel diarrhea

ANOMALY

- Intestinal diverticulosis (p 759)

These are rare disorders that are most commonly found in the jejunum, and may be subclinical or associated with vomiting, diarrhea or abdominal pain.

MECHANICAL

- Intussusception (p 756)

Acute onset of diarrhea may occur due to alterations in gut motility, however, vomiting is a more prominent clinical sign.

- Short bowel syndrome (p 760)

This iatrogenic syndrome is associated with resection of 75–90% of the small intestine and results in severe diarrhea and weight loss. Congenital forms of short bowel syndrome are reported, but are rare.

METABOLIC

- **Hyperthyroidism* (p 743)**

Intermittent diarrhea, vomiting or voluminous stools in an older cat with a good to ravenous appetite, obvious weight loss and a poorly groomed coat are characteristic of this disease.

- Exocrine pancreatic insufficiency (EPI) (p 751)

This is a rare disease in cats, but is typically associated with small bowel diarrhea, weight loss and a ravenous appetite.

- Hypoadrenocorticism (p 754)

The classic signs include depression, weakness, vomiting and diarrhea. However, GI signs do not occur in all cases, and the cause of the vomiting or diarrhea is unknown. Some cats will not develop concurrent mineralocorticoid deficiency with the glucocorticoid deficiency, and thus electrolyte disturbances will not be apparent.

NEOPLASTIC

- **Alimentary lymphosarcoma* (p 742)**

This is the most common neoplasm of the feline intestine, and because of the lymphocytic infiltrate and clinical presentation, is easily confused with IBD. Most cats with alimentary lymphoma are FeLV antigen negative. Aggressive chemotherapy is the only effective treatment, and may result in a 3–12-month survival time.

- Intestinal adenocarcinoma (p 750)

The intestinal tract is a much less common location for adenocarcinoma than the colon in cats. This tumor is the second most common intestinal tumor and tends to cause obstructive lesions of the ileum that frequently cause vomiting, but may also be associated with diarrhea. Siamese cats may be predisposed.

- Intestinal mast cell tumor (p 753)

Intestinal mast cell tumors are the third most common neoplasm affecting the feline small bowel, but are rare occurrences. This tumor is aggressive, poorly responsive to therapy and usually has metastasized by the time of diagnosis.

continued

continued

- **Other small intestinal neoplasia (fibrosarcoma, carcinoids, plasmacytoma) (p 757)**

Other malignant and benign neoplasms that may be associated with vomiting, diarrhea, weight loss or anorexia in cats include fibrosarcoma, plasmacytoma, hemangiosarcoma, leiomyosarcoma, etc. Clinical signs and prognosis are dependent on the location of the tumor, the type of tumor and its response to therapy. Tumors of the duodenum are rare and usually associated with extension of a local neoplasm.

- **APUDomas (p 758)**

Neoplasms of APUD cells are rare tumors in the cat. They include insulinomas, gastrinomas, pheochromocytomas and carcinoid tumors of the GI tract. Clinical signs will depend on the tumor type, but carcinoid tumors are most likely to cause diarrhea.

NUTRITIONAL

- **Food intolerance*** (p 740)**

Food intolerance is a non-immune-mediated condition associated with intermittent diarrhea or vomiting, with no pattern or association with eating, and it resolves when the food source is changed to omit the offending substance from diet. The clinical significance of food intolerance is unknown relative to other causes of diarrhea because of the difficulty in obtaining a definitive diagnosis.

IMMUNOLOGIC

- **Food allergy (dietary hypersensitivity)*** (p 739)**

Chronic vomiting appears to be more common than diarrhea in cats with food allergy, and cutaneous signs may also be present.

- **Idiopathic inflammatory bowel disease (IBD)* (p 745)**

IBD is a chronic inflammatory disease of the GI tract of unknown etiology. It affects cats of all ages, sexes and breeds, but is most commonly found in middle-aged, purebred adult cats. Lymphocytic plasmacytic enteritis is the most common histologic form of IBD, but eosinophilic and suppurative infiltrates occur as well.

INFLAMMATION (INFECTIOUS)

- **Inflammatory hepatobiliary disease (cholangitis) (p 746)**

The clinical presentation of cholangitis is non-specific and presenting signs include anorexia, lethargy, weight loss, vomiting, diarrhea, dehydration, hepatomegaly and icterus.

INFECTIOUS:

Viral:

- **Feline coronavirus infections (feline enteric coronavirus/feline infectious peritonitis) (p 749)**

Feline enteric coronavirus results in mild, self-limiting diarrhea or subclinical infection. In FIP, the GI tract is rarely affected singularly, and so, vomiting or diarrhea is often associated with the effects of the disease on other organs. Rarely, FIP causes intestinal granulomas that obstruct the GI tract and cause vomiting or diarrhea. Systemic signs of FIP may include lethargy, anorexia, pyrexia and CNS signs.

- **Feline immunodeficiency virus (p 749)**

Diarrhea is not a common presenting sign of cats with FIV, but diarrhea can occur secondary to the immunodeficiency disease or result from a purulent form of colitis that can occur in a small number of cats that are infected with FIV.

Bacterial:

- *Clostridium perfringens* enterocolitis/clostridial enterocolitis (p 748)

Diarrhea occurs due to sporulation of clostridial organisms and release of enterotoxin resulting in a secretory diarrhea that is usually small bowel in character, but may also have a large bowel component.

- Campylobacteriosis (p 750)

Campylobacter infection may cause mucoid, bloody diarrhea, weight loss, anorexia and fever in affected kittens or young cats. Most affected cats are from shelters or catteries that have crowded conditions and poor hygiene.

Protozoal:

- **Giardiasis* (p 744)**

Acute or chronic small bowel diarrhea is the most common clinical presentation. However, in some cats large bowel diarrhea also may occur.

Fungal:

- Histoplasmosis (p 755)

Diarrhea associated with intestinal histoplasmosis is uncommon in cats compared to dogs. The most common clinical signs in cats are associated with respiratory infection, or anorexia, fever and weight loss associated with systemic illness.

Parasitic:

- **Coccidiosis (isosporosis, cryptosporidiosis, toxoplasmosis)** (p 741)**

Infections that result in mild to moderate diarrhea are most common in neonates and immunosuppressed adults. Most adults have asymptomatic infestations. The species of coccidia most commonly associated with disease in cats are *Cystoisospora* spp., *Cryptosporidium parvum*, and occasionally *Toxoplasma gondii*. Toxoplasmosis has recently been observed in association with IBD.

Idiopathic:

- Idiopathic juvenile diarrhea (p 753)

This condition is associated with small bowel diarrhea and occurs in kittens or young cats less than a year of age. There is no known cause for the diarrhea and when the cat reaches adulthood, the diarrhea resolves.

- Protein-losing enteropathy (p 760)

This condition is much less common in cats than in dogs, but may result in chronic diarrhea, malabsorption, weight loss and hypoproteinemia. Primary lymphangiectasia is rare, but secondary causes of lymphatic obstruction, such as inflammation or neoplasia, are relatively more common and must be considered.

- Hypereosinophilic syndrome (p 758)

This rare disorder is associated with eosinophilic IBD and systemic eosinophilia (increased circulating eosinophils and eosinophilic infiltrate in the lymph nodes, etc). It is usually associated with chronic vomiting, diarrhea, and weight loss, and is poorly responsive to treatment.

INTRODUCTION

MECHANISM?

Chronic small intestinal diarrhea is distinct from acute diarrhea, in that the disease or disturbance causing the problem is **not self-limiting**.

Diarrhea is the **most consistent manifestation of intestinal disease**.

In cats with small bowel diarrhea for > 3 weeks duration, **an aggressive search for the cause** should be undertaken.

Characteristics of small bowel diarrhea include:

- **Large volume of watery or very soft feces.**
- **No mucus or hematochezia**, and if blood is present it occurs as **melena**.
- There is little or **no straining or tenesmus**.
- **Weight loss** and vomiting are commonly observed.
- The **frequency** of defecation is **normal to increased**.

Diarrhea occurs when there is an **increase in fecal water**, which can occur due to a variety of small or large intestinal disorders, but has been generally grouped into four categories: **osmotic, permeability, secretory and motility disturbances**.

Chronic diarrhea due to increased **osmotically active substances** present in the lumen is usually associated with **GI malabsorption syndromes** (EPI, liver failure, severe small intestinal disease, lymphangiectasia, etc.) or **dietary overload**.

Increased secretion of water and electrolytes is usually a cause of acute small bowel diarrhea, which occurs primarily as a result of activation of cellular second messenger pathways (cAMP, cGMP, etc.) by **enteric pathogens**. Conditions that cause diarrhea by increasing secretory mechanisms include bacterial infections with enterotoxigenic or endotoxin-producing species, the presence of unconjugated bile acids in the small bowel or increased secretion due to endocrine tumors.

The presence of **increased intestinal permeability** due to **inflammation, erosion/ulceration or necrosis** is

also an important cause of both acute and chronic diarrhea. Inflammatory bowel disease, lymphatic obstruction (due to lymphangiectasia or mucosal inflammation), systemic diseases that alter GI blood flow or mucosal integrity, neoplasia, enteric pathogens and parasites, and toxins may all produce diarrhea by this mechanism.

Altered intestinal motility, either increased or decreased segmentation or propulsion movements will cause diarrhea. Unfortunately, evaluation of intestinal motility is a difficult process, and differentiating cause from effect in motility problems even more challenging. Diarrhea due to intestinal motility disturbances may be caused by stagnant loop syndrome, dysautonomia, ileus, loss of segmentation or peristalsis due to drugs, toxins, etc.

Chronic small bowel diarrhea is often a sign of a **serious small intestinal disease** (e.g. inflammatory bowel disease, neoplasia, lymphangiectasia, severe food intolerance, or a chronic infectious disease) which should be **thoroughly investigated**.

However, **systemic disorders** such as EPI, renal failure, liver disease and some endocrinopathies (e.g. hyperthyroidism, APUD tumors and hypoadrenocorticism) will also cause chronic diarrhea and should not be overlooked.

WHERE?

Small bowel diarrhea can be the result of **disease in the small intestine** (duodenum, jejunum, ileum) or occur secondary to **organ failure** (hepatic, renal or pancreatic disease) or **endocrinopathies** (hyperthyroidism, hypoadrenocorticism, or rarely APUD tumors).

A careful **history and physical examination** will determine whether the problem is likely related to the GI tract or a systemic problem.

Diagnostic tests that will aid localization of the problem include a **hemogram, chemistry profile, fecal analysis, intestinal function studies (FTLI, cob/folate) and abdominal imaging studies** (radiographs or ultrasound).

WHAT?

Cats with small bowel diarrhea of a chronic nature often have **severe intestinal disease** (neoplasia, inflammatory bowel disease), or **systemic illness/organ failure** (hepatitis, pancreatic disease such as EPI or hyperthyroidism).

Diagnosis is based upon history and physical examination findings, radiography, hematology and serum chemistry profiles, serology if indicated for FeLV/FIV, etc., serum TLI, fecal analysis, including cytology or alpha-1 protease inhibitor testing, and histopathology.

DISEASES CAUSING SIGNS OF CHRONIC SMALL BOWEL DIARRHEA (> 3 WEEKS DURATION)

FOOD ALLERGY (DIETARY HYPERSENSITIVITY)***

Classical signs

- Vomiting or diarrhea.
- Anorexia and weight loss.
- Pruritus or miliary dermatitis.
- Alopecia.
- Seborrhea.

See main reference on page 667, Food sensitivity, in “The Cat With Signs of Chronic Vomiting” for details.

Clinical signs

Food allergy is an adverse reaction to food that has a **proven immunologic component**.

Gastrointestinal signs are variable, but can include **vomiting, diarrhea, flatulence, weight loss or anorexia**. Diarrhea can be profuse and watery suggesting small bowel disease, or mucoid and hemorrhagic, consistent with colitis. The true incidence of GI signs associated with food sensitivity is unknown.

Signs tend to occur suddenly after the animal has been on a particular diet for **months or years**.

There may also be dermatologic signs, such as pruritus, alopecia, miliary dermatitis, seborrhea, pustules, etc., which affect the head, face, ears and inner thigh especially, and are non-seasonal in occurrence.

Dermatologic signs need not be present to attribute GI signs to food allergy.

Respiratory tract hypersensitivity is reported in humans but is poorly documented in cats. However, the propensity for cats to develop airway hypersensitivity may warrant further consideration of this possibility.

Most cats are **young adults when signs first develop**, but the signs can occur in **any age, breed or sex** of cat.

Diagnosis

The **definitive diagnosis** of food allergy is only obtained by **feeding an elimination diet**. The signs will resolve after **6–9 weeks** (there is usually a clinical response within **1–3 weeks**), with reintroduction of the offending diet resulting in the reappearance of signs within 4–10 days.

Other diagnostic tests, including intradermal skin testing, ELISA testing, RAST testing, and gastroscopic food testing have all been tried in an attempt to find easier methods of making the diagnosis. However, all of these tests are fraught with **false-negative and -positive results** that limit their usefulness. The only **reliable test currently available is the food elimination trial**, which is also used in humans.

In most cats, the **hemogram and chemistry profile will be completely normal** or have mild non-specific changes associated with inflammation (e.g. eosinophilia, proteinuria).

The **elimination diet** chosen to make the diagnosis will depend on the cat's preferences for food, the owner's willingness to make homemade foods, and the clinical situation. However, the **best elimination diet is a diet** containing a **single, novel protein source** (turkey, venison, duck, rabbit, ostrich, kangaroo, crocodile, whitefish, etc.) and a **single, novel carbohydrate source** (rice, potato, etc.), with no other

additives except a pet vitamin. Use either a **commercial hypoallergenic diet or a homemade diet** (see page 741, Food intolerance, for details).

Intestinal biopsies will have **mild to severe infiltrates of inflammatory cells**, which may be lymphocytic, plasmacytic or eosinophilic or a combination of those cell types. There is currently **no way to differentiate the inflammatory infiltrates** present in cats with **food allergy** from those typically seen in cats with **IBD**.

Differential diagnosis

The presence of **dermatologic signs suggests that atopy and flea allergy as well as other dermatologic conditions** should be considered.

Some cats will have GI signs only, and thus other differentials such as food intolerance, parasites, and metabolic or neoplastic diseases should be considered. **Inflammatory bowel disease** is also a disease that **mimics food allergy** and is very difficult to differentiate from it.

Treatment

Once an **elimination diet** has been identified that successfully relieves the clinical signs, the cat should **remain on that diet indefinitely**. However, it is best to try to **identify a commercial diet that most closely resembles the elimination diet** so that the cat **receives a nutritionally complete and balanced diet**. Most homemade elimination diets are not nutritionally balanced and are not suitable for long-term maintenance.

Cats may develop a hypersensitivity to any diet, including the so-called hypoallergenic diet, and in that situation, another novel protein source will need to be selected.

Most cats with food allergy only respond partially or do not **respond at all to prednisolone therapy or antihistamines**.

The importance of **preventing access to any food other than the elimination diet** should be emphasized to the owners.

FOOD INTOLERANCE***

Classical signs

- Signs may range from intermittent vomiting or diarrhea to pruritus, dermatitis and other dermatologic signs.

See main reference on page 669, Food sensitivity in “The Cat With Signs of Chronic Vomiting” for details.

Clinical signs

Adverse reactions to foods may be **dermatologic or gastrointestinal** and the percentage of signs associated with either component is unknown.

Intermittent to persistent **vomiting (usually < 1 day) or diarrhea** are the most common GI signs. Flatulence and weight loss may occur.

Dermatologic signs may include pruritus, dermatitis or alopecia.

In contrast to food allergy, **food intolerance is a non-immunologic reaction, and can occur on the first exposure** to the offending food or additive. A wide variety of food ingredients may be responsible.

The relative occurrence of **GI versus dermatologic signs** and the importance of one or the other in the diagnosis of food intolerance is unknown. However, a combination of dermatologic and GI signs should raise the index of suspicion of a food-related problem.

Diagnosis

There is **no diagnostic test** for this problem other than to **observe a beneficial response to an appropriate dietary trial for 1 week**. Resolution of clinical signs is often apparent within 4 days.

The best elimination diet to obtain a diagnosis is made from **a single novel protein and novel carbohydrate source with no added colors or preservatives**. For the homemade diet, **boiled white rice or potato (1/3 cup) and a novel meat source** that the cat has not previously eaten (2/3 cups venison, rabbit, duck, ostrich, crocodile, kangaroo, tofu, turkey, whitefish, etc.) are good options. Use food intended for human consumption, not pet meat.

Alternatively, a **commercially available hypoallergenic diet** made from a single novel protein or protein hydrolysate is also a useful test diet. Once a diagnosis of food sensitivity (food intolerance or food allergy) has been made, a commercial hypoallergenic diet containing novel protein and carbohydrate sources should be used for long-term maintenance, as homemade diets are rarely balanced and complete.

Intestinal biopsies from cats with food intolerance may be normal, or may have **mild to moderate infiltrates of lymphocytes, plasma cells or eosinophils**, depending on the duration of intolerance and severity of clinical signs.

Differential diagnosis

Intermittent but unrelenting vomiting in an otherwise healthy cat suggests gastrointestinal motility disturbance, gastric parasites, early inflammatory bowel disease or antral pyloric hypertrophy.

In cats **where diarrhea is the presenting sign or occurs in addition to vomiting**, hyperthyroidism, chronic pancreatitis, early renal or liver disease, and other primary GI abnormalities such as neoplasia or intermittent intussusception, must be considered.

Treatment

Change to a diet that does not contain the offending substance. This may be as simple as changing from a grocery store brand to a premium brand food (or vice versa), but also may require changing to a **hypoallergenic food diet** (e.g. IVD's Limited Antigen diets, Hill's d/d or z/d, Eukanuba Response formula, Royal Canin Select Protein) or in some cases, formulating a **home-made diet** that is complete and nutritionally balanced.

Since the **abnormal gastrointestinal response is non-immunologic**, use of oral prednisolone is not likely to be beneficial.

COCCIDIOSIS (ISOSPOROSIS, CRYPTOSPORIDIOSIS, TOXOPLASMOSIS)**

Classical signs

- In young cats or kittens acute small bowel diarrhea occurs.

Classical signs—Cont'd

- Weight loss, anorexia and dehydration may occur if severely affected.
- Most adult cats will be asymptomatic or have subclinical infections.

See main reference on page 705 for details (The Cat With Signs of Acute Small Bowel Diarrhea).

Clinical signs

The principal clinical sign of coccidiosis is acute small bowel diarrhea, which may be bloody, mucoid or watery. It **usually occurs in young cats or kittens as acute diarrhea**, but may persist and present as chronic diarrhea. In severely affected kittens, weight loss, anorexia and dehydration may also occur.

Other signs that may be observed include **vomiting, weight loss, lethargy and dehydration**.

Adult cats that are infected with coccidian parasites (including cryptosporidia) are typically **asymptomatic**.

Young or immunocompromised cats with **cryptosporidiosis** will have **profuse, watery diarrhea and mesenteric lymphadenopathy** due to intestinal hypersecretion and malabsorption.

Toxoplasma infections are also **rarely associated with diarrhea**, but in cats with immunocompromise or other significant bowel conditions (e.g. IBD), quiescent toxoplasmosis may be re-activated and cause clinical signs.

Diagnosis

Diagnosis is made by identification of isosporoid oocysts in fresh feces.

The **oocysts of cryptosporidia are 1/10th the size of Isospora** (smaller than RBCs and 1/16th the size of a *Toxocara* cyst). *Toxoplasma* oocysts are only slightly larger.

Special flotation media (Sheather's sugar or zinc sulfate flotation) is required along with **special staining** (Kinyoun's carbolfuchsin negative) or **phase contrast microscopy**, to identify cryptosporidia.

Other methods of identification of fecal cryptosporidia include an **ELISA test**, but its effectiveness

in identifying feline species of cryptosporidia is unknown. A **PCR test for *Cryptosporidium* DNA** in the feces, or **electron microscopy of intestinal biopsy samples** may also be used.

Fecal samples submitted to the laboratory for **identification of cryptosporidia** should be **preserved in formalin** to minimize the risk of human infection.

Toxoplasma titers (both IgG and IgM) can be submitted to determine the presence of **acute, chronic or previous infections**. See main reference on page 958.

ALIMENTARY LYMPHOSARCOMA*

Classical signs

- Chronic, progressive weight loss, anorexia, diarrhea and/or vomiting.
- More common in middle aged to older cats.

See main reference on page 317 for details.

Clinical signs

Chronic, progressive weight loss, anorexia, diarrhea and/or vomiting are the most common signs.

Lymphoma commonly causes diffuse **intestinal thickening due to infiltrative disease**, but sometimes there are focal areas of intestinal constriction due to mass lesions or luminal constriction.

Palpable thickening or mesenteric lymphadenopathy may be important clues to the problem.

Diagnosis

The **history and clinical signs** may be too **non-specific** to be of particular help.

Palpable intestinal thickening or mesenteric lymphadenopathy is suggestive of neoplasia, but does not rule out other possible causes, such as inflammatory bowel disease, alimentary histoplasmosis or other infectious intestinal diseases (FIP, FIV, severe giardiasis).

Hemogram and chemistry profile results may be normal or will reveal non-specific abnormalities such as chronic non-regenerative anemia, hyper- or hypoproteinemia, elevations in liver enzyme concentrations,

hypercalcemia or abnormal electrolytes due to vomiting or diarrhea.

Imaging studies, especially abdominal ultrasound, are important in identifying and localizing intestinal abnormalities. **Fine-needle aspirates** of lymph nodes or affected segments of bowel may point toward the diagnosis.

The **key to diagnosis is identification of neoplastic lymphocytes in the intestinal mucosa or wall**. This may be achieved by fine-needle aspirates, endoscopic brush cytology or histopathology. **Endoscopic biopsies** are an excellent method of obtaining tissue for diagnosis, but the biopsies must be of good quality to be useful. **Samples must include mucosa and muscularis layers, and extend to the submucosa** to be diagnostic.

In cats with early, or very **well-differentiated lymphosarcoma, it may be impossible to distinguish lymphoma from severe IBD**, even with full-thickness biopsy samples. In these cases, **immunohistochemistry** will be required to separate monoclonal neoplastic cells from the polyclonal cell of IBD. Unfortunately, this technique is currently available at only a few institutions.

Differential diagnosis

The primary differential for alimentary lymphoma, both clinically and diagnostically, is **lymphocytic plasmacytic inflammatory bowel disease**. However, other important differentials include food intolerance/allergy and severe giardiasis, and systemic diseases such as cholangitis and hyperthyroidism.

Treatment

The best approach is to use **multiple-agent chemotherapy**, using a **treatment regimen of stages**: (1) induction of remission, (2) intensification, (3) maintenance and (4) rescue.

Cats treated with **prednisolone alone may improve initially, but once the tumor escapes remission, it is very difficult to re-induce remission**.

There are several protocols available, but the **COAP protocol is commonly used to induce remission**. C = cyclophosphamide, O = vincristine (oncovin), A = cytosine arabinoside, P = prednisolone. The **induction protocol generally takes 6–8 weeks**, and **side effects** with this protocol are **minimal**. The dose-limiting toxicity is hematologic, and thus, **weekly hemograms are required**

before each treatment. Specific dosing protocols are described in detail under alimentary lymphoma in the chronic vomiting section.

Intensification is only used if the induction phase does not result in complete remission of the tumor.

The most common agents used for intensification in cats are **doxorubicin** or **mitoxantrone**.

The **COAP protocol** is also used for maintenance in cats, but the treatments are spread out to every other week or every third week for six treatments, with the goal to be able to maintain the cat with treatment once every 4 weeks. **Maintenance therapy is continued until the tumor relapses.**

Rescue, or re-induction of remission, is necessary in almost all cats and generally occurs **6–8 months after the start of induction.** Rescue protocols are not as successful in cats as they are in dogs. There have been a wide variety of protocols recommended, and the reader is referred to an oncology text for further details. In most cases, the rescue protocol will involve **mitoxantrone, doxorubicin and the other COAP drugs.** See the alimentary lymphoma section under chronic vomiting for specific protocol details.

Prognosis

Most (80%) cats with lymphoma treated with multiple-agent chemotherapy protocols are expected to **live 3–9 months.** As many as **20% will live for longer than 1 year.**

Cats that are not treated will live for 4–8 weeks.

Feline leukemia-positive cats have a shorter survival time, not because they do not respond to chemotherapy, but due to development of other feline leukemia-associated disorders.

HYPERTHYROIDISM*

Classical signs

- Weight loss despite a good to ravenous appetite.
- Vomiting, diarrhea or voluminous feces.
- Polyuria/polydipsia.
- Poor coat condition.
- Hyperactivity.

See main reference on page 304 for details.

Clinical signs

Weight loss despite a good to **ravenous appetite** and **hyperactivity** are the most common signs.

Polyuria/polydipsia, poor coat condition, vomiting, **diarrhea or voluminous feces** individually occur in 30–50% of cats.

Gastrointestinal signs associated with hyperthyroidism are often **intermittent or relatively mild**, with the exception of weight loss and appetite changes. About **90% of cats have increased appetite**, but **a small number are depressed and have a reduced appetite** (apathetic hyperthyroidism).

Some cats will have **tachycardia, a gallop rhythm** or other signs associated with congestive heart failure (coughing, increased respiratory rate, weakness) secondary to **thyrotoxic heart disease**.

Diagnosis

The **definitive diagnosis** is an **elevated serum total thyroxine concentration** (total T_4). Other **non-specific abnormalities of the hemogram or chemistry profile** may include hemoconcentration, mild anemia, elevated serum alanine aminotransferase activity, or hyperglycemia.

A **thorough assessment of renal function** should be undertaken (BUN, creatinine, urinalysis) before initiating treatment of hyperthyroidism because the increased renal blood flow associated with hyperthyroidism may result in **acute renal decompensation when the thyroid disease is treated** (especially with surgical or radioactive iodine therapy).

Many cats will have a **palpable thyroid nodule**.

Cats with **signs of hyperthyroidism** but serum T_4 concentrations in the upper $\frac{1}{2}$ of the normal range should be tested using **free (unbound) T_4 levels**, as false lowering of the T_4 level may occur due to non-thyroidal illness.

In cats with **suspected hyperthyroidism**, but **normal total or free T_4 levels**, radioactive thyroid scan can be performed to confirm the diagnosis. See page 305.

Cats with tachycardia or an abnormal rhythm should also have **thoracic radiographs and an echocardiogram** performed to determine the extent of thyrotoxic heart disease and evaluate the need for therapy.

Differential diagnosis

The major differentials for an older cat with weight loss, vomiting or diarrhea include neoplasia, hepatic or renal disease, inflammatory bowel disease and chronic pancreatitis. However, the presence of cardiovascular signs, a ravenous appetite or hyperactive behavior with the GI signs should point to hyperthyroidism first.

Treatment

Treatment for hyperthyroidism includes both control of the over-secretion of thyroid hormone as well as its effects on the remainder of the body (e.g. thyrotoxic heart disease).

There are **three commonly used therapeutic approaches** to treatment of the hyperthyroid condition in cats: (1) **medical management** with methimazole or carbimazole, (2) **surgical removal** of the adenomatous thyroid, and (3) **radioactive iodine treatment** of the cat to destroy thyroid follicular cells.

See pages 305 and 671 for details (in The Cat With Weight Loss and a good Appetite and The Cat with Signs of Chronic Vomiting).

GIARDIASIS*

Classical signs

- Liquid, to semiformed, diarrhea with increased frequency and urgency.
- Most cats are bright, alert and afebrile.
- Many cats are asymptomatic.

See main reference on page 707 for details (The Cat With Signs of Acute Small Bowel Diarrhea).

Clinical signs

Most adult cats infected with *Giardia* spp. remain asymptomatic.

The **most common signs observed are the presence of liquid to semi-formed diarrhea**, associated with **increased frequency and quantity of defecation**, in an otherwise healthy cat.

Most cats remain bright, alert and afebrile.

Vomiting, dehydration, lethargy and anorexia may be observed in severe cases, but are **uncommon**.

Occasionally, **chronic small bowel diarrhea** with weight loss and poor body condition are observed.

Cats are more likely to also have evidence of acute or chronic large bowel diarrhea (with hematochezia, increased mucus and tenesmus) than are other species affected.

Diagnosis

The **diagnosis** is made by appropriate **fecal examination techniques**. **Zinc sulfate flotation is considered to be the most accurate and practical test**. **Three consecutive zinc sulfate flotations will identify 95% of infected animals**.

Other methods include examination of **fresh fecal saline smears for trophozoites** (only 40% of infected animals will be identified), **duodenal aspiration of fluid** for examination for trophozoites (requires endoscopy or laparotomy, but is 88% effective), or **fecal ELISA testing** for *Giardia*-specific antigens (good sensitivity, but not specificity).

Fecal ELISA testing is highly sensitive (93% sensitivity) but has low specificity (60% specificity).

Differential diagnosis

Many other infectious, parasitic, dietary, toxic and idiopathic causes of small bowel diarrhea must be considered since many cats will have mild signs and be otherwise healthy.

Treatment

Metronidazole (25 mg/kg/q 12 h PO for 5 days) continues to be recommended for treatment of giardiasis in cats. However, resistant strains of the protozoan are increasingly being reported, and thus this therapy may not be effective in all cases.

Side effects associated with metronidazole therapy include **gastrointestinal upset and neurologic signs**, such as seizures, coma and behavioral changes. All of these are **less common in cats than in dogs** and are reversible with discontinuation of treatment.

Other drugs that have been recommended for treatment of giardiasis are **quinacrine** and **furazolidine**, but these drugs may not eliminate the infection, only improve the clinical signs.

Fenbendazole has been shown to be effective in treatment of giardiasis in cats and dogs. Another benzimidazole, **albendazole**, is **not approved** for use in cats in the United States and it may be **teratogenic, hepatotoxic or cause bone marrow toxicity**. **Fenbendazole (50 mg/kg/day × 5 days)** has been recommended for treatment of giardiasis in cats, and especially those with other concurrent parasitic infections.

Proper disposal of feces and good sanitation is essential to remove any environmental contamination.

IDIOPATHIC INFLAMMATORY BOWEL DISEASE (IBD)*

Classical signs

- Vomiting, anorexia and weight loss are the most common signs of upper GI IBD.
- Diarrhea can occur, but is more prevalent with colonic disease.
- Affected cats are usually middle-aged or older, with no particular sex or breed predisposition.

See main reference on page 768 for details.

Clinical signs

Vomiting, which may be intermittent or severe, **weight loss and anorexia** are the most common signs.

Diarrhea is also observed in some cats, but is more prevalent with **disease affecting the distal small intestine or colon**.

Most cats with IBD have intermittent, chronic signs of GI disease, and with time, the signs progress to become more persistent and severe.

The disease is **most prevalent in middle-aged to older cats**, but the range is from 6 months to 17 years.

There appears to be **no breed or sex predisposition to IBD** in most studies, but purebred cats and males appear to be over-represented in some studies.

Diagnosis

IBD is a diagnosis of exclusion, that requires two steps: (1) the **histopathologic confirmation** of an excessive inflammatory response in the intestinal mucosa, and (2) **the elimination of the multitude of potential causes for GI inflammation**.

The majority of cats with IBD will have a **normal hemogram and serum chemistry profile**. However, **abnormalities are not uncommon, but they are not specific for IBD**. These include leukocytosis, mild non-regenerative anemia, increases in liver enzyme concentrations, mild hypoalbuminemia and mild hyperglycemia.

Fecal examination (flotation, direct exam, cytology) is essential to rule out parasitism, especially giardiasis.

Ultrasound examination is very important, not only in evaluation of the abdomen for structural abnormalities, but especially for **assessing bowel wall thickness and lymph node enlargement**, which have recently been shown to correlate well with the severity of IBD. Ultrasound is also important, as it may allow **fine-needle aspiration** of abnormalities which facilitate diagnosis, but also will help determine the best approach to take when obtaining the biopsies (**full thickness vs. endoscopic**).

Radiography, including contrast studies, **has not been shown to be helpful** in differentiating cats with IBD and those with other diseases.

Ultimately, endoscopic examination or a surgical exploratory will be necessary to obtain biopsies of the GI tract. Endoscopy is less invasive and allows visualization of the mucosal surface, which may help obtain more diagnostic biopsy samples. **Multiple (6–8) biopsies should be taken from various sites** including the stomach, duodenum, ileum and colon, even if there is no visible evidence of disease.

Since there are no simple, easy tests for food intolerance or allergy, **dietary elimination trials** should be conducted in all cats with signs of IBD or that have inflammatory infiltrates of the GI tract.

Differential diagnosis

The list of diseases that may mimic, cause or complicate IBD (e.g. cause GI inflammation and similar clinical signs) is extensive:

- Systemic diseases (**hyperthyroidism, pancreatic disease, liver disease**, feline viral diseases, **toxoplasmosis**).
- Parasitic diseases (nematodes, *Giardia*, *Cryptosporidia*, other parasites such as coccidia, *Entamoeba*).
- **Bacterial infection** (*Helicobacter*, *Campylobacter*, *Salmonella*, *Clostridia*, etc.).
- Metabolic diseases (EPI, serum cobalamin or folate deficiency).
- Nutritional disorders (**food intolerance/allergy**).
- **Neoplasia (lymphoma, adenocarcinoma, mast cell tumor)**.

Treatment

The first **key to successful treatment** of IBD is to have a **correct diagnosis**, and that is a real **challenge**.

Even if food allergy/intolerance has been ruled out, a **highly digestible, hypoallergenic or elimination diet is important in the treatment of IBD**. Cats with IBD have an abnormal gut immune system, thus the presence of additional dietary antigens may serve to exacerbate the inflammatory response. A “sacrificial” protein source may have to be used first, while the bowel is still subject to a strong inflammatory response, before moving onto a more permanent food choice.

The **mainstay of treatment** of IBD in cats is **immunosuppressive doses of prednisolone (2–4 mg/kg/day PO)**.

Metronidazole (10–15 mg/kg q 12 h PO) is also very effective, and in some cats, may be as effective as steroid therapy. Many clinicians start with metronidazole and dietary therapy, and then add prednisolone if the response to treatment is incomplete.

In cats with severe IBD that is not responsive to metronidazole, prednisolone and dietary therapy, **cytotoxic drugs may be considered**. However, **most cats with IBD do not require additional cytotoxic drug therapy** to manage their disease, so a careful re-evaluation of the patient is indicated to be sure you have the correct diagnosis. Drugs that may be considered include **chlorambucil (2 mg/m²)**, **azathioprine (0.3 mg/kg EOD)** and **cyclosporine (5 mg/cat/day)**. **Hemograms should be monitored every 2–3 weeks** to detect myelosuppression, and if cyclosporine is used,

cyclosporine therapy must be monitored by checking trough and peak drug levels.

Cats with a **poor response to treatment** or recurrent disease should be **carefully re-evaluated**, including re-biopsy if indicated. **Lymphoplasmacytic enteritis can be mistaken for lymphoma in the early stage**. Cats with IBD have been reported to have concurrent reactivation of toxoplasmosis. Food allergy/intolerance is extremely difficult to differentiate from IBD and in some cats finding the appropriate diet is a true challenge.

INFLAMMATORY HEPATOBILIARY DISEASE (CHOLANGOHEPATITIS)

Classical signs

- With lymphoplasmacytic forms, chronic weight loss, anorexia, vomiting and icterus are common signs.
- In neutrophilic cholangitis, the disease is more acute in nature, and fever, depression and icterus are typical.

See main reference on page 427 for details (The Yellow Cat or Cat With Elevated Liver Enzymes).

Clinical signs

Weight loss (often dramatic), anorexia, intermittent vomiting, and icterus are the most common signs in cats with lymphocytic cholangitis. These cats often are **middle aged**, there is **no breed or sex predisposition**, and they have **hepatomegaly**. **Concurrent pancreatitis and/or IBD** is seen in some cats and their illness is more chronic and subacute. In some cats, there is a **waxing and waning course with periods of normalcy** and a good appetite following episodes of signs.

Ascites (high protein content) is more likely with the lymphoplasmacytic form, but it is rare.

Cats with **neutrophilic cholangitis** are more often **male, febrile, depressed, icteric and have an acute onset of illness** that is rapidly progressive.

The **diarrhea** may be mild, with soft to unformed feces in cats with lymphocytic cholangitis, to severe, liquid diarrhea in cats with neutrophilic cholangitis.

Diagnosis

The **presence of icterus** helps to narrow the differentials list to **hepatic, pre-hepatic and post-hepatic diseases**.

The **hemogram in cats with hepatic disease is often abnormal** (e.g. mild, non-regenerative anemia, with RBC morphology having schistocytes, leptocytes or target cells present), but the changes are **not specific for liver disease**. However, it does help **rule out pre-hepatic causes of icterus**.

Serum chemistry abnormalities may include **elevated liver enzyme activities** (sometimes dramatically), **hyperbilirubinemia, hypocholesterolemia, hypoalbuminemia**, decreased BUN, and electrolyte alterations consistent with vomiting or dehydration, e.g. hypokalemia, hyponatremia.

Bilirubinemia and bilirubinuria are both common.

Serum bile acid assay (pre- and 2 hours post-prandial) may show mild to moderate elevations.

Urine sulfated bile acids is a new test of hepatic function that may also become useful in the diagnosis of liver disease.

Coagulation function (platelet numbers and function, and coagulation factors) should be evaluated since liver disease often adversely affects these functions.

Ultrasonography is the most **useful imaging modality**, because it can also be used to obtain **fine-needle aspirates or biopsies**. However, **needle biopsies are only accurate for diagnosis of cholangitis < 40% of the time**. In cats with cholangitis, **the liver may be normal, decreased or increased in size**, but typically will have a **hyperechoic pattern** due to the presence of **inflammatory infiltrates**.

Liver biopsies taken via surgical exploratory or laparoscopy **are more accurate**, and will also allow **placement of a feeding tube** (gastrostomy or jejunostomy tube) during the procedure, which is **essential for any cat that has not eaten for 3–5 days**.

In addition to **liver histopathology**, samples of hepatic tissue should also be submitted for **aerobic and anaerobic culture**.

Differential diagnosis

Cats that have **vomiting, diarrhea, and weight loss in addition to icterus**, the list of differentials is narrowed to **pre-hepatic causes** (hemolysis), **hepatic causes** (hepatic lipidosis, hepatic necrosis, hepatic failure, etc.), and **post-hepatic causes** (pancreatitis, neoplasia of stomach, pancreas, duodenum or bile duct, and common bile duct obstruction).

In **cats that are not icteric**, the list of potential causes broadens extensively to include the spectrum of metabolic, neoplastic, toxic and infectious causes of both systemic and primary gastrointestinal origin.

Treatment

Therapy for cats with cholangitis is **largely supportive**, but the histopathologic findings are crucial in **determining severity, the type of inflammatory infiltrate** (which is essential to choosing appropriate therapy), and the overall **prognosis** for the disease.

Most cats with severe liver disease will require **fluid therapy** to replace deficits, provide maintenance fluid support during the recovery period, and induce diuresis to assist removal of hepatotoxins and prevent tubular sludging from bilirubinuria and casts.

The fluids should be **isotonic, balanced electrolyte solutions**, but preferably **not containing lactate** which is not converted to bicarbonate in cats with liver failure and thus serves as an **additional source of acid** (Ringers solution and Normosol-R are replacement electrolyte solutions without lactate).

Vomiting should be controlled with a combination of **anti-emetic therapy** (e.g. metoclopramide or dolasetron) and **acid-blocking therapy** (H_2 **antagonists** such as famotidine, ranitidine or cimetidine), since cats with liver disease are **prone to the development of hypergastrinemic gastritis**.

Diarrhea is rarely severe enough to require therapy and often resolves as the anorexia worsens.

Cholorectic agents (ursodeoxycholic acid) should be used to **reduce bile sludging and improve bile salt flow**.

Cats with **neutrophilic cholangitis** should be given **broad-spectrum parenteral antibiotics**. Penicillin or metronidazole, and fluorinated quinolones or aminoglycosides combined together provide a good spectrum of activity for enteric pathogens. Ideally, the antibiotic choice should be based upon culture results, but **if the culture is negative or the cat is systemically ill**, antimicrobial chemotherapy should be initiated and is **continued for 3–6 months**.

Lymphocytic cholangitis is believed to be an **immune-mediated** phenomenon and has recently been shown to occur in association with inflammatory bowel disease, inflammatory renal disease and pancreatitis. **Prednisolone therapy** (2–4 mg/kg/day) is indicated in cats with **lymphocytic plasmacytic hepatic infiltrates**. The decision of when to decrease the dose to 1 mg/kg/day or eventually every other day depends entirely on the cat, its clinical response to treatment and clinicopathologic evidence of improvement.

Metronidazole (10–15 mg/kg/day PO) for 2–4 weeks or indefinitely is also used, especially in cats with concurrent IBD.

Ursodeoxycholic acid supplementation is also recommended (10–15 mg/kg/day PO) indefinitely for its cholorectic activity.

Nutritional support must be provided, and in the short term (1–3 days) **nasoesophageal feeding tubes** work well, but for longer periods, **esophageal feeding tubes** or a **percutaneous endoscopic gastrostomy (PEG) tube** should be placed to allow larger amounts of food per feeding, as well as feeding a blenderized cat food rather than liquid enteral diets.

Most anorectic or ill cats will benefit from **addition of B vitamins to the fluids**. However, fat-soluble vitamin deficiency may also develop in cats that are anorectic or have malabsorption. **Supplementation with vitamin K** (2.5–5 mg SC q 2 weeks) and in some cases, **vitamin E** should be considered in those cats.

In some cats with evidence of concurrent lipidosis, **supplemental taurine** (250–500 mg PO q 24 h) and **carnitine** (250 mg PO q 24 h) should be given.

Anti-oxidant therapy with S-adenosylmethionine (SAME) 20 mg/kg/day PO should be instituted for hepato protection.

CLOSTRIDIUM PERFRINGENS ENTEROCOLITIS

Classical signs

- Typically, there is acute small bowel diarrhea with or without anorexia or lethargy.
- Some cats develop chronic, intermittent diarrhea.

See main reference on page 721 for details (The Cat With Signs of Acute Small Bowel Diarrhea).

Clinical signs

The **most common clinical sign** is **severe, watery to mucohemorrhagic diarrhea**.

In most cats, the diarrhea only lasts a few days, but in some, it may persist and become chronic. Animals that have severe diarrhea will become dehydrated, lethargic and may be anorexic.

There is **no breed, sex or age predisposition**, but cats from **catteries or in stressed environments** are at increased risk.

Diagnosis

The **history and physical examination findings** help to focus the diagnostic approach toward infectious, parasitic and dietary causes of diarrhea.

The presence of the organism can be confirmed by **culture of fresh fecal specimens**. However, **because this bacterium is part of the normal flora, this is not definitive**.

Similar to the dog, the **presence of spores in large numbers (> 5/hpf)** on a stained fecal smear **does not correlate with the presence of enterotoxin**.

Reverse passive latex agglutination (RPLA) tests for clostridial enterotoxin are available and have been used in dogs and humans, but have **not been evaluated in cats**. In dogs, the test does not differentiate dogs

with clostridial diarrhea from normal dogs. A **positive enterotoxin assay determined by ELISA** (Techlab, Inc., Blacksburg, VA) in the context of clinical signs consistent with clostridial infection is strongly supportive of clostridial-associated diarrhea in dogs. The **clinical utility of this assay in cats has not been evaluated.**

PCR tests are also utilized for testing feces for **enterotoxin**, but are not universally available.

FELINE CORONAVIRUS INFECTIONS (FELINE ENTERIC CORONAVIRUS/FELINE INFECTIOUS PERITONITIS)

Classical signs

- Variable and vague clinical signs including weight loss, fever and anorexia.
- Vomiting or diarrhea are less common.

See main references on page 372 for details.

Clinical signs

The clinical signs are quite **variable and depend a great deal upon the stage when the cat presents for evaluation** and whether they have **enteric coronavirus infection or FIP.**

Cats with **fulminant FIP** will likely be **severely depressed, pyreptic, anorectic**, and have significant weight loss. Respiratory distress from **pleural effusion** is also common, as is the presence of ascites.

Cats with so-called **non-effusive**, or “dry” FIP, will have more **vague clinical signs**, including reduced appetite, fever, mild weight loss and general malaise. Some cats will have mild abdominal discomfort, respiratory signs and granulomatous retinal lesions.

In some cats, FIP **granulomas** will cause **more focal signs** associated with the body system that is affected.

Vomiting and/or diarrhea are usually secondary to the systemic effects of infection or due to granuloma formation in the GI tract.

Central nervous system signs range from ataxia to seizures, and behavior changes, are common in cats with the non-effusive form of FIP.

Most cats with enteric coronavirus have subclinical infections or only develop mild, self-limiting diarrhea.

Diagnosis

The **definitive diagnosis of FIP in cats is quite difficult**, especially in cases of focal or non-fulminant FIP.

Serologic tests are not useful, because most are **not specific for FIP rather than coronavirus infection.** The ELISA for the 7B protein of the FIP virus generates a relatively high number of false-negative and false-positive results. **Polymerase chain reaction (PCR) testing** is the best hope for a definitive test, but at present is **only definitive for confirmation that a cat does not have FIP.** The **PCR test still has false positives** that prevent it from being a good screening/diagnostic test.

Currently, **the definitive test for FIP remains histopathologic examination** and virus isolation.

FELINE IMMUNODEFICIENCY VIRUS

Classical signs

- Variable clinical signs which depend on the stage of the disease and its presentation (immunodeficiency disease, neoplasia, CNS disease, etc.).
- Chronic diarrhea sometimes occurs.

See main reference on page 339 for details.

Clinical signs

The **most common signs** in cats with FIV are **immunodeficiency diseases** such as **chronic or recurrent infections**, especially of the oral cavity (gingivitis/stomatitis), skin (dermatitis, neoplasia), ears (chronic otitis), urinary tract (cystitis) and GI tract.

Chronic enteritis or enterocolitis are associated with **chronic diarrhea, weight loss, anorexia and lethargy.**

In severe cases, the diarrhea is persistent and unresponsive to therapy.

Other clinical signs are associated with development of CNS disease, neoplasia or secondary infections that result in systemic illness.

FIV is **most prevalent in middle-aged, male cats that live outdoors** or are allowed to roam, and are prone to fighting.

Diagnosis

The **history and physical examination findings** are often suggestive of chronic immunodeficiency disease.

Hemogram and serum chemistry abnormalities are not specific, but **lymphopenia is a common finding**.

Diagnosis is made by determining the **presence of FIV antibody** on a commercially available ELISA test, as long as the cat has not been previously vaccinated with the FIV vaccine.

A western blot analysis or PCR test can be used to confirm the presence of the virus.

In cases where FIV is confirmed, a further search for **other infectious or parasitic causes** (*Cryptosporidia*, *Toxoplasma*, *Giardia*, *Campylobacter*, *Salmonella*, etc.) should be pursued because **concurrent infections with other agents are common with FIV**.

INTESTINAL ADENOCARCINOMA

Classical signs

- Weight loss, anorexia and vague signs of malaise.
- Vomiting is the more common than diarrhea.
- Most common in older, Siamese cats.

See main reference on page 677 for details.

Clinical signs

The **most common clinical signs are anorexia, weight loss and vague signs of malaise**.

Vomiting is more common than diarrhea because of the tendency of the tumor to produce an annular, obstructive lesion in the distal small intestine, however, diarrhea is not unusual. In general, the **GI signs occur late** in the course of the disease.

Abdominal pain may also occur, especially in cats with **metastatic disease**.

The disease is most common in **older, Siamese cats**.

Diagnosis

A **history of persistent lethargy, weight loss or anorexia in an older cat, especially a Siamese**, should raise suspicions of chronic GI disease and the need for further evaluation.

Abdominal palpation may reveal a thickened region of bowel or a firm mass.

A **routine hemogram and chemistry profile** is often **unremarkable** or has **non-specific abnormalities** associated with chronic disease, such as mild non-regenerative anemia, hypoproteinemia, or elevated liver enzyme concentrations.

Imaging studies such as **contrast radiography or ultrasound examinations** are useful in identifying and localizing the lesion. Ultrasound can also be used to obtain a **fine-needle aspirate of the mass or regional lymph nodes**. A **thoracic radiograph to check for metastasis** is also indicated.

Ultimately, the **definitive diagnosis is by histopathologic examination** of the tissue obtained either by **endoscopic or surgical biopsies**.

Surgical exploratory is often the best approach for both obtaining tissue for diagnosis, as well as allowing for surgical removal of the affected tissue. In addition, biopsies of regional lymph nodes can also be obtained.

CAMPYLOBACTERIOSIS

Classical signs

- Abdominal distention, colicky abdominal pain, and diarrhea are most common.
- Kittens are generally in poor body condition, or have other concurrent infections.

See main reference on page 726 for details.

Clinical signs

Campylobacter was isolated from **21% of cats with diarrhea and 4% of healthy cats** in one study. Other studies with and without diarrhea have reported isolation rates varying from 0–50%.

In cats, **clinical signs of campylobacteriosis are uncommon**, as most infections are asymptomatic in the

absence of other pathogens. **Concurrent infections with other intestinal pathogens**, such as *Giardia* or *Salmonella* may exacerbate signs.

Affected cats are usually **less than 6 months** of age.

The primary clinical sign of infection is **diarrhea**, which may be watery, bloody, mucoid or a combination.

Some kittens will become systemically ill with lethargy, dehydration and anorexia observed.

Most kittens will have acute diarrhea, but in some cats, **chronic, recurrent bouts of diarrhea** are observed.

Diagnosis

History and physical examination findings are important to rule out other causes, but may be unremarkable.

Routine hematology, chemistry profiles and imaging studies are typically **within normal limits**.

Diagnosis can be confirmed by culturing freshly obtained fecal samples. Samples can be transported at room temperature without special handling, but **must be cultured in a microaerophilic atmosphere**.

A **specific request for culture of *Campylobacter*** should be submitted if it is suspected.

Dark-field or phase contrast microscopy can also be used to identify the motile, curved bacteria on fresh fecal samples. **Gram-stained samples** can also be used to identify the gull wing-shaped rods in the feces. However, these approaches are less sensitive and require more technical skill.

Differential diagnosis

Infectious (*Salmonella*, *Clostridium*), **parasitic** (*Giardia*, *Cryptosporidia*, etc.), and **dietary** (food intolerance or dietary indiscretion) agents should all be considered.

Treatment

Since most cats with *Campylobacter* infections are asymptomatic, or it is associated with other infections,

the effectiveness of antibiotics for treatment of this disease is unknown.

Several antibiotics appear to be effective in eliminating the organism, including erythromycin (10 mg/kg q 8 h PO), metronidazole (5–10 mg/kg q 12 h PO), cephalosporins (20 mg/kg q 12 h PO), and fluorinated quinolones (5 mg/kg q 12 h PO).

EXOCRINE PANCREATIC INSUFFICIENCY

Classical signs

- **Weight loss despite a vigorous appetite**, which may include pica and coprophagy.
- **Fecal characteristics may be normal, soft and voluminous or watery diarrhea.**
- **Poor haircoat and greasy, flakey seborrhea are also common.**
- **Very rare in cats.**

Pathogenesis

The **most common cause** of exocrine pancreatic insufficiency (EPI) in the cat is **chronic pancreatitis**.

A less common cause of EPI is infestation with the feline pancreatic fluke, *Eurytrema procyonis*.

Other, possible causes of EPI in cats include **pancreatic adenocarcinoma**, and congenital pancreatic acinar hypoplasia or aplasia.

Idiopathic pancreatic acinar atrophy, the most common cause of EPI in dogs, **has not been reported in cats**.

In humans with EPI caused by chronic pancreatitis, diabetes mellitus occurs concurrently. **It is unknown whether cats with chronic pancreatitis and EPI will also progress to develop diabetes mellitus** as well, however, diabetes mellitus has been reported in a cat with EPI.

EPI is believed to develop when **> 90% of the enzymes of the exocrine pancreas are destroyed**. These enzymes play an integral role in assimilating the major food components: proteins, lipids and carbohydrates.

Pancreatic enzymes increase the efficiency of breakdown of macromolecules in the digestive tract and enhance the transport mechanisms for sugars, amino

acids and fatty acids. Thus, **without pancreatic enzymes, food substances are inefficiently broken down and cannot be readily transported across the intestinal lumen.**

Diarrhea occurs due to the **presence of large quantities of fats, protein and carbohydrates**, which are osmotically active.

Maldigestion of these important nutrients leads to **weight loss** and may also cause **deficiencies of vitamins, fatty acids or other essential nutrients.**

Clinical signs

This is a **rare disease in cats.**

The **most common clinical signs are polyphagia, diarrhea and weight loss.**

Vomiting and anorexia are also occasionally reported.

The feces are typically **pale, loose, voluminous**, and they may be quite **malodorous.**

Cats often have a **greasy, flaky haircoat due to the fat malabsorption.**

Deficiencies of fat-soluble vitamins can result in a bleeding disorder (vitamin K-responsive coagulopathy), which may present as excessive bleeding from venipuncture sites or spontaneous hemorrhage (nose bleeds, hematuria, melena, etc.).

Diagnosis

Results from **routine hematology and chemistry profiles will be normal** in most cats. Occasionally, elevations in hepatic enzymes or neutrophilia will be observed.

Routine **abdominal radiography and ultrasonography** is usually normal, and is **not diagnostic.**

Fecal proteolytic activity testing will reveal **undetectable levels of enzymes**, which is diagnostic for EPI, but the test is very labile, so **false-positive results may occur due to improper sample handling.**

A recently validated radioimmunoassay for **feline trypsin-like immunoreactivity (FTLI)** is available, much like the TLI test available for use in dogs.

Severely decreased FTLI concentrations (< 8 ug/L) are diagnostic for EPI in cats.

All cats with EPI should have a **serum cobalamin and folate assay**, since many cats with EPI are cobalamin deficient or have concurrent small bowel disease (folate levels will be low).

Differential diagnosis

The clinical signs are so non-specific that many other diseases that cause polyphagia, weight loss and diarrhea must be considered. **Hyperthyroidism**, diabetes mellitus, corticosteroid treatment or hyperadrenocorticism, **chronic renal failure**, heart failure, liver disease, dental disease, neoplasia, **and chronic intestinal diseases such as inflammatory bowel disease** are the main differentials.

Treatment

Most cats with EPI can be successfully treated by **dietary supplementation with pancreatic enzymes.** The powder products (1 tsp per meal) appear to be more clinically effective than tablets.

If the cat refuses to eat the food with pancreatic extract, raw pancreas can be offered, **but it is essential to use bovine pancreas to prevent transmission of Aujeszky's disease in porcine pancreas.**

A diet that contains **low amounts of insoluble fiber should be fed**, since insoluble fibers may interfere with pancreatic enzyme activity.

Some cats will not respond to enzyme supplementation alone, and this may be due to **concurrent cobalamin deficiency or small intestinal disease.** Cobalamin supplementation should be given **parenterally (100–250 µg SC once weekly** for 6–8 weeks, then monthly or bimonthly as needed).

In cats with **suspected vitamin K deficiency**, supplementation should also be initiated (vitamin K₁ 1 mg/kg/day PO).

It is **unknown whether or not cats develop small intestinal bacterial overgrowth as a complication of EPI** (as is common in dogs). However, in cats that do not respond as anticipated to pancreatic enzyme supplementation, addition of metronidazole or tetracycline to the treatment regime is indicated.

Prognosis

Because EPI is associated with the **irreversible loss** of pancreatic acinar tissue, **complete recovery is not possible**.

However, with appropriate management, cats with EPI will gain weight, pass normal feces and can live a normal life.

Prevention

There is no known way to prevent the development of EPI, however, if cats with chronic pancreatitis can be recognized and appropriately managed, it may be possible to prevent the consequences of chronic pancreatitis and the development of EPI.

IDIOPATHIC JUVENILE DIARRHEA

Classical signs

- The only presenting sign is chronic diarrhea.

Pathogenesis

Unknown pathogenesis.

Clinical signs

Disorder occurs in **kittens and young cats under a year of age**.

The only clinical sign is presence of **chronic small bowel diarrhea**.

Kittens are **otherwise healthy, active and gain weight**.

Diagnosis

The diagnosis is one of exclusion. Thus, infectious, parasitic, dietary and mechanical disorders must all be ruled out.

Cats with this syndrome are **often purebred cats, and the diarrhea is self-limiting once they reach adult age**.

Differential diagnosis

Because this is a disease of kittens, bacterial, viral, parasitic, protozoal, dietary and toxic causes of diarrhea must all be carefully considered.

Treatment

There is **no known effective treatment for this condition**, but it appears to be self-limiting as the kitten reaches adult age. The reason for this is unknown, but may be due to development of an adult, fully competent immune system.

Prognosis

Good once the kitten reaches adult age.

INTESTINAL MAST CELL TUMOR

Classical signs

- Weight loss, decreased appetite or anorexia and chronic diarrhea.

See main reference on page 687 for details.

Clinical signs

Systemic mast cell tumors produce GI tract signs through **release of histamine and other vasoactive substances**, which result in **gastroduodenal ulceration**.

Intestinal mast cell tumors are typically poorly differentiated, highly malignant tumors that appear to consist of degranulated (e.g. non-functional) neoplastic mast cells. However, they produce GI tract signs through **local effects** (e.g. obstruction) or **surface ulceration** (bleeding) rather than through the release of vasoactive substances, as is the case with systemic mast cell tumors.

The most common clinical signs are **weight loss, anorexia or decreased appetite, and chronic diarrhea**. Other signs include lethargy, vomiting or acute abdominal pain.

Melena or chronic asymptomatic blood loss may result in anemia, and sometimes is severe enough to cause weakness or lethargy.

In some cats, a **palpable thickened intestinal segment or a mass** will be present.

Intestinal mast cell tumors are very small, difficult to palpate until late, and tend to be solitary. They occur as

an infiltrating mass, but **metastasize early in the course of the disease**.

Intestinal mast cell tumors are not generally associated with development of massive splenomegaly or systemic mast cell infiltration like systemic mastocytosis.

Diagnosis

A **chronic history of weight loss or anorexia** in a middle-aged or older cat should raise the suspicion of intestinal neoplasia.

Routine hemogram and serum chemistry profiles will often be normal, but non-specific abnormalities such as mild non-regenerative anemia, hypoproteinemias or hypoalbuminemia, and electrolyte disturbances associated with chronic vomiting or diarrhea can be seen.

Other **tests of GI function** (e.g. fTLI, fecal alpha-1 protease inhibitor, cobalamin/folate assays, fecal analyses for parasites) should be considered or performed, but **will not be diagnostic**.

Imaging studies, especially ultrasound examination, will be the most helpful in localizing the lesion (which can be easily missed because they are often extremely small or focal). **Fine-needle aspirates** of focal masses can be obtained which will often help direct further diagnostic and treatment plans.

Endoscopy may be helpful, but in many cases, these tumors are present in the jejunum, and are unreachable by the endoscope.

If imaging studies are unavailable, or fine-needle aspirates are non-diagnostic, an **exploratory laparotomy is indicated**.

Differential diagnosis

The primary differentials for cats with chronic weight loss, anorexia and chronic diarrhea are IBD, neoplasia, lymphangiectasia, and systemic organ failure or dysfunction (renal disease, liver failure, etc.).

Treatment

Treatment is palliative and supportive for cats with intestinal mast cell tumors.

Surgical removal of the affected segment of bowel with **wide surgical margins** is the only therapy reported to be effective in prolonging survival. **Mesenteric, hepatic and splenic metastasis** are commonly observed by the time the tumor is diagnosed.

Chemotherapy has not been shown to increase survival time in cats with this disease, although **prednisolone** (2–4 mg/kg/day) and **histamine₂ blockers** (cimetidine, ranitidine, famotidine) are advocated to reduce secondary clinical signs associated with mast cell disease.

Nutritional support may be required in cats that refuse to eat, as they will develop hepatic lipidosis and protein calorie malnutrition.

The prognosis is poor, as the average survival time following diagnosis with this tumor is **4 months**.

HYPOADRENOCORTICISM

Classical signs

- Typically, lethargy, weakness and vomiting.
- Regurgitation (megaesophagus), diarrhea and abdominal pain may occur.

See main reference on page 752 for details.

Clinical signs

Lethargy, weakness and vomiting are the classic presenting signs, but diarrhea and abdominal pain may also be observed.

Megaesophagus, with resultant regurgitation, may occur due to muscle weakness, but it is **very uncommon in cats**.

Hypoadrenal crisis is associated with an acute episode of collapse due to severe alterations in **sodium and potassium** that result in severe muscle weakness and cardiovascular collapse. This is a **rare occurrence in cats compared to dogs**, but requires rapid recognition and response to stabilize the patient.

Diagnosis

The **history and clinical signs** are often **too non-specific to be helpful**, but are still important in development of a diagnostic approach.

The **classic hemogram and biochemical changes** include eosinophilia, lymphopenia, azotemia, hypercalcemia, hyperkalemia, hyponatremia and low or isospecific gravity.

However, **some cats will not have mineralocorticoid deficiency**, thus, **no electrolyte changes** will be evident on the chemistry profile.

Cats with **severe hyperkalemia** (> 7 mEq/L) will have characteristic ECG abnormalities and bradycardia.

Definitive diagnosis is by performing an ACTH stimulation test. Cortisol levels will be low and will not respond to ACTH administration.

Differential diagnosis

Because the clinical signs and routine blood work are non-specific, **a wide variety of metabolic, neoplastic, infectious and idiopathic conditions must be considered.** In many cats, the ACTH stimulation test is performed based on clinical suspicion, not clear physical or biochemical findings that suggest hypoadrenocorticism.

Treatment

In cats that are clinically dehydrated, have pre-renal azotemia or in an acute adrenal crisis, **fluid therapy with isotonic saline** is the initial treatment of choice. If there are **cardiac arrhythmias** or ECG abnormalities associated with **severe hyperkalemia**, **regular insulin** (0.2–0.5 U/kg IV) **and dextrose therapy** (0.5–1.0 g/kg IV slowly), **intravenous bicarbonate** (body weight (kg) \times 0.5 \times base deficit, or 0.5–1.0 mEq/kg over 6 h), **or intravenous calcium gluconate therapy** (0.5–1.0 ml/kg, IV slowly) may be administered to rapidly lower extracellular potassium levels.

Parenteral corticosteroids (dexamethasone, methyl prednisolone, which have some mineralocorticoid effects as well) should be administered in physiologic doses (0.2–0.4 mg/kg) initially, and **continued daily** (oral or injectable) as replacement therapy until the cat is stable.

Once the cat is in stable condition, **replacement of mineralocorticoid hormones** can be achieved orally (fluorinef) or with repository forms of the hormone, such as desoxycorticosterone pivalate (DOCP).

Therapy for cats with this disease will be lifelong, and **frequent rechecks** to allow dose adjustments will be required. Most cats will have a good quality of life with proper management of this disease.

HISTOPLASMOSIS

Classical signs

- Signs may indicate respiratory, eye, CNS, bone marrow or GI tract involvement.
- Typically, respiratory signs such as wheezing, coughing or dyspnea predominate.
- GI signs are usually associated with protracted, watery diarrhea, that may contain blood or mucus.

Pathogenesis

Histoplasma capsulatum is a soil-borne fungus, which is found in many temperate and subtropical areas of the world, especially where it is moist and humid. The organism grows particularly well if there is bird or bat excrement in the soil.

In the States, it is most frequent in Southern and Central USA around the **Ohio, Missouri and Mississippi Rivers**.

The majority of infections are subclinical or cause only mild, transient clinical signs.

Cats are equally susceptible as dogs, and the **majority of symptomatic cats are young** (< 4 years of age).

Infection is contracted via inhalation, although the GIT may also be a route of infection. Signs occur approximately 12–16 days after exposure.

Initial infection is confined to the respiratory tract, **but dissemination often occurs** resulting in chronic disease over months or years with signs referable to spleen (splenomegaly), liver (hepatomegaly, icterus, ascites), GIT (chronic diarrhea and weight loss), peritoneum (omental or mesenteric masses); lymph nodes (peripheral or abdominal lymphadenopathy), bone marrow (anemia, thrombocytopenia, leukopenia), bones (lameness and proliferative or lytic bone lesions), eyes (conjunctivitis, exudative anterior uveitis, multifocal

granulomatous chorioretinitis, optic neuritis), central nervous system (ataxia, seizures, circling, disorientation, anisocoria, paresis, decreased conscious proprioception), and occasionally skin (nodular or ulcerated lesions).

Clinical signs

The **most common clinical signs** of histoplasmosis in cats are **multisystemic**, including **depression, weight loss, anorexia, dyspnea or lameness**.

Other signs may include fever, pale mucous membranes, peripheral lymphadenopathy, icterus, hepatomegaly, skin nodules or splenomegaly.

The organism can be **most commonly found in the respiratory tract, bone, bone marrow, skin and GI tract**.

GI signs are not common in cats (as they are in dogs), but when they occur **chronic diarrhea, mesenteric lymphadenopathy and anorexia** are common.

Ocular changes may include conjunctivitis, anterior uveitis, retinal detachment or chorioretinitis.

Diagnosis

The clinical signs of disseminated histoplasmosis are consistent with **systemic illness** and are associated with a **wide variety of non-specific clinical and laboratory changes**.

Anemia of chronic disease is the **most common hematologic abnormality**.

Occasionally histoplasma organisms can be found in circulating mononuclear cells and eosinophils.

Thrombocytopenia is also a common abnormality.

Diagnosis of histoplasmosis by serology is unreliable as the sensitivity and specificity for the organism is poor.

The **best method of diagnosis** is to identify the organism in **cytologic or histopathologic examinations**. The **best tissues** for diagnosis of histoplasmosis in the cat are **bone marrow, lymph nodes, lung, liver or skin nodules if present**.

Differential diagnosis

There are a **wide variety of potential differentials** due to the different clinical presentation that may occur depending on the organ system affected.

Treatment

Itraconazole (10 mg/kg PO q 24 h) is the drug of choice for initial therapy. It is highly effective and has minimal toxicity, but is relatively expensive and treatment must be continued for 1 month (at least) beyond the resolution of clinical signs and evidence of disease (typically 6–9 months).

Other treatment options include fluconazole, ketoconazole and amphotericin B.

The **success rate with itraconazole therapy** is reported to be anywhere from 33% to >90%, but this depends in large measure on the severity of the infection at the time of diagnosis.

INTUSSUSCEPTION

Classical signs

- Abdominal pain, anorexia and vomiting.
- Diarrhea, weight loss, and lethargy occur in long-standing cases.
- Intussusceptions are usually seen in young cats or kittens.

See main reference on page 643 for details.

Clinical signs

With **high intussusceptions**, vomiting, abdominal discomfort, anorexia, lethargy, dehydration and hypovolemia leading to shock are the most common clinical signs.

Low intussusceptions (at the ileocolic junction) typically present with bloody, mucoid diarrhea, tenesmus, intermittent vomiting and weight loss. In many of these cases, the intussusception can be palpated.

Most intussusceptions are associated with acute disease, but **sliding intussusceptions** may result in chronic, intermittent signs.

A **palpable mass in the abdomen** may be evident, especially with low intussusceptions.

Diagnosis

Hemogram and serum biochemistry profiles will be variable depending on the severity and location of the

intussusception, however, dehydration, electrolyte abnormalities, anemia and leukocyte changes have all been observed depending on the site, severity and precipitating cause of the intussusception.

Radiographs and/or ultrasound examination of the gastrointestinal tract are the best means of confirming the diagnosis. Radiographs may not be definitive, but in most cases, an obstructive pattern (dilated loops of bowel, different bowel loop sizes) will be apparent. However, an **ultrasound of the abdomen will often definitively identify the intussusception**. Contrast studies may be used but should not be done at the expense of delaying treatment in severely ill cases. In the case of sliding intussusceptions, the diagnostic procedures should be performed when the clinical signs are most prominent.

Endoscopic examination or colonoscopy can also be used to obtain a diagnosis, especially with low intussusceptions.

Exploratory laparotomy may be required to obtain a definitive diagnosis, and is essential for treatment, **so in cats with evidence of intestinal obstruction, or in cats with acute abdomen and shock, surgery should be performed early.**

Differential diagnosis

Many diseases that can precipitate an intussusception (e.g. viral enteritis, foreign bodies, gastroenteritis, intestinal parasitism, etc.) **also have clinical signs that mimic it**. Thus, a thorough physical examination, diagnostic evaluation, and close patient monitoring are essential. **Mesenteric volvulus** is a very difficult condition to differentiate from intussusception, both clinically and radiographically.

Treatment

Intussusception must be considered a **surgical emergency**. Cats with signs of shock or endotoxemia should be prepared for surgery by **correcting fluid and electrolyte imbalances**, administration of **broad-spectrum, parenteral antibiotics** (combinations such as ampicillin or cefazolin and enrofloxacin, amikacin, cefoxitin or imipenam), and use of **histamine-2 blockers** (ranitidine or famotidine) or **protectants** if gastric erosions or ulceration is suspected.

Motility-enhancing drugs, such as metoclopramide, **are contraindicated** in patients with GI obstruction and should not be used.

After surgical correction, if gastric ulceration is not a complicating factor, oral alimentation should be instituted in the first 24 hours, to enhance the return of normal motility and reduce the possibility of post-operative ileus.

OTHER SMALL INTESTINAL NEOPLASIA (FIBROSARCOMA, CARCINOMAS, PLASMACYTOMA)

Classical signs

- Weight loss.
- Lethargy or depression.
- Anorexia.
- Vomiting and/or diarrhea.

Clinical signs

The **clinical signs observed will depend upon the tumor location** in the GI tract.

In cats, anorexia, weight loss and lethargy are the most common clinical signs of any gastrointestinal neoplastic disease.

Vomiting and/or diarrhea may be observed, but will be variable depending on whether the tumor is in the small intestine or colon, and whether it is diffuse or solitary in extent.

Diagnosis

Palpation of an intestinal mass is an important diagnostic tool, since many of these tumors are solitary and produce strictures or obstructions.

Hematology and serum biochemistry profiles may be within normal limits in cats with intestinal neoplasia.

Abnormalities associated with secondary effects of the tumor include dehydration, electrolyte imbalances, anemia of chronic disease, etc.

Radiographs of both the thorax and abdomen are an important, but sometimes non-diagnostic, tool.

Radiographs are best for assessment of pulmonary metastasis.

Ultrasound is an invaluable tool for lesion localization, determination of **lesion extent** and in some cases, obtaining a **fine-needle aspirate** or biopsy of the lesion.

Definitive diagnosis is by **histopathologic evaluation of a biopsy** or tissue obtained after surgical resection.

APUDOMAS

Classical signs

- Severe and in some cases intractable small bowel diarrhea.

Pathogenesis

Amine precursor uptake and decarboxylation (APUD) cells are a diffuse system of endocrine cells in the body (primarily associated with the GI tract and other endocrine organs) that are able to **secrete biogenic amines from amino acid precursors**.

APUD cells are responsible for the **potent secretory functions** that APUD tumors display (e.g. insulinomas, gastrinomas, pheochromocytomas and carcinoid tumors of the gut).

Clinical signs

The clinical signs are dependent on the tumor and effects, for example carcinoid tumors of the GI tract may produce **secretory diarrhea** in affected cats because of the vasoactive amines they produce.

These are **rare tumors**, and most tumors reported to date have been clinically silent.

Gastrinomas are also rare neoplasms that secrete gastrin, causing excessive secretion of hydrochloric acid by the stomach and resulting in **gastric and duodenal ulcer disease**.

Diagnosis

These are **rare neoplasms** that are extremely difficult to diagnose (because they are **very difficult to find**).

Some of these tumors (insulinoma, gastrinoma) can be **presumptively diagnosed by measuring the level of the hormone they produce**, but most APUDomas do not secrete hormones that are routinely measured.

Differential diagnosis

Because these tumors are so rare, **all other causes of chronic diarrhea should be considered** before pursuing the APUD tumors as the cause of diarrhea.

Treatment

The treatment of choice is to find and **surgically excise the tumor**. However, because **the tumors are often microscopic or extremely small**, they are often overlooked during an exploratory. In addition, by the time the tumor is large enough to find, it has often already metastasized.

Supportive care and symptomatic therapy are often the only avenue. For example, in cats with gastrinomas, histamine₂ blockers and proton pump inhibitors are used to help control the excessive secretion of acid.

Prognosis

Guarded to poor. These tumors are usually malignant, surgical excision is rarely curative and metastatic tumors are poorly responsive to chemotherapy.

HYPEREOSINOPHILIC SYNDROME

Classical signs

- Severe and in some cases intractable small bowel diarrhea.
- Peripheral eosinophilia and infiltration of the bone marrow, spleen, liver, lymph nodes and other organs with eosinophils.

Pathogenesis

Hypereosinophilic syndrome is a **relatively common variant of eosinophilic enteritis** in the cat, but is **distinct from eosinophilic leukemia**.

The disease is characterized by **infiltration of eosinophils** in bowel, lymph nodes, spleen, liver and

other organs, and **peripheral eosinophilia**, which separates this disease from eosinophilic IBD.

The **etiopathogenesis of this disorder is unknown**, but may be due to extensive antigenic dissemination or aberrant regulation of the normal eosinophilic response.

The disease is most common in middle-aged to older cats, and there is no breed or sex predisposition.

Clinical signs

The **clinical signs** are similar to those of cats with IBD except the **intestinal wall thickening** is more pronounced, **hepatosplenomegaly** is common, and **bloody diarrhea is common**.

Some cats will **cough**, have **skin lesions** (miliary dermatitis) and have **peripheral lymphadenopathy**, but these clinical signs are less common.

Diagnosis

The diagnosis is made by **histopathologic examination of liver, spleen, lymph node or intestinal biopsies** which will reveal infiltration of large numbers of normal eosinophils.

Differential diagnosis

The **primary differentials are eosinophilic IBD and eosinophilic leukemia**. Eosinophilic leukemia is differentiated from hypereosinophilic syndrome by its **localization of eosinophils to the peripheral circulation and bone marrow**. In **eosinophilic IBD**, eosinophils are found **only in the lamina propria of the intestine** and do not infiltrate other abdominal organs and lymph nodes.

Treatment

High-dose prednisolone therapy (3–6 mg/kg/day PO) is most commonly used, but **relapses are common**, even if the high doses of steroids are maintained.

An alternative therapy is with hydroxyurea (7.5 mg/kg q 12 h PO) for 3–14-day courses, as required to maintain the cat in remission.

Cats with hypereosinophilic syndrome often have **severe diarrhea**, and may require **nutritional or fluid support** until the disease is brought under control.

Prognosis

The **prognosis is guarded to poor**.

INTESTINAL DIVERTICULOSIS

Classical signs

- Moderate to severe, small or large bowel diarrhea, and weight loss, depending on the location and number of diverticuli.

Pathogenesis

Diverticuli may be congenital or occur secondary to intussusception or other intestinal obstructive processes.

Most clinical disease is associated with the diverticulitis and infection occurring at the site.

Clinical signs

Many intestinal diverticuli are **clinically silent** and are only found incidentally.

Diverticulitis may result in the development of **diarrhea, abdominal pain, lethargy or anorexia**.

Diagnosis

The **definitive diagnosis is made by imaging studies** (ultrasound, contrast rads) **or by visualization** (endoscopy or exploratory surgery).

Differential diagnosis

The **rarity of this problem** should suggest that all other possible causes of diarrhea and lethargy are ruled out before consideration of this condition.

Treatment

Surgical resection of the affected bowel segment in clinically affected patients. Cats with diverticuli but without signs of disease do not require surgery.

PROTEIN-LOSING ENTEROPATHY

Classical signs

- Weight loss, poor hair coat, inappetence, and chronic (may be intermittent) diarrhea.

Pathogenesis

Primary lymphangiectasia is rare as a cause of protein-losing enteropathy (PLE) in cats. Most cats have PLE secondary to **IBD or lymphosarcoma**.

PLE in cats may be associated with **other severe mal-absorptive or infiltrative diseases** (e.g. histoplasmosis, exocrine pancreatic insufficiency), but these are **rare causes of protein loss in cats**.

Clinical signs

The clinical signs are **dependent on the primary cause** of the PLE. Cat may have anorexia and weight loss only, or have chronic unrelenting diarrhea, along with inappetence.

Most cats are **middle-aged to older**, typical of the age range for IBD or lymphoma. PLE is simply **another complication of the primary process** and is not a diagnostic entity in cats.

Diagnosis

Cats with PLE will have **decreased serum total protein and albumin levels**, in addition to other abnormalities consistent with their primary disease.

Urinary protein loss, third space loss, lack of adequate intake and severe hepatic disease must all be ruled out before considering a diagnosis of PLE. **Fecal alpha-1 protease inhibitor levels**, a test for abnormal GI protein loss available for dogs, **have not yet been validated for use in cats**.

As for many other GI conditions, the definitive diagnosis of the inciting cause of PLE is obtained by biopsy.

Differential diagnosis

Since **PLE is not a definitive diagnosis**, a search for the primary cause is **essential**. Cats rarely develop

lymphangiectasia or idiopathic PLE as is reported in dogs.

Other causes for low albumin and serum protein levels must be considered when this abnormality is discovered, e.g. renal protein loss, severe hepatic disease, third space loss, and severe protein calorie malnutrition.

Treatment

Treatment of PLE is directed solely at **correction of the primary disease process**. Specific therapy for lymphoma or IBD will correct or at least control the cause of the protein loss.

Symptomatic therapy for severe intestinal protein loss includes a **highly digestible diet**. Alternative sources of protein for inclusion in the diet are **hydrolyzed protein diets** (Hill's z/d) and **elemental diets** (e.g. Vivonex).

Medium chain triglyceride (MCT) oil is not recommended for use in cats, as it is in dogs, because of the **increased risk of hepatic lipidosis**.

Prognosis

Guarded, as most cats with PLE have a disease that is difficult if not impossible to cure.

SHORT BOWEL SYNDROME

Classical signs

- Severe and in some cases intractable small bowel diarrhea.

Pathogenesis

Short bowel syndrome is classically due to **surgical resection of a large segment of the small intestine** that results in fluid overload to the colon and resultant diarrhea.

Other causes include ischemic intestinal diseases such as intussusception, bowel strangulation and intestinal volvulus.

Intestinal adaptation occurs in the large bowel, which ultimately results in a return to a soft or semi-formed fecal specimen, usually **within 2–6 weeks**.

If greater than 85% of the small intestine has been removed the chance for adaptation is poor.

Clinical signs

Diarrhea, dehydration and weight loss all occur as a result of short bowel syndrome.

Other signs are related to intestinal malabsorption, such as deficiencies of essential amino acids, vitamins or clotting factors.

Small intestinal bacterial overgrowth may also occur, resulting in vomiting or anorexia as well.

Diagnosis

The diagnosis is **presumptive if surgical resection is the cause**.

Cats are often **hypoproteinemic**, may be **hypcholesterolemic**, and have other **non-specific hemogram or chemistry abnormalities**.

Imaging studies can be used to confirm the diagnosis.

Differential diagnosis

Other diseases that may cause similar signs include **severe intestinal strangulation, intussusception and intestinal volvulus**, which is rare in cats.

Treatment

Tincture of **time** will allow the bowel to **adapt**.

Broad-spectrum antibiotics may be needed.

Low-fat, highly digestible diets are necessary to maximize absorption of nutrients.

Administration of vitamins and minerals is usually needed. Monitoring **prothrombin time and serum cobalamin levels** will help determine whether supplementation is needed. (Vitamin K₁ 5 mg/kg once, then 2.5 mg/kg q 12–24 h, cobalamin or multi-B complex injection weekly).

Parenteral nutrition may be required in some cats in the early stages to support them until bowel function returns.

Prognosis

The prognosis is guarded in cats in which diarrhea persists for longer than 2 months after the resection, as by that time, the chances of a return to normal function are poor.

34. The cat with signs of large bowel diarrhea (acute and chronic)

Debra L Zoran

KEY SIGNS

- Soft, mucoid, formed to semi-formed feces.
- + Fresh blood or straining.

MECHANISM?

- Large bowel diarrhea is induced by **increased secretion of water and electrolytes** by colonic epithelial cells, **overload of substrate** (from small bowel) or by **altered motility** (e.g. decreased motility, loss of segmentation).
- **Increased fermentable substrate** (e.g. carbohydrates such as soluble fibers, lactulose, etc.) may **increase fecal water** and create a softer fecal mass.

Signs of large bowel diarrhea:

- Soft, mucoid, formed to semi-formed feces.
- Hematochezia.
- Straining to defecate.
- Increased urgency to defecate.
- Small volume of fecal material expelled.
- Vomiting or weight loss not typically observed.

WHERE?

- **Acute, large bowel diarrhea is uncommon in cats** and is less likely to be associated with parasites (e.g. whipworms) or clostridial enterocolitis compared to dogs.
- **Chronic or recurrent large bowel diarrhea** may be caused by **local** (e.g. large bowel) or **systemic disease**, and thus a **thorough evaluation** that includes a **minimum database, imaging studies** (radiographs, ultrasound, etc.), or **endoscopy with collection of biopsies** is required to determine the cause.
- **Irritant colitis** secondary to ingestion of hair, feathers or other foreign material is a **common cause of acute large bowel diarrhea**.
- **Cats usually do not lose weight or have vomiting episodes in association with large bowel diarrhea** unless a systemic disease is the cause of the problem.

WHAT?

- **The most common causes of large bowel diarrhea are inflammatory** (inflammatory bowel disease), **neoplasia, metabolic diseases** (hyperthyroidism) and **mechanical** (hair, feathers or bone-induced colitis).
- **Food intolerance** may be a common cause of colitis, but is **not well documented in cats**.
- **Clostridial enterocolitis** is the **most common infectious cause of colitis in adult cats**, but the **incidence in cats is low** compared to other causes of large bowel diarrhea.

QUICK REFERENCE SUMMARY

Diseases causing signs of large bowel diarrhea

ANOMALY

- Congenital malformations (e.g. diverticulum, short colon syndrome, vascular ectasia) (p 779)
All are rare conditions that are observed in young cats or kittens, with the severity depending on the anomaly (e.g. short colon syndrome causes severe signs, while vascular ectasia and diverticular formations may initially be clinically silent).

MECHANICAL

- **Irritant (foreign body) colitis** (p 765)**

This is the acute development of colitis manifest by the presence of mucoid- to blood-streaked feces resulting from ingestion of hair, bones, string, feathers or other foreign material.

- Perineal hernia (p 776)

Perineal hernias cause perineal swelling associated with a mucoid- or blood-streaked fecal mass and straining to defecate. In long-standing cases, constipation may occur.

- Perianal tumors (p 777)

The tumor mass may cause straining to defecate and other signs of large bowel disease, or it may obstruct the passage of feces and cause constipation.

METABOLIC

- **Hyperthyroidism* (p 771)**

Hyperthyroidism may cause voluminous, soft and mucoid feces due to increased intake and reduced GI transit time, changes in metabolism (malassimilation of food) and motility disturbances.

- Pseudomembraneous colitis (antibiotic-induced colitis) (p 777)

Acute or chronic large bowel diarrhea may be caused by the use of anaerobic antibiotics resulting in overgrowth of pathogenic species that may be resistant to many or most antibiotics. Severe forms of this disease are rare in cats, but diarrhea due to antibiotic use is not uncommon.

NEOPLASTIC

- **Colonic adenocarcinoma* (p 774)**

This is the most common non-hematopoietic tumor of the GI tract and the most common colonic tumor in cats. It typically affects old cats (>10 years) and vomiting, weight loss and lethargy are more common signs than diarrhea.

- **Lymphosarcoma* (p 773)**

Lymphosarcoma tends to cause infiltrative disease that affects both the large and small intestine, but may be localized to the colon in some cases causing only signs of large bowel disease.

- Colorectal polyps (p 778)

These are benign growths that are clinically silent until they grow large enough to prevent normal fecal passage and cause large bowel diarrhea or constipation. Most cases reported in Siamese cats.

continued

continued

NUTRITIONAL

- **Food intolerance** (p 766)**

Food intolerance is a non-immune-mediated condition associated with intermittent diarrhea or vomiting, with no pattern or association with eating, and it resolves when the food source is changed to omit the offending substance from the diet. The clinical significance of food intolerance is unknown relative to other causes of diarrhea because of the difficulty in obtaining a definitive diagnosis.

IMMUNOLOGIC

- **Food allergy (dietary hypersensitivity)* (p 767)**

Chronic vomiting appears to be more common than diarrhea in cats with food allergy, and cutaneous signs may also be present.

- **Idiopathic inflammatory bowel disease (IBD)* (p 768)**

This is a chronic inflammatory disease of the feline GI tract that has no known cause. Depending on the extent of the disease, the diarrhea may be entirely of large bowel character, small bowel character or may be a combination of both. Weight loss and vomiting are also frequently observed clinical signs.

INFECTIOUS

- **Infectious colitis (*Clostridium* spp., *E. coli*, *Campylobacter* spp.)* (p 770)**

Clostridial spp. cause an enterocolitis characterized by acute onset of soft, mucoid- or blood-streaked feces that may become liquid, unformed small bowel diarrhea. Diarrhea is caused by overgrowth of clostridial spp. followed by subsequent sporulation and enterotoxin formation. *E. coli* is an uncommon cause of enterocolitis and large bowel diarrhea in cats.

- **Parasitic infections (*Giardia*, *Tritrichomonas*, *Cryptosporidia*, *Isospora*, *Toxoplasma*, *Balantidium* and *Trichuris*) * (p 775)**

Diarrhea is the primary clinical sign with *Tritrichomonas*, *Cryptosporidia* and *Cystoisosporidia* infections. Infections are inapparent except in young kittens and debilitated or immunocompromised adult cats. *Trichuris vulpis* is a rare cause of colitis or large bowel diarrhea in cats, but is occasionally found on fecal examination in cats from a contaminated environment.

Inflammatory:

- **Chronic pancreatitis (p 776)**

This disease is most often associated with vague, non-localizing signs, but hematochezia and diarrhea with a large bowel character are not unusual.

INTRODUCTION

MECHANISM

The signs of large bowel disease include:

- Increased mucus.
- Hematochezia.
- Straining or increased urgency to defecate.
- Soft to semi-formed feces.
- Normal or increased frequency of defecation but not increased volume.
- It is rarely associated with weight loss or vomiting.

The colon responds to inflammatory conditions by producing increased amounts of mucus.

Blood streaks or fresh blood is also a common presenting sign due to the proximity to the anus.

WHERE

Large bowel disease can result from disorders of ileocecal region, colon or rectum.

Historical and physical examination signs are important in localizing the problem to the large intestine.

Rectal examination is an especially important component of the physical examination when evaluating a cat for large bowel disease.

WHAT

Large bowel diarrhea can be caused by a variety of infectious, dietary, metabolic, mechanical, neoplastic or idiopathic disorders.

- Acute large bowel diarrhea is often managed by empirical therapy with anthelmintics, antibiotics or a diet change.
- The most common causes of acute large bowel diarrhea are parasites, dietary or infectious agents.

Chronic large bowel diarrhea is defined as the presence of signs for more than 3 weeks.

- Cats with chronic large bowel diarrhea should be thoroughly evaluated to determine the diagnosis,

both for effective therapy to be initiated and for providing an accurate prognosis.

- The **minimum database** should include a **CBC, panel, urinalysis and complete fecal examination** (fecal flotation, direct, cytology).
- **Other diagnostic approaches** that may be required include radiography, ultrasonography, endoscopic examination (especially for biopsy).
- **Surgery** on the colon is difficult, but in some neoplastic conditions or obstructive diseases, it will be required.

DISEASES CAUSING SIGNS OF LARGE BOWEL DIARRHEA

IRRITANT (FOREIGN BODY) COLITIS**

Classical signs

- Mucus- or blood-streaked, soft (semi-formed) stools.
- History of ingestion of feathers, hair, bones or other foreign objects (e.g. string, plants).

Pathogenesis

Colitis and large bowel diarrhea that is caused by the presence of **foreign objects** (e.g. hair, bones, feathers) is primarily due to the **irritation of the colonic epithelium**.

This results in **motility disturbances** and release of local **inflammatory mediators** that cause **secretory or motility changes** and ultimately, diarrhea.

Ingested hair, or a trichobezoar, is a **common cause of irritant colitis in cats**, especially in cats with long hair coats or with dermatologic disorders that result in excessive grooming.

Clinical signs

Irritant colitis causes large bowel diarrhea that is **intermittent and generally not severe** in nature. **Mucus- or blood-streaked, soft (semi-formed) stools** are the most common presenting signs.

The **history typically supports the presumptive diagnosis** (e.g. cat consumes prey, feces contains large amounts of hair or other foreign material).

Diagnosis

A **good history and visual examination of the feces** is especially helpful in making this diagnosis in cats with irritant colitis.

The **physical exam and minimum database** are usually **unremarkable** in these cats.

Survey radiographs may be helpful if there is **bony material** present in the colon, but **otherwise, imaging studies are not helpful**.

Fecal exams are not diagnostic, but may be helpful to reveal the **presence of large amounts of foreign material** in the fecal material.

Because the episodes are typically **intermittent, short lived** (few days at the most) and the **cat is normal in the intervening periods**, more **aggressive diagnostic evaluations are rarely indicated**.

Differential diagnosis

Other important differentials are infectious (clostridial enterocolitis), dietary indiscretion or food intolerance, and parasitic causes of large bowel diarrhea.

Treatment

Identification and removal of the offending substance is curative.

In cats in which the cause cannot be identified or removed:

- Addition of **bulk-forming laxatives** (e.g. psyllium, methylcellulose).
- **Lubricant laxatives** (petroleum-based laxatives found in hair ball remedies).
- **Foods that contain increased fiber** (canned pumpkin, coarse wheat bran) may be helpful.

Alternatively, feeding the cat a **diet that is high in insoluble dietary fiber to increase segmentation and propulsion movements in the colon**, may also be effective in decreasing occurrences of irritant colitis.

Prevention

Prevention is **most successful if the cause of the irritation is identified and removed**.

Removal of excess hair (grooming, brushing, clipping) from long-haired cats, **reduction of causes of excessive grooming** (management of pruritus, behavioral therapy), **prevention of prey consumption or ingestion of foreign objects** (e.g. string, rubber bands, etc.) are important measures in controlling foreign body colitis.

FOOD INTOLERANCE**

Classical signs

- **Dietary indiscretion:** Vomiting, small or large bowel diarrhea, inappetence.
- **Food intolerance:** Vomiting, small or large bowel diarrhea.

See main reference on page 669 (The Cat With Signs of Chronic Vomiting) for details.

Clinical signs

Dietary indiscretion is more commonly associated with vomiting, but colitis (**hematochezia, large bowel diarrhea, mucus-covered feces**) may occur if the substance ingested reaches the colon intact (hair, feathers, bones) or changes the colonic microflora due to bacterial overgrowth of *E. coli* or other pathogens.

The **signs are acute**, and often include **vomiting or inappetence** in addition to diarrhea.

Food intolerance is an adverse reaction to a food or food substance that is **not immunologic** in nature (e.g. reaction to protein, preservative, flavoring, etc.).

The **signs of food intolerance** may be acute, but **often are chronic and intermittent**, and can involve vomiting alone, diarrhea alone, or a combination.

Diagnosis

The diagnosis of food intolerance is based on cessation of clinical signs upon **elimination of the offending substance from the diet**, and recurrence of signs when the substance or diet is re-introduced to the cats.

A response should be seen with the non-offending diet, whether commercial or homemade, within 4 days if there is total compliance with the diet.

Dietary indiscretion is a presumptive diagnosis made based upon the history of eating lizards, beetles, plants, etc., lack of other physical examination or diagnostic (fecal examinations negative for parasites, normal fecal cytology, normal blood work and radiographs) findings.

Differential diagnosis

Food allergy is the major differential diagnosis for cats with food intolerance and it is very difficult to distinguish the two conditions clinically. Since the treatment for both food intolerance and food allergy is the same and the response to treatment should be identical, it is probably unnecessary in clinical practice to differentiate the two conditions.

Treatment

In most cats, **treatment of dietary indiscretion is symptomatic** (e.g. feeding a high-fiber diet for cats with large bowel signs, low-residue diet if both large and small bowel signs are present), with judicious use of antibiotics (for bacterial flora manipulation) and fluid support if needed. Prevent access to the offending material.

Treatment of food intolerance involves the removal of the offending substance from the diet, which is usually achieved by changing to a commercial diet containing different protein or carbohydrate sources, and no additives, flavorings, colorings, etc.

FOOD ALLERGY (DIETARY HYPERSENSITIVITY)*

Classical signs

- GI signs (vomiting, diarrhea, weight loss, inappetence) are most commonly associated with this condition.
- Dermatologic signs (pruritus, alopecia, papules) may accompany the GI signs in some cases.

See main reference on page 667 (The Cat With Signs of Chronic Vomiting) for details.

Clinical signs

Food allergy is an adverse reaction to food (usually protein, but may also be carbohydrate) that is **immunologic** (i.e. food allergy, hypersensitivity, delayed hypersensitivity).

The **signs are acute**, and often include **vomiting or inappetence** in addition to diarrhea.

The GI signs of food allergy **are usually chronic and may be intermittent**. They can involve vomiting alone, diarrhea alone, or a combination.

Clinical signs of food allergy may also involve the skin around the head and neck (pruritus, alopecia, dermatitis, otitis) as well as the GI tract, and vomiting or diarrhea is reported.

Those cats that develop GI signs usually have **vomiting or small bowel diarrhea**, however, some cats will develop **colitis** due to food allergy and have large bowel diarrhea, or episodes of mucoid feces.

Diagnosis

Diagnosis of food allergy is based on cessation of clinical signs upon **elimination of the offending substance from the diet**, and recurrence of signs when the substance or diet is re-introduced to the cats.

A response should be seen with the hypoallergenic diet, whether commercial or homemade, within 4 days if there is total compliance with the diet and the cat has not been previously sensitized to ingredients in the diet.

Intradermal skin testing and measurement of food-specific IgE in the serum have been advocated by some, but are fraught with both **false-negative and false-positive results** since most food allergies are not mediated by IgE. Also, IgE present in the skin does not correlate to IgE in the GI tract.

Gastroscopic food sensitivity testing has not been reported to be useful in cats.

Differential diagnosis

Colonic IBD is the major differential for cats with **severe or persistent signs**, and endoscopic biopsy will not distinguish between eosinophilia or inflammation

due to food allergy and that due to other causes. Cats with food allergy usually have signs that resolve within 4 days on an appropriate hypoallergenic diet. Signs of IBD do not usually resolve solely with a change in diet, although they may improve.

Treatment

Food allergy is diagnosed and treated by feeding an elimination diet for the dietary trial period.

Homemade diets allow the use of a **single novel protein source** (turkey, duck, venison, etc.) and a novel, **highly digestible carbohydrate source** (rice, potato) without preservatives, flavorings, or other additives that may be cause of the problem. Alternatively, use a commercial hypoallergenic diet containing protein and carbohydrate the cat has been previously exposed to.

However, homemade diets are not recommended for **long-term management** of food allergy as they are **not balanced or nutritionally complete**.

There are a number of **commercial diets that have been formulated as “hypoallergenic” or limited antigen diets**. Many of these diets (Hill’s, Innovative Veterinary Diets, Royal Canin, Iams, Nature’s Recipe, Nutro, and Wysong to name just a few) will be quite effective and **should be used for long-term dietary management** of intolerance or allergy to prevent nutritional deficiencies or excesses.

IDIOPATHIC INFLAMMATORY BOWEL DISEASE (IBD)*

Classical signs

- Diarrhea ranges from soft, mucoid blood-streaked feces to liquid diarrhea (more characteristic of small bowel disease).
- Other signs may include vomiting, anorexia, weight loss and lethargy.

Pathogenesis

The **etiopathogenesis** of colitis or IBD is **unknown**.

A **diagnosis of colonic IBD is based on exclusion** of all other causes of colitis in conjunction with the **histologic presence of an increased number of inflammatory cells in the lamina of the crypts**.

The **histopathologic changes** associated with colonic IBD are **quite variable** and include infiltration of the lamina with **lymphocytes and plasma cells (most common)**, eosinophils, macrophages, neutrophils, or a combination of these cells.

An **immunologic mechanism is suspected** primarily because of the response to immunosuppressive therapy, but this has not been proven.

The **disease in cats is so heterogeneous** (compared to human IBD) that it likely represents a **combination of genetic** (purebred cats have a higher incidence), **environmental, infectious (bacterial), dietary and immunologic components**.

Clinical signs

Hematochezia is the most commonly observed clinical sign in colonic IBD.

When **large bowel diarrhea** occurs, it may be either **mild and intermittent** or **persistent and severe** in character.

Most cats with the colonic form of IBD do not have vomiting, weight loss or decreased appetite, but it can occur in cats with severe disease or disease affecting the small and large bowel together.

The **presence or severity of diarrhea or hematochezia does not correlate with the histologic grade of disease**.

Diagnosis

Hematologic abnormalities are uncommon, but are consistently associated with severe colonic IBD and usually represent a typical stress response.

The most common biochemical abnormalities (when they occur) are **elevated hepatic enzyme activities** and **hypokalemia**. Hyperglobinemia may also occur.

Fecal floatation should be performed to rule out intestinal parasitism, including giardiasis and coccidia.

Fecal cultures are rarely indicated in acute colitis, but in chronic or recurrent colitis they should be performed.

Imaging studies may reveal a **thickened colonic wall or abnormal gas patterns**, but these findings are **non-specific**.

The **definitive diagnosis is achieved by histopathologic evaluation** of the colonic mucosa from biopsies obtained via endoscopy.

Endoscopic biopsies are less invasive, and are an accurate and rapid means of obtaining the diagnosis (if the biopsies are adequate), and they also allow examination of the mucosal surface.

Mild or moderate infiltrations of lymphocytes or plasma cells in the lamina of the colon are normal, or suggest inflammation that is due to normal response to a luminal pathogen.

The **amount of infiltration should be carefully graded** and the presence of other **alterations in crypt architecture** should be found before concluding that the inflammatory cells present are pathologic or suggestive of IBD.

Differential diagnosis

A **major differential for lymphoplasmacytic colitis is gastrointestinal lymphoma**. Lymphocytic infiltration in the GI tract may be very difficult to distinguish from a well-differentiated neoplastic infiltration.

Differentiating lymphoma from IBD is an important step in the diagnostic process, both for appropriate treatment planning as well as for giving an accurate prognosis.

The **presence of inflammatory cells in the lamina propria is not diagnostic for IBD**, because almost all other causes of colitis can result in the influx of inflammatory cells.

Another differential for colonic IBD is food sensitivity (food intolerance and food allergy). Some cats will have an **eosinophilic infiltrate**, but this is not consistent. **Dietary trials** must be instituted to investigate the possibility of food intolerance or food allergy. In contrast to elimination diets used for dermatological trials,

the duration of the elimination diet in cats with GI disease need not exceed 7 days as signs in most cats resolve within 3–4 days. A single novel protein and carbohydrate source diet is the best choice.

Clostridial enterocolitis or overgrowth of other intestinal flora are important infectious causes of colitis. Testing for clostridial toxin or culture for specific pathogen is the best means of diagnosis.

Campylobacter spp. are more common in **young kittens or immunocompromised adult cats** and can be identified on **fecal cytology** (motile, “seagull”-shaped bacteria) or via culture (the definitive means of making the diagnosis).

Metabolic diseases should also be considered, as they may **mimic or complicate IBD**. The metabolic diseases that should be ruled out include hyperthyroidism and chronic pancreatitis.

Treatment

The best approach is to use a **combination of dietary (increased fiber, hypoallergenic or low-residue) and pharmacologic therapy**.

There is **no single diet that will be effective in all cases**, and sometimes dietary trials using different diet types is necessary.

Diets with **increased insoluble fiber** (Hill’s r/d, Purina’s OM formula, IVD’s hifactor diet) increase normal segmentation, reduce fecal water and dilute luminal toxins, thus normalizing motility and reducing the stimulus for release of inflammatory mediators. In some cats signs are improved using high insoluble fiber and in others signs are worsened. High-fiber diets tend to be less palatable to cats and may cause constipation in some cats.

Diets that are **highly digestible, and hypoallergenic**, are also recommended for treatment of colonic IBD. By minimizing the opportunity to react to proteins in the diet, the response to therapy is often more predictable.

The **best hypoallergenic diet for ruling out food sensitivity is a homemade diet** (1/3 cup boiled rice or potato and 2/3 cup venison, rabbit, duck, ostrich, crocodile, kangaroo). For **long-term management of IBD**,

commercial diets are recommended because they are nutritionally complete and balanced.

Low-residue diets are usually **more appropriate for cats with small bowel IBD**, but in some cases, providing a diet that will result in reduced colonic residue is more effective.

The key to choosing a diet is recognizing that not all cats respond the same and a willingness to try a different approach is necessary.

- **Initial pharmacologic therapy** includes **prednisolone** (2–4 mg/kg q 12 h) and **metronidazole** (10–15 mg/kg q 12 h).
- **In cases that do not respond to these drugs**, tylosin (5–100 mg/kg q 12 h), sulfasalazine (11–22 mg/kg q 12–24 h) or olsalazine (no dose established in cats, but 5–10 mg/kg may be reasonable), may be added.
- **Chlorambucil and azathioprine** have been used in **refractory cases** of small bowel IBD, but usually are not required in colonic IBD. Cats are particularly sensitive to the myelosuppressive side effects of azathioprine.

Most cats will respond to a combination of dietary and prednisolone or metronidazole therapy and eventually can be maintained with dietary management alone.

Prognosis

The prognosis for **complete remission** is only **guarded to fair**.

However, most cats with colonic IBD can be **successfully managed with a combination of dietary and pharmacologic therapy**, and thus, the **prognosis for control is very good**.

INFECTIOUS COLITIS* (*CLOSTRIDIUM* SPP., *E. COLI*, *CAMPYLOBACTER* SPP.)

Classical signs

- Diarrhea ranges from soft, mucoid blood-streaked feces to liquid diarrhea (more characteristic of small bowel disease).
- Other signs may include vomiting, anorexia and lethargy.

Pathogenesis

Disease is induced by **changes in the diet, antibiotic therapy, ingestion of carrion or contaminated food, or stress** that results in **alteration of the normal colonic bacterial flora and changes in colonic motility**.

These changes allow **pathogens normally present** (*Clostridia*, *Campylobacter*, *E. coli*, etc.) **to overgrow or begin to secrete toxins** that change permeability, increase secretions, or cause release of inflammatory mediators.

Campylobacter is **much more common in young cats**, while **clostridial overgrowth** is more commonly seen in **adults**.

Clinical signs

Hematochezia and large bowel diarrhea that is mucoid, soft and self-limiting is common.

Diarrhea may become **more liquid with time and severity**, and is **more common with *E. coli* infections**.

Vomiting may occur, but is uncommon.

Anorexia or lethargy are **variably present**, depending on the severity.

Fever and other signs of infectious disease rarely occur with infectious colonic diseases.

Weight loss is uncommon due to the acute nature of the condition.

Historical information is very important in establishing the presumptive diagnosis.

Diagnosis

A definitive diagnosis is difficult, because **identification of these organisms in feces is not necessarily abnormal**.

- *Clostridium perfringens* enterotoxigenesis is **best diagnosed by positively identifying the presence of enterotoxin in the feces** (ELISA or RPLA assays are commercially available). Note: these assays have not been evaluated in cats, but the ELISA assay appears to be more specific in dogs. A positive enterotoxin test determined by ELISA

(regardless of spore numbers) in the context of clinical signs consistent with *C. perfringens* is strongly supportive of clostridial-associated diarrhea. In dogs, the RPLA test does not differentiate dogs with clostridial diarrhea from normal dogs and 25% of normal dogs have positive test results. In both cats and dogs, there appears to be poor correlation between the presence of fecal endospores and the presence of enterotoxin.

Campylobacter is also a **normal inhabitant** of the feline colon and thus, a **pure culture along with detection of the presence of enterotoxin is recommended for diagnosis**.

Pathogenic and nonpathogenic strains of *E. coli* can be cultured from feces and thus before a **diagnosis can be based upon the culture results and clinical presentation, the results should be confirmed by PCR testing for specific pathogenic strains**.

Once the diagnosis has been made, affected cats should be tested for FIV/FelV, in case the condition is secondary to immunocompromise by viral disease.

Differential diagnosis

Dietary indiscretion.

Parasitic enterocolitis (e.g. protozoal agents such as *Giardia*, *Tritrichomonas*, etc.), and mechanical diseases of the large bowel (e.g. intussusception, cecal inversion, foreign bodies) should all be considered when formulating a differential diagnosis.

Treatment

Clostridial enterocolitis: ampicillin (22–33 mg/kg PO q 8 h), amoxicillin (10–22 mg/kg PO q 12 h), metronidazole (5–15 mg/kg PO q 12 h), tylosin 5–20 mg/kg PO q 12–24 h), clindamycin (5–10 mg/kg q 12 h).

Campylobacteriosis: tetracycline (20 mg/kg q 8 h PO) tylosin (20 mg/kg PO q 12 h) or fluorinated quinolones (e.g. enrofloxacin).

***E. colibacillosis*:** trimethoprim-sulfonamide (15 mg/kg PO q 12 h), cephalosporins (10–30 mg/kg PO q 12 h), doxycycline (5–10 mg/kg PO q 12–24 h), or fluorinated quinolones (e.g. enrofloxacin, orbifloxacin, ciprofloxacin, etc.).

Dietary management should include feeding a **high-fiber diet, unless the signs also involve the small intestine**. In those cases, a low-residue diet is recommended.

Most cases in adults are self-limiting, but respond rapidly to antibiotics and dietary intervention. **In neonates or debilitated cats, additional supportive care** (e.g. fluid therapy) **may be required in severe cases**.

Prognosis

Good to excellent, especially with appropriate antibiotic therapy.

Prevention

In kittens or colonies of cats that have recurrent problems with infectious colitis, **minimizing stress, improving sanitation, and maximizing nutrition** will all help to reduce the occurrence of these stress-related diseases.

All cats should be tested to be sure that they are FelV/FIV negative.

HYPERTHYROIDISM*

Classical signs

- Weight loss despite a good appetite.
- GI signs (vomiting or diarrhea).
- Unkempt hair coat and increased dander are common.
- Tachycardia secondary to thyrotoxic heart disease.
- Hyperactivity or restlessness.

See main reference on page 304 for details.

Clinical signs

This disease is most commonly observed in **middle-aged to old cats** (> 8 years).

Weight loss is a very common feature of the disease.

Polyphagia, normal or decreased appetite, are all observed, but **ravenous appetite is the classic presentation**.

Hyperthyroidism may cause **hyperactive or restless behavior** and some cats are also irritable.

Decreased grooming habits, unkempt hair coat and increased dander are often reported.

Vomiting or diarrhea may be observed. Feces are usually voluminous due to increased intake and decreased gut transit time.

Tachycardia, and sometimes a **gallop rhythm** are present secondary to thyrotoxic effects on the myocardium that leads to **thyrotoxic heart disease** and heart failure.

Diagnosis

This is confirmed by presence of **elevated serum total thyroxine (T4) levels**.

Other diagnostic methods that may be used if the serum total T4 is in the upper half of the normal range, but the cat has clinical signs of hyperthyroidism include **radionuclide scanning, serum free T4 test, or a T3 suppression test**.

Abnormalities may be observed in routine blood screening tests (e.g. erythrocytosis, elevated liver enzyme activities) but these are not specific for thyroid disease.

If the cat has an **elevated heart rate or gallop rhythm** consistent with heart disease, **thoracic radiographs and echocardiography are indicated to assess the severity**.

Differential diagnosis

Other **metabolic diseases** and **extra-intestinal causes of GI signs, weight loss or tachycardia** that affect older cats should be considered carefully.

Differentials for chronic large bowel diarrhea include IBD, neoplasia and food intolerance or food allergy.

Major differentials associated with the systemic signs of hyperthyroidism are diabetes mellitus, chronic renal failure, neoplasia, IBD and hypertrophic or restrictive cardiomyopathy.

Treatment

Anti-thyroid drug therapy includes **methimazole (2.5–5 mg/cat q 12–24 h)**, with a maximum dose of 15 mg/day. Occasionally, side effects such as anorexia, vomiting, lethargy, pruritus, hepatotoxicity and hematologic changes may be observed, but will resolve if the drug is stopped. Carbimazole (5 mg PO q 8–12 h) is metabolized to methimazole.

Radioactive iodine therapy: if available is the treatment of choice. Iodine-131 is concentrated in adenomatous thyroid but spares normal tissue. Note: Use with extreme caution if the cat has concurrent renal disease as reduced renal perfusion post-treatment may worsen the condition, or unmask subclinical renal failure.

Cats treated with I-131 must be **isolated for a variable period (up to 3 weeks)** of time (depending on local laws) following treatment.

Surgical removal of a hyperplastic or neoplastic thyroid nodule is only **indicated if the disease is unilateral** (70% of cats have bilateral disease).

The **risk of anesthesia is reduced by prior treatment with methimazole** to make the cat euthyroid and also by **careful selection of anesthetic agents**. Xylazine, ketamine or other arrhythmogenic agents should not be used.

Bilateral thyroidectomy should be staged to minimize risk of hypoparathyroidism.

Management of thyrotoxic heart disease with beta-adrenergic antagonists (atenolol, 6.25–12.5 mg PO q 12–24 h) may be necessary in some cases, although cardiac complications usually resolve when the hyperthyroidism is treated. Other agents that may be considered include calcium channel blockers e.g. diltiazem (1.5–2.5 mg/kg q 8–12 h).

LYMPHOSARCOMA*

Classical signs

- Vomiting, small bowel diarrhea, weight loss and anorexia are the most common presenting signs.
- Large bowel diarrhea alone is rarely observed because the tumor is typically infiltrative throughout the GI tract.

See main reference on page 317 for details.

Clinical signs

Vomiting, small bowel diarrhea, weight loss and anorexia are the most common presenting signs.

Large bowel diarrhea alone is rarely observed because the tumor is typically **infiltrative throughout the GI tract**.

Palpation may reveal **thickened loops of bowel**.

Most cats with alimentary lymphoma are **FeLV negative** so associated clinical disease is uncommon.

Occasionally, lymphoma will present as a **solitary mass in the small intestine or colon, which obstructs the GI tract** and must be differentiated from adenocarcinoma and other neoplastic or granulomatous diseases.

Diagnosis

Routine hematology and chemistry profiles are often **within normal limits**.

Survey radiographs of the abdomen may reveal **thickened bowel loops or abnormal gas patterns**, but they also may be interpreted as normal.

Ultrasound examination of the abdomen is especially helpful in identifying **enlarged lymph nodes, liver or splenic changes** in echogenicity, and **measurement of intestinal wall thickness**.

- **Fine-needle aspirates** may be obtained via ultrasound guidance that will **facilitate a definitive diagnosis and staging**.

Endoscopy is also an important diagnostic tool in making a definitive diagnosis, because **multiple samples can be obtained for histopathologic examination**.

Differential diagnosis

The **primary differential** for lymphoma in cats is **severe lymphocytic plasmacytic IBD**, and it is suspected that this may be a precursor lesion to lymphoma in some cats.

Other **extra-intestinal causes of weight loss and vomiting** must also be considered, including pancreatitis, renal or liver disease, hyperthyroidism, diabetes mellitus, etc.

Other less-common neoplastic diseases to consider in cats are mast cell tumors, leiomyosarcomas and carcinoids.

Treatment

Combination chemotherapy with cyclophosphamide, vincristine and prednisolone (**COP protocol**) is the most commonly recommended regimen. Most cats treated with this protocol are expected to live 6–9 months, with 20% living longer than 1 year. Asparaginase or doxyrubicin can be added to increase the remission times or serve as the rescue.

- Cyclophosphamide (300 mg/m² PO q 3 weeks).
- Vincristine (0.75 mg/m² IV weekly for 4 weeks).
- Prednisone (2 mg/kg/day).
- Doxyrubicin (25 mg/m² IV q 3 wk).
- L-Asparaginase (10 000 IU/m² IM).

Other protocols exist for induction, maintenance and rescue, but the reader is referred to oncology texts for additional information.

Supportive care in the form of nutrition is essential for cats with alimentary lymphoma because they tend not to eat and often vomiting precludes oral alimentation.

Placement of **jejunostomy tubes** may be required in these cats.

Prognosis

Guarded to poor. Survival times are shorter for cats with alimentary lymphoma than other forms of lymphoma (e.g. multicentric or mediastinal), primarily because **response to chemotherapy is more variable** with these tumors.

In one recent report, mean survival was 230 days, but median survival was only 50 days.

COLONIC ADENOCARCINOMA*

Classical signs

- Vomiting, weight loss and anorexia are classical signs.
- Hematochezia, tenesmus or large bowel diarrhea occur with a distal location.

Pathogenesis

Adenocarcinoma is the most common tumor of the feline colon and most common non-hematopoietic tumor of the GI tract.

It usually occurs in **old cats (>10 years)** and has a **higher incidence in Siamese cats**.

It most commonly occurs as a solitary lesion causing signs of bowel obstruction due to a large mass or annular growth around the circumference of the bowel.

Malignant behavior with metastasis to regional lymph nodes, mesentery, liver and other abdominal organs is typical of this neoplasm.

However, it **rarely metastasizes to the lungs**.

Clinical signs

Vomiting, weight loss and anorexia are the classical signs.

Hematochezia, tenesmus or large bowel diarrhea are observed the more distal the tumor location.

Some cats may only have **lethargy, decreased appetite or weight loss without GI signs, so history and signalment** (old, Siamese cat) **are important clues**.

Physical examination may reveal an **abdominal mass or abdominal discomfort** upon palpation.

Diagnosis

Careful **abdominal palpation** may reveal a **mass or thickened bowel loop**.

Routine hematology and serum chemistry profile are **often within normal limits in the early stages of disease**.

Late changes may include **hypoproteinemia, hypoalbuminemia, electrolyte disturbances** due to vomiting or elevations in **liver enzyme** activities due to metastasis.

Imaging studies (radiography, **ultrasound**) are useful in identifying the abdominal mass and a preliminary diagnosis can be made via ultrasound-guided **fine-needle aspiration** of the mass in many cases.

Ultrasonography is also especially useful in **assessing regional lymph nodes and liver** for evidence of metastatic disease.

The **definitive diagnosis is obtained by histopathology**.

Endoscopy may be used to obtain biopsies, but **exploratory surgery with resection of the affected area and biopsy of regional lymph nodes or liver is diagnostic, prognostic and therapeutic**.

Differential diagnosis

Other intestinal diseases such as IBD, lymphoma, other tumors, or intussusception may have a similar clinical presentation.

Extra-intestinal diseases should also be considered when the clinical signs are vague. These include pancreatitis, hyperthyroidism, chronic renal failure, hepatic disease and neoplasia in other locations.

Treatment

The **treatment of choice** for colonic adenocarcinoma is **wide surgical excision**, even if the tumor has metastasized, which it usually has at the time of surgery.

Chemotherapy for metastatic disease has not been reported, but would **not be expected to be successful**.

Mean survival time following surgical resection is generally less than one year but this is not correlated with the presence of metastatic disease. Survival time is shorter without treatment.

Extensive surgical removal of the colon will require that the cat be fed a **highly digestible, low-residue diet** to minimize clinical signs of short bowel syndrome.

Prognosis

Long-term prognosis is poor. However, many cats will have lengthy (up to 15 months) periods of good-quality life following surgical resection.

PARASITIC INFECTIONS (*GIARDIA*, *TRITRICHOMONAS*, *CRYPTOSPORIDIA*, *ISOSPORA*, *TOXOPLASMA*, *BALANTIDIUM* AND *TRICHURIS*)*

Classical signs

- Mucus- or blood-streaked, soft (semi-formed) feces.
- Rarely, overt large bowel diarrhea in immunocompromised or very young cats.

Pathogenesis

There are **no major parasitic causes of large bowel diarrhea in the cat.**

However, **occasional infections with *Giardia*, *Tritrichomonas*, *Cryptosporidia*, *Isospora*, *Toxoplasma*, and *Balantidium* may be observed.**

Each of these parasites has a different life cycle and degree of pathogenicity in the host, but **none of these is a strictly large bowel parasite and most cause disease only in the very young, the very old, or sick, debilitated cats** (especially FIV- or FeLV-positive cats).

Whipworm eggs (*Trichuris serrate* and *T. campanula*) are occasionally observed in cats, but do not cause clinical disease and are believed to be either mis-diagnosed (e.g. *Capillaria* spp.) or are present because the cat ingested rodent or canine whipworm eggs in the environment.

Most of these **protozoan parasites (e.g. *Giardia*, *Toxoplasma*, *Cryptosporidia*) are pathogenic (zoonotic) to humans.**

Clinical signs

Most infections of these parasites in cats are **asymptomatic** and are accidentally found on a routine fecal examination.

Tritrichomonas is the exception, as kittens or young cats with *Tritrichomonas* infection will have persistent foul-smelling diarrhea.

Hematochezia, mucoid stools, large bowel diarrhea and flatulence have all been infrequently reported in cats with these parasites, but are **secondary to the primary disease (often FIV).**

Diagnosis

Fecal floatation, direct smears of feces, and fecal cytology have all been used to identify these parasites.

Multiple (at least three) zinc sulfate solutions on consecutive days are best to float *Giardia* and *Cryptosporidia* oocysts.

***Cryptosporidia* are so small** that identification is difficult without **special stains or advanced microscopy techniques.**

Cryptosporidia can also be identified by use of a **fecal ELISA test** (human test but effective in cat feces).

Toxoplasma will float in salt solution but are **very small (< 5 micron)** and may be missed without careful examination of the slide.

Diagnosis of *Tritrichomonas* is best confirmed by PCR testing or culture of the organism in feces using a special technique.

Differential diagnosis

Because these are **rare causes of large bowel disease in cats**, all other, more common, causes of colitis should be ruled out first.

If these parasites are found in the feces of an adult cat that is symptomatic, an immediate search for an **immunosuppressive disease** should be initiated (**ie. rule out FeLV, FIV, FIP, etc.**).

Treatment

***Tritrichomonas*: Ronidazole** (30–50 mg/kg PO q 12h)

***Giardia*: Metronidazole** (10–25 mg/kg PO q 12 h for 5–10 days) or **fenbendazole** (25–50 mg/kg PO q 24 h for 5–7 days)

Isospora: Sulfadimethoxine (25 mg/kg PO q 24 h for 10–14 days)

Cryptosporidia: Azithromycin (5 mg/kg q 24 h PO for 5 days then q 48 h)

Toxoplasmosis: Clindamycin (10–25 mg/kg PO q 12 h) (high dose recommended but often causes GI side effects), or **azithromycin** 5 mg/kg q 24 h for 5 days then q 48 h.

CHRONIC PANCREATITIS

Classical signs

- Clinical signs are vague and non-localizing in cats (e.g. lethargy, anorexia).
- Vomiting or diarrhea are less common.
- Hematochezia or large bowel diarrhea occur more often with chronic pancreatitis.

See main reference on page 318 for details.

Clinical signs

Anorexia and lethargy are the most common signs associated with feline pancreatitis.

Vomiting is less common (< 50% of cats vomit) and thus, dehydration is less common.

Chronic pancreatitis is also associated with vague clinical signs, but **hematochezia or large bowel diarrhea** may be observed.

Diagnosis

There is **no single, definitive test for pancreatitis** in cats.

Non-specific abnormalities on the hemogram may include neutrophilia or mild, non-regenerative anemia.

Serum chemistry abnormalities may include elevated liver enzyme activities and/or hyperbilirubinemia.

Serum amylase and lipase are of no use in the cat for diagnosis of pancreatitis due to false-negative and -positive results.

Loss of visceral detail or increased duodenal gas are sometimes observed on **survey radiographs**, but this is **not consistent**.

Ultrasonographic examination of the pancreas is a good method of detecting pancreatic abnormalities. However, this is still **not a specific or sensitive test for pancreatitis**.

Elevations in serum trypsin-like immunoreactivity (TLI) have been used as a screening test, but caution is advised because the assay often has **false-negative and -positive results**.

Feline pancreatic lipase immunoreactivity (fPLI) is the **most specific and sensitive serum test for pancreatitis** currently available. fPLI is 100% specific for pancreatitis.

fPLI and ultrasound examination, when used together, have a sensitivity of >90%.

PERINEAL HERNIA

Classical signs

- Straining to defecate.
- Large bowel diarrhea.
- Irritation or perineal swelling.

Pathogenesis

Perineal hernia occurs when there is failure of the pelvic diaphragm musculature to support the rectal wall. A peritoneum-lined sac protrudes through the defect and may contain pelvic and abdominal contents. The rectal wall stretches and deviates into the sac.

Feces are retained in the divided section of the rectal wall resulting in straining and difficulty defecating.

Weakness of the pelvic diaphragm musculature and herniation is often idiopathic but may be associated with previous perineal urethrostomy, megacolon, perineal mass or chronic colitis.

Clinical signs

Straining to defecate, constipation or less commonly, large bowel diarrhea, irritation or perineal swelling are all typical signs of perineal hernia.

Usually older cats are affected.

On rectal examination there are impacted feces in a rectal dilation or sacculation, and evidence of a defect in the pelvic diaphragm musculature.

Diagnosis

The diagnosis may be suggested by the **history or appearance of the perineal area and a rectal examination will confirm the problem** in many cases.

In cases where the diagnosis is in doubt, a **barium enema will outline the herniated rectal tissue**.

These hernias are rare in cats compared to dogs.

Treatment

Medical management using low-residue food and fecal softeners (e.g. lactulose) or enemas may help in cats with small hernias.

Surgery is considered the preferred treatment and several herniorrhaphy techniques have been described, although recurrence rates can be high (10–50%). In cats with megacolon, subtotal colectomy may resolve the constipation and tenesmus. Herniorrhaphy can be performed in cats that do not improve with medical therapy.

PERIANAL TUMORS

Classical signs

- Straining to defecate.
- Large bowel diarrhea or constipation.
- Perineal swelling.
- Licking excessively at the perineum.

Pathogenesis

These tumors occur more commonly in **older cats**.

Tumors of the perianal region in cats, unlike those in dogs, are usually **adenocarcinomas**. Perianal tumors are very rare in cats compared to dogs.

Clinical signs

Straining to defecate, large bowel diarrhea, perineal swelling, or constipation may all occur due to large perianal mass(es).

Cats often will lick at the area frequently which may draw attention to the region.

Diagnosis

In the majority of cases, the **presence of a perianal mass** will be the obvious cause of the intestinal disturbance.

Perianal tumors may **metastasize locally** (to regional lymph nodes or bones) **or to distant sites** (liver, lung or abdominal sites) and so, a **routine database, radiographs and ultrasound, and fine-needle aspirates of regional or enlarged lymph nodes should be performed**.

Fine-needle aspirates of the tumor can be used to identify the tumor type prior to surgical biopsy.

Differential diagnosis

The **primary differential** for this problem is **anal sacculitis or abscess**, which are more common problems, but **generally are less likely to cause problems with fecal passage**.

Treatment

Surgical resection of tumor with **wide margins to prevent recurrence**.

Histopathologic examination of the tumor as well as **biopsies of regional lymph nodes** is recommended for **confirmation of the diagnosis** and determination of the **prognosis**.

Fecal softeners (e.g. lactulose or docusate sodium) may be helpful if fecal material is difficult or painful to pass.

PSEUDOMEMBRANEOUS COLITIS (ANTIBIOTIC-INDUCED COLITIS)

Classical signs

- Mucus- or blood-streaked, soft (semi-formed) feces.
- Progression to severe large bowel diarrhea.

Pathogenesis

This disease is **caused by the use of antibiotics** (especially **clindamycin or cephalosporins**) that disturb the

normal bacterial flora of the colon resulting in **overgrowth of antibiotic-resistant, pathogenic species**.

Diarrhea due to clostridial spp. is not uncommon, but it is **usually due to *Clostridium perfringens***. *Clostridium difficile* **are not common inhabitants of the feline colon**, but may populate and overgrow in the right circumstances (primarily chronic antibiotic use).

This is a very **uncommon problem** in cats.

Clinical signs

Mucus- or blood-streaked feces which may progress to **severe large bowel diarrhea**.

In **some cases**, the diarrhea is **poorly responsive to treatment**.

Diagnosis

Historical correlation between the **development of mucoïd diarrhea and the use of antibiotics that have an anaerobic spectrum**.

Confirmation of the diagnosis requires **fecal culture** (requiring special handling) **or colonic biopsies** that confirm the presence of **pseudomembrane formation**.

Fecal analysis for Clostridial toxins A and B is very important for confirmation.

Differential diagnosis

Clostridial enterocolitis due to *Clostridium perfringens* is the primary differential, but **simple diarrhea** due to antibiotic therapy, diet changes or infectious or parasitic agents should be considered carefully.

Treatment

The **choice of antibiotic should be based upon culture results** due to resistance. **Metronidazole** has been used successfully in some cases.

Non-specific therapy for this disorder includes use of a **high-fiber diet** (or addition of insoluble fiber to the diet) **to normalize colonic function** (secretion and motility).

In **severe cases**, **long-term (weeks) antibiotic therapy** will be required to achieve control.

Prevention

Cautious use of antibiotics that have an anaerobic spectrum over a long period (weeks).

COLORECTAL POLYPS

Classical signs

- **Mucus- or blood-streaked, soft (semi-formed) feces.**

Pathogenesis

Benign growths of the colonic epithelium.

Rare in cats, but reported occasionally.

Most are found in the upper duodenum, near the pylorus or in the **ileum or proximal colon**, and **Siamese cats** are over-represented.

Clinical signs

May be clinically silent.

May cause **intermittent large bowel signs**: increased **tenesmus, mucus- or blood-streaked feces, or difficulty in passing feces** (constipation is possible).

Diagnosis

No changes in hematology or serum chemistries will occur.

Contrast radiography or ultrasound examination will delineate them, but **colonoscopy is the best diagnostic method**, and will allow visualization, biopsy and in some cases assist removal (if distal enough).

Differential diagnosis

Other neoplastic diseases of the large bowel: i.e. adenocarcinoma, focal lymphoma, mast cell tumors, carcinoids, etc.

Sliding or intermittent intussusception.

Granuloma due to **fungal or infectious disease** (e.g. FIP).

Treatment

Surgical removal is curative.

Recurrence is unusual.

Prognosis

Excellent.

CONGENITAL MALFORMATIONS (SHORT COLON SYNDROME, VASCULAR ECTASIA, DIVERTICULUM)

Classical signs

- Signs depend on the location of the anomaly.
- Large bowel diarrhea, constipation or abdominal pain (typhilitis).
- Young cats or kittens, and do not worsen with age, except with short colon syndrome.

Pathogenesis

The **etiopathogenesis** of the congenital malformations affecting the large bowel is **unknown**.

The **most frequently reported malformations** affecting the large bowel are **vascular ectasia, short colon syndrome and enterocyst formation**.

Vascular ectasia is a syndrome of **abnormal blood vessel formations** that results in abnormal bowel function (especially motility) due to the lack of a normal blood supply.

Short colon syndrome can be **congenital or iatrogenic** (secondary to surgical removal of the colon due to neoplasia or other disease). Cats with short colon syndrome are **unable to reabsorb water and electrolytes** and thus, are not able to form normal feces without providing very highly digestible diets that reduce the amount of ingesta that reaches the colon.

Diverticular formations are also found, however, they can be **congenital or secondary to chronic disease**.

Many diverticular formations are **incidental findings** and are not associated with abnormal colon function unless they are large or become diseased.

Clinical signs

Large bowel diarrhea and flatulence.

Constipation.

Abdominal pain (due to typhilitis or gas distention).

Diagnosis

These are **rare congenital diseases**.

Kittens are usually presented at just **weeks of age**.

Blood work (CBC, profile) will usually be completely **normal**.

Survey radiographs will **generally not be helpful, except in cases of short colon syndrome**, where the colon may be visibly abnormal.

Contrast radiographs may be **very helpful** in identifying **short colon syndrome**.

Ultrasonography is very useful in identifying an **abnormal enterocyst**, but **colonoscopy or surgical exploration** may be required to make the **definitive diagnosis**.

Differential diagnosis

The differentials are usually limited to **those things causing colonic disease in kittens**, e.g. parasites, infectious, mechanical (foreign objects) and dietary indiscretion or food intolerance.

Treatment

Treatment of **vascular ectasia and enterocysts** is via **surgical resection of the affected area(s)**.

Short colon syndrome must be managed medically by providing a **low-residue diet** (e.g. Hill's i/d diet, Iam's low residue diet or IVD neutral formula), **use of motility-modifying drugs as needed** (e.g. lomotil, loperamide), and **antibiotics when they are indicated**.

Prognosis

The prognosis is **guarded to good, depending on the anomaly** that is present.

Cats with **vascular ectasia or enterocysts** that can be **corrected surgically** have a **very good prognosis**.

Cats with **short bowel syndrome** have a very **guarded prognosis** and will require **life-long therapy**.

35. The constipated or straining cat

Albert E Jergens and Annette Litster

KEY SIGNS

- Reduced frequency of defecation.
- Tenesmus or painful defecation.
- Hard, dry, low-volume feces, sometimes with mucus.

MECHANISM?

- Constipation denotes infrequent or difficult defecation and is a common problem in cats. Straining (tenesmus) occurs when there is ineffectual defecation or urination, or irritation of the bowel or bladder wall.
- Straining may also be associated with conditions affecting the lower urinary tract. Refer to p. @ (The Cat Straining to Urinate).

WHERE?

- Disorders of the large intestine are the most common causes of constipation.

WHAT?

- Constipated cats may have underlying orthopedic or neurologic diseases which cause fecal impaction and clinical signs.

QUICK REFERENCE SUMMARY

Diseases causing a constipated or straining cat

DEGENERATIVE

- **Constipation (including idiopathic megacolon)*** (p 783)**

The hallmarks are reduced, painful, or absent defecation +/- tenesmus. Idiopathic megacolon denotes diffuse colonic dilatation with colonic hypomotility.

- **Dysautonomia (p 792)**

This is a rare cause of constipation, and associated clinical signs include sudden onset of depression and anorexia coupled with a variety of signs including regurgitation, mydriasis, constipation, bradycardia and dysuria. Dysautonomia was of regional importance in the UK in the early 1980s and more recently in the USA.

MECHANICAL

- **Hair matting* (p 789)**

Matting of the hair around the anus with feces is associated with poor grooming, and may cause perianal dermatitis and discomfort with defecation. It may also obstruct fecal passage through the anus. It occurs more often in obese cats, and long-haired cats.

METABOLIC

- **Dehydration and hypokalemia* (p 787)**

Metabolic conditions such as dehydration or hypokalemia can predispose to constipation by reducing fecal moisture and colonic muscle activity. Signs of dehydration, inability to jump, or ventroflexion of the neck may be evident.

NEOPLASIA

- **Neoplasia (p 791)**

Intraluminal or extraluminal tumors may cause mechanical obstruction to the passage of feces. Signs may include straining to defecate and evidence of fresh blood on the feces.

PSYCHOLOGICAL

- **Litter box dissatisfaction* (p 789)**

Litterbox dissatisfaction, caused by poor litterbox hygiene or inadequate litterbox access, may discourage regular defecation and result in constipation.

INFLAMMATION

- **Acute non-specific colitis** (p 786)**

This condition presents with an abrupt onset of large bowel diarrhea which is usually self-limiting. Signs include tenesmus, mucoid feces and hematochezia. Vomiting may occur.

- **Chronic colitis** (p 787)**

Chronic colitis causes hematochezia, large bowel diarrhea, and tenesmus, which are attributable to infectious, inflammatory, neoplastic and benign infiltrative mucosal diseases.

- **Perineal inflammation/infection (p 792)**

Conditions such as perineal abscesses, perianal fistulae and anorectal foreign bodies may cause pain, discouraging regular defecation and lead to constipation and/or tenesmus.

- **Lower urinary tract disease* (p 790)**

Hematuria, strangiuria and pollakiuria caused by lower urinary tract disorders must be differentiated from constipation by history and physical examination.

IATROGENIC

- **Drugs (p 791)**

Drugs such as opioid agonists, cholinergic antagonists, diuretics, phenothiazines and barium sulfate can cause constipation.

TRAUMA

- **Pelvic fractures* (p 788)**

Pelvic fractures may reduce the size of the pelvic canal, causing obstruction. In the acute phase following trauma, painful defecation may lead to constipation.

INTRODUCTION

MECHANISM?

Constipation may be suspected when a cat has chronic difficulty or pain while defecating; defecation is reduced in frequency; or reduced amounts of hard dry feces are passed. The **proximal colon in cats is particularly efficient at water reabsorption**, so prolonged transit times predispose to constipation.

Common signs of constipation include:

- **Reduced or absent defecation.**
- **Marked tenesmus.**
- **Painful defecation may be evidenced by crying out on defecation, numerous aborted attempts to defecate, or prolonged attempts to defecate.**
- **Reduced amounts of hard, dry feces which may have a mucus covering.**
- **Anorexia, lethargy, vomiting and weight loss are systemic manifestations** observed in cats with severe constipation.

Obstipation is the presence of **chronic intractable constipation with massive fecal impaction and inability to defecate**.

Idiopathic megacolon denotes **severe generalized colonic dilatation which is irreversible** and poorly responsive to aggressive medical therapy.

Tenesmus (straining) may also be associated with other colonic disorders that cause inflammation and diarrhea.

Cats with tenesmus may be straining to urinate, and if signs or physical examination findings suggest a urinary tract problem, the reader is referred to page 173 (The Cat Straining to Urinate).

WHERE?

Signs of constipation and straining result from problems involving the following sites:

- **Colonic lumen and mucosa.**
- **Urinary bladder and/or urethra.**

Physical examination (especially abdominal palpation) and history help localize the cause. **Posture** while straining often differentiates a problem with defecation from a urinary tract problem. **Defecation posture is**

a high squat with an arched tail, while urination posture is a low squat with a straight tail.

- Other signs suggesting a urinary tract problem include a small or large firm bladder, normal amounts of fecal material on abdominal palpation, and a history of small amounts of urine being produced associated with tenesmus. The urine may be discolored; typically there is hematuria.

Abdominal radiography and routine urinalysis most readily differentiate constipation from lower urinary tract disorders.

WHAT?

Causes for constipation are diverse and may include **orthopedic, neoplastic, pharmacologic, metabolic and neurologic etiologies** or they may be **idiopathic** in origin.

Abnormal evacuation of feces leads to constipation, colonic impaction and clinical signs.

The most common causes of straining to urinate include lower urinary tract disease or idiopathic cystitis, bacterial cystitis in older cats, neoplasia and uroliths.

Diagnosis of the constipated/straining cat is based on **history, physical examination findings, radiography, urinalysis and histopathology of colonic biopsy specimens.**

DISEASES CAUSING CONSTIPATION OR STRAINING

CONSTIPATION*** (INCLUDING IDIOPATHIC MEGACOLON)

Classical signs

- **Most common in middle-aged male cats, but may occur in any age, or gender.**
- **Reduced, painful, or absent defecation +/- tenesmus.**
- **Feces are hard, dry and low-volume, with or without mucus.**
- **+/- Anorexia, lethargy, weight loss, and vomiting with chronicity.**

Pathogenesis

Etiologies for constipation are diverse. While the majority of cases are idiopathic, pelvic canal stenosis, nerve injury and Manx sacral spinal cord deformity are also regularly diagnosed.

- **Idiopathic megacolon** is likely a **generalized dysfunction of colonic smooth muscle**. The disorder involves a **disturbance in the intracellular activation of smooth muscle myofilaments**, and affects both longitudinal and circular smooth muscle from both the proximal and distal colon. **Histologic evaluation is unhelpful** in the diagnosis of this condition. **Burmese are over-represented** with idiopathic megacolon.
- **Orthopedic causes** for constipation include pelvic fractures and pelvic canal stenosis.
- **Mechanical (extraluminal) obstruction** may be caused by **intra-abdominal tumors**.
- **Anal inflammation** may discourage defecation because of pain.
- **Perineal hair–fecal mats** may impede fecal passage, especially in obese cats that are unable to groom effectively. Long-standing mats are associated with perianal dermatitis which may contribute to the discomfort of defecating.
- **Nerve injury** may manifest as spinal cord injury or sacral spinal cord deformities (e.g. Manx cats). Affected cats usually present with accompanying clinical signs of nerve injury, such as urinary incontinence, poor anal sphincter tone, reduced perineal sensation or poor tail sensation, with reduced motor function of the tail in more severe cases.
- Constipation may be one manifestation of feline **dysautonomia**.

Abnormal evacuation of feces leads to constipation, colonic impaction and associated clinical signs.

Idiopathic megacolon in some cats has been reported in association with either intestinal pyogranuloma due to feline infectious peritonitis virus infection, or intestinal lymphosarcoma. Refer to the main references for these conditions.

Clinical signs

Constipation is most common in **middle-aged male cats**, but may be observed in cats of any age, gender or

breed. Burmese cats are over-represented with idiopathic megacolon.

Reduced, absent or painful defecation occurs over days to weeks.

Tenesmus is frequently noted.

Feces are hard, dry and low-volume, with or without mucus.

Systemic signs including lethargy, dehydration, anorexia, weight loss, vomiting, and mild to moderate mesenteric lymphadenopathy, are often seen in chronic cases.

Occasionally, small amounts of **brown mucoid liquid** are passed and can be **mistaken for diarrhea**.

Diagnosis

Cats with **megacolon** often have a **previous history of episodes of constipation**.

Careful history taking is necessary to identify any underlying causes. Check the frequency of litterbox cleaning, litterbox accessibility, drug administration, diet, and history of previous injuries. **Details of posture while straining are often helpful** in differentiating problems of defecation and urination.

Abdominal palpation reveals firm fecal masses in constipation, or severe, generalized colonic distention with impacted feces if megacolon is present. The perineal area should be checked for inflammation or hair matting.

Abdominal radiography serves to delineate the severity of fecal impaction.

Abdominal ultrasound examination may identify intra-abdominal tumors.

Digital rectal examination should be performed to detect/rule out intraluminal and pelvic causes for constipation.

Neurologic examination is completed to assess caudal spinal cord integrity and function.

- A diminished or absent perineal reflex with reduced anal sphincter tone is found with lower motor neuron lesions involving S₁–S₃ spinal cord segments, or pudendal nerve and/or pelvic nerve disorders.

Serum biochemistry analysis may detect electrolyte disturbances (e.g. hypokalemia) contributing to reduced evacuation of feces.

Differential diagnosis

Constipation can usually be easily differentiated from other causes of straining, such as lower urinary tract disorders, by physical examination.

Treatment

Therapy is dependent on the severity of constipation and the underlying cause. Any underlying causes such as litterbox problems, intraluminal or extraluminal obstructions, orthopedic disorders, anal inflammation or perineal hair matting should be corrected.

Animals with **mild to moderate constipation** may be treated as **outpatients**.

- **Tepid water enemas** (5–10 ml/kg q 8–24 h) or **commercially available pediatric enemas** (Microlax, 1–2 tubes/cat) should be administered as needed to facilitate fecal breakdown and passage.
- **Dietary fiber** serves to enhance fecal bulk, and has laxative effects. These effects are due to increased fecal water content, decreased intestinal transit time and increased frequency of defecation. A number of fiber supplements are available, including **psyllium** (Metamucil, 1–4 tsp mixed with food at each meal), or **wheat bran** (1–2 tsp mixed with food at each meal). Some cats find the sweetness of **canned pumpkin or canned creamed corn** (1–4 tbsp mixed with food at each meal) makes a more palatable fiber supplement.
- **Lactulose** (0.5 ml/kg PO q 8–12 h) is a hyperosmotic laxative which softens feces by reducing water absorption in the colon. **Milk** may be a more palatable alternative, as the lactose in milk is indigestible in most cats, causing it to act as a hyperosmotic agent.
- **Cisapride** (2.5 mg PO q 12 h) is a gastrointestinal prokinetic agent, which stimulates colonic motility from the gastroesophageal sphincter to the descending colon. It is believed to **enhance cholinergic neurotransmission in the gastrointestinal tract via stimulation of enteric neuronal serotonin receptors**. Cisapride may be used alone for the treatment of mild to moderate constipation, or with

lactulose on a daily basis for the prevention of constipation.

- **Emollient laxatives** act as anionic detergents to **increase the miscibility of water and lipid in the bowel contents**, enhancing lipid absorption but impairing water absorption. Dioctyl sodium sulfosuccinate (Colace, 50 mg PO q 24 h) and dioctyl calcium sulfosuccinate (Surfax, 50 mg PO q 12–24 h) are two examples of this class of drugs. **Care should be taken that the cat is well hydrated prior to the administration of these agents**, as they retard the absorption of water from the intestine.
- **Lubricant laxatives** act by easing fecal passage and decreasing water absorption from the colon by creating a coating layer on the mucosa. These agents (e.g. mineral oil or petrolatum products such as Laxatone or Kat-A-Lax) are **suitable only for mild constipation**, or for regular use to prevent constipation in mildly affected cats.

If there is **obstipation**, **manual extraction of feces** under general anesthesia is usually required to treat obstipation, as the condition is too severe to respond to enemas alone.

- **Balanced fluids** (e.g. Lactated Ringer's Solution, Plasma-Lyte A or Normisol-R) should be administered to rehydrate and correct fluid deficits. This is particularly important in older cats or if general anesthesia is required for treatment. An **endotracheal tube** should be placed to prevent inhalation pneumonia as manipulation of the colon may induce vomiting.
- After the distal colon has been lubricated by a warm water or saline infusion, forceps are inserted and used to carefully grasp or break down fecal material. A **constantly twisting motion**, clockwise and counterclockwise, should be used **to prevent the forceps accidentally grasping the colonic mucosa**. Alternatively, a spoon-shaped instrument, specifically designed for the purpose, may be used to gradually break down the fecal mass, while connected to a faucet to provide a steady trickle of warm water into the colon.
- **If any bleeding is noted on manual fecal extraction, the procedure should be aborted** to minimize the risk of intestinal perforation or devitalization of the colonic mucosa. It **may be preferable to perform manual extraction over**

short periods on consecutive days, rather than risk prolonged anesthesia and intestinal mucosal damage.

Severe constipation or megacolon is usually **non-responsive to aggressive medical management**. **Colotomy** may be required if manual fecal extraction is unsuccessful. Recurrent severe obstipation, refractory to dietary therapy, enemas or manual extraction, may be treated by subtotal colectomy.

Assessment of **serum electrolyte status** and administration of intravenous fluid therapy are particularly important in severely affected cats and in older cats. **Subtotal colectomy** is the preferred therapy in severe chronic constipation or megacolon.

While subtotal colectomy is a major surgical procedure, it provides a **permanent cure for idiopathic megacolon**. Postoperative diarrhea should be expected and usually lasts for about 2 weeks, although it may persist for 4–6 weeks in some cases. Post-operative diarrhea is less likely to occur if the ileocolic junction is not removed during the surgical procedure (i.e. subtotal colectomy rather than total colectomy).

Prognosis

Generally **good to excellent in cats with mild to moderate constipation**.

Cats with **severe constipation or megacolon** have a **favorable long-term prognosis following total or subtotal colectomy**.

ACUTE NON-SPECIFIC COLITIS**

Classical signs

- Acute onset of large bowel diarrhea (tenesmus, mucoid feces, hematochezia) predominates.
- +/- Vomiting with diarrheic episodes.
- Signs are usually mild and often self-limiting.

See main reference on page 762 (The Cat With Signs of Large Bowel Diarrhea) for details.

Pathogenesis

Acute colitis may be caused by **hair ingestion, infectious agents, dietary factors (indiscretion, additives) and/or parasites**.

The **cause is rarely identified** as most animals **spontaneously resolve or respond to symptomatic therapy**.

Clinical signs

There is an **acute onset of large bowel diarrhea** characterized by small-volume, high-frequency feces, sometimes accompanied by mucus or blood.

Straining to defecate is a common clinical sign.

Vomiting may accompany diarrheic episodes.

Signs are usually **mild and often self-limiting**.

Diagnosis

An **underlying cause** for gastrointestinal signs is **rarely identified**.

Signs tend to be **self-limiting** or they **respond to symptomatic therapy in 3–5 days**.

Perform **fecal flotation and direct fecal examinations** for intestinal parasites.

Fecal cytology is useful in identification of infectious agents (bacteria) and leukocytes may be seen with acute mucosal inflammation.

Culture feces if infectious (bacterial) colitis is suspected.

Differential diagnosis

The history and clinical features of acute non-specific colitis make most other diseases unlikely.

Treatment

Provide intravenous or **subcutaneous fluids** lactated ringers solution if dehydration is evident.

Feed **small but frequent meals** of an easily digested food.

Administer an appropriate **broad-spectrum anthelmintic** to eliminate parasitic infestations.

Antibiotics are **only** used in culture-proven cases of infectious colitis.

If the cat is long-haired or over-grooms, consider **clipping the coat** if other causes of colitis cannot be identified.

Prognosis

The prognosis for full recovery is **excellent** in most instances.

CHRONIC COLITIS** (INFECTIOUS, NEOPLASTIC, AND BENIGN INFILTRATIVE MUCOSAL DISEASE)

Classical signs

- Chronic large bowel diarrhea (tenesmus, small-volume mucoid feces, hematochezia).
- +/- Systemic signs (lymphadenopathy, anorexia, weight loss, +/- fever) if infectious cause.

See main reference on page 762 (The Cat With Signs of Large Bowel Diarrhea) for details.

Clinical signs

Hematochezia, small-volume, high-frequency feces, and straining are observed.

Systemic signs (lymphadenopathy, anorexia, weight loss, +/- fever) may be seen with infectious viral diseases (FeLV and FIV) and systemic mycoses.

Cats with **benign infiltrative mucosal disease** (e.g. lymphocytic-plasmacytic colitis) rarely have systemic signs except with concurrent small intestinal involvement.

Diagnosis

Laboratory testing detects evidence of infectious viral diseases.

Screen susceptible cats for **FeLV antigenemia and serum antibodies to FIV**.

Mucosal biopsies are required for definitive diagnosis of neoplastic, mycotic and benign infiltrative mucosal diseases causing chronic colitis.

Differential diagnosis

Chronic colitis should be **differentiated from more acute causes of tenesmus**, such as acute non-specific colitis, **and conditions causing small intestinal diarrhea**, because some causes of chronic colitis also involve the small intestine, resulting in signs of both large and small bowel involvement.

Treatment

Treatment for this condition is **based on treating the primary cause**. Lymphocytic-plasmacytic colitis may require a **food trial** to investigate a dietary etiology, combined with **oral prednisolone therapy at immunosuppressive dose rates** (2–4 mg/kg/day).

DEHYDRATION AND HYPOKALEMIA*

Classical signs

- Skin tenting, tacky mucus membranes, increased plasma protein and PCV.
- ± Muscular weakness, reluctance to jump, ventroflexion of the neck associated with hypokalemia.
- Reduced, painful or absent defecation +/- tenesmus.
- Feces are hard, dry with or without mucus.
- +/- Anorexia, lethargy, weight loss and vomiting depending on the cause.

See main reference on page 557 (The Polycythemic Cat (for dehydration)) and page 945 (The Cat With Generalized Weakness) and page 893 (The Cat With Neck Ventroflexion) for hypokalemia)) for details.

Pathogenesis

Both dehydration and hypokalemia may be caused by either **reduced intake** in anorexia, or by **increased losses, or by a combination of both**. This most commonly occurs in **chronic renal failure** in older cats. Other causes of **vomiting and/or diarrhea** may also result in dehydration and/or hypokalemia and constipation.

Dehydration exacerbates the already efficient reabsorption of water from the feline colon, and hypokalemia results in weakness of the colonic smooth muscle, slowing the

passage of fecal material to the rectum. The **increased fecal volume** that occurs over the extended time in the colon, and **fecal dryness**, worsen the condition.

The differential diagnosis of dehydration depends on the **primary cause**. Hypokalemia may be caused by any condition which causes **reduced intake from anorexia**, or **increased losses via the urinary or gastrointestinal tract**. Conditions commonly associated with increased loss of potassium include **chronic renal failure**, and any causes of **vomiting and/or diarrhea**.

Clinical signs

Depending on the severity of dehydration, signs progress from **subtle loss of skin tenting** to **dry mucous membranes** and **sunken eyeballs**. There are **signs of shock** in advanced cases.

Hypokalemic cats are **weak**, and may show a **reluctance to jump** or climb stairs, **ventroflexion of the head** and **poor limb tone**.

Reduced, absent or painful defecation may be present, and **tenesmus** is frequently noted.

Feces are hard, dry and may or may not be covered in mucus.

Systemic signs including lethargy, anorexia, weight loss and vomiting may be present, depending on the underlying cause.

Diagnosis

Clinical signs of **loss of skin elasticity and tacky mucous membranes**, accompanied by **elevations in PCV and total protein** are indicative of dehydration, together with evidence of **constipation (hard, dry feces and tenesmus)**.

Serum potassium concentration is low, determined by in-house or laboratory analysis.

Differential diagnosis

Severe constipation or megacolon can result in depression, anorexia and dehydration. Constipation resulting from dehydration and hypokalemia is more likely when an underlying disease with the potential to cause dehydration and hypokalemia is detected, and the constipation or megacolon is not severe.

Treatment

Treatment of dehydration is by **administration of fluid therapy** to correct hydration, electrolyte and acid–base status.

Potassium deficits can be corrected by **oral and/or IV supplementation**, depending on the severity of the problem. Fluid therapy may initially worsen hypokalemia because of expansion of blood volume and diuresis, so it may be beneficial to supply oral K⁺ concurrently. **Oral potassium should ideally be supplied as gluconate or citrate**, as KCl may worsen concurrent metabolic acidosis. Please refer to the main reference for correction of K⁺ deficits in dehydration on page 557.

Maintenance fluid rates are 70 ml/kg/day. **Fluid deficits and ongoing losses** should be estimated and added to maintenance rates so that the deficit can be corrected over the first 12–24 hours. Please refer to the main reference for treatment of dehydration on page 558.

Prognosis

The prognosis for constipation from dehydration and hypokalemia depends on the **primary cause** of the problem.

PELVIC FRACTURES*

Classical signs

- Inability to walk and severe pain on palpation of the pelvic area in a cat with a recent history of trauma.
- Dry hard feces and straining to defecate in a cat with evidence of healed pelvic fractures.

Clinical signs

Cats with recent pelvic fractures may be able to sit up, but are **rarely able to walk normally**. Attempts at abdominal and especially pelvic palpation elicit a **pain response**. When the tuber ischii are palpated from behind, there may be asymmetric movement in an anteroposterior direction. Attempts to defecate may be absent.

Cats with **old healed pelvic fractures** may have asymmetry on pelvic palpation, and differences in length of

pelvic limbs when they are compared with each other in full extension.

Constipation may result either from **pain associated with defecation, or obstruction from a narrowed pelvic cavity.**

Diagnosis

The pelvis should be **radiographed in two views** (lateral and DV or VD) to detect fractures and gauge pelvic narrowing.

Differential diagnosis

Any conditions that cause pain in the hindquarters and lumbosacral region, such as **severe bruising**, should be considered.

Conditions causing hindlimb paresis or paralysis may present as a refusal to move, as do pelvic fractures. A physical and **neurological examination** should be performed to differentiate these conditions.

Treatment

Pelvic fractures **often require surgical repair**, but depending on the position and degree of distraction of the bone fragments, **some may heal with extended cage rest** (4–6 weeks).

Laxatives and/or dietary fiber supplements should be provided to produce a soft stool that is easy to pass. See page 785 (Constipation) for details.

HAIR MATTING*

Classical signs

- Hair is matted with feces over the perineal region, usually in a long-haired or obese cat.
- Constipation or obstipation.

Clinical signs

Long-haired cats in unkempt condition may be presented with hair matted with feces over the perineal region. An **underlying cause** should be established for this lack of grooming, such as **inability to reach the perineal region** because of severe obesity, or an underlying condition causing **diarrhea or lethargy**, because

cats should normally be able to groom well enough to prevent this happening.

Morbidly obese cats frequently are unable to groom effectively around the anal region and may develop mats of feces adhered to hair. These result in perianal dermatitis if they are not removed. The discomfort and obstruction to defecation promote constipation.

Concurrent signs of constipation or obstipation are present including tenesmus and infrequent passage of hard dry feces.

Diagnosis

The diagnosis is made by an **inspection of the perineal region**. More information should be obtained to investigate an underlying cause by performing a **general physical examination and neurological examination**, and if indicated, **more specific blood and/or fecal tests**. The perineum should also be clipped and inspected.

Differential diagnosis

This condition is **self-evident on perineal examination**, but should be differentiated from **other conditions that cause inability to groom and reluctance to defecate**, such as pelvic fractures and perineal abscesses.

Treatment

The **perineum should be clipped and cleaned**. **Corticosteroid/antibiotic cream** may be applied morning and night if there are signs of perineal inflammation. Purulent skin infections should be treated with **oral antibiotics** such as doxycycline (5 mg/kg PO q 12 h 8 days).

Any **underlying cause** should be **treated appropriately**.

LITTERBOX DISSATISFACTION*

Classical signs

- Cats may urinate and defecate in inappropriate places.
- History of poorly cleaned litter box or insufficient litter boxes for the number of cats.
- Straining, hard dry feces.

Clinical signs

Litterbox dissatisfaction often results in **both defecation and urination in inappropriate places**.

Because of reluctance to use the litter tray, the cat may defecate infrequently, predisposing it to **chronic constipation**.

On close questioning of the owner, **litterbox hygiene may be unacceptable**. Alternatively, the **position of the litterbox may be unacceptable to the cat** because of noise or accessibility by other animals.

Diagnosis

The **owner must be questioned closely but tactfully** about the **frequency and method of litterbox cleaning**, and the **position of the litter tray**, especially in relation to noise levels and accessibility by other animals. **Type of litter material** and the cat's previous history in this regard should also be determined, as some cats do not accept a change in litter material readily. A **house call** may be required to fully assess the situation.

Differential diagnosis

Litterbox dissatisfaction must be differentiated from **other conditions causing reluctance to defecate**, such as painful pelvic or perineal conditions.

Treatment

The litterbox must be placed in a **quiet, secluded area easily accessed by the cat**, but not by other animals such as dogs. There should be **at least one litter tray provided per cat in the household**. The **litter should be completely changed and the tray scrubbed every day**. Just a **small amount** of the type of litter acceptable to the cat should be placed in the tray, **to facilitate frequent cleaning during the day**. Automatic litter trays may also be helpful.

LOWER URINARY TRACT DISEASE*

Classical signs

- Pollakiuria, dysuria and hematuria if non-obstructed.

Classical signs—Cont'd

- Affected cats may urinate in inappropriate places.
- Anorexia, weakness and anuria with urinary obstruction.

See main reference on page 176 (The Cat Straining to Urinate) for details.

Clinical signs

Pollakiuria, hematuria, stranguria and inappropriate urination are the most common signs. The bladder is typically small on palpation.

Anorexia, depression, vomiting and anuria occur with **urinary obstruction**. Typically the bladder is **distended and firm on palpation**.

Diagnosis

The diagnosis of non-obstructive LUTD is often based on **relevant history and a normal physical examination**. The majority (55–69%) of cats with signs of lower urinary tract disease have **idiopathic cystitis**; some have **struvite or calcium oxalate uroliths** (20%); and the remainder have a variety of conditions including anatomical defects, urethral obstruction, tumors and bacterial infection.

Urinalysis reveals hematuria, and is usually sterile. Depending on the cause, struvite crystalluria, bacteria or neoplastic cells may be evident.

A diagnosis of **obstructive LUTD** is based on history and palpation of a **turgid, distended bladder**, which is difficult or impossible to express. Radiography, including contrast radiographs, and ultrasonography will help to identify uroliths, neoplasia, anatomical defects and urethral obstruction.

Differential diagnosis

Distinguish LUTD from **other causes of straining associated with the gastrointestinal tract**.

Treatment

Non-obstructive LUTD generally resolves spontaneously or with symptomatic therapy in **5–7 days**.

- Modify the **diet** to minimize urine concentration by using canned food or add water to dry food. If urine pH is > 6.5 and there is struvite crystalluria, maximize urine acidity, and minimize magnesium intake using a diet designed to reduce struvite formation.
- Amitriptyline (2.5–12.5 mg/cat PO q 24 h) may be effective in reducing clinical signs in cats with idiopathic cystitis.
- Empirical use of antibiotics, anti-inflammatory agents and antispasmodics is **controversial**.

Obstructive LUTD is a medical emergency.

- Therapeutic strategies are directed at **relief of the obstruction and supportive therapy as needed. For prevention, use specific diets for struvite and calcium oxalate uroliths, and maximize dietary water intake.**

See a detailed discussion on obstructive LUTD see page 179 (The Cat Straining to Urinate).

NEOPLASIA

Classical signs

- ± Palpable abdominal mass.
- Straining, hard, dry feces.

Clinical signs

Abdominal neoplasms may obstruct the passage of feces along the large intestine.

Signs of neoplasia, such as **weight loss and a palpable abdominal mass**, may accompany the clinical signs of constipation and straining.

An abdominal mass may be palpable.

The abdominal neoplasms that have the potential to cause constipation because of their anatomical position and prevalence in cats are **lymphosarcoma** of the intestine or abdominal lymph nodes, **intestinal adenocarcinoma** and intestinal mast cell tumor.

Diagnosis

Abdominal neoplasms are most readily diagnosed by **abdominal ultrasound** followed by **fine-needle aspirate biopsy or surgical biopsy and histopathology**.

Abdominal radiographs may also be useful in visualizing the mass. The obstruction may be caused by **intraluminal or extraluminal masses**.

Differential diagnosis

Abdominal neoplasia must be differentiated from **other causes of abdominal masses** such as an **obstructed bladder or trichobezoars** (hairballs). This can be done by **abdominal ultrasonography or radiographs**, and clinical signs.

Treatment

Treatment of abdominal neoplasia **depends on the type of tumor identified on histopathology. Surgical excision** should be performed, sometimes followed by a **chemotherapeutic protocol**, depending on the histopathological diagnosis.

DRUGS

Classical signs

- History of drug use, such as opiates or kaolin/pectin.
- Signs of constipation.

Clinical signs

There are signs of constipation, such as **reduced frequency of defecation, and straining**, with an **appropriate drug history**, such as the administration of **opiates or kaolin/pectin**.

Overzealous use of **furosemide** promotes dehydration which predisposes to constipation.

Diagnosis

The diagnosis is made by a **thorough drug history** and **evidence of constipation** on abdominal palpation or radiographs.

Differential diagnosis

Drug-related causes of constipation should be differentiated from **other causes of constipation that do**

not have overt accompanying clinical signs on physical examination, such as idiopathic megacolon, acute or chronic colitis, and litterbox dissatisfaction. This is done by taking a **thorough drug and litterbox history**.

Treatment

The condition **resolves once the causative drug is withdrawn**.

PERINEAL INFLAMMATION/INFECTION

Classical signs

- History of pain or sensitivity in the perianal region or evidence of perianal wound or abscess.
- Signs of constipation.

Clinical signs

Cats are presented with a history of pain or sensitivity in the hindquarters, and sometimes a reluctance to sit or an unusual sitting posture. **On inspection of the perineum**, there may be hair loss and/or matting, and wounds or abscessation. Sometimes, an abscess is associated with one of the anal sacs.

Signs or history of constipation are present because pain associated with defecation promotes fecal retention.

Diagnosis

The condition is self-evident, but in some cats, **heavy sedation or general anesthesia may be required to thoroughly inspect the area**.

Differential diagnosis

Perineal inflammation or infection should be differentiated from **other conditions causing matting of the perineal hair**, such as chronic diarrhea or conditions causing poor grooming. This is done by performing a **thorough physical examination including the perineal region**.

Treatment

The **perineal area should be clipped and cleaned**. Wounds and/or abscesses should be **debrided and flushed with saline or an aqueous iodine solution**. Feces should be kept soft by the use of **laxatives and/or dietary fiber supplements** until healing has occurred. See page 785 (Constipation (including idiopathic megacolon)).

Oral antibiotics, such as doxycycline (5 mg/kg q 12 h 8 days) should be prescribed.

DYSAUTONOMIA

Classical signs

- Mostly young adult cats (< 3 years of age).
- Acute onset of depression and anorexia over 48 h.
- Constellation of signs including regurgitation, constipation, mydriasis and dry eyes.
- ± Protrusion of the third eyelids, bradycardia and dysuria.

Pathogenesis

Dysautonomia is an **idiopathic condition** characterized by **widespread degeneration of the autonomic ganglia**.

The condition was originally reported in the **UK and Europe**, but is rarely recognized at this time. There are rare reports of affected cats in the **USA**. While some of these cats were imported from the UK, a small number were bred in USA.

Recent evidence suggests that *Clostridium botulinum* **type C neurotoxin** may be involved. The toxin was detected **in the feces or ileum contents** in affected cats, and also in their **dry food**, but not in healthy control cats. Fourteen weeks after the outbreak, IgA antibodies to the toxin and organism were significantly higher in the feces of affected cats compared to unaffected cats.

Both sympathetic and parasympathetic nervous systems are affected.

The **predominance of gastrointestinal signs** relates to failure of parasympathetic stimulation of esophageal, gastric and colonic motility.

Loss of autonomic control to the eye and heart result in dilated fixed pupils and a fixed heart rate.

Tenesmus is attributable to **constipation and/or dysuria**.

Clinical signs

Dysautonomia is primarily seen in **young cats (< 3 years old)**.

Outbreaks in multicat households and single isolated cases have been reported.

Signs often develop **acutely** over 48 h, with nearly all cats **showing depression** and **anorexia**. In some cats, signs develop over several weeks, and weight loss may be evident.

Regurgitation associated with megaesophagus, vomiting, constipation, weakness and dry mucous membranes of the mouth, nose and eye, are the most commonly reported clinical signs.

Pupils are dilated and fixed, but the cat is visual. There is **protrusion of the third eyelids** in more than 90% of affected cats, and the eyes appear dry.

Bradycardia of 90–120 beats per minute occurs in about 60% of cats.

Loss of anal tone and fecal incontinence may be evident.

Dysuria and a distended bladder are less common signs. Urinary incontinence may also occur.

Occasionally **constipation or obstipation is the major presenting sign**, and the other signs are less obvious.

Diagnosis

A presumptive diagnosis is usually made based on the **characteristic clinical presentation**.

Survey and/or contrast radiography demonstrate **megaesophagus, delayed gastrointestinal transit and/or bladder distention**.

Confirmation of **abnormal autonomic function tests** may be pursued if indicated. **Ocular (pupillary) response tests** to 0.1% pilocarpine and 0.25% physostigmine may be performed.

- **Pilocarpine** is a direct-acting parasympathomimetic agent, which when applied topically will result in **miosis and retraction of the third eyelid**

to a normal position in a cat with dysautonomia, but will have no effect on a normal cat.

- This results from the phenomenon of **denervation hypersensitivity** in the dysautonomic cat, causing an **enhanced response to direct-acting agents**.

- By contrast, **topical physostigmine** is an indirect-acting parasympathomimetic agent, which acts by inhibiting cholinesterase to prevent local degradation of acetylcholine, causing **rapid miosis in a normal cat, but no response in a cat with dysautonomia**.

Determination of **plasma and urinary catecholamine concentrations** may also be useful. Plasma epinephrine and norepinephrine concentrations and urinary catecholamine levels are **reduced in cats with dysautonomia compared to normal cats**.

Differential diagnosis

The clinical features of classical feline dysautonomia make **most other diseases unlikely**.

Atypical cats may present with constipation or obstipation as the major sign. Careful physical examination, and an index of suspicion for dysautonomia are required to make a diagnosis in these cats.

Treatment

Treatment is **supportive but palliative** in most instances. Approximately 20–40% recover with supportive therapy. Recovery is over 2–12 months, and may not be complete.

Correct dehydration if present.

Prolonged nutritional support should be provided via parenteral or enteral means if there is persistent vomiting or regurgitation.

Parasympathomimetic drugs may be administered to improve oronasal secretion, and treat the ocular manifestations of the condition, especially decreased lacrimation.

- **Pilocarpine drops (0.25–1% solution 1 drop q 6–8 h).**
- **Physostigmine drops (0.5% 1 drop q 12 h).**

Metoclopramide (Reglan, 0.2–0.4 mg/kg PO or SC q 8 h) enhances gastrointestinal motility. The aim is

to decrease esophageal dilation and increase gastric emptying, and hence reduce vomiting and regurgitation.

- **Cisapride** (Propulsid, 2.5–5 mg/cat q 8–12 h) is thought to be more effective than metoclopramide, and can be combined with metoclopramide to improve gastric emptying and small intestinal motility. Cisapride is indicated in cats with esophagitis from vomiting. Cisapride is currently unavailable in the USA. Nizatadine (2.5–5 mg/kg PO once daily) or ranitidine (1–2 mg/kg PO q 8–12 h) may be used instead as colonic prokinetic agents.

Dysuria, urinary bladder emptying, and gastrointestinal motility may be improved with **bethanecol** (2.5–5.0 mg PO q 8–12 h, or 0.0375 mg/kg SC q 8–12 h). Start with the lower dose and increase if necessary, but beware of adverse effects such as bradycardia and arrhythmias).

Relieve constipation using **laxatives and enemas**. See page 785 (Constipation (including idiopathic megaesophagus)).

Manual emptying of the bladder and colon may be required if drug therapy is ineffective. Urine should be monitored for bacterial infection, and infection treated promptly.

Prognosis

Initial severity of clinical signs is not necessarily correlated with survival, and **response to treatment is a better indication of prognosis**.

The prognosis is **guarded to poor**, especially in cats with megaesophagus. If cats continue to regurgitate fluids after 1–2 weeks of treatment, consider euthanasia.

The mortality rate is approximately 60%, and surviving cats may have residual signs.

PART 10

Cat with signs of neurological disease

36. The cat with seizures, circling and/or changed behavior

Andrée D Quesnel[†] and Joane M Parent

KEY SIGNS

- Compulsive circling without a head tilt or loss of balance, accompanied by mental confusion.
- Personality changes, dementia, depression, staring into space, confusion, pacing, head pressing, frantic vocalization, aggression or running fits.
- Loss of consciousness, generalized, symmetrical and usually violent tonic and/or clonic motor activity resulting in complete recumbency, often with thrashing and limb paddling, accompanied by jaw champing, facial twitching and autonomic signs (e.g. mydriasis, hypersalivation, piloerection, micturition).
- Generalized seizures may be preceded or followed by localizing or lateralizing signs.
- Partial seizures have localizing signs to one part or side of the body, or are generalized but do not cause lateral recumbency.

MECHANISM?

- **Seizures** occur when a forebrain lesion irritates the surrounding neurons or when there is diffuse neuronal hyperexcitability as a result of a genetic predisposition (primary epilepsy), metabolic disturbance (e.g. hypoglycemia) or intoxication.
- **Circling** may occur with forebrain disease and is compulsive and obsessive in nature.
- **Changed behavior** arises from intellectual dysfunction, psychic perturbations, learning disabilities and memory losses.

continued

continued

WHERE?

- Most cats with seizures, compulsive circling or changed behavior from neurological disease have a **forebrain (thalamocortex) lesion**.

WHAT?

- Seizures are most often associated with tumors, encephalitides and inactive lesions (e.g. glial scar), while extracranial causes (metabolic and toxic) and idiopathic epilepsy are rare.
- Compulsive circling is caused by any kind of lesion located in the frontal lobe or rostral thalamus, although trauma, tumors and ischemic encephalopathy are the most common causes. Circling is usually toward the side of the lesion.
- Changed or abnormal behavior usually consists of subtle personality changes, and is most often associated with tumors, head trauma, ischemic encephalopathy, congenital and inherited forebrain anomalies, hepatic encephalopathy, feline infectious peritonitis, and feline immunodeficiency encephalopathy.

QUICK REFERENCE SUMMARY

Diseases causing seizures, circling and/or changed behavior

DEGENERATIVE

- **Likely symptomatic epilepsy*** (p 800)**

Recurrent seizures typically beginning as single seizures at intervals of several weeks to months. Frequency may remain low or progressively increase over time. Seizures are partial in onset (\pm aura, unilateral or localized motor activity, \pm localized post-ictal motor deficits) with or without secondary generalization (to violent tonic-clonic motor activity involving the whole body) which may obscure the partial signs.

- **Feline ischemic encephalopathy*** (p 804)**

Peracute onset of unilateral forebrain signs (mental depression and confusion, compulsive circling, hemiparesis) and rarely, severe cluster seizures or status epilepticus. Personality changes and/or post-ischemic epilepsy may be the only manifestation of the milder atypical form.

- **Cerebrovascular accidents** (p 808)**

Peracute onset of focal cerebral signs attributable to the forebrain (confusion, circling, pacing) or brainstem (depression, head tilt, loss of balance, nystagmus, facial paresis) or cerebellum (hypermetria, intentional tremors). Occasionally, seizures occur either as immediate cluster seizures or status epilepticus, or later as secondary epilepsy.

ANOMALY

- **Congenital and inherited forebrain anomalies*** (p 805)**

Developmental abnormalities, such as mental retardation, learning disability or loss of training are often evident historically in kittens and young adult cats (< 2 years old) presenting with abnormal mentation and behavior, central visual deficits and occasionally, secondary epilepsy.

METABOLIC

- **Hepatic encephalopathy*** (p 806)**

Episodes of mental alteration including depression, confusion, agitation, dementia or stupor occur together with bizarre behavior, hypersalivation and rarely, seizures. Mostly in young animals (< 1–2 years of age) with congenital portosystemic shunt.

- **Hypoglycemia** (p 809)**

Mental confusion, muscles tremors, weakness, ataxia and occasionally, seizures or coma. Typically, there is history of a diabetic cat receiving insulin therapy or hypoglycemic drugs.

- **Hypocalcemia* (p 817)**

Progressive neuromuscular hyperexcitability evidenced as muscle fasciculation, tremors or generalized tetany. Rarely culminates in terminal convulsive status epilepticus.

- **Uremia (p 819)**

CNS depression; occasionally, seizures. Typically, there are other signs of severe acute or chronic renal failure, for example anorexia, vomiting, dehydration, polydipsia, polyuria or anuria.

NEOPLASTIC

- **Forebrain tumors** (p 810)**

Typically middle-aged and older cats with progressive focal forebrain signs such as personality changes, mental depression, confusion, pacing, compulsive circling and subtle hemiparesis. Seizures may also occur.

NUTRITIONAL

- **Thiamine deficiency*** (p 808)**

Central vestibular signs (head tilt, loss of balance), mydriasis, spasmodic ventroflexion of the neck with whole-body contortions, which may be misinterpreted as seizures. Terminally, opisthotonos, coma and death.

INFLAMMATORY

- **Feline non-suppurative meningoencephalitis*** (p 803)**

Focal or multifocal neurological signs attributable to any portion of the CNS (hindlimb paresis and ataxia, head tilt and loss of balance, seizures) ± systemic (fever, inappetence, lymphadenopathy) and/or ocular (chorioretinitis) signs.

INFECTIOUS: VIRAL

- **Feline infectious peritonitis** (p 811)**

CNS signs (typically head tilt, balance losses, intentional tremors) accompanied by systemic (fever, lethargy, inappetence, weight loss) ± ocular signs (anterior uveitis, chorioretinitis) in cats usually younger than 3 years of age.

- **Rabies (p 819)**

Variable prodromal signs progressing often to a furious phase characterized by vicious and aggressive behavior +/- dysphagia, paralysis, convulsions, coma and death.

continued

continued

- **Feline immunodeficiency virus encephalopathy (p 819)**

Usually asymptomatic, but may cause subtle and non-specific behavioral changes such as depression, social withdrawal and roaming.

PROTOZOAL

- **Toxoplasmosis** (p 815)**

Focal or multifocal CNS signs are rare signs accompanying the more common systemic signs such as fever, or dyspnea or ocular manifestations (anterior uveitis, chorioretinitis) of the disease.

FUNGAL

- **Cryptococcosis** (p 812)**

Cerebral signs such as depression, circling and ataxia are often accompanied by chronic nasal discharge, cutaneous nodules or ulcers, or ocular signs including chorioretinitis, retinal detachment and panophthalmitis.

IDIOPATHIC

- **Idiopathic epilepsy* (p 816)**

Rare in cats and occurs as recurrent generalized motor seizures starting with single seizures at several week intervals in a young adult animal that has no other neurological signs or deficits.

TRAUMA

- **Head trauma (p 806)**

Peracute onset of cerebral signs such as confusion to dementia, pacing, circling or hemiparesis. Immediate onset of seizures and/or post-traumatic epilepsy may occur.

TOXIC

- **Intoxications** (p 812)**

Typically present with signs of depression or stimulation of the CNS (depression, agitation), together with autonomic system signs (miosis, hypersalivation) and neuromuscular signs (weakness, muscle tremors). Occasionally, convulsive status epilepticus.

INTRODUCTION

MECHANISM?

Seizures are generated by paroxysmal excessive discharge of thalamocortical neurons which are rendered focally or diffusely hyperexcitable by several mechanisms:

- **Structural brain lesions**, either active (e.g. encephalitis, tumor) or inactive (e.g. glial scar), irritate the surrounding neurons and transform them into transient or permanent epileptic foci; some areas of the brain are more likely to generate seizures (e.g. frontal and temporal lobes) than others (e.g. occipital lobe).

- In **idiopathic epilepsy**, no causes other than a genetic predisposition underlie the intrinsic neuronal disturbances.
- **Extracranial causes** of seizures (metabolic and toxic) diffusely affect the brain.

The clinical appearance of seizures varies a great deal, depending on the origin and extent of spreading of the seizure discharge within the brain.

Primary generalized seizures have a diffuse onset within both cerebral hemispheres.

- They manifest with a complete loss of consciousness and generalized, symmetrical and usually violent tonic and/or clonic motor activity that results in complete recumbency often with thrashing and limb pad-

dling. This is often accompanied by jaw champing, facial twitching and autonomic signs (e.g. mydriasis, hypersalivation, piloerection, micturition).

- In partial (focal) seizures with secondary generalization, the seizure is preceded by behavioral change (aura) or localized or lateralized motor signs or followed by motor deficits.

Partial (focal) seizures have a focal onset in one cerebral hemisphere and a limited propagation within one or both hemispheres.

- They manifest with variable degrees of alteration of consciousness ranging from normal to totally absent awareness and responsiveness.
- **Partial (focal) seizures have motor signs that may be either lateralized** to one side of the body, **localized** to one part of the body, or may even be **generalized** but not violent enough to cause complete recumbency (e.g. mild tremors of the whole body).
 - **Lateralized signs** include unilateral facial twitching, tonic or clonic movements of one or both limbs on one side, and spasmodic turning of the head to one side.
 - **Signs localized to one part of the body** include hindlimb weakness causing difficulty or inability walking, and bilateral facial twitching with or without spasmodic head bobbing.
- **Partial (focal) seizures of cats are often subtle and/or bizarre** and may be difficult to recognize as being seizure activity.
- Some partial (focal) seizures previously called psychomotor seizures mainly manifest with bizarre stereotypical and behavioral activities (e.g. hallucinatory prey or predator behavior with running fits).
- **Seizures preceded by an aura** (behavioral changes within a few seconds or minutes of the ictus onset) or followed by **localized post-ictal motor deficits** (e.g. hemiparesis) **are partial in onset**, even if they appear to be generalized from the beginning of the ictus.
- **Partial (focal) seizures may secondarily generalize** to tonic-clonic generalized seizures and this may occur so quickly that their initial partial phase may not be observed clinically; most generalized seizures of cats are probably within that category.
- The occurrence of partial seizures usually indicates that there is a **focal forebrain lesion** which excludes the possibility of idiopathic (genetic) epilepsy and extracranial (metabolic and toxic) causes of seizures.

Seizures must be differentiated from seizure-like events such as syncope, sleep disorders (e.g. excessive dream-like movements), movement disorders (e.g. myoclonia, tremors-tetany), narcolepsy-cataplexy, episodic behavioral disorders (e.g. fly catching, feline hyperesthesia), dysphoric and agitated anesthetic recovery, and paddling associated with decerebration.

Compulsive circling is usually accompanied by mental confusion with either depression or agitation. It is often associated with wandering, pacing and sometimes with an abnormal posture (head and eye deviation or turning, leaning).

- **Compulsive circling must be differentiated from vestibular circling** which is due to marked loss of balance.
 - The cat with compulsive circling does not have a head tilt (its head may however be turned), loss of balance, nystagmus and other vestibular signs. It usually has a normal gait (no detectable ataxia nor paresis) and often can walk in a straight line when it is motivated to do so (e.g. reach a specific goal such as a food plate).

Personality and behavioral changes due to forebrain diseases must be differentiated from pure behavioral disorders.

WHERE?

Forebrain (thalamocortex) diseases can cause any of the following signs:

- **Mentation abnormalities** ranging from depression to semi-stupor, or confusion.
- Subtle **personality changes** (e.g. loss of good or bad habits) to obvious **behavioral abnormalities** (e.g. dementia, aggression).
- Abnormal activities such as **wandering**, propulsive **pacing**, **head pressing** and compulsive **circling**.
- **Seizures**.
- Mild contralateral **hemiparesis** and **proprioceptive loss** causes either subtle gait abnormalities (e.g. knuckling) or is only detected as **postural reaction deficits** (e.g. proprioceptive positioning, hopping, lateral tactile limb placing).
- Central **visual loss** either causes the cat to bump into things, or is only detected by a **deficit in the menace response** together with normal pupillary light reflexes in the contralateral eye when the affected eye is tested.

- Impaired **facial sensation** is detected by decreased head withdrawal when the contralateral nasal septum, upper lip or whiskers are touched.

Large or diffuse forebrain lesions (e.g. tumors, edema) may cause signs of **increased intracranial pressure** (e.g. marked depression, bilateral miosis); this may evolve to **tentorial herniation** with signs of brainstem compression (e.g. coma, unresponsive mydriasis, abnormal respiratory patterns and death by respiratory arrest).

WHAT?

Most cats with **seizures** have a **structural forebrain lesion** that may be active (e.g. encephalitis, tumor, ischemic encephalopathy) or inactive (e.g. post-ischemic glial scar). Extracranial causes of seizures (e.g. metabolic, toxic) and idiopathic epilepsy are rare.

Compulsive circling may be caused by lesions affecting the **rostral thalamus or frontal lobe** and is usually toward the side of the lesion. Most common causes are neoplasia, trauma and ischemic encephalopathy.

Personality and behavioral changes result from lesions affecting the **limbic system** and associated areas of frontal and temporal lobes. Most common causes are neoplasia, trauma, ischemic encephalopathy, feline infectious peritonitis and hepatic encephalopathy.

Diagnosis is based on history, clinical examinations, CSF analysis (reference values in cats are a protein concentration ≤ 0.36 g/L (0.036 mg/dl) and a leukocyte count ≤ 0.002 cells/ 10^9 (2/ μ l) with the majority of cells being mononuclear cells), brain imaging and other ancillary tests.

DISEASES CAUSING SEIZURES, CIRCLING AND/OR CHANGED BEHAVIOR

LIKELY SYMPTOMATIC EPILEPSY***

Classical signs

- Recurrent seizures are the only problem.
- The initial seizure frequency is low but may increase over time.
- Seizures are partial in onset with or without secondary generalization.

Pathogenesis

Likely symptomatic epilepsy is **common** in cats.

It is most often caused by an **acquired** focal thalamo-cortical lesion that is no longer active but has transformed into an **epileptic focus** by irritating the surrounding neurons.

- Following an insult to the brain such as trauma, encephalitis or ischemia, the glial reaction may result in a persistent glial focus, which irritates the surrounding neurons.
- Seizure onset is usually delayed by a few to several months from an **initial brain insult**. The insult may have occurred in utero (e.g. porencephalic [cystic] lesions due to fetal encephalitis), at birth (e.g. dystocia-related cerebrovascular accidents) or later in life at any age. Post-natal diseases may have been symptomatic (e.g. encephalitis, ischemic encephalopathy, head trauma) or asymptomatic (e.g. atypical form of ischemic encephalopathy, non-suppurative meningoencephalitis).
- Symptomatic seizures occurring during the active phase of a cerebral disease may or may not lead to likely symptomatic epilepsy, depending on the extent of secondary gliosis.

Other rare **congenital or inherited** focal cerebral anomalies may also act as epileptic foci. These include lesions associated with surrounding gliosis (e.g. vascular malformations such as angiomas and arteriovenous malformations) or with intrinsic neuronal hyperexcitability (e.g. disorders of neuronal migration such as cortical dysplasia and heterotopias).

- Seizures usually start during adolescence or young adulthood.

Clinical signs

The initial **seizure frequency** usually is low with single seizures occurring at intervals of several weeks to months. The subsequent seizure frequency often remains low but may progressively increase over months or years due to a self-perpetuating electrical kindling-like phenomenon. This sometimes leads to intractable seizures with frequent and severe cluster seizures and status epilepticus.

Seizures are partial (focal) with or without secondary generalization. Secondary generalization may sometimes occur so quickly that no features of partial seizures may be detected clinically.

- Seizures preceded by an **aura** (behavioral changes a few seconds or minutes before the onset of ictus) or followed by **localized post-ictal motor deficits** (e.g. hemiparesis) are partial, even if they appear to be generalized from their onset.

Other static **neurological signs** (e.g. personality changes) and/or **thalamocortical deficits** (e.g. menace, facial sensation, postural reactions) may or may not be present, depending on the size and location of the lesion.

Diagnosis

There may be a **history** of neurological signs a few to several months before the seizure onset (initial cerebral insult). These signs should have improved or resolved; if not, an active brain disease is likely.

Neurological examination may be normal or reveal thalamocortical deficits that are often subtle; the responses obtained from both sides of the body must be carefully compared.

CSF analysis is usually normal. Mild non-specific degenerative changes such as an increased proportion of macrophages despite a normal leukocyte count may sometimes persist for months after the initial cerebral insult (e.g. trauma, ischemic encephalopathy).

Brain imaging may identify an inactive lesion; magnetic resonance imaging (MRI) is more sensitive than computed tomography.

In many cases with clinical evidence of likely symptomatic epilepsy (e.g. partial seizures, non-progressive focal thalamocortical deficits), the underlying cause remains unknown because the CSF analysis and brain MRI are normal. Such epilepsy previously classified as cryptogenic (hidden cause) is now called “likely symptomatic” epilepsy.

Differential diagnosis

Exclusion of other causes of seizures is often possible based on the **history** and **clinical examination**, even before any ancillary tests are performed.

- **Active brain diseases** often cause a higher initial seizure frequency, including cluster seizures and status epilepticus, and a rapid progression toward high-frequency seizures within the first few weeks

or months. A regressive course may occur with self-limiting conditions. Other progressive (or regressive) neurological signs and deficits, and abnormal CSF and/or brain imaging findings reflecting an active disease process are also likely to be present.

- **Idiopathic (genetic) epilepsy** causes primary generalized seizures that begin in young adult cats that have no other neurological signs and deficits (see page 816).
- **Intoxications** typically cause an acute onset of severe convulsive status epilepticus or cluster seizures that is usually preceded by signs of other body systems (e.g. vomiting) as well as diffuse neurological signs (e.g. mental depression, hyperexcitability, tremors). There are no periods of normalcy in between the seizures, which continue until appropriate treatment is provided or until death occurs (see page 812).
- **Metabolic causes** produce a high initial seizure frequency. Metabolic causes may be excluded when there are no other signs of metabolic disorders preceding and following the seizures (e.g. severe and classical signs of hepatoencephalopathy, hypocalcemic tremors – tetany, hypoglycemic weakness and confusion). They can also be excluded when there are partial seizures or focal (unilateral, asymmetrical) neurological signs or deficits. Metabolic diseases, like intoxications, produce generalized seizures and bilateral and symmetrical neurological dysfunction.

Treatment

Aggressive but rational **anti-epileptic drug therapy** is mandatory **if there is more than one single seizure every 6–8 weeks**.

- **Start phenobarbital** 1.5–2.5 mg/kg PO q 12 h.
 - Measure serum phenobarbital concentration **14 days after treatment initiation** and after any dosage modification. Measure trough level, that is, just prior to next treatment. Adjust the dosage to obtain an optimal phenobarbital concentration of 100–130 $\mu\text{mol/ml}$ (23–32 $\mu\text{g/ml}$) using the formula: optimal dosage = optimal phenobarbital concentration \div actual phenobarbital concentration \times actual dosage.
- **Add diazepam** (0.5–1.0 mg/kg q 12 h) if seizures are not well controlled (if > 1 seizure/6–8 weeks) despite an optimal phenobarbital concentrations 14 days after treatment initiation or change in drug dose.

- Measure serum benzodiazepine concentration at steady state (reached within 4–5 days) and adjust the dosage to obtain at least 500–700 nmol/L (ng/L); use the same formula as for phenobarbital.
 - Also measure liver enzymes to detect rare idiosyncratic acute hepatic necrosis induced by diazepam in cats.
- **Add gabapentin 10–40 mg/cat q 8 h** if seizures are still not well controlled despite optimal phenobarbital concentrations and benzodiazepine concentrations.
 - **Potassium bromide (KBr) is contraindicated** in cats; in a study of 26 cats treated with KBr, 42% developed respiratory signs from 7 weeks to 14 months after onset of therapy. Two cats died of their airway disease. **The safety of potassium bromide use in the cat remains a serious issue.** If there are no other options, monitoring monthly by way of thoracic radiographs should be done. The clinical signs resolve with the arrest of treatment (up to 17 months are required for full recovery).

Anti-epileptic drug therapy is likely to be required for life. Only if the cat remains seizure-free for longer than 6–12 months should **slow weaning** from drugs be attempted. Weaning should occur over a few months with one drug at a time. If more than one seizure/8 weeks recurs during or after drug withdrawal, resume treatment.

- **Status epilepticus and cluster seizures require emergency treatment.**
 - **First give a diazepam bolus of 0.5 mg/kg IV.** Repeat if the seizure has not stopped within 1–2 minutes or if another one begins.
 - **Immediately start a diazepam constant rate IV infusion** of 0.5 mg/kg/h to prevent seizure recurrence.
 - Mix the diazepam in an in-line burette with maintenance fluids. Prepare only 1–2 hour supply at a time as diazepam is rapidly adsorbed into the plastic tubing and is inactivated by exposure to light.
 - When no seizures have occurred after 4–6 hours, slowly decrease the infusion rate (25% steps every 4–6 hours).
 - **If > 2 seizures occur during the diazepam infusion, either give another diazepam bolus (0.5 mg/kg) and increase the diazepam infu-**

sion (to 0.75–1.0 mg/kg/h), **or give a phenobarbital IV bolus** (2–5 mg/kg) and add phenobarbital to the diazepam infusion (0.5–1 mg/kg/h) for at least 4–6 hours before attempting to decrease it. Because it takes at least 20 minutes for a phenobarbital IV bolus to exert its anticonvulsant effect, sustained seizure activity must be controlled with diazepam in the mean time.

- **If phenobarbital is to be started as a maintenance anti-epileptic drug, a loading dose of 15–20 mg/kg (slow IV bolus) may be given to immediately** achieve a therapeutic serum concentration of 60–110 $\mu\text{mol/L}$ (15–25 $\mu\text{g/ml}$). Maintenance dosing should be continued afterwards (2.5 mg/kg q 12 h PO or IM if the cat is sedated to the point it is unable to safely swallow). Phenobarbital is potentiated by diazepam. Close monitoring of the patient must be done when adding phenobarbital to diazepam.
- If the cat is already treated with chronic oral phenobarbital therapy and its phenobarbital concentration is known to be sub-therapeutic, it can be immediately increased by administering an IV bolus; each 1 mg/kg IV bolus will increase the phenobarbital concentrations by 5 $\mu\text{mol/L}$ (1 $\mu\text{g/ml}$).
- **If seizures are not adequately controlled, propofol at sub-anesthetic dosage can be administered.** Use an IV bolus of 1.0–3.5 mg/kg plus a continuous IV infusion of 0.01–0.25 mg/kg/min, to effect, for several hours (up to 12–48 hours, if necessary) before attempting weaning.
- **If high-frequency or sustained convulsive seizures persist** despite the above treatment, proceed to **general anesthesia with pentobarbital** (5–15 mg/kg slow IV over several minutes, to effect; wait 10 minutes to see maximal effect before giving more).
 - Add an IV continuous rate infusion of 5 mg/kg/h for at least 6 hours if other seizures occur afterwards.
 - **Intubation and ventilation are recommended** as well as close anesthetic monitoring (temperature, blood pressure, etc.).
 - **Isoflurane anesthesia is the last resort** for refractory seizures. It should be done for at least a few hours.

Prognosis

Good seizure control is often obtained with appropriate anti-epileptic drug therapy. Progression toward intractability may however occur despite adequate treatment and indicates a poor prognosis.

FELINE NON-SUPPURATIVE MENINGOENCEPHALITIS***

Classical signs

- Focal or multifocal CNS signs.
- Seizures.
- Occasionally, generalized tremors (“shaker cat syndrome”).

Pathogenesis

A **viral infection is suspected** even though the condition does not appear to be contagious. Signs are usually confined to a single cat in a household.

- Several feline (e.g. **herpesvirus type I**) and non-feline (e.g. **arboviruses**) viruses may infect the CNS of cats and produce a subclinical or clinical meningoencephalitis.

An **immune-mediated** process is also possible. This can be primary (idiopathic autoimmune) or secondary to various antigenic stimulation such as vaccination, CNS infection with a non-pathogenic virus or infection in another system.

Cats of **any age** and with or without outdoor access may be affected.

Clinical signs

The **clinical course is variable** with an acute or insidious onset and a static, progressive or regressive course.

The disease can produce **focal or multifocal signs** of variable severity attributable to **any portion of the CNS; central vestibular** (head tilt, balance losses, mental depression, postural reaction deficits), **spinal cord** (hindlimb proprioceptive ataxia and paresis), cerebellar and cranial nerve signs are most common and may occur alone or in any combination.

- **Seizures may occur** alone or with other signs during the active phase of the disease. They may present with the full spectrum of severity.
- **Delayed onset post-encephalitic secondary epilepsy** may also occur after a symptomatic or an asymptomatic course of the disease.

A **steroid-responsive “shaker cat syndrome”** similar to the “little white dog shaker syndrome” has been observed as the only clinical manifestation of the disease in a few cats.

Systemic signs including fever, inappetence, lymphadenopathy and mild hematological abnormalities (e.g. leukopenia, lymphocytosis, anemia) may sometimes precede or accompany the neurological signs. **Ocular signs** (e.g. chorioretinitis) may also be seen.

Diagnosis

CSF analysis may be normal or reveal a mild increase of the protein concentration (< 0.70 g/L) and/or a mononuclear pleocytosis (< 50 cells/ μ L) with numerous small lymphocytes and/or large foamy mononuclear cells.

Brain imaging (MRI) may be normal or show inflammatory lesions with contrast uptake. Obstructive or compensatory hydrocephalus and porencephalic (cystic) lesions may sometimes be seen.

Differential diagnosis

Other infectious encephalitis (e.g. FIP, toxoplasmosis, cryptococcosis) when there are other systemic signs, ocular involvement or a progressive course.

- **CSF analysis** is the best test to differentiate the disease from FIP. **Cats with FIP** usually have a higher CSF protein concentration and cell count with a predominance of neutrophils (see page 844). **Toxoplasmosis** can however produce similar CSF changes. Rarely, **cryptococcosis** may produce only mild CSF inflammation but culture and titers help with diagnosis when the organism is not visible in the CSF. Usually signs are rapidly progressive with cryptococcosis.

Other causes of seizures in cats should be considered when seizures are the only sign of the disease (e.g. **idiopathic and likely symptomatic epilepsies**).

Treatment

Treatment is generally **supportive to ensure fluid, electrolyte and nutritional requirements are met**.

Symptomatic anti-epileptic drug therapy should be instituted in cats with seizures (see Likely symptomatic epilepsy, page 802).

Glucocorticosteroids such as dexamethasone (0.25 mg/kg q 24 h to be decreased over a few weeks to months) may be beneficial in immune-mediated cases, but could be deleterious if a pathogenic virus is involved.

Prognosis

The prognosis is often excellent as signs resolve spontaneously over weeks or months. Sometimes it is poor because of progressive deterioration leading to death or euthanasia.

FELINE ISCHEMIC ENCEPHALOPATHY***

Classical signs

- **Peracute onset unilateral forebrain signs** (mental depression/confusion, compulsive circling, hemiparesis) \pm seizures.
- **Personality changes and/or post-ischemic epilepsy** several months later.

Pathogenesis

An **ischemic cerebral infarction** typically occurs in the parietal-temporal field of one cerebral hemisphere which controls contralateral sensorial (proprioceptive, nociceptive) and motor function as well as behavior. Secondary edema and necrosis lead to atrophy and gliosis.

- The lesion is usually unilateral, although it can be bilateral but markedly asymmetrical.
- A vasospasm phenomenon of the middle cerebral artery is suspected but its pathogenesis remains unknown. Cuterebra larval migration has been incriminated as a cause.

Young adults to middle-aged cats are usually affected.

Clinical signs

The **classical form** of the disease is seen with large ischemic lesions that may involve up to two thirds of an hemisphere.

Typically, there is **peracute onset of severe and unilateral forebrain signs** usually including mental depression, pacing, circling, hemiparesis, and deficits in the menace response, facial sensation and postural reactions.

- Rarely, seizures occur and may initially be difficult to control (e.g. cluster seizures or status epilepticus).
- **Rapid neurological improvement** occurs in the first 24–72 hours. Good recovery and **minimal residual signs and deficits** occur within a few weeks in most cases.
 - Rare complications that lead to neurological deterioration in the first 24 hours and sometimes to death or euthanasia include hemorrhage, increased intracranial pressure, tentorial herniation and intractable seizures.
 - **Personality changes, especially a more or less affectionate behavior** and tolerant attitude towards other animals, or for grooming, nail clipping, etc., may become apparent as the initial signs resolve.
 - Persistent seizures or delayed onset of post-ischemic secondary epilepsy may occur, but appear to be unusual.

The **atypical form of the disease** is caused by small and superficial ischemic lesions that often do not cause any clinical signs at the time of the infarction.

- A few **seizures** and/or **personality changes** may however occur.
- **Delayed onset post-ischemic secondary epilepsy** may be the only clinical manifestation. This may be a common cause of seizure disorders in cats.
 - The seizures are usually of low to moderate frequency initially and subsequently.
- No or only subtle unilateral or occasionally asymmetric bilateral **thalamocortical deficits** may be detected in these cats.

Diagnosis

CSF analysis may be normal or reveal mild non-specific degenerative changes (**increased proportion**

of **large foamy mononuclear cells**) that may persist for several months after the infarction.

Brain imaging (MRI is optimal) is the only means of antemortem diagnosis. It typically reveals the lesion in the parietal-temporal field of one cerebral hemisphere. A similar but much milder lesion may be seen in the other hemisphere.

Differential diagnosis

The typical form of the disease must be differentiated from the following:

- **Cerebrovascular accidents** are rare in cats and older animals are at greater risk. They may be associated with hypertension due to renal insufficiency, hyperthyroidism or blood hyperviscosity due to polycythemia vera.
- **Head trauma** is differentiated by the history and external signs of trauma to the head and face area.
- **Sudden decompensation or hemorrhage associated with a cerebral tumor** is usually seen in older cats with other preceding neurological signs, especially mentation and behavioral changes. A progressive rather than a regressive course would be expected afterwards.
- **Acute and severe encephalitides** (infectious and non-infectious) are more likely to produce initially progressive multifocal or diffuse signs.

In cats with the atypical form of ischemic encephalopathy with personality changes or seizures as the only sign, **behavioral disorders** and other **intracranial causes of seizures** such as idiopathic epilepsy, active brain diseases must be investigated.

Treatment

Treatment is symptomatic.

- To reduce cerebral edema and intracranial pressure in the typical form of ischemic encephalopathy, give:
 - **Glucocorticosteroids** (methylprednisolone sodium succinate [SoluMedrol®] 30 mg/kg IV or dexamethasone phosphate 0.25 mg/kg IV).
 - **Furosemide** (0.5–2.0 mg/kg IV) may be preferred to or combined with glucocorticosteroids when neurological signs are mild (mental depression/confusion, miotic pupils).

- **Mannitol** 25% (0.5–2.0 g/kg slow IV over 20–30 minutes) may be **indicated in severe cases** (semi-stupor, pinpoint pupils).
- To control seizures, give anti-epileptic drugs (see Likely symptomatic epilepsy, page 802).

Prognosis

The prognosis is **excellent** in most cases.

- **Persistent personality changes** are usually mild, but rarely they may make the animal unsuitable as a pet, for example severe aggression.
- **Post-ischemic epilepsy** is usually well controlled with adequate anti-epileptic drug therapy.

Recurrences of infarction are not reported to occur.

CONGENITAL AND INHERITED FOREBRAIN ANOMALIES***

Classical signs

- **Focal or diffuse forebrain signs** (mentation depression and confusion, central visual deficits with normal pupillary light reflexes, proprioceptive positioning and hopping deficits).
- **Abnormal development and behavior.**
- **Occasionally, seizures.**

Pathogenesis

Congenital hydrocephalus is uncommon and rarely symptomatic in cats. It may be primary (e.g. inherited) or secondary, for example obstructive and/or compensatory following fetal encephalitis. Signs are diffuse and mainly due to a lack of formation or loss of cerebral tissue, although intracranial pressure elevation may sometimes contribute to the signs.

Lysosomal storage diseases are inherited, progressive and lethal multisystemic degenerative disorders that often involve the CNS of young to adolescent kittens under 1 year of age. Initial signs are often attributable to cerebellar dysfunction.

Lissencephaly-pachygyria is due to an abnormal migration of cerebrocortical neurons. It usually causes learning disabilities, sometimes with behavioral abnormalities and seizures.

Dermoid cysts and other tumors of embryonic origin, for example teratomas and germ cell tumors, produce progressive focal forebrain signs that often become complicated by an increased intracranial pressure and/or secondary obstructive hydrocephalus.

Likely symptomatic **epilepsy** may be the only neurological sign in cats with small focal and inactive brain lesions (e.g. cysts, cortical dysplasia) (see Likely symptomatic epilepsy, page 801).

Clinical signs

Forebrain signs including mentation abnormalities, compulsive pacing or circling, central visual deficits with normal pupillary light reflexes and hemiparesis are present since birth, young kittenhood or early adult life. Neurological deficits and signs can be focal or diffuse, and static or progressive, depending on the underlying pathological process.

- Extensive or diffuse forebrain anomalies such as hydrocephalus or lissencephaly-pachygyria may manifest with **retarded development, learning disability**, loss of training, mental depression, abnormal behavior and visual deficits.
 - Severe hydrocephalus may also cause gait abnormalities as a result of cerebellar and brainstem distortion, as well as pacing and head pressing, especially when the intracranial pressure is elevated.

Symptomatic seizures may occasionally occur but usually are preceded by other signs of the anomaly (e.g. of hydrocephalus, tumors of embryonic origin, lysosomal storage diseases, lissencephaly-pachygyria).

Likely symptomatic **epilepsy** may occur. Seizures typically are initially of low frequency and are partial in origin, but can secondarily generalize to tonic-clonic seizures (see Secondary epilepsy, page 800).

Diagnosis

Facial and head deformities may be apparent with hydrocephalus, for example a domed calvaria with open suture lines and fontanelles.

CSF analysis is likely to be normal or only reveal mild non-specific degenerative changes.

Brain MRI will often show the underlying anomaly, for example porencephalic lesions.

Other specific tests, for example, ultrasonography through open fontanelles for hydrocephalus, enzymatic assays and biopsies of peripheral nerves or other organs for some lysosomal storage diseases are useful for obtaining a definitive diagnosis.

Differential diagnosis

Acquired forebrain diseases affecting young cats such as FIP and non-suppurative meningoencephalitis usually have a subacute onset and a rapidly progressive (or regressive) clinical course.

Hepatoencephalopathy due to portosystemic shunting would be distinguished by its episodic nature.

Treatment

Anti-epileptic drug therapy should be instituted for likely symptomatic epilepsy (see Likely symptomatic epilepsy, page 802).

Symptomatic medical treatment including glucocorticosteroids and surgical shunting for hydrocephalus is poorly documented in cats.

Lysosomal storage diseases are currently untreatable.

Prognosis

Prognosis is usually guarded to poor, with the exception of secondary epilepsy, which may be successfully controlled with anti-epileptic drugs.

HEPATIC ENCEPHALOPATHY***

Classical signs

- Episodes of hypersalivation, abnormal mentation and bizarre behavior.

Pathogenesis

Hepatic encephalopathy results when endogenous toxins produced by the action of the gut microflora on alimentary proteins are not removed from the systemic circulation by the liver. When a critical toxin level is reached, diffuse cerebral dysfunction ensues.

Hepatic encephalopathy is **most often due to a congenital portosystemic vascular shunt** and signs are usually noticed during the first year of life.

Severe acquired liver diseases also very occasionally cause hepatic encephalopathy in cats of any age. Other signs of liver disease will usually predominate including anorexia, weight loss and sometimes jaundice.

Clinical signs

Neurological signs are episodic. They develop then regress progressively over periods of a few to several hours.

- **Episodes may be precipitated by feeding**, especially when a high-protein diet is ingested in large amounts. Several (up to 8–10) hours may however elapse between meal times and onset of signs. Signs do not follow each meal, especially early in the course of the disease. Several days and sometimes a few weeks may elapse between episodes.

Neurological signs are of diffuse thalamocortical dysfunction:

- **Mentation abnormalities** include depression, confusion, staring into space.
- **Bizarre behavioral activities** may occur, for example pacing, head pressing, dementia with running fits, frantic vocalization and aggression.
- **Profuse salivation** is common. This may last for several minutes to hours and may be the first and only sign early in the course of the disease.
- Fine generalized muscle tremors (shivering).
- **Central blindness** and ultimately stupor and coma may develop in the advanced stage of hepatic encephalopathy.
- Episodes of dementia with frantic behavioral activities such as running fits, attacking inanimate objects and profuse salivation sometimes are misinterpreted as being seizure activity. **True seizures are rare** and usually occur as clustered seizures after the other classical and severe signs of hepatic encephalopathy have developed.

Systemic signs may include polyuria, polydipsia, vomiting, diarrhea, dysuria with hematuria (due to urate calculi) and delayed anesthetic recovery.

- Cats with congenital portosystemic shunts may be thin and small for their age.

Other physical and laboratory signs of liver failure will be obvious in cats with severe liver pathology.

Diagnosis

Pre- and post-prandial bile acids are usually markedly increased.

Laboratory abnormalities may include microcytic non-regenerative anemia, low albumin, urea and cholesterol concentrations, and urinary ammonium biurate crystals.

Fasting blood ammonia is markedly elevated in most (90%) cats with a portosystemic vascular shunt, especially during episodes of hepatoencephalopathy. This test is however inconvenient in most practices because blood samples must be drawn in cold heparinized tubes and immediately transported to an appropriate laboratory on ice for refrigerated centrifugation and assay, preferably within an hour of collection. False blood ammonia values may occur with hemolysis, prolonged venous occlusion and struggling at the time of venipuncture.

- An **ammonia tolerance test** identifies virtually all cats with a portosystemic vascular shunt but may precipitate severe signs of hepatoencephalopathy. Cats with a shunt have a blood ammonia concentration 30 minutes post-challenge that is > three times higher than the fasting values.

Abdominal radiographs may show a small liver in cats with congenital portosystemic shunt.

Abdominal echography may allow visualization of a congenital portosystemic shunt or may detect diffuse liver disease.

Differential diagnosis

Cats presented for bouts of hypersalivation are often erroneously diagnosed with a **stomatitis**, even though they may have no oral lesions. **Ingestion of irritant substances or plants** is another common misdiagnosis.

Some intoxications may produce signs similar to those of hepatic encephalopathy including depression or agitation, but are not recurrent unless re-exposure to the toxin occurs.

Treatment

Medical treatment is aimed at reducing the production and absorption of endogenous colonic toxins. Maintenance therapy includes a low-protein diet (e.g.

Prescription Diet feline k/d, Hill's Pet Nutrition), with added carnitine, taurine and arginine, antibiotics (e.g. metronidazole 7.5 mg/kg PO q 12 h, or neomycin 22 mg/kg PO q 8–12 h, or amoxicillin 22 mg/kg PO q 12 h) and lactulose (0.25–0.5 ml/kg PO q 8–12 h). See page 821, The Cat With Stupor or Coma, for further details.

Surgical treatment including ligation or use of an occlusive device offers the best chance for long-term control of clinical signs. This must be performed by an experienced surgeon to decrease the risk of excessive ligation which may cause rapid post-operative death due to portal hypertension and bowel ischemia. Like in dogs, severe seizures may develop in the first few post-operative days, and some cats have remained epileptic for months and years afterwards.

Prognosis

Prognosis is good if surgical treatment is feasible, for example with a single extrahepatic shunt, and is not complicated by portal hypertension. Recurrence of signs appears to be more common in cats than in dogs and occurs in more than 40–50% after a few years. It may be due to the persistence of shunting through a partially ligated vessel or the development of multiple secondary shunts because of chronic portal hypertension.

Prognosis is guarded with medical treatment as the condition often worsens over time.

THIAMINE DEFICIENCY***

Classical signs

- Inappetence, depression, intermittent vomiting.
- Central vestibular signs (reluctance to walk, nystagmus, loss of balance).
- Mydriasis with poor pupillary light reflexes.
- Spasmodic ventroflexion of the neck or opisthotonos.

See main references on page 848 (The Cat With Head Tilt, Vestibular Ataxia or Nystagmus) and page 899 (The Cat With Neck Ventroflexion).

Clinical signs

History of feeding all-fish diets (containing thiaminase), diets consisting of **entirely cooked meat** (thiamine destruction by heating), poor-quality, thiamine-deficient commercial diets, commercial food stored for long periods of time or in excessively hot conditions or, **pet meat preserved with sulfur dioxide** which destroys thiamine.

Depression and inappetence are initial signs. Later **mydriasis** with poor pupillary light response, but usually without blindness and **central vestibular dysfunction** occur with head tilt, loss of balance, spastic gait and tremors. Terminally, semicoma, crying, opisthotonos with limb spasticity and death result.

True seizures are uncommon and must be differentiated from periods of opisthotonic posturing with paddling, and from the spasmodic ventroflexion of the neck and body contortions that may be induced when the cat is picked from the ground. These are likely due to marked spatial disorientation because of the bilateral vestibular dysfunction.

Diagnosis

Diagnosis is based on a **history of dietary deficiency and response to thiamine supplementation** (10–20 mg thiamine IM q 8–12 h, then orally).

CEREBROVASCULAR ACCIDENTS**

Classical signs

- Peracute and rapidly resolving cerebral signs.

Pathogenesis

Cerebrovascular accidents are rare in cats.

Vascular events result in acute ischemic lesions. Vascular events include spontaneous hemorrhage from coagulopathies, thrombocytopenia and hypertension associated with chronic renal failure and hyperthyroidism. They also include thrombosis (e.g. polycythemia hyperviscosity syndrome) and embolization including septic and metastatic from rapidly growing cell type tumors.

Clinical signs

Peracute onset of non-progressive and rapidly regressive focal cerebral signs, including seizures alone or with other signs.

- Slight deterioration may occur over the first 24 hours as a result of edema or increased intracranial pressure before the condition improves. A rapidly progressive course is expected with septic and metastatic embolization.

Diagnosis

Diagnosis is based on a clinical course suggestive of a vascular event, that is, a peracute, onset of signs that improve rapidly.

Neurological signs and deficits are attributable to a focal CNS lesion. Multifocal lesions are however possible, for example, hemorrhage due to coagulation disorders or thrombocytopenia, or multiple metastasis.

Evidence of historical, clinical, laboratory and imaging findings related to the underlying cause such as polycythemia, hypertensive retinal changes, hyperthyroidism, abdominal tumor increase the index of suspicion when neurological findings are consistent with a vascular accident.

Differential diagnosis

The classical form of the feline ischemic encephalopathy is a cerebrovascular accident that occurs in young adult to middle-aged healthy cats.

Acutely decompensated brain tumor as occurs following spontaneous hemorrhage, or tentorial herniation may appear clinically similar.

Treatment

Treatment is specific if the cause is known and treatable.

Supportive and symptomatic therapy is indicated to control secondary brain edema and increased intracranial pressure (see Feline ischemic encephalopathy, page 805 and Head trauma, page 818).

Prognosis

The prognosis **depends on the severity** of the neurological signs and the underlying cause and whether it is treatable or not.

Recurrences may occur if the underlying cause persists (e.g. hypertension). The lesion localization is however likely to be different from one event to another.

Post-ischemic gliosis may result in **epilepsy**.

HYPOGLYCEMIA**

Classical signs

- Mental alteration, weakness, ataxia, visual loss.
- Seizures.

PATHOGENESIS

Because blood glucose is the primary energy source for the CNS, hypoglycemia causes **diffuse CNS dysfunction**. The nature and severity of the neurological signs depend on the rate of blood glucose decrease, level of glucose attained and duration of hypoglycemia.

Severe and symptomatic hypoglycemia is rare in cats except as a result of insulin over-dosage in diabetic cats. Rarely reported causes include insulin-secreting tumors, other tumors secreting insulin-like growth factor (IGF), sepsis and terminal hepatic disease.

Clinical signs

Signs may be episodic or persistent and include mentation abnormalities (e.g. depression, confusion, stupor), weakness, ataxia, central visual impairment and generalized seizures. Nervousness, muscle fasciculations and tremors may also occur.

- Seizures more often occur when there is a sudden and marked decrease in the glucose concentration, and are usually preceded by other more subtle signs of hypoglycemia such as confusion and weakness.

Severe and sustained hypoglycemia may cause diffuse cerebral anoxic injuries resulting in stupor-coma, decerebrate rigidity and miotic pupils. This may progress to irreversible damage (cortical necrosis) and permanent neurological sequela including blindness and secondary epilepsy.

Diagnosis

Serum glucose concentration is usually < 2.2 mmol/L (40 mg/dl).

Other historical, clinical and laboratory abnormalities may be evident, depending on the underlying cause.

More commonly, there is a history of diabetes mellitus treated with insulin or hypoglycemic drugs.

Differential diagnosis

Other episodic or peracute conditions such as metabolic disturbances, intoxications and encephalomyelitis should be considered depending on the clinical presentation.

Treatment

Treatment involves glucose administration (food, sugar water, corn syrup or dextrose 50% IV [1/2–4 ml/kg], according to the severity of hypoglycemic signs) and specific treatment of the underlying cause. See page 956 (The Cat With Generalized Weakness) and page 832 (The Cat With Stupor or Coma).

Diabetic cats need re-evaluation of their treatment regime. Some cats presenting with hypoglycemia are in diabetic remission and do not require further insulin or oral treatment.

Prognosis

Prognosis is good unless the underlying cause is associated with a poor prognosis (e.g. neoplasia) or significant structural cerebral damage has occurred.

FOREBRAIN TUMORS**

Classical signs

- Progressive forebrain signs (personality changes, circling, pacing) in middle-aged and older cats.
- Seizures.

PATHOGENESIS

Forebrain neoplasms cause **progressive focal neurological signs**, the nature and severity of which depend on the tumor location and growth rate.

- **Meningiomas are the most common.** Other brain tumors of cats include gliomas, pituitary tumors,

extension of nasal cavity and paranasal sinus neoplasms and metastatic brain tumors.

Clinical signs

Initial signs often include subtle personality and behavioral changes, mental depression, pacing and circling.

Seizures may manifest as the first and only sign, occur concurrently with other signs or develop later. The initial seizure frequency is variable but is inevitably progressive.

Focal signs such as contralateral hemiparesis with postural reaction deficits, **visual loss** and **decreased facial sensation** are often detected upon examination.

Tumors complicated with obstructive hydrocephalus and **increased intracranial pressure** cause more diffuse signs (e.g. **profound depression, bilateral miosis**). This may also lead to tentorial herniation which **often develops slowly and remains asymptomatic until an acute decompensation** is triggered by further tumor growth, spontaneous hemorrhage in or around the tumor, concomitant disease or stress, anesthesia and CSF collection.

- **Tentorial herniation** resulting in brainstem compression produces **coma, unresponsive mydriasis, abnormal respiratory patterns** and death from respiratory arrest.

Diagnosis

Skull radiographs are likely to be unrewarding except for some **meningiomas** which may result in thinning or thickening of the adjacent calvaria and increased density of adjacent soft tissue, and **neoplasms of the nasal cavity and paranasal sinus** which produce soft tissue density, osteolysis and bone proliferation.

CSF analysis may reveal mild to moderate increase of the protein concentration and/or pleocytosis (elevated leukocyte count); **CSF may be normal** with small and deeply seated tumors.

- **CSF collection is contraindicated in cats with signs of increased intracranial pressure** (marked mental depression, inappropriate miosis) because it may cause or exacerbate a tentorial herniation leading to death.

Brain imaging is essential to confirm the diagnosis and to localize the tumor when surgical or radiation therapy is considered.

Differential diagnosis

Other focal and slowly progressive brain diseases are uncommon in cats (e.g. *toxoplasma granuloma*, *cerebral abscess*).

Multiples tumors (e.g. meningiomas, metastases) may cause multifocal signs and must be differentiated from *encephalitis*.

Treatment

Surgical excision may be possible if the tumor is surgically accessible. Meningiomas on the dorsal surface of the cerebral hemispheres can be successfully removed.

Radiation therapy is a useful adjunct to surgical debulking, or can be used alone when surgical excision is not possible.

Chemotherapy is poorly documented for brain tumors of cats. Lomustine (a nitrosourea) has been safely used in the cat.

Palliative medical treatment using dexamethasone (0.12–0.25 mg/kg q 24–48 h) to decrease peritumoral edema.

Symptomatic anti-epileptic drug therapy should be instituted in cats with seizures (see Secondary epilepsy, page 801).

Prognosis

Long-term prognosis is poor except for convexity meningiomas (located on the dorsal surface of the cerebral hemispheres), which can often be completely excised with good survival, rapid recovery and low incidence of recurrence.

FELINE INFECTIOUS PERITONITIS**

Classical signs

- Multifocal CNS signs (head tilt, nystagmus, intentional tremors, ataxia, paresis).
- Systemic signs (fever, lethargy, inappetence, weight loss) +/- ocular signs.

See main references on page 844 (The Cat With Head Tilt, Vestibular Ataxia or Nystagmus) and page 352 (The Thin, Inappetent Cat).

Clinical signs

FIP causes multifocal or focal neurological signs attributable to any portion of the CNS. **Central vestibular signs** (head tilt, balance losses, nystagmus, mental depression, postural reaction deficits) are the most common and are often accompanied by **cerebellar signs** (intentional tremors, hypermetria).

- Seizures are unusual and do not occur as the only sign.

Affected cats usually have **other clinical and laboratory evidence of systemic involvement** (e.g. lethargy, inappetence, weight loss, fever, anemia, renal and hepatic signs).

Ocular signs are also common (e.g. chorioretinitis, anterior uveitis).

Typically, there is an insidious onset and a slowly progressive course over weeks.

Usually, **cats are less than 3 years old** and were obtained from a **large multiple-cat household, breeder or pet store**.

Diagnosis

CSF analysis is the most useful test when there are CNS signs; typically, there is a marked increase of the protein concentration (> 1 g/L; 100 mg/dl and often > 2 g/L; 200 mg/dl) and leukocyte count (> 100 cells/ μ l) with a large proportion of non-lytic neutrophils.

Serological testing has been of little diagnostic value except that a negative test suggests the disease is unlikely to be FIP. However, negative test results do occur rarely in cats with FIP, especially in the terminal stages.

The ELISA that detects antibody to the 7B protein, which is specific to the coronavirus strains causing FIP has not been shown to improve accuracy of diagnosis in clinical practice. Newer PCR methods may be useful.

Differential diagnosis

Other infectious and non-infectious encephalitis, for example non-suppurative meningoencephalitis and toxoplasmosis need to be differentiated from FIP. CSF analysis may help to differentiate these diseases.

Treatment

No treatment is effective once neurological signs are present. Glucocorticosteroid may temporarily improve the neurological signs.

CRYPTOCOCCOSIS**

Classical signs

- **Chronic nasal discharge, often with nasal distortion.**
- **Cutaneous lesions – nodules or ulcers.**
- **Occasionally, ocular and CNS signs.**

See main reference on page 19 for details (The Cat With Signs of Chronic Nasal Disease).

Pathogenesis

Infection is by inhalation of the organism contained in high concentration in soil contaminated by **pigeon droppings** or **eucalyptus tree debris**.

CNS infection occurs by direct extension through the cribriform plate or by hematogenous spread. A diffuse or focal granulomatous meningoencephalitis results.

Clinical signs

CNS signs can occur alone or with other signs (e.g. rhinitis, cutaneous lesions) and are usually rapidly progressive.

- Most commonly, cats exhibit **cerebral signs such as mental depression, behavioral changes**, circling, head pressing and ataxia; **seizures** may occur with forebrain involvement but are unlikely to be the only sign.
- Blindness with dilated and unresponsive pupils may occur due to optic neuritis.

Ocular signs including chorioretinitis, panophthalmitis, and retinal detachment are often associated with CNS involvement.

Diagnosis

CSF analysis may reveal mild to marked inflammatory changes, often with numerous cryptococcal organisms.

Serology from blood, CSF, aqueous humor and urine is highly specific and sensitive.

Identification of the organism may be made by cytology, histology or culture of various body fluids and tissues including CSF, nasal discharge and polyp-like masses, skin lesions, enlarged lymph nodes.

Differential diagnosis

Other infectious encephalitides such as FIP and toxoplasmosis need to be differentiated from cryptococcosis. With cryptococcosis the organism is usually evident in CSF, although occasionally culture may be required to demonstrate it.

Treatment

Fluconazole (2.5–10 mg/kg PO q 12 h) is best for CNS infections, or itraconazole (5 mg/kg PO q 12 h). See main reference on page 26 for treatment details.

Prognosis

The prognosis is guarded once CNS involvement occurs.

INTOXICATIONS**

Classical signs

- **Signs of CNS, autonomic or neuromuscular stimulation or depression.**
- **Rarely and terminally, convulsive status epilepticus.**

Pathogenesis

Signs of intoxications usually occur shortly after acute and accidental ingestion or topical contact. Cats' selective eating behavior is protective but their grooming habits may increase exposure.

Most intoxicants cause functional disturbances for example conduction failure or neurotransmitter imbalance in various portions of the nervous system, although others cause structural damage.

Intoxicants that may cause seizures include the following:

- **Pyrethrins and pyrethroids** (e.g. fenvalerate, allethrin, tetramethrin, deltamethrin). Signs of intoxication usually occur a few minutes to hours after excessive topical application of anti-flea and tick sprays, powders, foam, dips and shampoos.
- **Organochlorines** are used for pest control (e.g. lindane, methoxychlor, endosulfan, DDT, aldrin, chlordane, dieldrin, heptachlor, dicofol, endrin, perthane, toxaphen) and may contaminate water or food, or be absorbed through the skin and the mucous membranes.
- **Organophosphates** (e.g. dichlorvos, malathion, chlorpyrifos, fenthion, parathion, phoxime, cythioate, diazinon, safrotin, phosmet, tetrachlorvinphos, diazinon) **and carbamates** (e.g. propoxur, carbaryl, bendiocarb, chlorprophane, buphame methomyl) are insecticides used in various formulations to control fleas, ticks and mites on pets, in the house and yard, on crops, stored grains, soils, and have also been used as fly, ant and roach baits. Intoxication occurs by ingestion, dermal exposure and after inhalation.
- **Bromethalin** is a non-anticoagulant rodenticide available in bait form. Secondary intoxication due to the ingestion of bromethalin-poisoned rodents may occur.
- **Strychnine** is a rodenticide marketed as pellets or treated seeds.
- **Methaldehyde** is a molluscicide often mixed with bran flakes or pellets.
- **Lead** is ingested in old paint flakes or paint dust from sanding, linoleums, roofing materials, plaster board, putty, artist paint, lead objects (drapery and fishing weights, sinkers, bullets), used motor oils from leaded gasoline-burning engines, greases leaded gasoline, eating or drinking from improperly glazed bowls.
- **Other intoxicants potentially dangerous for cats** include penitrem mycotoxins (produced in spoiled dairy products such as cottage cheese), nicotine (gum and skin patches), caffeine, chocolate (theobromine) and illicit drugs (e.g. cocaine).

Clinical signs

Most intoxications are **acute** and produce **diffuse and rapidly progressive neurological signs**. These may be accompanied by signs of stimulation of other body systems, for example gastrointestinal with vomiting and/or diarrhea.

- **Neurological signs vary according to the intoxicant** and include various combinations of **CNS signs** (e.g. mental depression to coma, hyperexcitability, tremors, ataxia, paresis), **autonomic signs** (e.g. hypersalivation, miosis, diarrhea) and **neuromuscular signs** (e.g. muscle fasciculations-tremors, LMN signs).
- **True seizures are less common** than generally believed and must be differentiated from other seizure-like features of poisoning such as tremors, tetany or hysterical behavior. Seizures usually manifest as convulsive status epilepticus that continues until treatment is provided or until death ensues.
 - **Pyrethrins and pyrethroids** intoxications are usually mild and resolve in most cases within 24–72 hours. **Signs include depression, salivation, anorexia, vomiting, muscle tremors** (ear flicking, contractions of the cutaneous muscles, paw shaking), hyperexcitability or hyperactivity, disorientation, weakness, ataxia, dyspnea and rarely, seizures and death.
 - **Organochlorines** produce progressive or explosive onset of hyperesthesia, nervousness, agitation, hyperexcitability, salivation, vomiting, tremors, ataxia, nystagmus, blindness, opisthotonos, convulsive seizures, depression, coma and death.
 - **Organophosphates and carbamates** inactivate acetylcholinesterase resulting in excessive activity and fatigue of cholinergic end-organs and muscles. This includes **muscarinic signs** (miosis, bradycardia, vomiting, diarrhea, hypersalivation, lacrimation, dyspnea due to excessive bronchosecretions and bronchoconstriction, anorexia), **nicotinic signs** (muscle tremors, weakness), as well as **CNS signs** depression, behavioral changes, ataxia, hyperactivity, seizures).
 - **Strychnine** toxicity results in anxiousness and nervousness, extreme sensitivity to external stimuli (e.g. noise, bright light), muscle tremors, intermittent then sustained extensor rigidity with opisthotonos and tetany (pseudo-convulsions), hyperthermia and death by respiratory apnea and hypoxia.
 - **Methaldehyde** causes anxiety, restlessness, ataxia, tremors, salivation, vomiting, diarrhea, mydriasis, nystagmus, opisthotonos, tetanic convulsions, hyperthermia and death from respiratory muscle spastic paralysis.

- **Lead** poisoning induces gastrointestinal (anorexia, vomiting, diarrhea, constipation), renal (polyuria, polydipsia) and neurological (depression, central blindness, hyperexcitability, running fits, seizures, vocalization, ataxia, head pressing, opisthotonos, paraparesis) signs. Megaesophagus with regurgitation and pharyngeal/laryngeal paresis has been observed with chronic lead poisoning in cats.
- **Bromethalin** acute toxicity causes tremors, hyperexcitability, hyperesthesia, depression, fever, anisocoria, positional nystagmus, extensor rigidity, opisthotonos and seizures (running fits and generalized). Death may sometimes be delayed up to 2–3 weeks in cats. Chronic intoxication with lower dosages causes occasional vomiting, ascending paresis and ataxia with proprioceptive deficits, depressed spinal reflexes (patellar and withdrawal), tremors, depression and lateral recumbency. Recovery is possible after exposure is discontinued.
- Penitrem mycotoxins.

Diagnosis

Diagnosis is based on a **history of exposure** to a toxin capable of producing the observed signs within the documented time for exposure.

Toxicologic analysis may be diagnostic when performed on the following:

- **Tissues** (e.g. liver, kidney, fat, brain) for organochlorines, organophosphates, strychnine, lead, etc.
- **Vomit and stomach content** (for bromethalin, strychnine, methaldehyde).
- **Urine** (for strychnine).
- **Blood** for lead concentration and acetylcholinesterase activity (organophosphate poisoning).

Toxicity as a cause of seizures can be excluded when (a) there are no other diffuse neurological signs preceding the seizure onset (e.g. tremors, hyperexcitability), (b) when partial seizures occur, (c) when isolated seizures are interspersed with periods of normalcy, or (d) when focal neurological signs or deficits are present.

Differential diagnosis

Metabolic disturbances that are severe enough to cause obvious neurological signs including seizures in

cats are rare. Hypoglycemia is typically associated with insulin overdose in a diabetic patient, hypocalcemia is mainly seen after bilateral thyroidectomy, and hepatoencephalopathy causes episodic signs, which rarely occur in intoxications.

Inflammatory conditions (e.g. encephalitides, polyneuropathies) need to be ruled out. Usually history and physical examination findings differentiate these from intoxications.

Treatment

With dermal exposure it is important to bath the cat with soap or detergent to remove the toxin from the hair and skin. Intoxication with anti-flea and -tick sprays, dips, and aerosols containing insecticides such as pyrethrins, carbamates, organophosphates often occurs via dermal exposure.

When ingestion has occurred within the previous 2 hours, emesis may be indicated or contraindicated, according to the specific toxin and formulation that was ingested. Emesis may be induced with hydrogen peroxide 3% (2 ml/kg PO) or apomorphine (0.03–0.04 mg IV or 0.04–0.08 mg/kg IM). **Gastric lavage** performed under general anesthesia may be beneficial if emesis is not effective. Enemas also may be useful. **Activated charcoal** (0.1–1.0 mg/kg q 8–12 h) preferably administered with a cathartic such as magnesium sulfate (250 mg/kg) or 70% sorbitol (3 ml/kg) is also indicated to reduce gastrointestinal absorption.

Atropine sulfate (0.02–0.04 mg/kg IM or SC) will decrease salivation and muscarinic signs associated with organophosphate and other poisoning, but because of the risk of fatal bronchospasm it is only recommended if marked bradycardia is present.

Pralidoxime chloride (2-PAM, Protopam chloride) is useful to reactivate cholinesterase (10–15 mg/kg IM or SC q 8–12 h) and control nicotinic signs of organophosphate poisoning. It is most effective if exposure was within the previous 24–48 hours, if exposure was by the dermal route and if a slowly eliminated compound was involved (e.g. fenthion, chlorpyrifos).

Diphenhydramine also has antinicotinic activity.

Chelation therapy (e.g. calcium EDTA and/or penicillamine) is indicated for lead poisoning.

Treat cerebral edema (e.g. bromethalin, lead) with mannitol and/or glucocorticosteroids, and control seizures or pseudo-seizures with diazepam, phenobarbital, propofol and pentobarbital. See page 801 (Likely symptomatic epilepsy) for treatment details.

Provide supportive care including fluids, which also promote excretion of the toxin.

Prognosis

Prognosis is variable and depends on the severity of the signs and time between intoxication and treatment.

TOXOPLASMOSIS**

Classical signs

- Pneumonia, hepatitis, pancreatitis, myositis.
- Often, uveitis or chorioretinitis.
- Occasionally, focal or multifocal neurological signs.

See main reference on page 705 for details (The Cat With Signs of Acute Small Bowel Diarrhea).

Pathogenesis

Toxoplasma gondii is an opportunistic pathogen. Although subclinical infection is common in cats, **clinical disease rarely develops**.

- Clinical toxoplasmosis causing neurological signs in adult cats is believed to be mainly associated with concurrent stress, illness or immunosuppression that **reactivate a latent infection acquired at a young age by carnivorous associated with hunting**.

Toxoplasma gondii causes a **non-suppurative encephalomyelitis** that may be widely scattered throughout the CNS or localized in one area as a granuloma.

Clinical signs

Systemic signs including lethargy, anorexia, fever are most often related to pneumonia, dyspnea, tachypnea. Hepatitis, pancreatitis, myositis and myocarditis may also occur.

The enteroepithelial cycle with oocyst shedding almost exclusively occurs in young weanling kittens and rarely results in gastrointestinal signs.

Sudden death associated with acute *Toxoplasma* encephalitis may occur in approximately 30% of kittens infected at 6–12 weeks of age.

Ocular signs such as anterior uveitis and chorioretinitis are also common.

Neurological signs manifest rarely even though the organism is frequently found in the CNS.

- Acute to subacute multifocal or focal cerebral signs are more common. Seizures are unlikely to occur as the only sign.

Diagnosis

The antemortem diagnosis of clinical toxoplasmosis is difficult; it relies on serological demonstration of previous exposure and perhaps of recent or active infection, exclusion of other causes, and positive response to treatment.

CSF analysis may reveal a **mild to moderate increase of the protein concentration** (< 1.0 g/L) with normal or only slightly elevated leukocyte count (<50/μl). Organisms are only rarely seen on cytologic examination of CSF and other body fluids.

Demonstration of the organism in tissue biopsy sections will confirm the diagnosis only if inflammation is present.

Fecal examination is likely to be unrewarding because of the short period of oocyst shedding that occurs for only a few weeks after infection.

Serologic testing often cannot distinguish latent asymptomatic from active clinical infection. A positive IgM titer or a 4-fold increase in IgA or IgG titer suggests recent infection. However, in some cats, IgM titers remain positive for months to years after infection, and 20% of cats may not develop IgM titers. IgG titers may take 4–6 weeks to develop and high IgG titers (> 30 000) are commonly detected 6 years after infection. Positive titers occur in 30–60% of cats. Many adult cats with neurological signs are believed to have reactivation of a latent infection, rather than a newly acquired infection, which is typically detected by a positive 1 IgM titer or rising IgG titer.

Differential diagnosis

Other infectious and non-infectious causes of encephalomyelitis including FIP and non-suppurative meningoencephalitis should be considered.

Treatment

Clindamycin 12.5 mg/kg PO q 12 h doses for a minimum of 4 weeks.

Clarithromycin (7.5 mg/kg PO q 12 h) and **azithromycin** (7–15 mg/kg q 12 h) are newer macrolides which may be useful.

Prognosis

Prognosis is guarded with CNS involvement. Clinical signs of systemic illness usually begin to resolve within 24–48 h of beginning therapy but neurological signs may take weeks to improve and major neurological abnormalities may remain. Response may be poor, slow, incomplete, and recurrence may occur.

IDIOPATHIC EPILEPSY*

Classical signs

- **Recurrent primary generalized tonic-clonic seizures.**
- **The initial seizure frequency is low (< 1 single seizure every 6–8 weeks) but may later increase.**
- **Seizures begin in young adult cats (6 months to 5 years of age) that have no other neurological signs and deficits.**

Pathogenesis

This is believed to result from a **diffuse imbalance between neuronal excitatory and inhibitory mechanisms** that has no underlying cause other than a **genetic predisposition**.

Idiopathic epilepsy is rare and poorly documented in cats.

Clinical signs

Recurrent primary generalized tonic-clonic seizures should be the only sign.

- **There is no aura, no localized or unilateral signs** during the ictus and in the post-ictal phase.

The **initial seizure frequency** should be low with isolated single seizures at more than 6–8 week intervals.

- The **subsequent seizure frequency** could remain low or progressively increase, perhaps to the point of intractability, but this should not occur before several months to a few years from the seizure onset.

Onset of seizures should be during adolescence or young adulthood (probably between 6 months and 5 years).

Diagnosis

Diagnosis is by exclusion of other causes.

Physical and ophthalmological examinations should be normal. Abnormal findings would indicate the presence of another pathological process possibly related to the seizure disorder (e.g. fever, chorioretinitis).

Neurological examination should be normal. Other neurological signs or deficits would indicate that an active or inactive structural brain lesion is present.

CSF analysis should be normal. Abnormalities would reveal the presence of an active or a resolving brain disease.

Brain imaging (MRI) should be normal. Any abnormality could be related to the seizure disorder (e.g. active or inactive lesions).

Idiopathic epilepsy should be excluded when there are **partial seizures** (including seizures that appear to be generalized from their onset but that are preceded by an aura or followed by localized post-ictal signs), **a seizure onset before 6 months or after 5 years of age, an initially high seizure frequency, a rapid increase of the seizure frequency** within the first few weeks or months, other neurological signs or deficits, CSF changes or MRI abnormalities.

Differential diagnosis

Extracranial causes of seizures such as metabolic, toxic and hypoxic causes usually produce a sudden

onset of high-frequency seizures, often cluster seizures or status epilepticus, and other diffuse neurological and/or systemic signs before and in between the seizures.

Active brain diseases often cause a higher seizure frequency, interictal neurological signs and deficits, and abnormal findings upon CSF analysis or brain imaging.

Likely symptomatic **epilepsy** may sometimes be distinguished from idiopathic epilepsy only by the occurrence of partial seizures and/or the presence of focal neurological deficits because CSF analysis and MRI may also be normal.

Treatment

Symptomatic anti-epileptic drug therapy for life (see Likely symptomatic epilepsy, page 801).

Prognosis

Good seizure control should be obtained in most cases, although some cats can progress toward refractoriness, despite adequate anti-epileptic drug treatment.

HYPOCALCEMIA*

Classical signs

- Muscle fasciculation, especially involving the head and ears.
- Generalized weakness.
- Stiffness, tremors, tetany.
- Rarely, convulsive status epilepticus.
- Vomiting.

See main reference on page 962 for details (The Cat With Generalized Weakness).

Clinical signs

Symptomatic hypocalcemia is rare in cats. It is usually iatrogenic following bilateral thyroidectomy.

Signs are episodic or persistent and include multifocal muscle fasciculations, which often involves the face and ears. This may progress to generalized weakness with stiffness, panting, tremors and tetany. Terminally, convulsive status epilepticus may occur.

Diagnosis

Diagnosis is based on finding a **total serum calcium concentration** < 1.6 mmol/L (6.5 mg/dl) and ionized calcium level < 0.6 mmol/L (2.5 mg/dl).

Other historical, clinical and laboratory abnormalities may reflect the underlying cause, including idiopathic or post-thyroidectomy hypoparathyroidism, puerperal tetany, renal failure and phosphate enema.

Differential diagnosis

Other causes of neuromuscular hyperexcitability such as intoxications should be considered. With organophosphate toxicity, muscarinic signs are usually present (miosis, salivation, vomiting, bradycardia). Fenthion has few muscarinic signs and mainly produces muscle weakness.

Tetany must be differentiated from convulsive status epilepticus of hypocalcemia. The cat with tetany is conscious although it is very anxious.

Treatment

Calcium supplementation and specific treatment of the underlying cause is required.

- Use 0.5–1.5 ml/kg IV of 10% calcium gluconate. Infuse slowly over 10 minutes while monitoring heart rate. Stop if bradycardia develops. See Hypocalcemia, page 962 in “The Cat With Generalized Weakness” for treatment.

HEAD TRAUMA

Classical signs

- Peracute onset of cerebral signs ± seizures.
- Signs of head trauma, including hemorrhage in eyes, ears, nose.
- Delayed onset epilepsy.

Clinical signs

Concussion manifests with immediate and brief (a few seconds to minutes) mental confusion or loss of consciousness. Recovery is rapid and complete with no residual neurological signs as there are no parenchymal lesions.

Contusions and lacerations produce parenchymal lesions and signs that may worsen over the initial 24 hours because of edema and increased intracranial pressure, but improve afterwards.

- **Forebrain signs include mentation abnormalities** such as depression to semi-stupor and confusion, **behavioral manifestations** such as agitation and dementia, **compulsive activities** including restlessness with propulsive pacing and circling. Hemiparesis and central blindness may also occur.

Seizure onset is often with cluster seizures or status epilepticus occurring immediately or within the first 12–24 hours after trauma. These may initially be difficult to control.

Delayed onset post-traumatic epilepsy (see Likely symptomatic epilepsy, page 800) may occur a few to several months later.

Diagnosis

History and external signs of severe head trauma as a result of a road accident, fall from several stories or mistreatment by humans.

Post-traumatic epilepsy should be excluded if there were no serious forebrain signs and deficits at the time of a reported trauma, as well as when the seizure onset occurs more than 2 or 3 years after trauma.

- **Brain imaging** may demonstrate a parenchymal lesion. A skull fracture may or may not be present.

Differential diagnosis

Cerebrovascular accident may also manifest with an acute onset of severe focal cerebral signs but there are no history or external signs of trauma.

Onset of seizures with low to moderate frequency a few to several months after major head trauma has occurred is highly suggestive of post-traumatic epilepsy but other causes of seizures must be ruled-out.

Treatment

Re-establish or maintain adequate cerebral perfusion.

- **First treat hypotension and systemic shock**, if present, by giving **volume replacement fluids**:

- **Hetastarch** 6%, 10–20 ml/kg to effect, to be given in 5 ml/kg increments over 5–10 minutes to avoid nausea and vomiting,

OR

- **Hypertonic saline** (NaCl 7%), 4–5 ml/kg slow IV over 3–5 minutes.

- If volume replacement fluids are not available, give isotonic **crystalloid fluids** (e.g. NaCl 0.9%, LRS), 40–60 ml/kg/h IV, to effect administering just enough to re-establish euolemia and mean arterial blood pressure.
- **Whole blood transfusion or plasma administration** may be indicated when significant blood loss has occurred.
- **Administer supplemental oxygen** via a nasal or transtracheal catheter. If the cat is unconscious, intubate and ventilate at 10–20 breaths/minute to keep PaCO₂ around 30–35 mmHg.

Control secondary brain edema to prevent or reduce intracranial hypertension.

- If shock treatment has not sufficiently improved the cat's neurological status, if the cat is mentally very depressed or stuporous, or if its neurological status deteriorates (mental status, pinpoint pupils or progression to mydriatic and non-responsive pupils):
 - **Give furosemide** 0.5–2 mg/kg IV.
 - A few minutes later, **give mannitol** 0.5–1.0 g/kg IV slowly over 10–20 minutes. A dramatic decrease of the intracranial pressure and neurological improvement usually occurs within 15 minutes and lasts for 2–5 hours. If neurological deterioration occurs afterwards, mannitol can be repeated for a maximum of three doses over a 24-hour period. Careful monitoring of serum osmolality and electrolytes is mandatory.
- **Keep the head elevated at 15–30 degrees**, avoid pressure on the jugular veins from IV lines, bandage and bedding, and monitor mental status and pupil size continuously.

Glucocorticosteroid administration in the head trauma patient is controversial because of few documented beneficial effects and potential deleterious effects, etc. If the patient does not respond adequately to appropriate fluid, oxygen and mannitol administration, methylprednisolone (Solu-Medrol) may be given if hyperglycemia is not already present (30 mg/kg at time 0, and 15 mg/kg at 2 and 6 hours, followed or not

with a continuous intravenous infusion of 2.5 mg/kg/h for 24 hours).

Control cluster seizures and status epilepticus with anti-epileptic drugs (see Likely symptomatic epilepsy, page 801).

Emergency craniectomy may be indicated when aggressive medical treatment has not succeeded in stabilizing a patient with a depressed skull fracture, calvarial penetration with contaminated bone fragments or foreign material, and focal hemorrhage as documented by brain imaging (CT scan or MRI). Craniectomy with durotomy solely as a decompressive procedure may also be attempted.

RABIES

Classical signs

- Progression from mild behavioral changes, to aggression and vicious behavior, to paralysis and death.

Clinical signs

The development of the disease often follows three stages; an early short prodromal phase (1–2 days) characterized by a non-specific change in mental status; the cat may become shy and withdrawn or affectionate and unpredictable. This progresses into an aggressive and furious form (2–4 days) where the cat may viciously attack anything in sight. This may be accompanied by excessive drooling secondary to dysphagia. Convulsions may also occur. In the later stage (1–4 days) of the illness, the animal develops paralysis, coma and death.

Diagnosis

Any cat presented with an acute onset of aggression or with unusually fractious behavior, should be considered as a rabies suspect and handled with caution.

The diagnosis is made on post-mortem tissue using immunofluorescence antibody (IFA), ELISA and more recently polymerase chain reaction (PCR) testing.

The strain of rabies can be further diagnosed using monoclonal antibody testing.

Routine laboratory tests are unrewarding.

UREMIA

Classical signs

- Mental alterations, abnormal motor function and occasionally, seizures.
- Depression, anorexia.
- Polyuria, polydipsia, weight loss.

See main reference on page 334 (The Thin, Inappetent Cat) and page 231 (The Cat With Polyuria and Polydipsia).

Clinical signs

Neurological signs occur mainly in severely ill patients with advanced stage of acute or chronic renal failure.

Signs are often vague and include mental disturbances such as depression, confusion, restlessness, hyper-reactivity to various stimuli, delirium. Weakness may be evident sometimes with muscle spasms, myoclonia or tremors. Ataxia, head-bobbing and muscle fasciculations may also occur. The signs are likely caused by the debilitating effects of renal failure, uremic encephalopathy and associated metabolic disturbances including hypocalcemia, hypoglycemia, acid-base disturbances, anemia.

- **Seizures occur in severely ill cats** and more often with acute than chronic renal failure.

Diagnosis

Other historical, clinical and laboratory abnormalities consistent with severe renal failure and perhaps related to the underlying cause (e.g. ethylene glycol intoxication) are present. **There is no correlation between the degree of azotemia and the severity of the neurological signs.**

FELINE IMMUNODEFICIENCY VIRUS ENCEPHALOPATHY

Classical signs

- Usually asymptomatic.
- Rarely, behavioral abnormalities.

Clinical signs

Subtle and non-specific changes in behavior including depression, social withdrawal, compulsive roaming and psychotic behavior have been attributed to FIV encephalopathy. Signs have mainly been observed in the advanced stage of infection.

Diagnosis

Other systemic signs of FIV infection for example, weight loss, fewer immunodeficiency-related infections of the skin, respiratory or gastrointestinal tracts should have manifested by the time neurological signs develop.

CSF analysis may reveal a mild non-specific mononuclear pleocytosis (5–10/ μ l) with normal protein concentration. **A positive antibody test** on a **CSF sample not contaminated with blood** indicates CNS infection.

Unrelated CNS pathologies and secondary opportunistic infections (e.g. FIP, toxoplasmosis) would likely be responsible for neurological signs other than behavioral changes in FIV-positive cats.

Treatment

No effective treatment is known.

37. The cat with stupor or coma

Rodney S Bagley

KEY SIGNS

- Moderate to marked decrease in consciousness and wakefulness.
- Reduced or absent response to external stimuli.

MECHANISM?

- Stupor and coma result from diseases that alter consciousness and wakefulness.

WHERE?

- Disease of the intracranial nervous system including the supratentorial structures (cerebral cortex, thalamus) and the brain stem (midbrain, pons or medulla oblongata) may result in stupor or coma.
- Systemic (metabolic) disease may affect these areas secondarily and result in stupor or coma.

WHAT?

- Diseases of the intracranial nervous system resulting in coma include head trauma, brain tumor, encephalitis, vascular-based diseases and severe hypoglycemia.
- Many of these diseases result in increased intracranial pressure that perpetuates the clinical signs.
- These diseases are often severe.

QUICK REFERENCE SUMMARY

Diseases causing stupor or coma

ANOMALY

- **Hydrocephalus** (p 826)**

If hydrocephalus is congenital, cats may have an enlarged, “dome-shaped” skull. A fontanelle that persists during maturation may be palpable. Acquired hydrocephalus in adults will show no outward anatomical signs. Clinical signs include seizures, poor learning ability, behavior changes, paresis, cranial nerve deficits and changes in consciousness.

continued

continued

METABOLIC

- **Metabolic encephalopathy* (p 830)**

Metabolic encephalopathies secondary to hypoglycemia, hepatic or renal disease may be associated with signs of cerebrocortical dysfunction including seizures, behavior abnormalities and limb dysfunction. Neurological signs tend to be symmetrical. Other signs of a polysystemic disease such as vomiting and diarrhea may be present. Hypoglycemia results in a dazed cat with a drunken, wobbly gait and muscle trembling, which may progress to seizures and coma if severe and untreated.

- **Feline ischemic encephalopathy* (p 828)**

Clinical signs begin acutely and rapidly evolve. Clinical signs usually include circling, blindness and seizures.

NEOPLASTIC

- **Brain tumor*** (p 824)**

Tumors occur most often in older cats. Clinical signs may be acute in onset or slowly progressive. Seizures, circling, paresis, head tilts and nystagmus are most common.

NUTRITIONAL

- **Thiamine deficiency* (p 832)**

Decreased thiamine can result in brain stem disease in cats. Clinical signs initially begin with lethargy, inappetence and reluctance to walk. Later there is vestibular ataxia and episodes of spastic ventroflexion of the neck or opisthotonus, dilated pupils, stupor and coma.

INFLAMMATORY (INFECTIOUS)

- **Encephalitis* (p 829)**

Clinical signs are often diffuse and may not localize to a single area within the nervous system. Fever and leukocytosis are inconsistent findings. Systemic signs of disease such as fever, coughing, vomiting and diarrhea may accompany the neurologic signs. Feline infectious peritonitis, toxoplasmosis and *Cryptococcus* are more common causes of encephalitis. The systemic signs are consistent with the disease process.

TRAUMA

- **Head trauma*** (p 823)**

Usually associated with an acute onset of clinical signs reflective of an intracranial problem. Signs present often include alterations in consciousness, paresis and cranial nerve abnormalities. Fresh blood from lacerations on or around the head, skull fractures, blood in the ear canals, and scleral hemorrhage may be clues to a previous traumatic incident.

TOXICITY

- **Lead toxicity* (p 833)**

Rare in cats because of eating behavior, but they may be exposed through aerosolized paint dust during house renovations. Inappetence and weight loss are early signs. In addition to central nervous system signs of behavioral abnormalities and alterations in mentation, blindness, vomiting, diarrhea and hematologic abnormalities may be found.

INTRODUCTION

MECHANISM?

Stupor and coma result from diseases that primarily or secondarily affect the cerebral cortex and thalamus and/or the reticular activating system of the brain stem responsible for consciousness and wakefulness.

Systemic (metabolic) disease may affect these areas indirectly and result in stupor or coma.

WHERE?

Disease of the intracranial nervous system including the supratentorial structures (cerebral cortex, thalamus) and the brain stem (midbrain, pons or medulla oblongata) may result in stupor or coma.

WHAT?

Diseases of the intracranial nervous system resulting in coma include head trauma, brain tumor, encephalitis and vascular-based diseases.

Many of these diseases result in increased intracranial pressure that perpetuates the clinical signs.

These diseases are often severe.

The most common metabolic diseases producing stupor or coma are hypoglycemia secondary to insulin overdose in a diabetic cat and hepatic encephalopathy secondary to a congenital portosystemic shunt.

DISEASES CAUSING STUPOR OR COMA

HEAD TRAUMA***

Classical signs

- Acute onset of signs including stupor, coma, paresis, gait abnormalities and cranial nerve deficits, especially those involving pupillary responses.

Classical signs—Cont'd

- Evidence of external trauma to the head and face such as facial lacerations, bleeding from the nose and mouth, bruising, retinal hemorrhage or hemorrhage in the external ear canals.

Pathogenesis

Traumatic injury to the brain occurs most commonly from automobile trauma, although gunshot wounds and falls may also occur.

All of these disease processes result in mechanical disruption of intracranial tissues (primary injury) such as axonal shearing.

Primary injuries to the brain may initiate a number of secondary pathophysiological sequelae such as metabolic alterations in neuronal or glial cells, impairment of vascular supply to normal tissue (ischemia), impairment of cerebrovascular autoregulation, hemorrhage (intraparenchymal, intraventricular, extradural or subdural), irritation (seizure generation), obstruction of the ventricular system; edema formation, production of physiologically active products, and finally, increased intracranial pressure (ICP).

Hemorrhage, either within or around the brain, may result in rapid cerebral dysfunction.

In an experimental study of blunt craniocerebral trauma in cats, all had some degree of subarachnoid hemorrhage, and many had subdural hemorrhage. Fifteen percent of cats had subdural hematomas that displaced the corresponding cerebral hemisphere.

- Many also had cortical contusion. Intraparenchymal hemorrhage and petechiation were common, most often in the hemisphere directly receiving the blunt force.
- One-fifth of the cats had tentorial herniation.

Clinical signs

Signs usually begin acutely after trauma.

Intracranial signs most commonly seen include stupor and coma, paresis and gait abnormalities, and cranial nerve deficits, especially those involving pupillary responses.

Evidence of external trauma to the head and face such as facial lacerations, bleeding from the nose and mouth, bruising, or hemorrhage in the external ear canals may be clues to the traumatic etiology.

Diagnosis

The diagnosis of trauma is usually straightforward when the trauma is witnessed.

In some instances, when animals are presented with an acute onset of neurological signs and an unknown history, examining for external signs of trauma such as lacerations or skull fractures is important.

Evaluating the retinas and external ear canals for acute hemorrhage may also provide clues to the diagnosis.

Advanced imaging studies such as CT or MR imaging are useful, primarily for determining structural damage to the brain.

Differential diagnosis

External evidence of a traumatic incident is helpful to separate traumatic causes of stupor and coma from other intracranial diseases.

Sometimes cats with intracranial disease are unbalanced, weak or have seizures and fall. This may result in external injuries being misconstrued as the actual cause of the intracranial signs.

Treatment

Basic life support measures may be necessary including **blood or isotonic fluid administration**.

Corticosteroid administration for treatment of head trauma is commonly used but efficacy is often based upon anecdotal evidence. Beneficial effects of **methylprednisolone sodium succinate (30 mg/kg IV slowly)** in nervous system injury include inhibition of lipid peroxidation and its associated detrimental effects. The role of corticosteroids in the treatment of head trauma, however, is unclear and are currently not recommended in humans suffering from head trauma.

Hyperventilation keeping **PaCO₂** concentrations between 28 and 32 mmHg can **decrease ICP** due to the established effects of PaCO₂ concentrations on cerebral blood flow.

Mannitol is used to decrease cerebral edema and ICP. Mannitol has been thought to decrease cerebral edema primarily through its associated **osmotic effects**, although other effects such as concurrent **decreases in blood viscosity** and **free-radical scavenging** may, in fact, be more beneficial. By decreasing blood viscosity, cerebral perfusion will be increased at the same level of systemic blood pressure. Vasoconstriction will result, lowering cerebral blood volume and concurrently lowering ICP. Mannitol is administered at 1 g/kg IV over 5–10 minutes. **Maximal lowering of ICP** most often occurs in 10–20 minutes.

Furosemide (0.7 mg/kg IV) is a loop diuretic that may help to lower ICP primarily or may **potentiate the effects of mannitol**. Furosemide given 15 minutes after mannitol administration potentiates the intracranial pressure-lowering effects of the latter.

The **antioxidant drug, desferoxamine mesylate** has been shown to reduce cold-induced brain edema in cats.

Surgical treatment centers on evacuation of subdural hematomas, removal of depressed skull fractures, or debridement of damaged tissue and foreign material.

- Craniectomy and durotomy has been shown to lower ICP acutely by 15–65%, respectively, in cats, however, long-term benefits are uncertain.

Prognosis

Prognosis for life is good if signs are not severe.

Cerebrocortical and cerebellar injuries are more readily recoverable from than brain stem injuries.

Prevention

Keep cats in a controlled environment and prevent free-roaming.

BRAIN TUMOR***

Classical signs

- Middle-aged to older cats.
- Signs include seizures, circling, blindness, behavior changes, and may progress to stupor and coma.

Pathogenesis

Neoplasia can arise from structures within or surrounding the brain (primary brain tumors).

Neoplasia secondarily involves the brain via **metastasis** or via direct **extension from extraneural sites**. Primary tumors within the **skull, nasal cavity** or **frontal sinuses** can extend directly into the brain.

Meningioma is the **most common brain tumor** in cats. Meningiomas arise from the arachnoid layer of the meninges. Meningiomas are usually histologically benign, but occasionally are malignant.

Some younger cats with mucopolysaccharidosis have a high incidence of meningiomas.

Gliomas arise from cells of the brain parenchyma. These include **astrocytes and oligodendroglia**.

Choroid plexus tumors arise from areas where the choroid plexus is concentrated (the lateral, third and fourth ventricles).

Signs reflect either primary nervous parenchymal damage from the tumor, or secondary pathophysiological sequelae such as **hemorrhage and edema**. Frequently, these secondary sequelae are more devastating to intracranial function than the primary disease itself.

Clinical signs

Middle-aged to older cats are most commonly affected. Cats are usually older than 5 years of age with a median age of onset of clinical signs at 9 years of age.

Clinical signs are often slowly progressive, however, they can also occasionally begin acutely and be rapidly progressive.

Signs reflect the intracranial location of the lesion.

- Signs include seizures, circling, blindness, behavior changes, cranial nerve abnormalities, and may progress to **stupor and coma**.
- If the brain stem is involved, head tilt, nystagmus and paresis are most common.

Diagnosis

Routine laboratory evaluations (CBC, biochemistry profile) are not affected by intracranial neoplasia.

Hyperostosis of the skull is occasionally present on survey radiographs of the skull, especially with meningiomas. A “sky-line” view may be necessary to image this abnormality.

Diagnosis of a structural intracranial abnormality in the brain is most readily accomplished with **magnetic resonance (MR) imaging** or **computed tomography (CT) of the brain**.

- A broad-based, extra-axial (arising outside and pushing into the parenchyma) **contrast-enhancing mass** on CT or MR imaging is found in most instances of **meningioma**.
- The CT and MR appearance of gliomas is varied and enhancement after contrast administration may not be present. As these tumors arise from brain parenchymal cells, they are found within the neuroaxis (intra-axial).
- **Choroid plexus tumors**, because of the increased concentration of blood vessels within the tumor, **often enhance markedly** after contrast administration. Because of their association with the ventricular system, associated **hydrocephalus** is **common**.

Cerebrospinal fluid often contains **elevations in protein** content but this finding is not pathognomonic for brain tumors.

- Cerebrospinal fluid can contain **evidence of inflammation** (contains elevations in nucleated cells and protein content). If CSF is the only assessment made, an erroneous diagnosis of encephalitis may be made.
- **Cerebrospinal fluid** collection may be associated with an **increased mortality** in cats with space-occupying mass lesions within the intracranial space, because of the sudden decrease in pressure at the cisterna magna.

Differential diagnosis

Cats with intracranial tumors may present with signs similar to other intracranial diseases.

There are no pathognomonic clinical signs for intracranial tumor.

Congenital hydrocephalus may be associated with changes in the skull (“Dome-shaped” skull, persistent fontanelle), but these will not be present with acquired hydrocephalus.

Feline ischemic encephalopathy is usually associated with an acute onset of clinical signs localizing to the cerebral cortex.

Encephalitis may be associated with systemic diseases causing chorioretinitis, fever and leukocytosis.

Treatment

Corticosteroids (prednisolone 1–2 mg/kg q 12 h) may **reduce peritumoral edema** and improve clinical signs.

Surgical removal of primary brain tumors may be accomplished, especially with **meningioma**.

A well-encapsulated, firm whitish mass is most often encountered at surgery in cats. Cortical parenchyma is usually not infiltrated but rather compressed in cats, leaving indentations in the nervous tissue parenchyma after resection.

Radiation therapy at a total dose of 45–48 GY may control tumor growth.

Prognosis

Prognosis for life is good (22–27 months median survival) after surgical removal of meningiomas in cats.

Uncontrolled or untreated brain tumors usually result in **death of the cat in less than 6 months**, however, the natural course of affected cats has not been accurately determined.

Prevention

There is no known way to prevent these diseases.

HYDROCEPHALUS**

Classical signs

- Young cats may have a dome-shaped or bossed appearance to the head or persistent fontanelles.
- Other signs of hydrocephalus include seizures, poor learning ability, behavior changes, paresis, cranial nerve deficits and changes in consciousness.

Pathogenesis

Hydrocephalus is the term commonly used to describe a condition of **abnormal dilation** of the **ventricular system** within the brain.

Hydrocephalus can result from obstruction of the ventricular system, irritation of the ventricular lining (from inflammation or hemorrhage), loss of brain parenchyma (hydrocephalus ex vacuo), be present without an obvious cause (congenital), or rarely, be the result of overproduction of CSF associated with a choroid plexus tumor.

If the ventricular system is obstructed, CSF will be trapped behind the level of obstruction.

Anatomically **smaller areas of the ventricular system are common sites of obstruction**. These include the **interventricular foramen** and the **mesencephalic aqueduct**.

Obstruction can result from **tumor, granuloma, hemorrhage or inflammation**.

- With infectious diseases that affect the ventricular system, the ependymal layer may be damaged predisposing the underlying parenchyma to be penetrated by the agent or associated products.
- An inflammatory reaction ensues, further damaging local tissues.
- The ependymal cells may be lost and replaced by subependymal microgliaocytes or astrocytes. The end stage is a **granular ependymitis**.
- **Feline infectious peritonitis virus** infection is a common cause.

In **Siamese cats hereditary hydrocephalus** is transmitted as an **autosomal recessive trait**.

The cause of congenital hydrocephalus, however, is not always apparent. Speculation suggests that this abnormality may be due to an **obstruction of the ventricular system** during a **critical stage in development** and subsequent damage to the vulnerable maturing nervous parenchyma.

Feline cerebellar hypoplasia is caused by in utero infection with the panleukopenia virus (parvovirus), which affects the external germinal layer of the cerebellum and prevents the formation of the granular layer. Some affected cats have a concurrent hydrocephalus and hydranencephaly.

Hydrocephalus can result in **clinical signs due to loss of neurons** or neuronal function, **alterations in intracranial pressure**, or the associated pathophysiological effects of intracranial disease.

Clinical signs

In young cats prior to ossification of the cranial sutures, hydrocephalus may contribute to abnormalities of skull development such as a thinning of the bone structure, a **dome-shaped or bossed appearance** to the head or persistent fontanelles.

Clinical signs of hydrocephalus reflect the anatomical level of disease involvement.

Supratentorial, vestibular and cerebellar signs are most common.

As the supratentorial structures are often involved with hydrocephalus, **alterations in awareness and cognition are common.**

Many animals affected congenitally may appear to be **less intelligent** than normal.

Circling, paresis and seizure may also be seen.

Severity of clinical signs is not dependent upon the degree of ventricular dilation, but rather on a host of concurrent abnormalities including the underlying disease process, associated intracranial pressure changes, intraventricular hemorrhage, and the acuity of ventricular obstruction.

Diagnosis

Routine laboratory evaluations are normal.

Historical, invasive techniques for diagnosis of hydrocephalus such as pneumo- or contrast ventriculography have been replaced by non-invasive diagnostic modalities.

Survey radiographs may suggest the presence of hydrocephalus, however, are usually not helpful for definitive diagnosis. Findings associated with **congenital hydrocephalus** include loss of gyral striations, separation of cranial sutures (diastasis), and **persistent fontanelles**. If hydrocephalus is acquired **after the skull has formed, abnormalities are rarely encountered.**

Electroencephalography has been used to diagnosis hydrocephalus, primarily prior to advanced imaging.

Classically, **slow-frequency, high-voltage** (amplitude) activity is noted. This pattern, however, can be seen with **other encephalopathies** that destroy cortical parenchyma. Because of this, EEG is rarely used as the sole means of diagnosing hydrocephalus.

Ultrasound can be used to diagnosis hydrocephalus.

- This is most readily accomplished **when a fontanelle is present** providing an “acoustic window” as ultrasound waves do not usually penetrate the skull well enough.
- If the bone is intact, a craniotomy defect can be created.
- For imaging of the lateral and third ventricles, the bregmatic fontanelle may be used.
- Often, ultrasound can be performed in awake cats as a screening test to determine ventriculomegaly.
- Depending upon the size of the fontanelle, the **lateral and third ventricles** as well as the **mesencephalic aqueduct** are usually easily identified.

Computed tomography (CT), as a non-invasive intracranial imaging modality, is often useful in defining ventricular size.

Magnetic resonance (MR) imaging also affords evaluation of the ventricular system. This modality provides better parenchyma resolution than CT, and is especially useful for evaluation of the infratentorial structures.

Diffuse ventricular enlargement suggests congenital ventricular dilation or obstruction at the level of the lateral apertures or foramen magnum. **Focal ventricular enlargement** suggests **focal obstruction** or **parenchymal cell loss**.

Animals with an **asymmetric appearance** of the ventricles should be critically evaluated for **focal obstruction** of or impingement on the ventricular system due to **mass effect**.

Differential diagnosis

Congenital hydrocephalus may be associated with changes in the skull (“dome-shaped” skull, persistent fontanelle), but these will not be present with acquired hydrocephalus.

Cats with hydrocephalus may present with signs similar to other intracranial diseases. Rule out other **inflammatory, neoplastic and traumatic causes of intracranial disease.**

There are no pathognomonic clinical signs for acquired hydrocephalus in adult animals.

Correlation of degree of ventricular enlargement and clinical signs is poor.

Treatment

Medical treatment may include general supportive care, and medications to limit CSF production and reduce intracranial pressure.

Glucocorticoids are used to decrease CSF production, thereby, limiting intracranial pressure and further neurologic injury. Prednisone at 0.25–0.5 mg/kg is given orally twice daily. The dose is gradually reduced at weekly intervals to 0.1 mg/kg every other day. This dose is continued for at least one month. Then the medication is discontinued if possible.

Alternatively, **dexamethasone** may be given orally at 0.25 mg/kg every 6–8 hours. The dose can be gradually reduced over 2–4 weeks.

Some animals can be adequately managed with long-term glucocorticoid administration at low doses.

If no clinical benefits are observed within 2 weeks, or if side effects develop, other forms of therapy should be tried.

Surgical procedures where a shunt is placed in the ventricle are designed to provide controlled CSF flow from the ventricles of the brain to the peritoneal cavity. Commercial pediatric ventriculoperitoneal shunts are available for this purpose.

Prognosis

Generally poor unless definitive surgical correction is successful. In some cats, clinical signs can be managed on a long-term basis with medication therapy alone.

FELINE ISCHEMIC ENCEPHALOPATHY*

Classical signs

- Signs occur acutely and reflect a unilateral cerebrocortical abnormality.
- Signs include seizures, circling, blindness, behavior changes and may progress rapidly to stupor and coma.

Pathogenesis

Feline ischemic encephalopathy is an **ischemic necrosis** of the **cerebral hemisphere** of cats.

The distribution of the vascular change is usually in the area supplied by the **middle cerebral artery**.

Vascular lesions, however, are infrequently found at necropsy.

Some authors have speculated that this disease is the result of a Cuterebra migration.

One 7-year-old Siamese cat has been reported with an intravascular malignant T-cell lymphoma occluding the middle cerebral artery.

Clinical signs

Clinical signs **begin acutely**.

Signs often reflect a **unilateral cerebrocortical abnormality**.

Signs include **seizures, circling, blindness, behavior changes** and may progress to stupor and coma.

Diagnosis

Routine laboratory evaluations are normal.

Cerebrospinal fluid often contains **elevations in protein content** but this finding is not pathognomonic for this disease.

CSF may contain mild increases in nucleated cells (usually < 10 cells/ μ l). Neutrophils, macrophages and mononuclear cells are possible.

Diagnosis of a structural intracranial abnormality in the cerebral hemisphere is most readily accomplished with **magnetic resonance imaging** of the brain. Minimal changes, however, may be seen on MR studies with this disease.

Cerebral angiography would theoretically aid in the diagnosis of this disease, but is rarely performed.

Differential diagnosis

Rule out brain tumor, encephalitis, head trauma and hydrocephalus.

Treatment

No treatment has been shown to be effective.

Prognosis

Prognosis for life is good after the first 48 hours as this is a non-progressive disorder.

Residual neurologic deficits, most notably seizures, may persist throughout life. Behavioral changes, such as aggression or irritability may persist and make the cat less acceptable as a pet.

Prevention

None.

ENCEPHALITIS*

Classical signs

- Neurological signs are often diffuse or multifocal.
- Cervical pain can be present.
- Fever is an inconsistent finding.
- Chorioretinitis is often present on fundic examination.
- Other signs of polysystemic disease such as coughing, vomiting and diarrhea may be associated.

See main reference on page 859 for details (The Cat With Tremor or Twitching).

Clinical signs

Numerous infectious agents have been incriminated, with the incidence of infectious agents causing meningitis varying with geographic location. Systemic signs reflect the specific agent.

- Infectious agents causing brain disease include viral (**feline infectious peritonitis**), fungal (**cryptococcosis**, blastomycosis, histoplasmosis, coccidioidomycosis, aspergillosis), protozoal (**toxoplasmosis**, neosporosis), bacterial, rickettsial, and unclassified organisms (protothecosis).
- Involvement of the intracranial nervous system can occur with parasites such as **Cuterebra larvae**, **toxocara**, and aberrant **heartworm** migration.

Clinical signs are often diffuse or multifocal and may not localize to a single area within the nervous system. Clinical signs often reflect multiple levels of neurological involvement

Cervical pain can be present.

Fever is an inconsistent finding.

Fundic examination is important to look for clues of systemic inflammatory disease, as **chorioretinitis** is often present.

Other signs of a **polysystemic disease** process such as inappetence, weight loss, **nasal discharge**, **coughing**, **vomiting**, and **diarrhea** may be associated.

Diagnosis

Complete blood cell count may show evidence of systemic inflammation (e.g. leukocytosis).

Serum biochemical analysis may show evidence of systemic abnormalities if the disease diffusely affects the body (e.g. vasculitis) such as elevated globulin, CK, liver enzymes or creatinine.

Evaluation of titers for the infectious diseases often helps to rule in or out the diseases.

Cerebrospinal fluid analysis (CSF) will usually show evidence of **increased nucleated cells** and/or **elevated protein content**. Occasionally, CSF will be normal.

- Evidence of inflammation on CSF evaluation alone, however, is not specific for primary encephalitis as other CNS disease (e.g. **neoplasia**) **may result in a CSF pleocytosis** and protein increases.
- With feline infectious peritonitis (FIP), cerebrospinal fluid analysis may show a pleocytosis, with either **mononuclear** or non-lytic **neutrophils** as the predominant cell type and **elevated protein** concentration, often > 1 g/L (0.1 g/dl).
- With **toxoplasmosis**, cerebrospinal fluid frequently contains a pleocytosis, usually with mononuclear cells, and occasionally, eosinophils. Increasing IgG or a single positive IgM serum antibody titer is suggestive of active infection. Animals with **neurologic signs and positive IgM titers warrant treatment** for the disease.

With **cryptococcosis**, identification of the organism from cytological evaluation of samples such as CSF, nasal discharge, and skin lesions supports the diagnosis.

A neurophilic pleocytosis, and occasionally an eosinophilic pleocytosis may be found on CSF analysis. If positive, detection of the cryptococcal capsular antigen in serum is usually diagnostic. Tissue biopsy and fungal culture or fungal culture of CSF may be more definitive in the diagnosis as occasionally the serum titer is negative.

With parasites such as *Cuterebra* larvae, toxocara and aberrant heartworm migration, CSF may show inflammation with eosinophils in some instances.

Imaging studies (CT and MR) are helpful for defining structural lesions. **Multifocal, contrast-enhancing lesions** are usually seen. Occasionally, non-contrast-enhancing lesions are present, especially with toxoplasmosis.

Differential diagnosis

Multifocal signs are more suggestive of **encephalitis**.

Cats with encephalitis may present with signs similar to other intracranial diseases such as brain tumor, trauma, hydrocephalus and cerebrovascular disease.

Treatment

Treatment is directed at a specific infectious cause if found.

Without a definable cause of the encephalitis, the author uses **trimethoprim-sulfadiazine** (30 mg/kg PO q 12 h), **clindamycin** (25 mg/kg q 12 h), and **corticosteroids** (prednisone 1–2 mg/kg PO q 12 h) in combination.

While corticosteroids are contraindicated with infectious diseases, they are often beneficial in the acute treatment of brain inflammation and edema. These associated pathophysiological events often lead to more neurologic deterioration than the organism itself.

If rickettsial diseases are endemic, **chloramphenicol** or **doxycycline** can be substituted or added to the regime.

If the animal is receiving phenobarbital, do not use chloramphenicol as this drug will decrease the metabolism of the barbiturate and the animal will become comatose and possibly die. Also, chloramphenicol may result in bone-marrow suppression in cats.

With feline infectious peritonitis (FIP), no specific treatment is effective. Immunosuppressive therapy may result in short-term improvement of clinical signs.

With **toxoplasmosis**, treatment includes **clindamycin and trimethoprim** sulfa antibiotics.

For **cryptococcosis**, treatments that have had some success for cryptococcosis in cats include amphotericin B, fluconazole, itraconazole, and flucytosine. See page 26 (The Cat With Signs of Chronic Nasal Disease for treatment details).

With CNS parasites, treatment has not been attempted uniformly and treatment recommendations are anecdotal.

Prognosis

Many of the encephalitis are poorly responsive to treatment, and therefore morbidity and mortality is > 50%.

Some infectious encephalitis (e.g. toxoplasmosis) may be cured with appropriate treatment.

METABOLIC ENCEPHALOPATHY*

Classical signs

- **Hepatic encephalopathy** usually occurs in younger cats. Clinical signs include seizures, ptialism and mentation changes.
- **Cats with diabetic ketoacidosis** may have cerebral signs (depression).
- **Cats with hypoglycemia** may show depression, seizures and tremors.

Pathogenesis

Various metabolic imbalances within the body may produce physiologic alterations, toxins or by-products that effect nervous system functions.

Hepatic encephalopathy (HE) results when numerous putative neurotoxins reach the brain unmetabolized as they pass through an abnormally functioning liver or bypass hepatic detoxification.

Younger animals with HE usually have congenital portosystemic shunts, however, some animals do not have clinical signs of this disease until later into adulthood.

Hepatic encephalopathy in older animals can be associated with liver failure such as with cirrhosis.

Hypoglycemia can occur secondary to some endocrine disorders such as hypoadrenocorticism and insulinoma or from lack of production by the liver in young kittens or in cats with liver failure, and some tumors. However, it is **most common following overdose of insulin in diabetic cats**.

Because the central nervous system (CNS) requires a constant supply of glucose, clinical signs of hypoglycemia relate to CNS dysfunction and activation of the sympathetic nervous system and include depression, seizures and tremors.

Cats with **diabetic ketoacidosis** may have cerebral signs (depression), but whether these changes relate to the hyperglycemia or other physiologic derangements such as hyperosmolality is unknown.

Hypernatremia can result in abnormal mentation progressing to stupor and coma.

- Hypernatremia usually results from inadequate drinking. This may occur due to alterations in awareness of thirst or inability to physically move to water.
- Idiopathic adipsia can occur, usually in younger cats.

Hypernatremia and adipsia in an older animal should warrant an evaluation for structural intracranial disease such as hydrocephalus and brain tumor.

Renal failure and pancreatitis may affect cerebral function if severe, producing depression, stupor, tetany or seizures.

Clinical signs

Neurologic signs often include seizure, alterations in mentation, behavior abnormalities and paresis.

Neurologic signs are **often symmetrical** and **may be episodic**.

Clinical signs of **hepatic encephalopathy** include **seizures, ptialism and mentation changes**.

In hypoglycemia, clinical signs occur due to decreased CNS glucose supply (neuroglycopenic signs) or because of sympathetic nervous system activity.

- Weakness and seizures are most common. Affected animals may be depressed, and have intermittent twitches or tremors.

Clinical signs of hypernatremia include adipsia, depression, seizures progressing to stupor and coma.

Uremic encephalopathy may result in depression, stupor, myoclonic movements, generalized weakness and partial or generalized seizures.

Diagnosis

Diagnosis of metabolic encephalopathy is suggested by metabolic abnormalities on routine physical examination or laboratory evaluations (CBC, serum biochemical analysis, urinalysis).

Diagnosis of hepatic encephalopathy is supported by **abnormal liver function studies** such as elevated pre- or post-prandial **bile acids** or elevated fasting **ammonia**. Ammonia chloride challenge is rarely required in cats to make a diagnosis.

- Abdominal ultrasound may show abnormal liver vasculature.
- Portal vein angiography or direct visualization at surgery may be needed for accurate diagnosis.

Diagnosis of hypoglycemia is based upon finding **hypoglycemia** (blood glucose < 3.3 mmol/l: 60 mg/dl) in the face of clinical signs.

- Concurrent measurement of **serum insulin concentration** will help identify an insulin-secreting tumor, by demonstrating inappropriately high insulin concentration in the presence of hypoglycemia. Non-beta cell tumors producing hypoglycemia have low to undetectable insulin concentration during hypoglycemia.
- Insulin-treated diabetic cats with clinical hypoglycemia need re-evaluation. Some cats will be in **diabetic remission** and do not need **insulin**. Other cats have accidentally received a higher than normal dose. This may occur when insulin syringes are changed from U100 to U40 or from 0.5 ml to 1 ml syringes. Accidental overdose may also occur when someone other than the owner gives the insulin. Careful history taking will identify these problems.

Diagnosis of hypernatremia is based upon finding elevated serum sodium (> 165 mmol/l: 165 mEq/l) in the face of clinical signs.

- Diagnosis of a structural intracranial abnormality in the hypothalamus or pituitary region is most readily accomplished with computed tomography or magnetic resonance imaging of the brain.

Differential diagnosis

Rule out other inflammatory, neoplastic and traumatic causes of intracranial disease.

Treatment

Treatments should be directed at the underlying metabolic abnormality.

Medical treatment of hepatic encephalopathy centers on frequent small meals of a **low-protein diet**, **antibiotics** (metronidazole 7.5 mg/kg PO q 12 h and neomycin sulfate 20 mg/kg PO q 8–12 h), **L-carnitine** (250–500 mg/cat/day PO as aqueous solution), **taurine** (250–500 mg/cat/day in food), arginine (250 mg q 12 h in food), vitamins B, K₁ and E and **lactulose** (1–3 ml/cat PO q 8–12 h to produce a soft stool, beginning at the lowest dose and increasing as necessary). If the cat is severely depressed, lactulose should be given as a retention enema for the first 1–2 days. A solution of three parts lactulose to seven parts water is dosed at 18 ml/kg q 4–6 h. The solution is instilled via a Foley catheter as cranially in the colon as possible. The solution must be aspirated after 15–20 minutes. Fluid and electrolyte status should be monitored carefully to avoid dehydration and hypernatremia. Benzodiazepine receptor antagonists (e.g. flumazenil) may be useful in cats with severe encephalopathy, but are unproven.

If the clinical signs of hepatic encephalopathy are severe, or do not improve within 4–6 hours after institution of medical treatment, and if the animal is not dehydrated, mannitol (1–2 g/kg IV) followed by furosemide (0.7 mg/kg IV) can be administered as a treatment for possible secondary cerebral edema.

Surgical correction of a congenital portosystemic shunt may result in a permanent cure.

Diabetic cats with marked signs of hypoglycemia should be treated initially at home with **honey or a sugar-solution designed for human diabetics** poured on the owner's finger and rubbed on the cat's buccal mucosa. In hospital, treatment is with dextrose

(1/2–2 ml IV, 20–50% dextrose) to effect. The insulin dose should be decreased by 50% or stopped if the cat is in remission. Accidental causes of overdose should be resolved.

Cats with hypoglycemia associated with neoplasia, including insulinoma should be managed with frequent feeding and corticosteroids (0.5–6 mg/kg/day in divided doses) to antagonize insulin action. See page 962 (The Cat With Generalized Weakness) for further treatment details. Surgical removal of a pancreatic insulin-secreting tumor may normalize serum glucose concentrations.

Treatment for hypernatremia centers on **slowly decreasing serum sodium through fluid administration**. This is most safely accomplished with **oral administration of water**. If the hypernatremia has evolved slowly, extreme caution should be exercised when attempting to decrease serum sodium with fluid therapy. As a rule, **slowly decreasing serum sodium concentrations (over 2–3 days)** is safe, however, serum sodium should be measured frequently to avoid rapid decreases in sodium which can result in life-threatening cerebral edema. Do not decrease serum sodium by more than 0.5 mmol (mEq)/L/h (12 mmol/L/day) if the hypernatremia is chronic.

If metabolic encephalopathy results in cerebral edema, mannitol (1 g/kg IV bolus) and furosemide (0.7 mg/kg IV) can be given provided the cat is not dehydrated. Indications for therapy are severe signs or lack of improvement after 4–6 hours of appropriate medical treatment.

Prognosis

Prognosis depends upon the ability to treat the underlying disease process.

THIAMINE DEFICIENCY*

Classical signs

- Initially, lethargy, inappetence and ataxia.
- Later signs include weakness, ventral flexion of the neck, dilated pupils, stupor, and coma.

See main reference on page 848 for details (The Cat With a Head Tilt, Vestibular Ataxia or Nystagmus).

Pathogenesis

Occurs in **anorexic cats** or cats that are **fed all-fish diets** containing thiaminase.

This deficiency results in polioencephalomalacia of the oculomotor and vestibular nuclei, the caudal colliculus and the lateral geniculate body.

Clinical signs

Early non-specific signs are **typically lethargy and inappetence**.

The earliest localizing sign is **bilateral vestibular ataxia**, which appears as **an abnormal broad-based stance**, loss of balance and vertigo.

There is weakness and an **inability or reluctance to walk**. The cat sits **crouched with ventral flexion of the neck**.

Pupils are dilated and non-responsive or poorly responsive to light reflexes.

If untreated, signs **progress to semi-coma**, persistent vocalization, opisthotonus and death.

Episodes of spastic opisthotonus or ventroflexion of the neck and generalized muscle spasm may occur especially when the cat is lifted or stressed. They may be interpreted as seizures, but true seizure activity rarely occurs.

Diagnosis

No antemortem diagnostic test is available.

Diagnosis is based on **clinical signs** and **rapid response to thiamine**.

Differential diagnosis

Other **encephalopathies** and **encephalitis** are differentiated on history, CSF findings and lack of response to thiamine.

Head trauma may appear similar to late signs of thiamine deficiency, but can usually be differentiated on history and evidence of trauma. Thiamine-deficient cats are lethargic and inappetent days and weeks before signs are severe.

Hydrocephalus can present with central blindness and ataxia, but there is no response to thiamine.

Dysautonomia is a consideration in countries where it occurs. The bilateral non-responsive pupils and ventroflexion of the neck may appear similar to thiamine deficiency, but there is no response to thiamine.

Hypokalemic myopathy, myasthenia gravis, polymyositis and **organophosphate** toxicity can all cause ventral flexion of the neck. However, **ventral neck flexion in thiamine deficiency is the result of active muscle contraction** associated with increased muscle tone rather than passive ventroflexion from weakness. Thiamine deficiency responds to thiamine supplementation unless in terminal stages.

Treatment

Treatment is **administration of thiamine** dosed typically at 5–30 mg/cat/day per os. Maximum dose up to 50 mg/cat/day.

Severely affected cats should receive at least **1 mg parenterally**.

Change the diet to one with adequate thiamine and **supplement with thiamine for at least a week**.

Prognosis

Mildly affected cats usually recover rapidly following administration of thiamine.

Cats that have progressed to a comatose state have a poor prognosis.

LEAD TOXICITY*

Classical signs

- Rare in cats compared to dogs.
- Nervous system signs include mentation changes, seizures, ataxia, blindness.
- Gastrointestinal signs and hematologic abnormalities may accompany the CNS signs.

Pathogenesis

Lead toxicity usually results from ingestion of lead-containing products.

Removal of **lead-containing paint via sanding** may allow for lead-laden dust to be produced. If this dust

contaminates the cat's fur or adheres to the feet, enough lead may be ingested during normal grooming to cause toxicity.

Clinical signs

Early signs are lethargy, inappetence and weight loss.

Gastrointestinal signs (vomiting, diarrhea) and **hematologic** abnormalities (obvious basophilic stippling or nucleated red cells occur in less than 50% of cats with lead poisoning) may accompany the CNS signs.

Nervous system signs include **depression**, behavioral changes, tremors, seizures, ataxia, **blindness** and weight loss.

Diagnosis

Increased **lead levels** in the cat's **blood** best supports a diagnosis.

Differential diagnosis

Rule out other encephalopathies, encephalitis, head trauma, hydrocephalus and tumor.

Treatment

Chelation therapy with **calcium EDTA** (25 mg/kg SC, IM or IV q 6 h for 2–5 days) or **penicillamine** (10–15 mg/kg PO q 12 h) may be necessary to improve clinical signs.

Prognosis

Variable depending upon the degree of toxicity.

Prevention

Prevent exposure to the toxin.

38. The cat with a head tilt, vestibular ataxia or nystagmus

Joane M Parent

KEY SIGNS

- Cat leans, drifts, falls or rolls to the side of the head tilt.
- Rapid eyeball movement, either horizontally, vertically or rotatory.
- Reluctance to walk, crouched stance, exaggerated swaying of head, poor to absent normal nystagmus.

MECHANISM?

- Any disease affecting the vestibular system, peripherally or centrally, results in a head tilt that may or may not be associated with vestibular ataxia and nystagmus.
- Pendular (described as oscillatory) nystagmus is not vestibular in origin. It is the result of a defect in the visual pathways. It is always congenital.

WHERE?

- The vestibular system is affected either peripherally, in the inner ear within the petrosal bone, or centrally, within the cranial vault, in the brainstem, at the level of the rostral medulla.

WHAT?

- The diseases of the peripheral vestibular apparatus are the most common. They include idiopathic vestibular disease and otitis media-interna.
- Involvement of the central vestibular system occurs less frequently. The meningoencephalomyelitides, including principally feline infectious peritonitis and fungal conditions, are the most common causes.

QUICK REFERENCE SUMMARY

Diseases causing head tilt, vestibular ataxia or nystagmus

ANOMALY

- Congenital vestibular disease (p 848)
Varying degrees of head tilt, falling and rolling are present from birth. Reported in Siamese and Burmese kittens.

continued

continued

- Congenital pendular nystagmus (p 848)

Nystagmus is due to a congenital defect in the visual pathways observed mainly in Siamese and Himalayan cats. Nystagmus persists for life and is oscillatory in character.

NEOPLASTIC

- Neoplasia (p 845)

Chronic and progressive onset of a head tilt. The head tilt may be associated with facial nerve paralysis, decreased lacrimation and/or Horner's syndrome if the tumor is invading the tympanic bulla (squamous cell carcinoma is the most common tumor of the middle ear), or with somnolence, +/- ipsilateral proprioceptive deficits, +/- trigeminal and facial nerve deficits may occur if the tumor is intracranial at the level of the brainstem.

NUTRITIONAL

- Thiamine deficiency (p 848)

Acute onset of bilateral central vestibular signs (lethargy, pupillary dilatation, poor to absent physiological nystagmus, reluctance to move, and side-to-side exaggerated head movements), in cats fed a fish-based diet containing thiaminase or pet mince containing the preservative sulfur dioxide. Signs may also occur following a period of anorexia. A characteristic posture with ventro-flexion of the neck is present.

INFLAMMATORY (INFECTIOUS)

- Otitis media-interna (p 840)

Ipsilateral head tilt, with or without nystagmus, and with varying degrees of ataxia. Unilateral deafness may result. Neurological structures in the middle ear may also be affected leading to an ipsilateral facial paresis/paralysis, decreased lacrimation and/or a Horner's syndrome. Signs may appear 48–72 hours after an ear flush. Very rarely extension of the infection to the central nervous system occurs.

- Feline infectious peritonitis (FIP) (p 844)

History of chronic illness (fever, inappetence, weight loss, lethargy) that has been unresponsive to antibiotics. Ocular lesions may be present. The neurological disease is variable and depends on the location and extent of the central nervous system lesion. Seizures, changed behavior and head tremor are common. If head tilt is present it is always associated with somnolence, with or without cerebellar signs.

- Cryptococcosis (p 847)

Head tilt and altered mental status are associated with systemic manifestations such as anorexia, upper respiratory tract disease or skin disease. Chorioretinitis and optic neuritis often observed. The neurological disease is variable and depends on the location and extent of the central nervous system lesion.

INFLAMMATORY (NON-INFECTIOUS)

- Middle ear polyps (p 842)

Chronic, progressive onset of a head tilt, facial paresis/paralysis, decreased lacrimation, Horner's syndrome and unilateral deafness. Polyps can occur bilaterally. Upper respiratory signs may be present. A mass may be visualized in the external ear canal or the oropharynx.

IDIOPATHIC

- Idiopathic vestibular syndrome (p 839)

Acute to peracute non-progressive onset of a head tilt with ipsilateral falling or rolling in an otherwise healthy cat. The disorientation may be severe. If the disease is bilateral, the head tilt is not evident, the physiological nystagmus is poor to absent, and the cat moves in a crouched posture, low to the ground. The head swings from side to side in exaggerated motions.

IATROGENIC

- Aminoglycosides (p 849)

Acute onset of peripheral vestibular signs uni- or bilaterally following systemic or topical therapy with aminoglycosides. Deafness may accompany the vestibular signs.

- Ear flush (p 846)

Peripheral vestibular signs that appear immediately or in the 72 hours following an ear flush.

TOXIC

- Blue-tailed lizard ingestion (p 848)

In southeastern United States, ingestion of a blue-tailed lizard is thought to be the cause of an acute unilateral peripheral vestibular syndrome.

TRAUMA

- Fracture of the petrous temporal bone or tympanic bulla, and ethmoid fracture (base of the skull) (p 848)

Peripheral and central vestibular signs following a road accident.

INTRODUCTION

MECHANISM?

The presence of a **head tilt**, ipsilateral to the lesion, is the salient **feature of vestibular disease**. **Nystagmus and/or vestibular ataxia may accompany the head tilt**. The more acute the disease process, the more likely that nystagmus and ataxia are present. In vestibular ataxia, the animal leans, drifts, falls or rolls toward the side of the lesion. The **nystagmus can be resting or positional** (induced by holding the head in full extension), and, vertical, horizontal or rotatory in direction. The direction may change in time. **Pendular nystagmus** (oscillatory with rapid, short excursions) is **not a sign of vestibular disease**.

Occasionally, there is **bilateral vestibular disease**. The animal may be reluctant to move because of severe disorientation. If able to walk, there are **characteristic**

exaggerated motions of the head and neck and the cat moves in a crouched posture close to the ground. Physiological nystagmus is poor to absent. In these instances, a head tilt may not be present, or if present, is subtle on the most affected side.

Circling is not a feature of vestibular disease but is frequent with thalamic and cerebral diseases.

The most important diagnostic step is to differentiate if the disease involves the peripheral OR the central portion of the vestibular system.

Peripheral vestibular disease:

- The head tilt is toward the side of the lesion. The nystagmus is horizontal or rotatory but never vertical, and never changes in direction. The ataxia, if present, is on the side of the head tilt.
- By close proximity, the neurological structures associated with the middle ear may be affected leading to facial nerve paresis/paralysis, dry eye from decreased to absent lacrimation, and/or

Horner's syndrome, partial or complete. The cochlear part of the vestibulo-cochlear nerve may be affected leading to ipsilateral deafness.

- If the disease is **bilateral**, there is no head tilt or only a mild one on the side that is the most severely affected. The more acute the disease, the more severe the disorientation. The cat is reluctant to walk and has a crouched posture, low to the ground. The head characteristically moves from side to side in exaggerated motions and there is often ventroflexion of the head and neck. The physiological nystagmus (normal involuntary rhythmic typewriter-like movements of the eyes initiated by side-to-side movements of the head) is poor to absent.

Central vestibular disease:

- **The most consistent feature indicating central vestibular disease is the concomitant presence of somnolence, or quietness of the animal.** This may or may not be obvious at time of examination, **but will be evident with good history taking.**
- The head tilt is toward the side of the lesion. The **nystagmus is horizontal, rotatory or vertical and may change in direction.**
- Due to their close proximity, **other central nervous system structures may be involved ipsilaterally.** These include the ascending reticular activating system or ARAS (**somnolence**) and the ipsilateral trigeminal nerve (**loss of facial sensation and/or masticatory muscle atrophy**), abducent nerve (**strabismus**), facial nerve (**facial paresis/paralysis**), cerebellum (**tremors, hypermetria**), ascending sensory pathways (**proprioceptive deficits**) and descending motor pathways (**upper motor neuron weakness**).
- Bilateral involvement of the central vestibular system appears clinically similar to bilateral peripheral vestibular disorders in the early phase, except that the animal is more quiet or somnolent. If the cause is not corrected, involvement of other structures of the brainstem and/or cerebellum ensues.

Paradoxical vestibular syndrome.

- In this rare syndrome of central vestibular disease, the head tilt is contralateral to the lesion. The diagnosis is made on the presence of cerebellar signs or

postural reaction deficits ipsilateral to the lesion but contralateral to the head tilt.

WHERE?

Peripheral vestibular disease results from a problem in the petrosal bone or tympanic bulla.

- The peripheral part of the **vestibular apparatus** (receptors and nerve) is **situated in the inner ear**, in close proximity to the middle ear. The inner and middle ear are located within the petrosal bone or tympanic bulla. The **facial nerve, the parasympathetic innervation of the lacrimal glands** and the **sympathetic nerve for pupillary dilatation** are the neurological structures associated with the **middle ear**.
- Diseases of the inner ear can by extension reach the middle ear and vice versa.
- The neurologic structures of the middle ear are more resilient to insult than the receptors in the inner ear (receptors vs axons). As a result, middle ear disease may be present without neurological deficits. With time, facial paresis/paralysis and/or Horner's syndrome may appear.
- The **auditory receptors** are situated in the **inner ear** as well. Unilateral deafness goes unnoticed clinically but is diagnosed with electrodiagnostic testing (brain auditory-evoked potentials).

Central vestibular disease results from an intracranial problem in the brainstem, at the level of the rostral medulla. This area is in close proximity to the cerebellum and pons. This anatomical location is called the cerebello-ponto-medullary angle.

WHAT?

The most common causes of vestibular disease are peripheral and include:

- Idiopathic vestibular disease.
- Otitis media-interna.
- Less common causes are the middle ear polyps and tumors.

Central vestibular diseases are not as frequent as peripheral diseases.

- Inflammatory diseases are the most common, with the clinical signs directly related to the location and

severity of the inflammation. Although inflammatory diseases are multifocal or diffuse pathologically, this is often not the case clinically, where the neurological deficits in most cases can be assigned to one location.

Diagnosis is based on careful history taking (to disclose if there is somnolence or quietness of the animal), physical, neurological, otoscopic and ophthalmoscopic (including Schirmer tear test) examinations, serum protein concentration, cerebrospinal fluid analysis (CSF), CSF anti-coronavirus IgG titer, electrodiagnostic testing (brain auditory-evoked responses), bullae radiography, computed tomography (CT) and magnetic resonance imaging (MRI) scan.

Reference ranges for feline CSF.

- **RBC** $< 0.030 \times 10^9/L$ (30/ μ l)
- **WBC** $\leq 0.002 \times 10^9/L$ (2/ μ l)
- **Cytology (%)**
 - Monocytoid cells 69–100%
 - Lymphocytes 0–27%
 - Neutrophils 0–9%
 - Eosinophils 0
 - Macrophages (large foamy mononuclear cells) 0–3%
- **Protein** 0.036 g/L (36 mg/dl)

It is good practice to request electrodiagnostic testing (BAER) to evaluate for deafness. If deafness is concomitantly present, it is an indication of a more aggressive disorder and a thorough diagnostic work up should be pursued.

When a head tilt is present, or when there is facial paresis/paralysis or a Horner's syndrome, **bullae radiography is recommended** to evaluate the middle ear cavities. An open mouth view is best to compare the density between the bullae. Bulla radiography is not a sensitive tool. It may be normal despite the presence of disease. Computed tomography (CT) scan of the bullae is superior and should be done when available.

Regardless of the cause of the vestibular signs, nystagmus and vestibular ataxia usually resolve, but the **head tilt usually persists for the life of the animal**. It may be barely noticeable but may be **exacerbated after a general anesthetic or when the cat is ill**.

DISEASES CAUSING A HEAD TILT, VESTIBULAR ATAXIA OR NYSTAGMUS

IDIOPATHIC VESTIBULAR SYNDROME***

Classical signs

- Acute to subacute onset of a head tilt, falling, rolling and nystagmus.
- Disorientation can be severe with the cat unwilling to move and crying out with anxiety.
- Otherwise healthy cat.

Pathogenesis

Unknown.

Clinical signs

Possibly higher incidence in July and August in north-east United States.

Cats of **any age** or sex, median age is 4 years old.

Acute, non-progressive, unilateral and occasionally bilateral, **peripheral vestibular disturbance**.

The head tilt, ataxia and nystagmus (most often horizontal) can be severe with the animal crying out with anxiety, reluctant to walk, remaining in a crouched posture or with wide abduction of the limbs.

Rarely, can be bilateral.

Vomiting occasionally occurs, usually soon after onset of signs.

Affected cats are otherwise healthy.

Diagnosis

History of an acute to subacute onset, in a previously healthy cat, of severe disorientation, falling and rolling, that **improves rapidly (a few days to 2 weeks)** and without treatment.

The cat is otherwise healthy and has no other neurological signs.

The otoscopic examination is unremarkable.

Diagnosis is usually by exclusion of other diseases causing similar acute signs.

With currently available diagnostic techniques it may not be possible initially to differentiate this syndrome from otitis media-interna, but the **vestibular signs in otitis media-interna do not usually occur so acutely and severely.**

It is advisable to **perform BAERs.** If there is concomitant deafness, the idiopathic syndrome is ruled out as **only the vestibular system should be affected.**

Differential diagnosis

Otitis media-interna usually has a more progressive history. On otoscopic examination there may be otitis externa, mite infestation and/or a ruptured tympanic membrane. Signs of middle ear disease such as facial paresis/paralysis, decreased lacrimation and/or Horner's syndrome are often present. Radiographic changes in the tympanic bulla are rarely observed. Computed tomography and MRI scans are more sensitive for detecting changes.

Middle ear polyps can cause peripheral vestibular disturbance uni- or bilaterally but since the polyps originate from the middle ear, facial and/or sympathetic nerve deficits are present. The onset is mild and progressive. **Blue-tailed lizard** ingestion is believed to cause similar signs in the southeastern United States. Vomiting, salivation, irritability and trembling are also observed. Signs may be indistinguishable from idiopathic vestibular syndrome.

Aminoglycoside toxicity, especially topical streptomycin, can cause uni- or bilateral peripheral vestibular disturbance but the history reveals use of the drug.

Treatment

Supportive. In a few cats, fluid therapy, intravenously or subcutaneously, may be necessary initially.

Sedation (acepromazine 0.05–0.10 mg/kg IM, SC, IV to a maximum of 1 mg) may occasionally be required if the rolling is severe.

Antibiotics such as amoxicillin or cephalosporine for 10 days are indicated if otitis media-interna cannot be ruled out.

Glucocorticoids are not indicated.

Prognosis

Excellent.

Rapid improvement of the clinical signs within the first 2 weeks in all cats.

Most cats recover entirely but frequently have a mild residual head tilt.

OTITIS MEDIA-INTERNA ***

Classical signs

- Acute to chronic history.
- Variable degree of peripheral vestibular disturbance.
- Signs of otitis externa often present.
- Facial paresis/paralysis, decreased lacrimation and/or Horner's syndrome often present.

Pathogenesis

The **infection** extends **from an otitis externa** or **from the oro- and nasopharynx** by way of the eustachian tubes, **or hematogenously.**

Most infections are caused by *Staphylococcus* spp., *Streptococcus* spp., *Proteus* spp., *Pseudomonas* spp. or *Escherichia coli*.

Frequently, mites are the instigating factor for the otitis externa, which leads to secondary microbial infection with spread to the middle ear.

Clinical signs

The diagnosis of otitis media-interna is difficult as, except for surgical exploration of the tympanic bulla, the tests performed have a low diagnostic yield.

The cat may have a history of chronic otitis externa. The ear may be sore to touch. There may be head shaking or scratching and frequent pawing at the ear.

There may be **difficulty in prehension** or chewing food due to pressure on the petrosal bone region upon jaw opening as the temporo-mandibular joint is in the vicinity of the petrosal bone.

The corner of the mouth may be wet with saliva.

On otoscopic examination, the external ear canal may be red and inflamed with a brownish discharge. Mites may be present. The **tympanic membrane may be red and bulging or perforated**.

The onset and the neurological deficits depend on the extension and severity of the infection. The onset of the vestibular signs may be acute with a marked head tilt, disorientation and nystagmus, or, chronic with nothing else other than a mild head tilt.

The **concomitant presence of facial nerve paresis/paralysis, decreased lacrimation and/or Horner's syndrome confirms involvement of the middle ear**. The facial weakness may be subtle. Look for a complete closure of the lids following a single stroke of the finger on both lids at once. Look for saliva-stained hair at the commissure of the lips or for a droop of the lips on the side affected. The symmetry of the pupils is best assessed in a dark room to evaluate for the presence of a partial Horner's syndrome.

Facial nerve paralysis may be accompanied by **keratoconjunctivitis sicca** because innervation of the lacrimal glands is carried by the facial nerve. A Schirmer tear test should be routinely done in these cases to avoid the formation of corneal ulcer.

Unilateral deafness is often present, but can be substantiated only with electrodiagnostic testing (BAER).

Diagnosis

Otoscope examination may disclose an otitis externa, mite infestation or tympanic membrane bulging/perforation.

If there is an otitis externa, cytology and culture with sensitivity testing should be done. The same organism may be causing the middle-inner ear infection.

The presence of facial paresis/paralysis, decreased to absence of lacrimation or Horner's syndrome is a strong indicator of concomitant middle ear disease, but is not specific for infection.

On physical examination, there may be pain on opening the mouth or pain upon manipulation of the head.

Hearing should be evaluated with BAERs:

- Concomitant deafness indicates a more significant disease process such as in middle-inner ear infection, but is not specific for the disease. It is an indi-

cation that a more thorough diagnostic work up should be performed.

- Normal hearing does not rule out middle-inner ear infection because the auditory receptors are in the inner ear.

Bullae radiographs have a low sensitivity:

- It is important to obtain an open mouth view to visualize both bullae simultaneously for comparison.
- A normal study does not rule out middle-inner ear disease.
- The tympanic bulla may appear denser if there is an effusion.
- Thickening of the bulla or bone lysis may be observed in more severe and chronic infections.

Cytological examination and culture with sensitivity testing of the middle ear fluid is indicated when an effusion is suspected:

- The myringotomy is done using an otoscope to guide a 2½" spinal needle through the tympanic membrane.

CT or MRI scans are superior to radiographs to confirm tympanic bulla disease, but the changes detected are not specific for infection.

Surgical exploration of the middle ear with cytological examination and culture with sensitivity testing is the only definitive diagnostic tool in middle-inner ear disease.

Differential diagnosis

Idiopathic vestibular disease has an acute to per-acute onset in a cat that is otherwise healthy. There is no facial paresis/paralysis, decreased lacrimation, deafness or Horner's syndrome because the disease is limited to the vestibular part of the inner ear. Signs resolve over 1–2 weeks without treatment.

Neoplasia and middle ear polyps can be difficult to differentiate from middle-inner ear infection without an exploratory bulla osteotomy. If a polyp is visible in the external ear canal or in the oro-nasopharynx, a diagnosis of middle ear polyp is likely.

Treatment

If a bacterial middle-inner infection is suspected, early and aggressive treatment with antibiotics is best. If cul-

ture and sensitivity are not available, a broad-spectrum antibiotic is chosen such as trimethoprim-sulfa, cephalosporin or a penicillinase-resistant penicillin (enrofloxacin).

Antibiotic treatment should be continued for **6–8 weeks**.

If otitis externa is present, the antibiotic is chosen based on the culture and sensitivity of the external ear canal. The otitis externa should be treated as well. **Systemic treatment is preferable if the tympanic membrane is perforated or cannot be visualized.** Avoid topical drugs that are toxic for the vestibular and/or auditory system (gentamycin, neomycin). Selamectin (Revolution®) or systemic ivermectin (200–300 µg/kg IM, SC, PO) is preferable as a miticide rather than topical treatment.

Cats with radiographic changes in the bullae are treated with **surgical curettage of the tympanic bulla to allow drainage**, followed by long-term antibiotherapy based on the culture and sensitivity obtained from the sample collected at time of surgery. If the culture is negative, a broad-spectrum antibiotic as listed above is administered for 2–4 weeks.

If there is chronic or recurrent otitis externa, ablation of the external ear canal is indicated.

In the presence of paralysis of the eyelids, artificial tears are unnecessary if tear secretion is normal as the spread of the tear film is taken over by the third eyelid. **Artificial tears** should be administered 2–6 times daily in the affected eye, **if the Schirmer tear test is abnormal** (< 10 mm/minute), to avoid development of a corneal ulcer.

Prognosis

Facial paralysis and partial Horner's syndrome often remain, although the severity is much improved. An ipsilateral mild deviation of the face occurs over time.

The vestibular signs resolve in most cases, except for the head tilt, which frequently remains for the life of the animal.

The cases managed medically may recur and require surgical curettage at later date.

Prevention

Treat otitis externa effectively when it occurs.

Treat ear mites.

MIDDLE EAR POLYPS**

Classical signs

- Mild and slowly progressive head tilt.
- +/- respiratory signs.
- +/- signs of otitis externa.
- +/- facial paresis/paralysis, +/- Horner's syndrome +/- keratoconjunctivitis sicca, +/- deafness.

Pathogenesis

The pathogenesis is incompletely understood.

The polyp **originates from the middle ear cavity** and is **composed of inflammatory granulation tissue** covered by respiratory epithelium.

The instigating cause is not exactly known. Some believe that it is congenital, to explain its frequency in very young cats. Others postulate that it results from chronic inflammatory middle ear disease, secondary to upper respiratory infections. The respiratory infection would create abnormalities in the eustachian tube epithelium, resulting in poor middle ear ventilation and secondary inflammation.

Most cats with middle ear polyps have a **bacterial infection**. The most common bacterial isolates are *Pasteurella multocida*, *Streptococcus*, *Staphylococcus*, *Bacteroides* and *Pseudomonas*.

The polypoid growth has a tendency to exit the middle ear cavity. It can do so by rupturing the tympanic membrane and **emerging into the external ear canal**, causing characteristic signs of otitis externa, or it **enters the eustachian tube to exit into the nasopharynx** with subsequent upper respiratory signs. The frequency of each end location versus the other is unknown.

The polypoid growth within the middle ear cavity may **encroach on the inner ear leading to vestibular signs**.

Clinical signs

Typically occurs in **young cats**, but any age can be affected (**mean age 1–5 years**; range 6 months to 15 years).

The most common signs associated with a middle ear polyp, which extends into the nasopharynx, are upper respiratory signs including **noisy breathing, dyspnea with or without nasal discharge, sneezing or coughing** and gagging.

Less often are signs characteristic of otitis externa.

Rarely a head tilt may be present. The head tilt may occur without other signs, or with upper respiratory signs, or with a visible external ear canal polyp.

Since the polyp originates within the middle ear cavity, the neurological structures of the middle ear may be affected causing facial paresis/paralysis, keratoconjunctivitis sicca and/or partial or complete Horner's syndrome. These can also occur without other signs.

Diagnosis

A mild and transient head tilt may be the only abnormality on neurological examination.

The concomitant presence of a **fibrous mass in the external ear canal**, or **upper respiratory signs**, is pathognomonic for middle ear polyp.

The concomitant presence of facial paresis/paralysis, decreased lacrimation and Horner's syndrome with a head tilt is indicative of middle and inner ear disease but is not diagnostic for the type of disease.

If there are upper respiratory signs, **visualization of the polyp in the nasopharynx** under anesthesia is the most efficient way of reaching a diagnosis.

- A glistening, red or pinkish mass filling the nasopharynx, or originating from the eustachian tube may be found.

Otoscopic examination, which may necessitate sedation/anesthesia to evaluate both ear canals and tympanic membranes should be performed.

- Aural inflammation may be present.
- A pedunculated red, pink or grayish mass may be observed in the ear canal.

The polyp may also affect hearing. Presence of deafness is evaluated by doing BAERs.

When a head tilt is present and there is facial paresis/paralysis, decreased lacrimation or a Horner's syndrome, bulla radiography is recommended to evaluate the middle ear cavities. An open mouth view is best to compare the density between the bullae. Bulla radiography is not a sensitive tool. It may be normal despite the presence of uni- or bilateral polyps. CT and MRI scans are superior in the diagnosis of middle ear cavities, and one of these scans should be performed if available.

CT and MRI scans are the most sensitive imaging techniques to reach a diagnosis of middle ear disease, but are not specific for the type of disease.

The final diagnosis is obtained at the time of surgery. **Surgical exploration of the middle ear is the only reliable test to reach a diagnosis.** Cytology and culture and sensitivity of the curetted tissue should always be done.

Differential diagnosis

If the disease process involves the middle ear, otitis media-interna, middle ear polyp and neoplasia of the middle ear cavity cannot be differentiated without biopsies taken at the time of surgical bulla exploration.

Treatment

Removal of the polyp from its origin through a ventral bulla osteotomy is the best therapeutic approach to avoid recurrence. Removal by grasping the polyp and cutting it at the base from the nasopharyngeal or aural location leads to a high recurrence rate.

Horner's syndrome is a frequent complication of bulla osteotomy. It resolves in most cases in 1–3 weeks, but even if it remains, it does not alter the patient's quality of life.

The head tilt, if present at onset, usually remains for the life of the patient. Occasional transient vestibular ataxia is rarely reported as a surgical sequella of polyp removal.

The cat should be treated for 6–8 weeks with an **antibiotherapy** based on the culture and sensitivity done at the time of surgery.

Prognosis

Removal of the polyp by a ventral bulla osteotomy minimizes the risk of recurrence. Recurrence is frequent using oral or aural access to the polyp.

The head tilt usually remains but the other vestibular signs (ataxia and nystagmus) usually resolve.

If facial paralysis is present, ipsilateral deviation of the face ensues.

If a Horner's syndrome is present, it usually improves and the residual deficit (anisocoria) is of no clinical significance.

FELINE INFECTIOUS PERITONITIS**

Classical signs

- Head tilt in a cat systemically ill for a few weeks.
- Non-specific systemic signs such as fever, weight loss and lethargy.
- Chronic progressive disease.
- There may be neurological deficits other than a head tilt.

See main references on page 372 for details (The Pyrexia Cat).

Pathogenesis

The causative virus is a macrophage-tropic mutant of the ubiquitous feline enteric coronavirus.

The clinical disease **results from an immune-mediated response of the host** to macrophage-infected feline infectious peritonitis virus (FIPV). The severity of the disease is based on host susceptibility and strain virulence.

Clinical signs

Affected cats are **usually less than 3 years of age** and **from large multiple-cat households** or breeders.

The most common non-specific systemic signs are **fever, weight loss and lethargy**.

Thirty-five percent of the cats with FIP have neurological signs. These vary with the lesion location. Behavioral changes, head tremor, seizures, depression,

compulsive walking and decreased menace are some of the signs that may be observed.

Clinically, the disease frequently appears to be focal, although this is not the case at postmortem.

The head tilt is always associated with somnolence, with or without cerebellar signs, because the cerebellum is closely situated.

Chorioretinitis may be present (see The Blind Cat or Cat with Retinal Lesions).

Diagnosis

The history of a **young cat originating from a multi-cat household** or breeder, with a **protracted disease, vague systemic signs and neurological abnormalities** raises the index of suspicion for FIP.

The cerebrospinal fluid analysis on its own is not sensitive for a diagnosis of FIP.

- Cell counts and protein concentration can be within reference range especially if the disease is focal. Typically, there is a moderate to severe pleocytosis, with mononuclear cells or neutrophils as the predominating cell type, and a marked increase in protein concentration.
- **Protein concentration > 2 g/L increases the likelihood of FIP.**

MRI scan of the brain is helpful, as frequently there is **periventricular enhancement** suggestive of ependymitis, and hydrocephalus with ventricular dilatation. The MRI findings are more representative of the neuropathological extent of the disease than is the clinical presentation, which is often focal in nature.

Hematology and chemistry abnormalities are non-specific except for a high serum total protein concentration, which is frequent.

The anti-coronavirus IgG titer in CSF is consistently positive.

The polymerase chain reaction (PCR) test detects the presence of feline coronaviruses but is not specific to FIP coronavirus.

Immunohistochemistry and immunocytochemistry are techniques which appear promising for diagnosis of FIP. They use monoclonal antibody targeted against feline coronavirus to demonstrate coronavirus within macrophages in tissue or effusions. The concentration

of infected monocytes in CSF fluid may make the test less sensitive for diagnosis of FIP than if used for tissue sections.

At this point in time, no single test is diagnostic for the neurological form of FIP, but when the history, signalment, serum protein concentration, CSF results, CSF serology and MRI findings are combined, an ante-mortem diagnosis can be reached.

Differential diagnosis

Other inflammatory infectious diseases of the central nervous system may produce similar neurological abnormalities. However, no other central nervous system infections are typically presented with the gamut of abnormalities mentioned above.

Treatment

There is **no effective treatment for FIP**. Patients almost invariably die. Therapy is based on supportive care. Immunomodulating and antiviral agents seem promising in vitro but have not shown good results in cats.

Prognosis

Poor. Most cats **die of their disease from 6 weeks to 6 months** after the onset of the neurological signs.

Prevention

Since most cats with FIP are from a multiple-cat household or breeder, adequate cleanliness is essential to prevent fecal–oral spread of virus.

Vaccination may be preventive.

NEOPLASIA*

Classical signs

- Otitis externa initially.
- Subsequent development of peripheral vestibular signs.
- Swollen face.
- Facial nerve paresis/paralysis and Horner's syndrome are frequent.

Pathogenesis

The most **common tumor** affecting the middle-inner ear is the **squamous cell carcinoma**. The tumor arises from the epithelial lining of the ear canal and is usually aggressive, invading the adjacent tissue (middle and inner ears) then the skull. Squamous cell carcinomas of the ear canal are most commonly presented with neurological signs.

Ceruminous gland adenocarcinomas are also reported with some frequency in the middle-inner ear.

Clinical signs

Middle-aged to older cats.

Initially, the **signs relate to otitis externa**. There is a more or less rapid progression depending on the tumor type, to cause peripheral vestibular signs, i.e., a **head tilt, with or without nystagmus or vestibular ataxia**.

Due to the invading nature of the squamous cell carcinoma and the ceruminous gland adenocarcinoma, the facial nerve and the sympathetic chain in the middle ear are involved leading to **facial paralysis, decreased lacrimation and Horner's syndrome**.

There is **pain when the mouth is open**, which may result from involvement of the temporo-mandibular joint, soft tissue pain, microfractures (pathological), bone pain from lysis or involvement of the bulla structures.

The face may be swollen and firm on palpation.

Diagnosis

The history of an older cat presented with a **rapid onset of neurological signs** relating to the inner (vestibular signs and deafness) and **middle ear** (facial paralysis, decreased lacrimation and Horner's syndrome) with pain upon jaw opening and a swollen face increases the index of suspicion.

In most cases, **bullae radiography is diagnostic** for the presence of a destructive process. There is opacity in the tympanic bulla with sclerosis and lysis of the bone. Depending on the tumor and how invasive it is, adjacent bony tissue such as the temporo-mandibular joint and the zygomatic arch may also be affected.

Differential diagnosis

As in most cases of middle-inner ear disease, if there is no swelling of the face, surgical exploration of the bulla is the only reliable approach to reach a definitive diagnosis.

Middle ear polyp is usually in young cats, but can be in older cats. Typically, **the progression is slower**. The polyp may be visible in the ear canal or oro-nasopharynx. There is no pain, and no swelling of the face.

Treatment

Aggressive excision including ear canal ablation and lateral bulla osteotomy is the treatment of choice for malignant ear canal tumors. If excision is incomplete, radiation therapy can be a useful adjunct to surgery.

Prognosis

Prognosis is guarded because of the invasive nature of the tumor and advanced stage of the disease by the time neurologic signs are present.

Cats with ceruminous adenocarcinoma have a 75% 1-year survival rate following aggressive ear ablation and bulla osteotomy compared to a 33% 1-year survival after conservative surgical resection. The prognosis is more guarded for squamous cell carcinoma.

EAR FLUSH*

Classical signs

- Acute onset of peripheral vestibular signs that develop immediately or in the 72 hours following an ear flush.

Pathogenesis

The exact pathogenesis is unknown, but several mechanisms have been postulated to be involved. An ear flush that leads to such consequences is usually done under anesthesia or heavy sedation. If the signs develop immediately after the flush, it is possibly due to: (1) a **change in the temperature of the endolymph**; (2) **flooding of the inner ear** through a perforated tympanic membrane; or (3) a **toxic effect on the vestibular**

receptors by the product used to flush the ear (e.g. chlorhexidine, quaternary ammonium compounds).

If the peripheral vestibular signs develop 48–72 hours following an ear flush, an inner ear infection is suspected. Bacteria may have been introduced through a perforated tympanic membrane at the time of the flush. The ear flush may not be vigorous for this to occur because the tympanic membrane may have already been ruptured secondary to an otitis externa. Alternatively, topical (e.g. gentamycin-containing ear drops) or systemic treatment administered after the ear flush may be toxic to the vestibular receptors.

Clinical signs

Acute onset of peripheral vestibular signs in the 72 hours **following an ear flush**. The flush may have been an elective procedure or therapeutic for a severe otitis externa.

Diagnosis

Diagnosis is based on the history of acute vestibular signs following a recent ear flush.

Differential diagnosis

Idiopathic vestibular syndrome cannot be differentiated from the iatrogenic cause if the signs appear 2–3 days following the flush.

Treatment

Whenever acute vestibular signs appear to be associated with an ear flush, a **broad-spectrum antibiotic** such as trimethoprim-sulfa, a cephalosporine or amoxicillin should be administered for 2–6 weeks.

Prognosis

If the onset was immediate and due to a change in the temperature or flooding of the inner ear, then the **signs may disappear within a few hours**.

If the signs are the result of toxicity, **the head tilt may remain**.

If the signs appeared 2–3 days later, most vestibular signs resolve except for the head tilt, which usually persists for the life of the animal.

Prevention

If an elective ear flush is to be performed under anesthesia or with heavy sedation, **ensure the tympanic membrane is intact prior to the procedure.**

If the tympanic membrane cannot be visualized, **use only sterile normal saline**, as most ear-cleaning solutions contain components that are potentially ototoxic, such as propylene glycol, salicylic acid, malic acid, lactic acid detergents and diocetols.

Perform ear flush with extreme care. Cleansing the ear with rubber bulb syringes, plastic syringes or water-jet appliances may rupture the tympanic membrane.

If the ear needs cleaning in the consultation room, avoid using solutions that are acidic or potentially ototoxic. Instead of removing the debris manually, let the animal shake its head and dislodge the debris itself after the medication had been put and massaged into the external ear canal.

CRYPTOCOCCOSIS*

Classical signs

- Lethargic cat with a head tilt, +/- ataxia, +/- nystagmus.
- Concomitant upper respiratory tract signs.
- Anorexia, weight loss.

See main reference on page 26 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Typically, the cat has usually **been ill for a few weeks prior to the development of the neurological signs.**

The systemic signs may have been vague such as **decreased appetite, weight loss, lethargy**, or signs may relate to a specific system such as the upper respiratory tract, the skin or a combination of both.

Chorioretinitis may be present (see The Blind Cat or Cat With Retinal Lesions).

Diagnosis

The development of central nervous system signs in a cat **systemically ill for a few weeks** or having

upper respiratory tract signs and/or **draining skin lesions** should raise the index of suspicion for this infection.

A latex agglutination test measuring the cryptococcal polysaccharide capsular antigen can be performed on the serum, cerebrospinal fluid or urine. However, negative results do not exclude the possibility of disease.

The CSF analysis is often diagnostic because the characteristic budding yeast forms are visible. This is best seen using India ink, but new methylene blue, Diff Quick, and Gram's stain preparation are adequate. Sometimes organisms are not evident, but grow when the CSF is cultured.

- The CSF inflammatory response associated with *Cryptococcus neoformans* **varies greatly**. The CSF may be normal to grossly abnormal with WBC counts ranging from 0 to $> 500 \text{ cells} \times 10^6/\text{L}$ ($0\text{--}0.5 \times 10^9/\text{L}$).
- In mild inflammation, lymphocytes and monocytes predominate. In severe inflammatory responses, neutrophils and occasionally eosinophils are present.
- The protein concentration varies from mildly to markedly increased ($> 2 \text{ g/L}$).

If the disease is suspected, but the organism is not visible in the CSF, **CSF culture and/or serology** may provide a definitive diagnosis.

Cats may be simultaneously positive for feline leukemia virus (FeLV) and/or feline immunodeficiency virus (FIV), increasing their susceptibility to infection.

Differential diagnosis

Cryptococcosis cannot be differentiated from **feline infectious peritonitis** in cats presented with a protracted illness and vague systemic signs on history, physical and neurological examination alone. If *Cryptococcus* organisms are not visible, culture or serology may be necessary to establish the diagnosis.

Treatment

Fluconazole is the drug of choice because of its broad antifungal spectrum, its meningeal penetration even in the absence of inflammation, and the fact that serious side effects are uncommon. The recommended dose is 10

mg/kg/day divided twice daily for a period that extends beyond the resolution of all signs by 2–3 months. The drug should be given with food.

Ketoconazole should not be used. It does not penetrate the blood–brain barrier effectively and is hepatotoxic.

See page 26 (The Cat With Signs of Chronic Nasal Disease) for further details on treatment of cryptococcosis.

THIAMINE DEFICIENCY*

Classical signs

- Bilateral vestibular signs, i.e., a characteristic ventro-flexion of the neck associated with a crouched body posture and reluctance to move.
- Bilateral pupillary dilatation with poor light reflexes.

Pathogenesis

Thiamine is a co-enzyme in the oxidative metabolism for energy production in the central nervous system. Thiamine deficiency typically **produces lesions (polioencephalomalacia) in the brainstem gray matter** and more specifically in the vestibular, oculomotor and lateral geniculate nuclei. Focal, bilaterally symmetric hemorrhages are present in affected areas.

The deficiency occurs in cats that are fed an **uncooked all-fish diet** (due to the thiaminase content of the viscera), **diets entirely made of cooked meat** (where the thiamine is destroyed by heating), poor-quality thiamine-deficient commercial diets, or commercial food stored for long periods of time or in excessively hot conditions. In addition, the **meat preserver sodium metabisulfite** releases sulfur dioxide, which **destroys thiamine**. Pet mince meat containing this preserver is thiamine-deficient, and even when mixed with other food may have sufficient preserver to destroy all dietary thiamine.

Anorexia in a sick cat especially associated with polydipsia and polyuria or fluid diuresis **may precipitate thiamine deficiency** and complicate the primary illness.

Clinical signs

Lethargy and decreased appetite, sometimes with increased salivation, occur after 2–4 weeks on a deficient diet.

The cat has an **inability or a reluctance to walk** and therefore may appear weak. This is associated with a characteristic **rigid ventro-flexion of the neck**, a **crouched body posture** and loss of righting responses.

There is **bilateral mydriasis with poor light reflexes** from the involvement of the oculomotor and geniculate lateral nuclei.

Physiologic nystagmus is poor to absent.

Brief **episodes of opisthotonus or neck ventroflexing and muscle rigidity** may appear like seizures.

Bradycardia, and marked sinus arrhythmia may also occur.

If untreated, the cat becomes **comatose and dies**. The time of death varies from 1 week to a few weeks to months depending on the health status of the animal and the amount of thiamine in the diet.

Diagnosis

Diagnosis is based on a combination of a history that the cat has been quiet and anorexic, signs of a characteristic posture with poor to absent physiologic nystagmus indicative of bilateral vestibular disease and **documentation of a thiamine-deficient diet** (usually large quantities of uncooked fish).

Rapid response (within 24 hours) to treatment confirms the diagnosis.

Differential diagnosis

In bilateral idiopathic vestibular syndrome, the cat is healthy just prior to the development of the clinical signs. Thiamine-deficient cats are typically lethargic and anorexic.

Treatment

Injectable thiamine at 10–20 mg intramuscularly. For supplementation, give 5–30 mg/cat/day PO to a maximum of 50 mg/cat/day.

Change diet.

Prognosis

Prognosis is good if treatment is given early when the only clinical signs are bilateral vestibular signs.

Prognosis is poor in the late stage of the disease when the animal's consciousness is significantly altered.

CONGENITAL PENDULAR NYSTAGMUS*

Classical signs

- Siamese, Himalayan and white tiger cats.
- Pendular nystagmus, i.e., the phase of the nystagmus is equal on both sides.
- Present from birth.

Clinical signs

Typically, the **nystagmus has a rapid, short and oscillatory motion that is equal bilaterally**. It is observed especially when the cat is fixing its gaze.

The **defect is within the visual pathways and not the vestibular pathways**. No obvious visual impairment is present.

The nystagmus is **always congenital** and is **evident in the first few weeks of life**.

It occurs primarily in **Siamese, Himalayan** and white tiger cats.

Medial strabismus is usually simultaneously present.

Diagnosis

Diagnosis is based on the characteristic oscillatory nystagmus.

FRACTURES OF THE PETROUS TEMPORAL BONE OR TYMPANIC BULLA, AND ETHMOID FRACTURE (BASE OF THE SKULL)

Classical signs

- Altered consciousness and head tilt after a recent accident.
- +/- Facial nerve paresis/paralysis and Horner's syndrome.
- +/- Signs of brainstem involvement such as proprioceptive deficits.

Clinical signs

Sudden onset of head tilt associated with **somnolence or stupor** following a road accident or other trauma that caused a fracture at the base of the skull affecting the petrosal and ethmoid bones.

Facial paresis/paralysis and/or Horner's syndrome may be present if there is hemorrhage in the middle ear.

If the injury is primarily intracranial, facial paresis/paralysis and/or ipsilateral proprioceptive deficits may be present.

On otoscopic examination, **blood may be observed in the ear canal**.

Diagnosis

History of a road accident.

Brain auditory-evoked responses (BAER) may be helpful in localizing the lesion to mainly a peripheral or central location.

Survey radiographs of the skull are difficult to interpret because of the juxtaposition of multiple structures.

DRUG-INDUCED

Classical signs

- Unilateral or bilateral peripheral vestibular signs, following the use of drugs that are toxic for the vestibular receptors.
- Concomitant deafness is frequent.

Pathogenesis

Multiple drugs cause damage to the vestibular and/or auditory receptors separately or simultaneously.

Aminoglycosides especially streptomycin, **chloramphenicol, chlorhexidine, cisplatin, furosemide, salicylates and ceruminolytic agents** are a few of a long list of agents that may cause damage to these receptors.

Clinical signs

Toxicity occurs following **systemic or topical administration**.

The vestibular signs are peripheral and can be **unilateral, or bilateral**.

The signs may develop acutely following exposure to a high dose or after prolonged administration (> 14 days). Cats with renal dysfunction are at risk because decreased renal excretion of many drugs results in higher plasma concentrations.

The **vestibular signs may disappear** following discontinuation of the drug.

Diagnosis

The history of use of a drug potentially toxic for the vestibular receptors, topically or systemically.

The vestibular signs may appear immediately following an ear flush, or following topical treatment with a toxic medication, in a cat that has a perforated tympanic membrane.

Prevention

Avoid using any medication in the external ear canal if the tympanic membrane is perforated or cannot be visualized. This includes ceruminolytic agents and detergents.

CONGENITAL VESTIBULAR DISEASE

Classical signs

- Unilateral or bilateral vestibular signs present at birth or developing in the first 12 weeks of life.
- Siamese, Burmese and Tonkinese cats.
- Head tilt and tipping or rolling.

Clinical signs

Reported in **Siamese, Burmese and Tonkinese** cats.

Usually **unilateral vestibular signs**, but can be **bilateral**.

Head tilt with tipping, rolling or falling developing at birth or in the first 12 weeks of life. The head tilt can be marked and may vary with time.

The clinical **signs are non-progressive** and decrease in severity with time, but usually persist for life.

Diagnosis

Diagnosis is based on characteristic signs in a kitten from a susceptible breed.

BLUE-TAILED LIZARD INGESTION

Classical signs

- Southeastern United States.
- Unilateral peripheral vestibular signs following the ingestion of a blue-tailed lizard.
- The cat also salivates, vomits, trembles and is irritable.

Clinical signs

Acute onset of unilateral peripheral vestibular disturbance following ingestion of the blue-tailed lizard. The syndrome has not been well substantiated.

Varying degrees of vestibular signs associated with salivation, vomiting, trembling and irritability.

Spontaneous recovery occurs in most cats.

Death may occur.

Diagnosis

Acute onset of unilateral peripheral vestibular signs in a cat living in southeastern United States with access to lizards. Signs are indistinguishable from the idiopathic vestibular syndrome although salivation, vomiting and trembling are less common with the idiopathic disease.

39. The cat with tremor or twitching

Rodney S Bagley

KEY SIGNS

- Head and/or body tremor.
- Twitching.

MECHANISM?

- Tremor is an involuntary, rhythmic, oscillatory movement of all or part of the body. It results from the alternate or synchronous contraction of reciprocally innervated, antagonistic muscles.

WHERE?

- Disease of the nervous system (central and peripheral) and muscle may result in tremor, shaking or twitching.
- Usually tremors with increased amplitudes and slower frequencies (coarse tremor) are associated with cerebellar disorders. Those tremors with decreased amplitudes and faster frequencies (fine tremor) are associated with diffuse central nervous system disease or muscle weakness.
- Tremor can have differing amplitudes (the distance traveled during the movement) and frequencies (how fast the tremor is).

WHAT?

- Disease of the nervous system that results in persistent, generalized (whole body) tremor is usually diffuse (encephalitis).

QUICK REFERENCE SUMMARY

Diseases causing tremor or twitching

COARSE TREMOR AND TWITCHING (INTENTIONAL)

DEGENERATIVE

- Degenerative cerebellar diseases (p 857)

Using storage diseases as an example, these diseases tend to be breed-associated. Clinical signs usually begin in cats less than 1 year of age. Slowly progressive signs are typical and there is no hyperesthesia. When the disease involves the cerebellum, ataxia and hypermetria are most common.

NEOPLASIA

- **Neoplasia (p 858)**

Tumors involving the cerebellum usually occur in middle-aged to older cats. Clinical signs of cerebella dysfunction may occur acutely or be more chronically progressive.

INFECTIOUS/INFLAMMATORY

- **Cerebellar hypoplasia** (p 855)**

Cats are born with or develop this disease immediately after birth. Clinical signs become apparent when the cat begins moving and are most obvious when the animal begins walking (somewhere between 4–8 weeks of age). Intention tremor, ataxia and hypermetria are often found.

- **Encephalitis (p 859)**

Viral, fungal, protozoan, bacterial, rickettsial and parasitic agents are potential causes. Multifocal central nervous system signs are most common. Fever and leukocytosis are inconsistent findings. Other signs of a polysystemic disease such as coughing, vomiting or diarrhea may be associated.

TRAUMA

- **Head trauma* (p 856)**

Usually associated with an acute onset of clinical signs reflective of an intracranial problem. Signs present often include alterations in consciousness, paresis and cranial nerve abnormalities. Fresh blood from lacerations on or around the head, skull fractures, blood in the ear canals and scleral hemorrhage may be clues to a previous traumatic incident.

FINE TREMOR AND TWITCHING (UNINTENTIONAL)

DEGENERATIVE

- **Degenerative diseases of the nervous system (p 867)**

Some of these diseases are inherited with clinical signs beginning in cats less than 1 year of age. Examples include hypomyelination or dysmyelination and motor neuronopathies. Affected animals tend to have a “bouncy” movement. With other degenerative diseases, such as encephalomyelopathy of young cats and spongiform encephalopathy, tremoring may be acquired in young to middle-aged cats.

ANOMALY

- **Myotonia (p 866)**

Clinical signs are most often recognized in cats between 1–12 months of age. Classically affected cats have a stiff-stilted gait with increased size of the muscles. Tremor, if present, is usually of short duration and episodic.

METABOLIC

- **Hypocalcemia* (p 862)**

Most often occurs after thyroidectomy. Muscle weakness, tetany and tremors are typical. Preparturient hypocalcemia presents as anorexia, lethargy, trembling, muscle twitching and weakness. Primary hypoparathyroidism occurs in young to middle-aged cats and can result in similar clinical signs.

continued

continued

- Hypokalemia (p 865)

Typically older cats or Burmese < 1 year of age. Signs include weakness, inability or reluctance to walk or jump, stiff, stilted gait, neck ventroflexion and sensitivity to palpation of larger muscle groups. A short duration tremor may be present episodically and usually when the cat attempts purposeful movement.

NEOPLASTIC

- Neoplasia (p 869)

A 2-year-old cat has been reported with diffuse tremor resulting from multiple meningiomas. Clinical signs progressed to paresis and ataxia.

INFLAMMATORY

- Encephalomyelitis (p 864)

Clinical signs are often diffuse and may not localize to a single area within the nervous system. Fever and leukocytosis may be present but are inconsistent findings. The associated tremor tends to involve the entire body and is rapid and of low amplitude (fine).

- Myasthenia gravis (p 866)

Typically adult cats or Siamese < 1 year of age. Tremor usually is episodic and occurs during movement. Generalized weakness, a stiff, stilted gait prior to collapse, ventral neck flexion and decreased palpebral reflexes may also be seen. The gait improves with rest.

- Polioencephalomyelitis (p 868)

This is a diffuse nervous system disease that primarily affects the spinal cord. A viral cause is suspected. Signs have a slow onset and are chronically progressive. They include pelvic limb ataxia, paresis, hypermetria, intention tremors, decreased pupillary light reflexes, seizures and hyperesthesia over the thoracolumbar area.

IDIOPATHIC

- Feline hyperesthesia syndrome* (p 862)

A syndrome in which cats become suddenly startled, agitated and often run madly, usually when stimulated over the thoracolumbar area of the spine. Skin rippling and spasms occur usually over the lumbar region and the cat may lick or bite this area.

TOXICITY

- Toxins* (p 861)

Toxins such as organophosphate, hexachlorophene and ivermectin can affect nervous system transmission and result in tremor. Other signs such as miosis, salivation, urination, defecation and weakness may be present with OP toxicity. Ivermectin resulted in ataxia, tremor and weakness in a kitten.

INTRODUCTION

MECHANISM?

Tremor is an involuntary, rhythmic, oscillatory movement of all or part of the body. It results from the alter-

nate or synchronous contraction of reciprocally innervated, antagonistic muscles.

True tremor ceases with sleep.

Tremor can be **localized to one body** area or be **generalized** and involve the whole body.

Tremors usually have a characteristic distance of travel (amplitude) and speed of travel (frequency). Tremors can be categorized generally into those that have an increased amplitude with a slower frequency (**coarse tremor**) or a decreased amplitude with a faster frequency (**fine tremor**).

WHERE?

Disease of the **nervous system (central and peripheral)** and **muscle** may result in involuntary tremor, shaking or twitching.

Cerebellar disease usually results in a **coarser tremor** that worsens (increases in frequency or amplitude) **when the animal moves** in a goal-oriented fashion (intention tremor).

Other signs of cerebellar disease that accompany cerebellar tremor include **ataxia** (incoordination; swaying from side to side), **dysmetria** (“goose-stepping”; overflexing of the limbs when walking), **menace deficits** (with normal vision, palpebral, and pupillary light reflexes), **head tilt** and **nystagmus**.

Fine tremor (decreased amplitude and increased frequency) is more often associated with **diffuse neuronal disease** or **muscle weakness** that result in involuntary muscle contraction.

WHAT?

Diseases of the intracranial nervous system (primarily the **cerebellum**) resulting in tremor include **storage diseases**, **brain tumor**, **encephalitis** and **vascular-based diseases**.

Systemic metabolic diseases altering neuronal or muscle membrane potentials (such as hypoglycemia, hypocalcemia, hypokalemia) can result in tremor.

Diseases that **decrease neuronal impulse conduction via abnormalities of myelin** (hypomyelination) often result in tremor.

Diseases of the nervous system that result in **persistent, fine tremor** are usually **diffuse (encephalitis)**.

DISEASES CAUSING COURSE TREMOR

CEREBELLAR HYPOPLASIA**

Classical signs

- Signs are present from the early prenatal period.
- Clinical signs usually remain unchanged or may improve during life.
- Coarse tremor that worsens when the cat moves in a goal-oriented fashion (intention tremor).
- Other signs include ataxia, hypermetria, menace deficits, head tilt and nystagmus.

Pathogenesis

Cerebellar hypoplasia results from **in utero or immediately postnatal infection with the panleukopenia virus (parvovirus)**.

Infection of the fetus may occur when a pregnant queen is **vaccinated with a modified-live panleukopenia virus vaccination**.

This virus **destroys the external germinal layer of the cerebellum** and prevents the formation of the granular layer.

Some affected cats have a concurrent hydrocephalus and hydranencephaly.

Clinical signs

Clinical signs are most apparent when the animal begins purposeful movement and attempts to walk.

Tremor accompanying the disease usually has a **slower frequency** (2–6 times/second) and **larger amplitude**. The tremor **worsens** (increases in frequency or amplitude), **when the cat moves** in a goal-oriented way (e.g. bends down to eat), which is termed an intention tremor.

Other signs include **ataxia** (incoordination; swaying from side to side), **hypermetria** (“goose-stepping”; overflexing of the limbs when walking), **menace deficits** (with normal vision and pupillary light reflexes), **head tilt**, and **nystagmus** (combination quick followed by slow movement of the eyes).

Clinical **signs** usually **remain static** or **improve with growth** as the cat compensates, causing the tremor to become less apparent.

Diagnosis

Antemortem testing for this disease often results in negative or normal findings.

Routine laboratory investigations are normal.

Definitive diagnosis is usually rendered only at **necropsy** and histopathological examination of the nervous tissue.

In some instances of cerebellar atrophy, a **smaller than normal cerebellum** may be seen on **magnetic resonance imaging** of the intracranial nervous system. This is most readily seen on the sagittal view.

Occasionally, inflammatory cells may be present in cerebrospinal fluid examination in cats with active panleukopenia viral infection. Cerebrospinal fluid with the other degenerative cerebellar conditions and with previous panleukopenia infection is usually normal.

Differential diagnosis

In this age of cat, other inflammatory central nervous system abnormalities such as **toxoplasmosis** infection is possible.

Congenital anatomical defects of the cerebellar may be present.

Trauma occurring at a young age may permanently damage the cerebellum.

Treatment

No treatment is currently helpful for cats affected with this disease.

Prognosis

Clinical signs associated with previous panleukopenia virus infection of the developing cerebellum usually remain static or improve with growth, causing the tremor to become less apparent.

Prevention

Do not vaccinate queens with modified live panleukopenia virus vaccine.

HEAD TRAUMA*

Classical signs

- Acute onset of signs following a traumatic event.
- Evidence of external trauma to the head and face such as facial lacerations, bleeding from the nose and mouth, bruising, retinal hemorrhage, or hemorrhage in the external ear canals.
- Cerebellar involvement may result in intention tremor, decerebellate rigidity, ataxia, hypermetria, head tilt and nystagmus.

See main reference on page 823 for details (The Cat With Stupor or Coma).

Clinical signs

Exogenous injury to the brain occurs most commonly from automobile trauma, although gunshot wounds and falls may also occur.

Cerebellar involvement may result in **intention tremor, decerebellate rigidity** (extension of all four limbs and the trunk), ataxia, hypermetria, head tilt and nystagmus.

Signs usually begin acutely after trauma.

Intracranial signs most commonly seen include **stupor and coma, paresis and gait abnormalities**, and cranial nerve deficits.

Evidence of **external trauma to the head and face such as facial lacerations**, bleeding from the nose and mouth, bruising or **hemorrhage in the external ear**

canals may be clues to the traumatic etiology, however, some animals that are uncoordinated may fall and injure themselves secondarily.

Diagnosis

The diagnosis of trauma is usually straightforward when the trauma is witnessed.

In some instances, animals are presented with an acute onset of neurological signs and an unknown history, examining for external signs of trauma such as lacerations or skull fractures is important.

Evaluating the retinas and external ear canals for acute hemorrhage may also provide clues to the diagnosis.

Advanced imaging studies such as CT or MR imaging are useful, primarily for determining structural damage to the brain.

DEGENERATIVE CEREBELLAR DISEASES

Classical signs

- Signs usually begin or are present in cats less than 1 year of age.
- Signs usually are slowly progressive or remain unchanged.
- Signs include coarse tremor, hypermetria, ataxia, intention tremor and menace deficits.

See main reference on pages 934 and 935 for details (The Cat With Ataxia Without Weakness).

Pathogenesis

Cerebellar degeneration is usually an inherited disease.

A **hereditary cerebellar degeneration** has been described in Japan in cats. An autosomal recessive mode of inheritance was presumed.

Cerebellar degeneration with neuroaxonal dystrophy has been reported in domestic tricolored cats. This is inherited as an autosomal-recessive trait.

Storage diseases result from inherited (or less commonly, acquired) intracellular metabolic derangements that result in abnormal metabolism of cellular products. Cellular products accumulate and afferent neuronal

cells physiologically or mechanically, resulting in cellular dysfunction, and hence, clinical signs. Examples include **gangliosidosis**, **sphingomyelinosis**, **globoid cell leukodystrophy** and **mannosidosis**.

Clinical signs

Clinical signs usually begin between **3–12 months of age**.

Cerebellar disease usually results in a coarse tremor that worsens (increases in frequency or amplitude) when the animal moves in a goal-oriented fashion (intention tremor).

Other signs of cerebellar disease that accompany cerebellar tremor include ataxia (incoordination; swaying from side to side), dysmetria (“goose-stepping”; over-flexing of the limbs when walking), menace deficits (with normal vision and pupillary light reflexes), head tilt, and nystagmus (combination quickly followed by slow movement of the eyes).

Clinical signs of the hereditary cerebellar degeneration described in Japan in cats begin around 7–8 weeks of age and include head tremor along with ataxia, dysmetria, and intention tremor.

Cerebellar degeneration with **neuroaxonal dystrophy** in domestic **tricolored cats** results in **head tremors and shaking**. Clinical signs begin at 5–6 weeks of age and **progress to ataxia and hypermetria**. Affected kittens have a **lilac color** that **darkens with age**.

In cats with **sphingomyelinosis** (Niemann–Pick type C disease) clinical signs begin early in life (< 6 months) and progress to **ataxia and hypermetria**, absent menace responses, and occasionally positional nystagmus. **Death usually occurs by 8–10 months of age**.

Niemann–Pick type A disease occurs in **Siamese and Balinese cats**. **Head tremor, head bobbing and dysmetria** begin at 3–4 months of age. Clinical signs progress to **ataxia and paresis, worse in the pelvic limbs**.

Diagnosis

Antemortem testing for these diseases often results in negative or normal findings.

Routine laboratory investigations are normal.

Definitive diagnosis is often rendered only at **necropsy** and histopathological examination of the nervous tissue.

In some instances of cerebellar atrophy, a **smaller than normal cerebellum** may be seen on **magnetic resonance imaging** of the intracranial nervous system. This is most readily seen on the sagittal view.

Cerebrospinal fluid with these degenerative cerebellar conditions is **normal**.

With hereditary cerebellar degeneration described in Japan in cats there is marked loss of Purkinje cells upon histologic evaluation of the cerebellum.

In cats with sphingomyelinosis (Niemann–Pick type C disease) cerebellar atrophy, **Purkinje cell loss**, and **neuroaxonal dystrophy** are the **predominant pathological changes**.

Differential diagnosis

In this age of cat, other inflammatory central nervous system abnormalities such as **toxoplasmosis** infection is possible.

Congenital anatomical defects of the cerebellar may be present.

Trauma occurring at a young age may permanently damage the cerebellum.

Treatment

No treatment is currently helpful for affected cats.

Prognosis

Clinical signs associated with **degenerative cerebellar diseases** **progressively worsen**.

Animals are commonly euthanized due to the progressive incapacitation.

Prevention

Do not breed cats affected that have produced kittens with a presumed genetic or congenital cerebellar disease.

NEOPLASIA

Classical signs

- Signs usually begin in cats 5 years of age or older.
- Signs usually are progressive over weeks to months.
- Occasionally, clinical signs begin acutely.
- Intention tremor is often associated with other signs of cerebellar disease including ataxia, dysmetria, menace deficits, head tilt and nystagmus.

See main reference on page 824 for details (The Cat With Stupor or Coma).

Clinical signs

Signs reflect either **primary nervous parenchymal damage** from the tumor or **secondary** pathophysiological **sequelae** such as **hemorrhage and edema**.

Meningiomas are the **most common brain tumor** in cats and are usually histologically benign.

Less frequent tumors arise from astrocytes, oligodendrocytes, ependymal cells and choroid plexus cells.

Neoplasia may secondarily involve the brain via **metastasis** or via **direct extension** from extraneural sites.

Clinical signs usually begin in **cats 5 years of age or older**.

Clinical signs usually are **progressive over weeks to months**.

Occasionally, clinical signs begin acutely.

Intention tremor is often associated with other **signs of cerebellar disease** including ataxia (incoordination; swaying from side to side), dysmetria (“goose-stepping”; overflexing of the limbs when walking), **menace deficits** (with normal vision and pupillary light reflexes), **head tilt**, and **nystagmus** (combination quick followed by slow movement of the eyes).

Diagnosis

Routine laboratory investigations are normal.

Diagnosis of a structural intracranial abnormality in the brain is most readily accomplished with **magnetic resonance (MR) imaging** or **computed tomography (CT)** of the brain.

A **broad-based, extra-axial** (arising outside and pushing into the parenchyma) **contrast-enhancing mass** on CT or MR imaging is found in most **instances of meningioma**.

The CT and MR appearance of gliomas is varied and enhancement after contrast administration may not be present. As these tumors arise from brain parenchymal cells, they are **found within the neuroaxis (intra-axial)**.

Choroid plexus tumors, because of the increased concentration of blood vessels within the tumor, often **enhance markedly** after contrast administration. Because of their association with the ventricular system, associated **hydrocephalus is common**.

Cerebrospinal fluid often has **increased protein concentration** but this finding is not pathognomonic for neoplasia.

Cerebrospinal fluid can contain **evidence of inflammation** (contains elevations in nucleated cells and protein content). If CSF is the only assessment made, an erroneous diagnosis of encephalitis may be rendered.

Differential diagnosis

Congenital and inherited cerebellar diseases occur in younger animals.

Cerebrovascular, traumatic and inflammatory conditions can mimic the signs of a brain tumor.

Treatment

Corticosteroids (prednisolone 1–2 mg/kg q 12 h) may reduce peritumoral edema and improve clinical signs.

Surgical removal of primary brain tumors may be accomplished, especially with meningioma.

A well-encapsulated, firm whitish mass is most often encountered at surgery in cats. Cortical parenchyma is usually not infiltrated but rather compressed in cats,

leaving indentations in the nervous tissue parenchyma after resection.

Radiation therapy (45–48 Gy) may control tumor growth of some brain tumors.

ENCEPHALITIS

Classical signs

- Diffuse or multifocal neurological signs.
- Cerebellar signs such as intention tremor, ataxia, hypermetria, head tilt and nystagmus.
- Cervical pain can be present.
- Fever is an inconsistent finding.
- Clues of systemic inflammatory disease such as chorioretinitis are often present.
- Other signs of polysystemic disease such as coughing, vomiting or diarrhea may be present.

Pathogenesis

The source of the inflammatory reaction includes both infectious and non-infectious etiologies.

Numerous infectious agents have been incriminated, with the incidence of infectious agents causing meningitis **varying with geographic location**.

Infectious agents causing brain disease include **viral (feline infectious peritonitis)**, **fungal (cryptococcosis, blastomycosis, histoplasmosis, coccidioidomycosis, aspergillosis)**, **protozoal (toxoplasmosis)**, **bacterial, rickettsial** and unclassified organisms (**protothecosis**).

Feline infectious peritonitis (FIP) is caused by a coronavirus infection in cats. This virus can involve various areas of the nervous system including the intracranial structures and spinal cord. Very young and, conversely, very old cats seem predisposed. Of the two forms of FIP that exist in cats, the “dry” form commonly affects the nervous system. This viral infection results in an immune complex vasculitis, which is responsible for most of the pathological effects.

Toxoplasmosis (*Toxoplasma gondii*) can affect the nervous system at any level including the brain and spinal cord.

Neosporosis results in **necrotizing encephalitis** in cats experimentally inoculated with *Neospora caninum*. Only those cats that were concurrently immunosuppressed by administration of methylprednisolone had severe histological brain lesions.

Of the fungal diseases of the brain in cats, cryptococcosis caused by *Cryptococcus neoformans* is the most common. The central nervous system is often affected through **direct extension of the infection from the nasal passages** or from disseminated infection from other organs.

Involvement of the intracranial nervous can occur with parasites such as *Cuterebra* larvae, toxocara, and aberrant heartworm migration.

Clinical signs

Depression, inappetence or anorexia and weight loss are common.

Clinical signs often reflect multiple levels of neurological involvement. Neurological signs may indicate diffuse or multifocal disease and often do not localize to a single area within the nervous system.

Paresis, gait abnormalities, proprioceptive deficits, cranial nerve defects, and occasionally stupor or coma may occur.

Cerebellar signs such as intention tremor, ataxia, hypermetria, head tilt and nystagmus may occur with involvement of the cerebellum.

Cervical pain can be present.

Fever is an inconsistent finding.

Fundic examination is important to look for clues of systemic inflammatory disease as chorioretinitis, which is often present with diseases causing systematic infection.

Other systemic signs such as vomiting, coughing, and diarrhea may be seen concurrently.

Diagnosis

Complete blood cell count may show evidence of systemic inflammation (e.g. leukocytosis).

Serum biochemical analysis may show evidence of systemic abnormalities if the disease diffusely affects the body (e.g. vasculitis) such as elevated globulin, CK, liver enzymes or creatinine.

Evaluation of titers for the infectious diseases often helps to rule in or out the diseases.

Cerebrospinal fluid analysis (CSF) will usually show evidence of **increased nucleated cells** and/or **elevated protein content**. Occasionally, CSF will be normal.

- Evidence of inflammation on CSF evaluation alone, however, is not specific for primary encephalitis as other CNS disease (e.g. **neoplasia**) **may result in a CSF pleocytosis** and protein increases.
- With feline infectious peritonitis (FIP), cerebrospinal fluid analysis may show a pleocytosis, with either **mononuclear** or non-lytic **neutrophils** as the predominant cell type and **elevated protein** concentration, often > 1 g /L (0.1 g/dl).
- With **toxoplasmosis**, cerebrospinal fluid frequently contains a pleocytosis, usually with mononuclear cells, and occasionally, eosinophils. Increasing IgG or a single positive IgM serum antibody titer is suggestive of active infection. Animals with **neurologic signs and positive IgM titers warrant treatment** for the disease.

With **cryptococcosis**, identification of the organism from cytological evaluation of samples such as CSF, nasal discharge and skin lesions supports the diagnosis. A neutrophilic pleocytosis, and occasionally an eosinophilic pleocytosis may be found on CSF analysis. If positive, detection of the cryptococcal capsular antigen in serum is usually diagnostic. Tissue biopsy and fungal culture of CSF may be more definitive in the diagnosis as occasionally the serum titer is negative.

With parasites such as *Cuterebra* larvae, toxocara, and aberrant heartworm migration, CSF may show inflammation with eosinophils in some instances.

Imaging studies (CT and MR) are helpful for defining structural lesions. **Multifocal, contrast-enhancing lesions** are usually seen. Occasionally, non-contrast-enhancing lesions are present, especially with toxoplasmosis.

Differential diagnosis

Multifocal signs are more suggestive of **encephalitis**.

Cats with encephalitis may present with signs similar to other intracranial diseases such as brain tumor, trauma, hydrocephalus and cerebrovascular disease.

Treatment

Treatment is directed at a specific infectious cause if found.

Without a definable cause of the encephalitis, the author uses **trimethoprim-sulfadiazine** (30 mg/kg PO q 12 h), **clindamycin** (25 mg/kg q 12 h), and **corticosteroids** (prednisone 1–2 mg/kg PO q 12 h) in combination.

While corticosteroids are contraindicated with infectious diseases, they are often beneficial in the acute treatment of brain inflammation and edema. These associated pathophysiological events often lead to more neurologic deterioration than the organism itself.

If **rickettsial diseases** are endemic, **chloramphenicol** or **doxocycline** can be substituted or added to the regime.

If the animal is receiving **phenobarbital**, do not use **chloramphenicol** as this drug will decrease the metabolism of the barbiturate and the animal will become comatose and possibly die. Also, chloramphenicol may result in bone-marrow suppression in cats.

With feline infectious peritonitis (FIP), no specific treatment is effective. Immunosuppressive therapy may result in short-term improvement of clinical signs.

With **toxoplasmosis**, treatment includes **clindamycin** and **trimethoprim sulfa** antibiotics.

For **cryptococcosis** treatments that have had some success for cryptococcosis in cats include amphotericin B, fluconazole, itraconazole and flucytosine. See page 26 (The Cat With Signs of Chronic Nasal Disease) for treatment details.

With CNS parasites, treatment has not been attempted uniformly and treatment recommendations are anecdotal.

Prognosis

Many of the encephalitis are poorly responsive to treatment, and therefore morbidity and mortality is > 50%.

Some infectious encephalitis (e.g. toxoplasmosis) may be cured with appropriate treatment.

DISEASES CAUSING FINE TREMOR

TOXINS*

Classical signs

- Tremors may be persistent or intermittent.
- A history of exposure to a toxin is most helpful in diagnosis.
- Diffuse CNS is often present in association with other systemic signs such as vomiting and diarrhea.

Pathogenesis

Toxins may **lower the threshold** for stimulation or **directly stimulate muscles and nerves** to result in tremor.

Organophosphate intoxication potentiates the effect of acetylcholine at the neuromuscular junction and other synapses, by binding with and inactivating acetylcholinesterase. This leads to increased acetylcholine concentrations at the neuromuscular junction, increased receptor stimulation and fatigue.

Hexachlorophene causes vacuolation of white matter that leads to abnormal impulse generation.

Ivermectin increases **GABA (inhibitory neurotransmitter)** concentrations and effects in the CNS.

Clinical signs

Cats with **acute organophosphate intoxication** may have signs including **miosis, salivation, urination, defecation**, as well as **muscle weakness**.

A more persistent weakness without associated autonomic signs can occur with **chronic organophosphate toxicity**. Cats may attempt to **walk a few steps**, then **collapse in sternal recumbency** mimicking cataplexy/narcolepsy.

Hexachlorophene toxicity results in **tremors** as the primary clinical sign.

Ivermectin toxicosis has resulted in generalized ataxia, tremor, weakness, incoordination and miosis in a kitten.

Diagnosis

History of exposure to a toxic product is most helpful in establishing a diagnosis.

For organophosphate toxicity, decreased concentration of **serum cholinesterase activity** may lend support to the diagnosis. Depending upon the laboratory, values less than 500 IU/L (normal 900–1200 IU/L) are considered consistent with organophosphate toxicity. Cats with polyneuropathy from chronic OP toxicity may have normal serum cholinesterase activity.

Differential diagnosis

Rule out other diffuse causes of tremor such as metabolic disease.

Physiological functions such as shivering from cold or apprehension should be considered.

Treatment

For organophosphate toxicity, treatment includes propopam chloride **2-PAM** (20 mg/kg q 12 h IV) which reactivates cholinesterase and **diphenhydramine** (1–2 mg/kg PO q 8–12 h) which reduces muscle fasciculations.

- Atropine (0.2–0.4 mg/kg) can be given with acute toxicity to decrease autonomic signs. Current recommendations are that it **only be used if marked bradycardia** is present, because it may **precipitate respiratory arrest**. Salivation and defecation are not life threatening and generally do not require atropine.
- **Diazepam should be avoided** in these cats as it may result in generalized muscle tremor, hypersalivation, miotic pupils, and vomiting similar to acute muscarinic signs of organophosphate toxicosis.

No specific antidote exists for the other toxicities described here.

FELINE HYPERESTHESIA SYNDROME*

Classical signs

- Skin rippling and muscle spasms, usually over the lumbar area.

Classical signs—Cont'd

- Sudden startling or running.
- Glazed look with dilated pupils.
- Apparent hallucinations.
- Frantic meowing, growling, hissing, swishing of the tail.
- Licking or biting of the flank, back or tail.

Pathogenesis

The cause is unknown.

One theory is that this activity is a manifestation of a focal seizure.

Another theory suggests that it is similar to the obsessive-compulsive behavior associated with Tourette's syndrome in humans, which is the result of dopaminergic hyperinnervation.

Similar clinical signs have been associated with a vacuolar myopathy in cats and toxoplasmosis.

Others have suggested that this may be behavioral disorder.

Some believe that it begins with an inflammatory stimulus such as flea or food allergy dermatitis.

Clinical signs

Cats may become agitated and aggressive and show **skin rippling and muscle spasms, usually over the lumbar** area with stimulation such as stroking over the thoracolumbar region.

Cats may appear as though they were **startled**, then exhibit frenzied behavior such as **licking or biting** at the flanks, back and tail or running.

Cats may appear as though they are **hallucinating** and have dilated pupils.

Sudden startling, **running, frantic meowing**, growling, hissing, **swishing of the tail** may also occur.

Episodes may occur multiple times in a day and last 1/2 min to 5 minutes.

Diagnosis

Diagnosis is usually made solely on clinical signs.

A complete neurological examination should be performed to identify pain or deficits suggesting an underlying spinal lesion.

Spinal radiographs should be performed to rule out lumbar and lumbosacral lesions.

Biopsy of the paraspinal muscles should be used to rule out vacuolar myopathy.

IgM and paired IgG titers 3–4 weeks apart can be used to help rule out active toxoplasmosis.

Differential diagnosis

Rule out **dermatitis, lumbosacral spinal or nerve root compression and intracranial disease.**

Determine if the cat is exhibiting normal behavior during **estrus**.

Treatment

Initial treatment should be with anti-inflammatory drugs. Corticosteroid therapy (prednisolone) may help if a flea allergy or other inflammatory stimulus is suspected. NSAIDs like piroxicam or meloxicam or megestrol can also be tried.

Strict flea control may improve clinical signs.

Behavior-modifying drugs such as the tricyclic antidepressants amitriptyline (2 mg/kg or 5–10 mg/cat PO q 24 h), clomipramine (1–5 mg/cat PO q 12–24 h) or the selective serotonin uptake inhibitors fluoxetine (Prozac 0.5–4 mg/cat PO q 24 h) or paroxetine (Paxil, 0.5 mg/kg PO q 24 h) may be helpful in some cats.

Anticonvulsants (phenobarbital beginning at 3 mg/kg PO q 12 h with dose adjustments to maintain trough serum levels at 20–35 µg/ml) may help if anti-inflammatory and behavior-modifying drugs are unsuccessful.

Feeding food without preservatives has been suggested as helpful.

Carnitine/coenzyme Q12 may help cats with vacuolar myopathy. Also antioxidants and omega-3 fatty acids may be useful.

Decrease environmental stress.

Prognosis

Consistent results with any treatment have not been obtained.

Prevention

Flea prevention.

Decrease stress in the environment.

HYPOCALCEMIA*

Classical signs

- Tremor associated with this disorder is usually of short duration and episodic.
- Stiffness and muscle spasm may also occur.
- Twitching of the ears or facial muscles may be present.
- Weakness, lethargy and anorexia are typical.

Pathogenesis

Decreases in calcium **decrease the threshold for neuronal and muscle depolarization.**

Hypocalcemia most often results from **iatrogenic injury to the parathyroid gland** during surgical removal of thyroid tumors.

Primary hypoparathyroidism is reported but is rare.

Hypocalcemia associated with **queening (eclampsia)** is rarely reported but occurs.

Clinical signs

Clinical signs include **weakness, tetany and tremors.**

Spontaneous muscle depolarization can manifest as muscle fasciculation, cramping, rigidity and twitching.

Queens with **preparturient hypocalcemia** present with **anorexia, lethargy, trembling, muscle twitching and weakness.** They resemble the clinical picture of hypocalcemia in cows (**predominantly weakness**), rather than the violent muscle tremor of eclampsia in dogs.

Cats with primary hypoparathyroidism are more often male and typically range from 6 months to 7 years of age. Signs include lethargy and anorexia and a sudden or gradual onset of neuromuscular signs including focal (e.g. ears or facial muscles) or generalized muscle tremors, seizures, weakness or ataxia.

Diagnosis

Diagnosis is confirmed by finding decreased (usually less than < 1.5 mmol/l (6 mg/dl) serum calcium on serum biochemical analysis.

Differential diagnosis

Rule out other **inflammatory causes of muscle disease** and **acute organophosphate toxicity** (history of exposure, signs and low cholinesterase activity).

Physiological functions such as shivering from cold or apprehension should be considered.

Treatment

Treatment involves calcium supplementation and vitamin D therapy.

If clinical signs are present, rapid institution of treatment is indicated with 0.5–1.5 ml/kg IV of 10% **calcium gluconate**. **Infuse calcium slowly over 10 minutes while monitoring heart rate. Stop infusion if bradycardia occurs.**

Short-term maintenance involves either **SC calcium** (1–2 ml of 10% calcium gluconate diluted 1:1 in 0.9% saline q 8 hours) or **IV calcium** (10–20 ml of 10% calcium gluconate in 500 ml of 0.9% saline) with rate adjusted to maintain normocalcemia. Monitor calcium 2–3 times daily initially.

Longer-term maintenance includes **oral calcium** (25 mg/kg q 8–12 hours) and **vitamin D**. The active form of endogenous vitamin D₃ (called calcitriol or 1,25 dihydroxycholecalciferol) is used at 2.5–10 ng/kg q 24 hours or synthetic vitamin D₃ (dihydrotachysterol) at 0.02–0.03 mg/kg q 24 hours for 3 days, then 0.01–0.02 mg/kg q 6–24 hours.

Calcium should be monitored carefully, as hypercalcemia is nephrotoxic.

Adjustments to doses should be made every 1–3 days based on calcium concentrations.

If hypocalcemia is the result of thyroidectomy, calcium and vitamin D therapy can be reduced gradually over 2–3 weeks, and stopped if calcium remains in the normal range.

Prognosis

Acute hypocalcemia following bilateral thyroidectomy can be fatal if not recognized early and appropriate therapy instituted.

Prevention

When performing bilateral thyroidectomy, allow 3–4 weeks between removal of each lobe.

ENCEPHALOMYELITIS

Classical signs

- Any aged cat may be affected.
- A diffuse, whole-body, low-amplitude, higher-frequency tremor is present
- Animals may twitch periodically.
- Neurological signs are often diffuse.

Pathogenesis

This syndrome is associated with histological evidence of inflammation of the CNS. However, a consistent infectious etiology has not been identified.

Encephalomyelitis is a much rarer cause of tremor in cats compared to dogs.

Clinical signs

Any age of cat may be affected.

A diffuse, whole-body, low-amplitude (fine), higher-frequency tremor is present.

Animals may also twitch periodically.

Other neurological signs that may be present in cats with encephalomyelitis include seizures, blindness, conscious proprioceptive deficits and cranial nerve deficits.

Neurological signs may not localize to a single area within the nervous system.

Fever and leukocytes may be present but are inconsistent findings.

Evidence of chorioretinitis may be present on fundic examination.

Diagnosis

Cerebrospinal fluid may contain **increased numbers of nucleated cells** and/or **elevated protein** concentrations.

Nucleated cell counts can vary from mildly inflammatory ($0.005\text{--}0.020 \times 10^9$ cells/L [5–20 cells/ μL]; normal $< 0.002\text{--}0.005 \times 10^9$ cells/L [2–5 cells/ μL]) to greatly inflammatory ($> 0.05 \times 10^9$ cells/L [50 cells/ μL]).

The nucleated cell type is variable, but most often is a mononuclear cell population. Neutrophils may also be seen.

In cats with FIP, CSF protein concentrations are usually elevated at greater than 2 g/L (200 mg/dl), and nucleated cell counts are greater than 0.1×10^9 cells/L (100 cells/ μL).

In cats with FIP the predominant nucleated cell type present in the CSF is neutrophils

In cats with encephalitis from other suspected viral etiologies, CSF protein concentrations are usually less than 1 g/L (100 mg/dl), and nucleated cell counts are less than 0.05×10^9 cells/L (50 cells/ μL).

Advanced **imaging** studies (CT or MR) may show **multifocal lesions**. Often these **lesions are enhanced** by intravenous contrast administration.

Differential diagnosis

Rule out other inflammatory, metabolic, and degenerative causes of tremor.

Physiological functions such as shivering from cold or apprehension should be considered.

Treatment

Treatment with **corticosteroids** (prednisolone 2 mg/kg q 12 h initially) may improve clinical signs.

If clinical signs improve, the corticosteroid therapy should be slowly tapered (over months) to prevent recurrence.

Prognosis

Clinical response to corticosteroid is variable.

HYPOKALEMIA

Classical signs

- A short duration tremor may be present episodically and usually when the cat attempts purposeful movement.
- Aged cats or Burmese < 1 year.
- Ventral neck flexion.
- Stiff, stilted gait.
- Reluctance to walk or jump, and physical inactivity.
- +/- Sensitivity to palpation of larger muscle groups.

See main reference on page 893 for details (The Cat With Neck Ventroflexion) and on page 945 (The Cat With Generalized Weakness).

Clinical signs

Signalment is typically **aged cats > 8 years** or **young Burmese < 1 year** (usually 2–6 months).

Typically there is a history of **acute onset of weakness**. However, **decreased activity and inappetence** are often present for **weeks to months** prior to presentation.

A **short-duration tremor** may be present **episodically** and **usually when the cat attempts purposeful movement**

Clinical signs include **ventral neck flexion**, **stiff**, **stilted gait**, and **a reluctance to walk or jump**. Typically, weak cats do not walk far, but soon sit or lie, flopping down, instead of carefully sitting as normal cats do. Sensitivity to palpation of larger muscle groups may be noticed.

Dyspnea occurs when the potassium is very low ($2.0\text{--}2.5$ mmol/L), because of weakness of the respiratory muscles. It may occur after fluid administration because volume dilution and increased urinary potassium loss induced by diuresis may lead to further worsening of the hypokalemia.

Young Burmese cats are susceptible to this disease, and potassium depletion may have played a role in the previously described myopathy of Burmese cats.

Transient episodes of weakness may occur beginning between 2–12 months of age.

Diagnosis

Diagnosis is made by finding **decreased serum potassium concentrations** (usually < 3.5 mmol/L) in association with clinical signs. The severity of signs varies between cats when potassium is 2.5–3.5 mmol/L. Below 2.5 mmol/L and especially below **2.0 mmol/L**, **signs are life threatening**, with death occurring from respiratory muscle failure.

Serum creatine kinase (CK) may be elevated reflecting the myopathy associated with hypokalemia.

Electrodiagnostic evaluation is rarely performed. Abnormalities that may be found include increased insertional activity, fibrillation potentials and positive sharp waves, and some bizarre high-frequency discharges.

Muscle biopsies often have minimal change present. Mild myonecrosis is possible.

MYOTONIA

Classical signs

- Usually present in young cats as a congenital problem.
- Stiffness and muscle spasm found at gait.
- Steps are short and the limbs are stilted.
- There is an increase in muscle size.

Pathogenesis

Cats with myotonia have **sustained muscle contraction**, which is initiated voluntarily or with stimulation, and sustained involuntarily.

Myotonia most often occurs as a **congenital problem**.

Excessive muscle contraction is thought to be due to an **abnormal muscle cell membrane** that **supports persistent depolarization**.

Clinical signs

Signs are first evident in young cats < 1 –2 years of age.

Affected cats often have a **stiff, stilted gait** and have **large, bulky muscles on palpation**.

Muscle dimpling may occur with **direct muscle percussion**.

Tremor, if present, is usually of short duration and episodic.

Diagnosis

Electromyography demonstrates the characteristic **myotonic potentials** (sounds like a motorcycle revving its engines), and **muscle biopsies** may be supportive of the diagnosis.

Differential diagnosis

Rule out other myopathies such as **X-linked muscular dystrophy** (increased serum creatine kinase, typical muscle biopsy findings). Myotonia has characteristic EMG findings.

Treatment

No treatment has been described in cats.

MYASTHENIA GRAVIS

Classical signs

- Adult cats or Siamese < 1 year of age.
- Tremor with this disease is usually episodic and occurs during attempts at movement, muscle weakness induced by movement.
- Ventral neck flexion may also be seen.
- Decreased palpebral reflex is a helpful clinical sign.

See main reference on page 955 for details (The Cat With Generalized Weakness) and page 896 (The Cat With Neck Ventroflexion).

Clinical signs

Muscle tremors are usually episodic and occur in muscles that are being used.

This is a rare disease in cats. Generally a disease of **adult cats**, except for the **congenital form in Siamese** which presents at < 6 months of age.

Exercise intolerance and **episodic weakness induced by walking** or playing are typical signs. The cat may walk a few steps and flop down. Recovery occurs with rest.

A **stiff, stilted gait** is often noted prior to collapse.

Weakness of facial muscle may also be seen, and this is most evident as a **decrease in the palpebral reflex** and narrowing of the palpebral fissure. This appears to be a more consistent finding in cats versus dogs.

Megaesophagus is uncommon and may lead to aspiration pneumonia.

One cat has been reported with a **jaw-drop and dysphagia** as the only clinical signs.

Diagnosis

Diagnosis is based upon clinical signs of **exercise-induced weakness** that is **resolved with edrophonium**.

An edrophonium response test may suggest the disease if strongly positive. Edrophonium is an anticholinesterase that potentiates acetylcholine (ACH) at the neuromuscular junction. When given IV (0.1 mg/kg), this drug can reverse the clinical weakness seen with myasthenia gravis for a short period of time.

Electromyography and nerve conduction studies will be normal. A decremental response may be seen during repeated stimulation of a peripheral nerve in some, but not all cats.

Single-fiber EMG is a relatively new technique that may aid diagnosis of this disease in the future.

Documentation of **antibodies to the acetylcholine receptor** in serum appears to be the most definitive diagnostic test. In congenital disease, however, these antibodies will not be present.

DEGENERATIVE DISEASES OF THE NERVOUS SYSTEM

Classical signs

- Some degenerative diseases occur in younger animals and some in older animals.

Classical signs—Cont'd

- With the encephalomyelopathy of young cats reported in the United Kingdom, cats 3–12 months were affected, however, the disease was seen in cats up to three years of age. Clinical signs usually are progressive over weeks to months.
- With spongiform encephalopathy of older cats, muscle tremors may be seen in association with ataxia and pupillary dilation.
- Clinical signs of hypomyelination or dysmyelination consist of diffuse tremor accompanied by frenzied behavior and indiscriminate biting. Clinical signs are worsened with activity.
- Motor neuronopathies were in adult cats. Clinical signs included tremor, progressive weakness, cervical ventroflexion, dysphagia and muscle atrophy.

Pathogenesis

A number of degenerative nervous system diseases have been reported in various locations around the world. These include encephalomyelopathy, spongiform encephalopathy, hypo or dysmyelination and motor neuronopathies.

Some degenerative diseases occur in younger animals and some in older animals. Some of the degenerative diseases are inherited and signs begin in cats less than a year of age.

An **encephalomyelopathy of young cats** has been reported in the United Kingdom. Wallerian degeneration was noted primarily involving the spinocerebellar pathways and the ventral funiculus of the spinal cord. A viral etiology was suggested but not proven.

A **spongiform encephalopathy** occurs in **older cats** in the United Kingdom and a prion may be the cause.

Hypomyelination or dysmyelination of the CNS has been reported in two **Siamese cats**. Pathologically there was a deficiency of myelin primarily in the ventral and lateral aspects of the spinal cord. Abnormal oligodendrocyte numbers or function is the suggested pathogenic mechanism.

Motor neuronopathies are diseases that affect the **cell bodies** of the **lower motor neuron** leading to degeneration of the cell in the ventral horn of the spinal cord and occasionally the cranial nerve nuclei. Histologic lesions are most severe in the ventral spinal gray matter and consist of neuronal cell loss and gliosis.

Clinical signs

With the **encephalomyelopathy of young cats** reported in the United Kingdom, cats **3–12 months** were affected, however, the disease was seen in cats **up to 3 years** of age. Clinical **signs usually are progressive** over weeks to months.

Signs include **ataxia**, **paresis**, and **“head shaking”**. **Ataxia of the pelvic limbs** was the **initial clinical sign** noted.

Spongiform encephalopathy occurs in older cats, and clinical signs include **muscle tremors**, **ataxia**, **dilated unresponsive pupils**, jaw champing, salivation, and behavior abnormalities. In one additional cat the tremor was most obvious in the pelvic limbs. Signs progressed to **severe ataxia and hypermetria**.

Clinical signs of **hypomyelination or dysmyelination** consist of **diffuse tremor** accompanied by **frenzied behavior** and **indiscriminate biting**. Clinical signs are worsened with activity. Reported cats were young Siamese < 1 year of age.

Motor neuronopathies were reported in **adult cats** and signs included **tremor**, **progressive weakness**, **cervical ventroflexion**, dysphagia, and **muscle atrophy**.

Diagnosis

Antemortem testing for many of these diseases often results in negative or normal findings.

Definitive diagnosis is often rendered only **at necropsy** and histopathological examination of the nervous tissue.

In some instances of motor neuronopathies, mild to moderate fibrillation potentials were found in the appendicular and paraspinal muscles with electromyography.

Cerebrospinal fluid with these degenerative conditions is normal.

Differential diagnosis

Rule out other metabolic, inflammatory, and toxic causes of tremor.

Physiological functions such as shivering from cold or apprehension should be considered.

Treatment

No treatment is currently helpful or has been attempted for affected cats.

Prognosis

Clinical signs associated with **degenerative diseases progressively worsen**.

Animals are commonly euthanized due to the progressive incapacitation.

Prevention

Do not breed cats affected that have produced kittens with a presumed inherited disease.

POLIOENCEPHALOMYELITIS

Classical signs

- Young to middle-aged cats have been affected.
- Clinical signs have a slow onset and are chronically progressive.
- Signs are variable but include pelvic limb ataxia, seizures, paresis, hypermetria, intention tremors, decreased pupillary light reflexes, and hyperesthesia over the thoracolumbar area.

Pathogenesis

Lesions primarily occur in the **spinal cord** and include **severe degeneration and loss of neurons**, perivascular mononuclear cuffing, lymphocytic meningitis, neuron-phagia and glial nodules.

A viral etiology was suggested but not proved.

Clinical signs

Young to middle-aged cats have been affected.

Clinical **signs have a slow onset** and are **chronically progressive**.

Signs are variable but include **pelvic limb ataxia, seizures, paresis, hypermetria, intention tremors**, decreased pupillary light reflexes, and **hyperesthesia** over the thoracolumbar area.

Seizures were noted during sleep and were characterized by staring, clawing, biting and hissing.

Diagnosis

Two affected cats were leukopenic, with one having bone marrow hypoplasia.

Cerebrospinal fluid from one cat contained an elevated protein content.

One cat had diffuse, hyper-reflective tapetal areas and subretinal infiltrative lesions upon fundic evaluation.

Definitive diagnosis is often only made at **necropsy**.

Histological lesions are most severe in the spinal cord and included severe degeneration and loss of neurons, perivascular mononuclear cuffing, lymphocytic meningitis, neuronphagia and glial nodules.

Differential diagnosis

Rule out other inflammatory, metabolic and degenerative causes of tremor.

Treatment

No treatment has been attempted.

Prognosis

Clinical signs were progressive up until euthanasia.

NEOPLASIA

Classical signs

- A cat with multiple meningiomas presented with generalized tremors.

Pathogenesis

A 2-year-old cat with multiple meningiomas presented with generalized tremors. This cat was receiving chemotherapy for a previously diagnosed lymphoma.

Diffuse neoplastic involvement was present pathologically.

Clinical signs

Tremor was the **initial clinical sign** seen.

Clinical signs **progressed rapidly to ataxia and paresis**.

Diagnosis

Multiple tumors were found at necropsy extending from the parietal lobes of the brain to the lumbar spinal cord.

Differential diagnosis

Rule out other inflammatory, metabolic and degenerative causes of tremor.

Treatment

No definitive treatment was attempted.

40. The cat with anisocoria or abnormally dilated or constricted pupils

Rodney S Bagley

KEY SIGNS

- Inequality of pupil size.
- Inappropriately dilated or constricted pupils.

MECHANISM?

- **Anisocoria** is a resting inequality in pupil size.
- **An abnormally constricted pupil is referred to as a miotic pupil** and results from either excessive parasympathetic tone or decreased sympathetic tone.
- **An abnormally dilated pupil is referred to as a mydriatic pupil** and results from either decreased parasympathetic tone or excessive sympathetic tone.
- Mechanical abnormalities of the iris may also result in abnormal pupil size.

WHERE?

- Disease of the eye, the visual pathways, or the pathways innervating the pupil may result in anisocoria.

WHAT?

- Cats with anisocoria usually have primary ocular disease or abnormalities of iris innervation. Disease of the iris may also be present such as iris atrophy. Systemic disease that alters autonomic nervous system tone may also cause anisocoria.

QUICK REFERENCE SUMMARY

Diseases causing anisocoria or abnormally dilated or constricted pupils

MIOTIC (CONSTRICTED) PUPIL(S)

NEOPLASIA

- **Neoplasia* (p 881)**

Tumors involving the sympathetic nerves may result in miosis. Other signs consistent with Horner's syndrome are usually present. Signs of systemic disease (for example vomiting, diarrhea, enlarged lymph node size) may be found with diffuse diseases such as lymphoma and leukemia. Tumors of the middle/inner ear, which affect the sympathetic nerves, may result in pain, swelling and abnormal discharge from the affected ear.

INFECTIOUS/INFLAMMATORY

- **Anterior uveitis** (p 879)**

Infection or inflammation of the anterior chamber of the eye may result in miosis as a reflex response to pain or due to vascular congestion of the iris. Conjunctivitis, corneal edema and hypopyon often occur concurrently.

- **Spastic pupil syndrome** (p 878)**

Cats may have miotic or unresponsive pupils in association with feline leukemia virus (FeLV) infection. Usually the affected pupils do not dilate with dark adaptation and constrict poorly to light stimulation. Other signs of FeLV infection may be evident such as anemia, recurrent infections or neoplasia.

- **Middle/inner ear infection** (p 877)**

Otitis media/interna infection may affect the sympathetic innervation to the pupil and cause miosis. Other signs of Horner's syndrome such as prolapse of the third eyelid and enophthalmos are usually also present. Discharge from the ear or an abnormally appearing tympanic membrane are usually present.

IDIOPATHIC

- **Horner's syndrome*** (p 875)**

Horner's includes signs of miosis, enophthalmos, prolapse of the third eye, ptosis and vasodilation. Miosis and prolapse of the third eyelid are most consistent.

TRAUMA

- **Brachial plexus avulsion* (p 880)**

Characterized by decreased to absent movement, spinal reflexes, and muscle tone in a thoracic limb following being struck by a car or a fall. Miosis as well as other signs of Horner's syndrome can occur in the ipsilateral eye with damage to this area.

- **Head trauma** (p 879)**

Usually associated with an acute onset of clinical signs reflective of an intracranial problem. Signs present often include alterations in consciousness, paresis and cranial nerve abnormalities. Fresh blood from lacerations on or around the head, skull fractures, blood in the ear canals, and scleral hemorrhage may be clues to a previous traumatic incident.

TOXICITY

- **Toxins (organophosphate)** (p 880)**

Toxins such as organophosphates that interrupt or override sympathetic impulse transmission or stimulate parasympathetic nerve transmission can result in miosis. Often there are diffuse clinical signs present including salivation, urination, defecation, vomiting or diarrhea. Historical exposure to these toxins is important to ascertain.

- **Parasympathomimetic drugs (p 882)**

Miotic pupils can occur when drugs that stimulate the parasympathetic system centrally or peripherally are administered. If the drugs result in systemic parasympathomimetic signs, salivation, urination, defecation, vomiting, diarrhea or weakness may be present.

continued

continued

MYDRIATIC (DILATED) PUPIL(S)

DEGENERATIVE

- **Iris atrophy*** (p 883)**

Degeneration of the iris with age may result in a dilated pupil. Irregular pupil margins, tears in the iris and dyscoria are clues. Animals older than 5 years of age are most often affected.

- **Spongiform encephalopathy (p @)**

Rare in cats. Other clinical signs in addition to dilated pupils include muscle tremors, ataxia, jaw clamping, salivation and behavior abnormalities.

INFECTIOUS/INFLAMMATORY

- **Encephalitis* (p 888)**

Signs of diffuse intracranial nervous system dysfunction are often present including alteration in consciousness, gait abnormalities, paresis and cranial nerve abnormalities. Spinal hyperesthesia may also be found. If the disease affects diffuse body systems, anterior uveitis or chorioretinitis is often concurrently present. Fever and leukocytosis are inconsistently found.

NEOPLASIA

- **Neoplasia* (p 885)**

Tumors within or compressing cranial nerve III may result in ipsilateral mydriasis. If a space-occupying brain lesion is present, other signs seen may include circling, seizures, paresis and abnormalities of vision.

NUTRITIONAL

- **Thiamine deficiency** (p 884)**

Thiamine deficiency may result in dilated pupils. Anorexia and depression are early signs, ventral neck flexion and a crouched body position with reluctance to move are typical. Episodes of seizures – like muscle spasms with neck ventroflexion or opisthotonos may occur. Anorexic cats or cats on all-fish diets are at the highest risk for development.

IDIOPATHIC

- **Dysautonomia** (p 885)**

Reported most commonly in Europe, although the frequency has decreased. Sudden onset of depression and anorexia occur together with signs consistent with a lack of autonomic innervation. In addition to mydriasis, weakness, dry eye, xerostomia, prolapsed third eyelids, bradycardia, loss of anal reflex, incontinence and constipation may be seen.

TRAUMA

- **Head trauma** (p 883)**

Usually associated with an acute onset of clinical signs reflective of an intracranial problem. Signs present often include alterations in consciousness, paresis and cranial nerve abnormalities. Fresh blood from lacerations on or around the head, skull fractures, blood in the ear canals, and scleral hemorrhage may be clues to a previous traumatic incident. Unilateral caudal transtentorial brain herniation results in similar signs.

TOXICITY

● **Toxins* (p 887)**

Toxins that interrupt parasympathetic nerve transmission or stimulate sympathetic nervous impulses can result in mydriasis. Bites from Elapid (cobra type) snakes often result in mydriasis. Often there are diffuse clinical signs present including weakness, ataxia and prolonged bleeding from venipuncture sites. Fluoroquiroalone toxicity may result in a sudden onset of bilaterally dilated, non-responsive pupils. Historical information regarding exposure to these toxins is important to elucidate.

● **Parasympatholytic drugs (p 888)**

Dilated pupils are most commonly seen following either systemic or topical administration of atropine. With systemic administration tachycardia is often also present. Historical administration of or exposure to these drugs is an important clue.

INTRODUCTION

MECHANISM?

Diseases that affect the iris muscle, other ocular structures, the visual pathways, the nervous system innervation to the iris, or systemic autonomic nervous system functions may result in pupillary abnormalities.

Mechanical abnormalities of the iris such as synechia and iris atrophy are commonly associated with anisocoria.

Abnormalities in the parasympathetic or sympathetic input to the eye often are associated with abnormal pupil size.

Intraocular causes of anisocoria are covered in The Cat With Abnormal Pupil Size, Shape or Response (page 1287) and The Cat With Abnormal Iris Appearance (page 1292).

WHERE?

Disease of the eye, the visual pathways, or the pathways innervating the pupil may result in anisocoria.

The visual pathway includes the retina, optic nerve, optic chiasm, optic tract, lateral geniculate body, optic radiations and the occipital cortex.

Sympathetic innervation to the pupil is responsible for pupillary dilation and innervation to the vessels of the iris (Figure 40.1).

- Sympathetic control is initiated in the hypothalamus of the diencephalon.

- The impulse then descends through the brain stem and cervical spinal cord in the lateral tectotegmental spinal pathway.
- **This upper motor neuron (UMN) pathway synapses** on the cell bodies of the preganglionic sympathetic nerves located in the intermediolateral horns **in the T₁₋₃ spinal cord segments**.
- The preganglionic sympathetic nerves exit the spinal cord and run cranially in the cervical sympathetic trunk in the cranial thorax.
- **This pathway continues through the cervical area** with the vagus nerve forming the vagosympathetic trunk.
- The preganglionic nerves synapse in the **cranial cervical ganglion located just caudal to the ear. The postganglionic nerves run through the middle ear**, course with cranial nerve (CN) IX (glossopharyngeal nerve) and then with the carotid artery to enter the skull.
- These nerves then course in the cavernous sinus with the carotid artery, and **exit the skull through the orbital fissure**.
- The postganglionic sympathetic fibers travel with the ophthalmic branch of CN V (trigeminal nerve) to the eye and via the short ciliary nerve synapse on the dilator muscle of the pupil.
- Some postganglionic fibers innervate the smooth muscle fibers in the orbital sheath (musculus orbitalis).
- **Sympathetic innervation to eye includes** the muscle of the periorbita, eyelids (Muller's muscle), the third eyelid, the dilator muscle of the iris, and the

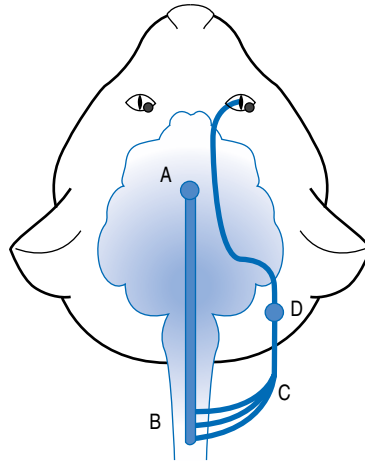

Figure 40.1. Schematic of the sympathetic innervation to the pupil. The information is initiated in the hypothalamus (A), travels caudally bilaterally in the spinal cord to the T1–T3 spinal segments (B), where the preganglionic fibers exit and travel cranially in the vagosympathetic trunk (C). The postganglionic fibers originate in the cranial cervical ganglion (D) and travel to the pupil.

vasomotor fibers to the blood vessels and chromatophores of the uveal tract.

Parasympathetic innervation to the eye occurs through cranial nerve (CN) III (oculomotor nerve) for pupillary constriction (Figure 40.2).

- The afferent pathway for pupillary constriction during light stimulation is the same as for vision from the globe to the lateral geniculate body.
- Prior to synapse in this region, the fibers responsible for the pupillary light reflex (PLR) leave the visual pathway and travel to the pretectal nucleus in the midbrain.
- These fibers project to the ipsilateral and contralateral parasympathetic nucleus of CN III (PSN CN III).
- Contralateral projection is functionally greater than the ipsilateral projection for this reflex, making **the direct pupillary light reflex stronger than the indirect**.
- **The parasympathetic nucleus of CN III is excited bilaterally** with impulses traveling from one eye. Cranial nerve III exits the skull through the orbital fissure and projects to the globe.
- The preganglionic portion of CN III synapses on the short ciliary nerves, which are the ultimate effector of pupil constriction.

- In cats, there are only two short ciliary nerves, a nasal (medial) and malar (lateral), compared to 5–8 in dogs.

WHAT?

Primary disease of the eye such as synechia, iris atrophy or glaucoma can result in an abnormal pupil.

Primary ocular disease of the eye such as uveitis can result in a constricted pupil.

Miotic pupils can result from parasympathetic overstimulation or lack of sympathetic influence.

Miotic pupils can result from an abnormality of sympathetic innervation to the eye. This can cause a miotic pupil alone (Horner's pupil) or in signs of complete sympathetic denervation of the orbit (Horner's syndrome: miotic pupil, prolapsed third eyelid, ptosis, enophthalmos, peripheral vasodilation, decreased sweating).

A large, poorly responsive or unresponsive pupil(s) is indicative of **parasympathetic denervation** of the iris. This can result from disease of cranial nerve III or its nucleus.

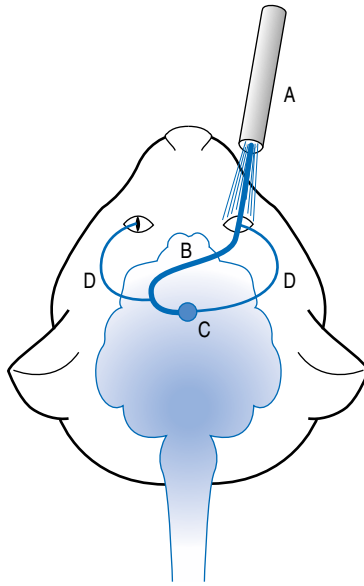

Figure 40.2. Schematic of the parasympathetic innervation to the pupil. The information is initiated by a light stimulus (A), travels caudally in the optic nerve, chiasm and optic tract (B), to the parasympathetic nucleus of cranial nerve III (C). The preganglionic and postganglionic fibers travel to the pupil with cranial nerve III (D).

A larger pupil can be seen ipsilateral to a prechiasmic lesion causing decreased vision. Examples include retinal disease and optic nerve disease (optic neuritis).

A larger pupil can be seen contralateral to an optic tract lesion.

Cerebellar disease may occasionally be associated with anisocoria.

- With unilateral lesions of the fastigial or interposital nuclei, pupillary dilation which is slowly responsive to light may be seen.
- Occasionally, the third eyelid may protrude and the palpebral fissure may be enlarged.
- The pupillary dilation occurs in the eye ipsilateral to an interposital nuclear lesion and contralateral to a fastigial nuclear lesion.

Dyscoria is an abnormality of the form or shape of the pupil or an abnormal reaction of the two pupils to light.

Enophthalmos is a backward displacement of the eyeball in the orbit.

Ptosis is drooping of the upper eyelid from paralysis of CNIII or sympathetic innervation.

DISEASES CAUSING MIOSIS

HORNER'S SYNDROME***

Classical signs

- Miosis occurs in association with prolapsed third eyelid, enophthalmos and ptosis.
- Any aged cat may be affected.

Pathogenesis

Horner's syndrome occurs because of an abnormality of, or injury to, the sympathetic innervation to the eye and surrounding structures.

Normal sympathetic innervation is responsible for pupillary dilation.

Any disease that interrupts sympathetic transmission to the eye can result in Horner's syndrome.

- **Infiltration** of these nerves by lymphoma or leukemia cells is possible.
- **Traumatic damage** to the sympathetic system can occur.

Many instances of Horner's syndrome in cats do not have a definable cause.

Clinical signs

Unilateral or bilateral miosis is the most consistent clinical sign of sympathetic denervation.

The affected pupil will not dilate normally in a dark environment.

Other clinical signs constituting a diagnosis of Horner's syndrome include prolapsed third eyelid, enophthalmus, ptosis, and rarely, vasodilation of uveal tract vessels.

If middle or inner ear disease is present, pain and swelling around or ventral to the bulla may be present. There may also be pain upon opening the mouth, swelling in or around the ear, and abnormal discharge in the ear canal may be present.

Diagnosis

The clinical diagnosis is based upon the presence of this constellation of characteristic clinical signs however, these clinical signs are not pathognomonic for any particular disease.

Pharmacologic testing of the eye to determine the location (pre- or postganglionic) of the disease is rarely helpful.

An otoscopic examination should be performed to examine for signs of middle ear disease.

Palpation in the cervical area around the vagosympathetic trunk should be performed to check for masses or other abnormalities.

Radiographs of the bulla may show increased opacity or bony abnormalities if middle ear disease is present.

Advanced imaging studies (computed tomography (CT) or magnetic resonance (MR) imaging) are used to look for intracranial, middle ear or spinal disease.

Cerebrospinal fluid should be collected and evaluated for protein content and cellularity.

If a cervical spinal cord problem is suspected, spinal radiographs, myelography, or advanced imaging (CT, MR) may be needed.

Differential diagnosis

Primary disease of the eye such as anterior uveitis **should be ruled out** by performing a thorough ocular examination.

A neurologic examination should be performed to rule out associated intracranial or spinal disease.

Treatment

As **Horner's syndrome is a clinical diagnosis** and not an etiological diagnosis, any disease of the sympathetic system should be treated specifically.

No treatment is available for idiopathic Horner's syndrome.

Prognosis

The ultimate prognosis will depend upon the underlying cause.

The prognosis for otitis media is good with appropriate surgical or antimicrobial treatment.

The prognosis for brain and spinal cord disease depends upon the nature of these diseases.

Cats with idiopathic Horner's syndrome may improve with time.

Idiopathic Horner's syndrome is not life threatening.

While being a cosmetic abnormality, Horner's syndrome is infrequently irritating to the cat.

MIDDLE/INNER EAR INFECTION**

Classical signs

- Miotic pupil and other signs of Horner's syndrome on affected side.
- Pain on palpation or swelling around or ventral to the bulla may be present.
- Otitis externa may be noted but is not constantly present.
- Pain upon opening the mouth and abnormal discharge in the ear canal may be present.
- Head tilt, facial nerve paralysis and nystagmus can result from middle ear disease.
- Abnormal odors may emanate from the ear canal.

Pathogenesis

Inflammation of the middle ear may result in damage to the sympathetic nerve for pupillary dilation, as well as damage to the VIIth (facial) cranial nerve. Extension to the inner ear may damage the VIIIth (vestibular) cranial nerve and receptors resulting in a head tilt, vestibular ataxia and nystagmus. See page 838 (The Cat With a Head Tilt, Vestibular Ataxia or Nystagmus).

Infection or inflammation of the middle ear can result via extension of these processes from the external ear or eustachian tube.

Infection can also occur secondary to systemic infections.

Allergic skin conditions, neoplasia, foreign bodies and trauma to the ear may be associated with middle ear infections.

Organisms present mainly are bacteria and fungi.

Grass awn migration into the middle ear is common in some geographic locations.

Clinical signs

On the affected side there is evidence of Horner's syndrome with a constricted pupil that does not dilate normally in a dark environment.

Pain on palpation or swelling around or ventral to the bulla may be present.

Otitis externa may be noted but is not consistently present.

Pain upon opening the mouth and abnormal discharge in the ear canal may be found.

Head tilt, vestibular ataxia with leaning, rolling, rolling to the side of the lesion and nystagmus result from inner ear disease. **Facial nerve paralysis** may result from middle ear disease, and is evidenced by an inability to close the eyelids and loss of sensory innervation to the inner surface of the pinna.

Abnormal odors may emanate from the ear canal.

Purulent discharge may be present in the external ear canal.

Diagnosis

A discolored and outwardly bulging tympanic membrane may be noted with otoscopic examination.

Increased density or bony changes of the bulla may be seen with skull radiographs highlighting the bulla.

Advanced imaging studies such as CT or MR **provide the best views** of the middle/inner ear.

Definitive diagnosis may be made with **myringotomy** and fluid analysis or with surgical exploration (bulla osteotomy).

Culture and sensitivity of any purulent discharge from the middle ear cavity should be performed.

Differential diagnosis

A direct otoscopic evaluation of the ear canal should reveal foreign bodies.

Tumors can result in associated local middle ear infection.

Predisposing causes of recurrent otitis externa such as allergic skin conditions, swimming, immunodeficiencies or anatomical abnormalities of the external ear canal may be evident.

Treatment

Infections from bacterial organisms should be treated with appropriate topical and systemic antibiotics based

upon culture and sensitivity results. Amoxicillin/clavulanic acid (14 mg/kg PO q 12 h) in combination is a reasonable antibiotic to begin treatment with prior to receiving culture and sensitivity results.

Antifungal drugs may be used locally or systemically depending upon the offending organism (see section on antifungal therapy).

Foreign bodies should be removed with forceps or a similar instrument or during surgery.

Surgical drainage (bullae osteotomy) **is often needed** for curative treatment.

Prognosis

The prognosis for treatment of middle ear disease with either appropriate antimicrobials or surgery **is usually good**.

Surgery of the bullae may result in complications such as a head tilt and facial nerve paralysis which may be persistent.

Prevention

Early appropriate treatment of otitis externa may be helpful in preventing extension to the middle ear.

Correcting anatomical defects of the ear canal decreases the risk of otitis.

Decrease or stop activities that predispose to water or foreign material collecting in the ear.

SPASTIC PUPIL SYNDROME**

Classical signs

- Pupils are usually fixed at a midrange size and do not dilate appropriately with dark adaptation.
- Pupil diameters may alternate in size between eyes.
- Pupil movement is abnormal (inability to fully dilate in the dark; sluggish constriction to light stimulation).

Pathogenesis

Many, if not all, of these cats are positive for the **feline leukemia virus**.

A **C-type RNA virus** has been demonstrated in the short ciliary nerves and ganglion of some cats.

Additionally, **feline immunodeficiency virus** may play an associated role.

Clinical signs

The pupils are usually fixed at a midrange size and do not dilate appropriately with dark adaptation.

The pupil diameters may alternate in size between eyes, and pupil movement is abnormal. There is inability to fully dilate in the dark and sluggish constriction to light stimulation.

Diagnosis

The diagnosis is suspected in a cat with the appropriate clinical signs that is also FeLV positive.

Differential diagnosis

Rule out **primary iris movement problems such as synechia**.

Treatment

There is no specific treatment for this disease.

Prognosis

The prognosis for the pupillary abnormality is variable.

The overall prognosis will be determined by other associated FeLV-related neoplastic conditions that may arise.

Prevention

Decrease exposure to other FeLV-positive cats.

Vaccination of FeLV infection may provide some prevention.

ANTERIOR UVEITIS**

Classical signs

- Miosis is often present in association with other signs of ocular inflammation including aqueous flare, iridal edema, corneal edema, conjunctivitis, hemorrhage from the iris surface and hypopyon.
- Blepharospasm and photophobia may be seen.
- In some instances, abnormal ocular discharge is present.

See main reference, page 1303 “The Cat With Abnormal Iris Appearance” or page 1165 “The Blind Cat or Cat With Retinal Disease”.

Pathogenesis

The underlying process is an **inflammation within the anterior chamber of the eye**.

The miosis may result from **ocular pain** mediated through a trigeminal (cranial nerve V) constrictor center (oculosensory pupillary reflex) or from **iridal vascular changes**.

Viral disease such as **feline infectious peritonitis infection** and protozoal diseases such as **toxoplasmosis** are often present.

Clinical signs

Miosis is often present in association with **other signs of ocular inflammation** including aqueous flare, iridal edema, corneal edema, conjunctivitis, hemorrhage from the iris surface and hypopyon.

Blepharospasm and **photophobia** may be seen.

In some instances, abnormal ocular discharge is present.

Diagnosis

Clinical evaluation of the anterior chamber for signs of inflammation is performed.

A fine needle aspirate of the anterior chamber may reveal inflammation. See page 1283 Infectious chorioretinitis or anterior uveitis in “The Cat With Abnormal Pupil Size, Shape or Response” for a description of the technique.

Titers for viral diseases (FeLV, FIV) and toxoplasmosis may be helpful.

Titers for feline infectious peritonitis are unreliable.

Differential diagnosis

Rule out other causes of ocular disease such as glaucoma.

Consider local infections such as herpesvirus, *Mycoplasma*, or *Chlamydia*, which cause conjunctivitis and ocular discharge.

Evaluate for systemic organ dysfunction that may accompany FIP and toxoplasmosis.

Treatment

Treatment depends upon the underlying cause. See page 1292 “The Cat With Abnormal Iris Appearance”.

HEAD TRAUMA**

Classical signs

- Miosis together with superficial lacerations, bleeding or bruising may indicate a traumatic etiology.
- Trauma to the central nervous system often results in paresis, abnormal consciousness or cranial nerve abnormalities.
- Trauma to the nerves of the brachial plexus may cause lower motor neuron signs (paresis or paralysis, decreased to absent spinal reflexes, decreased to absent muscle tone) in the ipsilateral thoracic limb.

Pathogenesis

External trauma to the body may damage the ocular structures or the nerves to the eye.

Bruising and functional damage (neuropraxia) as well as anatomical disruption (axonotmesis and neurotmesis) may result.

Brachial plexus avulsion resulting in miosis is most often associated with tearing or avulsion of sympathetic nerves that arise in the T1–T3 spinal cord segments and exit the vertebral canal.

Central nervous system trauma may disrupt the sympathetic pathways in either the brain or cervical spinal cord.

Misplaced hypodermic needles in the jugular furrow during blood collection can rarely damage the sympathetic nerves to the eye.

Clinical signs

Miosis may occur with trauma due to involvement of the sympathetic system.

Superficial lacerations, bleeding or bruising may indicate a traumatic etiology.

Trauma to the central nervous system often results in paresis, abnormal consciousness or cranial nerve abnormalities as well as miosis.

Trauma to the nerves of the brachial plexus may cause lower motor neuron signs (paresis or paralysis, decreased to absent spinal reflexes, decreased to absent muscle tone) in the ipsilateral thoracic limb as well as Horner's syndrome in the ipsilateral eye.

Diagnosis

The diagnosis is supported by either a history of known trauma or superficial evidence of lacerations or bruising.

Damage to the nerves of the brachial plexus may result in signs of denervation on electromyographic studies. Abnormal potentials usually begin around 5 days after the trauma.

Advanced imaging studies (CT or MR) provide the best views of the central nervous system.

Differential diagnosis

If active bleeding or bruising is present, an evaluation for underlying clotting disorders such as coagu-

lopathies, platelet abnormalities and vasculitis should be performed.

Treatment

Standard critical care protocols for treatment of traumatized animals should be implemented as needed.

Primary treatment for nervous injury is not possible.

If it could be determined that a nerve is compressed or lacerated, surgical decompression or reconstruction is theoretically possible but is rarely performed.

Prognosis

Milder injuries usually result in a favorable prognosis.

Conversely, severe injuries may result in permanent dysfunction.

Prevention

Keep animals in controlled environments that limit access to automobiles and other traumatic potentials.

Use caution during jugular venepuncture.

TOXINS (ORGANOPHOSPHATE)**

Classical signs

- Acute onset of miosis, salivation, urination, defecation and muscle weakness.
- Rarely, lethargy, anorexia and persistent weakness without associated autonomic signs.

Pathogenesis

Organophosphate intoxication potentiates the effect of acetylcholine at the neuromuscular junction and other synapses, by binding with and inactivating acetylcholinesterase. This leads to increased acetylcholine concentrations at the neuromuscular junction, increased receptor stimulation and fatigue.

A delayed neurotoxicity in cats is reported associated with the use of **chlorpyrifos** spray for household application against fleas. There is individual variation in

sensitivity to chlorpyrifos, and signs of toxicity have occurred even when used according to label instructions. Toxicity has also been reported with the **flea collars** containing chlorpyrifos.

Clinical signs

Cats with organophosphate intoxication may have **acute signs including salivation, urination, defecation and muscle weakness**.

Postural reactions and spinal reflexes may be depressed in some cats, but may be normal in other cats.

The pupils may be bilaterally dilated and poorly responsive to light stimulation.

Ventroflexion of the neck and muscle tremors may be evident.

Diagnosis

History of exposure to an organophosphate.

Serum cholinesterase activity may lend support to the diagnosis, but may be non-diagnostic for chronic organophosphate toxicity. Values less than 500 IU (normal 900–1200 IU) are considered consistent with organophosphate toxicity.

Electromyographic changes are occasionally present and include fibrillation potentials, positive sharp waves and bizarre high-frequency discharges. A decremental response to repetitive nerve stimulation may be present.

Beware that edrophonium (used to test for myasthenia gravis) **will produce an acute worsening** of signs, which should be treated with atropine (0.05 mg/kg IV).

Differential diagnosis

Rule out other diffuse causes of weakness.

Treatment

Treatment includes 2-PAM (20 mg/kg q 12 h IV) and **diphehydramine** (1–2 mg/kg q 8–12 h).

Atropine (0.2–0.4 mg/kg) can be given with acute toxicity to decrease autonomic signs. Current recommendations suggest its **use only if marked bradycardia** is present as this drug may precipitate respiratory arrest.

Salivation and defecation are not life threatening and generally do not require atropine.

Diazepam should be avoided in these cats as it may result in generalized muscle tremor, hypersalivation, miotic pupils and vomiting similar to acute muscarinic signs of organophosphate toxicosis.

NEOPLASIA*

Classical signs

- **Miosis with or without signs of Horner's syndrome.**
- **Accompanying signs depend on the location of the tumor.**
- **Tumors causing miosis can occur in the middle ear, ventral cervical area, cervical spinal cord and brain.**
- **A mass may be palpated in the ventral cervical area with neoplasia of the vagosympathetic trunk.**

Pathogenesis

Neoplastic disease may infiltrate or compress the sympathetic nerves centrally or peripherally.

If the **middle ear** is affected, the most **common tumors are adenocarcinoma and squamous cell carcinoma**.

Diffuse neoplastic diseases such as lymphoma and leukemias may infiltrate the sympathetic nerves.

- Lymphoma can be associated with feline leukemia virus infection.

Clinical signs

Miosis may be the primary sign or it may occur with other signs of Horner's syndrome. Other neurological signs depend on the location of the tumor.

Neoplasia involving the middle ear can result in pain upon opening the mouth or during palpation around the ear, abnormal otic discharge and swelling around the ear.

- Head tilt, facial paralysis and nystagmus can also be present when both the middle and inner ear are involved.

Neoplasia of the intracranial nervous system can be associated with circling, seizures, behavioral abnormalities, paresis or cranial nerve abnormalities.

Neoplasia of the cervical spinal cord can result in tetraparesis or hemiparesis and cervical pain. If the neoplasia involves the cervical intumescence or the brachial plexus, lameness, decreased reflexes, muscle atrophy and decreased muscle tone may be present in the ipsilateral thoracic limb.

A mass may be palpated in the ventral cervical area with neoplasia of the vagosympathetic trunk.

Lymph node enlargement may be found diffusely if a systemic neoplastic disease is present or locally in the submandibular nodes if middle ear disease is present.

Diagnosis

Palpation of the mass lesion in or around the location of the sympathetic nerves is helpful for diagnosis.

FeLV-positive status may suggest the presence of associated lymphoma.

Fine-needle aspiration of a mass may reveal neoplastic cells.

CBC may reveal circulating neoplastic cells or high WBC counts.

Bone marrow analysis may show the presence of lymphoma or leukemia.

Advanced imaging studies (CT or MR) provide the best views of the nervous system.

CSF analysis may rarely show neoplastic cells.

Increased density or bony changes of the bulla may be seen with **radiographs**, however, advanced imaging studies (CT or MR) provide the best views of the middle/inner ear.

Definitive diagnosis is made with surgical biopsy of a mass.

Differential diagnosis

If a mass lesion is found, other causes of proliferative tissue such as inflammation, infection, hemorrhage and fluid should be ruled out.

Treatment

Chemotherapies are used as definitive treatment of diffuse neoplastic diseases such as lymphoma and leukemia.

Focal masses may be amenable to **surgical resection**.

Radiation therapy may help some neoplastic lesions.

Prognosis

Long-term prognosis with neoplastic conditions such as adenocarcinoma and squamous cell carcinoma involving the ear is poor.

Remission may be achieved with lymphoma following appropriate treatment.

PARASYMPATHOMIMETIC DRUGS

Classical signs

- Local instillation of parasympathomimetic drugs into the eye can cause miosis.
- Systemically administered drugs such as bethanecol result in systemic parasympathomimetic signs, salivation, urination, defecation, vomiting, diarrhea or weakness.

Pathogenesis

Drugs or toxins can stimulate parasympathetic receptors of the iris locally or of the parasympathetic system centrally.

Clinical signs

If there is only **local instillation of parasympathomimetic drugs** into the eye (e.g. pilocarpine, demecarium), **miosis** is likely to be the only clinical sign.

If systemic drug administration occurs causing diffuse parasympathetic stimulation (e.g. bethanecol) **other clinical signs** could include salivation, urination, defecation, vomiting, diarrhea and weakness.

Diagnosis

A history of instillation or administration of these drugs in most helpful.

If the drug works by inhibiting acetylcholinesterase (e.g. organophosphate or carbamate), **cholinesterase activity measured in blood** may be helpful. Values less than 500 IU (normal 900–1200 IU) are considered consistent with toxicity.

Blood cholinesterase activity, however, may not be reflective of drug exposure in all instances, especially in chronic toxicity.

Differential diagnosis

Rule out other causes of miosis.

Treatment

If the drug was administered locally in the eye, stopping additional administrations and allowing time for the drug to be metabolized is most sensible, as this is rarely life threatening for the animal.

In some instances, **local administration of a parasympatholytic drug or sympathomimetic drug** may counterbalance the effects of the parasympathomimetic.

Prognosis

The prognosis is good if the drug was only administered locally in the eye as stopping additional administrations and allowing time for the drug to be metabolized will often bring about resolution of clinical signs.

Prevention

Avoid excessive or inappropriate use of these drugs.

DISEASES CAUSING MYDRIASIS

IRIS ATROPHY***

Classical signs

- Older cats, usually > 5 years of age.
- Pupils are inappropriately dilated.
- Often the margins of the iris are irregular or have tears within.
- The pupils constrict poorly with light stimulation.
- Dyscoria may also be present.

See main reference page 1299 “The Cat With Abnormal Iris Appearance”.

Pathogenesis

Iris atrophy is an age-related degeneration of the iris.

Clinical signs

Degeneration of the iris is a common cause of poor pupillary constriction in older animals.

Pupils are usually inappropriately dilated.

Often the margins of the iris are irregular or have tears within.

The **pupils constrict poorly** with light stimulation.

Dyscoria may also be present.

Diagnosis

Diagnosis is based upon the **characteristic clinical signs** consistent with iris degeneration in an aged cat.

Differential diagnosis

Rule out other causes of mydriasis.

Treatment

No treatment is necessary.

Prognosis

Iris atrophy is a non-life-threatening problem that does not result in morbidity.

HEAD TRAUMA**

Classical signs

- Mydriasis may occur secondary to caudal transtentorial brain herniation after brain trauma.
- Facial lacerations, bleeding from the nose and mouth, bruising, or hemorrhage in the external ear canals.

See main reference on page 823 (The Cat With Stupor or Coma).

Clinical signs

Signs usually begin acutely after trauma.

Intracranial signs most commonly seen include stupor and coma, paresis and gait abnormalities, and cranial nerve deficits.

With caudal transtentorial herniation, cranial nerve III is compressed and becomes dysfunctional.

This results in an **ipsilateral dilated pupil** which is poorly responsive to light stimulation.

Evidence of external trauma to the head and face such as facial lacerations, bleeding from the nose and mouth, bruising or hemorrhage in the external ear canals may be clues to the traumatic etiology.

Diagnosis

The diagnosis of trauma is usually straightforward when the trauma is witnessed.

In some instances, animals are presented with an acute onset of neurological signs and an unknown history, **examining for external signs of trauma** such as lacerations or skull fractures is important.

Evaluating the retinas and external ear canals for acute hemorrhage may also provide clues to the diagnosis.

Advanced imaging studies such as **CT or MR** imaging are useful, primarily for determining structural damage to the brain.

THIAMINE DEFICIENCY**

Classical signs

- Initially, lethargy, inappetence and ataxia.
- Later, weakness, ventral flexion of the neck, dilated pupils, stupor and coma.

See main reference on pages 848, 899 for details, “The Cat With a Head Tilt, Vestibular Ataxia or Nystagmus” and “The Cat With Neck Ventroflexion”.

Clinical signs

Occurs in **anorexic cats**, or cats that are fed **all-fish diets containing thiaminase**, or cats fed **meat containing the preservative sulfur dioxide**.

Thiamine deficiency **results in polioencephalomalacia** of the oculomotor and vestibular nuclei, the caudal colliculus and the lateral geniculate body.

Early, non-specific signs are typically **lethargy and inappetence**.

The earliest localizing sign is **bilateral vestibular ataxia**, which appears as an abnormal broad-based stance, loss of balance and vertigo.

There is **weakness and an inability or reluctance to walk**. The cat sits crouched with ventral flexion of the neck.

Pupils are dilated and non-responsive or poorly responsive to light reflexes.

If untreated, signs progress to semi-coma, persistent vocalization, **opisthotonos** and death.

Episodes of spastic opisthotonos or ventroflexion of the neck and muscle spasm may occur especially when the cat is lifted or stressed. They may be interpreted as seizures, but true seizure activity rarely occurs.

Diagnosis

No antemortem diagnostic test is available.

Diagnosis is based on clinical signs and rapid response to thiamine.

Differential diagnosis

Other encephalopathies and encephalitis are differentiated on history, CSF findings and lack of response to thiamine.

Head trauma may appear similar to late signs of thiamine deficiency, but can usually be differentiated on history and evidence of trauma. Thiamine-deficient cats are lethargic and inappetent days and weeks before signs are severe.

Hydrocephalus can present with central blindness and ataxia, but there is no response to thiamine.

Dysautonomia is a consideration in countries where it occurs. The bilateral non-responsive pupils and ventroflexion of the neck may appear similar to thiamine deficiency, but there is no response to thiamine.

Hypokalemic myopathy, myasthenia gravis, polymyositis and organophosphate toxicity can all cause ventral

flexion of the neck, but do not cause dilated pupils unresponsive to light.

DYSAUTONOMIA**

Classical signs

- Younger cats (< 3 years).
- Acute onset of depression and anorexia.
- Dilated pupils, xerostomia, keratoconjunctivitis sicca, prolapsed third eyelids.
- Bradycardia.
- Megacolon, constipation, loss of anal reflex.
- Incontinence, dysuria or distended bladder.
- Weakness.

See main reference on page 792, “The Constipated or Straining Cat”.

Clinical signs

Disease is confined to Europe or occurs in imported cats. The prevalence has decreased markedly and it is now uncommon.

Younger cats (< 3 years) are more often affected.

Clinical signs are often acute in onset over 48 hours with all cats showing depression and anorexia.

Other signs reflect autonomic system dysfunction and include ocular, gastrointestinal and urinary tract signs.

Ocular signs include fixed, dilated pupils without blindness, prolapsed third eyelids and dry eyes (keratoconjunctivitis sicca develops).

Gastrointestinal signs include regurgitation, megasophagus, constipation and megacolon, loss of the anal reflexes, dry mouth (xerostomia).

Bradycardia (90–120 beats/min).

Dysuria and/or distended bladder or incontinence.

Generalized weakness.

Diagnosis

Diagnosis is based primarily on clinical signs and evidence of autonomic dysfunction. The indirect-

acting parasympathomimetic, **physostigmine** (0.02 mg/kg IV) produces no ocular response, but direct-acting **pilocarpine (topically)** results in immediate miosis, demonstrating post-ganglionic denervation hypersensitivity. Normal cats do not demonstrate these responses.

Differential diagnosis

Differential diagnoses are many, depending on the predominant signs. Cats may present with a history of constipation or inability to urinate or dilated pupils, suggesting disease of the colon, lower urinary tract or eyes. Typical cases which exhibit most signs are classical for dysautonomia.

Treatment

No specific treatment is available, but supportive care is important, such as **syringe or tube feeding** and maintenance of fluid and electrolyte balance.

The urinary bladder should be emptied regularly to prevent distention and urinary tract infection.

Parasympathomimetic agents may improve some clinical signs.

- **Pilocarpine ophthalmic drops** (state frequency) may result in pupillary contraction and increase salivation.
- **Bethanechol** (1.25–5 mg PO q 8–12 h) may benefit constipation and urinary retention.
- **Metoclopramide** (0.2–0.5 mg/kg PO, SC, q 8 h) may improve gastric motility.

Up to a 70% mortality rate has been reported and surviving cats may have residual dysfunction such as urinary or fecal incontinence and pupillary abnormalities.

NEOPLASIA*

Classical signs

- \pm Mydriasis.
- Circling, seizures, behavior abnormalities, paresis or cranial nerve abnormalities.
- \pm Discharge from the ear.

Pathogenesis

Neoplastic disease may infiltrate or compress the cranial nerve III centrally or peripherally.

Diffuse neoplastic diseases such as **lymphoma and leukemias** may infiltrate the nerves.

Lymphoma can be associated with feline leukemia virus infection.

The most common intracranial neoplasia in cats is meningioma.

Peripheral involvement of cranial nerve III, most commonly occurs in the middle ear associated with squamous cell carcinoma or adenocarcinoma.

Clinical signs

Mydriasis may occur with involvement of the parasympathetic system within cranial nerve III.

Neoplasia of the intracranial nervous system can be associated with circling, seizures, behavior abnormalities, paresis or cranial nerve abnormalities.

Lymph node enlargement may be found diffusely if a systemic neoplastic disease is present or locally in the submandibular nodes if middle ear disease or other head neoplasms are present.

Diagnosis

FeLV-positive status may suggest the presence of associated lymphoma.

CBC rarely may reveal circulating neoplastic cells or high WBC counts.

Bone marrow analysis may show the presence of lymphoma or leukemia.

Advanced imaging studies (CT or MR) provide the best views of the nervous system.

CSF analysis rarely may show neoplastic cells. The most common change is a mild increase in CSF protein and normal or slightly increased cell counts.

Definitive diagnosis of neoplasia is made with surgical biopsy of a mass.

Differential diagnosis

If a mass lesion is found, other causes of proliferative tissue such as inflammation, infection, hemorrhage and fluid should be ruled out.

Treatment

Chemotherapies are used as definitive treatment of diffuse neoplastic diseases such as lymphoma and leukemia, see page 742 “The Cat With Signs of Chronic Small Bowel Diarrhea”.

Focal masses such as meningioma may be amenable to **surgical resection**.

Radiation therapy may help some neoplastic diseases.

Prognosis

Long-term prognosis for cats with meningiomas is good (~24 month median survival).

Remission may be achieved with lymphoma following appropriate treatment.

ENCEPHALITIS*

Classical signs

- **Mydriasis** can occur due to involvement of the oculomotor nerve.
- **Neurological signs** are often diffuse or multifocal, but may localize to a single area.
- **Cervical pain** can be present.
- **Fever** is an inconsistent finding.
- **Chorioretinitis** is often present.

See main reference on page 859 for details “The Cat With Tremor or Twitching”.

Clinical signs

Infectious agents causing brain disease include **viral** (feline infectious peritonitis), **fungal** (cryptococcosis, blastomycosis, histoplasmosis, coccidioidomycosis, aspergillosis), **protozoal** (toxoplasmosis), **bacterial**, **rickettsial**, and **unclassified organisms** (protothecosis). Signs depend on the area of the brain affected.

Mydriasis occurs secondary to **involvement of the oculomotor nerve** via direct inflammation of the nerve or damage due to nerve compression (i.e. from cerebral swelling).

Neurological signs are often **diffuse or multifocal** but may localize to a single area.

Cervical pain can be present.

Fever is an inconsistent finding.

Fundic examination is important to look for clues of systemic inflammatory diseases, as **chorioretinitis** is often present.

Diagnosis

Complete blood cell count may show evidence of systemic inflammation (e.g. leukocytosis).

Serum biochemical analysis may show evidence of systemic abnormalities if the disease diffusely affects the body (e.g. hyperglobulinemia).

Cerebrospinal fluid (CSF) analysis will usually show evidence of increased nucleated cells and/or elevated protein content. Occasionally, CSF will be normal.

- Evidence of inflammation on CSF evaluation alone, however, is not specific for primary encephalitis as other CNS disease (e.g. neoplasia) may result in CSF pleocytosis and protein increases.

Evaluation of titers for specific infectious diseases, is often necessary to make a diagnosis.

With feline infectious peritonitis (FIP), cerebrospinal fluid analysis may show a pleocytosis, with either mononuclear cells or neutrophils as the predominant cell type.

With toxoplasmosis, cerebrospinal fluid frequently contains a pleocytosis, usually with mononuclear cells, and occasionally, eosinophils. An increasing IgG titer or a single positive IgM serum antibody titer is suggestive of active infection. Animals with neurologic signs and positive IgM titers warrant treatment for the disease.

With cryptococcosis, identification of the organism from cytological evaluation of samples such as CSF, nasal discharge and skin lesions support the diagnosis. A neutrophilic pleocytosis and occasionally an eosinophilic pleocytosis may be found on CSF analysis. Detection of the cryptococcal capsular antigen is possible in serum, or CSF. Tissue biopsy and fungal culture, or culture of CSF may be more definitive in the diagnosis.

With parasites such as *Cuterebra* larvae, toxocara, and aberrant heartworm migration, CSF may show inflammation with eosinophils in some instances.

Imaging studies (CT and MR) are helpful for defining structural lesions. Multifocal, contrast-enhancing lesions are usually seen. Occasionally, non-contrast-enhancing lesions are present, especially with toxoplasmosis.

TOXINS*

Classical signs

- Cats with organophosphate intoxication may have acute signs including miosis, salivation, urination, defecation and muscle weakness.
- Envenomation from snakes may also cause dilated pupils. Weakness, ataxia and coagulopathy may occur.
- Sudden onset of unresponsive, bilaterally dilated pupils occasionally occurs with fluoroquinolone.

See main reference on page 949 “The Cat With Generalized Weakness” and page 861 “The Cat With Tremor or Twitching”.

Clinical signs

Cats with organophosphate intoxication may have acute signs including miosis, salivation, urination, defecation and muscle weakness or tremor.

- Occasionally the pupils have been reported to be bilaterally dilated and poorly responsive to light stimulation.

Snake envenomation may be associated with dilated pupils as well as ataxia, weakness or paralysis.

Sudden onset of bilaterally dilated pupils that are unresponsive to light occasionally occurs following **fluoroquinolone** use, especially when used at higher than recommended doses. Retinas appear normal on funduscopy. Prognosis for return of vision is guarded unless the toxicity is recognized early and the drug stopped.

Diagnosis

Serum cholinesterase activity may lend support to the diagnosis of organophosphate toxicity, but may be

non-diagnostic for chronic organophosphate toxicity. Values less than 500 IU/L (normal 900–1200 IU/L) are considered consistent with organophosphate toxicity.

Diagnosis of snake bite depends on the type of snake. Weak cats with mydriasis and evidence of rhabdomyolysis (markedly elevated creatine kinase) or coagulopathy (bleeding from venepuncture sites or increased activated clotting time) should be suspected if the snake bite is from an Elapid (cobra type) snake if in the right geographical location and season.

History of recent fluoroquinolone use, especially of doses higher than the recommended dose of 5 mg/kg q 24 h.

PARASYMPATHOLYTIC DRUGS

Classical signs

- Mydriasis with or without dry mouth, tachycardia, and ileus or constipation may be seen.

Pathogenesis

Some drugs or toxins prevent or reverse stimulation of the parasympathetic receptors. **Atropine** would be a commonly used example.

Clinical signs

If there is only local stimulation of the eye, mydriasis is likely to be the only clinical sign.

If systemic parasympathetic stimulation occurs, other clinical signs could include dry mouth, tachycardia, ileus or constipation.

Diagnosis

Determining a history of instillation or administration of these drugs is the only practical way of diagnosing this problem.

Differential diagnosis

Rule out other causes of mydriasis.

Treatment

If the drug was administered locally in the eye, stopping additional administrations and allowing time for the drug to be metabolized is most sensible as this is rarely life threatening for the animal. It may take **1–2 weeks for normal pupil responses** to return.

SPONGIFORM ENCEPHALOPATHY

Classical signs

- Dilated pupils in association with other clinical signs including muscle tremors, ataxia, jaw clamping, salivation and behavior abnormalities.

Pathogenesis

There is **vacuolation** within areas of the central nervous system.

No causative agent has been identified.

Speculation of an infectious agent (prion) as in other spongiform encephalopathies as a cause has been suggested.

Clinical signs

Dilated pupils.

Other signs include **muscle tremors, ataxia, jaw clamping, salivation and behavior abnormalities.**

Signs may progress to severe ataxia and hypermetria.

Diagnosis

Definitive diagnosis is made only at necropsy and histologic examination of the nervous system.

Differential diagnosis

Rule out other causes of mydriasis.

Treatment

No treatment has been used.

Prognosis

Affected cats have died or been euthanized.

41. The cat with neck ventroflexion

Daniëlle Gunn-Moore

KEY SIGNS

- Ventral flexion of neck and lowered head.
- ± Stiff stilted gait.
- ± Muscle weakness.
- ± Muscle pain.

MECHANISM?

- Neck ventroflexion is typically seen as part of generalized muscle weakness.

WHERE?

- The muscles, neuromuscular junction or nervous system.

WHAT?

- The most common cause of neck ventroflexion is **hypokalemic myopathy resulting from chronic renal failure**; less common causes include hyperthyroidism, hypokalemic myopathy of Burmese, myasthenia gravis, polymyositis and thiamine deficiency.

QUICK REFERENCE SUMMARY

Diseases causing neck ventroflexion

ANOMALY

- **Hypokalemic myopathy (of Burmese kittens)* (p 893)**

Burmese cats from 2–6 months of age. Generalized weakness, stiff stilted gait, muscle pain and, in severe cases, respiratory paralysis.

- **Devon Rex myopathy (p 900)**

Devon Rex cats from 8 weeks of age. Generalized weakness, marked neck ventroflexion and dorsal protrusion of scapulae. Exacerbated by exercise or stress.

- **Congenital myasthenia gravis (p 896)**

Seen in cats of less than a year old. Exercise-induced muscular weakness, progressive stiffness, and muscle tremors. Rarely, regurgitation or dyspnea.

METABOLIC

- **Chronic renal failure (hypokalemic myopathy)*** (p 893)**

Most commonly seen in older cats. Polyuria, polydipsia, weight loss, generalized weakness, stiff stilted gait, muscle pain and, in severe cases, respiratory paralysis.

- **Hypokalemic myopathy*** (p 893)**

Occurs in any age or breed of cat, but most commonly in older cats associated with chronic renal failure or hyperthyroidism. Also occurs in Burmese cats from 2–6 months of age. Generalized weakness, stiff stilted gait, muscle pain and, in severe cases, respiratory paralysis.

- **Hyperthyroidism (hypokalemic myopathy and/or thiamine deficiency)** (p 893, 899)**

Usually seen in older cats. Polyphagia, agitation, weight loss, generalized weakness, stiff stilted gait, muscle pain and, rarely, respiratory paralysis.

- **Iatrogenic** (p 893)**

Administration of inappropriate IV fluids or excessive furosemide. Generalized weakness and, rarely, respiratory paralysis.

- **Hypernatremic myopathy (p 903)**

Very rare cause of inappetence, muscle weakness, depression and myoglobinuria.

NEOPLASTIC

- **Hyperaldosteronism (hypokalemic myopathy) (p 893)**

Disease of older cats. Generalized weakness, stiff gait, muscle pain, polyuria, polydipsia and weight loss, and/or signs of systemic hypertension.

NUTRITIONAL

- **Thiamine deficiency* (p 899)**

Often with a history of fish-only diet. Anorexia and depression, followed by ataxia and vestibular signs. May progress to seizure-like episodes, stupor and death.

- **Inappropriate diet (hypokalemic myopathy) (p 893)**

Seen occasionally, due to inadequate potassium or over-acidification. Generalized weakness, stilted gait and muscle pain. May progress to renal failure.

INFECTIOUS

- **Toxoplasmosis polymyositis (p 897)**

Generalized weakness, muscle pain and reluctance to move. Often part of systemic illness. May have dysphagia, megaesophagus or pneumonia.

IMMUNE

- **Acquired myasthenia gravis* (p 896)**

Exercise-induced muscular weakness, progressive stiffness, muscle tremors, and occasionally, regurgitation and/or respiratory distress.

- **Immune-mediated polymyositis (p 897)**

Generalized weakness and pain. Occasionally with dysphagia or megaesophagus.

continued

continued

IDIOPATHIC

- Adult-onset motor neuron disease (p 903)

Chronic progressive generalized weakness with muscle tremors and fasciculations.

TOXIC

- Subacute organophosphate toxicity (p 901)

Generalized weakness, stiff stilted gait, muscle fasciculations or tremors. Muscarinic signs (miosis and salivation) may be absent.

INTRODUCTION

MECHANISM?

Neck ventroflexion is typically seen as part of more generalized muscle weakness. Since cats lack a nuchal ligament, muscle weakness in this species is often seen first as ventroflexion of the neck.

Affected cats often have a stilted gait and limb weakness, which may worsen on exercise.

They may also show muscle pain, dyspnea, dysphagia, or megaesophagus.

Cats with hypokalemic myopathy, polymyositis or adult-onset motor neuron disease may show evidence of muscle pain.

WHERE?

Neck ventroflexion can result from disease affecting the **muscles, the neuromuscular junction or the nervous system.**

Physical examination should look for evidence of cardiovascular disease or systemic illness. In many neuromuscular diseases generalized muscle weakness may be the only abnormality.

A complete blood count may rule out anemia or systemic infections. Serum biochemistry may indicate hypokalemia, hypernatremia, raised creatinine kinase level, renal insufficiency or hyperthyroidism.

Electromyographic studies, an intravenous edrophonium test (Tensilon test), assessment of serum anti-

acetylcholine receptor antibodies, determination of serum cholinesterase levels, serology for toxoplasmosis, FIV and FeLV, muscle and/or nerve biopsies, or a combination of these tests may be required to confirm a definitive diagnosis.

WHAT?

The **most common cause** of neck ventroflexion is **hypokalemic myopathy resulting from chronic renal failure.**

- Other causes of hypokalemic myopathy are seen less frequently. They include a hereditary defect in **Burmese kittens**, administration of inappropriate IV fluids or excessive furosemide, feeding **inappropriate diets** and, occasionally, **hyperthyroidism** or **hyperaldosteronism**.

Other causes of neck ventroflexion include primary myopathies (**immune-mediated** or **toxoplasmosis polymyositis, Devon Rex myopathy**), neuromuscular junction diseases (**myasthenia gravis, organophosphate toxicity, spider bite**), polyneuropathies (**adult-onset motor neuron disease**) and, very rarely, **hypernatremia**.

Although **thiamine deficiency** can cause neck ventroflexion, it usually causes an active rather than passive ventroflexion, together with excessive muscle tone, torticollis and seizure-like episodes of paddling or limb spasticity and opisthotonos.

This chapter deals with disorders that are likely to present with neck ventroflexion. While **this is mostly seen as part of generalized muscle weakness, not all cases of generalized muscle weakness present with neck ventroflexion.** Disorders that pri-

marily cause generalized weakness, of which neck ventroflexion may merely be a factor, include polyneuropathies (long-standing diabetes mellitus, idiopathic polyradiculoneuropathy), ethylene glycol toxicosis (or primary hyperoxaluria), various electrolyte abnormalities (hypophosphatemia), and severe anemia. For discussion of these conditions please refer to the chapter on The Cat With Generalized Weakness.

DISEASES CAUSING NECK VENTROFLEXION

HYPOKALEMIC MYOPATHY*** (INCLUDING HYPOKALEMIC MYOPATHY OF BURMESE KITTENS)

Classical signs

- General muscle weakness, neck ventroflexion, a stiff, stilted gait and muscle pain.
- In severe cases, respiratory paralysis.
- Other signs relate to the underlying disease, e.g. polyuria and polydipsia in chronic renal failure.
- May be seen with no other signs in Burmese kittens.

Pathogenesis

Hypokalemia may result from:

- **Decreased potassium intake** (incorrect diets).
- **Excessive losses** (chronic renal failure, renal tubular acidosis, **inappropriate IV fluid administration, excessive frusemide administration**, hyperaldosteronism, vomiting and diarrhea).
- **Increased potassium entry to cells** (Burmese kittens, hyperthyroidism, insulin over-dose).
- Varying combinations of all three.

Hypokalemia induces muscle weakness by causing a state of persistent depolarization and loss of excitability.

- Severe hypokalemia can result in rhabdomyolysis, however, the mechanism of action is unclear.

Hypokalemic myopathy is **most commonly associated with chronic renal failure*****.

- This results from excessive urinary losses, and can be exacerbated by feeding a diet with insufficient potassium (see below).

Diets that contain insufficient potassium, particularly when high in protein, or that are acidified, have the potential to induce hypokalemia, particularly when fed to a cat with existing renal failure.

- Long-term feeding of these diets can result in renal damage.

The **administration of IV fluids with insufficient amounts of potassium**** can result in clinically significant hypokalemia. This is most likely to occur in cats that have renal failure, have post-obstructive diuresis, have not eaten recently, or have been experiencing vomiting and/or diarrhea. The administration of excessive amounts of furosemide, particularly to animals that have not eaten recently, can have a similar effect.

Congenital hypokalemic myopathy may be seen in **Burmese kittens***.

- It is similar to periodic hypokalemic paralysis in man.
- It is believed to result from a sudden shift of potassium from the extracellular to the intracellular compartment.

Hyperthyroidism** may occasionally present with hypokalemia and/or thiamine deficiency and therefore result in generalized muscle weakness.

- It has been suggested that the hyperadrenergic state of hyperthyroidism enhances insulin release, which may lead to a shift in potassium into the intracellular compartment.
- Hypokalemia most typically occurs immediately after thyroidectomy, or may be associated with the stress of handling.
- Hypokalemia and hypocalcemia may occur concurrently.
- Correction of the hypokalemia may precipitate clinical signs of hypocalcemia.
- Hyperthyroidism may also cause weakness by affecting other mechanisms of muscle or nerve function.

Hyperaldosteronism (Conn's syndrome) is being reported more frequently.

- It is caused by a functional adrenal tumor, or adenomatous hyperplasia of the adrenal glands.

- The production of aldosterone results in excessive urinary potassium losses.

Clinical signs

Hypokalemia can affect **any age, sex or breed of cat**.

- It is seen most frequently in **older cats; associated with chronic renal failure**, hyperthyroidism and, occasionally, hyperaldosteronism.
- Hypokalemia in **Burmese kittens** is usually seen in kittens, of either sex, **from 2–6 months of age**.

Clinical signs of hypokalemia often take one of **two forms**; mild and chronic, or severe and acute.

- The **mild and chronic** form produces vague signs of inappetence, gradual weight loss and reduced activity (reluctance to walk or jump). In older cats these signs are often attributed to aging.
- The **severe form presents acutely** with **general muscle weakness**, often with neck ventroflexion, a stiff, stilted gait, reluctance to walk, and **muscle pain**.
- Signs of mild hypokalemia have often been present for weeks to months before the acute crisis.
- Some cats are anorexic or dysphagic.
- Some cats develop ataxia or collapse.
- Severely affected cats may die of respiratory paralysis.
- Clinical signs may be transient, episodic or persistent.
- Postural reactions and spinal reflexes are normal.

Cats with underlying **chronic renal failure** may also show:

- Polyuria, polydipsia, progressive weight loss and an ill-kept coat.

Cats with underlying **hyperthyroidism** may also show:

- Polyphagia, hyperactivity, irritability and weight loss.
- Some cats may be episodically or consistently “apathetic”.
- This may result from concurrent cardiac disease or hypokalemia.

Cats with underlying **hyperaldosteronism** may also show:

- Insidious weight loss, and signs of systemic hypertension.

Burmese cats with hypokalemic myopathy may also show:

- Clinical signs induced by exercise or stress.

- Head tremors, peculiar knuckling of the carpus, a tendency to sink on their hocks, and to sit with their stifles abducted.

Diagnosis

Signs of myopathy usually occurs when the serum potassium level falls **below 3.5 mmol (Eq)/L** (normal 4–5 mmol(Eq)/L).

Serum creatinine kinase (CK) levels are usually elevated (500–10 000 IU/L; normal 50–150 IU/L). In hypokalemic Burmese kittens CK can be very elevated (> 50 000 IU/L).

Once hypokalemic myopathy has been diagnosed it is necessary to differentiate between the various causes.

- Assessment of serum urea and creatinine levels, and urine specific gravity, will determine whether there is underlying renal disease.
- Serum thyroxine levels will be elevated in cases of hyperthyroidism.
- Cats with **hyperaldosteronism** become dehydrated, and eventually develop raised urea and creatinine levels.
 - This should not be misinterpreted as renal failure.
 - The adrenal tumor can usually be visualized by ultrasonography.
 - Plasma aldosterone levels will be moderately to markedly raised. In the case of hyperplastic change, the plasma aldosterone level may only be at the top end of the reference range, but the plasma renin activity will be mildly to moderately reduced.
- Calculating the **fractional excretion of potassium (FEK⁺)** can make an assessment of urinary potassium loss.
 - Collect urine and serum at the same time.

$$FE_{K^+} \% = \frac{\text{Urine potassium}}{\text{Serum potassium}} \times \frac{\text{Serum creatinine}}{\text{Urine creatinine}} \times 100$$

- The potassium and creatinine units must be the same.
- FE_{K⁺} should be < 5% in potassium-depleted cats with normal renal function (e.g. Burmese).
- **FE_{K⁺} > 10–15% indicates significant renal loss.**

- Losses can be determined more accurately measuring 24-hour urinary potassium loss.

Electrodiagnostic testing may be normal, or may show positive sharp waves and fibrillation potentials. Nerve conduction velocities are normal.

Muscle biopsies may reveal normal muscle, or mild myofiber necrosis, with little or no evidence of inflammation.

Differential diagnosis

Myasthenia gravis, polymyositis and organophosphate toxicity can all cause similar clinical signs.

Since hypokalemia is so readily detected by assessment of serum biochemistry, more sophisticated diagnostics are not usually required.

- If it becomes necessary to rule out specific differentials, electromyographic studies, IV edrophonium (Tensilon test), assessment of serum anti-acetylcholine receptor antibodies and serum cholinesterase levels, toxoplasmosis serology and/or muscle biopsy may be required.

Treatment

Severely affected cases may require immediate **IV potassium infusion**.

- This requires the use of an infusion pump, constant cardiac monitoring, and repeated evaluation of serum potassium levels (every 2–4 hours until the serum level has risen to 3.5 mmol (Eq)/L).
- In severe cases, despite potassium supplementation, IV fluid administration may result in hemodilution, diuresis with exacerbation of urinary potassium loss, progressive hypokalemia, and worsening clinical signs resulting in respiratory muscle paralysis and respiratory arrest.
 - **Inappropriate fluid administration is the most common cause of death in hypokalemic cats.**
 - It is therefore essential to monitor these patients closely.
 - Respiratory muscle paralysis typically occurs when serum potassium levels fall below 2 mmol/L.
 - Ventilatory support is required to save the cat and may need to be continued for 24–48 hours.

- **Where possible, give oral potassium prior to IV fluids.**
- **Oral administration of potassium is more effective in normalizing potassium than IV administration.**
- Only use fluids to administer potassium in the most severely affected cats.
- When using fluids give a low volume with a high potassium concentration e.g. 160 mmol (Eq)/L at 2.0 ml/kg/h. Ideally, do not exceed 0.5 mmol (Eq)/kg/h or cardiac arrest may occur.

Oral supplementation is necessary in all cases.

- It should be started immediately, as IV administration is often not adequate to normalize potassium.
- Potassium gluconate solution (Kaon Elixir), tablets or powder (Tumil K) can be added to food (4–10 mmol (Eq)/PO q 24 h, in divided doses).
- Feeding a diet that is high in potassium can also help.
- **The level of supplementation should be adjusted** according to serum potassium levels.
- The duration of supplementation will depend on the underlying cause.
 - Cats that had been fed an unsuitable diet, given inappropriate IV fluids or excessive amounts of frusemide will cease to require additional potassium once the precipitating cause has been corrected.
 - Cats with chronic renal failure will require long-term supplementation. Maintenance doses are typically 2–5 mmol (Eq)/cat q 12–24 h.
 - Some Burmese cease to need supplementation after they are about a year old, others need life-long supplementation, with an increasing need during periods of stress.

Where possible, **treat the underlying disease** or correct the dietary or fluid imbalance.

Cats with hyperaldosteronism may benefit from spironolactone (an aldosterone antagonist; up to 50 mg/kg PO q 24 h), in addition to potassium supplementation.

Prognosis

Severely affected cats, particularly those with respiratory distress, carry a guarded short-term prognosis.

The long-term prognosis is dependent on the nature of the underlying disorder.

- Complete recovery of muscle strength can take several weeks.
- In many cases, ongoing renal disease, hyperthyroidism or hyperaldosteronism will ultimately result in the cat's death.

Hypokalemic Burmese generally have a good prognosis, although some need life-long supplementation.

Prevention

Feed diets with sufficient potassium.

Measure serum potassium in 'at-risk' cats and supplement when levels are found to be low. 'At-risk' cats include:

- Cats with chronic renal failure.
- Hospitalized anorexic cats.
- Those receiving intravenous fluid therapy, high doses of frusemide or insulin therapy.
- Those with severe vomiting and diarrhea.

In Burmese cats, **pedigree analysis and a selective breeding program** may help to remove the condition.

MYASTHENIA GRAVIS (CONGENITAL AND ACQUIRED)*

Classical signs

- Exercise-induced muscular weakness, progressive stiffness, neck ventroflexion and muscle tremors.
- Facial weakness, narrowing of the palpebral fissure and protrusion of the third eyelids.
- Occasionally, regurgitation and/or respiratory distress.

Pathogenesis

Two forms of myasthenia gravis have been reported in cats, a **congenital** and an **acquired*** form.

The congenital form may be caused by a lack of acetylcholine receptors.

The acquired form occurs when auto-antibodies are directed against acetylcholine receptors.

Clinical signs

Compared to dogs, **myasthenia gravis is relatively rare in cats.**

- The **congenital form is seen in young cats**, usually kittens of less than 6 months of age.
- The **acquired form occurs in adults**, and Abyssinian and Somali cats may be predisposed.

The clinical signs are the same in both forms of the disease.

Affected cats tend to **sleep excessively** and are **reluctant to exercise.**

- When they do exercise they develop muscular weakness, which may be seen as progressive stiffness, a crouching gait, neck ventroflexion and superimposed muscle tremors.
- They eventually collapse in sternal recumbency, often with their head to one side of their front paws.
- Weakness may involve all four limbs simultaneously, or affect the fore- or hindlimbs more severely.

Weakness of the facial muscles may result in paresis of eyelids causing narrowing of the palpebral fissure, absence of a palpebral reflex, protrusion of the third eyelids, inability to close the mouth and apparent hypersalivation.

Dysphonia may be noticed, with a low or barely audible miaow.

Megaesophagus may occur occasionally, and lead to aspiration pneumonia.

Severe weakness of the respiratory muscles can also lead to respiratory distress.

Some cases of acquired myasthenia gravis have been associated with thymic abnormalities (thymoma, cystic thymus, thymic hyperplasia), and/or immune-mediated polymyositis (see below).

- Cats with thymoma may show signs of regurgitation, and/or dyspnea.
- The latter may result from the mass within the chest, or pleural effusion.

Diagnosis

Cats with myasthenia gravis are usually of good body condition, with normal complete blood counts and

serum biochemistry. Some may show slightly elevated creatinine kinase levels.

Thoracic radiography may occasionally show megaesophagus, thymic enlargement and/or aspiration pneumonia.

Tensilon test: Affected cats will usually show a brief positive response to the ultra-short-acting cholinesterase inhibitor edrophonium chloride (Tensilon: 0.2–0.5 mg/kg IV).

- Response is usually brief and may only be slight, e.g. widening of the palpebral fissure.
- Unfortunately, this test is not specific for myasthenia gravis.
- When using lower doses it is rare to produce a cholinergic crisis (bradycardia, hypersalivation, dyspnea and cyanosis). If this does occur it can be treated with atropine (0.05 mg/kg IV).

Electrodiagnostic testing will show a decremental response to **repetitive nerve stimulation**.

In the acquired form, **anti-acetylcholine receptor antibodies** can be detected in the serum and anti-receptor antibodies can be seen in muscle biopsies at the neuromuscular junction.

Differential diagnosis

Hypokalemic myopathy, polymyositis and organophosphate toxicity can all cause similar clinical signs.

The lack of changes in serum biochemistry, adequate serum cholinesterase levels, and the specific electromyographic findings will help to rule out these differentials. While cats with either myasthenia gravis or organophosphate toxicity may show a decremental response to repetitive nerve stimulation, the clinical signs will worsen if a cat with organophosphate toxicity is given IV edrophonium.

Definitive diagnosis of myasthenia gravis requires positive electromyographic studies and response to edrophonium and, in the acquired form, the presence of serum anti-acetylcholine receptor antibodies.

Treatment

Treatment usually consists of **pyridostigmine bromide** (Mestinon: 0.5–3.0 mg/kg PO q 8–12 h). The dose

needs to be adjusted for each individual cat, starting from a low dose.

Neostigmine (Prostigmine; 0.01–0.1 mg/kg IV, IM, SC) can be used to treat a myasthenic crisis. For longer-term use it can be given orally (0.1–0.25 mg/kg), but its short half-life requires it to be given q 4–6 h.

Some acquired cases require the addition of **prednisolone** (1–2 mg/kg PO q 12 h). The dose of corticosteroid can usually be reduced after a few days to weeks, and discontinued after a few weeks of alternate day dosing.

Some cats may go into remission. It can therefore be useful to monitor the serum anti-acetylcholine receptor antibody titer. Once it has fallen back to zero medication may be discontinued.

Where a thymoma is present, its removal may be beneficial.

Prognosis

Prognosis is very variable. Severe cases may die from aspiration pneumonia.

Some congenital and acquired cases will maintain improvement after withdrawal of medication.

It is not uncommon for acquired cases to go into remission, and recurrences may occur.

POLYMYOSITIS (IMMUNE-MEDIATED AND TOXOPLASMOSIS)

Classical signs

- Generalized muscle weakness, neck ventroflexion and/or dysphagia.
- Megaesophagus, regurgitation and/or aspiration pneumonia.
- Muscle pain, depression and reluctance to move.
- Often part of systemic illness.

Pathogenesis

Polymyositis may be **idiopathic, immune-mediated**, or result from *Toxoplasma gondii* or **retroviral infection**.

Polymyositis may affect both skeletal and smooth muscle, resulting in generalized weakness and megaesophagus.

Immune-mediated polymyositis may be associated with thymoma. When this occurs myasthenia gravis may be seen concurrently (see above).

In cats, most *T. gondii* infections are asymptomatic. When clinical signs are seen they most frequently relate to the lungs, liver, gastrointestinal tract, eyes or brain. Signs relating to muscle involvement are rare.

- Toxoplasmosis polymyositis is seen most frequently as part of more generalized disease.
- It occurs most commonly in peri-natally infected kittens or immunosuppressed adults.

While *Neospora caninum* has been shown to cause polymyositis experimentally, natural feline neosporosis has not been detected.

FIV infection may be able to cause an inflammatory polymyositis.

Clinical signs

Polymyositis may cause **generalized muscle weakness**, including **neck ventroflexion** and/or **dysphagia**.

Muscle pain may be present, the cats are often depressed and reluctant to move.

Signs of megaesophagus may include regurgitation and/or aspiration pneumonia.

Cats with concurrent thymoma may show regurgitation and/or dyspnea. The latter may result from the mass within the chest or pleural effusion.

Toxoplasmosis polymyositis is typically seen as part of more generalized disease. Affected cats are usually systemically ill, often with signs of pneumonia.

Diagnosis

Thoracic compression may be reduced when a thymoma is present. The presence of a thymoma can usually be confirmed by assessment of pleural fluid, a fine needle aspirate of the mass, or a Tru-cut needle biopsy.

Thoracic radiography may reveal megaesophagus, pneumonia or thymoma (and possibly pleural fluid).

In all except very chronic cases, serum creatinine kinase levels (and other muscle-associated enzymes) are elevated. In most cases the levels are moderate to markedly increased.

Serum antinuclear antibody tests may be positive in immune-mediated polymyositis.

Serum toxoplasmosis IgM (and sometimes IgG) levels are likely to be elevated in cases of toxoplasmosis polymyositis. Where only IgG levels can be assessed, paired serum samples usually show a fourfold increase in titer over a 2–4-week period.

All cases of polymyositis should be assessed for FIV and FeLV infection.

Electromyographic abnormalities may include spontaneous positive waves and fibrillation potentials.

Muscle biopsies may show multifocal infiltration of muscle fascicles with lymphocytes, macrophages and, occasionally, neutrophils. In the cases of toxoplasmosis polymyositis the organisms may be detected. However, failure to detect *T. gondii* cysts does not rule out this etiology.

Differential diagnosis

While **myasthenia gravis** and **organophosphate toxicity** can cause similar clinical signs, **the most important differential is hypokalemic myopathy**.

- Polymyositis and hypokalemic myopathy can be clinically identical, and both can have moderate to markedly elevated serum creatinine kinase levels.
- The lack of other changes in serum biochemistry, adequate serum cholinesterase levels, lack of serum anti-acetylcholine receptor antibodies, and electromyographic studies, will help to rule out these differentials.

Definitive diagnosis of polymyositis requires muscle biopsy and serological testing.

Treatment

Immune-mediated myositis may respond to **prednisolone** (1.5–2 mg/kg PO q 12 h).

- The dose of steroids can usually be reduced after a few weeks as the clinical signs resolve.
- Some cases need long-term, alternate-day, medication.
- Assessment of serum creatinine kinase levels may be helpful in monitoring these cases.

If a thymoma is present it should be surgically removed.

First-line **treatment for toxoplasmosis** (or neosporosis) consists of clindamycin (12–25 mg/kg q 12 h, PO or IM). If necessary, this can be given for a number of weeks.

- Alternatively, trimethoprim/sulfadiazine (30 mg/kg PO q 12 h) may be given either alone or in combination with pyrimethamine (0.5 mg/kg PO q 24 h).
 - Unfortunately, both of these drugs are unpalatable.
 - Since cats are particularly susceptible to the toxic effects of pyrimethamine it should be given for a maximum of 2 weeks.
 - Supplementation with folate (folic acid) is recommended (1 mg/kg PO q 24 h).
- Other, more modern, drugs may also be useful. These include azithromycin (7–15 mg/kg q 24 h, PO) or clarithromycin (7.5 mg/kg q 12 h PO, combined with pyrimethamine). Prolonged treatment may be necessary.

Prognosis

Prognosis for immune-mediated myositis is fair.

Despite aggressive therapy, prognosis for toxoplasmosis myositis is generally poor.

Prevention

It is not possible to prevent immune-mediated myositis. Cats may be prevented from becoming infected with toxoplasmosis by keeping them indoors, preventing them from hunting, and by feeding well-cooked food.

THIAMINE DEFICIENCY*

Classical signs

- Anorexia and depression, followed by ataxia, neck ventroflexion, torticollis and vestibular signs.
- May progress to seizure-like muscle spasms, stupor and death.
- History of fish-only diet.

Pathogenesis

Thiamine (vitamin B₁) is essential for normal carbohydrate metabolism and gluconeogenesis.

Since the central nervous system depends almost entirely on carbohydrate metabolism for its energy, it is particularly susceptible to the effects of thiamine deficiency.

Thiamine deficiency results in a progressive polioencephalomalacia (hemorrhage and necrosis). It predominantly affects the subcortical gray matter of the brain stem nuclei, particularly the vestibular, lateral geniculate and oculomotor (pupillary constriction) nuclei.

Thiamine deficiency can effect **any age, breed or sex of cat**.

It occurs most frequently in cats that are **fed a diet of mainly fish** (usually uncooked) that contain thiaminase (e.g. cod, catfish).

It may also result from prolonged anorexia or malabsorption, or the destruction of thiamine during food preparation (over-cooking) or prolonged storage. The meat preserver, sulfur dioxide, destroys thiamine and may produce thiamine deficiency in cats fed pet mince preserved with this compound. This can occur even when the mince is mixed with other food or supplemented with vitamins or brewer's yeast.

Clinical signs

Early signs include anorexia, intermittent vomiting, depression, ataxia and pupillary dilation.

Progression may result in **central vestibular signs** (including curling up when lifted, and/or a head tilt), neck ventroflexion, torticollis, behavioural changes, mydriasis, seizure-like muscle spasms or stupor.

True seizures are rare but episodes of opisthotonic posturing with paddling, spastic neck ventroflexion, and body contortions may occur, especially if the cat is lifted. These can have a seizure-like appearance.

Further progression may lead to coma and death.

Diagnosis

Measurement of blood thiamine level is not readily available.

Diagnosis is supported by improvement within 24 hours of thiamine supplementation.

Differential diagnosis

Hypokalemic myopathy, myasthenia gravis, polymyositis and organophosphate toxicity can all cause neck ventroflexion.

However, thiamine deficiency usually causes an active rather than passive ventroflexion, together with excessive muscle tone, torticollis, and more obvious central signs, such as a head tilt, behavioral changes, or seizure-like paddling or spasticity with opisthotonos.

Other differentials can usually be excluded by performing a thorough physical and neurological examination, assessing serum biochemistry (including renal enzymes, creatinine kinase and electrolytes), and a resting thyroxine level. Occasionally it may be necessary to assess serum cholinesterase levels or look for serum anti-acetylcholine receptor antibodies.

Treatment

10–20 mg/cat of thiamine IM, q 8–12 h. For longer-term supplementation; 5–30 mg/cat PO q 24 h.

If clinical signs are severe, oxygen may be beneficial.

The underlying cause should be corrected, e.g. feed a suitable diet. Oral thiamine supplementation is usually needed for a week after the diet has been corrected.

Prognosis

The prognosis is good if the condition is recognized and treated early.

Once a cat has become semiconscious, prognosis is poor.

Some chronic cases respond to treatment, but may be left with neurological deficits.

Prevention

Feed suitable diets and supplement anorexic cats with B vitamins.

DEVON REX MYOPATHY

Classical signs

- Young Devon Rex cats.
- Generalized muscle weakness, with marked ventroflexion of the head and neck, and dorsal protrusion of the scapulae.
- Signs may become accentuated during locomotion, micturition, defecation, stress or excitement.

Pathogenesis

The disease is inherited in an **autosomal recessive** manner.

The pathology is suggestive of a **muscular dystrophy**.

Skeletal and smooth muscles are affected (neck ventroflexion, megaesophagus).

Clinical signs

The disease is sometimes termed “spasticity” by breeders. However, there are no signs of central nervous system involvement.

Disease is seen in Devon Rex cats of either sex, with signs becoming **apparent from 3 weeks to 6 months of age**.

The severity of the disease varies between cats, and may be static or slowly progressive.

Affected cats show **generalized muscle weakness**, often with very **marked ventroflexion** of the head and neck, and **dorsal protrusion of the scapulae**.

- They typically have a high-stepping forelimb gait, and tire easily, with head bobbing, progressive protrusion of the scapulae, shortening of the stride, and superimposed muscle tremors.
- They eventually collapse in sternal recumbency, usually with their head to one side of their forepaws.

Clinical signs may be exacerbated by micturition, defecation, stress, concurrent illness, cold ambient temperature or excitement.

At rest they often adopt a characteristic “dog-begging” position, with their forepaws resting on a convenient raised object.

Signs of **megaesophagus** may include regurgitation and/or aspiration pneumonia.

Difficulty in maintaining a normal head position may result in **frequent episodes of laryngospasm after obstruction of the pharynx with food**. This is the most usual cause of death in these cats.

Mild muscle atrophy may occasionally be evident.

Diagnosis

Complete blood count and serum biochemistry, including creatinine kinase and aspartate aminotransferase (AST), are usually normal.

Thoracic radiography will usually reveal a megaesophagus and/or aspiration pneumonia.

Neurological examination, muscle tone and withdrawal reflexes are normal.

Electrodiagnostic studies may show sparse fibrillation potentials, and positive sharp waves. Nerve conduction velocities are normal and there is no decremental response to repetitive nerve stimulation.

Gross post-mortem examination may reveal megaesophagus, reflux oesophagitis, aspiration pneumonia and/or gastroparesis.

Skeletal muscle appears grossly normal. Histopathological changes vary between cats, and also within different muscles of the same cat.

- Findings range from normal, to those indicative of myopathy, possibly muscular dystrophy. They include increased variability in myofiber size, individual myofiber necrosis, regeneration and fibrosis.
- The degree of change depends on the severity of disease, and the advancing age of the cat.
- The dorsal cervical and proximal forelimb muscles, especially the *m. triceps brachii*, are usually most severely affected, and are therefore recommended for biopsy.

Nerves are not affected.

Differential diagnosis

Hypokalemic myopathy, myasthenia gravis, polymyositis and organophosphate toxicity can all cause similar clinical signs. The most important differentials are probably hypokalemia and congenital myasthenia gravis.

Devon Rex myopathy is the most likely diagnosis in a young Devon Rex cat which is showing typical clinical signs, its serum biochemistry is normal, it lacks a decremental response to repetitive nerve stimulation, has adequate serum cholinesterase levels, and its clinical signs worsen when it is given IV edrophonium (Tensilon test). Confirmation of the diagnosis requires pedigree analysis and muscle biopsy.

Treatment

There is no treatment for this condition. Aspiration pneumonia will require antibiotics.

Prognosis

Clinical signs may deteriorate up to 6–9 months of age, after which time the disease is usually stable or only slowly progressive.

The course of the disease will depend on the severity of the myopathy, particularly the degree of pharyngeal involvement. Laryngospasm is the usual cause of death.

Prevention

Since the disease is inherited, **pedigree analysis and a selective breeding program** are being used to remove the condition from the breed.

SUBACUTE ORGANOPHOSPHATE TOXICITY

Classical signs

- Muscarinic signs (miosis and salivation) may be absent.
- Generalized muscle weakness may be seen as neck ventroflexion, and/or a stiff stilted gait.

continued

Classical signs—Cont'd

- Muscle fasciculations or tremors may be present.

Pathogenesis

Organophosphate toxicity can affect **any age, breed or sex of cat**.

Organophosphate compounds irreversibly bind to acetylcholinesterases at cholinergic synapses, resulting in continuous stimulation.

In cats, **chronic exposure can result in peripheral neuropathies**.

Unlike other organophosphates **fenthion** toxicity produces predominantly nicotinic signs (muscle weakness), with few muscarinic signs (autonomic effects).

Clinical signs

The variety of clinical signs will depend on the degree of concurrent muscarinic involvement. In subacute or chronic cases these signs (miosis, salivation, vomiting, bradycardia) may be absent.

In chronic cases, or in fenthion toxicity, the only sign may be generalized muscle weakness, often seen as neck ventroflexion and/or a stiff stilted gait. Severe muscle weakness may cause respiratory paralysis.

Muscle fasciculations or tremors may be present.

There is no muscle pain.

Diagnosis

There is usually a history of exposure to an organophosphate, typically in the form of insecticide.

Complete blood count and serum biochemistry (including creatinine kinase) are usually normal.

A low **serum cholinesterase level** will support this diagnosis. In affected cats the levels are usually less than 500 IU (normal 900–1200 IU). However, in cases where chronic exposure has caused polyneuropathy the serum cholinesterase levels may be normal.

Electrodiagnostic testing will show a decremental response to repetitive nerve stimulation.

Tensilon test: IV edrophonium (Tensilon: 0.2–0.5 mg/kg) will usually induce a cholinergic crisis (bradycardia, hypersalivation, dyspnea and cyanosis), without a positive improvement in muscle strength. If this occurs it can be treated with IV atropine (0.05 mg/kg).

Differential diagnosis

Hypokalemic myopathy, myasthenia gravis and polymyositis can all cause similar clinical signs.

Lack of changes in serum biochemistry, lack of serum anti-acetylcholine receptor antibodies, and a negative response to IV edrophonium in the face of a decremental response to repetitive nerve stimulation, will help to rule out the differential diagnoses.

Diagnosis is usually confirmed on finding reduced serum cholinesterase levels, typically with a history of exposure to organophosphate.

Treatment

Supportive therapy may include use of IV fluids, nutritional support, control of body temperature and good nursing care.

Atropine (0.1–0.2 mg/kg SC, as required) may be used to chemically compete with acetylcholine binding to acetylcholine receptors.

Oximes (pralidoxime chloride; 20 mg/kg IM q 8 h) may help by releasing the inhibited cholinesterase. However, oximes are of most benefit if given within the first 24 hours of exposure.

Diphenhydramine has been used to reverse nicotinic signs in dogs with fenthion toxicity.

Prognosis

It is often not possible to save severely affected cats.

Less severely affected cats may recover, often following weeks of nursing.

Chronically affected cats may be left with permanent nerve damage.

Prevention

Prevent access to organophosphate compounds.

ADULT-ONSET MOTOR NEURON DISEASE

Classical signs

- Adult-onset, chronic, progressive disease.
- Generalized weakness, neck ventroflexion, and dysphagia.
- Muscle tremors/fasciculations (particularly of the head and tongue).
- Muscle atrophy.

Pathogenesis

The cause of this **rare disease** is unknown.

Clinical signs result from chronic degeneration and loss of motor neurons.

Clinical signs

Disease is seen in **adult cats**.

Chronically progressive signs include generalized weakness, neck ventroflexion, dysphagia and muscle atrophy.

Muscle tremors particularly affect the head.

Muscle fasciculations may be localized to the tongue.

Muscle palpation may cause pain.

Diagnosis

Complete blood count and serum biochemistry (including creatinine kinase) are usually normal.

Neurological examination reveals normal mentation, cranial nerve function and conscious proprioception.

Spinal reflexes are present initially, but are lost as disease progresses.

Electromyographic studies may reveal fibrillation potentials. Nerve conduction velocities may be normal or slightly reduced.

Muscle biopsies reveal evidence of denervation.

Histopathology of the spinal cord reveals neuron loss and gliosis in the ventral horns, and consequent atrophy of the ventral nerve rootlets.

Differential diagnosis

Hypokalemic myopathy, myasthenia gravis, polymyositis and organophosphate toxicity can all cause similar clinical signs.

Lack of changes in serum biochemistry, lack of serum anti-acetylcholine receptor antibodies, adequate serum cholinesterase levels, electromyographic studies, and slowly progressive disease all help to rule out the differential diagnoses.

Histopathology of the spinal cord is required to make a definite diagnosis.

Treatment

There is no known treatment.

Prognosis

Disease may take months to years to progress to the point where the cat requires euthanasia on humane grounds.

HYPERNATREMIC MYOPATHY

Classical signs

- Inappetence, progressive muscle weakness, and depression.
- Brown-stained urine (myoglobinuria).

Pathogenesis

This **very rare cause of myopathy** has only been documented in a single, 7-month-old, cat.

Hypernatremia resulted from “neurogenic” hypodipsia, related to hydrocephalus.

Severe hypernatremia may induce myopathy by accelerating sodium–potassium exchange in myocytes. This can cause an increase in intracellular sodium and a reduction in intracellular potassium. The clinical signs are therefore similar to those of hypokalemia.

Severe myocyte dysfunction can lead to membrane damage, myoglobinemia and myoglobinuria.

Clinical signs

The cat showed inappetence, depression and progressive muscle weakness, including neck ventroflexion.

Myoglobinuria caused the urine to be brown.

Clinical signs were transient. They resolved on correction of the hypernatremia.

Diagnosis

Serum biochemistry revealed marked hypernatremia (> 200 mmol (Eq)/L; normal 148–165 mmol (Eq)/L), and increased serum osmolality (431 mmol/kg (mOsm/L); normal 295–300 mmol/kg (mOsm/L)). The serum creatinine kinase level was moderately raised.

Electromyographic abnormalities included prolonged insertional activity, fibrillation potentials, positive sharp waves and bizarre high-frequency discharges. Nerve conduction velocities were normal.

Muscle biopsies were normal.

Contrast-enhanced computer tomography revealed marked hydrocephalus.

Endocrine studies revealed hypopituitarism, with hypoadrenocorticism, hypothyroidism and a lack of luteinizing hormone. The cat was small for its age, and never showed signs of estrus.

Differential diagnosis

Hypokalemic myopathy, polymyositis, myasthenia gravis and organophosphate toxicity can all cause similar signs.

The presence of severe hypernatremia should alert the clinician to the possibility of hypernatremic myopathy. Lack of hypokalemia and resolution of clinical signs on the correction of the fluid balance, would support the diagnosis.

Treatment

To increase the cat's water consumption it was fed a low-salt diet (PVD CV or NF, Nestlé Purina; Feline H/D, Hill's Pet Foods), to which water was added in excess of maintenance needs.

Correction of fluid balance resulted in resolution of clinical signs, and restoration of the hypothalamic-pituitary-adrenal axis.

Prognosis

While correcting the serum osmolality resulted in resolution of clinical signs in this case, this may not work in future cases, since response will depend on the nature of the underlying disorder.

PART 11

Cat with an abnormal gait

42. The weak and ataxic or paralyzed cat

Paul A Cuddon

KEY SIGNS

- Incoordination and decreased proprioception (misplacement or knuckling of the foot).
- Weakness of one or more limbs (feet cross or are placed too far apart).
- Complete loss of any voluntary movement (paralyzed).

MECHANISM?

- Ataxia and paresis occurs when there is **physical or functional disruption** to both the **motor and sensory pathways** of the nervous system.
- This can occur at any point along the neuraxis from the cerebrum to the peripheral nervous system.

WHERE?

- Cats solely presenting with ataxia and paresis/paralysis most commonly have **spinal cord disease**.

WHAT?

- The **most common causes** of spinal cord ataxia and paresis in cats are **infection/inflammation and trauma**.

QUICK REFERENCE SUMMARY

Diseases causing a weak and ataxic or paralyzed cat

ANOMALY

- **Congenital abnormalities of the vertebral body* (p 918)**

Tetraparesis or paraparesis and ataxia (UMN or LMN) usually in cats less than one year of age due to static or dynamic cord compression.

- **Congenital abnormalities of the spinal cord (spina bifida, etc.)* (p 918)**

LMN urinary/fecal incontinence, an easily expressible atonic bladder, megacolon and a hopping gait in young kittens at or soon after birth.

NEOPLASIA

- **Spinal lymphosarcoma*** (p 909)**

Chronic progressive ataxia, asymmetrical paraparesis and focal spinal pain in young adult cats often associated with FeLV infection.

- **Spinal meningioma** (p 914)**

Spinal pain and chronic progressive UMN or LMN tetraparesis or paraparesis in cats greater than 9 years of age.

NUTRITIONAL

- **Hypervitaminosis A* (p 921)**

Cervical pain and rigidity, thoracic limb lameness, and tetraparesis/tetraplegia in cats usually between 2–9 years of age.

INFLAMMATION (INFECTIOUS)

- **Feline infectious peritonitis*** (p 911)**

Chronic progressive tetraparesis or paraparesis in young cats less than 3 years of age, commonly accompanied by decreased mentation, seizures, intention tremor and/or central vestibular signs.

INFLAMMATION (IDIOPATHIC)

- **Feline polioencephalomyelitis* (p 917)**

A stiff, staggering gait with paraparesis and thoracolumbar spinal pain in cats of any age, often with decreased mentation and seizures.

ISCHEMIA

- **Aortic thromboembolism** (p 915)**

Acute femoral and sciatic nerve hyporeflexia, cold cyanotic pelvic limbs and painful firm gastrocnemius muscles in any aged cat.

- **Fibrocartilaginous embolism* (p 922)**

Acute, non-painful LMN paraparesis/paraplegia and urinary and fecal incontinence in any aged cat.

TRAUMA

- **Spinal cord trauma – fractures and luxations*** (p 912)**

An acute transverse myelopathy with varying degrees of UMN or LMN paresis to paralysis with spinal pain. Other signs include split nails and skin abrasions and bruising.

INTRODUCTION

MECHANISM?

Ataxia and paresis occur when there is **physical or functional disruption** to both the **motor and sensory pathways** of the nervous system.

Paresis is a deficit of voluntary movement, leading to weakness in one limb (monoparesis), both pelvic limbs (paraparesis), the limbs on one side of the body (hemiparesis), or all four limbs (tetraparesis). It is caused by disruption of the voluntary motor pathways anywhere from the cerebral cortex through the brainstem and spinal cord to the spinal cord segments and the peripheral nerves supplying muscles. Neurological testing to determine whether a cat is paretic includes gait analysis and postural reaction testing, which includes hopping, wheel-barrowing, hemi-standing/hemi-walking, and the extensor postural thrust. The term **paralysis** is reserved for the patient who has a complete loss of any voluntary movements.

Ataxia is a lack of coordination of the limbs or trunk produced by disruption of the sensory proprioceptive pathways of the spinal cord and brainstem. Lesions of the cerebellum and the vestibular system also can produce ataxia. Sensory ataxia, the disruption of sensory proprioceptive pathways, can be assessed via such tests as proprioception and tactile placing.

Most cats with **spinal cord disease** have a combination of **both ataxia and paresis**, since most myelopathies cause disruption of both the motor and sensory systems. In many circumstances, therefore, separation of ataxia and paresis becomes almost impossible on routine neurological examination.

WHERE?

Cats presenting solely with ataxia and paresis/paralysis most commonly have **spinal cord disease**.

Weakness and ataxia can also occur with cerebral and brainstem disease.

- However, cats with cerebral disease will usually show seizures, behavior change, aimless wandering, and pacing along with the ataxia and contralateral hemiparesis or tetraparesis.

- Cats with brainstem disease will demonstrate cranial nerve abnormalities as well as an ipsilateral hemiparesis or tetraparesis.

Most polyneuropathies manifest as generalized weakness **without** ataxia. In many cases of peripheral nerve disease, sensory tests such as proprioception and tactile placing will be normal despite obvious muscle weakness.

Localization of myelopathies is dependent on **determining whether the thoracic and pelvic limbs have upper (UMN) or lower motor neuron (LMN) signs**. Cats with UMN paresis will demonstrate normal to increased segmental spinal reflexes (myotatic or tendon reflexes, muscle tone and withdrawal reflexes) whereas cats with LMN paresis will show decreased to absent segmental spinal reflexes. An UMN bladder, likewise, will have increased tone and be difficult to express due to external (+/- internal) urethral sphincter hypertonia, whereas a LMN bladder will be flaccid (or atonic) and easily expressed due to external urethral sphincter hypo- to atonia.

The classic spinal cord divisions when localizing a myelopathy are as follows:

- **Cervical spinal cord (C1–C5)** – UMN tetraparesis to tetraplegia.
- **Cervical intumescence (C6–T2)** – LMN signs to thoracic limbs and UMN signs to pelvic limbs.
- **Thoracolumbar spinal cord (T3–L3)** – UMN paraparesis to paraplegia. UMN bladder dysfunction.
- **Lumbar spinal cord (L4–L6)** – mixed UMN and LMN paraparesis to paraplegia (LMN to the femoral nerve and UMN to the sciatic nerve). UMN bladder and perineal reflexes.
- **Lumbosacral spinal cord (L6–S2) or cauda equina injury** – LMN paraparesis to paraplegia associated with the sciatic nerve and LMN bladder.

WHAT?

The **most common causes** of spinal cord ataxia and paresis in cats are **infectious** (including feline infectious peritonitis virus (coronavirus)), **neoplasia** (lymphosarcoma) and **trauma**.

Primary spinal neoplasia (meningioma), inflammation (feline polioencephalomyelitis), and ischemia

(aortic thromboembolism and fibrocartilaginous embolism) are less common.

Intervertebral disc disease is very rare.

DISEASES CAUSING A WEAK AND ATAXIC OR PARALYZED CAT

SPINAL LYMPHOSARCOMA***

Classical signs

- Chronic progressive ataxia.
- Asymmetric paraparesis.
- Focal areas of spinal pain.

Pathogenesis

Lymphosarcoma is the **most common feline neoplasia**.

5–15% of cats with lymphoreticular malignancies develop neurologic involvement.

88% of cats with CNS involvement show thoracic and lumbar myelopathy, although the brain may also be affected.

Spinal lymphosarcoma is often **FeLV related**.

Epidural lymph channels and extramedullary hematopoietic tissue are possible sites for development of primary spinal lymphosarcoma.

Tumor growth commonly occurs longitudinally along the spinal canal (the epidural space is a low-resistance channel).

79% of cats with spinal lymphosarcoma have solitary epidural lesions.

Multifocal lesions are also possible, as is tumor involvement of multiple nerve roots.

Clinical signs

Spinal lymphosarcoma is most commonly seen in **young cats** (≤ 3 years).

Males are more commonly affected.

Most cats present with an initial insidious course of neurologic dysfunction followed by acute deterioration.

Tumors occur **predominantly between T3–L4**.

Involvement of the brachial intumescence and plexus also can occur.

Cervical spinal cord involvement is rare.

The most common clinical signs include **progressive ataxia, asymmetric paraparesis and focal spinal pain**.

If there is involvement of the **brachial or lumbosacral intumescences**, LMN signs will occur.

Nerve root involvement may result in lameness and limb pain.

Acute exacerbation of signs is commonly associated with hemorrhage.

Weight loss is the most common extraneural sign.

The **most common extraneural tumor site** associated with spinal lymphosarcoma is the **kidney**.

Diagnosis

Complete blood count, biochemistry parameters and urinalysis are often normal, although non-regenerative anemia or leukemia may occasionally be seen.

Many cats are **seropositive for FeLV** or positive on indirect fluorescent antibody testing of bone marrow.

Cerebrospinal fluid (CSF) analysis usually shows a mixed pleocytosis (mean of 161 cells/mm³ [161 cells/ μ l] with a range of 0–1625 cells/mm³ [0–1625 cells/ μ l]) and a protein increase (mean of 1.34 g/L [134 mg/dl] with a range of 0.12–4.05 g/L [12–405 mg/dl]).

A **monomorphic population of neoplastic lymphocytes** will be seen in some cases.

Survey spinal radiographs are usually normal.

MRI scan or myelography shows single or multiple **asymmetric extradural spinal cord compression(s)**.

Differential diagnosis

Infectious diseases, such as feline infectious peritonitis, toxoplasmosis and cryptosporidiosis also may produce signs of progressive spinal cord dysfunction.

However, unlike spinal lymphosarcoma, **most infectious conditions** usually result in **multifocal neurologic**

dysfunction, with involvement of the cerebrum, brain-stem and/or cerebellum.

- **Ocular manifestations** secondary to uveitis, chorioretinitis and optic neuritis are also often present with CNS infections.

CSF analysis often helps differentiate between infectious diseases and spinal lymphosarcoma.

- **Feline infectious peritonitis** usually produces a marked increase in protein (usually greater than 1 g/L [100 mg/dl] and often greater than 2 g/L [200 mg/dl]) and white blood cells (mean of 734 cells/mm³ [734 cells/μl] with a range of 69–2000 cells/mm³ [69–2000 cells/μl]), with a predominance of non-degenerate neutrophils (50–90%).
- CSF commonly reveals the organism in cats with **cryptococcosis**.
- ***Toxoplasma gondii*** usually produces a mild to moderate increase in protein (0.6–1 g/L [60–100 mg/dl]) and cell counts (30–100 cells/mm³ [30–100 cells/μl]), with the cell distribution being a mixed mononuclear and polymorphonuclear pleocytosis +/- eosinophils).

Serologic antibody or capsular antigen assays will also help differentiate the infectious diseases.

Feline polioencephalomyelitis can produce a primary thoracolumbar myelopathy.

- Since CSF in this disease also commonly shows a mild to moderate protein elevation (mean of 0.48 g/L [48 mg/dl] with a range of 0.1–0.7 g/L [10–70 mg/dl]) and a mild mononuclear pleocytosis (mean of 19 cells/mm³ [19 cells/μl] with a range of 0–46 cells/mm³ [0–46 cells/μl]), differentiation from lymphosarcoma may be difficult.
- Cats with polioencephalomyelitis, however, usually are FeLV negative.

Spinal neoplasia (especially meningioma) can mimic focal spinal lymphosarcoma.

- CSF analysis with **meningioma** usually only demonstrates a **protein increase**.
- Cats with **neoplasia** are usually **much older** (> 9 years of age) than cats with lymphosarcoma (≤ 3 years).

Treatment

Spinal lymphosarcoma is **radiosensitive**.

- Rapid reduction in tumor volume can occur within hours of delivering a **single large palliative dose of radiation** (3–4 Gy).

Chemotherapy is **important for systemic control** of lymphosarcoma although most chemotherapeutic agents do not cross the blood–brain barrier.

Cytosine arabinoside may also help control spinal lymphosarcoma.

- This anti-metabolite drug crosses the blood–brain barrier and reaches appropriate CSF levels.
- The recommended dosage is 100 mg/m²/day as a constant rate infusion intravenously for 4 days.
- An alternative regimen is 300 mg/m² subcutaneously twice daily for 2 days.
- Potential toxicity includes myelosuppression (at 5–7 days); vomiting; and anorexia.
- Tumor cells rapidly become resistant to this drug's action.

Surgical decompression of the spinal cord and/or nerve roots, and tumor resection or debulking is a potential treatment option, especially **if the tumor is localized**.

Follow-up radiation and chemotherapy is recommended.

Prognosis

Prognosis is poor for long-term survival, especially when most cats are infected with the FeLV virus.

Prevention

The only effective means of prevention is **test and removal programs** directed at **controlling the spread of FeLV**.

Routine vaccination with FeLV vaccines is recommended. However, there is the risk of development of vaccine-induced sarcomas with adjuvant killed FeLV vaccines. A new recombinant FeLV vaccine is now available.

FELINE INFECTIOUS PERITONITIS***

Classical signs

- Decreased mentation and menace.
- Central vestibular disease and facial paralysis.
- Chronic progressive tetraparesis to tetraplegia or paraparesis.
- Seizures and behavior change.
- Intention tremor.
- Systemic signs such as fever, inappetance, weight loss, dyspnea and gastrointestinal signs.

Clinical signs

Feline infectious peritonitis (FIP) may produce a **non-suppurative meningoencephalitis in 29% of infected cats**.

The CNS signs are **usually** associated with the **non-effusive (“dry”) form of FIP** (cell-mediated immunity is defective but not absent)

The neurological form of FIP has no breed or sex predilection, although **most cases are < 3–4 years of age**.

In most cases, the neurological signs are **multifocal** with a predominance of **caudal fossa signs (brainstem, vestibular nuclei and cerebellum)**.

- Signs can include nystagmus (positional, non-constant, rotatory, horizontal or vertical in nature), head tilt, body lean or rolling, facial paralysis, an ipsilateral hemiparesis or tetraparesis, intention tremor, and hypermetria or dysmetria.

The spinal cord and the cerebrum also can be involved.

- **Signs of cerebral disease** can include seizures, behavior change, decreased mentation, decreased menace response, compulsive walking, ipsiversive wide circling and head pressing.
- **Spinal cord involvement** will manifest as UMN and/or LMN tetraparesis or paraparesis with ataxia. Tetraplegia or paraplegia are the most severe consequences of spinal cord involvement.

Myelopathy is seen either as the sole abnormality or as part of a multifocal distribution in **25% of cases**.

The onset of FIP can be acute, although most cats have a chronic progressive course over 1 week to 3 months.

Extraneural signs may include fever, cachexia, poor body condition, dehydration, lethargy, muscle atrophy, chorioretinitis, dyspnea and gastrointestinal/hepatic signs.

Many cats present with the neurological form of FIP without extraneural signs.

Diagnosis

The diagnosis is **best** established via **CSF analysis** – marked elevation in protein (usually greater than 1 g/L [100 mg/dl] and often greater than 2 g/L [200 mg/dl]) and white blood cells (mean of 734 cells/mm³ [734 cells/μl] with a range of 69–2000 cells/mm³ [69–2000 cells/μl]), with a predominance of non-degenerate neutrophils (50–90%).

The **CSF FIP viral titer** is usually **positive** if CNS signs are present. It is probable that CSF anti-FIP viral immunoglobulin G is produced within the CNS.

Serum biochemical changes often consist of an elevation in total protein and hypergammaglobulinemia.

Serum FIP antibody titers are **not reliable**, and are elevated in only 58% of cats with the neurological form of FIP and are even negative in some cats.

Differential diagnosis

Numerous other infectious and immunological diseases can produce meningitis and encephalomyelitis in cats.

FeLV-associated CNS lymphosarcoma can usually be differentiated by CSF analysis, and a positive FeLV serum titer.

Cryptococcal organisms are **usually visible in CSF** with confirmation made by a latex agglutination assay or culture.

CNS toxoplasmosis is **rare** in the cat, usually producing signs of intracranial disease rather than myelopathy. Recent or active infection is diagnosed by demonstrating

a positive IgM titer, a four-fold increase or decrease in IgG serum titer, a CSF IgM antibody titer or a CSF IgG titer present at a higher CSF:serum ratio than another antibody present in serum that is not produced in CSF, e.g. calicivirus.

Feline polioencephalomyelitis usually produces only a mild to moderate increase in protein (mean of 0.48 g/L [48 mg/dl] with a range of 0.1–0.7 g/L [10–70 mg/dl]) and a mild mononuclear pleocytosis (mean of 19 cells/mm³ [19 cells/ μ l] with a range of 0–46 cells/mm³ [0–46 cells/ μ l]) on CSF. This is not typical of FIP.

Treatment

No effective therapy is known against FIP.

Immunosuppressive corticosteroid therapy may slow the **disease** course (1–2 mg/kg prednisone or prednisolone orally twice daily).

All cats with the neurological form of FIP will **eventually die** from their disease.

SPINAL CORD TRAUMA – FRACTURES AND LUXATIONS***

Classical signs

- Acute variably located spinal cord dysfunction (UMN or LMN signs).
- Focal spinal hyperesthesia.
- Spinal crepitus.
- External abrasions and bruising.

Pathogenesis

External spinal trauma can result from **automobile accidents, gunshot injuries, falls** from heights and blunt trauma.

Sacrocaudal fractures most often occur when the cat's tail is **forcefully pulled** away from the body.

- This most commonly occurs when the cat's tail is trapped under the tire of an automobile. The rotating tire luxates the tail at the sacrococcygeal junction or between two coccygeal vertebrae, resulting in damage to the coccygeal, sacral and lumbar nerve roots (cauda equina).

Most spinal fractures occur **at the junction of mobile and immobile segments** of the spine, such as the thoracolumbar, lumbosacral and sacrocaudal junctions.

Traction on the cauda equina in sacrocaudal luxations can also damage the nerve cell bodies in the caudal lumbar and sacral spinal cord due to cranial transmission of the forces through the dura mater and filum terminale of the cord.

The degree of spinal cord compression; the length of time of compression; and the velocity of the initial impact injury are important contributors to the resultant spinal cord injury.

There are two forms of spinal cord injury – **mechanical** (primary) **injury**, consisting of physical disruption of vessels and axons **and ischemic** (secondary) **injury**.

The latter leads to energy compromise within the spinal cord, cellular accumulation of calcium and resultant intracellular stimulation of enzymes.

This leads to protein and lipid breakdown (phospholipid hydrolysis), release of arachidonic acid, free radical and eicosanoid formation, and cell death.

Gray matter hemorrhages and white matter edema occur within minutes following acute spinal cord injury, progressing rapidly over the 4–6-hour post-traumatic period.

Clinical signs

Signs depend on the injury level and the degree of physical or functional disruption of the cord.

Signs in cats with sacrocaudal injuries **range from hyperesthesia over the tail base to flaccid analgesic tails** with varying degrees of urinary reflex dyssynergia or LMN urinary/fecal incontinence.

- **Reflex dyssynergia** involves a failure of urethral relaxation when the cat attempts to urinate and the bladder undergoes contraction. This leads to the production of only very small quantities of urine. The bladder will still be large and the cat will often dribble urine in between attempts to urinate.

Many cats with sacrococcygeal trauma also show **signs of LMN paraparesis** (sciatic nerve injury), consisting of dragging of the hind paws on their dorsum and a failure to flex the pelvic limb(s) when walking or when

the withdrawal reflex is performed. There will also be a hypo- to areflexia of the cranial tibial and gastrocnemius reflexes.

Palpation of the sacrocaudal area of the spine will result in crepitus and pain. The tail will often be malaligned with the sacrum and the rest of the vertebral column.

Cats with spinal trauma commonly have concurrent thoracic, abdominal or pelvic trauma.

Diagnosis

Neurological and physical examination determine the localization and severity of the cord injury.

Non-contrast spinal radiographs (lateral and across the table ventrodorsal views of the entire spine) establish the **type of vertebral disruption** (fracture vs. subluxation) and the location(s) of the vertebral trauma.

Myelography, MRI or CT scans will determine the **degree of spinal cord compression**.

Differential diagnosis

Any other cause of acute myelopathy must be considered as a differential diagnosis in cats with spinal trauma.

Most other causes can be eliminated based on history and physical examination – external abrasions, bruising, splintering of claws and spinal pain are seen with trauma.

Sacrocaudal fractures must be differentiated from **aortic thromboembolism**, which also can produce an acute onset of LMN paraparesis to paraplegia, with pain.

- However, cats with this disease **do not** have dysfunction associated with the perineum, bladder, rectum and tail.
- The **lack of femoral pulses** and the presence of **cold, cyanotic pelvic limbs** would strongly support aortic thromboembolism.

Pathologic vertebral fracture secondary to neoplasia will present as an acute, painful myelopathy, and may appear superficially similar to a traumatic fracture on non-contrast spinal radiographs. However, closer examination should reveal areas of **lysis within the involved vertebral body**.

Ischemic myelopathy secondary to **fibrocartilaginous embolism** most commonly involves the lumbosacral

intumescence as is the case with sacrococcygeal trauma.

- A differentiating feature of ischemic myelopathy is the **absence of spinal pain**.

Treatment

Initial medical emergency treatment should include **intravenous methylprednisolone sodium succinate (30 mg/kg)**, administered **within 8 hours** (and **preferably within 3 hours**) of the spinal trauma.

Continued treatment consists of a constant rate intravenous infusion of methylprednisolone at 5.4 mg/kg/hour or, if not possible, a second bolus intravenous injection (15 mg/kg) at 2 hours after the initial treatment, followed by 15 mg/kg at 6 hours and then 4 times daily for 24–48 hours.

Most cases of spinal trauma will require **emergency surgical intervention** (spinal cord decompression [laminectomy and/or hemilaminectomy] and spinal fixation).

The type of decompression and stabilization technique is determined by non-contrast and contrast spinal radiographs or CT/MRI scans.

Surgical spinal stabilization is rarely necessary in sacrocaudal fractures/luxations and, due to the often-marked separation of the involved vertebrae, is difficult to achieve.

Surgical decompression of the cauda equina in sacrocaudal trauma is also unnecessary since it is a traction, not compressive, injury.

If the cat is incontinent, attention should be paid to cleanliness, bladder and bowel management, and prevention of decubital ulcers, urine scalding, and cystitis.

If there is UMN or LMN urinary incontinence, **manual expression or indwelling catheterization** of the bladder is required.

Pharmacological management of UMN urinary incontinence or reflex dyssynergia, related to sacrocaudal trauma, consists of **phenoxybenzamine**, an alpha-adrenergic receptor antagonist, to relax the internal sphincter (5 mg orally three times daily) together with **diazepam** (1.25–2 mg/cat orally two to three times daily) to relax the external sphincter.

Bladder detrusor dysfunction can then be treated with **bethanechol**, a parasympathomimetic agent (5–10 mg orally two to three times daily).

Bethanechol may help LMN urinary incontinence (encourages detrusor muscle contraction).

Fecal retention can be treated by increasing the bulk of the feces with **bran, psyllium or canned mashed pumpkin**.

In cats with sacrocaudal injury with only tail paresis, conservative medical management will often result in return of tail function.

- If this does not occur after 4–6 months, amputation of the tail is recommended.

Prognosis

Prognosis is based on the severity of the spinal cord injury. The **milder the neurological deficits**, the **better the prognosis** for recovery.

Cats with severe myelopathy or cauda equina injury with analgesia have a very poor to hopeless prognosis since they commonly have physical or functional spinal cord or cauda equina transection.

- Only 25% or less of cats with flaccid tail, perineal analgesia and LMN urinary and fecal incontinence from a sacrocaudal injury will regain neurologic function.
- 75% of cats with only tail flaccidity can regain tail function.

Prognosis should **NEVER** be **determined based on the degree of radiographic displacement** of the involved vertebra(e).

Prevention

The only preventative measure is for cats to avoid situations where trauma is a distinct possibility.

SPINAL MENINGIOMA**

Classical signs

- Chronic, progressive UMN or LMN tetraparesis or paraparesis dependent on tumor location.
- Focal areas of spinal pain.

Pathogenesis

Although most meningiomas are found intracranially, they may also develop along the spinal cord with an **intradural, extramedullary predilection site**.

Meningiomas arise from any cell of the meninges – blood vessels, fibroblasts or arachnoid cells.

Spinal meningiomas are **usually solitary**.

Meningiomas produce signs by compressing the adjacent spinal cord causing vasogenic edema

Occasionally, other tumors such as an astrocytoma occur.

Clinical signs

Most cats are > 9 years of age.

The nature of the ataxia and paresis (UMN versus LMN signs) depends on the tumor's location.

A focal area of spinal pain or more diffuse spinal discomfort may occur weeks prior to the development of neurological dysfunction.

Signs are **slowly progressive**.

Diagnosis

Non-contrast spinal radiographs may reveal thinning or deformation of the vertebral lamina secondary to pressure necrosis from the expanding tumor.

Lumbar CSF most commonly reveals **increased protein** (> 0.25 g/L [25 mg/dl]) **without** an accompanying **pleocytosis**. Tumor cells are rarely seen.

MRI scan or myelography reveals an **intradural, extramedullary mass**.

Differential diagnosis

Any cause of chronic, progressive myelopathy should be considered.

The focal nature of the myelopathy with meningioma eliminates most infectious and inflammatory myelopathies, with the exception of FeLV-associated spinal lymphosarcoma.

Ischemia and trauma produce an acute myelopathy and can usually be eliminated.

Age of disease onset for meningiomas would eliminate congenital and inherited myelopathies.

Differentiation from lymphosarcoma often is based on CSF analysis (malignant lymphocytes).

Differentiation from nerve root tumors often requires **histopathology** following surgical removal.

Treatment

Surgical removal of the tumor is the **only definitive treatment**.

Post-operative radiation therapy is recommended.

Corticosteroids only transiently improve neurological function.

Prognosis

The long-term **prognosis** is **guarded to fair** if surgical removal of the tumor appears complete. Follow-up radiation probably further improves this prognosis.

Without surgery, the long-term prognosis is poor.

Prevention

There is no known prevention of spinal meningiomas in cats.

AORTIC THROMBOEMBOLISM**

Classical signs

- Acute LMN paraplegia.
- Severe pain associated with the pelvic limb musculature.
- Vocalization and anxiety.
- Weak or absent femoral pulses.
- Cyanotic and cold nail beds and foot pads.

Pathogenesis

Aortic thromboembolism results from a **thrombus** that is **dislodged from within the left heart or aorta**, leading to **obstruction of the aortic trifurcation** and severe **ischemia** to **pelvic limb muscles and nerves**.

In cats it is most commonly **associated** with **hypertrophic, dilated and restrictive cardiomyopathy**, with **thrombus** formation in the **left atrium**. It also occurs with thyrotoxic cardiac disease.

Thrombus formation requires either damage to the endocardium as occurs in cardiomyopathy, especially the dilated left atrium; blood stasis which also occurs in the dilated left atrium; or altered blood coagulability. Disseminated intravascular coagulation (DIC) was found in 75% of cats with cardiomyopathy and was associated with consumptive or liver-mediated coagulopathy or thromboembolism.

Embolism occurs when the thrombus lodges in a blood vessel.

The thrombus most often lodges in the distal aorta at the trifurcation, leading to a saddle thrombus and occlusion of blood supply to the hindlimbs. Ischemic neuromyopathy occurs and is most severe distal to the stifle. Signs are usually asymmetrical. Occasionally the right brachial artery is occluded, resulting in lameness or paresis of the right forelimb.

Occasionally cats with thromboembolic disease do not have underlying heart disease. Thrombosis may also occur with infectious or neoplastic disease.

Clinical signs

There is no breed or age predilection (average 9 years, range 2–16 years) although **males** are twice as likely to be affected.

Aortic thromboembolism usually produces an **acute onset of LMN paraplegia and severe pain**.

The hindlimbs drag behind the cat, as the hocks cannot be flexed. Hip extension and flexion is present.

Less severe ischemia leads to mild to moderate paraparesis or pelvic limb lameness.

The **gastrocnemius muscles** usually are **firm**, but soften 1–3 days after embolization.

Femoral pulses are weak or absent and the **nail beds** and footpads are **cyanotic and cold**. The distal limbs are often swollen.

Extraneural signs include vocalization, tachypnea/dyspnea, a **cardiac murmur** and **arrhythmias**. Heart

failure is present in about 50% of cats with aortic thromboembolism.

Dehydration and hypothermia are often present.

Tail movement, perineal reflexes and urinary function remain intact.

Diagnosis

Increases in serum creatine kinase (often 1000–10 000 IU/L [normal: 60–300 IU/L]) occur secondary to **severe muscle damage**.

Creatinine and BUN are increased in more than 50% of cats and may be prerenal or renal. In some cats, concurrent embolization of the renal artery occurs.

Thoracic **radiography** reveals **cardiomegaly** (85–90% of cats) and **pulmonary edema** and/or **pleural effusion** (66%).

Echocardiography most often reveals **hypertrophic cardiomyopathy** (\pm a left atrial thrombus).

Electrocardiography most commonly reveals **sinus tachycardia**. Atrial fibrillation, and supra-/ventricular arrhythmias can also be seen.

Doppler (color flow) will often demonstrate the decrease in blood flow through the site of thromboembolism.

MRI angiography will reveal a complete or partial blood flow obstruction at the aortic trifurcation.

Differential diagnosis

A major feature that differentiates aortic thromboembolism from traumatic, infectious, neoplastic and ischemic myelopathies is the presence of paraparesis to paraplegia without involvement of the perineum, tail and bladder.

Cold, cyanotic pelvic limbs without femoral pulses and firm gastrocnemius muscles also are unique.

Treatment

With current treatment modalities, the results of **palliative therapy are as good as aggressive thrombolytic therapies or physical removal of the thrombus**, and considerably less expensive.

- Physical removal is via surgery or balloon embolectomy.
- Thrombolytic agents include tissue plasminogen activator, urokinase and streptokinase.
 - Current information should be consulted on administration and monitoring of thrombolytic and intensive anti-thrombotic therapies if they are to be used.
- **Reperfusion effects are a major problem with aggressive thrombolytic therapies and physical removal.** Rapid onset of **severe hyperkalemia** associated with reperfusion is common and **often fatal**. **Renal hemorrhage** may also occur during thrombolysis, adversely affecting survival. **Clinical hemorrhage** may require a blood transfusion to control.

Palliative therapy consists of relieving pain, heparin to help prevent another clot forming in the left atrium, **fluid, electrolyte and nutritional support**, warmth, physiotherapy (passive massage and flexing/extending legs) and **treatment of underlying heart disease**. Potassium concentrations should be monitored carefully.

Pain control is an important part of management. Injectable analgesics and a fentanyl patch should be used to provide adequate levels of pain relief.

Excessive licking or chewing of the affected limb may occur resulting in self-mutilation. Loose bandaging of the limb or an Elizabethan collar are usually effective.

Dehydration and electrolyte imbalances, especially hyper- and hypokalaemia, need correcting. Nutritional needs should be met in anorexic cats by the placement of a nasoesophageal tube for feeding.

Treatment of the underlying cardiac disease is essential (see Chapter 25).

Acutely, heparin (400 U/kg subcutaneously followed by 200 U/kg subcutaneously three times daily) can be given to prevent further activation of the coagulation cascade, although **it will not have any effect on the formed thrombus**.

Continue palliative therapy for 5–6 days and look for rewarming of the toes and returning pulses as an initial sign of improvement. Doppler is useful for detecting blood flow. If there is no sign of reperfusion after

6 days, the prognosis is hopeless and the cat should be euthanized.

Various other treatments have been advocated but there are no studies showing increased survival. These include aspirin, periactin, acepromazine and vasodilator agents.

Aspirin may be beneficial during and after an episode of thromboembolism due to its **antiplatelet effects** and decreased production of the vasoconstrictor thromboxane A₂, as well as analgesic effects. The dosage is 1/4 × 325 mg adult aspirin (81 mg) every second to third day. Blockade of prostacyclin production by the endothelium with aspirin is of concern, and some advocate lower doses of aspirin more frequently (1–5 mg/cat q 24 h). Prostacyclin inhibits platelet aggregation and vasoconstriction.

Acepromazine (0.1–0.5 mg subcutaneously three times daily) can be used for **sedation** and **vasodilation**.

Vasodilation with alpha-blockers is advocated by some but unproven.

Long-term warfarin therapy may decrease the frequency of rethrombosis, but needs careful monitoring using the International Normalization Ratio (INR) for PT to achieve a INR between 2 and 3. Doses of 0.06–0.20 mg/kg PO q 24 h have been advocated. A lower dose of 0.5 mg/cat PO q 48 h has also been used.

Prognosis

Only 30–50% of cats survive the initial episodes and go home.

Most will re-embolize – **long-term prognosis is poor** (average survival is 6–11 months with therapy) with less than 50% surviving 1 year.

- 50% of cats have rethrombosis even when treated with warfarin.

Most cats that survive an initial episode will show varying degrees of **neurological recovery** to their pelvic limbs, although this often takes **weeks to months**. Rarely does the neuromuscular function fully recover.

Hypothermia and azotemia prior to therapy and hyperkalemia during thrombolysis are negatively associated with survival. Echocardiographic evidence of another

thrombus in the left atrium also decreases the long-term prognosis.

Prevention

Little can be done to prevent aortic thromboembolism if the underlying cardiac disease has not been previously recognized.

If cardiac disease is diagnosed, the risk of thromboembolism may be reduced by appropriate treatment of the cardiomyopathy (see Chapter 6). Efficacy of long-term aspirin (low dose 1–5 mg/cat q 24 h or a regular dose 81 mg/cat, q 48–72 h PO) or warfarin therapy in preventing thromboembolism has not been demonstrated, and most cats rethrombose.

FELINE POLIOENCEPHALOMYELITIS*

Classical signs

- Stiff staggering gait.
- Inability to jump.
- Chronic pelvic limb ataxia and paraparesis.
- Inability to retract their claws.
- Thoracolumbar hyperesthesia.
- Thoracic limb paresis and ataxia.
- Decreased mentation and seizures.
- Fever (in 50% of cases).

Pathogenesis

Feline polioencephalomyelitis is a **chronic, progressive** disease affecting the **spinal cord and brain** of cats.

The **cause** is **unknown**, although neuropathology is suggestive of a neurotrophic virus.

Recently, specific antibodies to the **Borna disease virus** have been found in 44% of cats with feline polioencephalomyelitis in Sweden.

Feline polioencephalomyelitis is a sporadic worldwide disease.

Clinical signs

Affected cats range from **4 months to 12 years of age**.

Both male and female cats are affected.

All domestic cat breeds as well as large non-domesticated cat species can contract the disease.

Neurologic **signs** usually **develop over 2–3 months** with a subacute to chronic progressive course.

The most striking neurologic signs include a **stiff staggering gait, inability to jump, pelvic limb ataxia and paraparesis**.

- Some cats have decreased spinal reflexes and some are unable to retract their claws.

Other signs may include thoracic limb ataxia and paresis, hyperesthesia over the thoracolumbar and lumbosacral regions, decreased mentation, behavior change, decreased pupillary light reflexes, hypersensitivity to external stimuli, impaired vision, seizures, increased salivation, intention tremors and pruritis.

With disease progression, **paraplegia eventually occurs**.

A **fever** is present in approximately **50% of cats**.

Diagnosis

CSF analysis usually reveals a **non-specific** mild to moderate elevation in protein (mean of 0.48 g/L [48 mg/dl] with a range of 0.1–0.7 g/L [10–70 mg/dl]) and a mild mononuclear pleocytosis (mean of 19 cells/mm³ [19 cells/μl] with a range of 0–46 cells/mm³ [0–46 cells/μl]).

Serologic testing for FIV and FeLV antibodies is negative.

Definitive diagnosis can only be made on **necropsy**.

Histopathology reveals a **disseminated meningoencephalomyelitis** with lymphocytic perivascular cuffs that is most severe in the spinal cord (gray matter) and brainstem.

Differential diagnosis

Infectious diseases (FIP and toxoplasmosis) also may produce signs of progressive spinal cord dysfunction, making differentiation based on neurological signs difficult. Uveitis, chorioretinitis and optic neuritis are often present with CNS infections, but not with polioencephalomyelitis.

Cats with spinal **CNS lymphosarcoma** commonly are FeLV positive and may have other systemic signs of tumor involvement.

CSF analysis may help differentiate between the infectious diseases, lymphosarcoma and feline polioencephalomyelitis (see sections on lymphosarcoma and FIP), although the range of values overlap between the diseases.

Treatment

Immunosuppressive steroid therapy (prednisone 1–2 mg/kg BID) is the recommended treatment against this disease, although data are lacking.

This may be combined with other immunosuppressive agents such as **cytosine arabinoside**.

Aggressive and persistent therapy may result in remission and possible cure after several months.

Prognosis

Prognosis is **guarded**. The disease tends to be progressive if untreated.

Prevention

Since this disease is of unknown etiology and very sporadic, there are no recommendations for prevention.

CONGENITAL ABNORMALITIES OF THE SPINAL CORD AND VERTEBRAE*

Classical signs

- UMN or LMN paraparesis or tetraparesis dependent on the anomaly and its location.
- Scoliosis (lateral curvature of the spine), lordosis (downward arching spine), or kyphosis (upward arching spine) resulting from a hemivertebra.
- Cervical pain and UMN tetraparesis to paralysis (atlantoaxial subluxation).
- LMN paraparesis to paraplegia (spina bifida and sacrococcygeal dysgenesis).
- LMN urinary and fecal incontinence (spina bifida and sacrococcygeal dysgenesis).
- Dorsal midline spinal defects or cystic structures – may drain CSF (spina bifida).
- Abnormal hair growth direction, a dimple on the skin surface or an open tract (spina bifida).

Pathogenesis

Spinal cord and vertebral **anomalies** are **classified** into abnormalities originating in the tissues of **mesodermal origin** (vertebral body and intervertebral disc) **and** those arising from tissues of **ectodermal origin** (spinal cord and meninges).

Malformations of mesodermal origin.

- **Block vertebrae.**
 - Caused by **improper segmentation of somites**, resulting in stable vertebral fusion.
- **Butterfly vertebrae.**
 - Abnormal **persistence of the notochord** (the embryological precursor of intervertebral discs), producing a midline cranial to caudal cleft in the vertebral body (when viewing the vertebra from the dorsoventral direction).
- **Hemivertebrae.**
 - Produced by **fusion of one lateral somite to one** on the contralateral side that is **not directly opposed or by a lack of vascularization**, leading to a failure of ossification in part of the vertebral body. This produces a **wedge-shaped vertebra**, and scoliosis, lordosis or kyphosis.
- **Transitional vertebrae.**
 - Sacralization of the last lumbar vertebra is the most common in cats. In this condition, the last lumbar vertebra has characteristics of both lumbar vertebrae and the sacrum.
- **Atlantoaxial subluxation.**
 - Results from **hypoplasia or aplasia of the dens** with secondary atlantoaxial instability.
 - It is either caused by a **developmental failure of dens** ossification **or an ischemic necrosis** and partial resorption **of the dens** as a result of trauma.
 - The cranial portion of the axis is displaced into the spinal canal producing cord compression.

Malformations of ectodermal origin.

- Abnormalities of the vertebral arch and spinal cord are primarily influenced by neural tube development.
- The **most common** anomaly is **spina bifida**.
- **Spina bifida.**
 - The defects of spina bifida vary from **incomplete fusion of the vertebral arch to incomplete fusion of the neural tube**, resulting in

abnormal formation and/or protrusion of the meninges and/or spinal cord.

- Pathogenesis may involve initial failure of closure or the reopening of a previously closed neural tube.
- Spina bifida occulta represents an incomplete closure of one or more vertebral arches without protrusion of meninges or spinal cord.
- **Spina bifida manifesta** includes **meningocele** (meningeal herniation through the vertebral arch defect) **and meningocele** (herniation of the spinal cord and meninges).
- The meningeal and/or spinal cord herniation may or may not communicate with the environment.
- **Sacroccygeal dysgenesis of Manx cats.**
 - An **autosomal semi-lethal dominant trait**, providing the genetic basis for the absent tail as well as numerous vertebral and spinal cord abnormalities.
 - Homozygotes usually do not survive.
 - There are four phenotypic subgroups – a complete absence of coccygeal, sacral +/- caudal lumbar vertebrae (the most severe); fused caudal vertebrae; mobile but kinked caudal vertebrae; and a normal tail.

Clinical signs

Clinical signs are dependent on the type of congenital malformation and its location.

Block vertebrae are usually stable.

- Occasionally they can be stenotic or angulated, causing extradural spinal cord compression.
- Disc extrusion can occur at disc spaces immediately cranial and caudal to the block vertebrae.

Butterfly vertebrae are generally incidental findings.

Hemivertebrae commonly lead to scoliosis, lordosis or kyphosis.

- Signs are due to spinal cord compression or repeated trauma associated with vertebral instability. Instability produces osseous changes that secondarily compress the spinal cord.
- Signs may be acute, chronic, progressive or intermittent, but are usually first noted within the first 1–2 years of life.
- Conformation may be visibly or palpably abnormal.

Sacralization of the caudal lumbar vertebrae can result in pain and LMN paraparesis secondary to cauda equina compression.

Atlantoaxial malformation can produce episodic **cervical pain or acute/chronic UMN tetraparesis** to tetraplegia, usually in cats less than 1 year of age.

- If spinal cord injury is severe, the cat can develop respiratory paralysis and caudal brainstem dysfunction.
- Episodic opisthotonos and rigidity occasionally occur which can be misinterpreted as seizures.

Spina bifida occulta is an incidental finding.

Spina bifida manifesta produces myelopathy dependent on the degree of incorporation of the spinal cord and/or cauda equina into the herniated meningeal sac.

- Most commonly the **caudal lumbar and sacral spine** is affected, resulting in **LMN paraparesis/plegia and urinary/fecal incontinence** in newborn kittens.
- Spina bifida can be observed at birth as **dorsal midline, open regions of the spinal canal** or cystic structures that may **drain CSF**.
- Abnormal hair growth, a skin dimple or an open tract are less severe manifestations.

Sacroccygeal dysgenesis produces a **hopping gait**.

- More severe signs at or soon after birth include **LMN urinary/fecal incontinence, megacolon, and LMN paraparesis/paraplegia**.
- Some are normal at birth but develop progressive signs over several weeks to months as the cat matures. Damage to the spinal cord with growth occurs as a result of spinal cord tethering (fixation).

Diagnosis

Breed association (Manx cat).

Signs are most commonly observed in **immature animals** (< 6 months of age).

The cat's conformation may be visibly or palpably abnormal (scoliosis, skin dimple, etc.).

Non-contrast spinal radiography demonstrates the anomaly.

- Block vertebra – joining of two adjacent vertebral bodies.
- Butterfly vertebra – sagittal vertebral body cleft.

- Hemivertebra – abnormal vertebral wedging and shortening.
- Atlantoaxial subluxation – abnormally shaped or absent dens.
- Spina bifida – vertebral arch defect.

Myelography demonstrates cord compression or a meningocele/meningomyelocele.

MRI scan or CT myelography reveals soft tissue abnormalities associated with a spinal cord that is tethered (fixed) by either meningocutaneous attachments (spina bifida) or by a failure of the terminal cord-like attachment from the spinal cord to the dura to stretch with growth. They will also reveal cord compression.

Differential diagnosis

Major **differentials for hemivertebra** include traumatic or pathologic **fracture with secondary collapse of the vertebral body**.

- **Hemivertebrae**, however, have **smooth end plates** and well-formed adjacent disc spaces.
- Difficulty in differentiation arises when vertebral osteophytes are present.

Differential diagnoses for block vertebrae include vertebral fusion secondary to discospondylitis, vertebral fracture/luxation, collapsed disc space secondary to disc extrusion, or previous disc surgery. However, all have associated reactive bone, which is not present with block vertebrae.

Atlanto-axial subluxation and spina bifida have few rule-outs, except trauma.

Treatment

Spinal cord compression from a **hemivertebra** can be treated via **surgical decompression and stabilization** (if necessary).

Treatment for **atlantoaxial subluxation** involves **stabilization** of the atlantoaxial joint via **ventral cross-pinning or screws** (preferred) or dorsal wiring.

Specific treatment for spina bifida and sacroccygeal dysgenesis is rarely attempted.

- If signs are associated with spinal cord tethering or there is a meningocutaneous fistula without primary spinal cord anomalies, reconstructive surgery may be possible.

Prognosis

Prognosis **depends on the type of congenital anomaly** and the degree of dysfunction.

Cats with mild signs due to a surgically treatable hemivertebra or block vertebra, have a guarded to good prognosis for improvement.

Morbidity and mortality is high with surgical stabilization of atlantoaxial subluxation.

- With **successful stabilization**, however, cats with initially mild to moderate neurological dysfunction have a **fair to good prognosis**.

Prognosis for cats with **spina bifida or sacrococcygeal dysgenesis with anomalies associated with the spinal cord or cauda equina**, is **grave**. These cats should be euthanized if the neurological dysfunction is incompatible with a good quality of life.

Cats with spinal cord tethering (spina bifida) have a potentially fair to good prognosis with surgery.

Prevention

Prevention of further congenital malformations is best achieved by a **spay/neuter program**.

HYPERVITAMINOSIS A*

Classical signs

- Cervical and thoracic limb hyperesthesia and rigidity.
- Thoracic limb lameness.
- Chronic progressive ataxia.
- Reluctance to move.
- Chronic tetraparesis to paralysis.

Pathogenesis

Hypervitaminosis A is a **skeletal disease**, secondary to **excessive intake of vitamin A** (liver or vitamin A supplementation (cod liver oil) (> 1000 IU/ml).

Clinical signs

Affected cats are usually 2–9 years of age.

Signs include **cervical and thoracic limb hyperesthesia and rigidity** due to extensive confluent **exostosis in the cervical and thoracic spine**, thoracic limb lameness, ataxia, reluctance to move, and tetraparesis to paralysis.

Other signs include lethargy, anorexia, constipation, weight loss and an unkempt haircoat due to an inability to groom.

Exostoses develop insidiously with the above signs occurring only after the disease is advanced.

Diagnosis

Non-contrast **spinal radiographs** show **new bone formation** involving the **cervical vertebrae**.

- The sternum, costal cartilages, and long bone metaphyses also show new bone formation.
- Joints may show arthrodiesis.

Differential diagnosis

Based on the clinical and neurological examinations, other differentials include infectious meningitis and myelitis, vertebral neoplasia, mucopolysaccharidosis and discospondylitis (rare).

Non-contrast spinal radiographs eliminate all differentials with the possible exception of mucopolysaccharidosis **VI**, a rare **autosomal recessive storage disease** produced by **deficiency** of the lysosomal enzyme, **arylsulfatase B**.

- Mucopolysaccharidosis VI occurs in **4–7-month-old Siamese cats**, producing spinal cord compression secondary to **fusion of the cervical and thoracolumbar vertebrae with bony proliferation**.
- These cats also have a flat, broad face, widely spaced eyes, corneal clouding and enlarged feet.

Treatment

Remove excess vitamin A from the diet to prevent further development of exostoses.

Use a **balanced commercial cat diet**.

Skeletal improvement is monitored by radiography and neurological examinations.

Analgesics may symptomatically treat the clinical signs.

- **Aspirin** – 10 mg/kg PO q 48 h.
- Narcotic analgesics such as **morphine** (4 mg/ml) – 0.5 mg/kg PO three times to four times daily.
- Non-steroidal anti-inflammatory drugs.
- Fentanyl patch.

FIBROCARILAGINOUS EMBOLISM

Classical signs

- **Acute, non-progressive, non-painful, asymmetrical LMN paraparesis to paraplegia.**
- **LMN urinary and fecal incontinence.**

Pathogenesis

Spinal cord infarction secondary to **fibrocartilaginous embolism** is uncommon.

The **embolus** is histochemically identical to the **fibrocartilage of the nucleus pulposus**.

It is unknown how the embolus reaches the spinal vasculature from its origin.

Embolization of arteries, veins or a combination of the two may occur.

Sudden increases in intra-abdominal pressure (hard exercise) may facilitate retrograde passage of disc material through the venous sinuses and spinal veins.

Embolism results in **segmental hemorrhagic necrosis and malacia of the spinal cord**.

Clinical signs

Clinical signs reflect the location of the lesion along the spinal cord.

In cats, the **lumbosacral intumescence** is the **most common** site of myelopathy, resulting in an **acute LMN paraparesis to paraplegia**, and **LMN urinary and fecal incontinence**.

Other findings include a **lack of spinal pain**, **lack of disease progression** and marked **asymmetry** of neurological dysfunction.

Diagnosis

Diagnosis is based on **exclusion of other etiologies**. History and neurological exam are important.

Survey radiographs are normal.

CSF analysis is variable, ranging from normal, hemorrhagic, or showing a mild mixed pleocytosis (6–25 cells/mm³ [6–25 cells/ μ l]).

Myelography will either be normal or occasionally show cord edema.

MRI diffusion studies may reveal the ischemic area of spinal cord, if the affected area is large enough.

Definitive diagnosis can only be made at **necropsy**.

Differential diagnosis

Differential diagnosis includes any cause of acute paraparesis to paraplegia.

The unique clinical signs and usual absence of abnormalities on work-up separate fibrocartilaginous embolism from other acute myelopathies.

Treatment

Immediate treatment consists of **methylprednisolone sodium succinate** (see spinal trauma).

Embolic myelopathy is **non-surgical**.

Long-term corticosteroid therapy is not recommended.

Prognosis

Prognosis depends on density of neurological dysfunction and degree of irreversible cord damage.

Cats with **severe LMN paraplegia**, **absent pain** sensation and LMN urinary incontinence associated with involvement of the lumbosacral intumescence have a **poor to hopeless** prognosis.

Cats with **less severe signs** have a **guarded to favorable** prognosis for partial to full recovery.

Prevention

There are no preventive measures that can be undertaken.

43. The cat with ataxia without weakness

Rodney S Bagley

KEY SIGNS

- Falling.
- Incoordination.
- Swaying from side to side.
- Goose stepping gait.

MECHANISM?

- Ataxia results from sensory proprioception dysfunction and causes falling and incoordination.

WHERE?

- Cerebellum, cerebral cortex (central controlling centers for movement), vestibular system (peripheral or central) or spinal cord (sensory spinocerebellar pathways).

WHAT?

- Diseases causing ataxia without weakness most commonly involve the cerebellum and include cerebellar hypoplasia (panleukopenia virus infection), hydrocephalus, storage disease, tumors and encephalitis.
- Diseases of the vestibular system most commonly involve the peripheral apparatus and include otitis media/interna, idiopathic vestibular disease and tumors.
- Diseases of the spinal cord rarely cause ataxia without weakness.
- Intracranial, cerebellar and vestibular causes of ataxia without weakness.

QUICK REFERENCE SUMMARY

Diseases causing ataxia without weakness

DEGENERATIVE

- **Inherited cerebellar diseases** (p 934)**

Hereditary cerebellar degeneration occurs in Japans. Clinical signs begin around 7–8 weeks of age and include ataxia, dysmetria, head tremor and intention tremor. **Inherited spongiform encephalopathy** occurs in Egyptian Mau cats in the USA resulting in ataxia and hypermetria beginning at 7 weeks of age. A different spongiform encephalopathy has been reported in older Egyptian Mau cats in the United Kingdom. Clinical signs include muscle tremors, ataxia, dilated unresponsive pupils, jaw champing, salivation and behavior abnormalities. Signs may progress to

severe ataxia and hypermetria. **Neuroaxonal dystrophy** in domestic tri-colored cats results in a head tremor beginning at 5–6 weeks of age with signs progressing to ataxia and hypermetria. Affected kittens have a lilac color, which darkens with age. A similar but separate neuroaxonal dystrophy has been described in cats of various colors. Clinical signs begin at 7–9 months of age and include ataxia with paraparesis.

- **Storage diseases** (p 935)**

Sphingomyelinosis (Niemann–Pick type C disease) results in ataxia and tremors beginning at less than 6 months of age. Clinical signs progress to hypermetria, absent menace responses, and occasionally positional nystagmus. Death usually occurs by 8–10 months of age. **Niemann–Pick type A disease** occurs in Siamese and Balinese cats. Head tremor, head bobbing and dysmetria begin at 3–4 months of age. Clinical signs progress to ataxia and paresis, worse in the pelvic limbs.

ANOMALY

- **Cerebellar hypoplasia*** (p 927)**

Cerebellar degeneration usually occurs in neonatal to younger animals due to congenital deformities or infectious causes (panleukopenia virus infection). Cerebellar hypoplasia results from in utero or immediately postnatal infection with the panleukopenia virus. Clinical signs are most apparent when the animal begins purposeful movement and attempts to walk. Ataxia, dysmetria, intention tremor and absent menaces responses with normal vision are common clinical signs. Clinical signs usually remain static or improve with growth. No treatment is helpful.

- **Hydrocephalus** (p 932)**

If hydrocephalus is congenital, cats may have an enlarged, “dome-shaped” skull. A fontanelle that persists during maturation may be palpable. Acquired hydrocephalus in adults will show no outward anatomical signs. Clinical signs include seizures, poor learning ability, behavior changes, paresis, cranial nerve deficits and changes in consciousness.

- **Congenital vestibular disease** (p 933)**

Congenital peripheral vestibular disease is seen in Siamese and Burmese cats. Clinical signs include head tilt, vestibular ataxia (cat leans, drifts, falls, or rolls to side of head tilt) and, in some, deafness. Signs may remain persistent throughout life or may improve spontaneously.

METABOLIC

- **Vascular diseases* (p 937)**

Rarely, thromboembolic disease or hemorrhage involves the cerebellum. An acute onset of cerebellar signs (incoordination, swaying from side to side, goose-stepping gait, intention tremor and reduced menace) in an older animal is most common with these types of diseases. A cat with polycythemia was presented for ataxia, possibly due to increases in serum viscosity.

NEOPLASTIC

- **Cerebellar and vestibular tumor*** (p 928)**

Primary or secondary neoplasia involving the cerebellum is uncommon. Intracranial tumors such as meningioma and choroid plexus tumors can affect both the cerebellum or vestibular system and result in ataxia. Other signs such as an intention tremor, goose-stepping gait, menace deficits, nystagmus and head tilt may be present. Occasionally tumors of the ear cause peripheral vestibular ataxia (cat leans, drifts, falls or rolls towards the side with a head tilt). Neoplastic disease occurs more often in older cats.

continued

continued

NUTRITIONAL

- **Thiamine deficiency* (p 938)**

Decreased thiamine can result in brain stem disease in cats. Clinical signs initially begin with lethargy, inappetence and reluctance to walk. Later there is vestibular ataxia and episodes of spastic ventroflexion of the neck or opisthotonos, dilated pupils, stupor and coma.

INFLAMMATORY/INFECTIOUS

- **Encephalitis*** (p 930)**

Neurological signs are often diffuse and may not localize to a single area within the nervous system. Fever and leukocytosis are inconsistent findings. Systemic signs of disease such as fever, coughing, vomiting and diarrhea may accompany the neurologic signs. Feline infectious peritonitis, toxoplasmosis and *Cryptococcus* are more common causes of encephalitis. Non-infectious causes are less common but include feline non-suppurative meningoencephalomyelitis (“staggering disease”).

- **Idiopathic encephalopathy* (p 939)**

An encephalomyelopathy of young cats reported in the United Kingdom had clinical signs of ataxia, paresis and “head shaking”. Cats 3–12 months old were affected, however, the disease was seen in cats up to 3 years of age. Ataxia of the pelvic limbs was the initial clinical sign noted.

- **Otitis media/interna** (p 936)**

Clinical signs may reflect either primary ear, vestibular, or auditory dysfunction. Head tilt is most common, but nystagmus and vestibular ataxia (leaning or falling to one side) may also be present. A painful external ear and or pain on opening the mouth is often present. The facial nerve may be involved. On otoscopic examination, the tympanic membrane is often discolored (hyperemic), opaque and bulging outward with middle ear disease.

Idiopathic:

- **Idiopathic peripheral vestibular disease*** (p 931)**

Acute onset of peripheral vestibular signs with nystagmus (horizontal or rotary), head tilt (toward the side of the lesion), rolling and falling. No other neurological signs are seen. Clinical signs, while initially severe, are restricted to the vestibular system. Otoscopic examination, bulla radiographs and other advanced imaging studies (computed tomography (CT), magnetic resonance (MR) imaging) are normal. Signs usually improve dramatically in 1–2 weeks regardless of treatment.

Trauma:

- **Head trauma*** (p 932)**

Usually associated with an acute onset of clinical signs reflective of an intracranial problem. Signs present often include alterations in consciousness, paresis and cranial nerve abnormalities. Fresh blood from lacerations on or around the head, skull fractures, blood in the ear canals, and scleral hemorrhage may be clues to a previous traumatic incident.

Toxicity:

- **Toxins* (p 938)**

Metronidazole at high doses has been reported to result in ataxia as the initial clinical sign. Paresis is usually present, and seizures and cortical blindness may also be noted. **Bromethalin**

toxicosis may also result in ataxia in the early stages. Signs progress to paresis, depression, tremors, seizures and decerebrate posture. **Ivermectin** toxicosis has resulted in generalized ataxia, tremor, weakness, incoordination and miosis in a kitten. **Griseofulvin** therapy resulted in ataxia in a 12-week-old kitten. **Aminoglycosides**, administered either systemically or topically, may cause vestibular signs. Streptomycin and gentamicin have the most pronounced effects on the vestibular receptors, while neomycin, kanamycin and amikacin preferentially damage auditory receptors. **Chlorhexidine** solution used to clean the external ear may result in vestibular signs.

INTRODUCTION

MECHANISM?

Ataxia is an abnormality of movement wherein the animal does not move in a straight line when walking but rather sways or falls, usually from side to side.

Ataxia indicates a problem with unconscious, sensory proprioception.

Lack of unconscious, sensory proprioceptive information can also result in **dysmetria**, including **hypermetria** (“goose-stepping”; overflexing of the limbs when walking) and **hypometria** (failure to flex and extend the limb properly) resulting in a “stiff” appearance of limb movement, and tremor.

WHERE?

Disease of the cerebellum, central controlling centers for movement, or sensory pathways traveling from the spinal cord to the cerebellum are often affected.

Disease of the vestibular system may also result in ataxia and incoordination.

Diseases of the spinal cord can result in ataxia due to involvement of the spinocerebellar pathways.

WHAT?

Diseases of the intracranial nervous system resulting in ataxia often involve the cerebellum.

These include cerebellar hypoplasia (panleukopenia virus infection), hydrocephalus, storage disease, tumors, encephalitis and vascular-based diseases.

Diseases of the vestibular system include those affecting the central vestibular areas (developmental diseases, hydrocephalus, storage disease, tumors, encephalitis and vascular-based diseases) and peripheral vestibular areas (congenital vestibular disease, trauma, otitis media/interna, idiopathic vestibular disease and tumors).

Diseases of the spinal cord include compressive, degenerative, inflammatory, vascular, neoplastic, and congenital diseases (see “The Cat With Limb Weakness”).

DISEASES CAUSING ATAXIA WITHOUT WEAKNESS

CEREBELLAR HYPOPLASIA***

Classical signs

- Signs are present from the early prenatal period.
- Clinical signs usually remain unchanged or may improve during life.
- Coarse tremor that worsens when the cat moves in a goal-oriented fashion (intention tremor).
- Other signs include ataxia, hypermetria, menace deficits, head tilt and nystagmus.

Pathogenesis

Cerebellar hypoplasia results from **in utero or immediately postnatal infection with the panleukopenia virus** (parvovirus).

Infection of the fetus may occur when a pregnant queen is **vaccinated with a modified-live panleukopenia virus vaccination**.

This virus **destroys the external germinal layer of the cerebellum** and prevents the formation of the granular layer.

Some affected cats have a concurrent hydrocephalus and hydranencephaly.

Clinical signs

Clinical signs are present from the early prenatal period but are most apparent when the animal begins purposeful movement and attempts to walk.

Tremor accompanying the disease usually has a **slow frequency** (2–6 times/second) and **large amplitude (course tremor)**. The tremor **worsens** (increases in frequency or amplitude), **when the cat moves** in a goal-oriented way (e.g. bends down to eat), which is termed an intention tremor.

Other signs include **ataxia** (incoordination; swaying from side to side), **hypermetria** (“goose-stepping”; overflexing of the limbs when walking), **menace deficits** (with normal vision and pupillary light reflexes), **head tilt** and **nystagmus** (combination quick followed by slow movement of the eyes).

Clinical **signs** usually **remain static** or **improve with growth** as the cat compensates, causing the tremor to become less apparent.

Diagnosis

Antemortem testing for panleukopenia often results in negative findings.

Routine laboratory investigations are normal.

Definitive diagnosis is usually only obtained at **necropsy** and histopathological examination of the nervous tissue.

In some instances of cerebellar atrophy, a **smaller than normal cerebellum** may be seen on **magnetic resonance imaging** of the intracranial nervous system. This is most readily seen on the sagittal view.

Occasionally, inflammatory cells may be present in cerebrospinal fluid examination in cats with active panleukopenia viral infection. Cerebrospinal fluid with the other degenerative cerebellar conditions and with previous panleukopenia infection is usually normal.

Differential diagnosis

In this age of cat, other inflammatory central nervous system abnormalities such as **toxoplasmosis** infection are possible.

Congenital anatomical defects of the cerebellum may cause similar signs.

Trauma occurring at a young age may permanently damage the cerebellum producing similar signs.

Treatment

No treatment is currently helpful for cats affected with this disease.

Prognosis

Clinical signs associated with previous panleukopenia virus infection of the developing cerebellum usually remain static or improve with growth, causing the tremor to become less apparent.

Prevention

Do not vaccinate queens with modified live panleukopenia virus vaccine.

CEREBELLAR OR VESTIBULAR TUMOR***

Classical signs

- Signs usually begin in cats 5 years of age or older.
- Signs usually are progressive over weeks to months.
- Occasionally, clinical signs begin acutely.
- Intention tremor is often associated with other signs of cerebellar disease including ataxia, dysmetria, menace deficits, head tilt and nystagmus.

See main reference on page 821 for details (The Cat With Stupor or Coma).

Clinical signs

Clinical signs usually begin in **cats 5 years of age or older**.

Signs are usually **progressive over weeks to months**.

Occasionally, clinical signs begin acutely.

Intention tremor is often associated with other **signs of cerebellar disease** including ataxia (incoordination; swaying from side to side), dysmetria (“goose-stepping”; overflexing of the limbs when walking), **menace deficits** (with normal vision and pupillary light reflexes), **head tilt**, and **nystagmus** (combination quick followed by slow movement of the eyes).

Signs reflect either **primary nervous parenchymal damage** from the tumor or **secondary** pathophysiologic **sequelae** such as **hemorrhage and edema**.

Meningiomas are the **most common brain tumor** in cats and are usually histologically benign.

- Less-frequent tumors arise from astrocytes, oligodendrogliaocytes, ependymal cells and choroid plexus cells.
- Medulloblastoma is a rare primary brain tumor that involves the cerebellum.
- Neoplasia may also secondarily involve the brain via **metastasis** or via **direct extension** from extra-neural sites.

Tumors involving the inner ear may damage the **peripheral vestibular system**, resulting in **vestibular ataxia**, in which the cat leans, drifts, falls or rolls toward the side of the lesion and has a head tilt. Nystagmus may also be present. Occasionally tumors extend through the tympanic membrane and are evident during otoscopic examination, but this is rare. See page 845 “The Cat With a Head Tilt, Vestibular Ataxia or Nystagmus”.

Squamous cell carcinoma and adenocarcinoma are the most common tumors affecting the peripheral vestibular system.

Diagnosis

Routine laboratory data (e.g. hematology, biochemistry, urinalysis) are normal.

Diagnosis of a structural intracranial abnormality in the brain is most readily accomplished with **magnetic resonance (MR) imaging** or **computed tomography (CT)** of the brain.

- A **broad-based, extra-axial** (arising outside and pushing into the parenchyma) **contrast-enhancing**

mass on CT or MR imaging is found in most **instances of meningioma**.

- The CT and MR appearance of gliomas is varied and enhancement after contrast administration may not be present. As these tumors arise from brain parenchymal cells, they are **found within the neuroaxis (intra-axial)**.
- **Choroid plexus tumors** often **enhance markedly** after contrast administration because of the increased concentration of blood vessels within the tumor. Because of their association with the ventricular system, associated **hydrocephalus** is **common**.

Cerebrospinal fluid often has **increased protein concentration** but this finding is not pathognomonic for neoplasia.

Cerebrospinal fluid may have **evidence of inflammation** (increased nucleated cells and protein content). If CSF is the only assessment made, encephalitis may be erroneously diagnosed.

Skull radiographs or advanced imaging are necessary to **assess the middle and inner ear**. Abnormalities seen with these studies, however, are not always definitive for neoplasia, and tissue diagnosis at surgery is often necessary to accurate assessment. Destruction (lysis) of the bone of the bulla is more often associated with neoplasia as compared to inflammation.

Differential diagnosis

Congenital and inherited cerebellar diseases occur in younger animals.

Cerebrovascular, traumatic and inflammatory conditions can mimic the signs of a brain tumor.

Treatment

Corticosteroids (prednisolone 1–2 mg/kg q 12 h) may reduce peritumoral edema and improve clinical signs.

Surgical removal of primary brain tumors may be accomplished, especially with meningioma.

A well-encapsulated, firm whitish mass is most often encountered at surgery in cats. Cortical parenchyma is usually not infiltrated but rather compressed in cats, leaving indentations in the nervous tissue parenchyma after resection.

Radiation therapy (45–48 Gy) may control tumor growth of some brain tumors.

Treatment options of tumors of the ear include surgical resection/debulking, radiation and chemotherapies.

ENCEPHALITIS***

Classical signs

- Diffuse or multifocal neurological signs.
- Cerebellar signs such as intention tremor, ataxia, hypermetria, head tilt and nystagmus.
- Cervical pain can be present.
- Fever is an inconsistent finding.
- Clues of systemic inflammatory disease such as chorioretinitis are often present.
- Other signs of polysystemic disease such as coughing, vomiting or diarrhea may be present.

See main reference on page 859 for details (The Cat With Tremor or Twitching).

Clinical signs

Depression, inappetence or anorexia and weight loss are common.

Clinical signs often reflect multiple levels of neurological involvement. Neurological signs may indicate diffuse or multifocal disease and **often do not localize to a single area within the nervous system.**

Paresis, gait abnormalities, proprioceptive deficits, cranial nerve defects, depression and occasionally stupor or coma may occur depending on the areas of brain involved.

Signs such as intention tremor, cerebellar ataxia (incoordination and swaying from side to side), hypermetria, head tilt and nystagmus may occur with involvement of the cerebellum.

Cervical pain can be present.

Fever is an inconsistent finding.

Fundic examination is important to look for clues of systemic inflammatory disease as chorioretinitis, which is often present with diseases causing systematic infection.

Other systemic signs such as vomiting, coughing and diarrhea may be seen concurrently.

Diagnosis

Complete blood cell count may show evidence of systemic inflammation (e.g. leukocytosis).

Serum biochemical analysis may show evidence of systemic abnormalities if the disease diffusely affects the body (e.g. vasculitis) such as elevated globulin, CK, liver enzymes or creatinine.

Evaluation of titers for the infectious diseases often helps to rule in or rule out the diseases.

- Infectious agents causing brain disease include viral (**feline infectious peritonitis**), fungal (**cryptococcosis**, blastomycosis, histoplasmosis, coccidioidomycosis, aspergillosis), protozoal (**toxoplasmosis**, neosporosis), bacterial, rickettsial, and unclassified organisms (protothecosis).
- Involvement of the intracranial nervous system can occur with parasites such as *Cuterebra* larvae, **toxocara** and aberrant **heartworm** migration.

Cerebrospinal fluid analysis (CSF) will usually show evidence of **increased nucleated cells** and/or **elevated protein content**. Occasionally, CSF will be normal.

- Evidence of inflammation on CSF evaluation alone, however, is not specific for primary encephalitis as other CNS disease (e.g. **neoplasia**) **may result in a CSF pleocytosis** and protein increases.
- With feline infectious peritonitis (FIP), cerebrospinal fluid analysis may show a pleocytosis, with either **mononuclear** or non-lytic **neutrophils** as the predominant cell type and **elevated protein** concentration, often > 1 g/L (0.1 g/dl). High serum coronavirus titers are not diagnostic.
- With **toxoplasmosis**, cerebrospinal fluid frequently contains a pleocytosis, usually with mononuclear cells, and occasionally, eosinophils. Increasing IgG or a single positive IgM serum antibody titer is suggestive of active infection. Animals with **neurologic signs and positive IgM titers warrant treatment** for the disease.

With **cryptococcosis**, identification of the organism from cytological evaluation of samples such as CSF, nasal discharge and skin lesions supports the diagnosis.

A neutrophilic pleocytosis, and occasionally an eosinophilic pleocytosis, may be found on CSF analysis. If positive, detection of the cryptococcal capsular antigen in serum is usually diagnostic. Tissue biopsy and fungal culture or fungal culture of CSF may be more definitive in the diagnosis, as occasionally the serum titer is negative.

With parasites such as *Cuterebra* larvae, toxocara and aberrant heartworm migration, CSF may show inflammation with eosinophils in some instances.

Imaging studies (CT and MR) are helpful for defining structural lesions. **Multifocal, contrast-enhancing lesions** are usually seen. Occasionally, non-contrast-enhancing lesions are present, especially with toxoplasmosis.

IDIOPATHIC PERIPHERAL VESTIBULAR DISEASE***

Classical signs

- Signs can occur in any age but are commonly young to middle-aged animals.
- Acute-onset severe head tilts and nystagmus are most common.
- Cats often cannot stand initially and will continually roll.

See main reference on page 839 for details (The Cat With a Head Tilt, Vestibular Ataxia or Nystagmus).

Clinical signs

Clinical signs are of an acute peripheral vestibular disorder with nystagmus (horizontal or rotary), head tilt (toward the side of the lesion), rolling and falling.

No other neurological signs are seen.

Often these animals are initially so incapacitated that they are misdiagnosed with cerebrovascular accidents.

Clinical signs, while initially severe, will usually improve in 3–5 days. The nystagmus is the first sign to abate.

If Horner's syndrome or facial nerve paresis are also present, other differentials should be considered.

Disease occurrence may have a seasonal bias. Cats in the northeast United States are commonly affected in late summer and early fall.

Diagnosis

Otoscopic examination, bulla radiographs, and other advanced imaging studies (computed tomography (CT), magnetic resonance (MR) imaging) are normal.

Diagnosis is based on clinical signs and lack of evidence of other causes of peripheral vestibular disease on imaging.

Differential diagnosis

Differential diagnosis of peripheral vestibular disease includes otitis interna, middle ear polyps in cats, and neoplasia (squamous cell carcinoma of the middle ear). These diseases can be differentiated from idiopathic peripheral vestibular disease because lesions are evident via otoscopic examination of the ear canal and tympanic bulla and/or with imaging studies (radiographs, CT, MRI).

Treatment

No specific treatment has been shown effective.

Antihistamines (diphenhydramine at 0.5–1 mg/kg q 8 h) may help some animals.

Prognosis

Clinical signs of idiopathic vestibular disease usually improve dramatically in 1–2 weeks regardless of treatment.

The nystagmus usually resolves quickly (within the first few days).

Improvements in posture and walking occur within 5–7 days, whereas a mild head tilt may remain persistent.

While most animals compensate well, some may have episodic ataxia when performing tasks such as jumping up on furniture.

Recurrence is possible.

HEAD TRAUMA***

Classical signs

- Acute onset of signs following a traumatic event.
- Evidence of external trauma to the head and face such as facial lacerations, bleeding from the nose and mouth, bruising, retinal hemorrhage, or hemorrhage in the external ear canals.
- Cerebellar involvement may result in intention tremor, decerebellate rigidity, ataxia, hypermetria, head tilt and nystagmus.

See main reference on page 823 for details (The Cat With Stupor or Coma).

Clinical signs

Exogenous injury to the brain occurs most commonly from automobile trauma, although gunshot wounds and falls may also occur.

Cerebellar involvement may result in **intention tremor, decerebellate rigidity** (extension of all four limbs and the trunk), ataxia, hypermetria, head tilt and nystagmus.

Signs usually begin acutely after trauma.

Intracranial signs most commonly seen include **stupor and coma, paresis and gait abnormalities** and cranial nerve deficits.

Evidence of **external trauma to the head and face such as facial lacerations**, bleeding from the nose and mouth, bruising or **hemorrhage in the external ear canals** may provide clues to the traumatic etiology.

- Occasionally, some animals that are incoordinated may fall and injure themselves secondarily, but this can usually be differentiated with good history taking.

Diagnosis

The diagnosis of trauma is usually straightforward when the trauma is witnessed.

In some instances, when animals are presented with an acute onset of neurological signs and an unknown history, examining for external signs of trauma such as lacerations or skull fractures is important.

- Evaluating the retinas and external ear canals for acute hemorrhage may also provide clues to the diagnosis.

Advanced imaging studies such as CT or MR imaging are useful, primarily for determining structural damage to the brain.

HYDROCEPHALUS**

Classical signs

- Dome-shaped or bossed appearance to the head or persistent fontanelles in a young cat.
- Seizures, poor learning ability, behavior changes, paresis, cranial nerve deficits and changes in consciousness.

See main reference on page 826 for details (The Cat With Stupor or Coma).

Clinical signs

In young cats prior to ossification of the cranial sutures, hydrocephalus may contribute to abnormalities of skull development such as a thinning of the bone structure, a **dome-shaped or bossed appearance** to the head or persistent fontanelles.

Clinical signs of hydrocephalus reflect the anatomical level of disease involvement.

Supratentorial, vestibular and cerebellar signs are most common.

As the supratentorial structures are often involved with hydrocephalus, **alterations in awareness and cognition are common.**

Many animals affected congenitally may appear to be **less intelligent** than normal.

Behavioral changes, paresis, cranial nerve deficits and changes in consciousness may occur.

Circling, paresis and seizure may also be seen.

Severity of clinical signs is not dependent upon the degree of ventricular dilation, but rather on a host of concurrent abnormalities including the underlying disease process, associated intracranial pressure changes, intraventricular hemorrhage, and the acuity of ventricular obstruction.

There are no pathognomonic clinical signs for acquired hydrocephalus in adult animals.

Correlation of degree of ventricular enlargement and clinical signs is poor.

Diagnosis

Routine laboratory data (e.g. hematology, biochemistry, urinalysis) are normal.

Historical, invasive techniques for diagnosis of hydrocephalus such as pneumo- or contrast ventriculography have been replaced by non-invasive diagnostic modalities.

Survey radiographs may suggest the presence of hydrocephalus, however they are usually not helpful for definitive diagnosis. Findings associated with **congenital hydrocephalus** include loss of gyral striations, separation of cranial sutures (diastasis) and **persistent fontanelles**. If hydrocephalus is acquired **after the skull has formed, abnormalities are rarely encountered**.

Electroencephalography has been used to diagnose hydrocephalus, primarily prior to advanced imaging. Classically, **slow-frequency, high-voltage** (amplitude) activity is noted. This pattern, however, can be seen with **other encephalopathies** that destroy cortical parenchyma. Because of this, EEG is rarely used as the sole means of diagnosing hydrocephalus.

Ultrasound can be used to diagnosis hydrocephalus.

- This is most readily accomplished **when a fontanelle is present** providing an “acoustic window” as ultrasound waves do not usually penetrate the skull well enough.
- If the bone is intact, a craniotomy defect can be created.
- For imaging of the lateral and third ventricles, the bregmatic fontanelle may be used.
- Often, ultrasound can be performed in awake cats as a screening test to determine ventriculomegaly.
- Depending upon the size of the fontanelle, the **lateral and third ventricles** as well as the **mesencephalic aqueduct** are usually easily identified.

Computed tomography (CT), as a non-invasive intracranial imaging modality, is often useful in defining ventricular size.

Magnetic resonance (MR) imaging also affords evaluation of the ventricular system. This modality pro-

vides for better parenchyma resolution than CT, and is especially useful for evaluation of the infratentorial structures.

Diffuse ventricular enlargement suggests congenital ventricular dilation or obstruction at the level of the lateral apertures or foramen magnum. **Focal ventricular enlargement** suggests **focal obstruction** or **parenchymal cell loss**.

Animals with an **asymmetric appearance** of the ventricles should be critically evaluated for **focal obstruction** of the ventricular system due to **mass effect**.

CONGENITAL VESTIBULAR DISEASE**

Classical signs

- Signs are usually present from the time the animal begins to walk.
- Head tilt and cat leans, drifts, falls or rolls to side of head tilt.
- \pm Deafness.

Pathogenesis

Congenital abnormality of the vestibular system usually involves the **peripheral vestibular system**.

Histologic lesions are often not found.

Clinical signs

Siamese and Burmese cats are often affected.

Clinical signs are usually present from the time the animal begins to walk or begin early in life.

Signs are usually referable to **unilateral vestibular disease**; bilateral disease is less common.

The most common clinical signs are **head tilt and vestibular ataxia** (cat leans, drifts, falls or rolls to side of head tilt).

In some cases deafness is also present.

With bilateral disease, there is no head tilt but the head moves from side to side in exaggerated motions. Normal physiological nystagmus (movement of eyes side to side with movement of head) is absent.

Clinical signs are non-progressive and usually **decrease in severity with time**, but remain life-long.

Diagnosis

Diagnosis is **based primarily upon clinical signs**.

Skull radiographs, advanced imaging studies (MR or CT), CSF analysis and otoscopic examinations are normal.

Brain stem auditory-evoked potential testing may be abnormal if there are associated problems with hearing.

Differential diagnosis

Otitis interna should be evaluated for.

Other inflammatory processes involving the vestibular receptors may produce similar signs.

Trauma to the vestibular receptors is possible.

Treatment

No treatment is helpful.

Prognosis

Clinical signs may remain persistent or improve throughout life.

INHERITED CEREBELLAR DISEASES**

Classical signs

- Signs usually begin or are present in cats less than 1 year of age.
- Signs usually are slowly progressive or remain unchanged.
- Signs include coarse tremor, hypermetria, ataxia, intention tremor and menace deficits.

Pathogenesis

Cerebellar degeneration is usually an inherited disease.

A **hereditary cerebellar degeneration** has been described in Japan in cats. An autosomal recessive mode of inheritance was presumed.

Cerebellar degeneration with neuroaxonal dystrophy has been reported in domestic tri-colored cats. This is inherited as an autosomal-recessive trait.

Clinical signs

Clinical signs usually begin between **3–12 months of age**.

Cerebellar disease usually results in a **coarse tremor** that worsens (increases in frequency or amplitude) when the animal moves in a goal-oriented fashion (intention tremor).

Other signs of cerebellar disease that accompany cerebellar tremor include **ataxia (incoordination; swaying from side to side)**, dysmetria (“**goose-stepping**”; overflexing of the limbs when walking), **menace deficits** (with normal vision and pupillary light reflexes), **head tilt**, and **nystagmus** (combination quick followed by slow movement of the eyes).

An hereditary cerebellar degeneration is described in **Japan** in cats with signs beginning around 7–8 weeks of age.

- Signs include head tremor along with ataxia, dysmetria and intention tremor. An autosomal recessive mode of inheritance was presumed.

Cerebellar degeneration with **neuroaxonal dystrophy** in domestic **tricolored cats** results in **head tremors and shaking**. Clinical signs begin at 5–6 weeks of age and **progress to ataxia and hypermetria**. Affected kittens have a **lilac color** that **darkens with age**.

- A similar but separate neuroaxonal dystrophy has been described in cats of various colors. Clinical signs begin at 7–9 months of age and include ataxia with paraparesis.

Spongiform encephalopathy in Egyptian Mau cats results in ataxia and hypermetria, and it is presumed inherited. Clinical signs begin at 7 weeks of age.

- Another spongiform encephalopathy has been reported in older Egyptian Mau cats in the United Kingdom. Clinical signs include muscle tremors, ataxia, dilated unresponsive pupils, jaw champing, salivation and behavior abnormalities. Signs may progress to severe ataxia and hypermetria.

Diagnosis

Antemortem testing for these diseases often results in negative or normal findings.

Routine laboratory investigations (CBC, serum biochemical analysis, urinalysis) are normal.

Definitive diagnosis is often rendered only at **necropsy** and histopathological examination of the nervous tissue.

In some instances of cerebellar atrophy, a **smaller than normal cerebellum** may be seen on **magnetic resonance imaging** of the intracranial nervous system. This is most readily seen on the sagittal view.

Cerebrospinal fluid with these degenerative cerebellar conditions is **normal**.

With hereditary cerebellar degeneration described in Japan there is marked loss of Purkinje cells on histological evaluation of the cerebellum.

Neuroaxonal dystrophy is associated with pathologic changes in the brain, brain stem, cerebellum and spinal cord.

Differential diagnosis

In this age cat, other **inflammatory** central nervous system abnormalities, such as **toxoplasmosis** infection should be considered. CSF analysis and serologic testing help to differentiate it from inherited cerebellar degeneration.

Congenital anatomical defects of the cerebellum may be present with similar signs.

Trauma occurring at a young age may permanently damage the cerebellum and result in similar signs.

Treatment

No treatment is currently helpful for affected cats.

Prognosis

Clinical signs associated with degenerative cerebellar diseases progressively worsen.

Animals are commonly euthanized due to the progressive incapacitation.

Prevention

Do not breed cats affected that have produced kittens with a presumed genetic or congenital cerebellar disease.

STORAGE DISEASES**

Classical signs

- Signs usually begin or are present in cats less than 1 year of age.
- Signs usually are slowly progressive or remain unchanged.
- Signs include coarse tremor, hypermetria, ataxia, intention tremor and menace deficits.

Pathogenesis

Storage diseases result from inherited (or less commonly, acquired) intracellular metabolic derangements that result in abnormal metabolism of cellular products.

Cellular products accumulate and afferent neuronal cells physiologically or mechanically, resulting in cellular dysfunction, and hence, clinical signs.

Although signs of storage diseases are predominately referable to the brain and especially the cerebellum, some of the storage diseases also affect the peripheral nervous system.

Examples include **gangliosidosis**, **sphingomyelinosis**, **globoid cell leukodystrophy**, and **mannosidosis**.

Clinical signs

Clinical signs usually begin between **3–12 months of age**.

Cerebellar disease usually results in a **coarse tremor** that worsens (increases in frequency or amplitude) when the animal moves in a goal-oriented fashion (**intention tremor**).

Other signs of cerebellar disease that accompany cerebellar tremor include **ataxia** (incoordination; swaying from side to side), **dysmetria** (“goose-stepping”; overflexing of the limbs when walking), **menace deficits** (with normal vision and pupillary light reflexes), **head**

tilt, and **nystagmus** (combination quick followed by slow movement of the eyes).

In cats with **sphingomyelinosis (Niemann–Pick type C disease)** clinical **signs begin early in life** (< 6 months) and progress to **ataxia and hypermetria**, absent menace responses, and occasionally positional nystagmus. **Death usually occurs by 8–10 months of age.**

- Similar clinical signs have been reported in a case of **type IV glycogen storage disease** in a Norwegian Forest cat.

Niemann–Pick type A disease occurs in **Siamese and Balinese** cats. **Head tremor, head bobbing, and dysmetria** begin at 3–4 months of age. Clinical signs progress to **ataxia and paresis, worse in the pelvic limbs.**

- An associated demyelinating polyneuropathy was found in one family of affected cats.

Diagnosis

Antemortem testing for these diseases often results in negative or normal findings.

Routine laboratory investigations (CBC, serum biochemical analysis, urinalysis) are normal.

Definitive diagnosis is often only obtained at **necropsy** and histopathological examination of the nervous tissue.

In some instances of cerebellar atrophy, a **smaller than normal cerebellum** may be seen on **magnetic resonance imaging** of the intracranial nervous system. This is most readily seen on the sagittal view.

Cerebrospinal fluid with these degenerative cerebellar conditions is **normal**.

In cats with sphingomyelinosis (Niemann–Pick type C disease) cerebellar atrophy, **Purkinje cell loss**, and **neuroaxonal dystrophy** are the **predominant pathological changes**.

Differential diagnosis

In this age cat, other **inflammatory** central nervous system abnormalities, such as **toxoplasmosis** infection should be considered. CSF analysis and serologic testing help to differentiate it from inherited cerebellar degeneration.

Congenital anatomical defects of the cerebellum may be present with similar signs.

Trauma occurring at a young age may permanently damage the cerebellum and result in similar signs.

Treatment

No treatment is currently helpful for affected cats.

Prognosis

Clinical signs associated with **storage diseases usually progressively worsen**.

Animals are commonly euthanized due to the progressive incapacitation.

Prevention

Do not breed cats affected that have produced kittens with a presumed genetic or congenital cerebellar disease.

OTITIS MEDIA/INTERNA**

Classical signs

- Signs can occur in any age.
- Head tilt and nystagmus are most common.
- Discharge from the ear, abnormal odors and ear pain may be present.
- Polypoid masses may be seen in the oropharynx or ear canal.

See main reference on page 836 for details (The Cat With a Head Tilt, Vestibular Ataxia or Nystagmus).

Clinical signs

Clinical signs may reflect either primary **ear, vestibular or auditory dysfunction**.

A **painful external ear** and/or pain on opening the mouth are often present.

Head tilt and nystagmus are the most common vestibular signs. **Vestibular ataxia** (cat leans, drifts,

falls or rolls to side of head tilt) may occur in more severe cases.

The **facial nerve** may be involved concurrently resulting in abnormalities of facial expression.

Abnormal odors or discharge from the ear canal may be present.

Oropharyngeal exam occasionally reveals an ear polyp.

Diagnosis

Otoscopic examination should be used to examine the tympanic membrane. This may be difficult in animals with severe otitis externa prior to cleansing.

- The tympanic membrane is often discolored (hyperemic), opaque and bulging outward with middle ear disease. Clear to yellow fluid may be seen behind the membrane.

Diagnosis may also be supported by abnormalities on **bullae radiographs or advanced imaging studies (MRI or CT)**.

- Often the bullae are fluid filled on either skull radiographs or advanced imaging studies.

Definitive diagnosis is made through **culture of the organism** via a myringotomy or at surgical exploration.

VASCULAR DISEASES*

Classical signs

- Acute onset of cerebellar signs.
- Head tilt, nystagmus, ataxia, hypermetria, and other cerebellar signs.

Pathogenesis

Injury to cerebellar tissue can occur as a result of **thrombosis or hemorrhage**.

Diseases that predispose to **hypercoagulability or vasculitis** predispose to vascular thrombosis.

Hemorrhage can occur as a result of **thrombocytopenia or coagulation abnormalities**.

Thrombosis leads to ischemia and cellular death.

A cat with polycythemia was presented for ataxia, possibly due to increases in serum viscosity.

Clinical signs

Clinical signs are usually acute in onset.

Head tilt, cerebellar ataxia (incoordination, swaying from side to side), **hypermetria, intention tremor and nystagmus** are possible.

Menace deficits with normal vision and papillary light reflexes may also be present.

Diagnosis

Routine laboratory evaluations (CBC, serum biochemical analysis, urinalysis) may show abnormalities in platelets or red blood cell mass or evidence of underlying systemic disease.

Coagulation studies and bleeding time assessment are useful in determining the cat's coagulation ability.

Advanced imaging studies may show evidence of hemorrhage or infarction in the cerebellum.

CSF analysis may show evidence of hemorrhage, however, should be performed with caution or avoided in animals with coagulation or platelet problems.

Differential diagnosis

Rule out other inflammatory, neoplastic and traumatic causes of cerebellar disease.

Treatment

Treatment should be directed at the underlying coagulation or bleeding disorder abnormality.

Rarely, if a hematoma is present, surgical removal may be helpful.

Prognosis

Prognosis depends upon the ability to treat the underlying disease process and the degree of cerebellar damage.

THIAMINE DEFICIENCY*

Classical signs

- Initially, lethargy, inappetence and ataxia.
- Later signs include weakness, ventral flexion of the neck, dilated pupils, stupor and coma.

See main reference on page 848 for details (The Cat With a Head Tilt, Vestibular Ataxia or Nystagmus).

Pathogenesis

Occurs in **anorexic cats** or cats that are **fed all-fish diets** containing thiaminase.

This deficiency results in polioencephalomalacia of the oculomotor and vestibular nuclei, the caudal colliculus and the lateral geniculate body.

Clinical signs

Early non-specific signs are **typically lethargy and inappetence**.

The earliest localizing sign is **bilateral vestibular ataxia**, which appears as **an abnormal broad-based stance**, loss of balance and vertigo.

There is weakness and an **inability or reluctance to walk**. The cat sits **crouched with ventral flexion of the neck**.

Pupils are dilated and non-responsive or poorly responsive to light reflexes.

If untreated, signs **progress to semi-coma**, persistent vocalization, opisthotonos, and death.

Episodes of spastic opisthotonos or ventroflexion of the neck and generalized muscle spasm may occur especially when the cat is lifted or stressed. They may be interpreted as seizures, but true seizure activity rarely occurs.

Diagnosis

No antemortem diagnostic test is available.

Diagnosis is based on **clinical signs** and **rapid response to thiamine**.

TOXINS*

Classical signs

- Metronidazole toxicosis results in ataxia, paresis, seizures and cortical blindness.
- Bromethalin toxicosis in the early stages may also result in ataxia. Signs progress to paresis, depression, tremors, seizures and decerebrate posture.
- Ivermectin toxicosis has resulted in generalized ataxia, tremor, weakness, incoordination, and miosis in a kitten.
- Griseofulvin therapy resulted in ataxia in a 12-week-old kitten.
- Aminoglycosides, administered either systemically or topically, may cause vestibular signs including ataxia.
- Chlorhexidine solution used to clean the external ear may result in vestibular signs including ataxia.

Pathogenesis

Metronidazole toxicosis has been reported to result in ataxia in cats.

- Usually, this is associated with high doses of the drug.
- As metronidazole is metabolized by the liver, however, toxic serum levels can occur with appropriate doses in animals with liver dysfunction.

Bromethalin toxicity results in vacuolization of the nervous system, most likely due to a lack of intracellular energy.

Clinical signs

Ataxia is usually the initial clinical sign of **metronidazole toxicity**.

- **Paresis** is usually present, and **seizures** and **cortical blindness** may also be noted.
- These signs in association with metronidazole administration should raise concern for toxicity.

The early stages of **bromethalin toxicosis** may also result in ataxia.

- Signs progress to paresis, depression, tremors, seizures and decerebrate posture.

Ivermectin toxicosis has resulted in generalized ataxia, tremor, weakness, incoordination and miosis in a kitten.

Griseofulvin therapy resulted in ataxia in a 12-week-old kitten.

- Clinical signs remained static up to 4 months after the initial presentation.

Aminoglycosides, administered either systemically or topically, may cause vestibular signs including vestibular ataxia (cat leans, drifts, falls or rolls to side of the head tilt), head tilt and nystagmus.

- Streptomycin and gentamicin have the most pronounced effects on the vestibular receptors, while neomycin, kanamycin and amikacin preferentially damage auditory receptors.

Chlorhexidine solution used to clean the external ear may result in vestibular signs.

Diagnosis

Serum concentrations of metronidazole will be in the toxic range if measured soon after clinical signs begin.

- If there is a delay in collecting blood for drug concentrations after the initiation of clinical signs, serum concentrations of metronidazole may decrease into the normal range even as the clinical signs remain persistent.

Diagnosis of other toxicities is supported by a history of exposure.

Differential diagnosis

Other diseases causing signs of vestibular disease include otitis interna, middle ear polyps in cats, and neoplasia (squamous cell carcinoma of the middle ear). These can usually be differentiated from toxicity on the basis of history, otoscopic examination and imaging of the bulla.

Treatment

There is no specific treatment for metronidazole toxicity.

- Discontinuation of the drug is imperative. A complete recovery is possible.

No specific treatment is available for the other toxicities.

Prognosis

With metronidazole toxicity, a complete recovery is possible after discontinuation of the drug if the signs are not severe.

Prevention

Avoid exposure to these products.

IDIOPATHIC ENCEPHALOPATHY*

Classical signs

- Ataxia, paresis, and “head shaking” in young cats up to 3 years old in the UK.
- Ataxia of the pelvic limbs was the initial sign.

Pathogenesis

Pathogenesis is unknown, although a viral etiology was suggested but not proven.

Wallerian degeneration was noted primarily involving the spinocerebellar pathways and the ventral funiculus of the spinal cord.

Clinical signs

An encephalomyelopathy of young cats reported in the United Kingdom had clinical signs of ataxia, paresis and “head shaking”.

Cats 3–12 months old were affected, however, the disease was seen in cats up to 3 years of age.

Ataxia of the pelvic limbs was the initial clinical sign noted.

Diagnosis

Diagnosis was made at necropsy.

Differential diagnosis

Diseases causing peripheral vestibular disease should be considered including otitis interna and middle ear polyps.

Treatment

No treatment was attempted.

44. The cat with generalized weakness

*Rodney S Bagley, Jacquie Rand, Terry King and
Fiona Campbell*

KEY SIGNS

- Weakness.
- Inability or reluctance to walk or jump.
- Stiff, stilted gait.
- Ventroflexion of the neck.

MECHANISM?

- Diffuse loss of muscle strength results in generalized weakness. Diseases of the peripheral nervous system, neuromuscular junction and muscle often result in generalized weakness. Systemic diseases affecting metabolism of or perfusion to, the muscles may also result in weakness.

WHERE?

- Peripheral nervous system, neuromuscular junction and muscle.

WHAT?

- Diseases include the peripheral neuropathies, neuromuscular junctionopathies (myasthenia gravis) and myopathies. One of the most common causes of weakness is hypokalemic myopathy.

QUICK REFERENCE SUMMARY

Diseases causing generalized weakness

DEGENERATIVE

- Degenerative neuropathies (p 963)

Weakness with decreased to absent spinal reflexes. Dropped hock appearance in young Birman cats, beginning 8–10 weeks of age. Storage disease may be associated with neuropathy. These diseases are often breed-specific with clinical signs beginning in cats less than 1 year of age.

- Degenerative motor neuronopathies (p 964)

Progressive weakness and muscle atrophy in adult cats, decreased to absent spinal reflexes, tremor especially of head and tongue, cervical ventroflexion and dysphagia.

continued

continued

- **Degenerative myopathies (X-linked muscular dystrophy, hereditary myopathy, Nemaline rod myopathy) (p 964)**

Any breed may be affected; inherited myopathy occurs in Devon Rex. Signs begin 2–24 months of age, weakness and reduced activity, stiff, choppy gait, increase in muscle mass and hypertrophy of the tongue (x-linked muscular dystrophy), ventral flexion of neck and dorsal protusion of scapula (hereditary myopathy of Devon Rex).

METABOLIC

- **Hypokalemic myopathy*** (p 945)**

Typically older cats or Burmese < 1 year of age. Signs include weakness, inability or reluctance to walk or jump, stiff, stilted gait, neck ventroflexion and sensitivity to palpation of larger muscle groups.

- **Diabetic neuropathy** (p 948)**

Often presents as a “dropped-hock” appearance in older cats with clinical signs of diabetes (polyuria, polydipsia, weight loss), subtle generalized weakness, reduced activity, difficulty jumping and some cats have a classic plantigrade stance.

- **Primary hyperoxaluria (p 967)**

Uncommon clinically in cats. Domestic short-hair cats 5–9 months old. Generalized weakness, with or without concurrent signs of renal failure.

- **Polymyopathy* (p 961)**

Signs include ventral flexion of the neck, apparent muscle pain, muscle weakness and a stiff gait. Age of onset varies from 3 months to 13 years and most are domestic short- or long-haired cats.

- **Hyperthyroidism* (p 960)**

Abnormal systemic metabolism affects muscle or nerve function. Concurrent hypokalemia is common. Signs may include weakness, ventral neck flexion and reduced physical activity. Typical signs of hyperthyroidism are weight loss, polyphagia, irritability or restlessness.

- **Hyperlipidemia (p 968)**

Lipid granulomas may compress the peripheral nerve. Typical signs include hyperlipidemia and lipemia retinalis in association with peripheral neuropathies involving individual peripheral, cranial or sympathetic nerves.

- **Hypernatremic myopathy (p 968)**

Rare disease with signs similar to hypokalemic myopathy. Ventral neck flexion, weakness, reduced physical activity and a “dropped-hock” appearance may occur.

- **Hypocalcemia (p 962)**

Most often occurs after thyroidectomy. Muscle weakness, tetany and tremors are typical. Preparturient hypocalcemia presents as anorexia, lethargy, trembling, muscle twitching and weakness.

- **Hypoglycemia* (p 956)**

Most often associated with insulin overdose in diabetic cats, but also rarely caused by an insulinoma in older cats. Signs include trembling, weakness, dilated pupils, reduced alertness, and if severe, seizures progressing to coma.

- **Reduced tissue oxygenation*** (p @)

Any cause of substantially reduced tissue oxygenation will cause weakness. Examples include severe anemia, methemoglobinemia associated with acetaminophen (paracetamol) toxicity, cardiac disease, hydrothorax including pyothorax and chylothorax, and severe bronchopulmonary disease or obstructive upper respiratory disease.

NUTRITIONAL

- **Thiamine deficiency*** (p @)

Decreased thiamine can result in brain stem disease in cats. Clinical signs initially begin with lethargy, inappetence and reluctance to walk. Later there is vestibular ataxia and episodes of spastic ventroflexion of the neck or opisthotonos, dilated pupils, stupor and coma.

INFECTIOUS

- **Acute sepsis** (p @)

Toxemia and reduced tissue oxygenation from acute bacterial sepsis may cause weakness and depression, resulting from bacteremias via the uterus (pyometritis), thorax (pyothorax), abdomen (peritonitis), skin (subcutaneous abscess). Pyrexia or hypothermia may be present. Signs referable to the infection site (dyspnea, vaginal discharge or uterine distention abdominal guarding, skin abscess) are often evident.

- **Toxoplasmosis*** (p @)

Protozoan organism that commonly affects the muscle or peripheral nerve. Most cats are asymptomatic. Signs are most severe in cats under 1 year of age and especially in young kittens. They include lethargy, anorexia, dyspnea, icterus, uveitis, retinal hemorrhage and central nervous system signs. Weakness or stiffness may occur with signs of spinal cord, peripheral nerve or muscle involvement.

- **Feline immunodeficiency virus** (p @)

A subclinical myopathy has recently been described. Diagnosis is based on a positive FIV antibody test and inflammatory changes on muscle biopsy, in the absence of *Toxoplasma gondii* organisms. Some cats had elevated CK and EMG abnormalities.

Inflammatory:

- **Myasthenia gravis*** (p @)

Typically adult cats or Siamese < 1 year of age. Signs include generalized weakness induced by movement, a stiff, stilted gait prior to collapse, ventral neck flexion and a decreased palpebral reflex.

- **Polyneuritis** (p @)

A rare cause of weakness with decreased spinal reflexes and conscious proprioceptive deficits.

- **Polymyositis*** (p @)

Primary inflammation of the muscles resulting in loss of muscle strength and neck ventroflexion.

Idiopathic:

- **Idiopathic peripheral neuropathy*** (p @)

A primary neuropathy without a definable cause. Signs include marked weakness with conscious proprioceptive deficits and decreased spinal reflexes. Lower motor neuron tetraparesis is the predominant sign. Signs are similar to dogs with polyradiculoneuropathy (Coon Hound paralysis).

continued

continued

- **Chronic relapsing polyneuropathy* (p 966)**

Peripheral neuropathy of cats which has no definitive cause. Marked weakness with decreased spinal reflexes and conscious proprioception. Signs similar to polyradiculitis neuropathy (Coon Hound paralysis) but cats recover then relapse months later.

- **Myotonia (p 967)**

A disease associated with excessive muscle contraction. Signs include stiffness and muscle spasm, short, stilted gait and increased muscle size.

- **Dysautonomia* (p 961)**

A disease primarily seen in younger cats (< 3 years) in Britain. Clinical signs are often acute in onset and reflect autonomic system dysfunction. They include depression, anorexia, dilated pupils, megacolon, constipation, xerostomia, keratoconjunctivitis sicca, prolapsed third eyelids, bradycardia, loss of anal reflex, incontinence and weakness.

TOXICITY

- **Organophosphate toxicity** (p 947)**

Toxicity usually occurs from misuse of flea and tick products and is associated with muscle weakness. Signs include acute onset of miosis, salivation, urination, defecation and muscle weakness. Rarely, persistent weakness occurs without associated autonomic signs. Cats may attempt to walk a few steps, then collapse in sternal recumbency mimicking cataplexy/narcolepsy.

- **Snakebite envenomation from Australian snakes** (p 950)**

Australian snake venoms are predominately neurotoxic and usually strongly coagulant. Usually there is no local reaction at the site of venom injection. Generalized muscle weakness and dilated pupils that are poorly responsive to light are features. Complete flaccid paralysis is a common finding. Vomiting and rapid respiration are present in 30% of cases. Excessive bleeding from venepuncture sites may be evident. Hypothermia is a poor prognostic sign.

- **Snakebite envenomation from USA snakes** (p 949)**

Coral snake envenomation is most often seen in the southeastern US. Clinical signs are of a progressive flaccid paralysis. Palpebral reflexes may be diminished, as is rectal temperature. Recovery rates have been good in a small number of reported cats.

- **Tick toxicity** (p 953)**

In Australia, toxin from the *Ixodes* tick affects muscle and nerve transmission and causes acute onset of flaccid paralysis, beginning in the hindlimbs and ascending and acute onset of dyspnea. In North America, *Dermacentor* and *Argas* ticks may also cause paralysis.

- **Red-back spider envenomation (*Latrodectus mactans hasselti*; Australia) (p 974)**

Envenomation occurs from the bite of the female red-back spider and often there is moderate to severe pain, erythema, edema and localized swelling at the bite site. Venom causes depletion of acetylcholine reserves at motor nerve endings, which may result in a patchy paralysis of voluntary muscle. The spider is found Australia-wide, avoiding only the hottest desert habitats and cold alpine altitudes.

- **Ciguatoxin intoxication (p 971)**

Signs begin within 3–6 hours of ingestion of a toxic meal of reef fish (toxin found in large carnivorous fish species). Toxins affect neuromuscular transmission and hindleg paresis and vomiting are the most prominent. Cardiovascular shock and/or respiratory distress may precede coma and death within 24 hours of ingestion.

- Tetrodotoxin intoxication (p 973)

Tetrodotoxin is produced by *Vibrio* bacteria in the intestines of marine fish including toadfish, pufferfish, newts and the blue-ringed octopus and accumulates in tissues. The toxins affect neuromuscular transmission. Signs begin 10–40 minutes after ingestion. Initial signs are gastrointestinal—drooling, vomiting and diarrhea. Neuromuscular signs follow with weakness and ataxia progressing to flaccid hindlimb paralysis. Pupillary dilation is usually a feature. With severe toxicity, cardiovascular shock and labored respiration often precede convulsions and death within hours.

INTRODUCTION

MECHANISM?

Loss of muscle strength causes generalized weakness. The gait may have a stiff, stilted appearance. Loss of cervical muscle strength results in an inability to hold the head up, which appears as ventroflexion of the neck, and is a common sign of weakness in cats.

WHERE?

Disease either of the peripheral nervous system, neuromuscular junction and/or muscle often results in generalized weakness.

Systemic diseases affecting metabolism or perfusion to the muscles may also result in weakness.

WHAT?

Diseases include the peripheral neuropathies, neuromuscular junctionopathies (myasthenia gravis) and myopathies. The most common cause of generalized weakness is hypokalemic myopathy. In some geographic locations, tick toxicity and snakebite are relatively common.

Hypoglycemia from an insulin overdose is a relatively common cause of metabolic weakness. Causes of reduced muscle oxygenation include severe anemia, methemoglobinemia associated with acetaminophen (paracetamol) toxicity, cardiac disease, hydrothorax including pyothorax and chylothorax, and severe bronchopulmonary disease or obstructive upper respiratory disease. Most of these causes of weakness have other prominent signs such as pale or cyanotic mucous membranes, dyspnea or heart murmur.

An evaluation for underlying metabolic disease is imperative in determining the cause of weakness.

Accurate diagnosis often requires evaluation with electrodiagnostics, and muscle and nerve biopsy.

Fibrillation potentials, positive sharp waves, and prolonged insertional activity are abnormal electromyographic findings, and occur when there is myocyte inflammation and abnormal membrane electrical activity. This occurs when there is muscle inflammation, degeneration or denervation.

DISEASES CAUSING GENERALIZED WEAKNESS

HYPOKALEMIC MYOPATHY***

Classical signs

- Aged cats or Burmese < 1 year.
- Ventral neck flexion.
- Stiff, stilted gait.
- Reluctance to walk or jump and physical inactivity.
- +/- Sensitivity to palpation of larger muscle groups.

See main reference on page 893 for details (The Cat With Neck Ventroflexion).

Pathogenesis

Potassium is important in maintaining normal muscle cell membrane potentials.

Potassium depletion can result in alterations in muscle cell membrane potentials, muscle cell glycogen content and synthesis, and blood flow to muscle.

Hypokalemia results in hyperpolarization of muscle cell membranes which then require greater stimulus for depolarization, leading to generalized muscle weakness.

Hypokalemia occurs when the **dietary intake is insufficient to replace urinary and fecal loss**.

A major contributing factor to hypokalemia in **older cats** is the inability of the kidney to conserve potassium.

Acidification of diets to prevent struvite urolithiasis increases renal and fecal potassium loss.

Diets deficient in potassium may induce signs. Clinical signs occurred in one group of cats fed a **vegetarian diet**.

Burmese cats have an **inherited hypokalemic myopathy** producing signs of periodic muscle weakness, with signs first evident **before 12 months of age**, usually between 4–12 weeks.

Clinical signs

Signalment is typically **aged cats > 8 years** or **young Burmese < 1 year** (usually 2–6 months).

Typically there is a history of **acute onset of weakness**. However, decreased activity and inappetence are often present for weeks to months prior to presentation.

Clinical signs include **ventral neck flexion, stiff, stilted gait** and a reluctance to walk or jump. Typically, weak cats do not walk far, but soon sit or lie, flopping down, instead of carefully sitting as normal cats do. Sensitivity to palpation of larger muscle groups may be noticed.

Dyspnea occurs when the potassium is very low (2.0–2.5 mmol/L), because of weakness of the respiratory muscles. It may occur after **fluid administration** because volume dilution and increased urinary potassium loss induced by diuresis may lead to further worsening of the hypokalemia.

Young Burmese cats are susceptible to this disease, and potassium depletion may have played a role in the previously described myopathy of Burmese cats. Transient episodes of weakness may occur beginning between 2–12 months of age.

Diagnosis

Diagnosis is made by finding decreased serum potassium concentrations (usually < 3.5 mmol/L) in association with clinical signs. The severity of signs varies between cats when potassium is 2.5–3.5 mmol/L. Below 2.5 mmol/L and especially below **2.0 mmol/L, signs are life threatening**, with death occurring from **respiratory muscle failure**.

Serum creatine kinase (CK) may be elevated reflecting the myopathy associated with hypokalemia.

Electrodiagnostic evaluation is rarely performed. Abnormalities that may be found include increased insertional activity, fibrillation potentials and positive sharp waves and some bizarre high-frequency discharges.

Muscle biopsies often have minimal change present. Mild myonecrosis is possible.

Differential diagnosis

Myasthenia gravis, polymyositis and organophosphate toxicity can all cause similar clinical signs. **Hypokalemia** is readily differentiated from these on serum potassium concentration and response to treatment.

Rarely snake bite or tick paralysis may cause weakness similar to severe acute signs of hypokalemia. Other clinical signs, history and serum potassium concentration allow differentiation. Typically, cats with bites from Brown or Tiger snakes have increased plasma (CK) activity and increased clotting times. Cats with tick bite have increased respiratory effort and a tick is usually found with careful searching.

Treatment

Supplementation with potassium is essential. **Oral supplementation is more effective** and is associated with fewer complications than intravenous administration. Concurrent and intravenous administration should be reserved for severely weak cats.

Caution should be used when administering potassium intravenously in fluids, as further decreases in serum potassium concentration may occur as a result of dilution and enhanced loss of potassium in urine.

Increased urinary potassium loss occurs secondary to renal sodium and water loss, when fluids are administered in excess of maintenance and induce diuresis. Clinical signs may then be exacerbated.

In severely weak cats, **use a low volume of fluid with a high potassium concentration** (e.g. 160 mmol (Eq)/L at 2 ml/kg/h. Do not exceed 0.5 mmol (Eq)/kg/h as cardiac arrest may occur.

If IV fluids are indicated because of dehydration, the rate of administration should not induce diuresis, as catastrophic decreases in potassium can occur. Until potassium is > 3.5 mmol (Eq)/h, maintenance fluid rates (e.g. 10 ml/cat/h) are recommended with potassium supplementation (80–160 mmol (mEq)/L of fluids) together with oral potassium supplementation (5–8 mg/cat PO q 12–24 h). Do not exceed 0.5 mmol (Eq)/kg/h of potassium in intravenous fluids.

Do not give fluids if the cat is not dehydrated or is not severely weak. Oral therapy (5 mg/cat bid to tid) is more effective.

Endotracheal intubation and ventilatory support is required if the cat is in respiratory muscle failure, and support may be required for 1–2 days.

Do not give steroids as these increase urinary potassium excretion.

Oral supplementation (potassium gluconate) is used for long-term management. An empirical dose of 2–6 mmol (mEq)/cat/day is usually effective. Regular monitoring of serum potassium is required to determine the effective maintenance dose for individual cats.

Prognosis

Prognosis is excellent provided respiratory paralysis does not occur.

Signs resolve in 24 hours to 3 days.

If respiratory paralysis occurs, intensive care and ventilatory support are required for survival.

Prevention

As many older cats may have underlying renal disease, periodic evaluation of renal function and serum potassium concentration is suggested.

ORGANOPHOSPHATE TOXICITY**

Classical signs

- Acute onset of miosis, salivation, urination, defecation and muscle weakness.
- Rarely, lethargy, anorexia and persistent weakness without associated autonomic signs.

Clinical signs

Organophosphate intoxication **potentiates the effect of acetylcholine** at the neuromuscular junction and other synapses, by binding with and **inactivating acetylcholinesterase**. This leads to increased acetylcholine concentrations at the neuromuscular junction, increased receptor stimulation and fatigue. **Chronic exposure** can result in **peripheral neuropathies**, as cats are one of the species most prone to delayed neurotoxicosis.

A **delayed neurotoxicity** in cats is reported associated with the use of **chlorpyrifos** spray for household application against fleas. There is individual variation in sensitivity to chlorpyrifos, and signs of toxicity have occurred even when used according to label instructions. Toxicity has also been reported with flea collars containing chlorpyrifos.

Cats with organophosphate intoxication may have **acute signs** including **miosis, salivation, urination, defecation and muscle weakness**.

Acute signs of **fenthion toxicity** are **muscle weakness with few autonomic signs**.

A more **persistent weakness without associated autonomic signs** can occur with **chronic** organophosphate toxicity. Cats may attempt to walk a few steps, then collapse in sternal recumbency mimicking catalepsy/narcolepsy. Typically, they are also lethargic and inappetent.

- Postural reactions and spinal reflexes may be depressed in some cats, but may be normal in other cats.
- The pupils may be bilaterally dilated and poorly responsive to light stimulation.
- Ventroflexion of the neck and muscle tremors may be evident.

Diagnosis

A **presumptive diagnosis is based on the presence of consistent signs and a history of exposure to an organophosphate.**

Concentration of serum cholinesterase activity may lend support to the diagnosis, but **may be non-diagnostic for chronic organophosphate toxicity.** Values less than 500 IU/L (normal 900–1200 IU/L) are considered consistent with organophosphate toxicity.

Electromyographic changes are occasionally present and include fibrillation potentials, positive sharp waves and bizarre high-frequency discharges. A decremental response to repetitive nerve stimulation may be present.

Beware that edrophonium (used to test for myasthenia gravis) may produce an **acute worsening** of signs. (**Treatment with atropine** (0.05 mg/kg IV) may help the associated parasympathetic signs).

Differential diagnosis

Rule out other diffuse causes of weakness. **For the acute form**, other **acute poisonings or toxicities** such as snake bite (increased CK, prolonged clotting times) or hypoglycemia (low plasma glucose usually in an insulin-treated diabetic cat) may appear similar. **Differentials for the chronic form** include thiamine deficiency (response to therapy), polymyositis (increased CK, abnormal EMG and muscle biopsy), hypokalemic myopathy (low plasma potassium), hypernatremia (very rare, hypernatremia), polyneuropathy (abnormal EMG and decreased nerve conduction velocities), hyperthyroidism (other clinical signs and elevated plasma thyroxine), and myasthenia gravis (IV edrophonium/Tensilon test, anti-acetylcholine receptor antibodies).

Treatment

Treatment includes protopam chloride (2-PAM) (20 mg/kg q 12 h IV) which reactivates cholinesterase and **diphehydramine** (1–2 mg/kg PO q 8–12 h) which reduces muscle fasciculations.

Atropine (0.2–0.4 mg/kg) can be given with acute toxicity to decrease autonomic signs. Current recommendations are that it only be used if marked bradycardia is present, because it may **precipitate respiratory arrest.** Salivation and defecation are not life threatening and generally do not require atropine.

Diazepam should be avoided in these cats as it may result in **generalized muscle tremor**, hypersalivation, miotic pupils and vomiting **similar to acute muscarinic signs** of organophosphate toxicosis.

DIABETIC NEUROPATHY**

Classical signs

- Subtle generalized weakness and reduced activity, difficulty jumping.
- Some cats have a classic plantigrade stance in the pelvic limbs.

Pathogenesis

The cause of the peripheral neuropathy is multifactorial, including diabetes-associated metabolic changes in the nerve metabolism and/or vascular abnormalities resulting in nerve ischemia.

Clinical signs

Many diabetic cats prior to initiation of treatment, or if poorly controlled, have **subtle generalized weakness**, usually evident as **reduced activity**, reluctance to move and **difficulty jumping.**

Some affected cats have a **classic plantigrade stance** in the pelvic limbs, suggesting **sciatic (tibial) nerve dysfunction** and tarsal extensor muscle weakness.

Diagnosis

Clinical signs of **polyuria, polydipsia, and weight loss**, together with hyperglycemia (usually blood glucose is > 17 mmol/L (309 mg/dl) and glucosuria, are usually diagnostic for diabetes.

Electromyographic abnormalities include evidence of **denervation** (fibrillation potentials and positive sharp waves) and **decreases in nerve conduction velocities.**

Nerve biopsies may show axonal degeneration and/or demyelination. These changes, however, are not specific for diabetic neuropathy.

Differential diagnosis

Traumatic **rupture of the gastrocnemius tendon** may cause similar signs.

Treatment

Twice daily insulin therapy is usually required to achieve good glycemic control. See page 237 (The Cat With Polyuria and Polydipsia).

Treatment of the hyperglycemia may result in improvement of sciatic nerve function if substantial peripheral nerve damage has not occurred prior to diagnosis and therapy.

ENVENOMATION BY SNAKES FOUND IN THE USA**

Classical signs

- Clinical signs are usually rapid in onset (within 24 hours of envenomation).
- Progressive lower motor neuron (flaccid) paralysis.
- Death is usually the result of respiratory muscle paralysis.

Pathogenesis

Coral snake envenomation is most often seen in the southeastern US.

Envenomation from Coral snakes results in a **blockage of transmission at the neuromuscular junction**.

The exact mechanism of action of the toxin is not completely defined.

Clinical signs

Signs usually are seen within 2–4 hours following envenomation, but may be delayed for several hours.

Cats present with a **rapidly progressive lower motor neuron (flaccid) paralysis**.

Rectal body temperatures may be slightly decreased.

Cranial nerve dysfunction (**decreased palpebral reflexes**) may result.

Respiratory paralysis can occur and result in death.

Physical examination may reveal small puncture wounds or the presence of small amounts of blood on the fur.

Diagnosis

A presumptive diagnosis is based on appropriate clinical signs and is supported by finding small puncture wounds.

Serum CK is often elevated.

Electrodiagnostic studies may reveal decreased or absent motor unit potentials with electrical stimulation.

Differential diagnosis

Other toxic neuropathies and myopathies may present with similar clinical signs.

Treatment

General supportive care is important including keeping the cat in a warm, comfortable environment and managing hydration status.

In the small number of cats reported with Coral snake envenomation, **recovery rates** have been **good**, usually within 2–5 days.

If respiratory paralysis results, **mechanical ventilation** may be required.

Antivenom is available for Coral snake envenomation, however, it may not neutralize all toxin present, and is relatively expensive.

Aspiration pneumonia may be a complicating factor that will require standard treatment for aspiration pneumonia.

Prognosis

Cats reported with Coral snake envenomation have had a **reasonably good prognosis for recovery**.

Respiratory paralysis may result in death unless respirator support is available.

Aspiration pneumonia may complicate the clinical signs.

Spontaneous recovery in instances with mild clinical signs is possible.

SNAKEBITE ENVENOMATION WITH AUSTRALIAN SNAKES**

Classical signs

- Australian snake venoms are predominately neurotoxic and usually strongly coagulant.
- Usually no local reaction at the site of venom injection.
- Generalized muscle weakness and dilated pupils that are poorly responsive to light are features.
- Complete flaccid paralysis is a common finding.
- Vomiting and rapid respiration are present in 30% of cases.

Pathogenesis

Bites from **Brown snakes** (*Pseudonaja* sp.), **Tiger snakes** (*Notechis scutatus*), **Taipan** (*Oxyuranus s. scutellatus*) and **Death Adders** (*Acanthophis antarcticus*) can cause **ataxia, paralysis and dilated pupils**.

Neurotoxins act specifically at the **neuromuscular junction** to **paralyze all skeletal voluntary muscle**.

Postsynaptic neurotoxins (tiger, brown, taipan, death adder) cause a non-depolarizing block of neuromuscular transmission by **occupying acetylcholine receptors** on the motor endplate. Flaccid paralysis ensues and death is possible from respiratory failure.

Presynaptic neurotoxins (tiger, brown, taipan) **block acetylcholine release** into the neuromuscular junction after depolarization. This action is delayed, becoming evident after 30–60 minutes.

Increased catecholamine release (stress, exercise, nerve stimulation) enhances the rate of intoxication whereas low temperatures delay this process.

Antitoxin cannot reverse presynaptic binding of toxin.

The **clotting mechanism is activated** via initiation of the conversion of prothrombin to thrombin and fibrinogen to fibrin (**tiger, brown, taipan, black**). This

causes continuous bleeding from sites including trauma sites, gastrointestinal tract, and lungs manifesting as hematemesis, hematuria, hemoptosis, etc.

- Coagulant manifestations often precede neurotoxin signs.
- Antitoxin effectively blocks the clotting mechanism activation.

Rhabdomyolysis (tiger, mulga, small-eyed) manifests as myoglobinuria.

Hemolysins (taipan, black) cause intravascular haemolysis and may manifest as jaundice, anemia, hemoglobinuria and perhaps kidney tubular necrosis.

Hyaluronidase in the venom is responsible for the rapid entry of the venom into the circulation.

The lack of local reaction at the bite site is probably due to the low quantity of proteolytic enzymes in Australian snake venom.

Clinical signs

There is marked variation in type and severity of signs but **flaccid paralysis and dilated pupils** that are poorly responsive are consistent findings, that is, neurological signs predominate.

Onset is usually sudden.

Dilated pupils, ataxia to paresis, trembling, flaccid paralysis, vomiting, diarrhea, respiratory distress, hypothermia, weakness, pallor, jaundice, dark urine and bleeding from multiple sites may all be present.

Less commonly there is a history of initial collapse followed by apparent full recovery followed by a steady progression of clinical signs over the ensuing hours, which may take from 5 minutes to 24 hours in the cat.

The bite site may not be found unless there is bleeding from the site.

Multiple bite sites usually result in the introduction of large quantities of venom.

Diagnosis

A **history of being bitten** by a snake and finding the snake greatly aids diagnosis, but more often the bite is unobserved.

Table 44.1 Comparison of main actions of snake venoms

	Neurotoxin	Coagulant	Myotoxin	Hemolytic
Tiger	+++	+++	+++	+
Death Adder	+++	+	—	+
Brown	+++	++++	—	+
Black	+	++	+++	+++
Copperhead	++	++	+++	++
Taipan	+++	++++	+++	+
Mulga	++	+++	+++	+
Small Eyed	+++			

Table 44.2 Comparative frequency of commonly observed signs of snakebites

	Snake specified- all animals				Animal specified (cats)
	Tiger	Brown	Black	Copperhead	
Sudden collapse soon after bite, temporary recovery then relapse	+	++	+		+
Neurological signs, weakness, ataxia, flaccid paralysis	++++	++++	++++	++++	++++
Excitement, trembling, salivation, vomiting, defecation, muscle spasm	+++	+++	+++	+++	++
Pupils dilated, pupillary light reflex slow or absent	++++	+++	+++	+++	++++
Local swelling	+	+	+++	++	++
Hemoglobinuria, Myoglobinuria, or jaundice	++	+	+		+
Non clotting blood, extended coagulation time, hematemesis, hematuria	++	++	++		++

+ 1–10% of animals show these signs; ++ 11–30% of animals show these signs; +++ 31–75% of animals show these signs; ++++ 75–100% of animals show these signs.

Typically the cat is presented with signs of a **sudden onset of paralysis, mydriasis** and has evidence of **extended clotting times**.

Identification of the snake venom using a **snake venom detection kit** to test samples from swabs of bite site,

urine (most reliable if clinical signs are present), or blood is useful, but adds to the cost of treating the cat. Knowledge of the test limitations is essential. Knowledge of the types of snakes found in the area aids selection of antivenom.

Table 44.3 Clinical pathology

	ACT	Fibrinogen	CPK	Hb'uria	Mb'uria
Brown	Increased	Decreased	-	-	-
Mulga	-	-	Increased	Increased	Increased
Black	-	-	Increased	Increased	Increased
Taipan	Increased	Decreased	Increased	-	Increased
Tiger	Increased	Decreased	Increased	-	Increased
Small-eyed	-	-	-	-	Increased
Death Adder	-	-	-	-	-

ACT - activated clotting time

CPK - creatine phosphokinase

Hb'uria - hemoglobinuria

Mb'uria - myoglobinuria

Increased creatine phosphokinase (tiger snake envenomation) may be found on biochemistry analysis.

Evidence of **neurological signs plus coagulant or myolysis or hemolysis** signs suggests snake envenomation.

Differential diagnosis

Tick paralysis may result in similar clinical signs of flaccid paralysis. Cranial nerve involvement is unusual in tick paralysis, and when present is often unilateral and associated with a tick on the head. Diagnosis is facilitated by finding a tick on the cat at the time of presentation.

Ciguatera and tetrodotoxin result in hindleg paresis and vomiting in a cat with access to reef fish or toadfish, puffer fish, newts or blue ringed octopus.

Red-back spider bite may result in initial vomiting followed by agitation, muscle weakness and incoordination. Muscular tremors and tachycardia may be present.

Thromboembolism is usually present in only one body area (either both pelvic limbs or a thoracic limb). Cats usually show clinical signs of pain. Affected muscles are usually firm and painful, with lack of evidence of perfusion (cold to touch, discolored, absent peripheral pulses).

Acute-onset sepsis results in profound weakness, hypothermia, tachypnea, bradycardia and hypotension evidenced as poor pulses, pale mucous membranes, increased capillary refill time.

Botulism and polyradiculoneuritis may result in a similar progressive flaccid paralysis. Both are relatively uncommon in cats.

Organophosphorus poisoning especially in the early stages may look similar (vomiting, salivating) Muscle weakness may be a more predominant clinical presentation. Cats also may appear flaccid.

Treatment

Prompt administration of adequate amounts of the **appropriate antivenom** is the mainstay of treatment.

Identification of the snake is often helpful when planning treatment, because both monovalent and polyvalent antivenoms are available. Polyvalent antivenom may be necessary if the snake can not be identified.

Dosages are often standardized and dispensed as one dose. **Anaphylactic reactions** are possible, so caution should be used when administering these products.

Choice of antivenom and dosage when the snake has not been identified **varies on locations around Australia**.

- Polyvalent antivenom.
- QLD north of Rockhampton – Brown 1000 U and Death Adder 6000 U.
- QLD south of Rockhampton – Tiger 3000 U and Brown 1000 U and Death Adder 6000 U.
- Tasmania – Tiger 6000 U, Victoria – Tiger 3000 U and Brown 1000 U.
- NSW, SA, WA, NT – Tiger 3000 U and Brown 1000 U and Death Adder 6000 U.

Antivenom is given diluted in 100 ml saline slowly over 15–30 minutes after premedication with chlorpheniramine (1 mg/kg IM), dexamethasone (2 mg/kg IV), and epinephrine (0.05 mg/kg SC). **Wait 20 minutes after premedication** before giving antivenom.

Table 44.4 Choice of antivenom dosage when snake has been identified

	Recommended antivenom for veterinary use	Initial dose (Units)
Tiger snake	Tiger snake antivenom	3000
Death Adder	Death Adder snake antivenom	6000
Taipan	Taipan snake antivenom	12 000
Brown	Brown snake antivenom	1000
Black	Tiger snake antivenom	3000
Mulga	Tiger snake antivenom	9000

Maintenance of airway and breathing may involve intubation and mechanical ventilation if there is respiratory paralysis. Oxygen therapy is indicated if there are moderate respiratory efforts.

Packed cell volume, total protein, urea and activated clotting time are minimal diagnostic requirements.

Fluid therapy is needed for resuscitation, rehydration, and maintenance (see treatment of dehydration, page 557, in *The Cat With Polycythemia*). Blood and plasma products may be necessary to control coagulation.

Monitor respiration (spO₂), **ventilation**, (ET, CO₂, blood gases), and circulation (heart rate, blood pressure, pulses, capillary refill time, electrocardiogram)

Monitor blood parameters (packed cell volume, total protein, BUN, potassium, CK, creatinine).

Monitor urine output to ensure that 1–2 ml/kg/h is being produced.

Nutritional support should be provided as recovery can be slow.

Nursing includes soft bedding, warmth, bladder and bowel control, analgesia, physiotherapy, catheter care, eye care.

Anticipate respiratory failure requiring mechanical ventilation, DIC, renal failure, aspiration, corneal ulceration, sudden death as complications.

TICK TOXICITY**

Classical signs

- Acute-onset flaccid paralysis, beginning in the hindlimbs and ascending.
- Acute-onset dyspnea.

Pathogenesis

Worldwide, 43 species of ticks have been reported to cause paralysis in domestic animals.

In North America, *Dermacentor andersoni*, *Dermacentor variabilis*, and *Argas (Persicargas) radiatus* are the species of ticks most commonly associated with paralysis.

In Australia, the paralysis tick is *Ixodes holocyclus*, which is found along the **eastern coast of Australia**.

Ixodes holocyclus is a **three-host tick**: larvae, nymphs and adult females engorge on a host over several days before detaching to develop to the next stage in the environment.

Native hosts of *Ixodes holocyclus*, bandicoots and possums, rarely develop disease.

Ixodes holocyclus produces disease in accidental hosts, including cats and dogs.

Most cases of tick toxicity occur during spring and early summer.

Usually a **single adult female tick** will cause disease; rarely, large numbers of larvae or nymphs will cause disease.

The tick must feed on the host for at least 5 days before disease develops.

The toxin produced by the tick acts to:

- **Inhibit the release of acetylcholine from the neuromuscular junction to produce flaccid paralysis.**
- **Block potassium efflux from cardiac myocytes to produce heart failure.**

Clinical signs

Acute onset of **paresis/ataxia of the hindlimbs** is the most consistent clinical sign. This rapidly progresses over several hours to **flaccid paralysis** and **ascends to involve the forelimbs and results in lateral recumbency**.

Dyspnea accompanies paralysis, and severe **dyspnea with forced expiration and cyanosis** occurs terminally.

A **change in voice** and **inappetence** may occur early in the course of disease.

Pupils are dilated and become non-responsive to light. The nictitating membrane may protrude across the globe.

The **gag reflex is impaired** and **drooling of saliva** occurs.

Regurgitation/vomiting can occur rarely at any stage.

Death can occur within 24–48 hours of onset of signs.

Scoring systems to describe the progressive stages of paralysis and respiratory compromise are as follows:

- **Gait score system.**
 - Score 1: Can walk: able to stand from recumbency and ambulate.
 - Score 2: Cannot walk: requires aid to stand but can maintain stance.
 - Score 3: Cannot stand: unable to maintain a standing position.
 - Score 4: Cannot right: unable to maintain sternal recumbency.
- **Respiratory score system.**
 - Score A: Normal character and rate (less than 30 breaths per minute).
 - Score B: Normal character and increased rate (greater than 30 breaths per minute).
 - Score C: Altered character with expiratory sigh/grunt (undefined rate).
 - Score D: Cyanosis and severe dyspnea.

Diagnosis

Diagnosis is made when clinical signs typical of tick toxicity are observed in an animal in an area where *Ixodes holocyclus* or other paralysis ticks are endemic and either:

- **One (or more) adult female *Ixodes holocyclus* tick(s)** or other paralysis ticks are found on the animal.
- A **“crater”**, the feeding lesion which remains after the tick has detached, is found on the animal.
 - **Multiple larval or nymphal *Ixodes holocyclus* ticks** are found on the animal.
 - A tick or “crater” is not found but the animal responds to specific treatment for tick toxicity.

Differential diagnosis

Various snake envenomations may present similarly but are not usually associated with dyspnea.

Visualization of the *Ixodes holocyclus* tick or other paralysis ticks are diagnostic. The brown dog tick, *Rhipicephalus sanguineus*, is found in some of the same areas as *Ixodes holocyclus*, but it very rarely parasitizes cats and is not associated with paralysis.

Treatment

Treatment involves removing the tick(s), administration of specific antitoxin serum and supportive care.

With *Ixodes holocyclus* (Australia), often clinical signs will progress during the first 24 hours of treatment due to the delayed onset of the toxin's action. In USA, signs usually resolve rapidly after tick has been removed, and supportive therapy is rarely necessary.

The **tick can be removed manually** using curved forceps or a pair of partially opened scissors to lever out the tick while avoiding any pressure on the tick's body. **Search thoroughly for additional ticks.** Apply tickicides (fipronil, pyrethrins) to kill any additional unseen ticks.

Tick Antitoxin Serum (TAS) for treatment of *Ixodes Holocyclus* toxicity is manufactured from canine serum so there is a **risk of anaphylaxis** when administered to cats. TAS can also produce a **vagally mediated systemic reaction** seen clinically as bradycardia, hypotension and circulatory shock (B-J reaction). To minimize these risks give:

- **Acepromazine** (0.03 mg/kg SC or IM) to relieve anxiety and respiratory distress. Wait 20–30 minutes before giving TAS.
- **Atropine** (0.04–0.1 mg/kg SC) to block the B-J reaction, reduce salivation, and produce bronchodilation. Wait 20–30 minutes before giving TAS.

- **Prednisolone sodium succinate** (5–10 mg/ kg IV) to reduce the likelihood and severity of anaphylaxis. Wait 10–30 minutes before giving TAS.
- **Epinephrine** 1:10 000 (3 ml SC) about 5 minutes prior to administration of TAS to reduce the likelihood of anaphylaxis.
- **TAS** (0.5–1 ml/kg) diluted 50:50 with 0.9% NaCl and warmed to room temperature; either give slowly IV (over 20–30 minutes) or give IP.

Supportive care.

- **Oxygen therapy** (oxygen cage, flow-by, nasal catheter, or positive pressure ventilation) is indicated for moderate to severe dyspnea.
- **Furosemide** (2–5 mg/kg IV) should be given to reduce pulmonary edema in dyspneic animals and repeated as necessary.
- **Metoclopramide** (0.5 mg/ kg IM or IV) is indicated in vomiting animals to reduce the risk of aspiration.
- **Eye ointment** should be applied to prevent corneal desiccation.
- **Nil per os** is essential until the gag reflex returns. Then introduce oral fluids slowly.
- **Parenteral fluids are not routinely indicated and must be used with care** due to the potential worsening of pulmonary edema. Colloid or heta/penta starch fluids may be used to maintain circulating fluid volume if the hematocrit is significantly elevated. Crystalloids may be given after 24 hours at submaintenance rates if slow return of the gag reflex delays introduction of oral fluids.
- If possible animals should be **positioned sternally** to minimize pulmonary ventilation–perfusion mismatching. Laterally recumbent animal should be positioned with the **shoulders elevated** to aid pharyngeal drainage and turned every 2 hours to reduce ventilation–perfusion mismatching.
- Urine retention often occurs and **manual expression of the bladder** may be needed during recovery.
- **Stress** must be minimized.
- Provision of a **cool (not cold) environment** may alleviate signs.

Prognosis

Prognosis for gait scores 1–3 and respiratory scores A–C is good. Gait score 4 and respiratory score D confers a guarded prognosis.

Cardiac effects may persist after limb paralysis has resolved. Cats should not be stressed for 2–3 weeks after recovery from paralysis. In dogs, stress may cause sudden death up to 3 weeks after discharge from hospital.

Prevention

Check daily for ticks.

Use a preventative product (fipronil, pyrethrins).

MYASTHENIA GRAVIS*

Classical signs

- **Adult cats or Siamese < 1 year of age.**
- **Episodic muscle weakness induced by movement.**
- **Ventral neck flexion.**
- **Decreased palpebral reflex.**

Pathogenesis

There are **two forms** of this disease; a **congenital form** that is not associated with antibody production, and an **acquired form** that is **associated with antibodies** being produced against the acetylcholine receptor.

The congenital form occurs **Siamese cats**. **Abyssinian cats** and possibly Somali's may be predisposed to the **acquired form**.

The acquired form can occur idiopathically, or **secondary to a variety of tumors** (thymoma). With thymoma, the tumor either produces excess antibody or antibody is produced against a similar antigen within the tumor and in muscle.

Clinical signs

This is a rare disease in cats. Generally a disease of **adult cats**, except for the congenital form in **Siamese** which presents at **< 6 months of age**.

Exercise intolerance and **episodic weakness induced by walking** or playing are typical signs. The cat may walk a few steps and flop down. Recovery occurs with rest.

Muscle tremors are usually episodic and occur in muscles that are being used.

A **stiff, stilted gait** is often noted prior to collapse.

Weakness of facial muscle may also be seen, and this is most evident as a **decrease in the palpebral reflex** and narrowing of the palpebral fissure. This appears to be a more consistent finding in cats versus dogs.

Megaesophagus is uncommon and may lead to aspiration pneumonia.

One cat has been reported with a jaw-drop and dysphagia as the only clinical signs.

Diagnosis

Diagnosis is based upon clinical signs of exercise-induced weakness that is resolved with edrophonium.

An **edrophonium response test** may suggest the disease if strongly positive. Edrophonium is an anticholinesterase that potentiates acetylcholine (ACH) at the neuromuscular junction. When given IV (0.1 mg/kg), this drug can reverse the clinical weakness seen with myasthenia gravis for a short period of time.

Electromyography and nerve conduction studies will be normal. A decremental response may be seen during repeated stimulation of a peripheral nerve in some, but not all cats.

Single fiber EMG is a relatively new technique that may aid diagnosis of this disease in the future.

Documentation of **antibodies to the acetylcholine receptor** in serum appears to be the most definitive diagnostic test. In congenital disease, however, these antibodies will not be present.

Differential diagnosis

Rule out other inflammatory, toxic and degenerative causes of muscle weakness and tremor.

Other causes of ventral neck flexion and generalized weakness include thiamine deficiency (response to therapy), polymyositis (increased CK, abnormal EMG and muscle biopsy), hypokalemic myopathy (low plasma potassium), hyponatremia (very rare, hypernatremia), polyneuropathy (abnormal EMG and decreased nerve conduction velocities), hyperthyroidism (other clinical signs and elevated plasma thyroxine) and

organophosphate toxicity (decreased serum cholinesterase activity).

Treatment

A long-acting anticholinesterase product (**pyridostigmine** Mestinon, 0.5–3 mg/kg PO q 8–12 hours) can be given to enhance the effect of ACH at the neuromuscular junction. Start at the lower dose and increase as required.

Cats may be more sensitive to the effect of this drug, and therefore, slightly lower dosages than those used in dogs should be used initially.

Additionally, immunosuppressive therapy with **corticosteroid** (1–2 mg/kg PO q 12 hours) or plasmapheresis may be needed to control clinical signs in acquired forms.

Prognosis

Prognosis for some animals is good, with occasional spontaneous cures or remission. Recurrences may occur.

Treatment responses may not be as dramatic in cats compared to dogs.

Complicating factors include severe weakness with respiratory compromise and aspiration pneumonia secondary to megaesophagus.

Prevention

Avoiding breeding from sires and dams known to produce congenitally affected offspring. Advise pedigree analysis to remove carriers.

HYPOGLYCEMIA*

Classical signs

- Trembling, weakness are most common.
- Dilated pupils.
- Reduced alertness or lethargy.
- If hypoglycemia is severe, seizures and progression to coma may result.

Pathogenesis

Hypoglycemia can also occur secondary to some endocrine disorders such as hypoadrenocorticism, lack

of glucose production by the liver in liver failure from lack of iron, and with some tumors (liver, spleen, GI) which may produce hypoglycemia through excess IGF-2 production.

Hypoglycemia is most often associated with **insulin overdose in diabetic cats**, but is also rarely caused by an **insulinoma** in older cats.

Because the central nervous system (CNS) requires a constant supply of glucose, clinical signs of hypoglycemia relate to **CNS dysfunction** and **activation of the sympathetic nervous system**.

Clinical signs

Signs include trembling, weakness, dilated pupils, reduced alertness, and if severe, seizures progressing to coma.

Insulinoma occurs in aged cats.

Diagnosis

Diagnosis of hypoglycemia is based upon finding hypoglycemia (blood glucose < 60 mg/dl; < 3.3 mmol/L) in the face of clinical signs.

Concurrent **serum insulin concentration** will help in determining the presence of an insulin-secreting tumor. Non-pancreatic tumors producing hypoglycemia are associated with low insulin concentrations.

Abdominal ultrasound may be helpful when assessing the pancreas, liver and lymph nodes for presence of tumor.

Differential diagnosis

Signs of hypoglycemia can mimic other seizure and generalized weakness disorders.

Treatment

Diabetic cats with clinical hypoglycemia are best treated with **intravenous dextrose** (20–50%) ½–2 ml to effect. Subsequent insulin doses need to be reduced by 50%. Some cats are in remission and do not need insulin.

Surgical removal of an insulinoma will normalize serum glucose concentrations if there are no metastases, and results in a better long-term outcome than medical management. Post-operative pancreatitis may be a complication.

Medical management of insulinoma or other tumor producing hypoglycemia is only **palliative** and consists of **frequent small meals** low in carbohydrate, diazoxide (12.5 mg bid PO) and **corticosteroids** (0.5–6 mg/kg/day in divided doses, beginning at lower dose) to increase blood glucose. The somatostatin analog octreotide (10–40 µg/cat SC bid–tid), has also been used in cats. Small doses of glucagon subcutaneously may be effective.

In some instances of insulinoma, intravenous dextrose administration may actually bring about worsening signs, most likely because these tumors retain some responsiveness to serum glucose concentrations and respond by increasing insulin secretion.

Prognosis

With insulinoma and other tumors producing hypoglycemia, clinical signs may be controlled, however the long-term prognosis is poor unless the tumor can be removed by surgery.

Correction of any underlying disorders will determine the ultimate prognosis.

REDUCED TISSUE OXYGENATION*

Classical signs

- **Palor, cyanosis, decreased capillary refill times, tachycardia and/or, hypothermia.**
- **Tachycardia, gallop rhythms, murmurs, coughing and vomiting with cardiac disorders.**
- **Tachypnea, panting and open-mouthed breathing with respiratory disorders.**
- **Facial edema with acetaminophen toxicity.**

See main reference page 118 for details (The Cyanotic Cat).

Pathogenesis

Any cause of substantially reduced tissue oxygenation will cause weakness. Examples include severe anemia, methemoglobinemia associated with acetaminophen (paracetamol) toxicity, cardiac disease, hydrothorax including pyothorax and chylothorax, and severe bronchopulmonary disease or obstructive upper respiratory disease.

Clinical signs

Signs may be generalized or localized and are most easily seen in the **mucous membranes, nail beds or conjunctiva**.

Palor, cynaosis, decreased capillary refill times, **tachycardia** and hypothermia are common associated signs.

Tachycardia, **gallop rhythms, murmurs**, coughing and vomiting may accompany cardiac disorders.

Tachypnea, panting, and open-mouthed breathing may accompany respiratory disorders.

Facial edema may be present with acetaminophen toxicity.

Diagnosis

PCVs and complete blood cell counts are used to determine the presence of anemia.

Arterial blood gas analysis is used to determine relative tissue oxygenation.

A **pulse oximeter** reading may aid in determining the degree of oxygenation.

Chest radiographs can be used to identify pulmonary and cardiac diseases.

In addition, an ECG and echocardiogram is useful when evaluating for heart disease.

Differential diagnosis

Other causes of weakness should not have cyanosis and pallor.

Treatment

Treat the underlying cause of the reduced oxygenation and provide oxygen if signs are marked.

Prognosis

Depends upon the underlying cause.

TOXOPLASMOSIS*

Classical signs

- Most cats are asymptomatic.
- Signs are most severe in cats under 1 year of age and especially young kittens.
- Lethargy, anorexia, dyspnea.
- Uveitis, retinal hemorrhage.
- ± Weakness.

Clinical signs

Most cats are asymptomatic.

Signs are most severe in cats under 1 year of age, especially young kittens, although any age of cat can be affected.

Lethargy, anorexia and dyspnea due to pneumonia are the most frequent signs of generalized infection.

Fever may be present.

Gastrointestinal or hepatic signs such as icterus, vomiting and diarrhea and abdominal effusion may occur as a result of diffuse organ involvement or from a granuloma.

Toxoplasma gondii can affect any area of the nervous system resulting in encephalitis, myelitis, peripheral neuropathy or myositis.

The organism damages the nerve and muscle either primarily, or secondarily through associated inflammation.

Weakness may be present if the **spinal cord, peripheral nerves or muscles** are involved.

Hyperesthesia on muscle palpation, stiff gait or shifting leg lameness suggests myositis.

Experimental inoculation with *meospora coninum* also causes clinical signs in cats.

Diagnosis

Diagnosis is based upon the presence of **IgM antibodies** to *Toxoplasmosa gondii*, which appear within

1–2 weeks and **persist for 3 months**, but sometimes for years, or **rising IgG titers** which appear by the fourth week of infection, increase over 2–3 weeks and persist for months or years. **Visualization** of the protozoan in **biopsy specimens** is also diagnostic.

Differential diagnosis

Rule out other myopathies (hypokalemic, polymyopathy) and inflammatory causes of muscle disease as well as other neuropathies.

Treatment

Treatment for toxoplasmosis currently is **clindamycin** (8–25 mg/kg, q 8–12 hours; do not exceed 50 mg/kg q 24 hours) for 14–28 days, however the **addition of trimethoprim sulfa drugs** PO, IM or SC may provide a better clinical response.

Newer drugs, such as **azithromycin** and **clarithromycin** (macrolides), are being tested in other species, but are unproven in cats.

Watch the literature for new recommendations.

THIAMINE DEFICIENCY*

Classical signs

- Initially, lethargy, inappetence and ataxia.
- Later, weakness, ventral flexion of the neck, dilated pupils, stupor and coma.

See main reference on page 848 for details (The Cat With a Head Tilt, Vestibular Ataxia or Nystagmus).

Clinical signs

Early non-specific signs are typically **lethargy and inappetence**.

The earliest localizing sign is **bilateral vestibular ataxia**, which appears as an **abnormal broad-based stance, loss of balance and vertigo**.

There is **weakness** and an **inability or reluctance to walk**. The cat sits crouched with **ventral flexion of the neck**.

Pupils are dilated and non-responsive or poorly responsive to light reflexes.

If untreated, **signs progress to semi-coma**, persistent vocalization, opisthotonos and death.

Episodes of **spastic opisthotonos or ventroflexion of the neck** and muscle spasm may occur especially when the cat is lifted or stressed. They may be interpreted as seizures, but true seizure activity rarely occurs.

Diagnosis

Diagnosis is based on **clinical signs** and **rapid response to thiamine**.

Cats that have progressed to a comatose state have a poor prognosis.

Differential diagnosis

Other encephalopathies and encephalitis are differentiated on history, CSF findings and lack of response to thiamine.

Head trauma may appear similar to late signs of thiamine deficiency, but can usually be differentiated on history and evidence of trauma. Thiamine-deficient cats are **lethargic and inappetent** days and weeks before signs are severe.

Hydrocephalus can present with central blindness and ataxia, but there is no response to thiamine.

Dysautonomia is a consideration in countries where it occurs. The bilateral non-responsive pupils and ventroflexion of the neck may appear similar to thiamine deficiency, but there is no response to thiamine.

Hypokalemic myopathy, myasthenia gravis, polymyositis and **organophosphate toxicity** can all cause ventral flexion of the neck. However, ventral neck flexion in thiamine deficiency is the result of active muscle contraction associated with increased muscle tone rather than **passive ventroflexion** from **weakness**. Thiamine deficiency responds to thiamine supplementation unless in terminal stages.

Treatment

Treatment is administration of thiamine dosed typically at 5–30 mg/cat/day per os. Maximum dose up to 50 mg/cat/day.

Severely affected cats should receive at least 1 mg parenterally.

Change the diet to one with adequate thiamine and supplement with thiamine for at least a week.

HYPERTHYROIDISM*

Classical signs

- Weakness and ventral neck flexion.
- Cats may progress to collapse with minimal exercise.

See main reference page 304 for details (The Cat With Weight Loss and a Good Appetite).

Clinical signs

The metabolic effects of the hyperthyroid state may in some way affect muscle and/or nerve function. Many of these cats are **also hypokalemic**. Clinical signs of **hypokalemia may be precipitated by thyroidectomy** and be apparent on recovery from anesthesia.

Weakness and ventral neck flexion occurs in a few cats with hyperthyroidism.

Cats may progress to **collapse with minimal exercise**.

Other typical signs of hyperthyroidism may also be present such as weight loss, polyphagia, irritability or **restlessness**.

Some cats are lethargic.

Intermittent vomiting or diarrhea occurs in many cats.

With practice, a **palpable thyroid nodule** is detected in most cats.

Diagnosis

In some cats, electromyography shows evidence of denervation.

Diagnosis is made by demonstrating **elevated serum total thyroxine (T4)** concentrations. When total T4 concentration is at the high end of normal, but signs are consistent with hyperthyroidism, measurement of **free T4** or a **T3 suppression** test may help to confirm the diagnosis.

Differential diagnosis

Differential diagnoses include other causes of hypokalemic myopathy such as chronic renal failure,

other myopathies and inflammatory causes of muscle disease.

Myasthenia gravis (positive tensilon test, anti-acetylcholine receptor antibodies), chronic organophosphate toxicity (history of exposure), and polymyositis (muscle biopsy) should be considered.

Treatment

The weakness may improve with treatment for hyperthyroidism.

Correct hypokalemia.

POLYMYOSITIS*

Classical signs

- Weakness and neck ventroflexion.

Clinical signs

Polymyositis may be **idiopathic, immune-mediated** or result from infections with *Toxoplasma gondii* or **feline immunodeficiency virus**.

Signs typically are of **generalized muscle weakness** and **neck ventroflexion**.

Megaesophagus may occur with smooth muscle involvement.

Thymoma may be present in some cats, and myositis may occur concurrently with myasthenia gravis.

Regurgitation and/or dyspnea may be present with megaesophagus and thymoma.

Diagnosis

Serum CK may be elevated.

Abnormal **spontaneous muscle electrical activity** consistent with myocyte inflammation and abnormal membrane electrical activity (e.g. fibrillation potentials, positive sharp waves, **complex repetitive discharges**) may be present on electromyography.

Multifocal areas containing mononuclear cell infiltrates are present in the muscle biopsy.

Differential diagnosis

Hypokalemic myopathy is differentiated on the basis of hypokalemia.

Myasthenia gravis may occur concurrently with myositis.

Chronic organophosphate toxicity is differentiated on the basis of a history of exposure and sometimes reduced cholinesterase activity.

Treatment

Corticosteroid treatment (1–2 mg/kg PO q 12 hours) may improve clinical signs.

DYSAUTONOMIA*

Classical signs

- Younger cats (< 3 years).
- Acute onset of depression and anorexia.
- Dilated pupils, xerostomia, keratoconjunctivitis sicca, prolapsed third eyelids.
- Bradycardia.
- Megacolon, constipation, loss of anal reflex.
- Incontinence, dysuria or distended bladder.
- Weakness.

See main reference page 792 for details (The Constipated or Straining Cat).

Clinical signs

Disease is confined to Europe or occurs in imported cats. The prevalence has decreased markedly and it is now uncommon.

Younger cats (< 3 years) are more often affected.

Clinical signs are often **acute in onset over 48 hours** with all cats showing **depression and anorexia**.

Other signs reflect autonomic system dysfunction and include:

- Ocular signs such as **fixed, dilated pupils without blindness**, prolapsed third eyelids and dry eyes (keratoconjunctivitis sicca develops).
- **Gastrointestinal signs** include regurgitation, megaesophagus, constipation and megacolon, loss of the anal reflexes, dry mouth (xerostomia).

- **Bradycardia** (90–120 beats/minute).
- **Dysuria** and/or **distended bladder** or incontinence with an easily expressive bladder.
- Generalized weakness.

Diagnosis

Diagnosis is based primarily on **clinical signs and evidence of autonomic dysfunction**. The indirect-acting parasympathomimetic, physostigmine (0.02 mg/kg IV) produces no ocular response, but direct-acting pilocarpine (topically) results in immediate miosis, **demonstrating post-ganglionic denervation** hypersensitivity. Normal cats do not demonstrate these responses.

Differential diagnosis

Differential diagnoses are many, depending on the predominant signs. Cats may present with a history of constipation or inability to urinate or dilated pupils, suggesting disease of the colon, lower urinary tract or eyes. Typical cases which exhibit most signs are classical for dysautonomia.

Treatment

No specific treatment is available, but supportive care is important, such as syringing or tube feeding.

Parasympathomimetic agents may improve some clinical signs.

- **Pilocarpine ophthalmic drops** (1%/1 drop q 6 h) may result in pupillary contraction and increase salivation.
- Bethanechol (1.25–5 mg PO q 8–12 h) may benefit constipation and urinary retention.
- Metoclopramide (0.2–0.5 mg/kg PO SC q 8 h) may improve gastric motility.

Up to 70% mortality rate has been reported.

POLYMYOPATHIES

Classical signs

- **Ventral flexion of the neck.**
- **Muscle weakness.**
- +/- **Apparent muscle pain and a stiff gait.**

Pathogenesis

Unknown.

Clinical signs

Age of onset varies from 3 months to 13 years.

Most cats were domestic short- or long-haired cats.

Ventral flexion of the neck and weakness was common.

Apparent muscle pain and a stiff gait may also be seen.

Diagnosis

Serum CK was usually elevated.

Many of these cats had low serum potassium levels and may have had **hypokalemic myopathy**. Some cats had clinical signs **resolve spontaneously**, others seemed to benefit from **corticosteroid therapy**.

Differential diagnosis

Rule out other inflammatory, toxic and degenerative causes of weakness.

Other causes of ventral neck flexion and generalized weakness include thiamine deficiency (response to therapy), polymyositis (increased CK, abnormal EMG and muscle biopsy), hypokalemic myopathy (low plasma potassium), hypernatremia (very rare, hypernatremia), polyneuropathy (abnormal EMG and decreased nerve conduction velocities), hyperthyroidism (other clinical signs and elevated plasma thyroxine), myasthenia gravis (IV edrophonium/Tensilon test, anti-acetylcholine receptor antibodies) and organophosphate toxicity (decreased serum cholinesterase activity).

Treatment

Some cats had clinical signs resolve spontaneously, others seemed to benefit from corticosteroid therapy (1–2 mg/kg PO q 12 hours).

Prognosis

Variable.

HYPOCALCEMIA

Classical signs

- Weakness, tetany and tremors.
- Muscle fasciculation, cramping, rigidity and twitching.

Pathogenesis

Decreases in calcium **decrease the threshold** for neuronal and muscle **depolarization**.

Hypocalcemia most often results from **iatrogenic injury to the parathyroid gland** during surgical removal of thyroid tumors.

Primary hypoparathyroidism is possible but rare.

Hypocalcemia associated with **queening (eclampsia)** is rarely reported but occurs.

Clinical signs

Clinical signs include **weakness, tetany and tremors**.

Spontaneous muscle depolarization can manifest as muscle fasciculation, cramping, rigidity and twitching.

Queens with preparturient hypocalcemia present with **anorexia, lethargy, trembling, muscle twitching** and weakness. They resemble the clinical picture of hypocalcemia in cows, rather than the violent muscle tremor of eclampsia in dogs.

Diagnosis

Diagnosis is confirmed by finding decreased (usually less than < 1.5 mmol/L (6 mg/dl) serum calcium on serum biochemical analysis.

Differential diagnosis

Rule out other **inflammatory** causes of **muscle disease** and **acute organophosphate toxicity** (history of exposure, signs and low cholinesterase activity).

Treatment

Treatment involves calcium supplementation and vitamin D therapy.

If clinical signs are present, rapid institution of treatment is indicated with 0.5–1.5 ml/kg IV of 10% **calcium gluconate**. **Infuse calcium slowly over 10 minutes while monitoring heart rate.** Stop infusion if bradycardia occurs.

Short-term maintenance involves either SC calcium (1–2 ml of 10% calcium gluconate diluted 1:1 in 0.9% saline q 8 hours) or IV calcium (10–20 ml of 10% calcium gluconate in 500 ml of 0.9% saline) with rate adjusted to maintain normocalcemia. Monitor calcium 2–3 times daily initially.

Longer-term maintenance includes **oral calcium (25 mg/kg q 8–12 hours)** and **vitamin D**. The active form of endogenous vitamin D₃ (called calcitriol or 1,25 dihydroxycholecalciferol) is used at 2.5–10 ng/kg q 24 hours or synthetic vitamin D₃ (dihydrotachysterol) at 0.02–0.03 mg/kg q 24 hours for 3 days, then 0.01–0.02 mg/kg q 6–24 hours.

Calcium should be monitored carefully, as **hypercalcemia is nephrotoxic**.

- Adjustments to doses should be made every 1–3 days based on calcium concentrations.

If hypocalcemia is the result of thyroidectomy, calcium and vitamin D therapy can be reduced gradually over 2–3 weeks, and stopped if calcium remains in the normal range.

Prognosis

Acute hypocalcemia following bilateral thyroidectomy can be fatal if not recognized early and appropriate therapy instituted.

Prevention

When performing bilateral thyroidectomy, allow 3–4 weeks between removal of each lobe.

DEGENERATIVE NEUROPATHIES

Classical signs

- Weakness with decreased to absent spinal reflexes.
- “Dropped-hock” gait in young Birman cats.

Pathogenesis

The cause of many degenerative neuropathies is not known.

Clinical signs

These diseases are often breed-specific with clinical signs beginning in cats less than 1 year of age.

Weakness with decreased to absent spinal reflexes are typical signs.

A degenerative polyneuropathy occurs in **young Birman cats**.

Clinical signs begin at 8–10 weeks of age.

- The gait is characterized by a “**dropped-hock**” appearance and **hypermetria** and **ataxia**.

Cats with **Neimann–Pick type-A storage disease** may have **alterations in peripheral nerves**. These diseases may have weakness as part of the clinical syndrome.

Other degenerative neuropathies may occur in a variety of breeds and at various ages.

Diagnosis

A tentative diagnosis is based on finding **signs of weakness** in a **young Birman** cat. Electrodiagnostic evaluations may reveal abnormalities such as fibrillation potentials, positive sharp waves, and decreased nerve conduction velocities depending upon the pathologic process present.

- In general, neuropathies with demyelination tend to be associated more commonly with decreased nerve conduction velocities, whereas neuropathies with predominant axonal abnormalities tend to be associated with fibrillation potentials and positive sharp waves (denervation potentials). Mild to moderate **fibrillation potentials, consistent with denervation**, or decreasing nerve conduction velocity may be found in some cases with electromyography and nerve conduction velocity testing, respectively.

Histologic lesions involving the axon or the myelin sheath may be present on peripheral nerve biopsy.

Differential diagnosis

Clinical signs may be similar to other diseases that affect the lower motor neuron including motorneuropathies, myopathies and some diseases of the neuromuscular junction.

Treatment

No effective treatment is known.

Clinical signs usually progress until euthanasia or death occurs months to years after initial onset of signs.

In rare instances, clinical signs may stabilize or even improve.

Prognosis

Many of these diseases are progressive, and treatments either have not been attempted or have not been beneficial.

DEGENERATIVE MOTORNEUROPATHIES

Classical signs

- Progressive weakness and muscle atrophy in adult cats.
- Decreased to absent spinal reflexes.
- Tremor, especially of the head and tongue.
- Cervical ventroflexion.
- Dysphagia.

See main reference on page 903 for details (The Cat With Neck Ventroflexion).

Clinical signs

Degeneration of the lower motor neuron cell bodies in the ventral horn of the spinal cord and occasionally the cranial nerve nuclei leads to chronic progressive signs.

All cats were adults.

Clinical signs included **progressive weakness and muscle atrophy, tremor**, especially of the **head** and tongue, ventroflexion of the neck and dysphagia.

Diagnosis

Mild to moderate **fibrillation potentials, consistent with denervation**, were found in the appendicular (limb) and paraspinal muscles with electromyography.

Histologic lesions were most severe in the ventral spinal gray matter, consisting of neuronal cell loss and gliosis. No effective treatment is known.

Differential diagnosis

Hypokalemic myopathy (low plasma potassium), chronic organophosphate toxicity (history of exposure), myasthenia gravis (tensilon test, anti-acetylcholine receptor antibodies, decreased serum cholinesterase activity).

Treatment

No effective treatment is known.

Clinical signs progress until euthanasia or death occurs months to years after initial onset of signs.

DEGENERATIVE MYOPATHIES (X-LINKED MUSCULAR DYSTROPHY, HEREDITARY MYOPATHY, NEMALINE ROD MYOPATHY)

Classical signs

- Signs begin 2–24 months of age.
- Weakness and reduced activity.
- Stiff, choppy gait.
- Increased muscle mass and hypertrophy of the tongue (X-linked muscular dystrophy).
- Ventral flexion of neck and dorsal protrusion of scapula (hereditary myopathy of Devon Rex).
- Any breed may be affected; inherited myopathy occurs in the Devon Rex.

Pathogenesis

An **X-linked muscular dystrophy** similar to Duchenne's and Golden Retriever myopathy has been described in **male cats**. A membrane-associated protein (**dystrophin**) is **deficient or absent**.

Cardiac muscle may also be affected.

A specific cause of the other myopathies has not been completely established.

Clinical signs

X-linked muscular dystrophy:

- The **gait is mildly stiff or stilted**, and cats tend to **bunny-hop to run**.
- Occasionally there is marked stiffness and reluctance to move.
- Cats often appear to have **increased muscle mass**, especially of the **neck** and **proximal limb** muscles, and stand with adducted hocks.
- The **tongue is hypertrophied** and may protrude partially. Excessive drooling of saliva occurs.
- **Dehydration** may be a recurring problem because the **tongue hypertrophy** makes it **difficult to drink**. Eating is also affected by the tongue hypertrophy.
- There may be a history of **gagging, regurgitation** or vomiting of food.
- Additionally, these cats may have fatal complications when undergoing **general anesthesia** or from manual restraint, as a result of **peracute rhabdomyolysis**.
- Signs generally develop **before 2 years of age**, and hypertrophy of the proximal limb muscles is evident as early as 10 weeks.

Hereditary myopathy in Devon Rex cats (see main reference page 900, The Cat With Neck Ventroflexion).

- Occurs in young (**3–23 months of age**) **Devon Rex cats**.
- Clinical signs include generalized muscle weakness, ventroflexion of the neck and **dorsal protrusion of the scapula**.
- Difficulty maintaining a normal head position when eating may result in **obstruction of the pharynx with food** and laryngospasm, which may be fatal.
- Megaesophagus may be present in some cats.

Nemaline rod myopathy:

- Weakness begins between 6–18 months of age.
- Clinical signs progress to a **choppy, hypermetric gait**.
- The patellar reflex is decreased, however flexion reflexes are present.

Diagnosis

These diseases usually require **electrodiagnostic evaluation and muscle biopsy** for definitive diagnosis.

X-linked muscular dystrophy:

- Increased serum **creatinine kinase (CK)** and **complex repetitive discharges** upon electromyographic (EMG) evaluation may be clues.

- **Muscle biopsy** shows muscle fiber hypertrophy, fiber splitting, myonecrosis, calcium deposition, internalized nuclei and occasional fiber-type grouping.

Hereditary myopathy of Devon Rex cats:

- Serum CK levels are normal.
- Occasional **fibrillation potentials** and positive sharp waves are found with electromyographic examination.
- Muscle biopsies show variability in muscle fiber size, internal nuclei, myofiber necrosis, regeneration and fibrosis.

Nemaline rod myopathy:

- Nemaline rods are characteristic within muscle biopsies.

Differential diagnosis

Polymyositis (increased CK, muscle biopsy), organophosphate toxicity (history of exposure, reduced cholinesterase activity), hypokalemia (serum hypokalemia) and congenital myasthenia gravis (positive tensilon test) are all differentials for degenerative myopathies.

Treatment

No effective treatment is known.

Long-term fluid therapy (subcutaneous) may be required in cats with X-linked muscular dystrophy for them to survive, as tongue hypertrophy limits fluid intake.

Prognosis

Clinical signs are progressive until euthanasia or death.

With X-linked muscular dystrophy, subcutaneous fluid administration may be required to maintain fluid balance. With support, cats may live many years after diagnosis. Sudden death may occur in association with anesthesia.

With **hereditary myopathy** in Devon Rex cats, progression of clinical signs occurs until 6–9 months of age. Clinical signs may stabilize after this time. Four in six cats die suddenly of laryngospasm due to obstruction of the pharynx with food.

With **Nemaline rod myopathy**, signs progress slowly over the first year.

Prevention

Pedigree analysis and selected breeding are required to remove the genes from the gene pool.

IDIOPATHIC PERIPHERAL NEUROPATHY, CHRONIC RELAPSING POLYNEUROPATHY, POLYNEURITIS

Classical signs

- Lower motor neuron tetraparesis is the predominant sign.
- Marked weakness with conscious proprioceptive deficits, and decreased spinal reflexes occur.

Pathogenesis

Nine cats have been reported with a suspected **idiopathic peripheral neuropathy** similar to polyradiculoneuritis (Coon Hound paralysis) in dogs.

Additionally, a **chronic, relapsing polyneuropathy** has been reported in one cat and eluded to in other publications.

A cat has been reported with severe, acute **polyneuritis** without evidence of an infectious etiology.

Clinical signs

In cats with a suspected **idiopathic peripheral neuropathy**, clinical signs were similar to those dogs reported with polyradiculoneuropathy (Coon Hounds paralysis) with paraparesis to tetraparesis, rapid muscle atrophy and decreased to absent spinal reflexes.

In **chronic, relapsing polyneuropathy** marked lower motor neuron tetraparesis occurred, recovered spontaneously and reoccurred months later.

Conscious proprioceptive abnormalities, depressed spinal reflexes and muscle atrophy were present in the limbs.

One cat was reported with a severe, acute **polyneuritis** with weakness, conscious proprioceptive deficits and decreased spinal reflexes.

Icterus and anemia were associated abnormalities.

Diagnosis

In cats with a suspected **idiopathic peripheral neuropathy**, diagnosis is made on the clinical signs of rapid onset of tetraparesis with loss of spinal reflexes. Muscle atrophy is evident within 7–10 days. One cat was examined pathologically and had axonal degeneration, fragmentation and loss of axons, as well as demyelination and accumulation of macrophages in the ventral nerve roots.

In **chronic, relapsing polyneuropathy**, electrodiagnostic evaluation showed fibrillation potentials and positive sharp waves in the limb and paraspinal muscles, as well as decreased nerve conduction velocities.

Demyelination and remyelination were present in nerve biopsies.

In the cat with the acute, severe **polyneuritis**, pathologically there was extensive destruction of myelin associated with macrophages.

Differential diagnosis

Rule out other inflammatory, degenerative and toxic causes of muscle or neuromuscular disease.

Snake bite (appropriate geographic location, increased CK and clotting times), tick paralysis (geographic location, abnormal breathing and tick), **botulism** (gastrointestinal signs) all cause marked tetraparesis but have other differentiating signs, **disk prolapse** may cause tetraparesis but cats are not flaccid in all four limbs, **traumatic spinal cord injury**, diffuse hemorrhage in the spinal cord and around the nerve roots appear clinically similar.

Treatment

Spontaneous recovery occurs in cats with **idiopathic peripheral neuropathy**.

Good nursing care is essential to provide fluids, nutrition and to prevent urine scalding and pressure sores.

With **chronic, relapsing polyneuropathy** improvement, if not resolution of clinical signs, may occur in some cats after corticosteroid therapy.

In the cat reported with acute, severe **polyneuritis**, no treatment was attempted.

Prognosis

In cats with a suspected **idiopathic peripheral neuropathy**, seven cats **recovered spontaneously** and completely without specific treatment within 4–6 weeks.

MYOTONIA

Classical signs

- Stiffness and muscle spasm.
- Short, stilted gait.
- Increased muscle size.

Pathogenesis

Cats with myotonia have **sustained muscle contraction**, which is initiated voluntarily or with stimulation, and sustained involuntarily.

Myotonia most often occurs as a **congenital problem**.

Excessive muscle contraction is thought to be due to an **abnormal muscle cell membrane**, which supports persistent depolarization.

Clinical signs

Affected cats often have **a stiff, stilted gait** and have **large, bulky muscles on palpation**.

Muscle dimpling may occur with **direct muscle percussion**.

Diagnosis

Electromyography demonstrates the characteristic myotonic potentials, and muscle biopsies may be supportive of the diagnosis.

Differential diagnosis

Rule out other myopathies such as X-linked muscular dystrophy (increased serum creatine kinase, typical muscle biopsy findings). Myotonia has characteristic EMG findings.

Treatment

No treatment has been described in cats.

PRIMARY HYPEROXALURIA

Classical signs

- Domestic short-hair cats, 5–9 months old.
- Generalized weakness, absent cutaneous trunci reflex.
- Signs of renal disease may or may not be present.

Pathogenesis

It is suspected that the systemic **oxalosis** damages the **peripheral nerves**.

Clinical signs

Primary hyperoxaluria was reported in a colony of domestic short-haired cats.

Cats developed clinical signs between **5–9 months of age**.

In some instances, clinical signs of **weakness** occurred **prior** to the onset of **renal failure**.

Postural reactions were depressed.

Spinal reflexes were inconsistently affected.

The **cutaneous trunci reflex** was **absent** in most cats.

Other signs of renal failure such as inappetence, weight loss, polyuria, polydipsia were sometimes present.

Diagnosis

Positive sharp waves, milder fibrillation potentials, and occasional bizarre high-frequency discharges were found with electromyographic examination.

Pathologically, the neurons in the ventral gray matter of the spinal cord and their proximal axons were most affected.

- Swollen axons were present in the ventral nerve roots and dorsal root ganglion cells.

Differential diagnosis

Rule out other congenital causes of weakness such as **hypokalemic myopathy** (Burmese, low plasma

potassium), **degenerative myopathies** (signs, muscle lesions on biopsy), and **myasthenia gravis** (some recovery with rest, and improvement after IV edrophonium).

Treatment

No treatment was attempted.

HYPERNATREMIC MYOPATHY

Classical signs

- Ventral neck flexion, muscle weakness and a “dropped-hock” gait.

Clinical signs

Rare disease with signs similar to hypokalemic myopathy.

Generalized progressive muscle weakness which may include **ventral neck flexion** and a “**dropped-hock**” appearance to the gait.

Diagnosis

Finding **elevated serum sodium** > 165 (mEq) mmol/L) in the presence of clinical signs.

Differential diagnosis

Hypokalemic myopathy (diagnosis based on finding hypokalemia i.e. plasma potassium < 3.0–3.5 (mEq) mmol/L).

Polymyositis (increased serum CK and muscle lesions on biopsy).

Myasthenia gravis (positive edrophonium tensilon test and anti-acetylcholine receptor antibodies).

Chronic organophosphate toxicity (diagnosis based on history and sometimes reduced cholinesterase activity).

Treatment

Treatment centers around decreasing serum sodium through fluid management. If the hypernatremia has evolved slowly, extreme caution should be exercised when attempting to decrease serum sodium with fluid therapy.

As a rule, slowly decreasing serum sodium concentrations over 2–3 days is safe. Serum sodium measurements should be determined frequently to avoid rapid decreases in sodium, which can result in life-threatening cerebral edema.

Long-term management is with a **low-sodium diet** (e.g. Hill’s Feline H/D) with **water added in excess** of maintenance requirements.

HYPERLIPIDEMIA

Classical signs

- Hyperlipidemia and lipemia retinalis.
- Peripheral neuropathies involving individual peripheral, cranial or sympathetic nerves.

Clinical signs

Hyperlipidemia in cats is usually the result of **primary idiopathic hyperlipidemia** or occurs secondary to **diabetes mellitus**.

Chronic weakness, paresis and decreased spinal reflexes may occur as a result of neuropathies secondary to hyperlipidemia.

The neuropathy results from **compression of nerves by lipid granulomata (xanthomas)**.

Signs depend on where the xanthomas form. Peripheral neuropathies involving individual peripheral, cranial or sympathetic nerves.

Diagnosis

Diagnosis is presumptive based on persistent fasting hyperlipidemia (present > 24 hours after feeding) in the presence of clinical signs of neuropathy and weakness.

Definitive diagnosis is on biopsy of the granuloma or autopsy.

Differential diagnosis

Diabetic neuropathy may appear similar and hyperlipidemia also occurs with diabetes. Xanthomas have been reported associated with the hyperlipidemia of diabetes, but are not thought to be the cause of most

diabetic neuropathies. Persistent hyperglycaemia above 16 mmol/L (288 mg/dl) is diagnostic of diabetes.

Other neuropathies (e.g. neoplastic, idiopathic, inflammatory) are not associated with persistent fasting hyperlipidemia.

Treatment

Feeding a **low-fat diet** resulted in resolution of the neuropathy in 2–3 months in a few cats with peripheral neuropathy.

Gemfibrozil (7.5–10 mg/kg daily) is indicated if dietary therapy does not normalize triglyceride concentrations.

Marine (fish) oils rich in omega-3 fatty acids may help to decrease triglyceride concentrations.

ACUTE SEPSIS

Classical signs

- Generalized weakness or flaccid paralysis.
- Hypothermia.
- Tachypnea.
- Bradycardia.
- Hypotension (poor pulses, pale mucous membranes, increased capillary refill time).

Pathogenesis

Toxemia and reduced tissue oxygenation from acute bacterial sepsis may cause **weakness and depression**.

Toxemia may be associated with bacteremias originating in the **uterus** (pyometritis), **thorax** (pyothorax), **abdomen** (peritonitis) or **skin** (subcutaneous abscess).

Pyrexia or hypothermia may be present, and **signs referable to the infection site** are often evident including dyspnea, vaginal discharge, abdominal guarding or skin abscess.

Hypothermia weakens the immune system, depresses the myocardium, bluntens the vasculature response to catecholamines and reduces cellular function.

Hypothermia may be associated with up-regulation of anti-inflammatory cytokine activity. **Cardiac insufficiency** is common, and coagulopathies often ensue.

Bradycardia is an inappropriate response to critical illness, and its mechanism is unknown. Increased vagal tone, sympathetic stimulation, and induction via hypothermia have all been postulated to be involved. It may be exacerbated by hypoglycemia or hyperkalemia which may accompany the septic state.

Depression of myocardial function is exacerbated by hypothermia, and continues after rewarming. Intracellular calcium overload contributes to **diastolic dysfunction**. **Systolic dysfunction** occurs secondary to ischemia, myocardial edema or infarction.

Cytokines increase vascular permeability and hypoalbuminemia reduces oncotic pressure. When combined with depressed myocardial function, the septic cat is **susceptible to fluid overload** during treatment for hypovolemia.

Anemia results in local hypoxia and local lactic acidosis.

Clinical signs

Depression and anorexia are typically present, and if sepsis is severe, the cat may be **profoundly weak or collapsed**.

Pyrexia or hypothermia may be present

Signs suggesting the infection site such as dyspnea, vaginal discharge or uterine distention, abdominal guarding, or skin abscess are often evident.

The classic signs of sepsis, labeled the “sepsis triad” (**fever, tachycardia, tachypnea**) or the hyperdynamic phase, are rarely recognized.

Sepsis in cats often presents as the “shock triad” (**hypotension, bradycardia, hypothermia**). Hypotension is evidenced as poor pulses, pale mucous membranes and increased capillary refill time.

Localized infection will often cause pyrexia, but sepsis often presents at a stage where fever is no longer sustained and **hypothermia** has developed.

Heart rate often follows temperature.

Diagnosis

Diagnosis is based primarily on **clinical signs and history**, especially if a site of infection is found.

Finding of the “shock triad” of **hypotension, bradycardia, and hypothermia** is highly suspicious.

White cell count alterations are common. Neutrophilic leukocytosis with left shift may be evident, but with overwhelming sepsis, **leucopenia with neutropenia or a degenerative left shift** occur. Monocytosis occurs with long-standing or deep-seated infection.

Thrombocytopenia can be seen from day 1.

Red cell count changes include **anemia** from hemolysis, or a falling PCV and schistocytes associated with DIC.

Coagulation testing (PT, APTT, ACT, FDPs) may indicate DIC.

Hypoalbuminemia is common.

Icterus is common, and usually results from hemolysis rather than cholestasis.

Differential diagnosis

Rule out other causes of acute muscle weakness such as metabolic, inflammatory or toxic causes.

Identification of a focus of infection such as peritonitis, pyothorax, pyometritis, pyelitis or subcutaneous abscess helps to differentiate sepsis from other causes of weakness.

Weakness with hypothermia, hypotension and bradycardia are pathognomonic.

Treatment

The **basis of therapy** is ventilation, infusion, and pumping (VIP), together with **early antimicrobial treatment**.

Ventilation reduces the work of breathing, and includes **oxygen, PEEP, intubation and/or mechanical ventilation** as necessary.

Infusion of fluids is essential. **Colloids** rapidly increase intravascular volume, and can be combined with **crystalloids** to support interstitial volume. Use

fresh whole blood if anemic, **plasma** if hypoalbuminemic, and give **clotting factors** via fresh whole blood or fresh frozen plasma if coagulopathic. Do not use a glucose solution unless hypoglycemic.

Cardiac pumping support via use of **positive inotropes** (dopamine, dobutamine, epinephrine) is essential.

Resuscitation goals are to **restore oxygen delivery** through correction and maintenance of arterial pressure, and adequate arterial oxygen content. The aims are to correct hypothermia, hypovolemia, bradycardia and anemia. If perfusion is still inadequate, address hypotension with inotropic and vasopressor support.

Rewarm with warm intravenous fluids, warm humidified oxygen, forced air heating, incubators and circulating water blankets. Care is necessary as active external **rewarming can cause a paradoxical decrease in core temperature, acidosis and shock**, because of the return of cold blood with lactic acid from the periphery.

Bradycardia is treated with adequate warming, fluid bolus, atropine (0.04 mg/kg IV), and a positive inotrope/chronotrope.

Hypovolemia is treated with crystalloids (55–60 ml/kg bolus rate IV) and colloids (5 ml/kg bolus rate IV). Adjust fluid rate to maintain envolemic status. Monitor respiratory rate and depth, and lung sounds carefully because pulmonary edema and pleural effusion are common.

Hypotension refractory to fluid therapy is treated with **exogenous catecholamines**, but many patients become refractory after 72–96 hours.

- **Dopamine** (5–20 µg/kg/min CRI) has positive inotropic, chronotropic and some vasoconstrictor effects, and has few adverse side effects.
- **Dobutamine** (5–20 µg/kg/min CRI) increases cardiac output and oxygen delivery. Seizures occur with continued (> 24 hours) use.
- **Epinephrine** (0.05–0.1 µg/kg/min CRI).
- Vasopressin.

Anemia requires **red cell transfusion** if the PCV is less than 20%.

Pain control helps maintain mental well-being, and is titrated to effect as responses are variable and affected by underlying hepatic and renal dysfunction:

- For **mild to moderate pain** use butorphanol (0.2–0.8 mg/kg IV q 2–6 h).

- For **severe pain** use methadone (0.2–0.4 mg/kg IM q 4–6 h), or morphine (0.1 mg/kg IM q 2–6 h or 0.12 mg/kg/h CRI) with or without diazepam (0.2 mg/kg IV).

Hypoglycemia is treated with 2½–5% dextrose added to IV fluids and/or boluses of dextrose at 0.25–0.50 g/kg increments.

Hyperglycemia is treated with low doses of regular insulin IV as CRI of 40–60 mU/kg/h.

Hyperkalemia is treated by adding 2 g potassium (26.8 mmol) per IL fluids, with a maximum CRI of 0.5 mEq/kg/h.

Hypocalcemia. If not giving blood products, use lactated Ringer's solution (Hartmann's) as the IV fluid, and give a slow IV bolus of calcium gluconate (20 mg/kg).

Hypomagnesemia. Administer Plasma-Lyte 148 which is compatible with blood.

Antimicrobial therapy. Early identification of the most likely pathogen is advantageous. Use antibiotic combinations (\geq two antimicrobials is now routine) to gain synergy, spectrum and reduced emergence of resistance.

- Acceptable combinations while awaiting culture results include:
 - Ampicillin (20–50 mg/kg q 6 h), gentamicin (6 mg/kg q 24 h) and metronidazole (20–40 mg/kg q 24 h).
 - Cephazolin (20–40 mg/kg q 8 h), gentamicin (6 mg/kg q 24 h) and metronidazole (20–40 mg/kg q 24 h).
 - Enrofloxacin (5–11 mg/kg q 24 h), metronidazole (20–40 mg/kg q 24 h).
- OR
 - Ticarcillin/clavulanate (30–50 mg/kg q 8 h) \pm gentamicin (6 mg/kg q 24 h)
- OR
 - Enrofloxacin (5–11 mg/kg q 24 h)
 - Ampicillin, cephazolin, or ticarcillin/clavulanate as above.
 - CAUTION: do not use gentamicin if there are signs of renal dysfunction. Enrofloxacin has been associated with blindness which is often irreversible.

Prognosis

Prognosis is guarded to poor, and a successful outcome relies on early intervention, and detection and elimination of the site of infection.

Prognosis worsens if shock signs (hypotension) do not respond to resuscitation within a few hours.

Severe hypothermia ($T < 35^{\circ}\text{C}$), or **neutropenia** (neutrophil count $< 1.0 \times 10^9/\text{L}$) are poor prognostic signs.

FELINE IMMUNODEFICIENCY VIRUS MYOPATHY

Classical signs

- Subclinical myopathy evident on muscle biopsy.

See main reference on page 339 for details (The Thin, Inappetent Cat).

Clinical signs

A **subclinical myopathy** has been shown to occur in experimentally infected FIV cats.

Diagnosis

A presumptive diagnosis is based on evidence of a subclinical myopathy in a FIV positive cat where other potential causes of myopathy have been excluded.

Some cats had **elevated CK levels and changes on EMG evaluation**.

Muscle biopsies may show inflammatory changes.

- Predominant histologic characteristics were perivascular and pericapillary lymphocytic infiltration and myofiber necrosis, phagocytosis and regeneration.

CIGUATOXIN INTOXICATION

Classical signs

- Signs begin within 3–6 hours of ingestion of a toxic meal of reef fish.
- Hindleg paresis and vomiting are the most prominent.
- Cardiovascular shock and/or respiratory distress may precede coma and death within 24 hours of ingestion.

Pathogenesis

Ciguatoxin is the main toxin that **accumulates in the flesh and viscera of large carnivorous species of fish**

associated with **coral reefs** (mostly **coral trout**, **Spanish mackerel**, **barracuda**).

A marine benthic dinoflagellate, *Gambierdiscus toxicus*, is believed to produce a precursor to ciguatoxin, gambiertoxin, which undergoes biotransformation within the stomach of herbivorous fish. The resultant ciguatoxin is absorbed from the stomach and sequestered in the muscles and viscera (potency increases tenfold in the process).

Ciguatoxin is heat stable and not affected by cooking.

Ciguatoxin is **lipid soluble** and may cross the blood–brain barrier, which accounts for the CNS effects.

An associated toxin, **maitotoxin**, is water soluble and is believed to account for the **gastrointestinal effects**.

Ciguatoxin interferes with the sodium channels located on the cell membrane of neurons. In the muscle sarcolemma it **increases sodium permeability** of the cell membrane. Increased sodium permeability **enhances activation**.

Cardiac effects are the **most life threatening** and involve **arrhythmias** and **negative inotropy**. Focal myocardial necrosis is evident histologically.

Centrally mediated **interference with phrenic nerve conduction** may lead to **respiratory failure and death**.

Clinical signs

Cats fed reef fish are at risk of poisoning, as are humans, even though incidences are low. Cats fed **viscera and liver** of these fish may consume a lethal meal because ciguatoxin levels are 50 times greater than in fish flesh.

Signs begin within 3–6 hours of ingestion of a toxic meal and **may last up to 14 days**.

Neurological signs include **hindlimb paralysis** extending to forelimbs in severe cases, and **ataxia**. **Gastrointestinal signs** include **hypersalivation** and **vomiting**.

Less severe cases may have some mild gastrointestinal signs and mild paresis.

Respiratory difficulty and arrhythmias may also occur. Death from respiratory failure can occur several days later.

Cardiovascular effects are biphasic. **Low doses** of toxin tend to induce hypotension, hyperventilation, **bradycardia** and atrioventricular block. As toxin absorption increases, the **higher doses cause** hypertension, **tachycardia**, respiratory depression and perhaps cardiac arrest.

Recovery is slow and **signs may persist for 1–2 weeks**.

Diagnosis

History of access to coral reef fish.

Presence of **gastrointestinal signs along with neurological signs** is supportive.

A rapid **calorimetric immunoassay** (the “stick test”) conducted on the fish flesh is inexpensive and quick and of use in ciguatera endemic regions.

Differential diagnosis

Rule out other causes of neurological signs, especially **tick paralysis** and **brown snake envenomation**. Cats with ciguatoxicity typically have gastrointestinal signs, a history of access to reef fish, **a lack of voice involvement** (typical in tick paralysis), and **no coagulation defects** (typical in brown snake).

Rule out **toadfish** (tetrodotoxin) poisoning largely via history of access as well as **pupillary dilation and voice changes** are more typical of tetrodotoxin.

Treatment

No specific treatment is available. Symptomatic and supportive measures including maintenance of body fluids and artificial respiration may be required.

Gastric lavage and/or induction of emesis in the early stages of intoxication may decrease the severity of signs.

Atropine (up to 1 mg/kg) helps control the gastrointestinal signs as well as reduces the bradycardia and hypotensive components of the cardiovascular effects.

Lignocaine by constant rate infusion (400 µg/kg/min) has been shown to **alleviate the cardiovascular effects** of ciguatoxin in the cat, probably by blocking the sodium channels.

Calcium gluconate (200 µg/kg/min CRI) infusion has been found to be of value in offsetting cardiac effects.

Propranolol (beta-blocker) at 1 mg/kg IV has been used to control severe tachycardias.

Mannitol (1 g/kg) infusions have not been shown to be successful in the cat, despite its reputation as the treatment of choice in humans, presumably through its effect as a free radical scavenger.

Current research is centered on production of an anti-toxin using monoclonal antibodies.

TETRODOTOXIN INTOXICATION

Classical signs

- Signs begin 10–40 minutes after ingestion.
- Initial signs are gastrointestinal – drooling, vomiting and diarrhea.
- Neuromuscular signs follow with weakness and ataxia progressing to flaccid hindlimb paralysis.
- Pupillary dilation is usually a feature.
- With severe toxicity, cardiovascular shock and labored respiration often precede convulsions and death within hours.

Pathogenesis

Tetrodotoxin accumulates in the **flesh and viscera of toadfish** (*Sphaeroides hamiltoni*) and **puffer fish, newts and the blue ringed octopus**. It is produced in the intestines of these species by *Vibrio* bacteria.

Tetrodotoxin is heat stable and is not affected by cooking.

Tetrodotoxin is a **powerful vasopressor and neurotoxin**. It exerts its action by inhibiting the excitability of neurones by **blocking the sodium channels** and decreases sodium permeability of the cell membrane (ciguatoxin has the opposite effect).

Tetrodotoxins **function similarly to local anesthetics and prevent depolarization of excitable tissues**.

Tetrodotoxin affects **skeletal muscle membranes and vasomotor nerves**, causing **hypotension**. Reduced neuromuscular junction impulse conduction manifests

as **flaccid paralysis** especially of the **hindlimbs and diaphragm**.

Although cardiac muscle is less sensitive than nerve or skeletal muscle tissues, severe intoxication can cause bradycardias, heart block and asystole as well as ventricular fibrillation.

Clinical signs

Signs begin **10–40 minutes after ingestion**.

Pawing at the mouth and licking of the lips probably equates to human reports of paraesthesia or numbness around the mouth and lips with a tingling (prickling) sensation.

Drooling, vomiting and diarrhea are usually followed by **muscular weakness and ataxia**. **Voice loss and dyspnea** occur once muscular weakness is evident.

Flaccid paralysis, especially of the hindlimbs, develops rapidly following initial signs of weakness and ataxia.

Bradycardia, cyanosis and hypotension are variable.

Pupillary dilation is usually a feature.

Death may ensue with terminal convulsions, labored breathing, tachycardia and hypotension evident.

Diagnosis

Diagnosis is usually based on a history of **rapid onset of neurological signs after access to a toxin source**.

No routine diagnostic laboratory tests are available.

Autopsy tissue samples can be tested by gas chromatography for toxin.

Differential diagnosis

Ciguatoxicosis typically causes similar signs although **slower in onset** and longer in duration and usually less intense and less acutely life threatening. **Pupillary dilation is not a feature of ciguatoxin**.

Tick paralysis signs are less intense and more slowly progressive and the presence of a tick is diagnostic.

Brown snake envenomation typically includes coagulation deficits.

Treatment

Gastric lavage and administration of activated charcoal are useful to remove unabsorbed toxin.

Airway maintenance, oxygen therapy and mechanical ventilation may be required.

Hypotension is treated with fluid resuscitation (up to 50–60 ml/kg of crystalloid replacement fluids) with or without peripheral vasoconstriction via norepinephrine (0.2 µg/kg/min) or dopamine (5–10 µg/kg/min CRI)

Etamiphylline (210 mg IM per cat), a cardiac and respiratory stimulant, has benefited some cases.

RED-BACK SPIDER ENVENOMATION (AUSTRALIA) (LATRODECTUS MACTANS HASSELTII) AND BLACK WIDOW SPIDER ENVENOMATION (USA) (LATRODECTUS MACTANS)

Classical signs

- Pain and swelling initially localized to the area of the spider bite. Pain may spread to remote areas over 30–60 minutes and may include abdominal pain.
- Vomiting is a variable sign.
- Agitation, muscle weakness, and incoordination occur later (1–24 hours).
- Muscular tremors and tachycardia.

Pathogenesis

Pain is produced at the **spider bite site and beyond** via an unknown mechanism which is presumed to be related to the presence of **algesic agents (e.g. histamine, 5-hydroxytryptamine, bradykinin)**. These act directly on nociceptors to promote the formation of prostaglandins and other inflammatory mediators which may act in synergism with the venom components to enhance pain production.

Venom is a protein (alpha-latrotoxin) of 130 000 daltons molecular weight, which is **predominantly neurotoxic in action**.

The **toxin action on the presynaptic terminal** of the **neuromuscular junctions** results in initial **outpouring of the neurotransmitters** (acetylcholine and norepinephrine) followed by depletion of acetylcholine reserves at motor nerve endings. This may result in **paralysis of voluntary muscles**.

The accompanying widespread **release of catecholamines causes hypertension**.

Clinical signs

Erythema, edema and localized swelling at the bite site occur within seconds to minutes after the bite. The pain increases in intensity within 5–15 minutes, causing generalized hyperaesthesia, vocalization, **chewing or licking** at the bite site and holding of the affected limb off the ground; swelling of the limb may occur.

Pain may appear widespread for example abdominal pain, causing **abnormal postures** such as hunched appearance, and may occur within 30–60 minutes of the bite.

Malaise, depression and vomiting may ensue.

Restlessness, tremors and weakness especially of the affected limb are common, and usually occur within 3 hours, but could be up to 24 hours

Tachycardia and hypertension occur in several cases.

Diagnosis

A presumptive diagnosis is based on the history of sudden onset of **severe pain in a cat with access to spiders** or finding a **collapsed cat with no coagulation defects** near where red-back or black widow spiders have been found.

Differential diagnosis

Snake bite envenomation typically displays **coagulation defects** as well as flaccid paralysis **without obvious pain**. Hindleg paralysis associated with poor circulation is a feature. Cold, purple-blue skin and absent pulses are typical.

Trauma can usually be differentiated if other injuries are evident.

Polymyositis or polymyopathy tends to be more generalized and much less intense; there is less rapid progression and no localization to an area.

Acute abdomen typically is more confined to the abdomen and is not accompanied by weakness unless advanced. Diagnostic tests such as abdominal ultrasound, abdominocentesis and/or diagnostic peritoneal lavage may be necessary to help differentiate.

Treatment

Supplemental oxygen by mask, head box, or nasal tube should be administered at 100–200 ml/kg, if the cat is dyspneic or distressed.

Ice packs may aid local pain relief. Pressure bandages may enhance pain and probably do little to restrict venom movement once systemic signs are present. This is because there is usually a ½–3-hour lag between the bite and the onset of systemic signs.

Administer **red-back spider antivenom** (500 units IM or diluted 1:50 slowly IV or **black widow spider antivenom** (equine origin) used similarly. Repeat the dose if no appreciable response is observed in 1–2 hours. The efficacy may be reduced if given after paralysis occurs.

Administer **pain relief with opioids** (e.g. buprenorphine 0.1–0.5 mg/kg) each 4–8 hours as needed.

Fluid and electrolyte therapy is necessary, especially correction of **calcium and potassium** deficits. Replacement isotonic crystalloid fluids should be used and these may need to have 20–80 mEq/L potassium added, depending on the serum potassium concentration. Calcium supplementation may be necessary and if serum levels can be monitored, increments of 5–10 mg/kg of calcium gluconate may be given each hour added to IV fluids.

Rest, warmth and close observation are important.

45. The cat with lameness

Maurine Thomson

KEY SIGNS

- Difficulty walking.
- Limping.
- Inability or reluctance to bear weight on limb.

MECHANISM?

- Structural or functional disorder of one or more limbs resulting in an altered gait or stance.

WHERE?

- Generally a disorder of the musculoskeletal system, occasionally neurological, metabolic or referred pain.

WHAT?

- Most lameness in cats is associated with trauma, particularly cat fight injuries or motor vehicle accidents.

QUICK REFERENCE SUMMARY

Diseases causing lameness

DEGENERATIVE

- **Degenerative joint disease* (p 981)**

Less common in the cat than dog, and often asymptomatic. Usually secondary to external joint trauma.

- **Intervertebral disc disease* (p 982)**

Rare in the cat, can cause paresis or lameness.

ANOMALY

- **Hip dysplasia (p 987)**

Rare in the cat compared to the dog, and occurs mainly in Persians. Usually asymptomatic in cats.

- Osteochondrosis dissecans (p 988)

Rare in the cat, reported in the shoulder joint.

- Femoral neck metaphyseal osteopathy (p 988)

Similar appearance to Legg–Calve–Perthes disease in dogs. Occurs rarely, exclusive to young male cats less than 2 years of age.

- Feline mucopolysaccharoidosis (p 988)

Rare inherited disorder of Siamese cats, which may cause a stiff gait.

- Osteogenesis imperfecta (p 989)

Rare inherited disorder of osteogenesis, which is characterized by brittle bones, which fracture readily with minor trauma.

- Scottish fold osteochondrodysplasia (p 989)

Occurs in Scottish folds resulting in periarticular exostoses and ankylosis.

- Pectus excavatum (p 989)

Congenital abnormality resulting in dorsal to ventral narrowing of the thorax. May be associated with limbs splaying laterally and impaired ambulation.

- Spina bifida (p 989)

Characterized by a closure defect in the neural arches, and is inherited with the gene for taillessness in Manx cats; causes variable neurological deficits.

NUTRITIONAL

- Hypervitaminosis A (p 990)

Seen occasionally in cats on all-liver diet. Causes joint ankylosis and spinal pain.

- **Nutritional hyperparathyroidism*** (p 990)

Due to diet low in calcium. Seen in young kittens on an all meat diet. Causes osteopenia and pathological fractures.

- Rickets (p 991)

Seen in young cats fed diet with calcium:phosphorus imbalance and vitamin D deficient. Causes osteopenia and thickening of physal growth plates.

NEOPLASTIC

- Neoplasia (primary neoplasia of bone, synovium, connective tissue or spinal cord and secondary metastatic neoplasia to digits from lung carcinomas) (p 977)

Rare in cats. Generally occurs in older cats and may present acutely or with an insidious onset of lameness. There is usually swelling at the site of the neoplasia.

INFECTIOUS

- **Cellulitis and soft tissue abscesses***** (p 979)

One of the most common causes of lameness in the cat, secondary to cat fight wounds. Usually acute onset of lameness, with variable signs of systemic illness.

- Bacterial septic arthritis or osteomyelitis (p 983)

Usually secondary to bite wound or hematogenous spread from septic foci. See lameness and typical discharging sinus.

continued

continued

- Localized tetanus (p 985)

Occasionally causes paresis or paralysis of a solitary limb in the initial stages, but usually advances to generalized tetanus.

- Viral arthritis (p 983)

Can occur secondary to calici virus exposure or vaccination; also coronavirus.

- Fungal infections (p 984)

Histoplasmosis, Coccidiomycosis, Sporotrichosis usually cause non-healing lesions, draining sinuses or osteomyelitis.

- Toxoplasmosis (p 984)

More often causes CNS signs such as ataxia, and paresis but can cause stiff gait, shifting lameness and muscle and joint pain.

- Neospora caninum (p 985)

Causes encephalomyelitis with ataxia and paresis and polymyositis.

IMMUNE MEDIATED

- Feline progressive polyarthritis (erosive) (p 985)

Rare disease; proliferative subtype occurs as acute onset in 1–5-year-old male cats, deforming subtype occurs as chronic onset in older cats. Usually several joints affected, most commonly carpus and tarsus. Proliferative subtype often has systemic signs of illness. Deforming subtype may be FeLV positive.

- Immune-mediated polyarthritis (non-erosive) (p 985)

Rare disease, due to deposition of immune complexes in the synovial membrane. Usually carpus and tarsus affected. May be idiopathic or associated with SLE or chronic infection.

TRAUMA

- **Fractures, luxation, muscular contusions*** (p 980)**

Very common cause of presenting lameness.

- Cruciate rupture (p 982)

Occurs much less frequently in the cat than the dog, and usually less symptomatic.

- Patellar luxation (p 983)

Occurs only rarely in the cat, predisposition in Devon Rex cats.

INTRODUCTION

MECHANISM?

Lameness can occur in any limb, and is defined as interference in the normal locomotion of the cat. It is usually pain related, and is secondary to tissue injury which has caused structural alteration, edema and inflammation.

The severity of the lameness will vary with the severity and type of the injury or insult, varying from a mild to a non-weight-bearing lameness.

Generally periosteum has the densest nerve supply of the deep tissues, and has the lowest pain threshold, followed by the joint capsule, tendon, fascia and muscle.

Mechanical lameness can result from an abnormal limb conformation such as shortening, angulation or a rotational abnormality.

Referred pain is pain felt in a part of the body other than that where the cause of pain is located.

Signs of weakness can be confused with lameness. See *The Cat With Generalized Weakness* (page 941). Paresis and ataxia can also be confused with lameness. *The Weak and Ataxic or Paralyzed Cat* See (page 908).

WHERE?

The origin of the lameness may be from bone, muscle, joint or neurological.

Diagnosis requires a good physical examination and orthopedic examination to localize the lameness in the affected limb or limbs.

WHAT?

The most common causes of lameness in the cat are cellulitis or an abscess from a cat bite injury, and motor vehicle trauma resulting in fracture or luxation.

The site of the injury is generally localized by palpation of pain and swelling at the affected site.

Cellulitis is often associated with pyrexia and lethargy.

Motor vehicle trauma is often associated with other signs of external injury such as grazes or scuffed nails, with or without dyspnea or internal injuries.

DISEASES CAUSING SIGNS OF LAMENESS

CELLULITIS/SOFT TISSUE ABSCESS***

Classical signs

- Acute lameness of affected limb.
- Pain and soft tissue swelling at site of injury.
- Often associated with pyrexia, anorexia, lethargy.
- Wounds in close proximity to a joint can cause septic arthritis.

Pathogenesis

Occurs secondary to a penetrating bite wound, and is one of the most common causes of lameness in the cat.

Many bacteria are present in the oral cavity of cats, but *Pasteurella*, *Bacteroides* and *Fusobacterium* are the most common organisms responsible for abscess formation, though a mixture of anaerobes and aerobes may also be present.

Infection may take the form of a discrete abscess or a diffuse cellulitis.

Occasionally L-forms of bacteria which lack bacterial walls are involved.

Clinical signs

Acute lameness.

Soft tissue swelling and pain at the affected site.

Often a small scab and evidence of a bite wound can identify the area of penetration.

Associated with variable signs of systemic illness, including depression, pyrexia and anorexia.

L-forms produce a syndrome of fever and persistently draining, spreading cellulitis and synovitis that often involve extremities. Lesion is unresponsive to most antibiotics except tetracycline group.

Diagnosis

History of a cat fight.

Clinical signs of penetrating injury.

Abscess formation can be demonstrated by aspiration of purulent material.

L-form bacteria produce a discharge containing predominantly macrophages and neutrophils, but organisms cannot usually be detected cytologically or grown on culture. Response of syndrome only to tetracycline group antibiotics suggests diagnosis.

Differential diagnosis

Soft tissue injury caused by another form of external injury.

Foreign body reaction.

Osteomyelitis often causes swelling and sinus formation. Rare in the cat and usually associated with an open fracture or bite wound.

Treatment

Abscess formation generally requires lancing, and flush with weak solution of chlorhexidine, followed by course of antibiotics sensitive to *Pasteurella*, i.e. amoxycillin and clavulonic acid 12 mg/kg for 5 days.

Rarely there may be extensive regions of necrosis, which may require debridement and delayed closure.

Cellulitis treated by broad-spectrum antibiotics, i.e. amoxycillin and clavulonic acid, or cephalosporins.

Osteomyelitis may be a rare secondary complication resulting in sinus formation after initial healing of the abscess.

L-form bacteria respond rapidly to tetracycline (22 mg/kg tid PO) or doxycycline (5 mg/kg bid PO).

Prognosis

Normally **excellent**, and resolves after initial treatment.

With extensive injury the prognosis is still excellent, although it may require more prolonged treatment.

With septic arthritis some degree of degenerative joint disease will occur, although cats tolerate this with less clinical symptoms than dogs.

FRACTURES, LUXATION, MUSCULAR CONTUSIONS***

Classical signs

- Acute, usually non-weight-bearing lameness of affected limb or limbs.
- Soft tissue swelling at the site of injury.
- Abnormal movement or angulation of the affected bone or joint.

Pathogenesis

Usually due to external trauma from a motor vehicle accident.

Can also occur from other external trauma such as dog attack, malicious attack or fall.

Hindlimb lameness in young cats less than 7 months of age is usually due to **disruption of the growth plate to the femoral head rather than hip luxation.**

Type and location of the fracture or luxation will depend on the type of forces that have occurred at the time the injury was sustained.

Clinical signs

Acute lameness of the affected limb.

Pain and swelling localized by physical examination.

Most common sites of fractures are femur, humerus, pelvis, tibia and radius.

Hip luxation is the most common form of joint disruption in the mature cat.

Pain localized to the hip in young cats is more likely due to separation of the femoral head.

Fracture/luxation injuries may be open or closed.

Open shearing injuries of the carpus and tarsus often occur due to the minimal degree of soft tissues covering over these regions.

Diagnosis

Usually history of trauma.

Localization by physical examination.

Radiography is normally required to demonstrate exact type and location of the fracture or luxation.

Differential diagnosis

Cellulitis can cause a similar degree of soft tissue swelling and lameness. Usually differentiated by evidence of penetrating wound and pyrexia.

Neoplasia of a bone or joint can present suddenly if associated with a pathological fracture. Very rare in the cat, and usually differentiated on radiographs.

Nutritional hyperparathyroidism in the young cat can present suddenly due to spontaneous fractures. Radiographically will see generalized osteopenia, with history of poorly balanced diet.

Treatment

Will depend on the location and extent of the injury.

Simple fractures in young animals may be amenable to external coaptation, i.e. splints or casts.

More extensive fractures generally require some form of internal fixation. See relevant textbooks dealing with orthopedic diseases and management.

Joint sprains or other soft tissue injuries usually respond well to brief periods, i.e. 2 weeks or less, of immobilization, or simple rest.

Prognosis

Depends on the location and degree of severity of the injury.

With appropriate treatment most injuries have a very good prognosis for return to normal function.

Excision arthroplasty in the cat for treatment of femoral head separation or fracture has a very good to excellent prognosis following surgery.

Cats are generally less symptomatic for osteoarthritis following joint trauma than are dogs.

DEGENERATIVE JOINT DISEASE*

Classical signs

- Chronic, insidious lameness of the affected limb.
- Lameness may be worse after sleeping, or when first rising.
- May have thickening of the affected joint, with decreased range of movement.
- Much less common in the cat than the dog.

Pathogenesis

Generally secondary to joint trauma such as open fracture, or penetrating bite wound.

Can occur secondary to joint conformational abnormality such as hip dysplasia in Persian cats, patellar luxation or cruciate rupture.

May be part of an immune mediated polyarthritis, e.g. systemic lupus erythematosus.

Can occur secondary to septic arthritis from hematogenous spread or direct contamination.

Occasionally occurs in association with acromegaly from excess growth hormone.

Clinical signs

Insidious lameness which may be exacerbated by strenuous activity.

Usually some degree of joint thickening and reduced range of motion on physical exam.

Often does not cause any clinical signs of lameness and may be incidental finding.

Diagnosis

History of insidious or vague intermittent lameness.

Radiographs demonstrate signs of osteoarthritis such as osteophytes, periosteal proliferation and periarticular joint thickening.

Differential diagnosis

Joint neoplasia, which is very rare in the cat. Usually expect more extensive swelling and consistent lameness.

Treatment

Most cats are not symptomatic for osteoarthritis, or if associated with a sudden exacerbation of the joint normally respond well to conservative management. This involves rest and short-term non-steroidal anti-inflammatory drugs, i.e. aspirin 10 mg/kg every 48 hours or corticosteroids, i.e. prednisolone 0.25 mg/kg daily, or other non-steroidal anti-inflammatory drugs, e.g. carprofen, ketofen or meloxicam depending on availability and registration for use in cats.

Encourage weight loss in fat cats.

In severe cases of osteoarthritis associated with erosive arthritis or joint instability, arthrodesis may be warranted.

Prognosis

Generally very good when single joint is involved.

With severe polyarthritis long-term prognosis is poor, with most cases relapsing after therapy.

INTERVERTEBRAL DISC DISEASE*

Classical signs

- Much rarer in the cat than the dog.
- Usually results from traumatic herniation of the disc.
- Clinical signs vary with the location of the disc herniation.
- Signs may be acute or progressive in onset.

Pathogenesis

Usually results from traumatic herniation of the disc, resulting in acute spinal cord compression.

Much rarer in the cat than the dog.

Clinical signs

Location of the site of herniation dictates type of clinical signs seen.

Usually associated with paresis of the hindlimbs. See The Weak and Ataxic or Paralyzed Cat (page 908).

Diagnosis

Lesion identified by neurological examination.

Confirmation of disc herniation by radiographs, myelography or CT imaging.

CRUCIATE RUPTURE

Classical signs

- Acute onset of hindlimb lameness.
- May have thickening of the affected joint due to synovitis, with pain evident on palpation of the stifle.
- Positive cranial drawer sign or tibial thrust.
- Much less common in the cat than the dog.

Pathogenesis

Usually due to external trauma such as a fall, hyperextension injury of the stifle, or excessive internal rotation of the tibia.

Generally causes rupture of the anterior cruciate, rarely is the caudal cruciate involved, unless there has been major stifle disruption.

Clinical signs

Acute lameness of the affected hindlimb.

Generally there will be stifle swelling and pain present on joint palpation.

A positive cranial drawer sign or tibial thrust is generally evident on palpation, though pain may prevent an adequate examination of the joint.

Chronic cases may show a mild intermittent lameness as opposed to the acute injury.

Diagnosis

By identification of a positive cranial drawer sign and pain in the stifle.

Differential diagnosis

Traumatic disruption of all stifle ligaments due to excessive trauma. Usually palpation will reveal laxity in a mediolateral direction also if the collaterals have been disrupted.

Treatment

Conservative therapy with rest and anti-inflammatories is generally sufficient for return to normal function in most cats.

Degenerative joint disease will usually occur, but this does not normally cause clinical signs of lameness.

In refractory cases the stifle can be stabilized with an extra-articular surgical technique. See relevant texts on surgical management of cruciate disease.

Prognosis

Generally the prognosis is very good to excellent with both conservative and surgical management.

PATELLAR LUXATION

Classical signs

- Can be congenital or acquired secondary to trauma.
- Much rarer in the cat than the dog, though a predisposition occurs in purebred cats such as the Devon Rex.
- Lameness may be worse after sleeping, or when first rising.
- May have thickening of the affected joint, with decreased range of movement.

Pathogenesis

The congenital form occurs secondary to malalignment of the quadriceps mechanism, generally resulting in a medial luxation of the patella.

Varying degrees of deformity of the trochlear groove and tibial tuberosity can occur depending on the severity of the luxation.

The acquired form can occur secondary to external joint trauma from a fall or motor vehicle accident.

Clinical signs

The congenital form is characterized by varying degrees of lameness depending on the severity of the condition. The lameness is often insidious and intermittent.

Usually occurs in young, purebred cats.

The acquired form can occur at any age, usually presenting with an acute lameness.

Palpation of the stifle will demonstrate luxation of the patella.

Diagnosis

Palpation of the stifle demonstrates patellar luxation, usually in a medial direction.

Lameness present in the affected limb, which varies with the severity of the underlying disease.

Treatment

In cats with clinical disease surgery is generally warranted.

Type of surgery varies with the severity of the disease, ranging from lateral imbrication, deepening of the trochlear groove and transposition of the tibial tuberosity.

Prognosis

Generally excellent, despite the progression of some degree of degenerative joint disease.

BACTERIAL SEPTIC ARTHRITIS OR OSTEOARTHRITIS

VIRAL ARTHRITIS

Classical signs

- Lameness may be of a single limb or multiple.
- If all limbs involved will be reluctant to ambulate at all.
- Can cause erosive or non-erosive signs radiographically.
- Considered rare in the cat as a cause of lameness.

Pathogenesis

Bacterial:

- Generally from a blood-borne infection that arises from a septic focus elsewhere in the body.
- Can occur from direct bite wound or open joint injury.
- Rarer in cats than dogs.
- Can occur in kittens secondary to umbilical vein infections.
- *Pasteurella* species are most commonly identified.
- Can be due to bacterial L forms, which are mutant bacteria, which have lost their cell wall.

Viral:

- **Calicivirus** polyarthritis can occur uncommonly in young kittens following natural exposure or after live attenuated vaccination.
- Lameness usually occurs 7–10 days after mild respiratory tract signs, though can occur in the absence of respiratory signs.
- **Coronavirus** has also been associated with polyarthritis.

- The effusive form of **feline infectious peritonitis** (FIP) virus occasionally causes lameness, with leakage of fluid into joint spaces.
- The granulomatous form of FIP may cause paresis or paralysis as a result of spinal cord inflammation.

Mycoplasma:

- *M. gatae* is linked to arthritis and tenosynovitis in older cats.
- Mycoplasmal infection may incite an antigenic response resulting in the formation of immune-mediated disease such as rheumatoid-like (deforming) arthritis.

Clinical signs

Acute onset of lameness in one or several limbs.

Usually associated with **systemic signs such as pyrexia, lethargy.**

May appear weak rather than lame if all four limbs involved.

Usually demonstrate joint pain on manipulation of limbs.

Diagnosis

Radiographic signs may demonstrate changes of erosion and periosteal proliferation in advanced cases, but may show no abnormalities initially.

Arthrocentesis generally required for cytology and culture and sensitivity.

Differential diagnosis

Weak or paretic cat can appear similarly. See The Weak and Ataxic or Paralyzed Cat (page 908).

Immune-mediated polyarthritis.

Treatment

Antibiotics for bacterial infection depending on results of culture and sensitivity.

L form infections respond well to 10–14-day course of tetracycline or doxycycline.

Calicivirus is often self-limiting, and cats recover well.

TOXOPLASMOSIS

Classical signs

- More commonly causes CNS signs such as ataxia and paresis.
- Can cause a stiff gait, shifting leg lameness, hyperaesthesia on muscle palpation and joint pain.

See main references on page 705 for details (The Cat With Signs of Acute Small Bowel Diarrhea) and page 958 (The Cat With Generalized Weakness).

Clinical signs

CNS signs seen most frequently, see The Paretic Cat (page 911).

May cause shifting limb lameness.

Can cause arthritis and myositis.

Diagnosis

High IgM titers suggest recent infection, but do not confirm that *T. gondii* is responsible for the clinical signs in a given cat.

The organism can sometimes be seen in a muscle biopsy or very rarely in CSF.

FUNGAL INFECTIONS

Classical signs

- Cats less commonly affected than dogs.
- Lameness due to fungal osteomyelitis.
- Can be a single bone involved, or more commonly multiple sites affected.
- Spores usually inhaled from the soil.

See main references on page 368 for details (The Pyrexia Cat) and page 401 (The Cat With Enlarged Lymph Nodes).

Clinical signs

Occurrence tends to be location dependent:

- *Coccidioides*: south-western USA, Mexico, Central and South America.

- *Blastomyces*: small area of distribution mainly in North America and near fresh water.
- *Histoplasma*: widespread in temperate and subtropical regions of the world, not Australia.
- *Cryptococcus*: worldwide distribution.
- *Sporotrichosis*: worldwide distribution.

Result in non-healing tumor-like lesion of the distal limbs and draining sinus tracts (sporothrix) or lameness due to fungal osteomyelitis.

Radiographically, see tumor-like lesions present in the bone with bone bony destruction and proliferation seen.

Diagnosis

Organism is often evident in cytological preparation of aspirates or discharge from lesion or in a biopsy section.

Positive fungal titer may aid diagnosis.

NEOSPORA CANINUM

Classical signs

- Neurological signs such as ataxia and paresis.
- Polymyositis frequently present.

Clinical signs

Polymyositis and encephalomyelitis with ataxia and paresis are seen most frequently.

Diagnosis

Serum titers and muscle biopsy results are the most common methods of diagnosis.

LOCALIZED TETANUS

Classical signs

- Retrograde axonal transport of the toxin from an infected focus.
- Can cause paralysis of single limb.
- Usually progresses to generalized tetanus.

See main references on page 1340 for details (The Cat With an Abnormal Third Eyelid).

Clinical signs

Occurs following penetrating trauma and tissue devitalization.

Retrograde axonal transport of the *Clostridium tetani* neurotoxin occurs.

Can see **paresis or paralysis of a solitary limb in the initial stages.**

Generally **advances to generalized tetanus.**

Diagnosis

History of recent wound and clinical signs.

EMG findings characteristic with persistent electrical motor unit discharges following needle insertion or tapping of muscles.

Serum antibody titer to tetanus toxin compared with control cats may aid diagnosis.

IMMUNE-MEDIATED POLYARTHRITIS (NON-EROSIVE)

Classical signs

- Are considered rare diseases in the cat.
- Can be acute or chronic onset.
- Often associated with other systemic signs such as lethargy, pyrexia and anorexia.
- Can cause erosive or non-erosive signs radiographically.

Pathogenesis

Erosive form (feline progressive polyarthritis):

- Chronic progressive polyarthritis has proliferative and deforming subtypes.
- Proliferative form occurs in male cats aged 1–5 years.
- Deforming type occurs more rarely in older cats.
- Severe subchondral bone destruction may occur, leading to joint instability and deformity.
- Radiographic signs are similar to those of rheumatoid arthritis in other species.
- Often associated with feline leukemia virus-positive cats.

- Mycoplasmal products have been postulated to chronically stimulate immune-mediated diseases such as deforming arthritis.

Non-erosive form: (immune-mediated polyarthritis).

- Can be due to systemic lupus erythematosus, chronic infection elsewhere, or idiopathic.
- Due to deposition of immune complexes in the synovial membrane which incites an inflammatory response.
- The inciting agent is usually not identified, but if the cat is on medication this may be a potential source and should be discontinued.

Clinical signs

Deforming type of progressive polyarthritis has a **chronic onset**. All other forms tend to be **acute onset of lameness and stiffness**.

Often affects **carpus and tarsus** more severely than other joints.

Diagnosis

Radiographic signs in erosive forms show marked **destruction and deformity** of the distal joints often resulting in **luxation or subluxation** but with minimal periosteal proliferation.

The proliferative form is characterized by **periarticular soft tissue swelling** in the early stages, then progressing to extensive **periarticular proliferation**. This is most frequently seen in the carpi, tarsi and smaller distal joints.

Arthrocentesis preferably done on two or more joints. Joint fluid is generally slightly increased in amount, slightly turbid, and with reduced viscosity. Cytology typically reveals a non-septic purulent inflammation, with cell counts in the range of 4000–70 000 nucleated cells/ μ l, and predominantly non-degenerative neutrophils. A variable number of small and large mononuclear cells may also be present.

Joint cultures are negative for bacteria and *Mycoplasma*.

Rheumatoid factor, ANA and LE cell tests are consistently negative.

Hematological parameters are generally unremarkable.

Differential diagnosis

Infectious arthritides, such as viral infections.

Causes of weakness and paresis in the cat. See The Weak and Ataxic or Paralyzed Cat (page 908).

Treatment

Remove the cause if secondary to drug administration or chronic infection.

Treatment consists of immunosuppressive doses of corticosteroids for several months, or in combination with chlorambucil at 1.0–1.25 mg/cat once daily, and prednisolone 10–20 mg twice daily until resolution of clinical signs, then slowly taper the dose of prednisolone over 2–4 months. Continue the chlorambucil at the same dose every other day. Combination of prednisolone and gold salts (aurothioglucose 1 mg/kg by injection once a week) has also been used.

Prognosis

Good initial response to drugs, but greater than 50% of cases are likely to relapse, becoming more refractory to treatment.

NEOPLASIA (PRIMARY NEOPLASIA OF BONE, SYNOVIUM, CONNECTIVE TISSUE OR SPINAL CORD AND SECONDARY METASTATIC NEOPLASIA TO DIGITS FROM LUNG CARCINOMAS)

Classical signs

- Rarer in the cat than dog.
- May be acute or insidious onset of lameness.
- Usually associated with swelling at site of neoplasia.

Pathogenesis

Primary bone tumors are rare in the cat. Osteosarcoma is the most commonly identified tumor.

Generally occurs in cats older than 10 years.

Primary bone tumors are much less metastatic in the cat than the dog.

Metastatic spread from carcinomas to bone is very rare in the cat, compared to the dog.

Can get carcinomas of the digits secondary to primary lung tumors.

Joint neoplasias are very rare in the cat, and are due to synovial cell sarcomas or other soft tissue sarcomas.

Multiple cartilaginous exostoses or feline osteochondromatosis can transform to a malignant disease in the cat.

Lameness can also occur from nerve sheath tumors of the plexus or spinal cord, but these are very rare in the cat.

Clinical signs

Can be acute or insidious onset of lameness.

Rarely can be associated with pathological fracture.

Usually thickening identified at site of disease, which may or may not be painful.

Diagnosis

Radiographically, will see bone lysis in the metaphyseal region of long bones, or joint thickening and proliferation.

Histopathology is required for definitive diagnosis.

Thoracic radiographs should be taken to demonstrate primary lung tumor if multiple digits are swollen, or prior to amputation to rule out metastatic disease.

Differential diagnosis

Osteomyelitis.

Septic arthritis.

Treatment

If no evidence of metastatic disease, amputation is the treatment of choice.

If a solitary tumor of a digit is present, often this can be removed and the limb saved.

Prognosis

If no evidence of metastatic disease, then amputation is often curative, with median survival times greater than 2 years.

Primary bone tumors in the cat are a lot less aggressive than in the dog and generally not followed with chemotherapy.

HIP DYSPLASIA

Classical signs

- Usually occurs in Persian and long-haired cats.
- Usually asymptomatic in cats compared to dogs.
- Generally requires only conservative management.

Pathogenesis

Congenital disorder of Persian and other long-haired cats.

Radiographically, see luxation of the coxofemoral joint, with varying degrees of osteoarthritis present.

Clinical signs

Usually no clinical signs of lameness are seen.

Pain may be exhibited on flexion and extension of the hip joints.

Occasionally may show signs of a stiff gait or lameness, which is exacerbated by excessive activity.

Diagnosis

Pain on manipulation of the hip joints in a long-haired cat.

Radiographic evidence of hip laxity and osteoarthritis.

Treatment

Usually conservative management consisting of rest, weight loss and intermittent anti-inflammatory drugs is all that is required in symptomatic cats.

If lameness persists femoral head and neck arthroplasty results in an excellent prognosis.

OSTEOCHONDROSIS DISSECANS

Classical signs

- Onset of forelimb lameness in the cat less than 1 year of age.

Pathogenesis

Very rare in the cat.

Has been reported as cause of shoulder lameness.

Occurs due to a defect in osteochondral ossification.

Clinical signs

Insidious forelimb lameness in cats less than 1 year of age.

Pain identified on full extension and flexion of the shoulder joint.

Diagnosis

Radiographically a thickened flap of cartilage or joint mouse can be identified in the shoulder joint.

Treatment

Surgical removal of the cartilaginous flap.

Prognosis

Excellent.

FEMORAL NECK METAPHYSEAL OSTEOPATHY

Classical signs

- Onset of hindlimb lameness in the cat less than 1 year of age.

Pathogenesis

Uncommon condition.

Reported in male cats less than 2 years of age.

Idiopathic necrosis of femoral neck.

Clinical signs

Vague, progressive hindlimb lameness.

May be bilateral.

Diagnosis

Radiographically, see radiolucency of the femoral neck and proximal femoral metaphysis.

Differential diagnosis

Traumatic fracture of the femoral neck.

Treatment

Femoral head and neck osteotomy.

Prognosis

Excellent.

FELINE MUCOPOLYSACCHARIDOSIS

Classical signs

- Rare inherited disorder in Siamese and Siamese cross cats.
- Causes a stiff gait and paraparesis.
- Cats also have a broad maxilla, corneal clouding, pectus excavatum and neurological abnormalities.

Clinical signs

Rare inherited disorder that occurs as a result of a lysosomal enzyme deficiency in Siamese and Siamese cross cats.

Usually present at less than 6 months of age.

Typically have dysmorphic facial features (a broad maxilla), plump paws (from thickened skin) and corneal clouding.

Generally exhibit a stiff gait and paraparesis with diffuse neurological signs.

Also present with a chronic mucoid ocular discharge and chronic respiratory tract infections.

Diagnosis

Constellation of clinical signs suggests the diagnosis.

Radiographs show dysplastic femoral heads and necks and subluxated hip joints.

Excessive granulation of neutrophils, and **vacuolation of lymphocytes** are suggestive.

Positive urine toluidine test for sulfated beta glycosaminoglycans is consistent with diagnosis.

Definitive diagnosis is via enzyme assays of leukocytes and skin fibroblasts to demonstrate deficient beta glucuronidase activity.

OSTEOGENESIS IMPERFECTA

Classical signs

- A defect in osteogenesis results in multiple spontaneous fractures.
- Present with multiple sites of bony pain due to fractures, or unwilling to ambulate.
- Lameness generally of young cats.

Clinical signs

A heritable disease with failure of osteoprogenitor cells to develop into mature osteoblasts.

Results in bones that are very brittle and fracture spontaneously.

Spontaneous fractures can occur in any bones, although the long bones are more commonly affected.

Diagnosis

Radiographically the cortical bone is very osteopenic, with multiple fractures present.

SCOTTISH FOLD OSTEOCHONDRODYSPLASIA

Classical signs

- Disease affecting cats with at least one fold-eared parent.
- Lameness generally occurs at 5–6 months of age.

Pathogenesis

Inherited disorder of fold-ear cats.

Get shortening of the coccygeal vertebrae, metacarpal and metatarsal bones and phalanges.

They may develop periarticular exostoses and joint ankylosis.

PECTUS EXCAVATUM

Classical signs

- A congenital disorder characterized by dorso-ventral flattening of the thorax.
- Kittens and cats show variations in respiratory and cardiovascular abnormalities.
- Also associated with lateral limb deviation.

Clinical signs

A deformity of the sternal and costal cartilages resulting in narrowing of the thorax.

Occurs as a congenital abnormality of cats, with the specific cause unknown.

Can be associated with the so-called “wimmer’s” syndrome, in which there is lateral deviation of the limbs and impaired ambulation.

Kittens and young mature cats < 1 year of age may show respiratory and cardiovascular abnormalities associated with flattening of the thorax.

Diagnosis

Based on clinical signs and radiographic findings of dorso-ventral flattening of thorax and lateral deviation of limbs.

SPINA BIFIDA

Classical signs

- Congenital disorder caused by a closure defect of the vertebral arches.
- Inherited with the gene for taillessness in Manx cats.

(continued)

Classical signs—Cont'd

- Varying degrees of severity of the condition exist.

See main references on page 920 for details (The Weak and Ataxic or Paralyzed Cat).

Clinical signs

Improper closure of the neural tube during embryogenesis occurs, with varying severity of neurological signs seen affecting hindlimb function and urinary and fecal control.

In the Manx cat it is often associated with sacral dysgenesis.

Diagnosis

Based on clinical signs, radiographic findings.

HYPERVITAMINOSIS A**Classical signs**

- Due to excessive intake of vitamin A, usually from an all-liver diet.
- Lameness occurs due to bony exostoses around the cervical vertebrae and ankylosis of joints.

Pathogenesis

Due to excessive vitamin A intake over several months, usually from an all-liver diet.

Causes bony exostoses of spine and osseous hyperplasia and proliferation at joint margins, particularly the shoulder and elbow joints.

Excess vitamin A causes increased reactivity of the periosteum, resulting in bony proliferation at sites of joint capsule and soft tissue attachments to bone.

Clinical signs

Cats are often reluctant to move around, and are very painful.

They often display an abnormal posture with a stiff neck and gait.

Diagnosis

Radiographically there is ankylosis of cervical and cranial thoracic vertebra, and new bone proliferation around shoulder and elbow joints.

History of diet almost exclusively of liver.

Treatment

Correction of the diet, ideally on a balanced commercial diet.

May require short-term analgesics.

Prognosis

Correction of the diet halts the progression of disease, and some remodeling of existing bone may occur. However, bony changes are often permanent and pain may persist.

NUTRITIONAL HYPERPARATHYROIDISM**Classical signs**

- Lameness present in multiple sites in young kittens.
- Due to a diet deficient in calcium, such as an all-meat diet.

Pathogenesis

Due to increased parathyroid hormone from persistent hypocalcemia, either from an absolute dietary calcium deficiency or secondary to excessive phosphorus intake relative to calcium.

Causes generalized osteopenia.

Most commonly seen in kittens on an all-meat diet. Occurs with an all-meat diet even if the kittens have access to milk.

Clinical signs

Osteopenia can result in spontaneous fracture.

Diagnosis

History of inadequate diet.

Radiographs demonstrate diffuse osteopenia, with or without folding fractures.

Treatment

Correct the diet by adding calcium, or more appropriately, change to a balanced commercial diet formulated for kittens.

Confine if multiple folding fractures are evident.

Prognosis

Very good if fractures have not resulted in malunion.

Residual deformity of the spine and pelvis may result in chronic partial bowel obstruction with constipation.

RICKETS

Classical signs

- Lameness present in multiple sites in young kittens.
- Due to a diet deficient in vitamin D or insufficient mineral content, such as an all-meat diet.

Pathogenesis

Diet deficient in vitamin D or with insufficient mineral content causes the cartilaginous matrix of the growth plate not to calcify.

Results in osteopenia and widening of the growth plates.

Clinical signs

Osteopenia can result in spontaneous fracture.

Abnormalities of the growth plate with rickets can cause angular limb deformities.

Diagnosis

Diffuse osteopenia, and may see pathological fractures.

With rickets see widened growth plates and osteopenia.

Treatment

Correct the diet by feeding a balanced commercial diet, and adequate exposure to light.

May require confinement if multiple fractures have occurred.

Prognosis

Usually excellent prognosis if there is not abnormal limb angulation. Correction of the diet corrects the underlying osteopenia and growth plate defect.

PART 12

Cat with behavioral problems

46. The cat with aggression

Kersti Seksel

KEY SIGNS

- Body position, piloerection.
- Hissing, spitting.
- Spraying.
- Scratching, biting.

MECHANISM?

- Aggression is a **threat, challenge or attack** that is directed towards one or more individuals.
- It can be intra- (members of the same species) or interspecific (members of other species).
- Aggression may be normal or abnormal depending on the context.
- Aggression can be **overt** (active, e.g. obvious distance increasing signals) or **covert** (passive, e.g. blocking access).
- Several types of aggression may occur concurrently (see list below).

WHERE?

- The **hypothalamus and amygdala** are involved in defense and aggression.
- **Monoamines and androgenic steroids act as modulators** of established offensive and defensive aggressive behaviors.

WHAT?

- Currently **11 diagnostic categories of feline aggression** are recognized and they may co-occur. The actual prevalence of each category is unknown.
- Most causes of aggression are the result of the **interplay between environmental and genetic factors**, as well as previous experiences (learning).
- Medical conditions and drugs have also been associated with feline aggression.

QUICK REFERENCE SUMMARY

Diseases causing aggression

- **Play aggression** (p 995)**

Aggression usually exhibited by young cats with no contact with other cats in early development. Often directed towards humans, but can be other cats or animals. May involve stalking, chasing, pouncing and biting (usually inhibited) but rarely vocalization and is directed towards moving objects.

- **Redirected aggression** (p 996)**

Aggression directed towards another cat or a human when the original target of the aggression is not accessible. It is of sudden onset, can be prolonged in duration and usually alters the behavior of the victim.

- **Intercat, intermale aggression** (p 998)**

Aggression directed by an entire male cat towards another entire male cat in response to its presence in the near proximity, and is more common during the breeding season.

- **Fear aggression** (p 999)**

Aggression seen in a confined or cornered animal, and it is usually preceded by attempts to escape. Cats can be fearful of people, places, other cats, or various stimuli such as noises or odors.

- **Aggression when patted** (p 1000)**

Exhibited towards humans after tactile stimulation of variable duration. It can occur even if the cat seeks the initial attention.

- **Impulse control or status-related aggression** (p 1002)**

Aggression directed towards people when the cat is actively or passively prevented from controlling an interaction or situation. The cat may even initiate contact and demand attention but then attack.

- **Territorial aggression* (p 1003)**

Aggression exhibited in response to an intruder, another cat or person, coming into an area in which the cat has established itself. The cat does not try to avoid encounters with the intruder.

- **Pain aggression* (p 1004)**

Aggression exhibited in response to a painful stimulus.

- **Predatory aggression (p 1005)**

Aggression exhibited in response to a natural prey object.

continued

continued

- **Maternal aggression (p 1006)**

Aggression exhibited in response to the proximity of any human or animal which is perceived as threatening the kittens.

- **Idiopathic aggression (p 1007)**

Unprovoked and unpredictable aggression. No underlying cause can be identified and diagnosis is by exclusion. Very rare in cats.

INTRODUCTION

MECHANISM?

As a behavioral event, aggression can be **both a description and a diagnosis**.

Aggression is a non-specific sign. It may be **passive (covert)** or **active (overt)** and involve a threat, challenge or an actual attack.

Signs may be **visual (changes in body posture, piloerection)**, **auditory (hissing, spitting)**, or **olfactory (spraying, scratching)** and may involve use of **teeth** and/or **claws**.

Covert or passive aggression may involve behaviors such as staring or sitting in doorways and blocking access, and as such is often missed by the owners.

Overt or active aggression may involve more obvious visual signs such as hissing, spitting growling, swatting and actual fighting.

Excitation of the ventromedial hypothalamus (VMH) and amygdala leads to a defensive response.

- The **medial amygdaloid nucleus** is involved with **intraspecies aggression**.
- Stimulation of **lateral amygdala** facilitates **predatory attack and defensiveness**. More defensive cats have less predatory aggression.

In most behavioral conditions, the underlying pathogenesis is unknown but is likely to be neurochemically complex.

WHERE?

The hypothalamus and amygdala are involved in defense and aggression.

Monoamines and androgenic steroids act as modulators of established offensive and defensive aggressive behaviors.

WHAT?

There are 11 diagnostic categories of aggression – play, redirected, intercat/intermale, fear, aggression when patted, status related, territorial, pain, predatory, maternal or idiopathic.

Most causes of aggression are the result of the **interplay between environmental and genetic factors** and previous experience (learning).

Medical conditions such as toxoplasmosis, ischemic vascular problems, hepato- encephalopathy, encephalitis, meningioma, lead poisoning, arthritis, sensory (hearing and/or sight) deficits, hyperthyroidism, epilepsy, feline lower urinary tract disease, feline immunodeficiency virus, and rabies have all been associated with feline aggression.

The use of **medications** such as **anesthetic agents and corticosteroids** has been linked with feline aggression.

Careful history taking and physical examination is essential in making a diagnosis.

- A complete description of physical location, body posture, vocal and physical signals, and the behavior sequences are essential data to make an accurate diagnosis.
- Diagnosis may involve complete blood work and radiography to rule out contributing medical factors.

Behavior-modifying drugs are increasingly being used in the treatment and management of behavior problems in cats. The rationale for using psychotropic medication is based on their purported neurochemical actions in the brain. Most drugs in common use are not registered for this purpose in cats. Drugs should always be an adjunct to behavior modification therapy not a replacement.

- **Many classes of medications** have been used in the treatment of behavior problems including antihistamines, anxiolytics, antidepressants and anti-

convulsants. Medications that may have anxiolytic actions include the benzodiazepines, tricyclic antidepressants (TCAs), antihistamines, azaperones, barbiturates, selective serotonin re-uptake inhibitors (SSRIs) and beta blockers.

CATEGORIES OF AGGRESSION

PLAY AGGRESSION**

Classical signs

- Aggression involves stalking, pouncing, chasing, hiding, laying in wait but rarely vocalizing.
- May involve biting as well as scratching.

Pathogenesis

As with most behavioral conditions the underlying pathogenesis is as yet unknown, but is likely to be neurochemically complex.

Young cats, possibly orphaned, **hand raised or early weaned** are most likely to exhibit this type of aggression due to lack of appropriate socialization. Social play is seen between 4–12 weeks of age, and by 14 weeks of age is replaced by social fighting.

It is likely to be **associated with owner-facilitated learning** (that is the owner encourages rough play or attacks) and long-term potentiation or early orphaning and the absence of appropriate stimuli during the sensitive period for modulating responses.

Clinical signs

The cat may **stalk, chase, pounce and lay in wait for people** passing by and rarely vocalizes. The cat may also bite but the bites are usually inhibited.

Targets are usually moving objects or people and may be another cat or other animal in the household, especially an older one, in the household.

Young cats, especially early weaned, are more likely to show this type of aggression and it may be normal behavior.

It is sometimes difficult to recognize play aggression as some cats play more roughly than others and do not retract their claws when they swat.

Diagnosis

Based on careful complete behavioral history and thorough physical examination. Key features include:

- **A young cat, that lacked contact with its mother** or conspecifics (other members of its own species) in the socialization period may be more likely to exhibit this type of aggression.
- The behavior occurs when **the target is moving** at the time the aggression occurs.
- **The cat does not vocalize** and the bites are usually inhibited.

Differential diagnosis

Other types of aggression need to be considered.

- **Predatory aggression** may have similar signs and vocalization rarely occurs in either type of aggression, however in cases of play aggression, the target is not normally considered prey.
- **Redirected aggression** may have some signs in common but a lack of history of precipitating events and an early environment lacking in social contact will suggest play aggression. Additionally, cats with play aggression will stalk and lay in wait for their victim whereas this is not usually seen in redirected aggression.
- **Status-related aggression** may have similar signs but this is usually seen in cats after social maturity (after 2–4 years of age).

Cats may exhibit several types of aggression concurrently.

Treatment

The cat should be provided with appropriate toys that dangle or move and can be kept at a distance from people, for example cat dancers™, cat wire toys, or cat tracks™ on which to pounce and direct these behaviors.

- The toys need to be changed at regular intervals, even daily, for the cat to maintain interest.
- The cat may need to be taught how to play, and then encouraged to play with toys.

Rough play, especially using hands or other body parts, **should be discouraged**.

- Whenever the cat plays in this manner, play should be interrupted or suspended.
- The cat's attention should be directed to appropriate toys instead.

Direct punishment, such as smacking, may actually encourage the behavior and is **generally unhelpful** and may lead to other problems, such as fear aggression.

Indirect punishment not connected with the owner, such as clapping hands, may help to distract the cat and the owner can then divert attention to a favorite toy.

Provision of a regular routine that involves interactive play time involving toys 2–3 times daily for 5–10 minutes is important to provide a natural outlet for the behavior.

A **second kitten**, preferably one that is not very young, may help to teach appropriate behavior.

Prognosis

Generally favorable if owners are prepared to put in the time.

Generally decreases with age.

REDIRECTED AGGRESSION**

Classical signs

- Sudden onset of aggression.
- The original target of the aggression (e.g. other animal or cat outside) is not accessible.
- The cat then directs its aggression towards an unrelated target, a person or another cat, that enters the area soon after.

Pathogenesis

As with most behavioral conditions underlying pathogenesis is unknown, but is likely to be neurochemically complex. The ventromedial **hypothalamus** likely to be involved and long-term potentiation involving excitatory amino acids and post-synaptic second messenger systems may be involved in the repeated displays.

Cats have been used as models for “kindling”. Once stimulated, the cells then have a very low threshold for stimulation and cats stay reactive and aroused for up to 24 hours.

Clinical signs

The eliciting factors of the aggression are different in the initial and subsequent episodes.

The **first episode is triggered by a stimulus that the cat is thwarted** in its attempts to respond to and may be missed.

- The cat is highly aroused and directs its attention onto the next person or cat it sees. For example, a cat sees another cat through the window, it is highly aroused but is thwarted in its attempts to reach it. Another cat in the household then enters the room and the cat redirects the aggression to the second cat.

In the second, and subsequent episodes, the initial stimulus no longer has to be present to elicit the aggression, just the target of the first attack.

Additionally, the behavior of the target also changes. Often this results in a prolonged conflict, with the second cat now acting warily, running away, and showing avoidance behavior, whenever the first cat enters the room or approaches.

The cat is highly aroused and may growl, hiss, pace, lash its tail, piloerect, have dilated pupils and inflict serious bites if approached or handled.

Diagnosis

Possible history of previous encounter with another cat or thwarted access to some arousing stimuli (e.g. sight, sound or smell of another cat or animal, e.g. possum).

Sudden onset of aggression.

Physical examination reveals no evidence of problems, e.g. pain, middle cerebral artery infarct.

Differential diagnosis

Other types of aggression should be considered.

- **Intercat, intermale aggression** is usually directed between entire males in the breeding season.
- **Territorial aggression** is commonly directed towards a new cat introduced into the household or a visitor. The cat does not try to avoid the perceived intruder and may directly approach.
- **Fearfully aggressive cats** usually show classic body postures (lowered body position, piloerection, flattened ears, etc.) and will give many warning signals to try to avoid conflict.
- **Status-related aggression** is usually not of sudden onset and the cat may initiate contact or attention but then threatens or attacks.

Cats may exhibit several types of aggression concurrently.

Treatment

It is **inadvisable to approach any highly aroused cat**, especially to try to calm or reassure it. The cat should be left alone until it is calmer. This may be 24 hours.

If another cat is involved, then **the cats should initially be separated** regardless of whether it is the victim or the instigator (the thwarted one).

- They should be **placed in separate rooms** so that they can hear and smell each other, but no visual contact occurs.
- The cats should be **rotated around all the rooms** until they have distributed their scent in all rooms.
- While separated a **regular routine should be established** with each cat so that feeding and playing occur at a set time each day. Ideally the cats are fed 5–6 small meals each day.

Treatment then involves **slowly reintroducing the cats to each other** (the same way a new cat is introduced into the household).

- The aim is for them to have a **positive association with each other**. This essentially means that “good” things such as play or feeding only happen in the presence of the other cat.
- The cats are then slowly reintroduced. Initially they are **only in the same room during meal times and are separated at other times**. They are placed in cages (or on a cat harness and lead) at opposite ends of the room and are fed at this time. This should create a positive association with food and the presence of the other cat.
- If no hissing or spitting occurs and the cats eat the food, **the cages are gradually brought closer** and closer to each other over a period of days and meals. This may take several weeks or even months.
- Then **one cat at a time is allowed out of its cage** to explore and if no aggression occurs then both are allowed to interact under supervision.
- The re-introduction needs to be slow.

Anxiolytic medication may also be needed to treat one or both cats.

- **Tricyclic antidepressants** (TCAs) such as **amitriptyline** (0.5–1 mg/kg PO q 12–24 h, average 5–10 mg/cat PO q 24 h) or **clomipramine** (0.5 mg/kg PO q 12 h) or selective serotonin re-uptake inhibitors (SSRIs) such as **fluoxetine** (0.5 mg/kg PO q 24 h) may be useful for the aggressor.

- **Benzodiazepines**, such as diazepam (0.2–0.4 mg/kg PO q 12 h – average 1–2 mg/cat PO q 12 h), may be necessary for the victim. Care as it can lead to hyperexcitement and has been associated with hepatopathy.
- **Azaperones** – Buspirone has been reported to be helpful in some cases (0.5–1.0 mg/kg PO q 8–12 h).
- **Blood biochemistry** analysis should be done prior to medication to determine a **baseline especially for liver and kidney** parameters as all are metabolized by the liver and excreted through the renal system. These parameters should be checked every 6–12 months depending on the age and general health status of the cat.
- The cats may require medication for a prolonged period – up to 6–12 months – and then should be slowly weaned off.

The synthetic pheromone, Feliway®, can also be beneficial. It should be sprayed on 4–6 prominent objects in each room at cat nose height for a period of 30–45 days and is said to decrease anxiety. A Feliway® diffuser plugged into the room in which the cat spends most of its time can also be very helpful. Treatment should continue for at least 1 month.

If aggression is directed towards a person, the cat should be avoided in all stimulating circumstances.

- Whenever the cat is calm desensitization and counter-conditioning can be used. This means **rewarding the cat** (this may involve feeding or playing) **for being relaxed** in the person’s presence and walking away if the cat starts to become aroused.
- Punishing the cat will exacerbate the problem as it may lead to even greater arousal.

Prognosis

Generally good if it is a single event and people can recognize the initiating stimuli and avoid them.

Poor if the aggression is intense, of long duration and there are multiple stimuli that cannot be identified.

Even though the aggression is of sudden onset it may take weeks, or even months, for the cats to be successfully reintroduced.

INTERCAT, INTERMALE AGGRESSION**

Classical signs

- Usually seen in entire males at around 2–4 years of age.
- May be associated with social role (status) in neutered cats and tends to appear later.

Pathogenesis

Male–male aggression involves hormonal changes associated with sexual maturity and neurochemical changes associated with social maturity. The brain is masculinized prenatally and the production of testosterone later leads to presence of male behaviors. Aggression also involves limbic system changes and changes in the serotonin system.

In entire males, intermale aggression usually starts when they reach social maturity, at **around 2–4 years of age**, but may be seen after sexual maturity at 1–3 years of age.

In neutered cats, it occurs later and is associated with their social role or status. It is less likely to occur in cats that were well socialized as kittens.

Clinical signs

Very common.

Usually seen in entire males around 2–4 years of age, but may occur as early as 1 year of age.

- Behavior may be normal male–male aggression associated with mating. It increases during breeding season and with overcrowding.
- In male–male aggression the cat flattens its ears, howls, hisses, piloerects and uses both the teeth and claws in fights.

In social aggression the signs depend on the mode and may be active (threatening) or passive (blocking access). Outright fighting is rare. Cats that have been well socialized before 12 weeks of age are less likely to fight or inflict serious damage.

- May be associated with social role (status) in neutered cats and tends to appear later.

Diagnosis

Diagnosis is based on a complete behavioral history (an entire male cat showing aggression during breeding

season) and thorough physical examination to rule out any concurrent medical conditions.

Differential diagnosis

Other types of aggression need to be considered.

- **Territorial aggression** is commonly directed towards a new cat introduced into the household or a visitor and is not associated with breeding.
- **Status-related aggression** is more often displayed towards people and the cat may initiate contact and then threaten or bite if it cannot control the situation.

Need to recognize what is normal male–male aggression as this may not require treatment.

Cats may exhibit several types of aggression concurrently.

Treatment

Prepubertal and post-pubertal castration reduces or stops the frequency of fights in about 90% of cases between entire males.

Treatment may involve **changing the social environment** as well as the neurochemical one. Cats in the same household should be reintroduced slowly as described above for redirected aggression (page 997). It is important not to try to introduce them too fast or too soon.

Anxiolytic medication may also be needed to treat one or both cats to alter the neurochemical environment.

- **Tricyclic antidepressants** (TCAs) such as amitriptyline (0.5–1 mg/kg PO q 24 h, average 5–10 mg/cat PO q 24 h) or clomipramine (0.5 mg/kg PO q 24 h) or **selective serotonin re-uptake inhibitors** (SSRIs) such as fluoxetine (0.5 mg/kg PO q 24 h) may be useful for the aggressor.
- **Benzodiazepines**, such as diazepam (0.2–0.4 mg/kg PO q 12 h average of 1–2 mg/cat PO q 12 h), may be necessary for the victim. Care as it can lead to hyperexcitement and has been associated with hepatopathy.
- **Azaperones** – Buspirone has been reported to be helpful in some cases (0.5–1.0 mg/kg PO q 8–12 h).
- **Blood biochemistry analysis** should be done prior to medication to determine a baseline especially for liver and kidney parameters as all are metabolized by the liver and excreted through the renal system.

These parameters should be checked every 6–12 months depending on the age and general health status of the cat.

- The cats may require medication for a prolonged period – up to 6–12 months – and then should be slowly weaned off.

The **synthetic pheromone, Feliway**, can also be beneficial. It should be sprayed on 4–6 prominent objects in each room at cat nose height for a period of 30–45 days and is said to decrease anxiety. A Feliway® diffuser in the room where the cats spend most of their time has also proved useful.

Prognosis

Intermale aggression generally responds well to treatment.

Social aggression can be more difficult to treat especially if it is very long-standing and getting worse. Clients need to be able to recognize it early but this is often difficult with passive (covert) aggression where the cat just blocks access to areas.

The prognosis is relatively good with early intervention, and if the cats share the area and different times.

FEAR AGGRESSION**

Classical signs

- Cats can be fearful of people, places, other cats, or various stimuli such as noises or odors.
- The aggression exhibited may be a combination of offence and defense.

Pathogenesis

As with most behavioral conditions the underlying pathogenesis is unknown, but is likely to be neurochemically complex. **The amygdala and long-term potentiation are involved in learning fear**, while the forebrain is involved in unlearning fear. The locus ceruleus (LC), the principal norepinephric nucleus, is involved with supplying the limbic system and hence the “emotional” signs seen with fear.

Genetically two types of cat personality are recognized – either **timid and fearful cats** or **confident,**

friendly cats, and is affected by the temperament of the tom. This may account for some fearful behavior seen in cats.

Inadequate or lack of socialization and handling prior to 12 weeks of age may also contribute to the cat’s responses to people.

Inadequate or lack of socialization with other cats early in life may contribute to the cat’s responses to other cats.

Cats learn to be fearful of certain situations, especially if they have had a bad experience with no opportunity to escape (e.g. rough handling, noises, smells at veterinary hospitals).

Inappropriate punishment can also cause fear and lead to aggression.

It may also be **exacerbated by accidental reinforcement**, that is attempting to calm an anxious cat by speaking softly or stroking and hence rewarding the fearful or aggressive behavior.

Clinical signs

Fearful cats will typically hiss, spit, growl, swat, pilo-erect, flatten their ears against the head and show a low, hunched or crouched body position. Additionally, they may try to flee or attack, depending on the circumstances. **Pupillary dilation** is common and the **mouth is open with teeth bared**.

Often the behavior is a combination of offence and defense.

The fearful cat generally will **initially attempt to avoid the stimulus** if that is an option and **many warning signals are given**.

Aggression is usually the last resort but is violent and may become learnt.

Diagnosis

The diagnosis is based on a complete behavioral history and a thorough physical examination to rule out medical causes.

A history of exposure to a fear-provoking stimulus, combined with a description of body language (ears back, “Halloween” cat) and aggression typify fear aggression.

Differential diagnosis

Other types of aggression should be considered.

- **Redirected aggression** may have some signs in common but different body language and history of fear-provoking events will suggest fear aggression.
- Although some of the signs are similar cats that exhibit **play aggression** generally have a more confident body posture and behavioral history and context of the aggression are different. There is no stalking or pouncing involved in fear aggression.
- **Territorial aggression** is usually directed towards another cat or person and the cat is confident and approaches the intruder and threatens. Fearfully aggressive cats will try to avoid contact.

Cats may exhibit several types of aggression concurrently.

Treatment

Depending of the severity of the problem the cat may need no treatment or may need behavior modification, such as desensitization and counter-conditioning, in combination with psychopharmacological intervention in severe or long-standing cases.

Behavior modification involves desensitization and counter-conditioning by slowly introducing the cat to the fearful situation in a gradual, controlled sequence.

- First, **the cat is offered a tasty treat** such as vegemite, chicken, cheese or dehydrated liver. If the cat eats then it is usually a good indication that it is not too anxious.
- Then, while the cat is eating, the **fearful stimulus**, such as a person, is **gradually introduced at a distance**. The initial distance should be great enough not to cause any fearful response from the cat.
 - If the cat continues to take food the person approaches the cat very slowly.
 - The time frame for the gradual approach may vary from **days to months** depending on the severity of the problem.
- The cat should not be forced into the fearful situation as that will exacerbate the fear.

Anxiolytic medication may also be needed to treat the cat to alter the neurochemical environment.

- **Tricyclic antidepressants (TCAs)** such as amitriptyline (0.5–1 mg/kg PO q 12–24 h, average of 5–10 mg/cat PO q 24 h) or clomipramine (0.5 mg/kg PO q 24 h) or **selective serotonin re-uptake inhibitors (SSRIs)** such as fluoxetine (0.5 mg/kg PO q 24 h) may be necessary.
- The cat may require medication for a **prolonged period (up to 6–12 months)**. Attempts to wean off medication should be slow and some cats may need life-long treatment.
- **Blood biochemistry** should be done prior to medication to determine a baseline especially for liver and kidney parameters as all medications are metabolized by the liver and excreted through the renal system. If long-term or life-long medication is needed then repeat blood test should be done at 6–12-month intervals depending on the age and general health status of the cat.

The **synthetic pheromone, Feliway®**, can also be beneficial. It should be sprayed on 4–6 prominent objects in each room at cat nose height for a period of 30–45 days and is said to decrease anxiety. A Feliway® diffuser in the room in which the cat spends most of its time has also proved useful.

Punishment, or forced restraint will aggravate the situation and should be avoided. It may increase the anxiety and impede learning.

Prognosis

Prognosis is good if the behavior is of recent onset, the cat is adult and the fear-eliciting stimuli can be defined.

Prognosis worsens if the problem is of long duration or the cat stays aroused or reactive for long periods after exposure to the fear-provoking stimulus.

The prognosis may be poor if the cat is genetically timid and there has been no early exposure during the sensitive period (before 12 weeks of age).

AGGRESSION WHEN PATTED**

Classical signs

- The cat may suddenly bite or scratch people after tactile stimulation of variable duration.

Pathogenesis

As with most behavioral conditions underlying pathogenesis is unknown, but is likely to be neurochemically complex. Long-term potentiation, excitatory amino acids, “kindling”, and increased arousal are all contributing factors.

Some cats have a very low tolerance to being patted or stroked. The cat may even seek out attention and jump on the owner’s lap, but still not tolerate long periods of stroking.

The behavior is reported to be **more common in unneutered males** and is thought to relate to social grooming behavior.

It can be a **manifestation of status-related aggression.**

Clinical signs

The cat may swipe or bite if the petting stops, or if the stroking is carried out for a prolonged period.

- Some cats appear to be content just sitting on a lap as long as no stroking or other tactile stimulation occurs.

The cat may stiffen, or lash with the tail and may or may not give a warning bite while being patted.

Owners are most commonly bitten or scratched on the hands and arms.

Diagnosis

Based on the behavioral history of **sudden aggression during petting** with no obvious warning but the owner learns to recognize the signs of twitching and stimulation.

Thorough physical examination is essential to rule out medical causes such as pain due to **arthritis**, etc., that may cause the cat to resent being handled or **dermatological conditions** that may cause irritability or inflammation of the skin.

Differential diagnosis

Other types of aggression such as:

- Although some of the signs are similar cats that exhibit **play aggression** generally have a more confident body posture and the behavioral history and context of the aggression are different. There is

no stalking or pouncing involved and the **aggression only occurs when the cat is being petted or soon after the petting stops.**

- **Status-related aggression** has similar signs but will also be exhibited in other contexts, not just associated with petting and it may also involve passive aggression such as blocking access to rooms, etc.
- **Pain** needs to be considered as an underlying or concurrent factor. However, pain aggression may be exhibited in other contexts, not just associated with petting.

Cats may exhibit several types of aggression concurrently.

Treatment

Many of these cats can be **taught to gradually tolerate longer periods of stroking.**

Initially determine how long the cat can tolerate attention.

- If the cat usually tolerates a short period of stimulation, e.g. 3 minutes, but not 4 minutes the cat should be slowly stroked for only 2 minutes, that is the period should always be below the cat’s current threshold for non-tolerance of stimulation. The cat should then be rewarded with food treats.
- **The time can be gradually increased over a period of days/weeks** until the cat tolerates longer and longer periods. Always stop the stroking prior to the cat showing signs of arousal.
- The training session should be **held at predictable times each day.**

Punishment is not effective as it tends to lead to more aggression as the cat is already aroused and over-stimulated.

Anxiolytic medication may also be needed to treat the cat to alter the neurochemical environment.

- **Tricyclic antidepressants** (TCAs) such as amitriptyline (0.5–1 mg/kg PO q 12–24 h, average of 5–10 mg/cat PO q 24 h) or clomipramine (0.5 mg/kg PO q 24 h) or **selective serotonin re-uptake inhibitors** (SSRIs) such as fluoxetine (0.5 mg/kg PO q 24 h) may be necessary.
- **Blood biochemistry analysis** should be done prior to medication to determine a baseline especially for liver and kidney parameters as all are metabolized by the liver and excreted through the renal system. These parameters should be checked every 6–12

months depending on the age and general health status of the cat.

- Some cats may require medication for a prolonged period (up to 6–12 months or even life-long) and then should be slowly weaned off if possible.
- Feliway® sprayed on hands before handling may also help decrease arousal.

Prognosis

Some cats never learn to like being stroked, and the safest option is to leave them alone.

Punishment tends to aggravate the situation and should be avoided.

STATUS-RELATED AGGRESSION**

Classical signs

- The cat may try to control territory or people by blocking access to an area.
- The cat may bite when approached or handled yet solicit attention and then bite if it is or is not given.
- Biting may also occur when the attention ceases.

Pathogenesis

The behavior is about the cat's need to control specific situations or interactions and may indicate an underling anxiety. It involves **overt as well as covert behaviors**. See expanded section on aggression when patted (page 1000).

As with most behavioral conditions underlying pathogenesis is unknown, but is likely to be neurochemically complex. The hypothalamus is the primary area involved with threat displays. There may be genetic as well as learnt components.

It may be associated with lack of impulse control.

Clinical signs

The cat may bite when the owner attempts to approach, lift, move or handle the cat (overt aggression).

The cat may also block access to areas for example by sitting in doorways and staring (covert aggression).

It can also involve behaviors such as **soliciting attention by biting**.

Diagnosis

Diagnosis is based on a complete behavioral history that indicates the aggression occurs in contexts where the cat is displaying assertive or controlling behaviors.

Thorough physical examination is essential to rule out medical causes such as **pain**, for example due to arthritis, or dermatological conditions that may cause irritability or inflammation of the skin that may also elicit aggression.

Differential diagnosis

Other forms of aggression including:

- **Territorial aggression** is usually seen in a different context and is directed towards another cat or person that approaches the defined territory and the cat threatens.
- **Aggression when patted may be a part of status-related aggression** however, that is the only context in which the behavior is elicited.
- Although some of the signs are similar in cats that exhibit **play aggression** the behavioral history and context of the aggression are different. Additionally in play aggression the cat is younger and there is generally stalking or pouncing involved.

Many cats can exhibit several types concurrently.

Treatment

Identify and then avoid all situations that may be provocative, e.g. approaching, stroking, handling.

Instigate a behavior-modification program where the cat is taught to earn all attention or rewards by deferring to the owner.

- It has to **come or sit at the owner's request**, prior to any interaction with the owner.
- It is **not allowed to initiate any interaction**. If the cat does solicit attention the owner should completely ignore the cat or walk away.
- **No reward/attention is given until the cat defers** and responds to the command (e.g. sit or come).

Desensitization and counter-conditioning to handling, moving, etc., can be done and the cat rewarded for

appropriate acceptable behavior – see aggression when patted for details (page 1000).

- If the cat shows any sign of aggression then move away and stop all interactions.
- **Physical punishment should be avoided** as that will exacerbate the problem.
- **Anxiolytic medication** may also be needed to treat the cat to alter the neurochemical environment.
 - **Tricyclic antidepressants** (TCAs) such as amitriptyline (0.5–1 mg/kg PO q 24 h, average of 5–10 mg/cat PO q 24 h) or clomipramine (0.5 mg/kg PO q 24 h) have proven useful in some cases.
 - **Selective serotonin re-uptake inhibitors** (SSRIs) such as fluoxetine (0.5 mg/ kg PO q 24 h) have also proved useful and can be easier to administer as they are available in a liquid formulation.
 - **Benzodiazepines** are **generally not recommended** as they may disinhibit aggression.
 - Blood biochemistry analysis should be done prior to medication to determine a baseline especially for liver and kidney parameters as medications are metabolized by the liver and excreted through the renal system. These parameters should be checked every 6–12 months depending on the age and general health status of the cat.

The cat may require life-long medication or for prolonged periods of up to 6–12 months. Attempts to slowly wean off medication may be made.

Prognosis

The behavior can usually be managed, not cured, with owner education and compliance.

The prognosis is poor if the eliciting stimuli cannot be defined, the attacks are severe or people cannot read the cat's body language.

Punishment tends to aggravate the aggression and should be avoided at all times.

TERRITORIAL AGGRESSION*

Classical signs

- The aggressive behavior is directed towards intruders approaching or entering into the cat's established domain.

Pathogenesis

As with most behavioral conditions the underlying pathogenesis is unknown. There is often an underlying anxiety component.

The cat's territory may be patrolled and can be marked by rubbing, bunting and/or spraying to maintain social distance and define hierarchy.

The aggression can be intra- and interspecific (between members of the same species or between other species), including people.

Classical signs

The cat exhibits aggression to anyone approaching or entering its territory and may attack.

The behavior may be **more marked in entire toms in the breeding season**.

Aggression decreases with increased distance away from the territory.

It is **often seen when a new cat is introduced** into the household or the **cat returns from a visit to a cattery or veterinary hospital** and now is not recognized by the other cat.

Diagnosis

Diagnosis is based on a complete behavioral history and a thorough physical examination.

Differential diagnosis

Other types of aggression should be considered including:

- **Status-related aggression and territorial aggression may co-exist**, however, the contexts in which territorial behavior is elicited will be different.
- **Intercat intermale aggression is seen in entire males during the breeding season**, whereas territorial aggression may be seen at other times and may be exhibited by males and females.

Cats may exhibit several types of aggression concurrently.

Treatment

Avoid situations that may be provocative to avoid reinforcing the behavior.

- If directed towards another cat within the home they may **need to be separated** - see section on redirected aggression on how to reintroduce (page 997).

Anxiolytic medication may also be needed to treat the cat to alter the neurochemical environment.

- **Tricyclic antidepressants** (TCAs) such as amitriptyline (0.5–1 mg/kg PO q 12–24 h – average of 5–10 mg/cat PO q 24 h) or clomipramine (0.5 mg/kg PO q 24 h) or **selective serotonin re-uptake inhibitors** (SSRIs) such as fluoxetine (0.5 mg/kg PO q 24 h) have proved useful in managing the behavior of the aggressor.
- **Benzodiazepines**, such as diazepam (0.2–0.4 mg/kg PO q 12 h – average of 1–2 mg/cat PO q 12 h), may be necessary for the victim to alter its behavior. Care with benzodiazepines as they may disinhibit aggression.
- **Blood biochemistry** should be done prior to medication to determine a baseline especially for liver and kidney parameters. The cat may require medication for a prolonged period of up to 6–12 months and then should be slowly weaned off.

The **synthetic pheromone, Feliway®**, can also be beneficial. It should be sprayed on 4–6 prominent objects in each room at cat nose height for a period of 30–45 days and is said to decrease anxiety. A Feliway® diffuser placed in the room that the cats spend most of their time has also proved helpful.

The cats may need to be permanently separated or one of the cats may have to be rehomed if the problem is very severe or long-standing.

If directed towards people deny the cat access to areas that may be guarded. If the cat shows any signs of aggression then move away and stop all interactions.

Physical punishment should be avoided as it will exacerbate the problem.

Prognosis

May be difficult to treat if long-standing or severe but it can usually be managed with environmental manipulation.

Prognosis is worse if directed towards other cats and is long-standing and severe.

PAIN AGGRESSION*

Classical signs

- The cat responds to being handled or approached in an aggressive manner.
- History of a painful stimulus or elicitation of pain.

Pathogenesis

This is a defensive behavior and can become fear aggression if associated with long-term painful treatment or chronic pain.

Any source of pain or painful stimulus can lead to the cat exhibiting aggression. The stimulus may range from actual handling of a painful area to just patting, grooming or trying to medicate the cat.

As with most behavioral conditions the underlying pathogenesis is unknown. Long-term potentiation associated with true pain or circumstances in which the pain was originally elicited is likely to be involved.

Clinical signs

The cat may show signs of **offensive (distance increasing signals)** or postures such as staring, swatting with the front paw, growling) or **defensive** (signals or postures such as arched back, piloerection, flattened ears, hissing) **aggression** and/or **avoidance with handling**.

The signs may be exhibited prior to any manipulation or when the cat is approached.

Diagnosis

Diagnosis is based on a complete behavioral history and a thorough physical examination.

Hematological and biochemistry analysis and imaging techniques such as X-ray may be required to make a diagnosis.

Differential diagnosis

Other types of aggression should also be considered but the diagnosis should be able to be made on physical examination and history.

- **Status-related aggression or aggression when patted** may have similar signs, however, **the history of any painful stimulus or elicitation of pain** should delineate the problem.
- **Fearful behavior or aggression may be secondary to pain.** The behavior can then become learnt.

Cats may exhibit several types of aggression concurrently.

Treatment

Relieve the source of the pain (appropriate analgesics or anti-inflammatory medication as indicated).

Treat the anxiety associated with the pain (anxiolytics, e.g. diazepam, tricyclic antidepressants, e.g. amitriptyline – see page 1001 for dose rates).

Avoid all accidental reinforcement by patting, telling the cat “it’s okay” in an effort to calm, especially when the cat is aroused. This may reward aggressive behavior and may prolong the response.

Avoid all potentially painful situations.

Some learnt aggression may result. The cat has associated previous handling with pain, so **desensitization and counter-conditioning** may also be necessary so that the cat learns to relax when handled.

- Offer treats when the cat remains relaxed when approached or gently handled.
- Gradually increase the amount of time and the area that is being manipulated, rewarding for relaxed and non-aggressive responses.

Try to prevent the aggression developing by providing appropriate analgesia with all painful manipulations, especially surgery.

Avoid punishment as that may exacerbate the aggression.

Feliway® may help decrease arousal.

Prognosis

Depends on adequacy of the pain relief, as well as duration of pain and duration of the aggression but generally good.

Prevent occurrence if possible.

PREDATORY AGGRESSION

Classical signs

- The cat exhibits signs of predatory behavior such as stalking in silence, a lowered body posture, crouching and sudden lunge or pounce when target moves suddenly but it is directed towards non-prey.

Pathogenesis

Predatory aggression needs to be differentiated from predatory behavior, which is normal and instinctive. The focus of predatory aggression (e.g. non-prey item, body part) and outcome (do not eat) are different.

The cat shows all the contextual behaviors of predatory behavior, stalking in silence, lowered body posture, crouching and sudden lunge or pounce when target moves suddenly, **but it is out of context.**

There are no warning signs and may be directed towards people as well as other animals.

As with most behavioral conditions the underlying pathogenesis is unknown. The hypothalamus is involved with active biting and attack. Experimentally **stimulation of the lateral amygdala facilitates predatory aggression**. More defensive cats appear to show less predatory aggression.

Clinical signs

The cat stalks and may lie in wait for the “victim”, then pounces when the target moves.

There are no preceding threats.

Although the behaviors are the same as predatory behavior (normal), the context in which the behaviors are exhibited make this behavior abnormal.

Diagnosis

Diagnosis is based on a behavioral history (of sudden attacks with no preceding threats, that is usually directed towards moving targets), which are not normal prey and a thorough physical examination.

Differential diagnosis

Other types of aggression such as:

- **Predatory behavior** that is directed towards prey (rodents, birds and although it may be undesirable is normal behavior and should be differentiated from predatory aggression when non-prey are the targets. It is instinctive behavior hence difficult to modify. The cat may not eat the prey item even if caught.
- **Play aggression** has many of the elements of predatory aggression but the context is different. It is also seen more in **younger cats** that are practicing their hunting skills and it is more easily redirected.
- **Status-related aggression** should also be considered however, the silent stalk and pounce is not seen with status related aggression.

Cats may exhibit several types of aggression concurrently.

Treatment

For aggression directed towards prey.

- **Avoid all potentially problematical situations.**
- Confine cat indoors or to a specific area to prevent predation.
- Confine cat outdoors in wire-mesh enclosures, runs and tunnels. These are being sold as ‘modular cat parks’ which are modular enclosures that can be joined together to provide extensive outdoor enclosures for the cat.
- Supervise when outside.
- **Provide appropriate toys** for mental stimulation and ability to hunt. Vary these on a daily basis.
- Put several bells at intervals on the cat’s collar to provide warning to prey.

For aggression directed towards non-prey.

- Avoid all potentially problematical situations.
- Confine cat to a specific room or area to **prevent access to victim**, especially at times the cat is most likely to exhibit this behavior.
- **Put several bells on the cat’s collar** at varying intervals so that the victim has warning signal of the cat’s presence. This is not always successful but worth trying.
- **Redirect the pounce onto toys.** When the aggression is directed towards people, toys dangled at the end of a fishing rod, to keep the cat at a distance from the person, can be helpful.

Distracters such as loud noises can be useful when the owner sees the cat in pre-pounce mode. **They should not be used as a punishment** as that may redirect the aggression.

This can be a dangerous situation especially when the targets are children and the elderly as the cat can inflict severe damage. **Euthanasia** or **re-homing** may need to be considered as options.

Prognosis

Good if the cat can be monitored and the behavior redirected or the cat confined to prevent access to prey.

Not good if the target is a helpless individual and the cat cannot be monitored.

MATERNAL AGGRESSION

Classical signs

- The queen threatens when she, the kittens or the nesting are approached. She will attack if cornered.
- It may involve aggression directed towards the kittens.

Pathogenesis

This occurs in the periparturient period and may involve protecting the nest area as well as the kittens.

This is normal behavior if the approach distance is long or generalized. It is due to hormonal influences on the hypothalamus, and associated with the presence and the proximity of the kittens.

The queen may be aggressive in the presence of male cats and this may be related to the fact that free-ranging males have been reported to commit infanticide.

The behaviors seen may also be anxiety related and hence the neuropathology is the same.

Clinical signs

Generally the queen will hiss and give other long-distance signals when she, the kittens or the nesting area is approached.

It usually involves more threats than actual attack and usually is directed toward unfamiliar individuals.

Attack tends to be a last resort and occurs if she is cornered.

Some queens may cannibalize their own kittens and this is considered to be abnormal. It may happen if the queen is stressed or malnourished and the incidence has been reported to increase if the litter is very large, it is a second pregnancy, or the kittens are ill. However, it can be normal if the queen eats stillborn or aborted fetuses. It may also occur during overzealous eating of the placenta after birth.

Diagnosis

Diagnosis is based on the behavioral **history of aggression in the presence of kittens** and thorough physical examination to exclude pain or other causes of aggression.

Differential diagnosis

Other types of aggression should be considered such as territorial, pain and status-related aggression, however this type of aggression should be easily differentiated as it occurs **only in queens with kittens in the periparturient period**.

Cats may exhibit several types of aggression concurrently.

Treatment

Avoid approaching the queen during this period.

Separate the queen from other cats, especially males.

Spey the queen that exhibits infanticide.

Prognosis

The aggression should resolve when the kittens are removed from the queen but may recur with the next litter.

IDIOPATHIC AGGRESSION

Classical signs

- The aggression is unprovoked and unpredictable.

Pathogenesis

This is a diagnosis of exclusion and very rare.

It is not well understood and reflects truly abnormal behavior.

As with most behavioral conditions the underlying pathogenesis is unknown, but is likely to be neurochemically complex. It is a very rare condition and may reflect seizure activity.

Clinical signs

Sudden mood changes and aggressive episodes with neither obvious provocation nor predicability.

It has been described as “**toggle-switch**” aggression as it may start suddenly as if a switch has been turned on. It can stop just as suddenly and the cat may appear to be unaware of any change in its behavior.

Diagnosis

Diagnosis is based on a behavioral history of **sudden episodes of unpredictable aggression** and thorough physical examination and rule out of all other causes, both medical and behavioral.

Differential diagnosis

All other types of aggression as well as **medical causes, such as seizures**, should be considered.

Treatment

It is difficult to treat using standard behavior-modification techniques because it is truly unpredictable.

- Additionally, avoiding situations that may be provocative is not possible as there is no true provocation or obvious context.

Treatment with anticonvulsants such as **diazepam** or **phenobarbitone** should be considered.

No physical punishment should be used.

Prognosis

Poor as the underlying cause is not known.

47. The cat with anxiety-related behavior problems

Kersti Seksel

KEY SIGNS

- Over-grooming (including psychogenic alopecia, feline hyperesthesia and self-mutilation).
- Pica.
- Inappropriate vocalization.
- Inappropriate elimination (spraying).

MECHANISM?

- Anxiety, fears, phobias, stereotypies and obsessive-compulsive disorder (OCD) are neurochemically related but do not have the same underlying mechanism.
- Anxiety is the anticipation of future danger or misfortune.
- Obsessive-compulsive disorders are constant and repetitive behaviors that appear to serve no obvious purpose and interfere with the animal's normal functioning.
- Stress is thought to play a key role in the development of anxiety-related conditions.

WHERE?

- The prefrontal cortex, amygdala and limbic system, and hypothalamus (hypothalamic-pituitary-adrenal axis) are involved in the regulation of fear.
- Serotonin, norepinephrine, dopamine and GABA are all involved in the development of fear and anxiety.
- The anatomical focus of OCD is believed to be the limbic system.

WHAT?

- Anxiety-related disorders include excessive self-grooming, changes in appetite and inappropriate elimination (spraying).

QUICK REFERENCE SUMMARY

Diseases causing anxiety-related behavior problems

PSYCHOLOGICAL

- **Over-grooming (including psychogenic alopecia, feline hyperesthesia and self-mutilation)** (p 1015)**

Alopecia diagnosed by exclusion when no underlying medical problem is evident. Hair loss and saliva discoloration are only evident on parts of the body that can be reached by the teeth and/or tongue. Plucked hair has microscopic evidence of shear.

- **Pica (eating non-food material)* (p 1018)**

Ingestion of non-nutritive substances that appear to be of no benefit to the cat.

- **Inappropriate vocalization** (p 1017)**

Vocalization that is excessive in duration, intensity or frequency that is not associated with other causes such as pain or symptoms of estrus.

- **Inappropriate elimination – spraying*** (p 1012)**

Marking of usually prominent vertical areas with or without urine, and often associated with overt or covert intercat aggression.

INTRODUCTION

MECHANISM?

Anxiety, fears, phobias, stereotypies and obsessive-compulsive disorder (OCD) are neurochemically related but probably do not have the same underlying mechanism. OCD in humans is classified as a subset of anxiety-related disorders. Anxiety is thought to be the common factor underlying stereotypic behaviors and OCD.

Anxiety is the anticipation of future danger or misfortune without any obvious cause. The threat may be real or imagined and may be normal or abnormal depending on the context.

- When it is out of context and occurs at a constant and elevated level then it is likely to become a problem.

Anxiety is usually accompanied by signs of **hypervigilance** (e.g. scanning), **autonomic hyperactivity** (e.g. gastrointestinal upsets) and **increased motor activity** (e.g. pacing).

Anxiety disorders constitute more than 75% of problems diagnosed in veterinary patients presented to behavior clinics.

Obsessive-compulsive disorders include stereotypies and self-directed behaviors.

- They are constant and repetitive in form, appear to serve no obvious purpose, and interfere with the animal's normal functioning.
- They are **often derived from otherwise normal behaviors like grooming, eating or walking** but are abnormal in that they are excessive in duration, frequency or intensity in the context in which they are performed.

Stress or anxiety in cats may be manifest as a change in appetite (e.g. a decrease in appetite or pica); grooming (e.g. increased or decreased); elimination (e.g. spraying or non-spraying marking); changes in social interactions (e.g. vocalization); and physical activity (e.g. increased or decreased).

WHERE?

Positron emission tomography scans indicate **biochemical and structural abnormalities in anxiety, panic and OCD.**

- The prefrontal cortex, central nucleus of the amygdala, limbic system and hypothalamus (hypothalamic-pituitary-adrenal axis) are involved in the

regulation of fear and anxiety. Long-term potentiation of fear and anxiety is a contributing factor.

- Serotonergic, noradrenergic, dopaminergic and GABA-ergic systems are involved in the development of fear and anxiety. The neurotransmitter **serotonin** has been identified as a **mediator of fear and anxiety**.
- The locus coeruleus, which is part of the noradrenergic system, is involved in the mediation of many of the physiologic responses associated with anxiety such as hypervigilance.
- The anatomical focus of OCD is believed to be the limbic system. Computed tomography indicates that the basal ganglia near the caudate nucleus are involved.
- Dopaminergic, serotonergic and opioid pathways are thought to be involved in compulsive and self-injurious behaviors.
- **Aberrant serotonin metabolism and possibly endorphin metabolism** are thought to contribute. Increased dopamine in the basal ganglia and a relative increase in the serotonin metabolite 5-hydroxy indole acetic acid (5-HIAA) in the cerebrospinal fluid (CSF) have also been detected.

Stress responses are modulated through **altered cholecystokinin, opioid and dopaminergic mechanisms**.

- Physiological measurements of stress include: increased catecholamine levels and resultant tachycardia (sympathetic autonomic nervous system); increased corticosteroid levels resulting from stimulation of the pituitary-adrenal axis; decreased neutrophil/lymphocyte ratios; and altered response to adrenocorticotrophic hormone (ACTH) stimulation test.

Production and release of **substance P** may also be responsible for some behavioral effects such as salivation and gastrointestinal distress.

WHAT?

Anxiety can occur after sensitization to a specific stimulus and then become generalized to other situations. It may also be non-specific in origin.

Anxious or stressed cats may exhibit a variety of non-specific signs such as **autogrooming, changed appetite or spraying**.

The following are the most common signs of anxiety exhibited by cats. The actual prevalence of anxiety-related conditions is unknown but they are probably the most common class of disorders in pet animals.

Medical conditions such as **hyperthyroidism** have been **associated with feline anxiety**, as have some medications.

The longer that these conditions are unrecognized and untreated, the more complex they become.

Diagnosis is based on a complete behavioral history and thorough physical examination. It may involve complete blood work, dermatological and neurological work up, as well as radiography to rule out contributing or concurrent medical factors.

CONDITIONS CAUSING ANXIETY-RELATED BEHAVIOR PROBLEMS

INAPPROPRIATE ELIMINATION-SPRAYING***

Classical signs

- Urination and/or defecation outside the litter box.

Pathogenesis

Elimination problems are the most common behavioral problem reported in cats, accounting for between **40–75% of behavioral problems**.

Both males and females, neutered and entire, present with elimination problems. They have been reported in all breeds and across all age groups.

Cats that are urinating out of the litter box usually squat, produce a **large quantity of urine**, use a horizontal surface and often scratch afterwards. In contrast to marking, urination outside of the litter box is associated with the elimination of waste.

Predisposing factors for inappropriate urination include:

- **Medical conditions** such as cystitis, diarrhea, constipation, feline lower urinary tract disease and diseases causing polyuria.
- **Litter box aversion** may be due to a new type of litter or a dirty box. Aversion can also be induced by “catching” the cat in the litter box prior to performing potentially unpleasant procedures such as medicating or grooming.
- **Litter box location preference** can develop. Many cats prefer to eliminate in quiet or safe places where

they will not be disturbed, e.g. under beds, behind furniture. They may have learnt to urinate in the location where the litter box was originally placed, even though the litter box has now been relocated.

- **Litter box location aversion** can also develop if the cat has an unpleasant experience while in the box. Cats that experience pain while urinating (e.g. with cystitis, arthritic pain) may develop an aversion to using the litter tray in that location.
- **Substrate preference.** Some cats prefer to scratch in soft textures or surfaces, others on hard.
- **Substrate aversion.** Some cats do not like getting their feet wet or dirty so they will not use soiled litter boxes. Every cat litter also has a different odor, so many cats develop a preference or aversion to a particular scent.
- **Fear and anxiety.** Separation anxiety can cause elimination problems, and this is usually seen when the owner is absent. The cat may choose to eliminate on the objects associated with the owner, e.g. clothes, bedding, briefcases, shoes. It is usually seen after separation greater than 12 hours, or immediately the owner returns. Fearful cats may eliminate where they are hiding, as often they are too frightened to go to the litter box.

Spraying is a marking behavior, often associated with anxiety. It may be territorial, sexual or agonistic. In multi-cat households it is associated with overt or covert aggression.

- **Cats that squat** usually stand, but may squat, usually produce only a **small quantity** of urine, frequently use vertical surfaces but may use horizontal surfaces and **rarely scratch** afterwards.
- It is estimated that 10% of castrated males and 5% of spayed females spray at some time in their life. Spraying appears to be more common in multi-cat households with a 100% chance of at least one cat spraying in a household with more than 10 cats. Male cats that live with a female cat are more likely to spray than those living with another male cat.
- **Predisposing factors include:**
 - **Medical conditions** ranging from those associated with the urogenital system such as renal calculi, renal failure and cystitis, as well as viral diseases such as FIV and FELV and impacted anal glands. It is reported that up to 30% of cats that present for spraying may have a concurrent medical condition.

- **Hormonal factors.** Entire cats spray more than neutered cats, and male cats spray more than female cats.
- **Territorial**, agonistic encounters or any highly arousing circumstances.
- **Environmental stimuli** such as the sight, sound or smell of another cat, within the household, as well as outside.
- Anxiety-related problems including separation anxiety, changes in routine (for example, moving house), the introduction of a new spouse, new baby or new cat in the area.

Inappropriate defecation is associated with the elimination of waste.

Predisposing factors for inappropriate defecation include:

- **Medical conditions** such as cystitis, diarrhea and constipation have been reported as associated factors.
- **Cats that experience pain** while defecating (e.g. constipation, arthritic pain) sometimes develop an aversion to using the litter box.
- Factors, which predispose to inappropriate urination also predispose to inappropriate defecation. These include **litter box aversion, litter box location preference, litter box location aversion, substrate preference, substrate aversion, fear and anxiety.** Rarely defecation may be a marking behavior.

Clinical signs

The elimination of urine or feces in an inappropriate location. The **amount and frequency may also be altered.**

Inappropriate elimination is a non-specific sign. It may be associated with a medical condition, fear or anxiety, or factors associated with the litter box.

Inappropriate urination or defecation involves the cat **passing normal amounts of urine or feces** outside the litter box.

Spraying or urine marking involves the cat passing **small amounts of urine** usually on **vertical objects**, often in response to an anxiety-provoking stimulus.

Diagnosis

Diagnosis is based on a **complete behavioral history** with a finding of inappropriate elimination. A thorough physical examination, hematological and biochemical

analysis, urinalysis, even radiography may be required to exclude medical causes.

Careful questioning of the owner is important to differentiate urine marking from inappropriate urination. Medical problems need to be dealt with prior to, or at least concurrently with, any behavioral therapy that is instigated.

The treatment of a non-specific sign such as inappropriate elimination is not acceptable and will ultimately lead to treatment failures.

Differential diagnosis

Medical problems need to be dealt with prior to, or at least concurrently with, any behavioral therapy that is instigated. One or several of the following should be considered as contributing to the possible underlying causes.

- Medical conditions such as cystitis, diarrhea, constipation, feline lower urinary tract disease, diabetes, renal disease and urinary incontinence.

Treatment

Treatment of inappropriate urination and/or defecation.

After addressing any medical problem, the treatment involves: (1) Increasing the attractiveness of the area the owner wants the cat to use, and (2) Decreasing the attractiveness of the area that the cat wants to use.

- **Litter box problems.** To help make the litter box more attractive to the cat:
 - **Change the type of litter.** Alternatives include sawdust, soil, rabbit pellets, shredded newspaper (or recycled-paper litter), clumping litters, sand or other type of commercial litter. Sometimes a combination of substrates is effective. Cats appear to prefer finely textured litter that is not too heavy (fine sand consistency).
 - Try an empty litter box for those cats that prefer smooth surfaces like bath tubs and sinks.
 - Increase the frequency with which the litter box is **cleaned and changed**.
 - **Change the cleaning agent** used to clean the litter box. Do not use disinfectants, try using soapy water or water only.
 - **Increase the number of litter boxes** (a good rule of thumb is one litter box per cat and one extra).
 - Cover the litter box to make it more private for the cat. Often just putting a cardboard box, with

appropriate openings, over the litter box is helpful. Sometimes changing the type of litter box also helps, such as one with higher or lower sides.

- **Make the location of the litter box more acceptable to the cat.** Place a litter box over the area being used by the cat. Then very gradually change the location of the litter box until it is in an area that is more socially acceptable. This may mean gradual increments as small as 5 cm daily.
- **Decrease the attractiveness of the area** the cat prefers to use by changing its significance. Most cats will not eliminate in their feeding or play areas so try feeding the cat in this spot. Dry cat food appears to work best as it takes longer to consume. Some very determined cats will eat the food first, then eliminate in the area. Superglueing 8–10 pieces of dried cat food to an old saucer or piece of cardboard and placing it in the cat's favorite elimination spot will provide a long-term stimulus of food.
- Leave the cat's toys or bedding in the area.
- Confine the cat to a small area to retrain the cat. Only allow access to larger areas gradually once the cat uses the litter box consistently.
- Make the area less accessible and less pleasant to the cat by covering the area with thick plastic, aluminum foil, double-sided sticky tape, Snappy trainers, sandpaper or place trays of marbles in the area so the cat cannot get a solid surface on which to stand.
- If the cat persists in urinating or defecating in the bath tub sometimes leaving a few inches of water in the bottom helps to control this behavior.
- **For inappropriate elimination related to anxiety,** remove or **minimize the cause of the anxiety** if possible. Provide a **regular predictable routine**, such as feed and play at a set time each day.

Treatment of spraying.

- **Owner education** of normal cat behavior is important so that they understand that the **behavior cannot always be eliminated** but can be managed.
- Treatment of any concurrent or underlying medical problem is essential.
- Remove or **minimize the cause of the anxiety** if possible. Provide a **regular predictable routine**, such as feed and play at a set time each day.
- **Environmental manipulation:** This can often be difficult to achieve in practice, although theoretically it should work well. It is rarely possible or

practical to remove the neighbor's cat, the new baby, or new spouse, or entirely prevent other anxiety-provoking circumstances such as moving house. However, if possible:

- Decrease the number of cats in the household.
- Decrease the access to windows and doors to decrease the sight, sound and smell stimuli.
- Change the amount of time spent indoors/outdoors.
- Prevent access to arousing stimuli.
- Make the sprayed areas less attractive to the cat to spray on by making them feeding or play areas instead.
- Feliway®, the synthetic analog of the F3 fraction of the cheek gland pheromone of cats, may help if sprayed daily for 30 days onto soiled areas.
- A Feliway Diffuser® plugged into the room in which the cat(s) spend most of their time has proven to be helpful in decreasing spraying, especially if inter-cat aggression is contributing to the spraying.

Surgery for spraying cats.

- **Neutering the entire cat.** Spraying is a marking behavior and in 87% of entire male cats, castration alone solves the problem.
- **Olfactory tractotomy** is reported to be effective in about 50% of refractory cases in males and in most females. The surgical transection of the olfactory tract causes anosmia (loss of sense of smell), which is thought to be an important factor in spraying. This technique is rarely used or recommended now.

Pharmacological treatments: These treatments are generally aimed at reducing the anxiety level of the cat by altering the neurochemical environment, and should be used in conjunction with behavioral modification and environmental manipulation techniques.

- Potential side effects should be explained to the owner prior to instigating any therapy, as most of the drugs are not registered for use in animals. Hematological and biochemical analysis should be carried out prior to instigating drug therapy. Anxiolytic medication should always be gradually withdrawn, never suddenly stopped.
- Medications that influence serotonin metabolism, such as the selective serotonin reuptake inhibitors and the tricyclic antidepressants have been used in the treatment of anxiety-related disorders. Anxiolytic medication has also proved useful in some cases.

- **Tricyclic antidepressants (TCAs)** such as:
 - Amitriptyline (0.5–1 mg/kg PO q 12–24 h, average of 5–10 mg/cat PO q 24 h).
 - Clomipramine (0.5 mg/kg PO q 24 h).
 - Nortriptyline (0.5–2.0 mg/kg PO q 12–24 h).
- **Selective serotonin re-uptake inhibitors (SSRIs)** such as:
 - Fluoxetine (0.5 mg/kg PO q 24 h).
 - Paroxetine (0.5 mg/kg PO q 24 h) (2.5 mg/cat) have been successful in controlling signs in some cases.
 - Fluvoxamine (0.25 mg/kg PO q 12 h) – concurrent use with benzodiazepines should be avoided.
- **Benzodiazepines** such as:
 - Diazepam (0.2–0.4 mg/kg PO q 12 h, average of 1–2 mg/cat PO q 12 h) They affect depth perception, so cats may fall off objects or miss objects when they jump until they learn to compensate. At therapeutic levels, there should be a calming effect but little or no effect on motor or mental functions. Cats may stagger for the first 1–2 days, but this should then spontaneously resolve. If it does not, then the dose should be decreased or withdrawn, as the potential for cumulative effects and toxicity due to the intermediate metabolite may occur. Use with caution in aggressive animals as diazepam may lead to disinhibition and potentiate aggression. Adverse effects usually disappear with a decrease or withdrawal of medication. High doses have been associated with increased liver enzymes, hepatotoxicity and convulsions, especially in overweight cats.
 - Oxazepam (0.2–0.5 mg/kg PO q 12–24 h) has been successful in other cases and is useful if diazepam produces excessive sedation.
- **Azaperones.**
 - Buspirone (0.5–1 mg/kg PO q 8–12 h).
- **Antihistamines.**
 - Cyproheptadine (0.4–0.5 mg/kg PO q 12 h) has been reported to be successful in some cases of spraying.

Cleaning the soiled areas with non-ammonia-based products such as enzymatic washing powders is important. Products such as Anti-Icky Poo have also been advocated as successful in eliminating odors. Additionally, neutralizers such as Bac to Nature used after cleaning can be effective in removing the odor.

Punishment is not effective in changing behavior. It serves to further increase the anxiety, as well as impede learning of non-anxious behavior.

Multi-cat households: For treatment to be effective it is essential that a correct diagnosis is made and the correct cat(s) treated. One way of trying to determine which cat is spraying in a multi-cat household is to administer fluorosceine to each cat in turn. All cats should be tested, as it is not unusual for more than one cat to spray. Place five or six fluorosceine strips (or liquid) in a gelatin capsule and give once daily for 3–5 days until the cat(s) is identified. An ultraviolet light will make it easier for the owner to detect fluorosceine in urine. A washout period of 24–48 hours between each cat has been recommended. However, fluorosceine is not an infallible way of detecting urine and a study has shown that the substrate as well as an individual cat's metabolism will affect detection rates. Additionally, fluorosceine may stain the substrate.

Prognosis

The **prognosis is generally good for both inappropriate elimination and spraying.** However, it depends on owner commitment, the success in determining the underlying cause, and the ability to manage the underlying problem. Prognosis also **deteriorates with increased length of time** that the behavior is left untreated and with recidivistic events.

Owner education of normal feline behavior is essential to achieve compliance.

OVER-GROOMING (INCLUDING PSYCHOGENIC ALOPECIA, FELINE HYPERESTHESIA AND SELF-MUTILATION)**

Classical signs

- Hair loss and discoloration only on the parts of the body that can be reached by the teeth and tongue.
- Plucked hair has evidence of shearing.
- Ulceration and self-mutilation may occur.

Pathogenesis

Normal adult cats spend about 30–50% of their time awake grooming.

Grooming serves many purposes including cleaning, removal of parasites, thermoregulation and alleviation of stress (e.g. after punishment, intercat aggression).

Self-licking, biting and hair loss are non-specific signs.

As with most behavioral conditions, the exact pathogenesis is unknown but likely to be complex.

- It may be a behavioral response to environmental conditions which stress the cat and result in stereotypic or obsessive-compulsive behaviors over time.
 - There are numerous reported **causes of anxiety in cats** which include **any environmental changes** such as: moving; a new baby or spouse; separation from the owner; too many cats in the household or area; presence of new cats in the area; loss of territory; punishment from the owner; presence of attacking birds (e.g. magpies) and lack of stimulation.
- **Lowered serotonin and increased dopamine levels** are associated with some obsessive-compulsive disorders. Dopamine is also associated with stress.

Medical conditions such as flea allergy, dietary allergy, sensitivity to dust mites **can trigger** the initial grooming episodes.

Currently **feline hyperesthesia, over-grooming, self-mutilation and psychogenic alopecia** are considered to be **part of the anxiety response.**

Clinical signs

Hair can be removed by plucking, barbering or just by licking and excoriation.

Self-licking, biting and alopecia are seen **wherever the cat can reach**, especially around the sides and rump, back legs and groin. The **head and back of neck may still have a normal hair coat.**

- Usually the **alopecia is non-symmetrical** and the **skin may look normal.**
- The **hair** in the area is a **ginger or rusty brown color** due to the action of the saliva.

Microscopic examination of **plucked hair shows evidence of shear.**

In some cats, over-grooming becomes excessive and self-mutilation and ulceration occur in the affected areas. Secondary bacterial infections may then occur necessitating treatment. **Occasionally**, the over-grooming is so severe that **ulcers develop in the mouth**

(tongue, pharynx and hard palate) making eating difficult or impossible. Bleeding may occur associated with hard palate ulcers.

In feline hyperesthesia syndrome, cats may become agitated and aggressive and show skin rippling and muscle spasms, usually over the lumbar area after stimulation such as stroking. They may exhibit frenzied behavior such as licking or biting at the flanks, back or tail or frantic running.

Diagnosis

Diagnosis is based on a complete behavioral history, and thorough physical examination including a complete blood count and biochemistry panel.

No evidence of dermatological causes, such as atopy, external parasites, food allergy is identified.

Microscopic examination of **plucked hair has evidence of shear**. Hair that is lost due to **endocrine conditions has telogen bulbs visible**.

Differential diagnosis

Any skin disease causing pruritus should be eliminated.

- **External parasites**, dermatitis of **fungal or bacterial origin** are differentiated on the basis of dermatological examination.
- **Food allergy** is differentiated by use of a food trial for 6–8 weeks that leads to resolution of signs when a novel protein such as venison or duck is introduced.
- **Endocrine disorders** are differentiated on the basis of **distribution of hair loss** that is usually **symmetrical**, as well as microscopic examination of hair indicating the **presence of telogen bulbs**.
- **Feline hyperesthesia syndrome** is a poorly understood condition which may be differentiated on the basis of signs of extreme sensitivity to touch on the dorsal region, skin rippling, biting or licking of the area with no obvious dermatological or neurological basis.
- **Pain** associated with any condition including trauma or infection is differentiated by response to analgesia or alleviation of pain.

Treatment

Treatment of any concurrent or underlying medical problem is essential, such as elimination of fleas, or resolution of food allergy by changing the diet.

Remove or minimize the cause of the anxiety if possible.

Provide a **regular predictable routine**, such as feed and play at a set time each day. Treatment involves altering the neurochemical as well as the physical environment. Potential side effects should be explained to the owner prior to instigating any therapy, as most of the drugs are not registered for use in animals.

- Medications that influence serotonin metabolism, such as the selective serotonin reuptake inhibitors and the tricyclic antidepressants have been used in the treatment of anxiety-related disorders. Anxiolytic medication has also proved useful in some cases. The comparative effectiveness of each medication remains to be evaluated and may depend on eliciting causes.
- **Tricyclic antidepressants** (TCAs) have proved to be effective.
 - **Amitriptyline** (0.5–1 mg/kg PO q 12–24 h, average of 5–10 mg/cat PO q 24 h). Start at the lowest dose and increase after 10 days if no response.
 - **Clomipramine** (0.5 mg/kg PO q 24 h).
- **Selective serotonin re-uptake inhibitors** (SSRIs) such as **fluoxetine** (0.5 mg/kg PO q 24 h) have been successful in controlling signs in some cases. Toxicity has been reported in humans when used with cyclosporine.
- **Benzodiazepines**, such as diazepam (0.2–0.4 mg/kg PO q 12 h – average of 1–2 mg/cat PO q 12 h) are effective in some cats. Oxazepam (0.2–0.5 mg/kg PO q 12–24 h) is useful where diazepam leads to excessive sedation.
- Blood biochemistry analysis should be done prior to medication to determine baseline concentrations especially for liver and kidney parameters. The cat may require **medication for a prolonged period (up to 6–12 months)** and then **slow withdrawal of medication** should be attempted. If cats require longer-term or lifetime medication, biochemistry parameters should be monitored every 6–12 months.

Punishment is not effective in changing behavior. It serves to further increase the anxiety, as well as impede learning of non-anxious behavior.

Prognosis

Prognosis is **variable** and depends on owner commitment, success in determining an underlying cause, and management of the underlying problem. Prognosis

deteriorates with increased length of time the problem is left untreated.

INAPPROPRIATE VOCALIZATION**

Classical signs

- Vocalization of increased duration, frequency or intensity.

Pathogenesis

Excessive vocalization may be a **normal innate behavior in some breeds** such as the Siamese.

Vocalization may indicate a **need for social contact, attention or food**. This has been reported in cats that are on restricted-calorie diets.

Septal, ventral hypothalamic lesions as well as hippocampal abnormalities have been associated with excessive vocalization.

Anxiety resulting from social stressors such as the **presence of other cats, a change in routine, or after a move** has been implicated as a trigger.

Excessive vocalization may be a **function of aging**, cerebral degeneration and alteration of neurotransmitter activity. It may be seen in aged cats exhibiting other signs of senile behavior.

Clinical signs

Vocalization is a non-specific sign.

With excessive vocalization associated with anxiety, the **vocalization is of changed duration, frequency or intensity**.

It may be nocturnal, or just more noticeable at night.

It is **relatively common in older cats** with decreased perceptual and locomotor abilities. It may also be due to reduced cognitive function (senility).

Diagnosis

Diagnosis is based on a **complete behavioral history** documenting inappropriate vocalization. A thorough physical examination, and hematological and biochemical analysis must exclude medical causes.

Hyperthyroidism is excluded based on a normal thyroxine (T4) concentration.

Differential diagnosis

Estrus is a normal behavior and may be **differentiated on the basis of the presence of classical behavioral signs** of restlessness, frequent urination, spraying, rolling, lordosis, etc., during the breeding season. As the cat is seasonally polyestrus these will recur on average every 3 weeks for several months if the cat is not mated.

Oriental breeds tend to vocalize more than other breeds and this is a normal behavior that is differentiated on the basis of breed.

Vocalizations that are a normal behavioral response to physical stressors such as **cold** and **hunger** are differentiated on the basis of a thorough history and **response to removal of these stressors**.

Cognitive dysfunction (aging, senility) is differentiated on the basis of age (cats are usually **more than 12 years of age**) as well as the presence of other signs which may include changes in sleep-wake cycles, decreased social interaction with owners, disorientation, and loss of previously learnt behaviors such as toilet training. Cognitive decline is of gradual onset.

Hyperthyroidism is differentiated on the basis of **classical signs** (weight loss, increased appetite, restlessness, increased vocalization) and **elevated T4 concentration**.

Feline hyperesthesia syndrome is a poorly understood condition which may be differentiated on the basis of signs of extreme sensitivity to touch on the dorsal region, which stimulates skin rippling, biting or licking of the area and often frantic running. Diagnosis is based on signs and lack of other dermatological or neurological disease.

Pain associated with any condition including trauma or **urinary tract infection** is differentiated by response to analgesia or alleviation of pain.

- Vocalization may decrease with pain, so it is important to know what is normal for the cat.

Attention-seeking behavior is differentiated on the basis of a history that is suggestive that vocalization **only occurs in the presence of the owner** when the owner is not paying attention to the cat.

Travel can induce a panic or fear response in cats, and this can be differentiated on the basis of history that the behavior occurs only in these circumstances.

Treatment

Owner education of normal cat behavior is important so that they understand that the **behavior cannot be eliminated** but can be managed.

Treatment of any concurrent or underlying medical problem is essential.

Remove or **minimize the cause of the anxiety** if possible.

Provide a **regular predictable routine**, such as feed and play at a set time each day.

Environmental enrichment with toys that are changed daily, places to hide, and opportunities to play provides a stimulating mental and physical environment for the cat.

Treatment may also involve altering the neurochemical as well as the physical environment.

- Medications that influence serotonin metabolism, such as the selective serotonin reuptake inhibitors and the tricyclic antidepressants have been used in the treatment of anxiety-related disorders. Anxiolytic medication has also proved useful in some cases. Potential side effects should be explained to the owner prior to instigating any therapy, as most of the drugs are not registered for use in animals.
- **Tricyclic antidepressants** (TCAs) such as:
 - Amitriptyline (0.5–1 mg/kg PO q 12–24 h, average of 5–10 mg/cat PO q 24 h) or clomipramine (0.5 mg/kg PO q 24 h).
- **Selective serotonin re-uptake inhibitors** (SSRIs) such as:
 - Fluoxetine (0.5 mg/kg PO q 24 h) have been successful in controlling signs in some cases.
- **Benzodiazepines** such as:
 - Diazepam (0.2–0.4 mg/kg PO q 12 h, average of 1–2 mg/cat PO q 12 h) have been successful in others cases. However, benzodiazepines can lead to increased vocalization in some cats.
- The **monoamine oxidase inhibitor** (MAOI) **selegiline** (deprenyl) at 0.5 mg/kg PO q 24 h has been reported to be effective in some cases for cognitive dysfunction associated with senility.
- Blood biochemistry and hematology analysis should be done prior to beginning medication to

determine baseline values especially for **liver and kidney parameters**. The cat may require medication for a prolonged period (up to 6–12 months). **Gradual withdrawal** of medication could be attempted by reducing the dose by half every 2–4 weeks once the symptoms have been successfully controlled for 2–3 months.

Punishment is not effective in changing behavior as it further increases anxiety and impedes learning of non-anxious behavior.

Prognosis

The **prognosis is variable**. It depends on owner commitment, the success in determining the underlying cause and the ability to manage the underlying problem. Prognosis also **deteriorates with increased length of time** that the behavior is left untreated.

Owner education of normal feline behavior is essential to achieve compliance.

PICA (EATING NON-FOOD MATERIAL)*

Classical signs

- **Abnormal ingestion of non-nutritive substances.**

Pathogenesis

Plant eating may be due to lack of access to grass or vegetation, or be normal investigatory behavior. Young cats especially, may chew, but not necessarily ingest, non-food substances as part of their normal exploratory behavior.

It may represent **obsessive-compulsive disorder** (OCD) with stereotypic chewing or mouth movements. The chewing is carried out differently from eating food items.

Neurochemical and neuroanatomical changes are seen on positron emission tomography scans with OCD.

Wool chewing is a ritualistic or stereotypic behavior. Generally these behaviors are more annoying than damaging, unless they start interfering with the animal's normal functioning.

- More common in **oriental breeds such as Siamese and Burmese**, although it has been reported in all breeds including crossbreeds.
- No sex predisposition for wool eating has been reported.
- Behavior is reported to begin **from 2–8 months of age up to 1–2 years of age**.
- It is reportedly more common in cats that are **entirely indoors**.
- It can be **triggered by stress**.
- **Hunger stimulates the behavior**.
- Postulated causes include:
 - **Early weaning** (at 2–4 weeks); in contrast, feral cats may suckle until 6 months of age.
 - Insufficient handling of kittens before homing.
 - Insufficient fibre in the diet.
 - Separation anxiety.
 - Having no opportunity to develop exploratory and hunting behaviors.
 - A malfunction in the neural control of appetitive behavior.
- Some cats appear to **grow out of it** and the problem resolves during early adulthood without treatment.
- Wool chewing and pica appear to be **inherited**.

Wool sucking may be different in that it **occurs in very early-weaned cats**.

Ingestion of houseplants may occur in cats confined indoors with no access to grass or vegetation. Ingestion of small amounts of grass or other vegetation is normal behavior in cats.

Clinical signs

Pica may include the ingestion of substances such as soil, rubber, paper, wood, string, houseplants, wool or fabric.

Individual cats tend to **ingest one type of substance only**.

Fabric-eating cats appear to **start by eating woollen fabrics**. They **may then proceed to other fabrics** such as cotton, silk and synthetics, but this is not always the case.

- Cats do not appear to like eating raw wool. It is postulated that they do not like the taste or texture of the lanolin.

While the cat is chewing it appears to be **totally engrossed**. They pull and tug on the wool, then grind

with their molars. Note that **some cats just suck** the item, and this behavior may be of different origin.

Quite large quantities can be ingested.

- This is a problem if blankets, socks and sweaters are eaten, as there is the **potential for intestinal obstruction**.

Diagnosis

Diagnosis is based on a behavioral history of observation of the ingestion of non-food substances, and exclusion of other underlying disease. A thorough physical examination including a neurological examination should be performed.

A complete blood count, and biochemical analysis including measurement of electrolytes should be performed to exclude medical conditions.

Normal serum lead levels.

Normal thyroxine (T4) concentration.

Differential diagnosis

Hyperthyroidism is differentiated on the basis of typical signs (weight loss, increased appetite, restlessness, increased vocalization) and elevated T4 concentration.

Lead poisoning is differentiated on the basis of signs of weight loss, inappetence and elevated blood lead concentration.

Other neurological disease causing pica, such as encephalitis (e.g. feline infectious peritonitis (FIP) or neoplasia, should be excluded based on neurological examination and other ancillary tests (e.g. CSF analysis).

Dietary deficiencies are differentiated by examination of the diet.

Intestinal parasites are differentiated by presence of eggs on fecal flotation.

Normal investigative behavior is differentiated on the basis of which substances are ingested and the amount consumed. It is more common in young cats.

Lack of access to grass or vegetation resulting in ingestion of small quantities of houseplants is usually confined to indoor cats.

Treatment

Avoid allowing the cat **access** to potentially harmful ingestible materials.

Taste deterrents such as **bitter apple** or **chilli** can prove effective and may be more potent if they are paired with a **distinctive scent such as eucalyptus oil or cologne**, to provide an additional (olfactory) cue that the material is to be avoided. Thus, the cat learns to associate the smell of the oil with an unpleasant taste and eventually the scent alone is enough for the cat to avoid the material. This appears to deter some cats if the behavior is of recent origin.

Provide a regular predictable routine to minimize stress.

- Provide **set times to interact, play and feed the cat**.

Increase environmental enrichment by providing toys and mental stimulation.

- Provide an indoor garden with grass, catnip and/or cat mint as a safe source of vegetation, as well as environmental enrichment.

Other suggestions reported to help are:

- Allow the cat **access to dried food all day**.
- **Increase the fiber content** of the diet by adding bran or vegetables.
- Provide **gristly meat and raw bones to chew** on to increase time spent chewing and eating.
- Give small strips of woolen fabric or sheepskin to ingest with their meal. This must **ONLY** be done under veterinary supervision, and the owner warned that it could lead to constipation or intestinal obstruction.

Do not use direct punishment as this may increase anxiety and exacerbate the problem.

- Environmental punishments such as double-sided sticky tape or **Snappy trainers** may help keep cats away from some areas. A Snappy trainer is a standard mousetrap with a red plastic paddle attached to the moving lever. When the lever is activated, the paddle flips over. This is designed to scare the cat but the paddle prevents injury, because the cat cannot get its paw or face caught in the trap.

Treatment with **psychotropic medication** may be needed if a diagnosis of OCD is made. Potential side effects should be explained to the owner prior to instigating any therapy, as most of the drugs are not registered for use in animals. Anxiolytic medication should always be gradually withdrawn, never suddenly stopped.

- Premedication hematology and serum biochemistry analysis is recommended to provide baseline values, which is especially important if the cat has to stay on long-term or life-time medication. These should be repeated every 6–12 months depending on the age and health status of the cat.
- **Tricyclic antidepressants** such as:
 - Amitriptyline (0.5–1 mg/kg PO q 12–24 h, average of 5–10 mg/cat PO q 24 h). Start at the lowest dose and increase if no response seen after 10 days.
 - Nortriptyline (0.5–1 mg/kg PO q 12–24 h). This is useful if cat is very sedated with amitriptyline.
 - Clomipramine (0.5 mg/kg PO q 24 h).
- **Selective serotonin re-uptake inhibitors** such as:
 - Fluoxetine (0.5 mg/kg PO q 24 h) have proved useful in some cases.
- A **minimum treatment period of 6 months** is recommended as some medications may take 6–8 weeks to reach therapeutic levels.
 - **Gradual weaning off medication** can be attempted when the behavior has been **successfully managed for 3 months**. This can be achieved by halving the dose every 2–4 weeks as long as the symptoms are still controlled.

Prognosis

Treatment takes time and patience so owner commitment is essential.

Prognosis is guarded if an inherited predisposition is suspected. However, most cases can be successfully managed.

Prognosis is good in young cats when signs constitute normal investigative behavior.

PART 13

Cat with skin problems

48. The cat with miliary dermatitis

Ruadhri Michael Seosaimh Breathnach and Mike Shipstone

KEY SIGNS

- Multiple papulocrustous skin lesions.

MECHANISM?

- Miliary dermatitis is a distinct clinical entity, consisting of the presence of multiple papulocrustous lesions affecting the skin. Pruritus contributes to lesion development. Alopecia and secondary infection are common sequelae.

WHERE?

- Skin – widespread papulocrustous lesions can develop in many sites of the body. The precise location of lesions will vary with the specific condition.

WHAT?

- Most cases of miliary dermatitis are due to hypersensitive reactions, with flea allergy being the most common. Other causes include ectoparasitism, microbial infections, neoplasia and various miscellaneous factors such as dietary imbalances, etc.

QUICK REFERENCE SUMMARY

Diseases causing miliary dermatitis

NUTRITIONAL

- Essential fatty acid or biotin deficiency (p 1041)

Widespread papulocrustous dermatitis. Dry, brittle coat in growing cats. Excess scale formation. Uncommon in cats on well-formulated diets. History of a poorly formulated diet, or poor storage conditions leading to rancidity, or prolonged antibiotic therapy.

INFECTIOUS:

Bacterial:

- Staphylococcal dermatitis (p 1041)

Erythema, scale and crustiness. Hair follicles are commonly involved. Papules are common, but not pus. Primary staphylococcal dermatitis is uncommon in cats.

Fungal:

- **Dermatophytes** (p 1032)**

More common in young kittens. Erythematous plaques, alopecia and scale. Lesions may progress to larger gray areas of alopecia and hyper-keratosis.

Parasitic:

- **Flea dermatitis*** (p 1025)**

Extremely common problem. Pruritus, alopecia and crustiness occur commonly on the dorsal spine and abdomen. Fleas and/or flea feces may be evident in the coat, but may require careful combing to find.

- *Otodectes cynotis* (p 1037)

Papulocrustous dermatitis, often associated with otitis externa. Pruritus, alopecia and secondary infection. Miliary dermatitis is less common than otic signs.

- *Notoedres cati* (notoedric mange) (p 1039)

Severe pruritus. Only common in certain geographical areas. Alopecia, hyperkeratosis and gray, crusty exudate. Secondary infection common.

- *Cheyletiella* species (cheyletiellosis) (p 1036)

Seborrhea and papules, most marked on dorsum. Mild to moderate pruritus. Movement of mites in heavy infestations resembles walking dandruff.

- *Neotrombicula autumnalis* (neotrombiculosis) (p 1038)

Erythema, papules and alopecia. Moderate to marked pruritus. Any contact surface on the body can be involved. Feet, head and limbs most common sites. Larval stages appear as red-orange dots to the naked eye.

- *Felicola subrostratus* (p 1035)

Pruritus, alopecia and occasional secondary infection. Lice and lice eggs may be visible. Often associated with neglect, malnutrition, matted coats, etc.

continued

continued

- Cat fur mite (*Lynxacarus radovsky*) (p 1040)

Dry, dull coat with scale and scurf. Hairs are easily epilated leading to patchy alopecia. Variable pruritus. Common sites include tail-head, perineum and thighs. Only common in limited geographic locations.

IMMUNE-MEDIATED

- **Flea allergic dermatitis (FAD)*** (p 1025)**

Extremely common cause of miliary dermatitis. Lesions most prevalent along dorsal spine, caudo-medial thighs and ventral abdomen. Signs may be seasonal or perennial. Pruritus is a classical feature.

- **Adverse food reaction (food hypersensitivity)** (p 1029)**

Probably the second most common allergic cause of miliary dermatitis. Results in moderate to marked pruritus, often involving the head and ears, which is often poorly responsive to corticosteroids. Non-seasonal and may mimic many other cutaneous disorders. Concurrent signs of gastrointestinal or respiratory involvement are usually absent. An affected cat may have been on diet for some time.

- **Atopic dermatitis** (p 1030)**

Variably pruritic condition which may present as miliary dermatitis, symmetrical alopecia or eosinophilic granuloma complex. Secondary infection may occur. Some animals have only alopecia, and no history of pruritus or skin lesions. Can be seasonal or perennial. Most common in young to middle-aged cats.

- **Mosquito bite hypersensitivity** (p 1031)**

Variable pruritus with lesions most commonly affecting hairless areas of head, nose, ears and pads. Lesions include papules, crusted papules, plaques, nodules and alopecia. Common in certain geographical locations.

- **Drug reaction/hypersensitivity (p 1034)**

Uncommon cause of miliary dermatitis, but can occur in any age group. Signs vary from mild erythema to urticaria to necrosis/sloughing. Variably pruritic. Often mimics many other dermatoses. Most common signs are erythema, pruritus and self-induced trauma in areas where topical medications are being applied.

- **Intestinal parasite hypersensitivity (p 1035)**

Multifocal or generalized papulocrustous reaction pattern. Seborrhea and pruritus. Gastrointestinal signs occasionally present. Pruritic.

- **Auto-immune dermatoses (p 1042)**

Primarily a pustular or erosive group of conditions resulting in scale, erosions and alopecia. Face, ears and feet are common sites. Pruritus and pain are variable.

IDIOPATHIC

- **Idiopathic (p 1043)**

Papulocrustous dermatitis. Pruritic. Diagnosis of exclusion when all other etiologies ruled-out.

INTRODUCTION

MECHANISM?

Miliary dermatitis is a term used to describe a cutaneous reaction pattern in cats consisting of **multiple papulocrustous lesions**. It is important to emphasize that it is a clinical, not an etiological, diagnosis. Miliary dermatitis should be suspected when a cat shows evidence of:

- **Multiple papulocrustous lesions** on the skin surface.
- Lesions which typically appear in clusters.
- Alopecia.
- Secondary bacterial infection is sometimes present. The skin/coat may feel hot and sticky.
- The **mechanism of lesion** development is often **inflammatory or immune-mediated in nature**, but can vary with the underlying etiology.
- **Pruritus** is a significant feature, which contributes to lesion development. The typical **response of cats to pruritus** is to **lick or over-groom** rather than scratch, and it is believed that the barbs on the tongue may contribute to lesion development.
- Controversy exists as to whether the term miliary dermatitis should be limited to a few distinct causes, rather than an exhaustive list of differentials.
- A definitive etiology is not always apparent, and in such cases the cat is usually treated symptomatically.

WHERE?

Skin: Widespread papulocrustous lesions can develop in many sites of the body.

- The precise location of lesions will vary with the specific condition.
- The most common sites affected include the **dorsal trunk, flanks, caudo-medial thighs and ventral abdomen**.

WHAT?

Most cases of miliary dermatitis are due to **hypersensitivity reactions**.

- **Flea allergic dermatitis** is by far the most common underlying **etiology** of this syndrome.
- **Food allergy, atopic dermatitis** and other hypersensitive disorders are less common.

- Other causes include **ectoparasitism** and microbial infections.
- Neoplasia and various miscellaneous factors such as dietary imbalances are possible causes in a small minority of cats.
- Diseases covered in The Cat With Pruritus Without Miliary Dermatitis may also present with miliary dermatitis and should be considered.
- Many factors including the history, age of cat, lesion distribution and even geographical location should help to limit the list of differentials in certain cases.

DISEASES CAUSING MILIARY DERMATITIS

FLEA ALLERGIC DERMATITIS (FAD)***

Classical signs

- Moderate to severe pruritus, seasonal or all year round.
- Numerous papules mainly on the dorsum and ventral abdomen.
- Self-trauma leads to alopecia, crustiness, erosions and secondary infection.
- Because cats are very efficient at grooming the fleas from the coat, fleas or flea dirt may or may not be seen.

Pathogenesis

Ctenocephalides felis is the species most frequently involved in flea allergic dermatitis on a worldwide basis. Other species of flea, including **hedgehog and rabbit fleas** may be involved.

Flea allergic dermatitis is the **most common hypersensitive skin disease** reported in cats, and has been associated with many cutaneous reaction patterns, such as **miliary dermatitis, symmetrical alopecia and feline eosinophilic granuloma complex**.

The hypersensitive response develops following binding of **haptens in flea saliva** to dermal collagen.

Whilst flea allergic dermatitis can represent both a type I and type IV hypersensitive reaction in dogs, only the **immediate type reaction** is currently recognized in cats.

The development of hypersensitivity is **not dependent on the number of fleas** infesting or biting the host.

It is postulated that the presence of **atopy may predispose** to the development of flea allergic dermatitis.

The clinical condition may be **seasonal or perennial** in individual animals, depending on geography and other environmental conditions.

Clinical signs

Numerous papules are principally seen on the **dorsum, caudo-medial thighs, flanks and ventral abdomen**, though individual lesions can occur in other sites.

Pruritus is a classical feature. The manifestation of which may be **biting, licking, rubbing, chewing, scratching** or any combination of these. This may be done out of the owner's view, so tufts of hair in the environment, hair caught in the teeth or within the feces are clues to pruritus. Self-trauma leads to alopecia, crustiness, erosions and secondary infection.

There may be **evidence of fleas, or flea feces** may be present within the coat.

Lesions present as a **papulocrustous dermatitis** with alopecia, and rarely, secondary infection characterized by pyotraumatic dermatitis.

Severely affected animals may be depressed and inappetent, with occasional cases showing peripheral lymphadenopathy.

Other cutaneous reaction patterns may be evident.

Some affected cats may also be infested with *Dipylidium caninum*.

Diagnosis

A tentative diagnosis is **based on the history and physical examination.** Finding fleas on the cat is not essential, although fleas and/or flea feces will be present in some cats. Cats are very efficient at grooming the fleas from the coat, and fleas or flea dirt may or may not be seen.

Using a fine flea comb is essential in cases of low levels of infestation, particularly when the coat color is dark. The comb should be brushed through the entire coat including the **perineal, inguinal and ventral**

chin. The collected debris should be examined on a white piece of paper. The **flea feces** appear as fine black fragments, but can be present as fine coils. This will turn a red/brown (rust) color if water is dropped onto it, because the major component of the feces is dried blood.

An **intradermal challenge** with commercially available flea saliva antigen may be used, with the reaction being read at 15–20 minutes. The reaction is compared to a positive and negative control (histamine and phosphate-buffered saline). In practice, however, **this test may be difficult** or even impossible to interpret in cats. The presence of a positive test does not confirm flea allergic dermatitis nor does a negative test rule it out. It **merely shows sensitization to the allergen**, NOT whether or not this sensitization is significant.

Blood eosinophilia and skin biopsy may be suggestive of flea allergic dermatitis, but are not in themselves diagnostic.

Serological tests based on such techniques as ELISA are available, although their sensitivity and specificity are still under some investigation. The problem is that the incidence of sensitization in normal cats is so high, that **the positive predictive value of the test is low.**

Response to a strict insect elimination trial may prove a **more reliable means of establishing a retrospective diagnosis.** One method is to apply Fipronil spray to the whole body at 0, 2 and 4 weeks and assess the reduction in pruritus. **Greater than 80% improvement confirms the diagnosis.** An approximately **50% improvement** shows that **insects are a component** of the problem, and **< 30%** rules the diagnosis out. However, in practice, the percentage improvement may be difficult to gauge.

Differential diagnosis

All of the conditions included in this chapter should be considered as differential diagnoses. However, flea allergic dermatitis is by far the single most common cause of this syndrome.

Other differentials which warrant consideration include **atopic dermatitis, food allergy and various ectoparasitic and microbial skin infections.**

Response to a strict insect elimination trial as outlined is the first step in the investigative process.

Treatment

Flea control is vitally important. A wide variety of anti-flea preparations are available, for example, topical powders, sprays, spot-on formulations and collars. Active ingredients that act as adulticides include: **pyrethrins, organophosphates, fipronil, imidacloprid, nitenpyram and selamectin.** **Insect growth regulators (lufenuron, methoprene, pyriproxyfen)** may also be used as part of a complete control program to reduce environmental stages of the lifecycle. It is essential to treat in-contact dogs and cats because they may act as reservoirs that will contaminate an environment.

The ideal flea control program should include the **concurrent use** of an **adulticide** to eliminate adult fleas on the pet, and an **insect growth regulator** to control immature flea stages.

- The easiest adulticide to apply is a **monthly “spot on” application of either fipronil, imidacloprid or selamectin** (all have similar therapeutic claims), together with an insect growth regulator, which may be administered topically (methoprene, fenoxycarb, pyriproxyfen), orally (lufenuron) or as a depot injection (lufenuron).
- This **integrated approach** is **essential** because **no adulticide has 100% consistent activity** for the registered duration of action. This means that **viable egg production** may begin **from day 22** after application, although the application interval is 30 days. The modern adulticides (fipronil, imidacloprid and selamectin) are only available as products with a recommended dosing interval of 30 days. Thus, the **integrated approach** ensures that any **eggs laid are non-viable**, and also **delays development of resistance** to both the adulticides and the insect growth regulators. It also means that any infestation picked up through contact with untreated animals or their environment does not become established on the treated animal, or continue to contaminate its environment.

In **sick or neonatal** animals, simple **combing of the coat** with a flea comb may be sufficient to remove fleas.

Systemic corticosteroids are indicated initially, for example, prednisolone (1–2 mg/kg q 24 h for 7–10 days), tapering over 7–14 days to 0.25–0.5 mg/kg q 48 h as required. If good flea control can be achieved, long-term cortisone use is unnecessary.

Depot corticosteroid preparations and megestrol acetate are sometimes used when oral therapy is unable to be given, but are more likely to be associated with side effects.

Antihistamines may be useful, although they generally have a slow onset of action and so may need to be combined with prednisolone for the first week or two of therapy. Chlorpheniramine (2–4 mg q 12 h PO) or hydroxyzine (2 mg/kg q 12 h PO) are the most commonly used.

Topical or systemic antimicrobial therapy may be used if secondary bacterial infections are present.

Hyposensitization has been attempted, but to date most reported results have been disappointing. However, work is continuing with different vaccine antigens and future results may be more encouraging.

Prognosis

The **prognosis is good** but **strict flea control** must be maintained life-long or relapses will occur. To date, hyposensitization results have been disappointing.

Transmission

Fleas are transmitted principally by **contact with an infested environment**, although some direct animal-to-animal transfer is possible. The hypersensitive component is not contagious.

Prevention

Adoption of **strict flea control measures** (see flea dermatitis).

Intermittent or long-term alternate day use of prednisolone may be required to control clinical signs if the flea control is inadequate.

FLEA DERMATITIS***

Classical signs

- Lesions on dorsum and ventral abdomen.
- Pruritus, alopecia, crust formation and secondary bacterial infection.
- Fleas and/or flea feces may be seen but may be difficult to find.

Pathogenesis

The movement and blood-sucking activities of fleas leads to **irritation, pruritus and self-trauma**.

Many species can parasitize the cat. *Ctenocephalides felis* is the dominant species involved.

The rabbit flea, *Spilopsyllus cuniculi*, may cause pinnal dermatitis.

Adult *C. felis* begin feeding immediately on the host. If reproduction is not disturbed, the female may produce **up to 50 eggs a day (average 25)** and lay for **up to 100 days**, so the potential for environmental contamination is large, although the normal grooming habits will significantly reduce this.

The **lifecycle** is typical for insects with an egg, larvae, pupa, and adult stage, and under conditions of ideal temperature and humidity, may **occur in as little as 21 days**. However, the duration of the pupal stage is very variable and if conditions are not ideal, the flea may rest in the pupae in a dormant state for up to 180 days, extending the overall lifecycle to around 200 days.

C. felis acts as the intermediate host for *Dipylidium caninum*, so the cat may also be infected with tapeworms.

Many cases of infestation are sub-clinical, but these animals may act as the reservoir contaminating the environment for other co-habiting clinically affected animals.

Transmission is via direct contact with an **infested environment**, although some direct transfer from an infested animal may occur.

Clinical signs

Pruritus and self-trauma occur, and are expressed as **licking or over-grooming rather than scratching**. This results in alopecia, crust formation, miliary dermatitis and secondary infection.

Lesions occur mainly along the **dorsal, inguinal and ventral abdominal areas**.

Severe infestation may lead to anemia, especially in young kittens.

Occasionally, *D. caninum* segments are identified in feces.

Diagnosis

Diagnosis is based on clinical signs and finding evidence of fleas. The absence of fleas on examination does not rule out a diagnosis, because cats are very efficient at grooming the fleas and flea dirt from the coat.

Fleas may be detected by a methodical examination of the skin and coat, and with the use of a flea comb. Flea feces can be identified by its red-brown color when suspect material is placed onto damp white paper.

Evidence of infestation on **in-contact animals** or in the environment may be relevant.

Response to a strict insect elimination trial is a reliable means of diagnosis.

Flea dermatitis is the **result of flea infestation**. It does not imply or require a hypersensitivity or allergic response to be developed in the affected animal for lesions to occur. The pruritus and self-trauma are related to the **irritation of the flea feeding and moving through the coat**.

Differential diagnosis

Other ectoparasitic, hypersensitive and psychogenic skin conditions. Response to a strict insect elimination trial (outlined under flea allergic dermatitis) is the first step in investigation.

Treatment and prevention

A **wide variety of anti-flea preparations** are available. See section on flea allergic dermatitis. It is essential to treat in-contact dogs and cats, because they may act as reservoirs that will contaminate an environment.

In sick or neonatal animals, simple combing of the coat may be sufficient.

Antibiotics and glucocorticoids may be indicated.

Prognosis

Prognosis is excellent with diligent flea control. However, re-infestation is common.

Transmission

Transmission is by direct or indirect contact, but occurs largely from a **contaminated environment**.

FOOD ADVERSE REACTION (FOOD HYPERSENSITIVITY)**

Classical signs

- Moderate to marked pruritus, often involving the head and ears.
- Often poorly responsive to corticosteroids.
- Non-seasonal.
- May mimic many other cutaneous disorders.
- Concurrent signs of gastrointestinal or respiratory involvement are usually absent.

Pathogenesis

Adverse food reaction or food hypersensitivity accounts for **1–2% of feline dermatoses** seen in practice, and is probably the second most common allergic cause of miliary dermatitis.

Adverse food reactions have been reported to be associated with both **immediate and delayed hypersensitive reactions**.

Ingestion of the offending allergen may occur for months to years before there is sensitization and subsequent clinical reaction.

No sex, age or breed predisposition.

Cats may become sensitized to whatever is being fed, and so the common allergens will vary with local feeding habits of the country. However, **beef, lamb, fish, milk and chicken** are most often implicated.

Clinical signs

The dominant clinical sign is **pruritus**, the manifestation of which may vary from **licking, rubbing, biting, scratching** through to severe excoriation. Pruritus is often poorly responsive to corticosteroids.

Lesions include **erythema, papules, pustules, crusts and ulcers**.

Whilst any part of the body can be involved, the **head and ears are common sites**.

Gastrointestinal tract and respiratory signs are occasionally present.

Peripheral lymphadenopathy is rarely present.

Signs of adverse food reaction may mimic many other cutaneous disorders.

Diagnosis

Intradermal and scratch testing are of **no practical benefit** in establishing a diagnosis.

Serological testing is available, but has a very low predictive index and is **not recommended**.

Feeding a true elimination diet for a period of 6–13 weeks, and **demonstrating recovery**, and then **relapse on challenge** with the original diet, is the only accurate method of making a diagnosis. An accurate dietary history is essential so that the **protein selected** for the diet is one that the **cat has never been exposed to**. Depending on the local feeding history this could be goat, horse, rabbit, kangaroo, duck or venison. This diet is **fed exclusively** for the period of the feeding trial.

- If the condition then markedly improves, the diagnosis is confirmed by provocative exposure to the previously incriminated diet. If the cat is food allergic, **a flare in pruritus is expected within 7–10 days**, although most will flare within 24–48 hours of exposure.
- In practice, however, many owners are content to simply let their cat remain on the new diet. If this is done, then they must be warned that the diagnosis has not been confirmed, and that any return in the clinical signs warrants further investigation for other allergic diseases that may have been out of season at the conclusion of the food trial (e.g. atopy, flea allergic dermatitis).
- Once the diagnosis has been confirmed by provocative exposure, the cat can be left on the new diet, provided it is complete and balanced. Alternatively, a **sequential rechallenge with individual food allergens** can be done to try and identify the specific food that is causing the problem, because in over 90% of cases **only 1 or 2 allergens are involved**. All the previous diet components should be fed sequentially over a short period so that it minimizes the chance of a seasonal change occurring, causing a flare in atopic dermatitis, which may then erroneously be attributed to a specific food.

Differential diagnosis

All of the conditions included in this section can be considered as differential diagnoses. However, flea allergic dermatitis is the single most common differential for this syndrome.

Other differentials which warrant consideration, include **atopic dermatitis and various ectoparasitic and microbial skin infections.**

The **investigation must follow a step-wise process** to eliminate other diseases and confirm the diagnosis. That is, if signs still persist after a strict insect elimination trial with control of any secondary infection, a food trial is performed. If the clinical signs still persist, then other differentials including atopy must be considered.

Treatment

A **nutritionally balanced elimination diet** will need to be **fed long-term.**

- If home-produced diets are to be fed for maintenance, they must be properly balanced to meet the animal's long-term nutritional requirements. A home-prepared diet can be balanced using a meat protein, combined with a carbohydrate (potato, sweet potato, tomato, lentils) supplemented with a balanced calcium source (with correct calcium:phosphorus ratio), safflower, flax seed oils and a multivitamin additive.

Alternatively, commercial hypoallergenic diets are more convenient and provide a nutritionally balanced diet designed for long-term maintenance. A variety of hypoallergenic diets is available including diets using hydrolyzed protein (e.g. Hills z/d).

Prognosis

The prognosis is excellent. However, some cats may later become hypersensitive to the new diet.

ATOPIC DERMATITIS**

Classical signs

- Pruritic dermatosis presenting as miliary dermatitis, symmetrical alopecia or eosinophilic granuloma complex.

Classical signs—Cont'd

- Self-trauma, alopecia and secondary infection.
- Some animals have only alopecia and no history of pruritus or skin lesions.
- Seasonal or year round.

Pathogenesis

The precise pathogenesis of atopic dermatitis is not well understood in cats. A **genetic predisposition is suspected** but has not been proven.

Clinical signs may be **seasonal or non-seasonal depending on the allergen(s)** involved.

Most cats first develop **clinical signs before 3 years of age.**

There are no known breed or sex predilections.

The route of entry of the offending allergen(s) is not well understood, but may include both **inhalation and cutaneous absorption.**

A range of allergens including **dust mites, grass, weed and tree pollens and mold spores** have been identified as causing disease. The clinical signs are not related to the specific allergen sensitivity identified.

Clinical signs

Some cats with atopic dermatitis have **pruritus, papulocrustous lesions and/or alopecia.**

Other cats are not seen to be pruritic by the owner, and may have no lesions on the skin but present with a **non-inflammatory alopecia.** In these cats examination of the hairs in the affected area will show that they have been cropped and have broken ends.

Distribution of lesions is not as well defined as in dogs, although the **face and ears** are frequently involved.

Cats may present with a particular cutaneous reaction pattern, such as **eosinophilic granuloma complex, symmetrical alopecia or miliary dermatitis.**

Occasionally peripheral lymphadenopathy may be seen, particularly in cats with miliary dermatitis or eosinophilic plaques.

Some cats may present with **respiratory signs** including rhinitis, chronic cough or asthmatic wheeze.

Diagnosis

In cats with no history of pruritus, a **trichogram and possible trial therapy with an Elizabethan collar** should be considered to ensure the lesions (particularly alopecia and miliary dermatitis) are not self-induced. When questioning the owner, all manifestations of pruritus should be described including biting, rubbing, licking, biting scratching, as some owners only recognize or equate scratching with itch.

- A **trichogram** is collected by **plucking hairs** using mosquito forceps, padded with tape, from the affected area. The ends of the hairs are examined microscopically for signs of trauma including splitting, fractures, cropped, squared off ends, rather than a smoothly tapered end of the undamaged hair.

Histopathology is not diagnostic.

Intradermal skin testing is potentially useful using a panel of allergens based on geographical location. All tests **should include dust mites**, but the grass, weed and pollen selection will depend on the specific location. Allergen manufacturers generally have well-established recommendations for specific antigen selection in the USA and Europe. However, it should be emphasized that the results of intradermal testing can be difficult to interpret in some cats.

Serological tests (ELISA, etc.) for the detection of allergen-specific IgE are commercially available, although data to confirm the sensitivity and specificity of many of these tests are **often lacking**.

Differential diagnosis

All conditions included in this section can be considered as differential diagnoses.

- **Flea allergic dermatitis** is the single most common differential for this syndrome, and should be first ruled out by a thorough insect elimination trial.
- **Adverse food reaction** is the next most common condition, and can be eliminated on the basis of a strict food trial.
- Other differentials which warrant consideration, include various ectoparasitic and microbial skin infections.

Treatment

Prednisolone (initial dose 1–2 mg/kg/day for 7–10 days) should be used to control the clinical signs. The dose may be gradually tapered over 2–3 weeks to 0.5–1.0 mg/kg q 48 h as required to control clinical signs.

Antihistamines such as chlorpheniramine (2–4 mg/cat twice daily) may be effective.

Essential fatty acid supplements of the omega 3 and omega 6 series may help in treatment regimes, particularly if combined with prednisolone or chlorpheniramine.

Hyposensitization is often the treatment of choice, and can be expected to give some control in 60–70% of cases. An accurate diagnosis of the offending allergen(s) is essential.

In **severe, refractory cases** immunosuppressive therapy using **chlorambucil** (0.1–0.2 mg/kg q 24 h) has been reported, but should only be used where high-dose prednisolone (2–3 mg/kg q 24 h) has been unsuccessful. **Cyclosporin** (5 mg/kg q 24 h for 2–3 weeks and then reducing to 5 mg/kg q 48–72 hours) has been effective, but large-scale controlled studies have yet to be published.

Prognosis

The prognosis is good, although on-going medication or hyposensitization, will be required.

If the allergen(s) can be successfully avoided, e.g. tobacco smoke, then the prognosis is excellent.

Prevention

Future episodes may be ameliorated by appropriate medication or hyposensitization.

Whilst a specific inherited predisposition has not yet been proven in cats, judicious breeding programs may be appropriate.

MOSQUITO BITE HYPERSENSITIVITY**

Classical signs

- Papules, erosions, crusting and depigmentation of the nose and pinnae

Classical signs—Cont'd

principally, although the preauricular skin may also be affected.

- The footpads may become swollen and develop fissures and scale.
- Pruritus is variable.

Pathogenesis

Disease is restricted geographically to **areas where mosquitoes are endemic**, and is more common in **spring and summer** in association with an increase in mosquito breeding, and regresses through winter.

The condition is **seasonal**, and involves **cats with outdoor access**.

Some components appear to involve a **type I hypersensitive response**.

Lesions resolve spontaneously when the cat is moved to a **mosquito-free environment**.

Clinical signs

All ages and breeds of cat are affected.

Pruritus is variable, and is not a constant feature.

Initial **papules and plaques** commonly **ulcerate and crust** over.

Later lesions include **nodules, alopecia, excess scale and depigmentation**.

Sites include the **bridge of the nose, ears and preauricular areas**. Other sites include the chin, lips and feet. The **pads** are swollen with cracking and scale formation.

Pyrexia, peripheral blood eosinophilia and peripheral lymphadenopathy may be seen.

Diagnosis

Diagnosis is based on the response to therapy, or by maintaining the animal indoors. There is no specific laboratory test.

Differential diagnosis

All conditions included in this section can be potentially considered as differential diagnosis.

In mosquito bite hypersensitivity, the **presenting lesions and restriction to the hairless areas of the head and feet** are quite characteristic.

Flea allergic dermatitis is the most common differential for this syndrome. Other differentials, which warrant consideration **include food hypersensitivity, atopic dermatitis and various ectoparasitic and microbial skin infections**.

Treatment and prevention

Maintain the cat indoors during the mosquito season or at times of potential mosquito feeding.

Use suitable mosquito repellents containing **dimethyl metatolilimide (DEET)** or put **butoxypolyporpon** on areas of the cat likely to be bitten.

Glucocorticoids can be used judiciously to ameliorate clinical signs.

DERMATOPHYTES**

Classical signs

- More common in young kittens.
- Erythematous plaques and scale.
- Lesions progress and expand to form larger grayish areas of alopecia and hyperkeratosis.
- Infection may be sub-clinical.

Pathogenesis

Dermatophyte species **parasitize the superficial keratinized layers of the skin**, hair follicles and nails.

Microsporum can is is frequently involved in the cat.

Younger or immunosuppressed cats are at particular risk.

Dermatophytes can induce a localized inflammatory or even a hypersensitive response.

Infection may lead to **hyperkeratosis, epithelial hyperplasia and folliculitis**. This can result in hair shaft breakage and alopecia.

Secondary bacterial infection may occur.

Viable dermatophyte organisms can still be isolated from lesions after clinical resolution. In the case of *M. canis*, viable **fungal elements can survive up to 18 months in the environment**.

A genetic predisposition is possible in certain breeds (e.g. Persians).

M. canis has a **high zoonotic potential**, and it has been reported in 30–70% of cases, that at least one in-contact human becomes infected in households with infected cats.

Transmission is via **direct contact** with infected animals or **indirect contact of contaminated environment or fomites** (bedding, grooming equipment, etc.). Spores have survived in the environment for over a year.

Clinical signs

The **face, head and feet** are common initial sites.

Raised, erythematous plaques and scale may be seen clinically.

Alopecia develops and lesions expand to form larger plaques, which appear grayish and hyperkeratotic.

Initial **hair loss** occurs in the **center of the lesion**. Hairs on the periphery appear discolored and brittle.

Upon regression, initial hair re-growth appears in the center of the alopecic areas.

Secondary bacterial infection is common.

Infection that involves the **whiskers or nail beds** may lead to **deformities** of these structures on resolution of the infection.

Infection of deeper tissues may result in **nodular skin lesions**.

Diagnosis

Fluorescence under ultraviolet light (Wood's lamp), may **detect approximately 30–80%** of cases of *M. canis* infections. The Wood's lamp must be turned on and warmed up for 5–10 minutes prior to use to allow the wavelength of light produced to stabilize. The affected area is exposed to the light in a dark room for 3–5 minutes. A positive result is a bright apple green **fluorescence of individual hair shafts, not the scale and sebum**.

Skin scrapings and hair plucks may allow identification of the **spores and fungal hyphae** on the **outside of the hair shaft**. Rarely, fungal hyphae can be identified on stained acetate preparations of the epidermis overlying lesional skin.

Fungal culture of scrapings, hair plucks and nail samples can identify the species of dermatophyte involved.

Biopsies of affected tissue can be collected to allow visualization of dermatophyte hyphae in the follicles or stratum corneum. This may require special stains to highlight the fungal elements.

Differential diagnosis

Dermatophytosis is a **follicular infection** and as such the major differentials also affect the follicles and include **demodicosis and staphylococcal folliculitis**.

Differentials for circular areas of alopecia with crust and inflammation include **pemphigus, flea bite hypersensitivity, food allergy and atopy**.

Treatment

A variety of agents are available for both **topical and systemic treatment** of dermatophytosis.

Topical agents include **clotrimazole, ketoconazole, enilconazole and miconazole**.

Systemic agents include **griseofulvin** (from 10–50 mg/kg/day for 4–8 weeks). As this is potentially **teratogenic**, it should not be administered to pregnant cats. Anemia, leucopenia, vomiting, diarrhea, depression, pruritus, fever and ataxia have been described. This reaction is thought to be idiosyncratic but may be more common and more severe in Persian, Himalayan, Siamese and Abyssinians and FIV-positive cats. Thus, if it is used, bone marrow monitoring via complete blood tests must be done.

Ketoconazole (10 mg/kg bid PO) for 4 weeks is also effective. Hepatic dysfunction and pregnancy are contraindications. Although more expensive, itraconazole (2.5–5.0 mg/kg bid PO) and fluconazole (10–20 mg/kg bid PO) are highly effective and generally less toxic.

Terbinafine (30–40 mg/kg PO sid) is a newer systemic agent with relatively high efficacy, although treatment may need to be administered for up to 4 months or more.

Although fungal vaccines have not been effective as prophylactic agents in challenge exposure experiments, data are available to indicate they may be beneficial as an adjunct to conventional therapies once clinical disease has occurred.

Anecdotal reports on the efficacy of lufenuron have not been supported by corroborative data.

The **hair coat should be clipped** in affected cats. In short-coated cats, clip a **6 cm margin around all lesions**. In long-haired cats, the **body should be completely clipped** including the whiskers. The rationale is to **remove infective material** that would otherwise be shed into the environment, and **make topical treatment easier** for the owner.

Secondary bacterial infections should be treated with **appropriate antibacterial therapy**.

Prognosis

Prognosis is generally good, but if lesions persist after 8 weeks of treatment, suspect either a **resistant strain**, an **underlying systemic disorder** that is interfering with a normal immune response, or that the **genetic background of the cat** (e.g. Persians) is such that prolonged treatment may be necessary.

Prevention

New animals in catteries should be isolated until confirmed free of infection.

Isolate infected animals. **All in-contacts** should be examined and **treated prophylactically** with a systemic medication **until all cats are culture negative**. This is especially **important in large pure-bred catteries**.

Disinfect premises and potential fomites with undiluted bleach (5.25% sodium hypochlorite) or 1% **formalin**, or dispose of bedding, clothing, grooming combs, etc.

Immunity to dermatophyte infection is not complete at the time of clinical resolution.

DRUG REACTION/HYPERSENSITIVITY

Classical signs

- Variably pruritic affecting skin or mucous membranes.

Classical signs—Cont'd

- A wide range of skin reactions is possible, varying from urticaria, to erythema multiforme to auto-immune skin disease.
- Often mimics many other dermatoses.
- Most common signs are erythema, pruritus and self-induced trauma in areas where topical medications are being applied.

Pathogenesis

Virtually **all drugs are capable of inducing an adverse reaction**. Reactions to drugs are predictable or unpredictable. Unpredictable reactions may have an immunological or genetic basis.

- **Predictable reactions** occur when the adverse effects are **related to the drug's mode of action**, and are normally **dose-dependent**.
- **Unpredictable or idiosyncratic reactions** are normally not dose-dependent, and are related to the cat's **immunological response** to the drug, or are **the result of differences in the individual's susceptibility to the drug**, commonly because of a metabolic variation, for example an enzyme deficiency.

Predictable reactions include signs such as **alopecia due to corticosteroids** or anti-neoplastic drugs.

Immunological reactions can be types **I, II, III or IV hypersensitivity** responses.

Some cases of toxic epidermal necrolysis (TEN), erythema multiforme (EM) and systemic lupus erythematosus (SLE) may have an underlying drug etiology, but these presentations are rare in cats.

Certain drugs are over-represented in many surveys, including **sulfonamides, penicillins and cephalosporins**.

Generally, **drug reactions occur in the first few weeks of therapy**, and while the drug is still in the body. However, exposure and sensitization to the drug could have been in the preceding weeks or months. Re-exposure in these circumstances can lead to the very rapid (within hours) development of new lesions.

Clinical signs

The clinical signs can **mimic** most, if not all, **other types of skin diseases**.

Erythema, papules, plaques, vesicles/bullae and urticaria may be seen initially, and may become annular or ulcerate.

Necrosis and sloughing of affected skin is possible, particularly in more severe cases.

The most common morphologic patterns in cats are **contact dermatitis** to topical agents, and **pruritus with self-induced traumatic lesions**.

Common sites include the **mouth, face, ears, mucocutaneous junctions, groin and feet**.

Pruritus is variable, but can be severe.

The **extremities** may exhibit lesions, including annular areas of necrosis and ulceration, particularly if a vasculitis reaction is involved.

Systemic signs including inappetance and pyrexia may be present.

Diagnosis

A definitive diagnosis is often difficult to make, and may only be confirmed retrospectively. **Suggestive factors include:**

- Prior history of drug administration.
- The reaction pattern resembles one of hypersensitivity.
- The clinical signs resolve following withdrawal of the drug. Provocative exposure is theoretically possible, but not recommended.
- Histopathology is suspicious, but not diagnostic.

Differential diagnosis

All conditions included in this section can be considered as differential diagnoses.

The most common presenting pattern for a drug reaction in cats is contact dermatitis, so the index of suspicion should be increased if an animal suddenly deteriorates, and develops **erythema, pruritus and self-induced trauma in areas where topical medications are being applied**.

Treatment and prevention

Withdraw the suspect medication.

Symptomatic therapy to alleviate signs.

Do not use the offending drug or any cross-reacting drug in the future in that patient.

Prognosis

Generally good, unless lesions affect a significant area of skin, e.g. necrosis.

The prognosis is more guarded for serious systemic involvement.

INTESTINAL PARASITE HYPERSENSITIVITY

Classical signs

- Multifocal or generalized papulocrustous reaction pattern.
- Pruritus.
- Seborrhea and urticaria.
- GI tract signs sometimes exhibited.

Clinical signs

No age, breed or sex predilection is reported.

Pruritus and a papulocrustous reaction pattern, either **multifocal or generalized** is reported.

Seborrheic dermatitis with erythema, grease and scale may be present. Urticarial lesions may be present.

Gastrointestinal tract signs may be present.

Diagnosis

Confirm the presence of intestinal parasites with **fecal tests**. **Ascarids, hookworms, tapeworms and coccidia** have all been reported causing the disease.

A **tentative diagnosis** is possible based on **resolution of skin signs** with appropriate anthelmintic therapy.

FELICOLA SUBROSTRATUS

Classical signs

- Pruritus, alopecia and occasional secondary infection.
- Lice and lice eggs may be evident on visual inspection.
- Cat may be immunosuppressed or have intercurrent disease.

Pathogenesis

Felicola subrostratus is a **biting louse**. The adults feed on epithelial debris and hair.

Pruritus develops as a result of the movement and feeding behavior of the louse.

Infestation is commonly a disease of **poor hygiene, immunosuppression or over-crowding**.

Cats with **matted coats** are more at risk.

Disease is more common in **colder months** of the year.

Transmission is via **direct contact** with an infested animal or with **contaminated bedding or grooming equipment**. They do not survive for more than a few days off the host.

Clinical signs

Infestation may be sub-clinical, but in most cases **pruritus** is reported. **Alopecia, seborrhea and secondary infection** can develop subsequent to the lice infestation.

Common sites include **body apertures** (mouth, anus, vulva) and **under long, matted hair**.

The cat may exhibit signs of intercurrent disease.

Diagnosis

Diagnosis is based on finding lice by **gross visual inspection**. Both the adults and eggs are visible. A hand-held magnifying lens may aid this exercise.

Clear acetate tape can be used to trap and immobilize adults for identification microscopically. The lice are stuck to the acetate tape, which is then adhered to a glass microscope slide for examination.

Differential diagnosis

All conditions included in this section can be considered as differential diagnoses.

Flea allergic dermatitis is the single most common differential for miliary dermatitis and should be ruled out with a strict insect elimination trial.

Other differentials which warrant consideration include **food hypersensitivity, atopic dermatitis and various ectoparasitic and microbial skin infections**.

Treatment and prevention

Pyrethrins are commonly used. **Ivermectin and fipronil** are not licensed for this particular indication, yet appear to have good efficacy. Organophosphates are less popular and have a much lower safety index. **Selemectin** is registered for use on cats and should be effective.

Repeat treatment is indicated to kill newly hatched eggs.

Grooming equipment and in-contact animals should be treated also.

Predisposing factors should be addressed. Grooming of the coat is important.

Prognosis

Excellent, if predisposing factors are addressed.

CHEYLETIELLA SPECIES (CHEYLETIELLOSIS)

Classical signs

- Pruritus.
- Seborrhea and papules. Often referred to as “walking dandruff”.
- Most common in young animals.

Pathogenesis

Cheyletiella mites are **superficial, surface dwellers** that feed on skin debris and are quite mobile.

Cheyletiella blakei is the most common species in cats.

The entire life cycle is completed on the host in as little as 21–35 days.

The feeding behavior leads to **pruritus and self-trauma**.

A hypersensitive response may develop.

Most common in young animals.

Mites are contagious.

These mites are **zoonotic** and may cause a pruritic, papular rash on in-contact people.

Clinical signs

Initially, a **fine dry scale with minimal pruritus** may be seen along the backline, but with time the **pruritus may become extreme** along with an increase in the severity of the scale formation.

Some cats will develop a **widespread papulocrustous reaction**.

The mites are large (~400 µm) and visible to the naked eye. In heavy infection, movement of mites through the coat may resemble the appearance of “**walking dandruff**”.

Diagnosis

Diagnosis is based on **clinical signs** and **finding the mites**. Mites and mite eggs may be visible on the skin or hair coat with a magnifying glass.

If mite numbers are low, the chance of success is increased by **combing the coat with a fine comb**. The collected debris is then examined microscopically for the presence of mites.

Occasionally, mites have been detected via fecal floatation techniques as a result of grooming.

Differential diagnosis

The differential diagnoses for the early lesions of **mild scale** include **ectoparasitism, poor nutrition, diabetes or hepatic disease**.

With more severe pruritus and a papulocrustous eruption, all the differentials for miliary dermatitis need to be considered. Combing with a fine comb and examination of the debris microscopically will facilitate a diagnosis.

Treatment and prevention

Pyrethrins are effective. Other effective agents include **sulfur preparations and ivermectin** (not licensed). **Selamectin** is registered for cats and should be effective. Organophosphates are more toxic and should be used with great care, if at all.

In-contact animals should also be treated.

Prognosis

Prognosis is excellent with appropriate treatment.

Transmission

Transmission is via **direct contact** with an infested animal or with **contaminated bedding or grooming equipment**. The immature stages do not survive for more than a few days off the host, but the **adult female may survive up to 10 days**.

OTODECTES CYNOTIS

Classical signs

- Signs of miliary dermatitis may be accompanied by an exudative otitis externa.
- Pruritus, alopecia and secondary infection.
- Lesions around head and neck.

Pathogenesis

Otodectes mites cause **irritation** because of their **movement** and **feeding habits**. They **feed on the epithelium and tissue fluid** from the superficial epidermis. The resultant inflammation leads to pruritus and self-trauma.

The primary site of infestation is the **external ear canal**, although ectopic infestations may also be found on other areas including the **abdomen, neck, rump and tail**.

Papules and secondary staphylococcal dermatitis develop on the skin.

The life cycle typically takes **3 weeks**. Eggs are laid, and after 4 days hatch to produce a larva which feeds for 3–10 days. The larva then molts to form a protonymph, and after a short resting phase, the protonymph molts to form a deutonymph. Adults are produced once the deutonymph molts and can survive for approximately 2 months.

Sub-clinical infection is common.

Most cats acquire the infestation as kittens from a **carrier queen**. An entire litter may be affected.

Clinical signs

Many cases present with a **waxy otitis externa** and **head-shaking** due to irritation generated by the mites feeding. Classically the debris has a **brown “coffee ground”** appearance. However, the amount of debris can range from minimal to near complete obstruction of the canal.

The **ectopic infestations** can cause **pruritus, alopecia, miliary dermatitis and secondary infection** which resembles other allergic disease, but is less common than otic signs.

Diagnosis

Diagnosis is based on clinical signs and finding the mites. Mites are often visible on otoscopic examination.

- Samples of exudate can be examined using magnifying glasses, or microscopically on slides to identify mites.

Ectopic infestations may not be identified on cytology, rather a presumptive diagnosis is made on **response to systemic miticide therapy**.

Differential diagnosis

The aural manifestation of mites is quite distinct, but **other infectious causes of otitis (including bacteria and *malassezia*)** need to be ruled out.

The ectopic infestation may cause a pruritic dermatitis that can resemble **flea allergic dermatitis, food hypersensitivity, atopic dermatitis and various ectoparasitic and microbial skin infections**.

Treatment

Otitis externa may be treated with **drops containing agents such as milbemycin, pyrethrins/piperonyl butoxide, thiabendazole or lindane. Fipronil and imidacloprid** have also been reported as effective topical therapies. If the discharge is marked, the ears may need to be cleaned with a **ceruminolytic first** to allow adequate penetration and dispersion of the miticide.

Systemic medications that are effective include selamectin and ivermectin (200 µg/kg subcutaneously or orally, repeated 2 weeks later). However, ivermectin is

not licensed for this purpose. The systemic medication is essential in cases (or suspected cases) of ectopic infestation, and because of the highly contagious nature of mites, all in-contact animals should also be treated.

Antibacterial treatment, with or without corticosteroids, may be indicated to allviate severe self-trauma.

Prognosis

Prognosis is excellent with appropriate treatment.

Prevention

Repeat treatment of the affected cat and all in-contact animals is required to prevent reinfection.

Transmission

Transmission occurs via **direct spread** from one cat to another in most cases, but mites may survive off host for a short period.

NEOTROMBICULA AUTUMNALIS (NEOTROMBICULOSIS)

Classical signs

- Pruritus.
- Erythema, papules and alopecia.
- Feet, head and limbs commonly involved.
- Larval stages appear as orange-red dots with the naked eye.

Pathogenesis

There are over 700 species of harvest mites, although only approximately 20 have been identified as causing animal disease.

The adult stages are not parasitic and are free living, feeding on decaying vegetable matter. The six-legged **larval stages** of the mites are **parasitic** of animals and feed on surface debris.

The resultant reaction may give rise to significant **self-trauma** and in some cases a **hypersensitivity** response may develop.

More common in **summer** and **autumn**, particularly in **grassy areas or hedgerows**.

Larval stages are **contracted** from **gardens, hedges**, etc, and are not normally spread from cat to cat.

Clinical signs

Pruritus occurs, and in some cases is extreme, and **self-trauma**.

Papules, crusted papules, alopecia are common and secondary infections of the affected areas may also develop.

The most common areas affected are in contact with the vegetation, so **feet, lower limbs, ventrum and the head are common sites**.

Infestation seems to be more common around the **head and ears** of cats, but this can be differentiated from *Otodectes* by the bright red/orange color of the larvae.

Diagnosis

Diagnosis is based on clinical signs and finding the mite. Larval stages are the **size of a pin-head**, and are a characteristic bright orange-red color, tightly adhered to the skin.

The mites may be collected via mild **superficial scrapes** or adhering the mites to acetate tape and transferring this to a glass microscope slide for examination.

Differential diagnosis

All conditions included in this section can be considered as differential diagnoses.

Allergies (flea, food and atopy) are the most common, and can be differentiated by identification of the characteristic mites on the skin and at the sites of the papulocrustous eruptions.

Treatment

Sulfur-containing products are effective. Non-licensed agents include **fipronil** and **ivermectin**. **Selemectin** is registered for use on cats, has a similar mode of action as ivermectin and should be effective, although no efficacy data have been published for this indication. Organophosphates are less popular because of their toxicity and low safety index, and should be used with care.

Corticosteroids may be indicated to relieve pruritus.

Prognosis

Prognosis is excellent with appropriate treatment. However, **re-infestation is common** if the cat has continued access to the infested vegetation.

Prevention

Repeat courses of treatment are required to combat re-infestation.

Keep cats away from contaminated grass and hedgerows during summer and autumn.

NOTOEDRES CATI (NOTOEDRIC MANGE)

Classical signs

- Severe pruritus, with marked secondary changes.
- Ears, neck, face and occasionally paws.
- Alopecia, hyperkeratosis and gray, crusty exudate.
- Secondary bacterial infection.

Pathogenesis

The **burrowing activity** of *Notoedres cati* produces mechanical irritation, with resultant inflammation.

A hypersensitive response may develop.

The **mites feed on skin debris**.

N. cati has been reported virtually worldwide in the past. However, its occurrence today seems to be very **localized or sporadic**.

Infestation is generally spread via **direct contact**, and is **highly contagious**, so that entire litters may be affected.

Clinical signs

Initial lesions usually appear on the **tips and edge of the ears**, and then spread over the face and neck.

The mites **burrow through the superficial epidermis** and this leads initially to the production of **very small papules**. With time the **skin thickens** and **marked hyperkeratosis** develops, which is seen grossly as **thick scale** and **crust formation**. This may develop a yellow to gray color.

Pruritus is marked which may lead to **self-inflicted trauma** and quite severe excoriation which may then become **secondarily infected**.

Less commonly the **feet** may also be involved.

Diagnosis

Diagnosis is based on clinical signs and finding the mites. The mites are found in burrows in the superficial epidermis. **Superficial skin scrapes** should be collected: use a blunt scapel blade to remove the surface scale and crust. This material is transferred to a microscope slide for examination.

Biopsy of affected skin may reveal mites or eggs along with non-specific superficial perivascular inflammation.

Differential diagnosis

All conditions included in this section can be considered as differential diagnoses.

Flea allergic dermatitis is the single most common differential for miliary dermatitis.

Other differentials which warrant consideration include **food hypersensitivity, atopic dermatitis and various ectoparasitic and microbial skin infections**.

Treatment and prevention

Lime-sulfur dips or shampoos (2.5%) are highly effective. Treatment should be repeated every 10–20 days. **Malathion** dips (0.25–1.25%) and **amitraz** washes (0.025%) are also effective.

Ivermectin (usually at dose levels of 200–300 µg/kg SC although occasionally at dose levels as high as 1000 µg/kg SC for 2–3 treatments) has been successfully used, but is not licensed.

Antibacterial cover and corticosteroids may be indicated.

In-contact animals should be treated if appropriate.

Prognosis

Prognosis is excellent with appropriate treatment. In some cases, an immune response may develop leading to resolution of infection, even without treatment.

CAT FUR MITE (*LYNXACARUS RADOVSKY*)

Classical signs

- Dry, dull coat with hairs easily epilated.
- Excess scale and scurf.
- Tail-head, perineum and thighs affected.
- Variable pruritus.

Pathogenesis

Lynxacarus radovsky is reported in northern Australia, USA and certain other tropical regions.

All stages of the life cycle are found on the cat.

Adult and larval stages **feed on skin debris and secretions**.

The mites generally do not burrow. Hence, **lesions are mainly found on the coat**.

Immunosuppression may be a factor.

Transmission is via **direct contact**, but the contagious nature of the mite is variable.

Clinical signs

Typically there is **scurfiness of the coat**. The **mites appear as white flecks** on the hairs, towards the tips and are best visualized on cats with dark coat colors.

The **coat is dull and dirty**, and the hairs are frail and easily epilated leading to **patchy alopecia**. In more severe cases, a **generalized maculopapular to exfoliative dermatitis** may develop.

Lesions common along the **lower back and perineal/thigh areas**.

Pruritus is mild to absent, unless lesions develop on the skin.

Diagnosis

Diagnosis is based on clinical signs and finding the mites. Examination of affected hairs under the **microscope** reveals **adult mites attached to the hair**.

Differential diagnosis

All conditions included in this section can be considered as differential diagnoses.

Flea allergic dermatitis is the single most common differential for this syndrome.

Other differentials, which warrant consideration, include **food hypersensitivity, atopic dermatitis and various ectoparasitic and microbial skin infections.**

Treatment and prevention

Lime-sulfur dips are effective, although several dips may be required. Other routine agents are also effective.

Selemectin may be effective and **ivermectin**, whilst not registered for this use, has been reported as effective.

In-contact animals may require treatment. Not all in-contact animals will be infested.

Assess for underlying immunosuppressive diseases.

Prognosis

Prognosis is excellent, provided there is no underlying immunosuppressive disorder.

STAPHYLOCOCCAL DERMATITIS

Classical signs

- Erythema and scale/crustiness.
- Hair follicles often involved.
- Lesions may progress to papules, but pus is rare.

Clinical signs

Primary staphylococcal dermatitis is rare in cats. Consequently, there may be signs of an underlying immunosuppressive disease which allows the infection to develop.

There may be erythema and scale/crustiness.

The **hair follicles are usually involved**, which commonly leads to **papule formation centered on the follicle**, so a miliary dermatitis pattern may develop.

Frank purulent material or pustules are rarely present.

Staphylococcal infection may present as **abscesses** or infections of the **ears or conjunctiva**. Generally the **infections are superficial**, involving the epidermis to superficial dermis, and deeper infections are infrequent.

Diagnosis

Cytological examination of either acetate preparations or impression smears of the lesions (papules) may show the presence of activated (multi-nucleated) **neutrophils**, along with **cocci** either extra- or intracellularly. This is the fastest method and may easily be performed in the consultation room.

Culture from infected lesions may be helpful. Care is required, as most normal cats possess coagulase-positive staphylococci on their skin.

Biopsy may show evidence of bacterial folliculitis, pyoderma or deeper infection.

ESSENTIAL FATTY ACID OR BIOTIN DEFICIENCY

Classical signs

- Widespread papulocrustous dermatitis.
- Dry, brittle coat, with excess scale.

Pathogenesis

Deficiencies of essential fatty acids (EFA) are **uncommon**. They are reported in animals fed dry **diets** that are **poorly formulated or inappropriately stored**, home-made recipes, and diets that are poorly preserved. Cats require **arachidonic acid and linoleic acid** in the diet.

Rancidity may lead to a deficiency of essential fatty acids, as can a **deficiency of antioxidants**.

Essential fatty acid deficiency leads to **abnormal keratinization, hyperplasia and hyperkeratosis**. Clinical signs only develop after several months.

Biotin deficiency can arise from **diets rich in uncooked eggs or prolonged antibiotic therapy**.

Clinical signs

Papulocrustous lesions can be seen particularly with **biotin deficiency**.

Excess scaling, alopecia and a poor hair coat occur in cats with essential fatty acid deficiency.

The skin becomes **thick and greasy**. Affected sites include the **ears, feet and various skin folds**.

Pruritus and secondary infection occur.

Diagnosis

Diagnosis is based on **clinical signs** and a **detailed dietary history** or **food analysis** demonstrating deficiency of the appropriate dietary component.

Biopsy is non-specific.

Differential diagnosis

All conditions included in this section can be considered as differential diagnoses.

Flea allergic dermatitis is the single most common differential for this syndrome.

Other differentials which warrant consideration include **food hypersensitivity**, **atopic dermatitis** and **various ectoparasitic and microbial skin infections**.

Treatment

Rectify the dietary imbalances present, using commercial diets where appropriate.

Change any feeding practices which predispose to biotin or essential fatty acid deficiencies.

Prognosis

Prognosis is excellent with correction of the diet.

Prevention

Feed a well-balanced diet that meets current international standards for feline diets. **Store food at appropriate temperatures** and **use before expiry date**.

Anticipate possible biotin deficiency **if the cat requires prolonged antibiotic therapy** and prevent by **supplementing with a B-group multivitamin including biotin**.

AUTOIMMUNE DERMATOSES

Classical signs

- Vesico-bullous, pustular or erosive lesions.
- Erythema, pustules, scale, erosions and alopecia in pemphigus foliaceus.
- Common sites include the face, ears, feet, footpads, groin and nipples.

Classical signs—Cont'd

- In SLE and discoid lupus erythematosus, lesions consist of exfoliative erythroderma, seborrhea, scale, crusts and alopecia. The face and ears are commonly involved.

Pathogenesis

The pathogenesis varies dependent on the form of autoimmune disease present. Many accepted theories may not be relevant to cats.

Pemphigus foliaceus is the **most common clinical form** of autoimmune disease in cats.

- Tissue is damaged from a **type II hypersensitivity reaction** where IgG or IgM antibody binds to cellular antigens, resulting in destruction of the cells. In pemphigus, **antibodies** are directed against **intercellular space substances** and parts of the **epidermal cell wall**. This leads to release of enzymes causing degeneration of intercellular space substances and destruction of the intercellular bridges. The result is loss of intercellular adhesion, and break down of the cohesion between neighboring cells, called acantholysis. Separation of epithelial cells occurs causing bullae, erythema, scaling, crusting, ulceration and tissue proliferation.

In **systemic lupus erythematosus (SLE)**, tissue is damaged by a **type III hypersensitivity reaction**. **Circulating immune complexes** composed of IgG or IgM antibodies bound to antigens diffuse through the vascular endothelium into the tissues and **activate the complement cascade**. This stimulates migration of mononuclear cells and neutrophils into the area, producing vasculitis and tissue destruction.

- In SLE, damage to keratinocytes by **ultraviolet light** is thought to predispose to antibody formation.
- Damaged keratinocytes release various mediators, which potentiate the inflammatory response.

Clinical signs

Pruritus and pain are variable. Many cats with pemphigus or discoid lupus erythematosus (DLE) are otherwise healthy.

Pemphigus foliaceus presents as **erythematous macules or pustules**. The pustules are quite fragile and

may be quite transient and develop to form **scale, crusts, erosions, epidermal collarettes** and later **alopecia**. Occasionally a positive Nikolsky sign may be present. This is considered positive if, when the edge of the lesion is rubbed, the skin is easily peeled/pushed off the underlying dermis.

Lesions are common on the **face, ears, feet, groin and nipples**, but may become generalized. Often the **feet lesions** present as a characteristic, **thick creamy/cheesy exudate around the nail beds**.

Mucocutaneous and oral involvement are rare.

In **SLE**, lesions are extremely variable but may include **exfoliative erythroderma** (generalized **erythematous hue to the skin** along with generalized scale), **crusts and alopecia**. The **face, pinnae and feet** are commonly involved.

Lesions in **discoid lupus erythematosus** are similar to SLE, with the **face and pinnae** most commonly affected. Pedal involvement is uncommon.

Diagnosis

Cytology of pustular lesions of pemphigus may show **non-degenerate neutrophils** along with **rafts of acantholytic keratinocytes** (rounded up with a viable nucleus).

Histopathology is the procedure of choice for the diagnosis of pemphigus, however, it is not always diagnostic. Classically, lesions of **pemphigus foliaceus** will show **subcorneal pustules** with large numbers of **acantholytic keratinocytes**, and may be associated with non-degenerate neutrophils. **Discoid lupus erythematosus** classically shows a **superficial lichenoid inflammatory** infiltrate (lymphocytes, plasma cells), along with hydropic degeneration of the basal epithelial layer. **SLE** has a similar histopathologic picture as discoid lupus, except that the predominate inflammatory cell are **lymphocytes**, there may be **thickening of the basement membrane and vasculitis** may be associated with the inflammation.

Tests for **antinuclear antibody titers** in serum are recommended for diagnosing SLE. However, most published data relates to the dog and man.

Differential diagnosis

Differentials for **pemphigus** include **bacterial folliculitis, dermatophytosis, demodicosis** which are common, and discoid lupus and SLE which are much rarer.

Treatment and management

Immunosuppressive doses of prednisolone (2.2–4.4 mg/kg orally per day) until complete resolution is achieved. The dose may then be **gradually tapered**, reducing the dose by 25% per fortnight in a step-wise process. Cats that fail to respond to prednisolone may respond to **dexamethasone** (0.2–0.4 mg/kg q 24 h).

Chlorambucil (0.1–0.2 mg/kg q 24–48 h) has been additionally employed in difficult cases.

Gold therapy may be useful for refractory cases of pemphigus (aurothioglucose 1 mg/kg IM weekly until remission). After remission, the dose is reduced to q 14 days for 28 days and then to q 28 days for 3 months. Both chlorambucil and aurothioglucose may cause **bone marrow suppression**, and so **complete blood counts** should be **performed weekly** during the induction, then monthly whilst on therapy.

Insufficient data are currently available to make any recommendation on the use of cyclosporin in the management of feline pemphigus complex.

Cats with **discoid lupus erythematosus** may respond to **avoiding sunlight**, and application of **sun-screens or topical glucocorticoids**. If this is unsuccessful, **systemic medication** may be required. **Niacinamide** (nicotinamide or vitamin B3) in combination with **doxycycline** has been used in dogs (but not cats) with variable efficacy. Other alternatives are prednisolone, chlorambucil or aurothioglucose.

Cats with **SLE** require **systemic immunosuppressive therapy** (prednisolone, chlorambucil).

Prognosis

The long-term **prognosis for pemphigus complex and discoid lupus is generally good**.

The prognosis for **SLE** depends on the extent of other organ system involvement.

IDIOPATHIC MILIARY DERMATITIS

Classical signs

- Papulocrustous dermatitis.
- Pruritus.

Clinical signs

Pruritus and self-trauma occur, and are expressed as **licking or over-grooming rather than scratching**. This

results in alopecia, crust formation, miliary dermatitis and secondary infection.

Lesions occur mainly along the **dorsal, inguinal and ventral abdominal areas**.

Diagnosis

Diagnosis is based on clinical signs and exclusion of all other etiologies after extensive diagnostic work-up.

49. The cat with pruritus without miliary dermatitis

*Ruadhri Michael Seosaimh Breathnach
and Mike Shipstone*

KEY SIGNS

- Licking or over-grooming.
- Alopecia, erythema.
- + Papules, plaques.

MECHANISM?

- Pruritus in cats usually manifests as licking or over-grooming, rather than scratching or self-trauma obvious to the owner. In many instances, owners are not aware that the cat is pruritic.

WHERE?

- Skin.

WHAT?

- Diseases presenting with pruritus without miliary dermatitis are most commonly eosinophilic plaques, poxvirus and neoplasia. However, all the differentials covered in Chapter 48 (The Cat With Miliary Dermatitis) should be considered for a cat that presents with pruritus, even if no miliary dermatitis pattern is evident.

QUICK REFERENCE SUMMARY

Diseases causing pruritus without miliary dermatitis

INFECTIOUS

Viral:

- **Feline orthopoxvirus infection** (p 1047)**

Initial solitary lesion is commonly present on the head or neck. Numerous papules develop later. Ulceration and scab formation occurs. Alopecia and scarring are evident when the scabs fall off. Pruritic.

Parasitic:

- **Demodicosis (p 1047)**

Localized or generalized alopecia of the face and trunk. Erythema and scale. Periocular and nasal involvement is common. Most cases are non-pruritic.

continued

*continued***Neoplastic:**

● Cutaneous lymphoma (p 1049)

Presentation varies. Multiple erythematous nodules, ulcers or proliferative lesions. Exfoliative erythroderma with general flushing and scaling of skin. Lymphadenopathy and systemic illness may be present. Uncommon.

● Mast cell tumor (p 1050)

Single or multiple lesions which are usually benign. Papules and plaques are common. Poorly circumscribed dermal masses are possible. Head and neck are common sites. A papular form occurs in young Siamese on the head and ears and may spontaneously regress.

Miscellaneous:

● Contact dermatitis (p 1048)

Erythema and papules on affected surfaces. Pruritus leads to skin thickening and hyperpigmentation.

● Eosinophilic plaques** (p 1046)

Well-circumscribed plaques, which often ulcerate. Common on the abdomen and medial thighs. Very pruritic.

INTRODUCTION**MECHANISM?**

Pruritus is not as common a presentation in feline practice as compared to the situation in the dog. That is not to say that the problem is unusual, rather it points to the fact that feline pruritus may manifest in ways other than scratching, or self-trauma, which is immediately obvious to the owner. In many instances, owners are not aware that the cat is pruritic. The cat may be presented with a complaint of excessive licking, alopecia or miliary dermatitis.

WHERE?

Skin.

WHAT?

The list of differential diagnoses for pruritus in cats is long. Most cases are due to **infectious agents** such as microbes and ectoparasites, or **hypersensitivities**. As miliary dermatitis is frequently associated with pruritus, all of the differentials covered in Chapter 48 (The Cat With Miliary Dermatitis) should be considered for the

animal that presents with pruritus, even if no miliary dermatitis pattern is clinically evident. This chapter lists some additional conditions, which may also present with pruritus and are less likely to have miliary dermatitis.

DISEASES CAUSING PRURITUS WITHOUT MILIARY DERMATITIS**EOSINOPHILIC PLAQUES******Classical signs**

- Raised “glistening” plaques, well circumscribed and often ulcerative.
- Pruritus.
- Regional lymphadenopathy possible.

Clinical signs

Eosinophilic plaques are usually multiple, raised, round to oval lesions, often several centimeters in diameter. Common sites include the **abdomen, medial thighs and mucocutaneous junctions**.

Frequently there is ulceration and serum oozing from the lesion, which may give the classic “**glistening**” appearance to the lesion.

The lesions are generally **markedly pruritic**, evidenced by **licking and trauma** to the area.

Regional lymphadenopathy and **secondary infection** are sometimes present.

Affected cats may also exhibit **indolent ulcers**, **eosinophilic granulomas** or **ocular lesions**.

Diagnosis

Diagnosis is via biopsy and demonstration of the **characteristic histopathology** consisting of markedly **thickened epidermis with spongiosis and eosinophil infiltration**, which may also extend to affect the follicular epithelium. Erosions may be present.

Peripheral blood eosinophilia may be present.

Intercellular immunoglobulin is frequently found within the epidermis; however, this should not be mistaken for an autoimmune skin disease.

FELINE ORTHOPOXVIRUS INFECTION**

Classical signs

- Initial single lesion around head or neck.
- Numerous papules develop later, and frequently erode or ulcerate.
- Scab formation. When scabs fall off, alopecia and scarring evident.
- Pruritus and secondary infection.

Clinical signs

Orthopox virus is more common in **young to middle-aged cats**.

The **initial lesion** is a **macular eruption** (5 mm diameter), which rapidly progresses to a **non-healing ulcer** with a raised indurated border on the head, neck or forelimbs.

Eroded or ulcerated papules, which **scab over**, **appear in several sites**.

When the scabs fall off, areas of **alopecia and scarring** are evident. These lesions gradually heal. As some lesions heal, new lesions may also develop.

Pruritus is variable, but may be present at all stages.

New hair growth takes 6–8 weeks.

Secondary infection, abscesses or cellulitis are possible.

Vesicular to ulceroproliferative **lesions may develop in the mouth, pharynx, conjunctiva and on the muzzle**.

Many cats are **systemically ill** with mild pyrexia, inappetence and depression, particularly during the viremic stage.

Diagnosis

Diagnosis is based on biopsy demonstrating **intracytoplasmic inclusion bodies** (types A or B). Healing lesions may be negative for inclusion bodies.

Electron microscopic examination of an unfixed scab or biopsy material can identify orthopoxvirus particles. Immunohistochemical techniques can also be performed on skin biopsies.

Viral isolation techniques are available in specialist laboratories.

Serological tests are available at certain laboratories.

DEMODICOSIS

Classical signs

- Localized/generalized alopecia of face and body trunk.
- Erythema and scaliness. Secondary infection.
- Periocular and nasal involvement is particularly common.

Pathogenesis

Whilst **most normal animals** have a **low mite burden** probably derived from maternal transmission, cats with clinical demodicosis have a **proliferation in mite numbers**.

Immunosuppression appears to be an **important factor**, and has been associated with diabetes mellitus, FeLV and FIV infections, hyperadrenocorticism and systemic lupus erythematosus.

A genetic predisposition has not been reported in cats.

In cats, there are two species of democid mites that are recognized to cause disease.

Demodex cati inhabits **hair follicles and sebaceous glands**. *Demodex gatoi* appears to replicate within pits of the **stratum corneum**. The clinical significance of a third, as yet unnamed species, is currently unknown.

The **proliferation of mites** leads to damage to hair shafts, folliculitis and **follicular disruption**.

Clinical signs

D. cati causes disease which is **variably pruritic**, consisting of **patchy erythema, scale, crust and alopecia**, more commonly seen affecting the **eyelids, periocular area, head and neck** although generalized disease may also develop.

Pruritus is not a dominant feature in most cases.

Secondary infection is possible, particularly if there is significant self-trauma.

D. gatoi causes signs that are more consistent with **allergic skin disease**, including **severe pruritus, alopecia, scale, crust and excoriation**, particularly on the **head, neck and elbows**. Some cats may develop more generalized disease.

Diagnosis

Diagnosis is based on clinical signs and demonstration of the mites via skin scrapes. Superficial scrapes are sufficient for *D. gatoi*; however *D. cati* requires deeper scrapings. Squeeze the affected area, apply a small amount of mineral oil to the skin and scrape using a blunt scalpel blade until capillary oozing is present.

Biopsy may also be used to demonstrate mites.

Differential diagnosis

Differential diagnoses which should be considered for *D. gatoi* include **hypersensitivities (atopy, food, flea), contact dermatitis and psychogenic causes**. Careful skin scrapings should be performed, followed by therapeutic trial (e.g. lime-sulfur weekly for 4–8 weeks). If there is no response to a treatment trial, then a food elimination trial and other diagnostic tests should be performed.

Treatment

Lime-sulfur baths (once/week for 4–8 weeks) are safe and effective. This agent has sometimes been combined with **phosmet**.

Amitraz (0.0125–0.0250%) applied topically once a week for 6–8 weeks is effective, although clinicians should beware of toxicity.

Efficacy of ivermectin in feline demodicosis is unclear.

D. gatoi is contagious, so **all in-contact cats should be treated simultaneously**.

Address any underlying immunosuppressive disease.

Prognosis

Spontaneous remission is possible in **some younger animals** after weeks to months.

However, in many cats signs persist and may worsen over time. The prognosis is affected by underlying disease conditions that cannot be rectified, e.g. FIV or FeLV infection.

Prevention

Avoid stress and treat potentially immunosuppressive diseases (diabetes mellitus, hyperadrenocorticism).

There is no evidence to currently support the exclusion of clinically affected animals from a breeding program, although such an approach may be judicious.

CONTACT DERMATITIS

Classical signs

- Erythema and papules on contact surfaces.
- Pruritus and secondary infection.
- Skin thickening and hyperpigmentation.
- Severe cases may develop ulceration.

Pathogenesis

Irritant contact dermatitis is more common than contact allergic dermatitis.

Primary irritant contact dermatitis causes an inflammatory response in the majority of exposed cats. No prior sensitization is required.

Allergic contact dermatitis is an **immunologic response** to a hapten. Haptens are small chemically reactive compounds that must bind to a protein before becoming a complete antigen. The initial phase of the hypersensitivity is the afferent phase during which time the immune system is sensitized. Experimentally this may be as little as 3–5 weeks, although it is much longer in naturally occurring cases (> 2 years in > 70% of cases). Subsequent exposure in a sensitized animal leads to the development of the efferent (or elicitation) phase, during which time a gross clinical lesion develops.

Whilst a delayed-type hypersensitive reaction has traditionally been suspected, recent studies have shown this may not be the case.

Clinical signs

Initial lesions may present as **erythema, macules and papules**. Chronically, alopecia, hyperpigmentation, lichenification, excoriation may develop.

Lesions are initially confined to the **hairless (or sparsely haired) contact areas** including **ventral abdomen, thorax, scrotum, lips, point of chin, concave aspect of pinnae**. However, the lesions may be widespread for an agent applied over most of the body, e.g. shampoo.

Irritant contact dermatitis may occur as a **single episode**, whereas **contact allergic dermatitis** often has repeat episodes.

Diagnosis

Irritant contact dermatitis is often initially suspected on the basis of **clinical signs and history** of acute exposure to an irritant compound.

Response to symptomatic therapy and avoidance is helpful in supporting the diagnosis.

Provocative exposure is possible, but often unnecessary.

In the case of contact allergic dermatitis, the diagnosis may be confirmed by **provocative exposure or patch testing**.

Close patch testing may be performed by applying the suspected allergen(s) to the skin, and then applying a body bandage to secure the site. This is removed after 48 hours and the site examined for the presence of erythema and edema at 72 and 96 hours.

Biopsy is non-specific.

Differential diagnosis

Other hypersensitive, ectoparasitic and psychogenic skin conditions should be considered.

Whilst the lesions and clinical signs may be similar, generally it is possible to differentiate on the basis of the **lesion distribution** limited to hairless areas, **history of exposure** and **response to provocative exposure and patch testing**.

Treatment

Treatment involves **avoiding the suspect irritant or allergen**. If this is not possible, some form of symptomatic therapy will be required as long as exposure to the irritant/ allergen continues.

Glucocorticoids (topical or systemic). In some instances **topical cortisone** creams may be sufficient. If not, then **oral prednisolone** may be used (2 mg/kg q 24 h for 5 days, then 1 mg/kg q 48 h as required).

Symptomatic therapy, if appropriate.

Mild, non-medicated cleansing shampoos may be used to remove irritant chemicals.

Prognosis

Prognosis is excellent, if avoidance possible.

If not, then judicious glucocorticoid medication is indicated.

Prevention

Try to avoid any offending irritants or allergens.

CUTANEOUS LYMPHOMA

Classical signs

- Presentation varies with tumor type.
- Non-epitheliotropic forms exhibit multiple erythematous nodules, with occasional exfoliative erythroderma.
- Epitheliotropic forms exhibit exfoliative erythroderma, plaques/nodules, ulcers or proliferative lesions.
- Lymphadenopathy occurs in epitheliotropic cases.

Clinical signs

Clinical signs vary markedly.

Non-epitheliotropic forms commonly present as **multiple, solid erythematous nodules**, dermal or subcutaneous in position.

Exfoliative erythroderma seen as **generalized flushing** of the skin with excess scale formation. **Arciform (semicircular) or solitary lesions** are less common.

Epitheliotropic forms commonly present in the later stages as one or a combination of the following: exfoliative erythroderma, ulcers and depigmentation at mucocutaneous sites, multiple plaques or nodules.

Ulcerative or proliferative **oral lesions** are possible.

Generalized lymphadenopathy may be present in many epitheliotropic cases.

Earlier lesions include focal alopecia, erythroderma and scale.

Signs of systemic illness may be present, and include **inappetence, lethargy and depression**.

Diagnosis

Diagnosis is based on **characteristic histopathology**.

Direct immunofluorescence testing may reveal deposition of immunoglobulin in the affected cells. This should not be mistaken for a diagnosis of pemphigus complex.

MAST CELL TUMOR

Classical signs

- Lesions are very variable from single or multiple lesions, well-circumscribed papules and plaques to poorly circumscribed multiple dermal masses.
- Head and neck common sites.

Clinical signs

Lesions are most commonly reported around the **head and neck**.

Four different presentations are recognized:

- **Multiple poorly demarcated masses** (up to 5 cm in diameter), which are often edematous and fixed to the skin.
- **Smaller (2–10 mm) multiple, well-circumscribed papules** which are solid and light in color.
- A **plaque-type form** (1–7 cm), which is erythematous, firm, raised and well circumscribed. These plaques are **generally pruritic** and may **ulcerate**.
- Solitary, often alopecic, well-circumscribed, variably sized (3–30 mm), **dermal nodules** are occasionally seen.
 - A **papular form** on the **head and ears of young Siamese cats** (6 weeks to 4 years) which may spontaneously regress.

Diagnosis

Diagnosis is based on **characteristic histopathology**.

Stained impression smears and tissue aspirates are often diagnostic.

Electron microscopy is often required for rarer forms.

Treatment

Surgical excision is the treatment of choice for **solitary lesions** that cause difficulties.

In **disseminated forms**, **prednisolone** (0.5 mg/kg sid) may be used.

The majority of these tumors in the cat are **not malignant**, and so chemotherapeutic and radiotherapeutic measures are often unnecessary. However, a metastatic rate of up to 22% has been reported in one study.

The rare papular form in Siamese cats often spontaneously regresses.

50. The cat with alopecia

Ruadhri Michael Seosaimh Breathnach and Mike Shipstone

KEY SIGNS

- Partial or complete loss of hair.

MECHANISM?

- Alopecia is the loss or absence of hairs from areas of the body that would normally possess hairs.
- The most common mechanism is the excessive loss from over-grooming because of pruritus. The characteristic feature of this mechanism is the presence of damaged/fractured ends to the remaining hair shafts in the area of alopecia.

WHERE?

- Skin.

WHAT?

- Numerous pruritic conditions, most commonly allergic in origin, lead to alopecia from self-trauma. Occasionally self-trauma can also arise for psychogenic reasons. Non-pruritic causes may be congenital or hormonal in etiology, with hyperthyroidism and diabetes mellitus most common. Folliculitis is seen with microbial or ectoparasitic infections, leading to non-pruritic loss of hair.

QUICK REFERENCE SUMMARY

Diseases causing alopecia

PRURITIC CAUSES OF ALOPECIA

INFLAMMATORY

- Allergic (p 1030)

If fractured or cropped hairs are present in the affected areas, pruritus is the most likely cause. See Chapter 48 (The Cat With Miliary Dermatitis or Pruritus).

NON-PRURITIC CAUSES OF ALOPECIA

FAILURE OF NORMAL HAIR PRODUCTION

ANOMALY

- **Congenital/genetic alopecia** (p 1055)**

Focal or generalized alopecia seen at birth or in first months of life. Alopecia may be pathologic, or result from an intentional breeding program where it is not viewed as abnormal, for example perauricular alopecia in some Siamese cats and generalized alopecia of Sphinx cats.

- **Pili torti (p 1062)**

Generalized alopecia which can also involve the feet and eye regions resulting in pedal dermatitis and paronychia. Many affected kittens die.

LOSS OF EXISTING HAIRS

METABOLIC

- **Hyperadrenocorticism (p 1063)**

Alopecia and an unkempt coat. Thin and fragile skin. Secondary infection and comedones possible. Systemic signs often present.

- **Hyperthyroidism** (p 1058)**

Systemic signs are present in most cats and include polyphagia, weight loss, restlessness, tachycardia and/or intermittent vomiting or diarrhea. Cutaneous signs occur in 30% of cats and include dry or greasy seborrhea, matting of the coat, focal or regional alopecia and thinning of the skin.

Symmetrical alopecia is occasionally seen.

- **Diabetes mellitus** (p 1059)**

Polydipsia, polyuria, weight loss and polyphagia or inappetence are typically present. A poorly groomed seborrheic coat is common with generalized fine dry scale, and thinning of the skin. Symmetrical alopecia on abdomen, perineum or groin regions may be present. Secondary bacterial or fungal infections are sometimes present.

- **Telogen defluxion (p 1062)**

Gradual alopecia affecting part or all of the body several months after a stressful event. Rest of skin appears normal.

NUTRITION

- **Dietary alopecia (p 1065)**

Patchy or generalized alopecia. Seborrhea and poor coat quality. Secondary infections are possible.

NEOPLASTIC

- **Alopecia mucinosa (p 1065)**

Alopecia and excess scale of the head, neck and ears. Plaque-type lesions may develop later and have histological findings consistent with lymphoma or mycosis fungoides. Very rare disease.

PSYCHOLOGIC

- **Psychogenic** (p 1056)**

Loss of hair from excessive grooming commonly affects the abdomen, thighs, inguinal region, forelegs or dorsal spinal region. Hairs appear broken and uneven, and the coat can feel rough.

continued

continued

Affected skin may become thickened and hyperpigmented. An environmental stressor may be identified in the history.

INFLAMMATION/INFECTION:

Bacterial:

- **Staphylococcal dermatitis* (p 1064)**

Primary staphylococcal dermatitis is uncommon in cats, and an underlying disease process should be suspected. Typically there is erythema, scale and crustiness. Hair follicles are commonly involved. Papules are common, but rarely is pus present.

Fungal:

- **Dermatophytosis** (p 1060)**

More common in young kittens. Erythematous plaques, alopecia and scale. Lesions may progress to larger gray areas of alopecia and hyperkeratosis.

Parasitic:

- **Demodicosis* (p 1061)**

Localized or generalized alopecia of face and trunk. Periocular and nasal involvement are most common. Lesions have erythema and scale. Most cases are non-pruritic.

Immune:

- **Alopecia areata (p 1066)**

Focal or multi-focal alopecia which is gradual in onset, and not symmetrical. The skin is not inflamed and there is no pruritus. Hyperpigmentation may occur chronically. Rare.

Toxic/drug

- **Drug reaction* (p 1061)**

Usually associated with immunosuppressive or anti-neoplastic agents. Alopecia is most common on the body trunk, but can affect other sites. Secondary infection is often present. Glucocorticoids may produce cutaneous signs of hyperadrenocorticism.

INTRODUCTION

MECHANISM?

Alopecia is the loss or absence of hairs from areas of the cat's body that would normally possess hairs.

- This phenomenon can result either from a **failure to grow hair** or as a consequence of the **abnormal loss** of hairs.

Some causes of alopecia are **genetically programmed**. **Acquired cases** may arise because of **hormonal** influences that interfere with hair growth, or as a result of **folliculitis**. Hairs may also be lost as a direct result of **self-trauma** for a variety of reasons.

- Failure to grow hair **may be a life-long problem**, as occurs in congenital or genetically programmed alopecias.

Abnormal hair loss has a wide variety of causes, and is **normally divided** clinically into those cases which are

accompanied by pruritus and those which are not. The majority of cases seen in feline practice are due to self-trauma as a consequence of pruritus.

The **breakage of hair shafts** may occur in dermatophytosis and psychogenic dermatoses.

Cessation of hair growth may arise due to endocrinopathies, telogen defluxion and drug reactions.

Hairs may also be shed following an episode of folliculitis.

Rare causes of feline alopecia include pancreatic neoplasia.

Some conditions give rise to specific **focal alopecia**, often in association with underlying skin pathology, such as injection reactions, solar dermatitis or squamous cell carcinoma.

The term **feline symmetrical alopecia** (FSA) represents a cutaneous reaction pattern, rather than a distinct syndrome.

- It is characterized by a seemingly **non-pruritic, symmetrical alopecia affecting the abdomen, caudo-medial thighs, proximal tail and perineum**. Affected hairs are easily epilated and no inflammatory changes are usually present in the skin.
- Most, if not all, such cases are the result of **pruritus or self-trauma due to an underlying problem**, and are not related to sex steroids or other hormones.
- Feline symmetrical alopecia is not included as a distinct condition in this chapter. Rather the clinician is encouraged to investigate such cases to see if an underlying etiology such as **flea allergic dermatitis or psychogenic factors** can be identified.
- If no such cause can be found, then the term idiopathic feline symmetrical alopecia may be used.

The histologic appearance of the hair follicle varies with the stage of the follicle's growth cycle. **Anagen** is the active growth phase and is characterized by a well-developed hair follicle bulb. **Catagen** is a transition period between the active growth and resting stage. **Telogen** is the resting stage, characterized by a small dermal papilla, separate from the bulb, absence of an inner root sheath and a club or brush-like hair.

WHERE?

The abnormal organ is **skin**, but it may be affected secondarily by disease of other body systems.

Alopecia can affect any part of the body, although certain conditions tend to cause hair loss in characteristic areas.

The hair loss may be **partial or complete, focal or generalized**.

WHAT?

Numerous pruritic conditions lead to **alopecia from self-trauma**. **Allergic diseases** are the most common and are covered in the chapters on Miliary dermatitis and Pruritus.

- Self-trauma can also arise for **psychogenic reasons**.
- Folliculitis is seen with **microbial or ectoparasitic infections**.

Non-pruritic alopecia can be **congenital or acquired**.

- Congenital alopecia often arises because of intentional breeding programs and is considered normal for the breed.
- **Hormonal causes** of acquired alopecia include **diabetes mellitus, hyperthyroidism and hyperadrenocorticism**.

DISEASES CAUSING NON-PRURITIC ALOPECIA

CONGENITAL/GENETIC ALOPECIA**

Classical signs

- Focal or generalized alopecia or thin hair coat present at birth.
- Further hair loss may occur in the first few months of life.
- Excessive sebum or wrinkling of the skin.
- Often breed specific and considered normal.

Pathogenesis

Congenital alopecia has been reported in Sphinx cats with affected individuals being the result of an intentional breeding program involving cats with a spontaneous mutation.

Animals born with congenital alopecias may possess additional ectodermal defects.

The mode of inheritance involves a monogenic recessive trait. However, in Russian hairless cats, the alopecia is determined by a semi-dominant gene with the participation of other genes.

Congenital hypotrichosis has been reported in several breeds including Burmese, Devon Rex, Cornish Rex, Siamese and Birman cats. The condition is inherited as an autosomal recessive trait in Birman and Siamese cats.

Although several kittens in the one litter may be affected, no sex predisposition has been reported.

Skin pathology can vary from hypoplasia to complete absence of hair follicles and related adnexal structures.

Clinical signs

Clinical signs vary with the specific condition and the breed involved. Alopecia or thin hair coat is **present at birth**. **Further hair loss** may occur in the **first few months of life**.

Depending on the syndrome, there may be an absence of primary hairs.

Congenital alopecia may be **pathologic**, but is more often the **result of an intentional breeding program**, and is not viewed as abnormal by the owner.

Alopecia may be regional or focal, for example preauricular alopecia seen in some Siamese cats.

A more **generalized alopecia** known as feline alopecia universalis is seen in Sphinx cats. These cats have no primary hairs and no whiskers.

- **Excess sebum** is commonly present on the skin due to an abnormal opening of the sebaceous glands onto the skin surface.
- Poor grooming habits frequently lead to poor skin hygiene.

Devon and Cornish Rex cats, Siamese, Burmese and Birmans can exhibit **hypotrichosis**. The hair coat

appears to be quite sparse so that the underlying skin is more visible. This is the result of selective breeding. Many kittens in a litter can be involved.

- The hair coat can be deficient or totally absent at birth. Any hair initially present can be lost in the first months of life.
- Excessive wrinkling of the skin occurs in these kittens.
- Affected Burmese kittens also lack whiskers and claws.

Diagnosis

Diagnosis is often possible on the basis of the breeding history and clinical signs.

Histopathology of affected skin can provide additional diagnostic information.

Treatment

Mild anti-seborrheic shampoos (containing sulfur, salicylic acid) may be required intermittently in Sphinx cats to remove the excess sebum accumulation.

Owners should also be warned to minimize UV exposure in cats with non-pigmented skin, so that cumulative actinic damage is avoided later in life.

PSYCHOGENIC**

Classical signs

- Loss of hair commonly affecting the abdomen, thighs, inguinal region, forelegs or dorsal spinal region.
- Hairs appear broken and uneven and the coat can feel rough.
- Affected skin may become thickened and hyperpigmented.

Pathogenesis

The main reason for the alopecia is **excessive or inappropriate grooming behavior**.

Most cases are presumed to have an **underlying psychological component**.

Various stressful factors can be involved including a new pet, change of home or routine, or competition from a dominant animal.

The action of **licking/chewing** is postulated to **stimulate release of ACTH and MSH**. This in turn can lead to an increase in endorphin production.

- **Endorphins help to reduce stress**, but may reinforce the behavior pattern.

Some cats concentrate on a particular area, and lick or chew incessantly at that site. This can lead to significant lesion development.

Other cats may have milder signs or the excessive licking/chewing may be concentrated over a much wider area.

Excessive grooming, etc. may not actually be noticed by the owner, as many cats are secret groomers.

Clinical signs

Hair loss is typically concentrated on the **areas of the body where the cat can access** to lick or chew.

The **ventral abdomen, inguinal region, inner thighs and inner aspects of the forelegs** are common sites.

Some cats concentrate on the **dorsal spinal region, particularly in the lumbar and sacral/tail areas**.

The licking/chewing behavior leads to fracture of the hair shafts, roughening of the coat and alopecia.

Some cats develop an inflammatory pattern, characterized by red plaques.

The alopecia may be symmetrical in some cases.

Long-standing cases develop thickening and hyperpigmentation of the affected sites.

Diagnosis

A **tentative diagnosis is based on clinical signs** and excluding other causes of alopecia. A definitive diagnosis is rarely possible.

A detailed history should be taken to try and elucidate any cause of stress or anxiety. If one cannot be identified, it does not rule out a diagnosis of psychogenic alopecia.

Even if the owner has not noticed excessive grooming behaviour, facts such as tufts of hair in the animal's bed or the vomiting up of hairballs are suspicious. Videotaping of cats in the cattery may reveal evidence of self-grooming.

Clinical examination reveals short, broken hairs, often with roughened ends. The hairs are not easily epilated.

- A trichogram reveals broken tips to the hairs and may also demonstrate that some of the hairs were in anagen.

All the other differentials for alopecia need to be ruled out. Thus a basic work-up consisting of skin scrapings, fungal culture etc. is normally warranted. Flea dermatitis and flea allergic dermatitis are particularly important differentials.

Biopsy is non-diagnostic, but may help to rule-out many other differentials.

Placing an Elizabethan collar on the cat for a period of weeks will often lead to a significant re-growth of hair in affected areas.

Differential diagnosis

Alopecia can be caused by all the conditions listed in this chapter. Exogenous administration of **progestogens or glucocorticoids** should also be excluded, as should dietary causes. Ectoparasites also need to be excluded, particularly **fleas**. Diabetes mellitus, hyperadrenocorticism and hyperthyroidism can produce similar alopecia but systemic signs are present.

Treatment

Try to remove or ameliorate any stressful factors that may be acting as the underlying cause.

An **Elizabethan collar** will often give a clinical improvement. However, it does not properly address the issue and is resented by many cats.

In cases that warrant such an approach, medical therapy may be attempted. **Phenobarbitone** (2–6 mg/kg orally bid) and **diazepam** (1–2 mg/cat orally sid or bid) have both been employed.

Naloxone, an endorphin blocker, has been used successfully at a dosage rate of 1 mg/kg subcutaneously every few weeks.

Clomipramine and various progestogens have also been reported to be somewhat effective.

Some of the above medications are not licensed for use in cats in many countries.

Prognosis

The prognosis depends totally on **whether the inciting cause can be identified and resolved**.

If not, then long-term management, sometimes involving drug therapy is generally required.

HYPERTHYROIDISM**

Classical signs

- Systemic signs including polyphagia, weight loss, restlessness, tachycardia.
- Dry, greasy, seborrheic or matted coat.
- Focal or regional alopecia or shedding of the coat.
- Overgrown nails.

See main reference on page 304 (The Cat With Weight Loss and a Good Appetite).

Clinical signs

Hyperthyroidism occurs mainly in **older cats** (> 8 years of age).

The majority of cats have **systemic signs including polyphagia, weight loss, restlessness, tachycardia and/or intermittent vomiting or diarrhea**.

Approximately **30%** of cats with hyperthyroidism **exhibit cutaneous manifestations**.

Often there is excessive matting of the hair coat, and the cat may groom excessively.

A dry coat, or dry or greasy seborrhea may be present.

Alopecia, when present, may be patchy, regional or generalized, and in some cases may appear symmetrical.

- The major site affected by alopecia is the **body trunk**.

Thinning of the skin (or loss of skin elasticity) is a common finding.

Excessive rates of nail growth may give rise to **overgrown claws**.

Diagnosis

A tentative diagnosis is based on **age, history and clinical signs**.

An **enlarged gland or thyroid nodule** may be palpable.

Various abnormalities may be encountered on routine hematological and biochemical analysis.

- These commonly include increases in serum ALP, AST, LDH and blood urea concentrations.
- Changes on hematology are variable and unreliable.
- A mature neutrophilia, or an eosinophilia, are sometimes present.

Cardiac abnormalities may be detected on ECG and echocardiography.

A definitive diagnosis is based on finding an increased basal thyroxine (**TT4**) concentration in blood.

As not all hyperthyroid cats will exhibit elevated values for basal thyroxine, measurement of free thyroxine, a triiodothyronine (T3) suppression test or TRH stimulation test may be necessary. Further testing should only be performed if signs are consistent with hyperthyroidism, and thyroxine concentration is in the top half of the reference range.

- **Free thyroxine** must be measured with a validated feline assay using equilibrium dialysis, and if available, is the easiest test to use in cats with clinical signs consistent with hyperthyroidism but thyroxine concentration does not exceed the upper limit of the reference range.
- In the **T3 suppression test**, thyroxine and T3 concentration are measured before and 3 hours after the administration of seven doses of 20 µg of liothyronine sodium (T3) at intervals of 8 hours. Euthyroid cats will exhibit a significant drop in thyroxine concentration (approximately 50%) after T3 administration, and a significant rise in total T3 concentration. Hyperthyroid cats will have no significant inhibition.
- In the **TRH stimulation test**, thyroxine concentration is measured before and approximately 4 hours after the intravenous administration of 0.1 mg/kg of TRH. Hyperthyroid cats exhibit no significant stimulation of thyroxine concentration

(< 50% increase in concentration) following TRH administration, whereas euthyroid cats or cats with non-thyroidal illness show a more significant increase (>60%).

Radionuclide thyroid scanning is available in certain specialist referral centers.

Differential diagnosis

Alopecia can be caused by all the conditions listed in this chapter. However, as most cats presenting with this complaint will have a combination of systemic and cutaneous signs, the major differentials would be **hyperadrenocorticism and diabetes mellitus**. Exogenous administration of progestogens or glucocorticoids should also be excluded.

Treatment

Medical treatment may be attempted using either carbimazole or its metabolite, methimazole. Carbimazole is generally given at a dosage rate of 5 mg/cat q 8 h until the cat is euthyroid. Once euthyroid, the frequency of administration may be reduced to twice daily. Carbimazole has also been used prior to surgery.

Surgery can be performed in many cases **to remove the hyperplastic or neoplastic tissue**. The effects of hyperthyroidism on other tissues increase the anesthetic risk.

- If a nodule can be felt on one side of the gland only, some veterinarians prefer to remove just that one lobe. Others choose to remove the gland in its entirety and may supplement the cat with exogenous thyroid hormones. If all four parathyroid glands are also removed, supplementation with calcium and vitamin D is required. Severe life-threatening hypocalcemia can occur rapidly after surgery and needs intensive monitoring and treatment.

Radioactive iodine therapy can be employed in certain referral establishments. The hyperfunctional thyroid cells concentrate the radioactive iodine, whilst surrounding normal tissue receives a much smaller dose. This technique is simple and effective in many cats.

DIABETES MELLITUS**

Classical signs

- Polydipsia, polyuria, weight loss and polyphagia or inappetence.
- Plantigrade stance.
- Scurfy seborrheic haircoat.
- Symmetrical alopecia of the groin, perineum, abdomen and hindlimbs.

Clinical signs

Polydipsia, polyuria, weight loss and polyphagia or inappetence are typically present. Cutaneous manifestations are less obvious.

A **poorly groomed seborrheic** coat is commonly present. It is most commonly a **dry scurfy seborrhea**.

Alopecia involving the **groin, perineum, lateral abdomen and hindlimbs** is occasionally present, and may or may not be symmetrical.

A few cats with diabetes mellitus also have underlying hyperadrenocorticism, which may be responsible for some of the cutaneous signs.

The **skin appears thin and hypotonic**, which may be from hyperadrenocorticism or protein catabolism as a result of the failure to properly utilize glucose.

Secondary bacterial and fungal skin infections may occur because the immune system is compromised.

- Staphylococcal dermatitis, *Candida* spp. infections and dermatophytosis have all been reported.

A rare skin manifestation is the presence of **xanthomas**. These are benign, granulomatous lesions associated with abnormal lipid metabolism.

Diagnosis

A tentative diagnosis is based on **history, clinical signs and glycosuria**, with or without ketonuria.

Definitive diagnosis is confirmed by documenting **persistent fasting hyperglycemia** (blood glucose > 12 mmol/L).

Routine biochemical analysis may demonstrate increased hepatic enzymes, cholesterol and triglyceride

concentrations. Electrolyte abnormalities (sodium and potassium) may also be present.

Radiology and ultrasonography usually reveal **hepatomegaly**.

Demonstrating **increased fructosamine** concentration is useful to confirm that hyperglycemia is persistent and not transient. The normal fructosamine concentration in the cat is 175–400 $\mu\text{mol/L}$.

DERMATOPHYTOSIS**

Classical signs

- More often in young kittens, rather than adults.
- Erythematous plaques, alopecia and scale.
- Lesions progress to larger grayish areas of alopecia and hyperkeratosis.

Pathogenesis

In cats, **94–98% of cases are caused by *Microsporum canis***. Occasionally lesions are caused by *Trichophyton mentagrophytes* or *Trichophyton terrestre*, but *Microsporum gypseum* is rare.

The prevalence of dermatophytosis **varies with the climate and the natural reservoirs**. In a hot, humid climate, a higher incidence is observed than in a cold, dry climate. The mere presence of a dermatophyte spore is generally insufficient to cause infection and clinical disease. Transmission occurs via contact with an infected particle. In the case of *M. canis*, this occurs via contact with an **infected animal or environment**. Infection with *M. gypseum* is via exposure to **spores in soil**, and *Trichophyton* infection occurs via contact with rodents (usually asymptomatic carriers), horses, cattle or a contaminated environment.

A **minimum number of spores** is required for infection along with **other factors** that allow an infection to develop.

These factors include: **grooming behavior** (provides mechanical removal of the spores), presence of **micro-trauma on the skin** which allows invasion, increased **hydration and maceration** of the skin also increases probability of infection establishing. The **immune competence** of the host is extremely important.

Recovery from infection requires a strong cell-mediated immune response. Anti-dermatophyte antibodies do not provide protection, and a failure to form a strong cellular response may be the cause of chronic infection or tolerance in some cats. Concurrent **immunosuppressive drug therapy, compromised immune status**, poor nutrition, stress and the presence of intercurrent disease, e.g. multiple-cat environment with poor health care (strays) with endemic infections (FIV/FelV) may facilitate transmission.

Clinical signs

Skin fungal infections are more commonly seen in **young kittens, rather than adults**.

Initial lesions are commonly present on the face, head and feet. Large areas of the body can be involved.

Raised, erythematous plaques may develop, and are accompanied by scaling.

Alopecia develops and lesions expand to form larger plaques, which appear grayish and hyperkeratotic. Erythema may still be a feature.

Initial hair loss tends to be in the **center of the lesion**. Hairs on the periphery appear discolored and brittle. As lesions regress, initial hair re-growth appears in the center of the alopecic areas.

Secondary bacterial infection is commonly seen. Infection may involve the whiskers or nail beds, with resultant deformities.

Infection of deeper tissues may result in **nodular skin lesions**.

Infection may be sub-clinical or mild, and easily overlooked.

Diagnosis

A **tentative diagnosis** is based on **clinical signs**. **Definitive diagnosis** is based on **skin scrapings, hair plucks and fungal culture**.

Fluorescence under ultraviolet light (Wood's lamp), may detect approximately half the cases of *M. canis* infections in cats.

Skin scrapings and hair plucks may be examined microscopically for the presence of spores or hyphae.

Fungal culture of scrapings, hair plucks and nail samples can identify the precise species of dermatophyte involved, but is time-consuming.

Biopsy of affected tissue may confirm a diagnosis. Special stains may be required.

DEMODICOSIS*

Classical signs

- Non-pruritic alopecia typically periocular and nasal.
- Erythema and scaliness are often present.

Clinical signs

Most cases exhibit **focal, partial alopecia particularly in the region of the eyes, nose and ears**. Lesions may also develop on the chin, thorax, abdomen, inner thighs, flanks and perineum.

Mild erythema, scale and occasional papules.

The alopecia may become more generalized in some cases.

Hyperpigmentation and bilaterally symmetrical alopecia may develop.

Secondary infection and a crusting dermatitis may be seen. Pruritus is not a dominant feature in the majority of cases.

Diagnosis

A **definitive diagnosis** is based on identifying ***Demodex* species mites** in skin scrapings. Superficial scrapes are normally sufficient for detecting *D. gatoi* and the other unnamed species in the epidermis. *D. cati*, on the other hand, requires deeper scrapings.

Mites may also be detected on biopsy.

Attention should be paid to identifying any underlying cause of immunosuppression.

DRUG REACTION*

Classical signs

- Alopecia primarily of the body trunk.
- Bacterial, and less commonly, fungal skin infections.

Classical signs—Cont'd

- Ulceration or necrosis on trunk, limbs or mucocutaneous junctions may be evident.
- History of treatment with immunosuppressive or anti-neoplastic drugs.

Pathogenesis

Most of the drugs implicated in cutaneous drug reactions are **immunosuppressive or anti-neoplastic agents**. The reaction pattern varies with the specific drug.

Drugs such as **glucocorticoids and anti-neoplastic agents** can often **interfere with hair follicle activity**, resulting in alopecia.

Clinical signs

Drugs such as **glucocorticoids and anti-neoplastic agents** may produce **alopecia**, primarily affecting the body trunk.

- The **skin** may become **thin and hypotonic**, particularly with glucocorticoid medication.
- The classical cutaneous changes of hyperadrenocorticism may develop.
- Secondary bacterial or fungal infection is not uncommon.

When the reaction mimics a **hypersensitive response**, the signs may be more severe and involve **ulceration or necrosis**. The **extremities and mucocutaneous junctions or trunk** may be affected (see page 1034, The Cat With Miliary Dermatitis).

Diagnosis

Diagnosis can be difficult in some cases, because the drug reaction may cause cutaneous or systemic signs similar to the disease for which the cat was initially placed on that medication.

A **tentative diagnosis is based on history and clinical signs**. As alopecia is well recognized as a complication of treatment with glucocorticoids and anti-neoplastic agents, use of these drugs should always be ascertained from the history.

Withdrawal of the drug usually leads to a **gradual resolution** of the alopecia, although this is not true in all cats. If the cutaneous changes are not interfering

with the quality of life, drug withdrawal may not be appropriate, depending on the underlying condition for which the drug was prescribed.

If drug hypersensitivity is suspected, see page 1034, The Cat With Miliary Dermatitis, for details of diagnosis.

Differential diagnosis

Alopecia can be caused by all the conditions listed in this chapter. However, the major differentials would be **diabetes mellitus, hyperadrenocorticism and hyperthyroidism**. Dietary causes should also be excluded.

Treatment

If appropriate, the offending medication should be withdrawn.

Treat any secondary infection, and crusted or ulcerated areas with appropriate antimicrobial agents and symptomatic therapy as indicated.

PILI TORTI

Classical signs

- Generalized alopecia by 10 days of age.
- Pedal dermatitis and nail-bed infections.
- Affected kittens normally die or require euthanasia.

Pathogenesis

The pathogenesis is unknown.

Curvature of the hair follicle results in flattening and rotation of hair shafts.

This leads to a generalized alopecia in young kittens, with **virtually all secondary hairs** becoming involved. Primary hairs are not usually affected.

Pili torti is usually an inherited disorder in man, with affected individuals having additional systemic and skin abnormalities.

Acquired syndromes similar to pili torti are additionally reported following various physical and chemical insults in man.

Both autosomal dominant and recessive inheritance patterns have been reported in human patients with a combination of pili torti and varying degrees of hearing loss. Other ectodermal defects are also documented in affected individuals.

A localized form of disease may occur secondary to follicular inflammation.

Clinical signs

Appears as **generalized alopecia** in young kittens affecting secondary but not primary hairs. Most affected kittens have marked alopecia by 10 days of age.

Periocular and pedal involvement are commonly present. Affected kittens thus commonly present with **pedal dermatitis and paronychia**.

Affected kittens usually **die or are euthanized**.

Diagnosis

A **tentative diagnosis** is based on the **history and clinical signs**.

A **definitive diagnosis** is possible with **skin biopsy** of affected areas and examination of affected secondary hairs.

Electron microscopy of these secondary hairs can provide additional diagnostic information.

Treatment

No treatment is available.

TELOGEN DEFLUXION

Classical signs

- Alopecia affecting any or most parts of the body.
- Gradual shedding of telogen hairs, usually 1–3 months after a stressful event.
- Skin is clinically normal.

Clinical signs

Telogen defluxion normally results from the **premature cessation of hair growth** in anagen follicles because of a stressful factor, e.g. pregnancy, internal disease, etc.

Signs compatible with the underlying problem may be present or have been present in the past.

Telogen defluxion results in **widespread loss of hairs** from many or most parts of the body.

The hair loss normally **occurs 1–3 months** following the stressful event.

The skin is clinically normal.

The hairs themselves often appear normal. They are not fractured or broken.

Diagnosis

A **tentative diagnosis** is based on the combination of **history and clinical signs**. Often, the history or signs would indicate a stressful event such as pregnancy or internal disease within the last 1–3 months.

Examination of hair samples microscopically reveals the typical features of telogen hairs. These include uniform shaft diameter, as well as slightly clubbed and non-pigmented roots.

- There is no evidence of dysplastic changes or fracturing of the hair shaft.

Skin biopsy is of little additional benefit, because it simply reveals that all the hair follicles are in telogen.

Re-growth of the coat within a few months if the stress factor is removed or managed successfully can be used to confirm the diagnosis retrospectively.

HYPERADRENOCORTICISM

Classical signs

- Polyuria, polydipsia and polyphagia.
- Abdominal distention and pot-bellied appearance.
- Alopecia of the trunk, lateral thighs and ventrum, and unkempt hair coat.
- Thin, fragile skin.
- Bruising and tearing of the skin with mild trauma.
- Secondary bacterial skin infections and poor wound healing.

See main reference on page 251 (The Cat With Polyuria and Polydipsia).

Clinical signs

The majority of cats with hyperadrenocorticism have **systemic signs including polyuria, polydipsia and polyphagia**. Intermittent inappetence or anorexia may be present.

Many cases have **concomitant diabetes mellitus**.

Abdominal distention, giving a pot-bellied appearance is commonly seen.

Muscle wastage is a prominent feature.

Affected cats exhibit **alopecia and an unkempt hair coat**. Hair loss is commonly seen on the **trunk, flanks and ventrum**.

Hyperpigmentation occurs in a small number of cases. Secondary bacterial dermatitis may be a feature. Abscessation is occasionally present.

The **skin is thin and very fragile** in many cases. This leads to bruising and tearing with mild trauma.

Affected cats have **poor wound healing ability**. Comedone formation is also present in some cases.

In many cases, the disease is iatrogenic and there is a long history of depot glucocorticoid or progestagen use.

Diagnosis

Routine hematology and biochemistry values are not as markedly affected by hyperadrenocorticism in cats as they are in the dog. Consequently, many of the changes seen in the dog are inconsistently found in the cat.

- When present, such changes are frequently attributable to secondary diabetes mellitus, e.g. **hyperglycaemia, hypercholesterolaemia**.

The cat does not have a glucocorticoid-induced isoenzyme of alkaline phosphatase.

Urine specific gravity may on occasions be reduced to isosthenuric levels, except in cats with secondary diabetes mellitus, where glycosuria will affect the specific gravity value.

Adrenal function tests are not as well established in cats compared to dogs.

A normal **urine cortisol:creatinine ratio** is useful for **excluding hyperadrenocorticism**, but lacks specificity for diagnosis.

The **low-dose dexamethasone suppression (LDDS) test using 0.1 mg/kg** is the screening test of choice for feline hyperadrenocorticism. Cats with pituitary-dependent hyperadrenocorticism may fail to suppress, or exhibit suppression at 3 or 4 hours followed by “escape” of suppression at 8 hours. The latter pattern is diagnostic for pituitary-dependent disease, and makes further testing unnecessary.

The **corticotropin (ACTH) stimulation test** is best used to differentiate endogenous from iatrogenic hyperadrenocorticism, rather than as a diagnostic test for hyperadrenocorticism, because 15–30% of cats with hyperadrenocorticism have a normal response.

The **combined dexamethasone suppression/ACTH stimulation test** has been used successfully to diagnose hyperadrenocorticism in cats. The combined test does not appear to be more advantageous than either the ACTH stimulation or dexamethasone suppression test evaluated separately.

Measurement of endogenous ACTH concentrations is useful in differentiating pituitary-dependent from adrenal hyperadrenocorticism. Normal to increased ACTH concentrations support a diagnosis of pituitary-dependent disease. Low concentrations support adrenal disease. This test must only be used after hyperadrenocorticism is confirmed by other tests.

Abdominal ultrasonography may provide evidence of unilateral or bilateral adrenal enlargement.

Exogenous administration of progestogens or glucocorticoids should also be excluded.

Differential diagnosis

Hyperthyroidism and diabetes mellitus are the major differential diagnoses as most cats presenting with hyperadrenocorticism will have a combination of systemic and cutaneous signs.

Treatment

The **success rates** reported with drugs including **mitotane, ketoconazole and metyrapone** have been **poor to moderate**.

- Whilst successful management is possible in individual cases, the overall results are not as encouraging as in the dog.

- Metyrapone has been used successfully prior to **adrenalectomy** in some cats.

Adrenalectomy is favored by many authors as the **current treatment of choice**. This procedure can result in a significant survival time and a reduced insulin requirement.

- **Unilateral adrenalectomy** is performed in cases of an **adrenal tumor**. **Bilateral removal** is performed for **pituitary-dependent** hyperadrenocorticism.
- **Mortality rates higher than 25%** have been reported post-operatively, especially where diabetes mellitus is present.
- **Post-operative complications** include electrolyte imbalances, pancreatitis, thrombosis and sepsis. Glucocorticoids and mineralocorticoids are required peri- and post-operatively. Following successful control of the hyperadrenocorticism, the requirement for insulin therapy in diabetic cats may be reduced or abolished altogether.

STAPHYLOCOCCAL DERMATITIS*

Classical signs

- Erythema and scale/crustiness.
- Hair follicles are often involved.
- Lesions may progress to papules, but pus is rare.

Clinical signs

Primary staphylococcal dermatitis is rare in cats. Consequently, there may be signs evident which relate to an **underlying disease condition** e.g. diabetes mellitus or FeLV/FIV.

Erythema and scale/crustiness are seen clinically.

The hair follicles are usually involved. Lesions may progress to appear as **papules**, and thus take on a **miliary pattern**.

Affected cats may exhibit **alopecia** over the **head and neck**. Other common sites affected include the **feet, ears and dorsum**.

It is rare for purulent material to be present in or on the lesions.

Staphylococcal infection in the cat is more commonly seen as abscesses or infections of the ears and conjunctiva. Deeper infections, such as granulomas with fistulation, are infrequent.

Diagnosis

A tentative diagnosis is based on **clinical signs**.

Staphylococci can be readily cultured from infected lesions. Care must be exercised in interpretation of culture results, however, as most normal cats possess coagulase-positive staphylococci on their skin.

Biopsy of affected tissue may show evidence of **bacterial folliculitis, pyoderma or deeper infection**.

DIETARY ALOPECIA

Classical signs

- Patchy or generalized alopecia.
- Seborrhea and poor coat quality.
- +/- Secondary skin infection.

Clinical signs

This syndrome is not commonly seen in practice, except where economic conditions are poor or cats are fed on **improperly balanced diets**, for example, vegetarian diets, or diets low in vitamin A.

Alopecia may be patchy or generalized.

Seborrhea and **poor coat quality** are sometimes seen.

Hairs may be brittle and easily broken.

Poor skin hygiene and immune function may predispose to secondary skin infections.

Diagnosis

A tentative diagnosis is based on clinical signs and a detailed dietary history.

Other causes of alopecia need to be ruled out.

Differential diagnosis

Alopecia can be caused by all the conditions listed in this chapter. However, the major differentials would be

diabetes mellitus, hyperadrenocorticism and hyperthyroidism. Exogenous administration of **progestagens or glucocorticoids** should also be excluded.

Treatment

Correct the underlying dietary imbalance.

Often, simply feeding a well-balanced commercial formulation appropriate to the cat's requirements, will be sufficient to give an overall improvement within weeks to months.

ALOPECIA MUCINOSA

Classical signs

- Alopecia and scaling of affected skin on the ears, head and neck.
- Plaque-type lesions may develop at lesion site at a later date.

Clinical signs

Alopecia mucinosa is a **very rare** syndrome in cats, which is suspected of being a **precursor lesion** for **cutaneous lymphoma**.

Typically there is **alopecia**, which affects the **head, ears and neck**, and **fine scaling** of the affected skin. Pruritus is not a feature initially.

Within months, plaques may develop at the lesion site. Biopsy of these plaques has yielded results compatible with **cutaneous lymphoma or mycosis fungoides** in the two cats reported in the literature.

Diagnosis

Diagnosis is based on **biopsy of the affected skin**. Initial histopathology reveals **mucinosis of the epidermis** and of the outer root sheath of the hair follicles.

Later, biopsy specimens of plaque-type lesions may reveal findings consistent with cutaneous lymphoma or mycosis fungoides.

Treatment

No effective treatment is currently available. Treatment as for cutaneous lymphoma could be attempted if the

biopsy results were suggestive of this. There are too few case reports to make any prescriptive treatment recommendations.

The prognosis is therefore poor.

ALOPECIA AREATA

Classical signs

- Gradual onset of focal or multi-focal areas of alopecia.
- Non-pruritic.
- The skin is non-inflamed and appears otherwise normal.
- Long-standing lesions may become hyperpigmented.

Pathogenesis

In humans, an **immune-mediated basis** is suggested by:

- Accumulations of lymphoid cells around hair bulbs during the active phase of the disease.
- Occasional association of alopecia areata with other immune-mediated diseases.
- Increased incidence of various autoantibodies in alopecia areata.
- Decreased numbers of circulating T-cells.
- Deposition of C3 or IgG or IgM at the basement membrane zone of hair follicles.

Clinical signs

Rare condition in cats.

Typically there are **single or multiple sites of alopecia**, which are generally **well-demarcated** and usually **non-symmetrical**. Hair loss is gradual.

The most common locations affected include the **head, neck and trunk**.

The affected skin appears otherwise normal. There is **no inflammation evident** grossly and pruritus is not a feature.

Chronic lesions may develop **hyperpigmentation**.

Diagnosis

A **tentative diagnosis** is based on the **history** of gradual hair loss, and the **clinical signs** of well-demarcated alopecia, without any significant inflammation.

Biopsy of early skin lesions reveals a **mononuclear inflammatory cell infiltrate** both surrounding and within the **hair follicles**.

At later stages, the inflammation is largely absent. Catagen and telogen hair follicles predominate at this time-point. Follicular atrophy is also evident. In some biopsy specimens, there is complete absence of follicles.

Treatment

There may be **spontaneous re-growth** of hair in **some cats** after a variable period of time.

Glucocorticoids have been employed by a variety of routes. However, no data are available to support the use of glucocorticoid medication in the treatment of this disease.

51. The cat with skin lumps and bumps

Rodney Clement Straw

KEY SIGNS

- Soft or firm masses on the skin or under the skin.

MECHANISM?

- Masses are usually inflammatory and infectious in nature.
- Neoplasia is less common and may be caused by cumulative solar irradiation (SCC), viruses (fibrosarcoma), as a sequel to vaccination (sarcoma) or have an unknown etiology.

WHERE?

- Skin, subcutaneous tissue and superficial, palpable anatomical structures.

WHAT?

- Most cats with skin lumps and bumps have inflammatory lesions such as abscesses; neoplasia is less common.

QUICK REFERENCE SUMMARY

Diseases causing skin lumps and bumps

ANOMALY

- Multiple cartilaginous exostosis (p 1079)
Young cat (less than 2 years old) with hard masses fixed to underlying bone on extremities or skull, scapula, ribs, pelvis or multiple sites. These are progressive and painful swellings.

MECHANICAL

- Foreign body* (p 1073)
Typically vegetable material such as a grass seed or awn is involved. Relatively acute onset of swelling, often with draining tracts. Can become chronic discharging sinus and location of swelling may move in position on the body.

continued

continued

NEOPLASTIC

- **Squamous cell carcinoma** (p 1069)**

Usually occurs in older cats and appears as a crusty or ulcerated lesion in poorly pigmented and sparsely haired regions of skin.

- **Basal cell tumor* (p 1070)**

Solitary cutaneous lesion in an older cat usually on the dorsum.

- **Fibrosarcoma* (p 1071)**

Soft, subcutaneous mass with poorly defined margins; 50% occur on the limbs and 25% on the head and neck.

- **Fibroma (p 1077)**

Small, solitary, non-invasive mass in the skin or subcutaneous tissue.

- **Mast cell tumor* (p 1074)**

Solitary or multiple cutaneous masses especially on the head and neck of oriental breeds. Usually firm, raised, well-circumscribed, hairless dermal nodules between 0.5–3 cm in diameter.

Intermittently pruritic and occasionally ulcerated (especially histiocytic form). If disseminated, there may be signs of systemic illness including weight loss, anemia, vomiting and anorexia.

- **Sweat gland neoplasia (p 1077)**

Subcutaneous masses often around the base of the ear and ear canal.

- **Hemangioma and hemangiosarcoma* (p 1075)**

Appear as dark-red, cutaneous nodule or nodules. In the subcutaneous and muscular tissue appear as a soft mass, and there may be a zone of echymosis surrounding the mass. May also appear as an ulcerated lesion on the nose.

- **Cutaneous lymphosarcoma (p 1078)**

Very rare tumors in cats. Appear as solitary or multiple skin or subcutaneous masses varying from a few millimeters to over a centimeter in diameter. Can be moist and erythematous or dry and flaky. Mucocutaneous junctions may be involved with areas of superficial ulceration. Lesions may consist of plaques, papules, nodules and areas of erythema, focal alopecia with crusting and ulceration.

- **Melanoma (p 1079)**

The majority appears as dark-pigmented nodules in the skin of the head, and very rarely on the extremities. Ocular melanomas may occur and very rarely melanoma involves the oral cavity.

- **Mammary gland tumors* (p 1076)**

Nodule or nodules in the mammary chain, on average 3 cm in diameter. Often multiple, and may involve both mammary chains. May be ulcerated.

INFECTION

- **Catfight abscess*** (p 1079)**

Painful subcutaneous mass, usually febrile.

- **Fungal (p 1080)**

Variably ulcerated, cutaneous or subcutaneous mass. (e.g. *Cryptococcus* sp.)

TRAUMA

- **Hematoma (p 1080)**

Subcutaneous mass, acute onset, painful.

INTRODUCTION

MECHANISM?

Masses seen on the skin, or palpable masses on or under the skin are usually inflammatory, or less commonly neoplastic in origin.

Neoplasia may be caused by cumulative solar irradiation (SCC), viruses (fibrosarcoma), as a sequel to vaccination (sarcoma) or have an unknown etiology.

Multiple cartilaginous exostosis is probably of viral etiology.

WHERE?

Skin, subcutaneous tissue and superficial, palpable anatomical structures.

WHAT?

Most cats with skin lumps and bumps have inflammatory lesions such as **abscesses**; **neoplasia** is less common and often more serious, requiring early diagnosis and prompt appropriate treatment.

DISEASES CAUSING LUMPS AND BUMPS ON THE SKIN

CATFIGHT ABSCESS***

Classical signs

- Painful subcutaneous mass, usually febrile.

See main references on page 390 (The Pyrexial Cat) and page 401 (The Cat With Enlarged Lymph Nodes).

Clinical signs

There is a sudden onset of swelling under the skin often with a discharging sinus.

Many cats are depressed, febrile and/or anorexic.

Diagnosis

Purulent exudate or sheets of neutrophils with intra- and extracellular bacteria are evident on cytology.

SQUAMOUS CELL CARCINOMA**

Classical signs

- Reddened flaky skin on sparsely haired, non-pigmented skin.
- Non-healing ulcer on predisposed areas of head.

Pathogenesis

Chronic exposure to **UV light** may lead to the development of **dysplasia of epithelial cells in poorly pigmented and sparsely haired skin**. The effect of UV irradiation is **cumulative**, and the dysplastic cells may undergo neoplastic change, with development of carcinoma in situ. This lesion will progress to **invasive squamous cell carcinoma**.

Clinical signs

Most squamous cell carcinomas occur on the **head of older cats**.

- Predisposed sites include **non-pigmented areas** of the nasal planum, eyelids (including the third eyelid) and periorbital skin, infra-auricular skin and pinnae.

Lesions vary from small areas of **reddened and flaky skin**, to **deep ulcers** with peripheral zones of swelling and proliferation.

- Characteristically cats are presented because of **chronic non-healing ulcers**. There can be considerable necrosis and odor with advanced lesions.

Squamous cell carcinoma occasionally involves the **ear canal**.

- In advanced lesions there can be **extension** to the **osseous bullae**, and **vestibular signs** may be present.

Bone lysis accompanies advanced-stage lesions, particularly those located in the **periorbital area or ear canal**.

Diagnosis

A **tentative diagnosis** is based on the history and typical lesions located on poorly pigmented and sparsely haired regions.

Definitive diagnosis depends on histopathological evaluation of a biopsy specimen.

Radiological studies are rarely useful unless there is considerable extension to underlying bone.

Cytology may be helpful.

Cytological evaluation of any enlarged **regional lymph node** can be very useful for **staging**.

Differential diagnosis

The main differential diagnosis is **eosinophilic granulomas** of the lips, which can appear similar to squamous cell carcinoma lesions on the nasal planum.

- Eosinophilic granuloma lesions are usually **confined to the lips** and are often quite symmetrical.
- Diagnosis is based on histopathology or perhaps cytology. Classical cytological appearance is of sheets of well-differentiated eosinophils.

Treatment

The treatment of choice is **ablative surgery with wide margins**.

- This may involve such procedures as removal of pinnae, nasal planectomy, full-thickness eyelid resection, enucleation with partial orbitectomy and reconstructive procedures such as caudal auricular artery axial pattern flap.

Resected specimens should be evaluated histopathologically for completeness of resection. Incomplete resection is associated with very high rates of tumor recurrence.

Cryosurgery may be useful for carcinoma in situ, or early stages of invasive squamous cell carcinoma, and is particularly useful for small lesions of the eyelids.

- At least two freeze–thaw cycles (rapid freeze and slow thaw) should be used.
- The lesion and a cuff of normal-appearing surrounding tissue should be frozen to -25°C or colder.
- Unfortunately recurrence rates are high.
- **Radiation therapy** can be used, and generally is most effective for carcinoma in situ or early stages of invasive squamous cell carcinoma. Radiation therapy includes:

- Soft external beam therapy delivered by orthovoltage machines.
- Electron beam treatment from a linear accelerator.
- Brachytherapy using radioactive implants.

Prognosis

Prognosis varies with the stage of disease, but is usually good.

Squamous cell carcinomas of the skin are generally very **slow to develop and progress**.

- However, cats with late stages of disease seem to deteriorate quickly.

Metastasis to regional lymph nodes occurs late in the course of the disease.

The major debilitating signs are associated with the local tumor.

- Pulmonary metastases are rare for solar-induced cutaneous squamous cell carcinoma.

With **complete surgical excision**, the prognosis is very good, and **80–100%** control rates can be achieved.

New lesions can develop as a consequence of continued exposure to the sun.

Prevention

Prevent exposure of high-risk cats to UV irradiation by **keeping them indoors** during high-risk times of the day.

- It is very difficult to prevent sun exposure in climates where UV irradiation is high.

In geographic regions where there is a high risk of UV irradiation, **breeding cats with pigmented skin** would decrease the incidence of tumors.

Tattooing non-pigmented skin does not prevent the development of squamous cell carcinoma.

BASAL CELL TUMORS*

Classical signs

- Skin nodule often on the dorsum.
- May have intact epithelium or variably ulcerated.
- Often chronic history.

Pathogenesis

Basal cell tumors result from **malignant transformation of the basal cells** of the skin.

The etiology of these tumors is unknown, but they tend to affect **older cats**.

Clinical signs

Basal cell tumors are a **common** skin tumor in **older cats**.

These tumors develop in the basal epithelium of the skin.

The tumors are **usually solitary**.

- They usually occur on the skin on the dorsum of the head, neck, thorax and lumbar area.

Diagnosis

Cytological examination of a fine-needle aspirate may be suggestive, but definitive diagnosis requires **histopathological evaluation** of a biopsy specimen.

Differential diagnosis

Diagnosis cannot be necessarily made by the gross appearance, and basal cell tumors need to be differentiated from other skin neoplasms such as **squamous cell carcinoma** and **mast cell tumors** by histopathology.

Treatment

Nearly all basal cell tumors can be permanently **controlled by complete surgical excision**, although the histological appearance of these tumors would tend to imply an aggressive natural behavior.

- Margins of about 5–10 mm are appropriate.

Prognosis

The **prognosis is very good** if these tumors are removed completely.

- Only rarely have metastases been reported.

Prevention

Since the etiology is unknown, preventative measures cannot be recommended.

FIBROSARCOMA*

Classical signs

- Soft, subcutaneous mass with poorly defined margins.
- Slowly growing.
- Not painful.

Pathogenesis

Fibrosarcomas are non-encapsulated tumors of malignant **mesenchymal cells** with potential for **local tissue invasion**.

Feline sarcoma virus, which is a retrovirus that depends on feline leukemia virus for replication, causes **multicentric fibrosarcomas** in young cats.

The cause of solitary fibrosarcomas in older cats is usually unknown.

There is a form of fibrosarcoma that grows in vaccination sites that is thought to be associated with post-vaccination inflammation (**vaccine-associated sarcoma, VAS**).

- Killed vaccines with aluminum salt adjuvant have been implicated as causative agents, but the true etiology, pathogenesis and epidemiology are still unknown.
- Rabies vaccines have been implicated, but other vaccines may also play a role.
- Frequency of occurrence varies worldwide.
- There is a low incidence in some countries such as Australia, perhaps because rabies vaccine is not used.

Solitary fibrosarcomas in adult, FeLV-negative cats are **locally invasive** and have a **low metastatic rate** (approximately 10% of cats will develop distant metastasis).

Clinical signs

Typical signs are a **solitary, soft, subcutaneous mass** growing larger and firmer over a period of months. With increasing size, the mass may **ulcerate** and become secondarily infected.

The **multicentric form** occurs in cats generally **less than 5 years of age**.

Vaccine-associated sarcoma arises in the area of vaccination, usually in the **interscapular space** in the dorsal subcutaneous tissue.

Fibrosarcomas are usually **not painful**.

Tumors may occur anywhere on the body, with **50% occurring on limbs** and **25% on the head and neck**.

Diagnosis

Cytological examination of **fine-needle aspirates** demonstrates **mesenchymal cells** with malignant characteristics. This suggests fibrosarcoma.

Definitive diagnosis requires **histopathological evaluation** of properly acquired biopsy material.

- Care must be taken to perform the biopsy, so the entire biopsy site may be removed with the tumor at the time of resection.

There is usually an inflammatory component to the histology of vaccine-associated sarcoma, with predominantly lymphocyte and macrophage populations.

Histological grading including determining the **mitotic index**, derived from evaluating ten high-power fields, may add prognostic information.

Regional radiography may help determine the local tumor stage and direct surgical planning.

Thoracic radiography and **regional lymph node cytology** are required for staging although metastasis is rare for cats with solitary fibrosarcoma.

Cats with viral multicentric fibrosarcoma will be FeLV positive.

Differential diagnosis

Fibromas and old wounds with abundant fibroplasia can have similar cytological appearance on fine-needle aspirates.

Other names are given to these soft tissue sarcomas such as spindle cell tumors, neurofibrosarcomas or nerve sheath tumors.

Treatment

Wide surgical excision is the treatment of choice.

- **Tumor margins** should be evaluated histologically for completeness of resection.

- Adjuvant chemotherapy has been recommended but has not been shown to be beneficial.

Cats with **multicentric fibrosarcomas** can only experience **temporary palliation**.

- Surgery cannot be expected to cure these cats.

Cats with vaccine-associated sarcoma are also more difficult to treat.

- Recurrence and metastasis has been reported after surgery.
- Combinations of **surgery, external beam radiation and chemotherapy** show promise in controlling these very aggressive tumors.

Prognosis

The **prognosis is good** for **solitary fibrosarcomas** in adult cats where complete surgical excision has been performed.

- The ability to completely excise the mass depends on the tumor location, tumor size and expertise of the surgeon.

Histological grade including mitotic index may help predict survival following surgery, and cats with high-grade tumors should be followed more closely or may be given adjuvant therapy.

The **prognosis is poor** with **multicentric fibrosarcomas**.

Vaccine-associated sarcoma is associated with a **variable prognosis** with often disappointing outcomes even with wide excision.

Prevention

The Vaccine-Associated Feline Sarcoma Task Force (VAFSTF) was formed to address this evolving and important issue and can be found at <http://www.avma.org/vafstf/default.htm> on the Internet.

The VAFSTF has made a number of recommendations:

- Cats should not be vaccinated unnecessarily.
 - Rabies vaccines licensed for every 3 years should not be given yearly and strictly indoor cats should not be vaccinated for FeLV.
- Vaccines should not be given in the interscapular space.
 - It is suggested that the **rabies vaccines** are given on the **right hindlimb** and the FeLV be given on the left hindlimb.

- It is recommended that these vaccines be given in a distal location when possible, so that the limb may be amputated if a sarcoma develops, thus sparing the cat's life.
- Other vaccines should be given over the lateral shoulders away from the interscapular site.
- Single-dose vial usage is recommended.
 - **Multi-vaccine products should be avoided.**
- When giving booster vaccinations, **previous vaccine sites should be avoided.**
- In the past, it has been suggested that IM administration be performed instead of SQ injection. This may only result in more difficult detection, reducing the chance of early detection and surgical cure.
- Monitoring for masses occurring in common vaccination sites should be performed by owners and reported to the veterinarian.
 - **Vaccine-associated granulomas are common.** A recent study evaluated cats receiving rabies vaccines from four different manufacturers, and found that 100% of the cats developed local reactions. Reactions often occurred within a few weeks, and resolved by 1–2 months later.
- Do not vaccinate cats that have had a prior history of a vaccine-associated sarcoma.

GUIDELINES FOR RECORDING SUSPECTED CASES OF VACCINE-ASSOCIATED SARCOMA

The location, vaccine type, manufacturer, serial numbers of the vaccine should be recorded in each patient's record.

All other medications administered subcutaneously or intramuscularly should be recorded as well.

Any vaccine response, whether inflammatory or neoplastic, should be reported to the vaccine manufacturer.

- Also report outcome of the case as it becomes known.

MANAGEMENT OF VACCINE-ASSOCIATED SARCOMA IN CATS

If a **mass** in a vaccine site **persists for longer than 1 month**, or if it exhibits rapid growth, a Tru-cut®, wedge or **excisional biopsy** should be performed.

- If a granuloma is identified, a conservative resection may be planned, if excision was not already performed.

- If a sarcoma is identified, then **wide or radical surgical excision** should be performed.

Test for FeLV to reduce the suspicion of FeSV-related sarcoma.

Although the rate of distant metastasis is low, it is recommended that thoracic radiographs be performed prior to excisional surgery.

Wide surgical excision with margins of up to 5 cm has been recommended. Margins should be evaluated via histology.

Wide surgical excision with less than 5 cm performed at the first occurrence with adjuvant external beam radiation therapy has a good chance of long term control of this cancer.

Recurrent tumors are always more difficult to manage than the initial tumor with adjustments external beam radiation therapy.

FOREIGN BODY*

Classical signs

- **Mass under the skin, often with a discharging sinus.**
- **Swelling may “come and go” and may be chronic.**

Pathogenesis

Any foreign body under the skin may result in an **abscess or chronically draining lesion**. The foreign body is usually of plant origin such as a grass seed or awn, but may even be a tooth broken off during a cat fight.

Clinical signs

Typically there is an acute onset of a **soft tissue swelling** under the skin, which can occur anywhere on the body.

The swelling may be acute or chronic.

Purulent material sometimes drains from a sinus in the mass.

The swelling is variably painful, and is often less painful if chronic.

The owner may describe the lesion as “moving”, because it may appear in slightly different locations if the foreign body is migrating. Alternatively it may appear to “come and go”.

The mass is persistent, and wound drainage is only **partially responsive to antibiotics**.

Diagnosis

Definitive diagnosis requires identification of the foreign body.

Fine-needle aspirate cytology is consistent with granulomatous inflammation and contains neutrophils and macrophages.

The foreign body is usually discovered at surgery, and rarely by radiography or ultrasonography.

Treatment

Treatment involves **surgical removal of the foreign body**, and drainage or removal of the sinus tract.

Perioperative antibiotics are indicated.

Prognosis

Prognosis is **excellent** with surgical removal of the foreign body, but the foreign body can be hard to find.

MAST CELL TUMORS*

Classical signs

- Solitary or multiple cutaneous masses.
- Usually on the head and neck.
- Usually firm, raised, well-circumscribed, hairless dermal nodules between 0.5–3 cm in diameter.
- Intermittently pruritic and occasionally ulcerated (especially histiocytic form).
- If disseminated, there may be signs of systemic illness.
- Weight loss, anemia, vomiting and anorexia.

Pathogenesis

Mast cell tumors are comprised of **anaplastic mast cells** and **histiocytic cells**.

There is no known etiology for feline mast cell tumors.

Siamese cats appear to be predisposed.

Clinical signs

Mast cell tumors typically appear as firm, raised, well-circumscribed, hairless **dermal nodules** varying in size from 0.5 cm. They are **often multiple**; 20% were multiple in one report and the majority in another.

The **head and neck** are more commonly affected than the trunk or limbs.

Tumors are usually **not painful**, but may be **itchy**. Occasionally the tumors may become **ulcerated**, especially the histiocytic form.

Mast cell tumors can have visceral involvement, but the **visceral form** usually occurs as a **separate entity** (see systemic mastocytosis, page 689).

Lesions may become **erythematous and edematous after manipulation** (Darier’s sign).

Cats with **systemic involvement** are **usually sick**, with weight loss, anorexia, vomiting, diarrhea (variably with bloody stools), anemia and even shock.

- Usually, however, cats with cutaneous mast cell tumors are otherwise healthy.

There are **two major forms** of cutaneous mast cell tumors in cats, **mastocytic and histiocytic**.

- **Mastocytic** mast cell tumors occur typically in **middle- to old-aged cats**.
- Most mastocytic tumors are the compact form with a fairly benign behavior.
 - A few are the **diffuse form**, which are more **anaplastic and malignant**.
- **Histiocytic** mast cells tumors are **uncommon**, occur in cats **less than 4 years of age** (mean age 2.4 years) and **Siamese are predisposed**.
- Histiocytic tumors usually occur as multiple cutaneous nodules around the head.
 - These lesions are of **low grade** and may even spontaneously regress.

Diagnosis

Fine-needle aspirate cytology is often diagnostic showing round cells with metachromatic granules. **Histopathology** is usually necessary to **diagnose the histiocytic form** where granules are not prominent.

Extension to regional lymph nodes is not common, but any enlarged node should be evaluated at least by fine-needle aspirate.

In cats where **disseminated disease** (spleen or intestinal forms) is suspected, tests such as hematology, serum biochemistry, buffy coat smear or bone marrow aspirate, coagulation studies, thoracic and abdominal radiography and abdominal ultrasonography should be considered.

Differential diagnosis

Other cutaneous neoplasms should be considered as differential diagnoses. Differentiation is based on fine-needle cytology or histological examination.

Treatment

For the mastocytic form, surgery is the preferred treatment. Surgical margins need not be as wide as for canine mast cell tumors (3 cm), since most have a relatively benign biological behavior. **Wider margins** are necessary in the case of **diffuse mastocytic forms**. Conservative resection is appropriate for the histiocytic form.

Cats with the splenic form benefit from **splenectomy**, even though tumor cells may be disseminated.

Little is known of the efficacy of adjuvant therapy for mast cell tumors in cats.

Prognosis

In general, the prognosis for most cats with mast cell tumors is very good.

Most cats experience **long-term control** after complete surgical excision.

Local recurrence rates for the mastocytic form following surgery **vary up to 24%**.

- If the tumor recurs, it usually does so within 6 months of surgery.

The metastatic rate has been reported to be as high as 22%.

Some cats do acquire new primaries.

HEMANGIOMA AND HEMANGIOSARCOMA*

Classical signs

- Dark red cutaneous nodule.

Pathogenesis

Hemangiomas are benign tumors of vascular endothelium. The **malignant, anaplastic** counterpart is **hemangiosarcoma**.

Hemangiosarcomas of the nasal planum and eyelid may be solar induced.

Clinical signs

Hemangiomas and hemangiosarcomas are **very rare in cats**.

In the skin, they usually appear as **red to dark-red nodules of varying size**.

- **Spontaneous hemorrhage** from the lesions may be a feature.

They may also appear as an **ulcerated lesion on the nose**.

Hemangiosarcoma can occur in the **subcutaneous and muscular tissue as a soft mass**, and there may be a **zone of echymosis** surrounding the mass.

Hemangiosarcoma can also occur in **visceral organs**, and rarely the skin lesions may be secondaries to primary disease in the viscera.

Diagnosis

Cytological examination may be unrewarding because the cells do not exfoliate well.

- Malignant mesenchymal cells may be found at the feathered edge of cytology slides.

Definitive diagnosis requires histological examination.

Treatment

Surgical resection is the treatment of choice, and for hemangiosarcomas, as wide a margin as possible should be taken, preferably greater than 10 mm.

Prognosis

Hemangiomas are benign.

Cutaneous and subcutaneous hemangiosarcomas appear to be **locally invasive** only, and metastases are not common.

Hemangiosarcomas have a high metastatic potential when intra-abdominal or intrathoracic organs are involved.

However, **hemangiosarcomas involving muscles** also appear to have a high incidence of **metastasis**.

MAMMARY GLAND TUMORS*

Classical signs

- Nodule or nodules in the mammary chain, on average 3 cm in diameter.
- Often multiple, and may involve both mammary chains.

Pathogenesis

There is a **seven-fold greater risk** of mammary carcinoma in **intact cats** compared to spayed cats.

- Unlike in dogs, ovariohysterectomy before the first estrus does not eliminate the possibility of mammary tumor, but appears to have some sparing effect.

It has been observed that **long-term progesterone therapy** in cats is associated with an increased incidence of mammary tumors and dysplasias.

Mammary tumors are the **third most common tumor** in cats.

- The overall risk is 25.4/100 000 female cats.
- Age range is 2.5–19 years with **70% between 9–13 years**, and an average of 10.8 years.
- There is no breed predilection.

The majority of mammary gland tumors are **malignant (86%)**.

- Of the malignant tumors, **adenocarcinoma** is the predominant type.
- Mammary neoplasia can further be evaluated based on (1) cellular differentiation and the degree of tubule formation, (2) nuclear pleomorphism, and (3) the frequency of mitosis.

- Adenocarcinomas may further be divided into tubular, papillary and solid carcinomas.

Clinical signs

The tumors usually lie in the **subcutaneous tissue adjacent to the nipple**, and adhere to the overlying skin.

- The size of tumor is variable, with a mean size of **3 cm** and rarely exceeding 9 cm in diameter.

About 15–25% are ulcerated at the time of diagnosis.

Local invasion into underlying musculature and cutaneous ulceration is **common**.

Feline mammary tumors **grow rapidly**.

- The average duration of the history at the time of diagnosis is 5 months.

About **66%** of feline mammary tumors will be **multiple**, and about **35%** involve **both chains** of mammae.

Regional lymph nodes are involved early.

Some cats with tumors that have been present for a long time may present with signs referable to **metastasis**, including **weight loss, dyspnea and coughing**.

Differential diagnosis

Benign lesions such as **adenomas, focal mammary dysplasia and fibromas** can mimic the gross appearance of mammary gland tumors, and can be differentiated on histopathology.

Diagnosis

Presumptive diagnosis of a mammary gland tumor can be made on the presence of a mass in the breast tissue.

Cytological examination of a fine-needle aspirate may reveal malignant cells, but false-negative cytology is possible.

Definitive diagnosis can only be made by a surgical biopsy and **histological examination**.

Due to the high metastatic potential of female mammary gland tumors, **chest radiography** should be performed **before any surgical procedure**.

Treatment

The treatment of choice is **radical mastectomy of all glands on the affected side**, because of the high local

recurrence rate, high rate of malignancy and the frequent multicentric origin of feline mammary gland tumors.

- The **opposite side should be removed in 2–4 weeks**, or a bilateral mastectomy performed if possible.
- All **regional lymph nodes** should be palpated and removed if enlarged.
- In cases of local recurrence, a second surgery is often possible and may be indicated to prolong survival.

Doxorubicin alone (1 mg/kg IV every 21 days for 4–5 treatments), or **doxorubicin and cyclophosphamide** (200 mg/m² IV or orally) combination chemotherapy may help as adjuvant therapy to prolong the disease-free survival.

Prognosis

The prognosis in **general is poor**.

- The **median survival time** of cats treated with surgery alone is **10–14 months**.

Tumor volume has a significant effect on postoperative survival time.

- Cats with a total tumor volume of < 9 cm³ can be expected to survive greater than 18 months, cats with a total tumor volume of 10–27 cm³ can be expected to survive 12 months, and cats with a tumor volume greater than 27 cm can be expected to survive 7 months.

Cats with **well-differentiated tumors** appear to survive longer than those with poorly differentiated tumors.

FIBROMA

Classical signs

- Solitary cutaneous or subcutaneous mass usually not greater than 10 mm in diameter.

Pathogenesis

Fibroma is caused by **benign hyperplasia of fibrocytes**. The cause not known.

Clinical signs

Fibromas are either **slow growing** or have a long history of stable size.

Typically they appear as a **non-painful small cutaneous or subcutaneous mass**, usually less than 10 mm diameter, which is generally not ulcerated.

Tumors are **mobile**, and **not invasive** to adjacent structures.

Diagnosis

On **fine-needle aspirate**, not many cells exfoliate and the cells do not have characteristics of malignancy. The cells are elongated with small nuclei.

A fibrous and tough texture is often noticed when performing needle aspirates.

No bone lysis is evident in adjacent skeletal structures.

Definitive diagnosis requires **histopathological examination** of an excised specimen.

Treatment

Excisional biopsy is diagnostic and curative.

Prognosis

Prognosis is excellent.

SWEAT GLAND NEOPLASIA

Classical signs

- Masses of the head and neck, especially around the external and middle ear canal.

Pathogenesis

Sweat gland tumors arise from **apocrine or ceruminous gland cells**. Most commonly they arise around the external and middle ear canal.

The etiology of sweat gland tumors is unknown.

Most of these adnexal tumors are **malignant (carcinomas)**, and are **locally invasive** with a **variable metastatic potential**.

Extension to regional lymph nodes and later to the lung can be seen.

Clinical signs

Ceruminous and apocrine gland neoplasms are **relatively common** in cats, however perianal tumors are rare.

Cats usually present because of a **mass** often around the base of the ear and ear canal, or for **signs of otitis externa**.

Regional lymph nodes may be enlarged.

Diagnosis

Cytological examination and demonstration of **typical polyhedral cells in rafts with nuclear pleomorphism** and other malignant characteristics may be helpful as a screening test, but **definitive diagnosis** requires **histological evaluation** of a biopsy.

Regional lymph nodes, particularly cranial cervical nodes, need to be evaluated by cytology, histology or both, and **pulmonary radiography** should be performed for staging.

- Palpate the neck carefully and perform **fine-needle aspirate cytology on any enlarged nodes**, or remove or perform Trucut needle biopsy on such nodes for histopathology.
- Take thoracic radiographs in both lateral projections and ventrodorsal or dorsoventral projections.

Treatment

Wide surgical excision including total ear ablation for external ear canal ceruminous carcinomas is the treatment of choice.

Adjuvant radiation and chemotherapy have been described, however many lesions will progress despite extensive treatment.

Prognosis

Long-term remission is possible where clean surgical margins are attained in cats with no metastatic disease.

Overall a fair prognosis must be given.

CUTANEOUS LYMPHOSARCOMA

Classical signs

- Solitary or multiple skin or subcutaneous masses varying from a few millimeters to over a centimeter in diameter.
- Can be moist and erythematous or dry and flaky.
- Mucocutaneous junctions may be involved with areas of superficial ulceration.

Pathogenesis

Cutaneous lymphosarcoma lesions are comprised of **diffuse infiltrates of malignant, poorly differentiated lymphoid cells (B-lymphocytes)**. A **T-cell form (mycosis fungoides)** has been described.

Since affected cats are usually older and FeLV negative, the cause of this disease is not well understood.

Clinical signs

These tumors are **very rare** in cats.

Appear as **solitary or multiple skin or subcutaneous masses** varying from a few millimeters to over a centimeter in diameter.

- Can be **moist and erythematous or dry and flaky**.
- **Mucocutaneous junctions** may be involved with areas of superficial ulceration.

Lesions may consist of **plaques, papules, nodules, and areas of erythema, focal alopecia with crusting and ulceration**.

Usually there is **no systemic involvement**, and there are minimal abnormalities on hematology or serum biochemistry.

Diagnosis

Cytological examination showing **abundant malignant round cells** is useful to establish a presumptive diagnosis.

Definitive diagnosis requires **histopathology**.

Treatment

For **solitary lesions**, excisional surgery may be curative.

Small lesions may respond well to **superficial radiation therapy**.

Single or multimodal chemotherapy may be used, but the response to therapy is often disappointing. **Mycosis fungoides** may be treated with **retinoides** such as isotretinoin.

Prognosis

The prognosis for cats with **widespread disease** is **poor**.

Cats with small solitary lesions may do well initially with surgical excision, but **generalized disease** is likely to occur within 12 months.

MELANOMA

Classical signs

- Black pigmented cutaneous lesion.

Pathogenesis

- Melanoma can be induced experimentally with feline sarcoma virus, but this is not thought to be involved in the pathogenesis of the clinical disease.

Clinical signs

Melanoma is **very rare** in cats and can be **benign or malignant**.

The majority appears as **dark-pigmented nodules in the skin of the head**, and very rarely on the extremities.

Very rarely melanoma involves the oral cavity.

Ocular melanomas usually affect the **intraocular structures or the eyelid**, and may occur in the uveal tract.

Diagnosis

Cytological examination showing **heavily pigmented large solitary cells or lightly grouped cells** varying from round to spindloid in shape is highly suggestive,

but a definitive diagnosis should be obtained by histopathology.

Treatment

Treatment of choice is **surgical excision**, preferably with margins of 10 mm or greater. **Cryosurgery** is an alternative for small lesions or eyelid tumors.

Prognosis

The prognosis for non-ocular dermal melanomas is fair; reported metastatic rates are 5–25%.

MULTIPLE CARTILAGINOUS EXOSTOSIS

Classical signs

- Multiple firm masses palpable mostly over the ribs, scapulae, pelvis, the skull and possibly some long bones in a young, skeletally mature cat.
- Swellings are progressive and painful.

Pathogenesis

Multiple cartilaginous exostosis is thought to have a **viral etiology** because virtually all cats are **FelV positive**. It does not appear to have a familial basis as it does in dogs.

There is **continuous bone growth** from **ectopic cartilage caps** particularly on flat bones, and at sites such as the scapulae, vertebrae, mandible and skull.

Lesions **progress after skeletal maturity**, unlike the static character of solitary cartilaginous exostoses in mature dogs.

Exostoses may undergo **malignant transformation**.

Clinical signs

Multiple firm masses occur which are palpable mostly over the ribs, scapulae, pelvis, the skull and possibly some long bones in a **young, skeletally mature cat**.

Rapid progression may occur over just a few weeks to months, resulting in prominent hard swellings causing pain, lameness and loss of function.

Occur in young cats, less than 2 years old.

Differential diagnosis

The main differential diagnosis is **osteosarcoma** which usually only affects one bone at presentation.

Diagnosis

Diagnosis is based on clinical signs, radiographic findings and biopsy results.

Radiographic appearance is of **multiple, focal exostoses** that blend with normal underlying bone.

Most cats are **FeLV positive**.

Definitive diagnosis relies on histopathology.

Treatment

Lesions can be excised for palliation, but there is no effective cure.

Prognosis

Prognosis is extremely poor, because the lesions are usually progressive, and recurrence following surgery is common. The disease is painful and debilitating.

Fungal

Classical signs

- Variably ulcerated, cutaneous or subcutaneous mass. (e.g. *Cryptococcus* sp.).

Clinical signs

There are often ulcerated skin lesions which do not respond to antibiotics.

Numerous common and less common fungi are capable of producing cutaneous masses in cats including *Cryptococcus*, *Sporothrix* and *Coccidioides*.

Systemic signs such as inappetence, weight loss and fever may be present. Dyspnea or CNS signs may be present in some cats.

Diagnosis

The diagnosis is made by demonstrating the organisms on cytology, histology, fungal culture or serology.

HEMATOMA

Classical signs

- Subcutaneous mass, acute onset, painful.

Clinical signs

Hematomas may occur as solitary or multiple subcutaneous swellings. Purple discoloration of the overlying non-pigmented skin may be evident. There may be a history of trauma or coagulopathy.

Diagnosis

A presumptive diagnosis is based on ruling out other disorders by fine-needle cytology (peripheral blood, macrophages and other inflammatory cells may be identified), combined with a history of trauma or identification of a coagulopathy.

RECOMMENDED READING

Withrow SJ, MacEwen EG (eds) Small Animal Clinical Oncology, 3rd edn. WB Saunders Co., Philadelphia, 2001.

52. The cat with non-healing wounds

Gregory Burton

KEY SIGNS

- Erosion, ulceration.
- Nodules or plaques with ulceration or fistulae.
- Serosanguineous to purulent exudate +/- tissue grains.
- Subcutaneous fibrosis.
- Extracutaneous symptoms may be present.

MECHANISM

- Non-healing wounds occur where there is a failure of re-epithelialization, dermal fibroplasia and or angiogenesis.

WHERE?

- Skin (diseases involving the epidermis, dermis, panniculus and cutaneous blood vessels) and mucocutaneous junctions.

WHAT?

- Most cats with non-healing skin wounds have infections (mycobacteria, aerobic and/or anaerobic bacteria, or fungi). Neoplasia, allergies, immune-mediated and metabolic diseases are less common.

QUICK REFERENCE SUMMARY

Diseases causing non-healing wounds

ANOMALY

- Cutaneous asthenia (p 1100 - 1101)
Congenital disease resulting in hyperextensibility and fragility of the skin. Kittens present with spontaneous tears or necrotic, slow-healing crusted ulcerations.
- Epidermolysis bullosa (p 1101)
Congenital epidermal basement membrane disease with signs evident shortly after birth. Skin, foot pad and mouth ulcers particularly at frictional areas. Nail shedding is common.

continued

continued

METABOLIC

- **Acquired cutaneous fragility syndrome (p 1098)**

Thin, fragile skin which is not hyperextensible, and which tears easily. Secondary to metabolic conditions such as hyperadrenocorticism (endogenous or iatrogenic) or diabetes.

- **Xanthoma (p 1099)**

Plaques or nodules with a yellowish-white appearance which often ulcerate and occur mostly over bony protuberances (areas of incidental trauma). Most common in cats associated with hyperlipidemia.

- **Metabolic epidermal necrosis (MEN) (p 1099)**

Crusting lesions at mucocutaneous junctions and pressure points in an unwell cat. Skin lesions are secondary to pancreatic or hepatic disorders.

NEOPLASIA

- **Squamous cell carcinoma** (p 1089)**

Occurs in old cats (average age 9 years). Multiple or single lesions occur on the pinnae, philtrum, nares, forehead and palpebrae, in non-pigmented, thinly haired areas. Lesions may be proliferative or ulcerative, and are slow to metastasize.

- **Multicentric squamous cell carcinoma in situ (p 1089)**

Occurs in older cats (> 10 years). Multifocal lesions occur over the head, neck, shoulders and forelimbs on pigmented, thickly haired skin. Begin as hyperkeratotic macules and evolve to thick-crusted, ulcerated plaques. Progress slowly, with waxing and waning signs.

- **Melanoma (p 1097)**

Occurs in older cats (average age 10 years) as solitary lesions on the head or neck. Size and shape are variable ranging from a dome, to a plaque or polypoid shape, and ulceration is frequent.

- **Basal cell carcinoma (BCC) (p 1097)**

Frequently pigmented and/or cystic tumors of the head, neck, thorax, nasal planum and eyelids of older cats. Usually solitary and frequently ulcerated.

- **Mast cell tumor* (p 1092)**

Occur as single to multiple tumors on the head of older cats. Tumors may “enlarge” and become erythematous after palpation or aspiration. Rarely young Siamese cats have multiple nodules around the head.

- **Cutaneous lymphoma (p 1097)**

Very rare tumors in cats. Signs of T cell tumors (mycosis fungoides) include “non-inflammatory” alopecia, scaling, erythroderma (diffuse reddening of the skin), hypopigmentation of hair or skin, ulceration, plaques and nodules. B cell neoplasia produces dermal nodules with or without ulceration. Systemic signs of weight loss, diarrhea and respiratory distress may be present.

NUTRITIONAL

- **Pansteatitis/vitamin E deficiency (p 1104)**

Cats eating diets high in oils, especially fish oils may develop fever, lethargy, painful skin, generalized firm feel to the subcutaneous fat, and skin sinuses with gelatinous exudate.

INFLAMMATORY/INFECTIOUS

Viral:

- **Pox virus (feline cowpox)* (p 1091)**

Caused by orthopoxvirus, which is not uncommon in Western Europe. Transmission is via direct contact with rodents, mostly in male free-roaming adult cats. Focal ulcer or abscess is followed 7–10 days later by generalized small (0.5–1 cm) crusted ulcers. Concurrent pneumonia is a poor prognostic sign.

- **Herpesvirus 1* (p 1092)**

Cutaneous manifestation of feline rhinotracheitis infection produces ulcerative lesions seen mostly on the nasal planum. There may or may not be concurrent ocular or respiratory disease.

Bacterial:

- **Bacterial infections*** (p 1086)**

Usually preceded by history of skin penetration, e.g. cat fight. Actinomycotic mycetoma are characterized by the triad of tumefaction, sinus tract formation and tissue grains within the exudate. Other bacterial infections include *Nocardia*, *Staphylococcus*, L forms, and *Yersina pestis*. *Staphylococcus* produces a firm subcutaneous to dermal nodule, which may be alopecic, ulcerated, abscessed with or without numerous draining tracts. *Yersina pestis* (plague) infection commonly results in submandibular lymphadenopathy, fever and subcutaneous abscessation. L forms produce cellulitis 4–5 days after injury. The cellulitis spreads rapidly with the development of multiple fistulae and febrile response. Septic arthritis is a common sequel, and affected joints ulcerate producing a grayish mucinous exudate.

Mycobacterial:

- **Atypical mycobacterial infections*** (p 1085)**

Occur secondary to skin penetration, for example, the cat bite abscess that does not heal. Insidious progression from circumscribed plaque or nodule to multiple sinuses with seropurulent exudate, board-like fibrosis and pain on palpation. Occur mostly on the tail-base and ventral abdomen.

- **Feline leprosy* (p 1090)**

Mostly young cats (1–3 years). Non-painful, ulcerated nodules on the limbs and head.

- **Cutaneous tuberculosis (p 1093)**

Mostly caused by *M. bovis* from ingestion of unpasteurized milk. Abscesses, nodules, ulcers and plaques develop with thick green or yellow exudates. Many cats have other organ involvement including GIT, CNS or respiratory signs.

Fungal:

- **Sporotrichosis (p 1095)**

Traumatic implantation of fungi occur via vegetable foreign bodies, or secondary to a cat fight. Sporotrichosis is an important zoonosis. The cutaneolymphatic form is most common. It appears as a wound on a limb, with a tract of nodules which may ulcerate, extending along the local lymphatics.

- **Eumycotic mycetoma (p 1093)**

Occurs in geographic areas along the Tropic of Cancer. Infection occurs via wound contamination. Ulcerated papules or nodules on the limbs or face, which develop draining sinus tracts. Black or

continued

continued

white grains are evident in the mycetoma from the fungal hyphae. Black-grained – *Curvularia geniculata* and *Madurella grisea*. White-grained – *Pseudoallescheria boydii* and *Acremonium hyalinum*.

- **Pseudomycetoma (p 1094)**

Occurs exclusively in Persian cats. Subcutaneous nodules form mainly on the dorsum and may ulcerate. They represent granulomas from *Microsporum canis* infection. More typical signs of superficial dermatophytosis may be evident.

- **Cryptococcosis* (p 1089)**

Skin lesions occur as multiple or single papules and nodules, which often ulcerate. They may or may not occur with CNS, respiratory or ophthalmic signs. Most common sign is a firm swelling over the bridge of the nose or planum nasale, or a polyp-like mass in the nasal opening.

- **Pheohyphomycosis (p 1095)**

Occurs as a solitary nodule, usually on the paw, nose, limb or trunk. The lesion may ulcerate with sinus formation. Dissemination is rare.

- **Histoplasmosis, blastomycosis and coccidiomycosis* (p 1090)**

Chronically draining lesions together with dyspnea and weight loss. Blastomyces and coccidioidomyces are very rare in cats. Histoplasmosis is most frequent along Ohio, Missouri and Mississippi river valleys in the US.

Immune-mediated:

- **Feline eosinophilic granuloma complex*** (p 1088)**

Brightly erythemic plaque associated with incessant grooming of the site, or appears as an indolent ulceration of the upper lip adjacent the nasal philtrum. Oral ulcerations and nodules may be present.

- **Vasculitis and miscellaneous ulcerative dermatoses (p 1103)**

Ulcerations of extremities (nose, ear tips, tail tip and foot-pads). In some cats is associated with neoplasia or a drug reaction.

- **Erythema multiforme/toxic epidermal necrolysis (p 1105)**

Multifocal (erythema multiforme) or confluent (toxic epidermal necrolysis) ulceration and crusting of skin and mucous membranes.

Idiopathic:

- **Idiopathic feline ulcerative dermatosis (p 1103)**

Sudden appearance then insidious course of ulceration and crusting of the dorsal cervical area. Pruritus is variable but may be intense and not glucocorticoid responsive.

Toxic/drug:

- **Chemical dermatitis (p 1102)**

Hair loss, ulcers or crust-covered erosions on contact sites. Oral ulceration and ptyalism may result from ingestion of the chemical during grooming.

Trauma:

- **Traumatic panniculitis (p 1104)**

Non-antibiotic responsive, discharging wound in inguinal or dorsolumbar area which presents 2–3 weeks after blunt trauma at that site.

INTRODUCTION

MECHANISM?

Wound healing is characterized by chronologically overlapping phases of inflammation, proliferation (epithelial regeneration and fibroplasia), angiogenesis and tissue remodeling.

Wound healing is prolonged or prevented if there is **prolongation of inflammation** (e.g. because of infectious agents), or **proliferation is inhibited** (e.g. from ischemia, ongoing cellular injury, anti-mitotic drugs), or there is **inhibition of angiogenesis or altered tissue remodeling** (e.g. from increased tissue protease activity).

Each stage of wound healing is intrinsically interdependent. Interference at any stage can lead to a failure of wound healing.

Wounds that have **not resolved within 3 weeks** should be considered non-healing wounds.

WHERE?

Epidermis, dermis, panniculus and cutaneous blood vessels.

WHAT?

Non-healing wounds involving the **epidermis** are most commonly: neoplasia, viral, chemical toxicity, immune-mediated diseases and congenital abnormalities.

Non-healing wounds involving the **dermis** are most commonly: infectious agents, hypersensitivity diseases, neoplasia.

Non-healing wounds involving the **panniculus** are most commonly: infectious agents, traumatic ischemia.

Non-healing wounds involving **blood vessels** are most commonly: immune-mediated disease.

DISEASES CAUSING NON-HEALING WOUNDS

ATYPICAL MYCOBACTERIAL INFECTIONS***

Classical signs

- Alopecic plaques with multiple fistulae.
- Chronic serosanguineous exudate.
- Progressive subcutaneous fibrosis.
- Discomfort on palpation of skin.

Pathogenesis

Mycobacteria organisms are ubiquitous within the environment in soil and water. They enter the body via **penetrating wounds** including cat fights, vegetable foreign body and abrasions.

Organisms most frequently isolated include *Mycobacterium smegmatis*, *M. fortuitum*, *M. chelonae*, *M. thermoresistibile*, *M. xenopi*, *M. phlei*. They are selective for the panniculus because of their triglyceride requirement and the immunological advantage. The **complex cell wall structure allows mycobacteria to survive intracellularly**.

Clinical signs

Initially there is a **circumscribed plaque or nodule** that progresses to **alopecic areas** with **numerous fistulae**.

Serosanguineous exudates are typical.

Board-like thickening of the skin and **pain** is evident on palpation. Lesions occur most commonly on the **ventral abdomen and lateral flanks**.

There may be a **history** of trauma to skin.

Diagnosis

Diagnosis is based on **demonstration** of the **organism** in the exudate or in biopsied tissue.

Cytological examination of material obtained from the sinus tracts reveals **pyogranulomatous inflammation**. Ziehl–Neelsen (ZN) stain may show acid-fast bacilli.

Histopathological examination requires **deep biopsy** to include subcutaneous fat. Take a wedge section avoiding the sinuses. This is submitted in formalin for routine H&E stains, Gram stain for bacteria, Gomori methanone silver stain for fungi and ZN stain for mycobacteria. Histopathology reveals pyogranulomatous to granulomatous panniculitis with neutrophil-rimmed lipocysts. With ZN stain low numbers of **acid-fast bacilli** may be seen **within the lipocysts (extracellular)**.

Culture additional wedges biopsies collected. Sterilely trim off the epidermis, and submit the remaining tissue in a sterile, saline-moistened gauze swab for culture. Specifically request mycobacterial culture if suspected. Aspiration of wound fluid and rapid inoculation of a culture medium may be better than a deep tissue sample, if you have ready access to a laboratory that specializes in mycobacterial culture and identification.

PCR confirmation of mycobacteriosis and species identification is available at some laboratories.

Differential diagnosis

Differential diagnoses include **bacterial mycetoma, subcutaneous mycosis, sterile panniculitides**. Clinical signs can be indistinguishable if tissue grains are not evident. Special stains of histological sections and anaerobic, aerobic, fungal and mycobacterial culture allow for differentiation.

Treatment

Treatment involves **prolonged antibiotic therapy** (months) to reduce the size of the lesion **combined with surgical excision**.

Where possible, choice of antibiotic should be based on in-vitro sensitivities.

Commonly used drugs for atypical mycobacteria include **doxycycline** 5 mg/kg/day, **fluoroquinolones** 5 mg/kg/day, **clofazimine** 2–8 mg/kg/day and **clarithromycin** 10 mg/kg bid. **Combinations** may be considered where sensitivities are not known.

Surgery requires a wide excision. Extensive reconstruction may be required following excision of affected tissue.

Antimicrobial drugs should be continued for several months post-operatively.

Prognosis

Prognosis is guarded where extensive disease exists at the time of presentation. Early diagnosis, including identification of the organism, and aggressive surgical and antimicrobial treatment offers a more favorable outcome.

BACTERIAL INFECTIONS***

Classical signs

- Nodules, plaques or abscesses.
- Fistula formation.
- Serosanguineous to purulent to “tomato soup” exudate +/- tissue grains.

Pathogenesis

Infections usually involve **commensal mouth organisms** or **ubiquitous environmental organisms** introduced to the skin through traumatic implantation via claw wounds, bites, vegetable, foreign bodies, etc.

Organisms include:

- **Actinomyces** from oral and bowel flora.
- **Nocardia**, a soil saprophyte.
- **Staphylococcus** from the oral cavity.
- **Yersinia pestis** (plague) from a lagomorph or rodent reservoir and transmission via inhalation, ingestion or arthropod vector.
- **L forms** which are mutated from the parent organism.

Clinical signs

Actinomyces and **Nocardia** have **several different presentations** but dissemination is rare.

- **Cutaneous form** is associated with firm **subcutaneous to dermal nodules** which frequently are ulcerated, abscessed or contain numerous drainage tracts.
 - Head, neck, flank, thoracic and abdominal wall are the most common sites.

- The exudate often appears as “**tomato soup with sulfur granules**”.
- Regional lymph nodes are enlarged.
- Actinomycotic mycetoma are characterized by the triad of tumefaction, sinus tract formation and tissue grains within the exudate.
- **Effusive form** occurs in the chest or abdomen. Signs include fever and depression as well as respiratory distress or abdominal enlargement.
- Osteomyelitis form presents with lameness, fever and hyperesthesia.

Staphylococcus (botryomycosis) produces a firm subcutaneous to dermal nodule that may be alopecic, ulcerated, abscessed, with or without numerous draining sinuses.

- Visceral forms have been reported with symptoms varying dependent on organ involved.

Yersina pestis (plague) infection commonly results in submandibular lymphadenopathy, fever and subcutaneous abscessation.

- Septicemia has also been reported and mortality rates are up to 33%.

L forms produce **cellulitis** 4–5 days after injury. The cellulitis spreads rapidly with the development of **multiple fistulae** and febrile response.

- Lameness from septic arthritis is a common sequel. Joints are affected by hematogenous spread, and may be distant to the initial site. Lower limbs, especially the tarsus and carpus, are the most commonly affected.
- Most affected joints ulcerate producing a grayish mucinous exudate.
- There is no systemic spread of lesions throughout the body.

Diagnosis

Diagnosis is based on clinical signs and identification of the organism.

Cytological examination of exudates or a **squash preparation** of the “**sulfur granules**” may reveal the organism.

Biopsy and histological examination is often required to demonstrate organisms. **Special stains should be requested**, for example, Gomori Methanin Silver or Ziehl-Neelson (ZN) stains because organisms such as acid-fast bacilli, are not always visible on routine H&E.

Culture of deep tissue is required for successful diagnosis. A large tissue sample is best, for example, a cubic centimeter of tissue. Prepare the biopsy site as for sterile surgery, remove an elliptical biopsy which must include the subcutaneous fat, and avoid sampling sinuses because of surface contamination. Trim the epidermis and submit the remaining tissue in a sterile moistened swab within an air-tight sterile specimen container for culture.

- Request aerobic, anaerobic, fungal and mycobacterial culture.
- If copious exudate is present, aspirate the exudate into a sterile syringe, cap the syringe and submit for culture.

For plague, culture is a public health risk.

Indirect fluorescent antibody testing of a fine-needle aspirate, or of tissue collected by biopsy gives the fastest diagnosis for plague. False negatives can occur.

Serology for plague requires two blood samples to demonstrate an increasing titer. Maximum titer occurs at day 12 after infection, therefore the first sample for serology must be collected early to be useful.

L forms are **not visible in tissue samples** even with special stains, and **do not grow on culture**. On electromicroscopy, organisms are visible **intracellularly within phagocytes**. Diagnosis is often made by response to tetracyclines as a therapeutic trial.

Differential diagnosis

Differential diagnoses that should be considered include atypical mycobacteriosis, cutaneous tuberculosis, dermatomycoses, foreign bodies, sterile and nutritional panniculitides and neoplasia.

Treatment

Treatment differs depending on the organism

Nocardia: treatment involves lavage, drainage and debridement combined with long-term antimicrobial therapy (enrofloxacin 5 mg/kg). Treatment should continue for several months after all lesions resolve.

Actinomyces: Penicillin is the drug of choice (e.g. amoxycillin 12 mg/kg twice daily). This should be combined with **en bloc excision of lesions**, and careful

search for foreign bodies. Treatment course should be prolonged for 3–4 months.

Botryomycosis: **En bloc excision** combined with long duration anti-staphylococcal **antimicrobials** (e.g. cephalaxins 22 mg/kg twice daily).

Plague: **aminoglycosides, tetracyclines and trimethoprim-sulfur** are effective, but penicillins are not.

L forms: are exquisitely sensitive to **tetracyclines** (e.g. doxycycline 5 mg/kg/day).

Prognosis

Prognosis varies from fair to good depending on the practicality of surgical excision, and presence or absence of dissemination.

Prevention

For plague, strict flea control in endemic areas is indicated.

Zoonotic potential

Plague (*Yersinia pestis*) is an important zoonotic organism, and great care should be taken so that human infection does not occur from suspect cats. The relevant authorities should be notified.

FELINE EOSINOPHILIC GRANULOMA COMPLEX ***

Classical signs

- Glistening, erythemic plaque (eosinophilic plaque).
- Ulceration of the upper lip adjacent the philtrum (indolent ulcer).

Pathogenesis

Eosinophilic plaque and **indolent ulceration** are cutaneous reaction patterns in cats associated with allergic skin disease.

Clinical signs

Eosinophilic plaque presents as variably sized, alopecic, glistening, red plaques most commonly found on the **ventral abdomen and medial thighs**.

Indolent ulceration presents as a progressive erosion on the **upper lip and/or nasal philtrum** region.

Diagnosis

Diagnosis is based on clinical and histological appearance.

Histopathology of eosinophilic plaque shows severe spongiosis, and intense neutrophilic and eosinophilic dermal infiltration. Peripheral blood eosinophilia is often present.

Indolent ulceration has a very characteristic clinical appearance. Histopathology is non-specific but rules out neoplasia. Blood eosinophilia is absent.

It is important to note that **indolent ulcer and eosinophilic plaque are clinical symptoms**, and are not a diagnosis. **The underlying allergy needs to be determined.**

- **Allergy investigation** involves a flea elimination trial, a food allergy trial using a novel protein for 6–12 weeks, and intradermal skin testing for atopy.

Differential diagnoses

Differential diagnoses which should be considered for **eosinophilic plaque** include pyoderma, lymphoma and mast cell tumor.

The **differential diagnosis** to consider for **indolent ulcer** is neoplasia.

Treatment

Specific treatment involves treating the underlying cause using flea control, dietary allergen avoidance or hyposensitization for aeroallergies.

Non-specific treatment to reduce inflammation involves use of **corticosteroids** (2–4 mg/kg daily) until signs are controlled, and then reducing dose to low-dose alternative day therapy.

- **Chlorambucil, aurothioglucose and progestagens** may be indicated if specific therapy and corticosteroids are not effective. Use of progestagens is discouraged because of the high incidence of drug-induced complications.
- **Cyclosporin 5 mg/kg/d (not registered for use in cats).**

Prognosis

Prognosis is good if the allergy is identified, and signs can be controlled with specific therapy.

SQUAMOUS CELL CARCINOMA (SCC)**

Classical signs

- Proliferative and/or ulcerative lesions on non-pigmented facial extremities.

See main references on page 1069 for details (The Cat With Skin Lumps and Bumps).

Clinical signs

Squamous cell carcinoma affects **any gender or breed of cat**, and the **average age** of affected cats is **9 years**.

The **pinnae, philtrum, nares, forehead and palpebrae** are the most affected sites, especially in non-pigmented, thinly haired areas.

Lesions are multiple in 45% of affected cats.

Lesions may be **proliferative or ulcerative**, and occasionally cutaneous horns are seen.

SCC tends to be **locally invasive** and **slow to metastasize**.

Nail-bed SCC behave more aggressively.

Diagnosis

Diagnosis is based on histopathology of the lesion which shows **irregular cords of keratinocytes** which breach the dermo–epidermal junction and invade the dermis. Cellular atypia, dyskeratosis, loss of cellular orientation with or without solar elastosis may be evident.

CRYPTOCOCCOSIS*

Classical signs

- Soft tissue swelling over the bridge of the nose (Roman nose) or polyp in nasal opening.
- Single or multiple papules or nodules in the skin which may ulcerate.

See main references on page 25 for details (The Cat With Signs of Chronic Nasal Disease) and page 847 (The Cat With a Head Tilt, Vestibular Ataxia or Nystagmus).

Clinical signs

Typically there is a **firm swelling over the bridge of the nose** or planum nasale giving the appearance of a Roman nose, or there is a **polyp-like mass visible in the nasal opening**.

Cutaneous lesions occur in up to 40% of cases, and consist of **papules or nodules** varying from 0.1–1 cm in diameter.

Lesions may ulcerate and exude serous fluid, or remain as intact nodules.

Skin lesions may be **single or multiple**, and occur alone, or with involvement of other organs.

Lesions favor **face, pinnae and paws**, and can occur with or without co-existent respiratory, CNS or ophthalmic signs.

Diagnosis

Diagnosis is based on clinical signs and **demonstration of the organism** in association with the lesion.

Cytological examination of fluid draining from a skin lesion, nasal exudate, a fine-needle aspirate of a skin nodule, spinal fluid, vitreal or aqueous paracentesis stained with **new methylene blue** (NMB) and Gram stains usually demonstrates the organism. Organism is **yeast-like** (5–15 µm) and is surrounded by a **wide, clear capsule**.

Serology to detect cryptococcal capsular antigen in blood, CSF or urine is useful if positive. Note that this test may be negative when the disease is localized to the skin.

Tissue biopsy can be used to identify the **pleomorphic yeast-like organisms with a refractile halo** (mucinous capsule). PAS and methanamine silver stains make the organisms more readily detectable.

Differential diagnosis

Differential diagnoses that should be considered for the cutaneous form of cryptococcosis include feline

leprosy, atypical mycobacteria, bacterial granuloma, other fungal granulomas, xanthoma and neoplasia.

FELINE LEPROSY*

Classical signs

- Young cats in coastal locations.
- Painless, ulcerated nodules on head and/or limbs.

Pathogenesis

The causative agent of feline leprosy is thought to be *Mycobacterium lepraemurium*.

Infection is probably acquired from cats **contacting rodents**. Cat-to-cat transmission has not been reported.

The incubation period is **2–12 months**. Immuno-deficiency is not needed for infection to occur.

Clinical signs

Typically occurs in young cats in coastal locations.

Multiple or single cutaneous nodules mostly on the head and limbs.

Lesions are **painless, and often ulcerated**, but rarely fistulated or exudative.

Local lymphadenopathy may be seen but visceral dissemination is rare.

Diagnosis

Diagnosis is based on clinical signs and demonstration of the organism.

Cytological examination demonstrates **pyogranulomatous inflammation with intracellular acid-fast bacilli**.

Histopathology shows **tuberculoid or lepromatous forms** of the organism.

Culture is rarely used in diagnosis because the organism has fastidious growth requirements.

PCR where available.

Treatment

Treatment is best accomplished via a **wide surgical excision**.

Spontaneous remission has been reported.

The organism has been reported to respond to **fluoroquinolones and clofazamine**. Dose of clofazamine is 2–8 mg/kg daily then twice weekly for 1–2 months. Reversible pinkish-orange discoloration of the skin and elevated liver enzyme (alanine transferase) have been reported.

Zoonotic potential.

There is no zoonotic potential.

HISTOPLASMOSIS, BLASTOMYCOSIS AND COCCIDIOMYCOSIS*

Classical signs

- Dyspnea.
- Weight loss.
- Chronically draining skin lesions.

See main references on pages 371, 387 for details (The Pyrexia Cat) and page 755 details (The Cat With Signs of Chronic Small Bowel Diarrhea).

Clinical signs

Histoplasmosis is most frequent along Ohio, Missouri and Mississippi river valleys in the US. Blastomyces and coccidiomyces are very rare in cats.

Clinical signs are often non-specific and include fever, anorexia and weight loss.

Dyspnea and harsh lung sounds without coughing is common in histoplasmosis and blastomycosis, but occurs in only 25% of cats with coccidiomycosis.

Solitary, regional or generalized peripheral and visceral **lymphadenopathies** are frequently present.

Pale mucous membranes, icterus, hepatomegaly or splenomegaly may be evident, most often with histoplasmosis.

Chronically draining skin lesions are the most frequent sign of infection in cats with coccidiomycosis, and were reported in 56% of cats in one study.

- Lesions begin as small bumps and progress to abscesses, ulcers or draining tracts.

- **Draining skin lesions** may occur in blastomycosis and are usually a manifestation of systemic disease rather than local disease.
- Skin lesions may occur with histoplasmosis.

Ocular signs are common with blastomycosis, but infrequent with histoplasmosis and coccidiomycosis, and may include conjunctivitis, anterior uveitis, retinal detachment or chorioretinitis.

Gastrointestinal signs may occur infrequently with histoplasmosis, and include chronic diarrhea and mesenteric lymphadenopathy.

Osseous lesions produce soft tissue swelling and lameness.

Diagnosis

Diagnosis is based on the history of travel to endemic area, clinical signs and **identification of the organism** in cytological or histological samples.

Serology may be useful for diagnosis of blastomycosis and coccidiomycosis, but is unreliable for histoplasmosis.

Culture for histoplasmosis is not recommended in a veterinary practice because the organism is a dangerous zoonotic.

Direct animal-to-animal, or animal-to-human transmission has not been reported, and infection occurs from a common environmental source.

Differential diagnoses

Differential diagnoses that should be considered include disseminated mycobacteriosis, feline plague and neoplasia.

POX VIRUS (FELINE COWPOX)*

Classical signs

- Focal ulcer, or large abscess with cellulitis.
- Followed 7–10 days later by generalized small (0.5–1 cm) crusted ulcers.
- Occurs in roaming adult male cats.

See main references on page 1113 for details (The Cat With Paw or Pad Problems).

Pathogenesis

Orthopoxvirus infection causing **feline cowpox** is not uncommon in Western Europe.

Transmission is via **direct contact** with **rodents**, usually through a bite or already broken skin. The oronasal route of transmission may also be possible.

Disease occurs mostly in **male free-roaming adult cats**.

The viremic stage virus is transported via monocytes.

Clinical signs

Primary lesions vary from a **small ulcer on the head or limbs**, to a **large abscess with cellulitis**. Secondary lesions appear 7–10 days later as generalized small (0.5–1 cm) crusted ulcers.

Mild **lethargy**, **anorexia** and **coryza** occur.

With immunosuppression, for example with concomitant FIV, **pneumonia** and **non-healing wounds** may occur.

Pneumonia is a poor prognostic sign.

In immunocompetent cats, host **healing occurs within 4–6 weeks**.

Diagnosis

Diagnosis is based on finding **characteristic histopathological changes**, consisting of typical ballooning degeneration and viral inclusion bodies within the epidermis.

Viral culture can be used for definitive diagnosis of the virus.

Differential diagnoses

The **differential diagnosis** which should be considered for the primary lesions is a cat bite abscess; for secondary lesions, causes of miliary dermatitis should be considered. In immunocompromised cats, bacterial and fungal granulomas, systemic mycoses, tuberculosis and neoplasia are differentials.

Treatment

No specific treatment is available.

Antibiotics and symptomatic treatment should be used where indicated.

Corticosteroids are contra-indicated.

Prognosis

Prognosis is good in an immunocompetent cat and spontaneous resolution occurs in 4–6 weeks.

Transmission

Scabs shed virus, which survives in cool dry environs for **months to years**.

Cats represent a common **zoonotic threat** to people. Normal hygiene measures generally suffice for prevention.

FELINE HERPES VIRUS*

Classical signs

- **Non-healing ulceration of the dorsal nasal bridge or nasal planum.**

See main references on page 7 (The Cat With Acute Sneezing or Nasal Discharge) and page 1212 and page 1208 (The Cat With Ocular Discharge or Changed Conjunctival Appearance).

Pathogenesis

Feline rhinotracheitis is an α herpesvirus.

Trauma may initiate nasal lesions.

Clinical signs

Chronic non-healing ulceration or erosion on the **nasal planum or dorsal nasal bridge** may occur with herpesvirus infection.

Ulceration can also occur elsewhere, including on the paws.

The cat may or may not have signs of concurrent ocular or respiratory disease.

Diagnosis

Histopathological examination of a biopsy shows **eosinophilic dermal inflammation**. In acute lesions, basophilic, intranuclear **inclusion bodies** may be evident within the epithelium at the margin of the ulcer.

Demonstration of feline herpesvirus 1 in tissue from the ulcer by **PCR** is available from some laboratories.

Virus culture is available from some laboratories.

Virus can be demonstrated in lesional tissue with **electron microscopy**, but this is not routinely available.

Differential diagnosis

Chronic non-healing erosions on the nasal planum or bridge of the nose may occur with mosquito bite hypersensitivity, squamous cell carcinoma and eosinophilic granuloma complex. Differentiation is based on appearance of the lesion and any other associated lesions, and biopsy with histopathology.

Treatment

Lysine supplementation (250 mg PO daily).

Prognosis

Based on reports in the literature, it suggests a guarded prognosis. However in the author's experience, lysine therapy has resulted in resolution of the ulcer.

MAST CELL TUMOR*

Classical signs

- **Single to multiple tumors on the head of older cats.**
- **Tumors may “enlarge” after palpation or aspiration.**
- **Rarely young Siamese cats have multiple nodules around the head.**

See main references on page 1074 for details (The Cat With Skin Lumps and Bumps).

Clinical signs

The average age of cats with mast cell tumors is **10 years**, and there is no sex or breed predisposition.

Tumors may occur at any site, but the **head is most frequently affected**.

Appearance varies from a **discrete solitary nodule** to **multiple papulonodular tumors** to a **plaque-like mass**.

Skin tumors may “enlarge” and become erythematous after palpation or aspiration.

Paraneoplastic syndromes may be evident including gastrointestinal tract ulceration, delayed wound healing, hypotension, cutaneous flushing, local ulceration and swelling and coagulation abnormalities.

Histiocytic mast cells tumors are uncommon, occur as multiple skin nodules around the head of cats less than 4 years of age (mean age 2.4 years) and Siamese are predisposed.

Diagnosis

Diagnosis is based on demonstration of characteristic mast cells associated with a skin mass. Fine-needle aspirate shows **round cells with granules**, which stain well with Wright’s stain.

Histopathological examination shows a **round cell tumor with variable pleomorphism** and granule formation, which is dependent on the grade of the tumor.

Abdominal radiology, ultrasound and laparotomy may be useful for staging the tumor.

CUTANEOUS TUBERCULOSIS

Classical signs

- Yellow/green thick purulent exudate from skin lesions.
- Lymphadenopathy.
- GIT, respiratory, CNS or ophthalmic signs.

Pathogenesis

Mycobacterium bovis is the causative agent in 96% of cases. *M. tuberculosis*, *M. avium* and *M. microti* have also been reported.

The reservoir of *M. bovis* is **infected cattle**.

Cats are infected via ingestion of **unpasteurized milk** or **eating contaminated meat** or **offal**.

M. tuberculosis is a reverse zoonosis.

The method of transmission with *M. avium* and *M. microti* is unknown. It may involve the cat’s natural predation of rodents and birds.

Incubation period in natural infections is **months** to greater than **one year**.

A breed susceptibility for *M. avium* infections has been reported in the **Siamese** cat.

Clinical signs

Skin lesions are usually part of a more generalized disease, evident in 56% of cases.

Single or multiple **ulcers, abscesses, plaques** or **nodules** with thick green or yellow **purulent exudate**.

Additional signs vary with route of entry and degree of dissemination of the organism, and may include **GIT, respiratory, CNS or ophthalmic signs**.

Diagnosis

Diagnosis is based on clinical signs and **identification** of the **organism**.

History, physical examination, radiography, urinalysis and blood testing (hematology and biochemistry) are important in the diagnostic work-up.

Cytological examination may reveal **acid-fast bacilli** in **skin aspirates or biopsies**, or in **urine**.

On microbiological culture the organisms are **slow to grow**, and require **special media**.

Intradermal skin testing with BCG or purified protein derivative (PPD) is not reliable.

Serological testing is unreliable in cats.

EUMYCOTIC MYCETOMA

Classical signs

- Papules or nodules on the limbs and face.
- Sinus formation.
- White or black tissue grains in the mycetoma.

Pathogenesis

Eumycotic mycetomas are **subcutaneous fungal infections**.

Organisms are ubiquitous in soil. **Infection occurs via wound contamination.**

Most frequently occurs in geographic areas along the Tropic of Cancer.

Black-grained mycetomas are produced by *Curvularia geniculata* and *Madurella grisea*.

White-grained mycetomas are produced by *Pseudallescheria boydii* and *Acremonium hyalinum*.

Clinical signs

Solitary papules occur on the **limbs and face**, and evolve to painful nodules and fistulae, resulting in sinus tracts.

White or black tissue grains are evident in the mycetoma, which represent the fungal hyphae.

Infection may involve the underlying deeper structures.

Diagnosis

Diagnosis is based on clinical signs and **demonstration of the organism**.

For **cytological examination**, make a squash preparation of the tissue grains. Gritty grains may need 10% KOH digestion first. Fungal hyphae are visible microscopically.

Histopathological examination reveals **granulomatous to pyogranulomatous inflammation** and **tissue grains of fungal hyphae**.

Culture requires special media using SDA.

Immunodiffusion is available in some laboratories. Some fungi can be diagnosed by serum testing for specific antibodies with agar immunodiffusion. Tissue samples may also be stained with fluorescein conjugated with specific antibodies.

Differential diagnosis

Differential diagnoses that should be considered include mycobacterial infections, neoplasia, actinomy-

cotic mycetoma, pseudomycetoma, botryomycosis, foreign bodies and chronic bacterial abscesses.

Treatment

Wide surgical excision is the treatment of choice, which may require limb amputation to remove sufficient tissue.

Antifungal therapy is often ineffective. The imidazoles are worth trying where in vitro sensitivities are not available, for example itraconazole (10 mg/kg twice daily). Anorexia and elevated liver enzymes are the most frequently encountered adverse effects.

Prognosis

Cutaneous mycetomas are not life threatening, but **can be difficult to resolve if wide surgical excision** is not possible.

PSEUDOMYCETOMAS

Classical signs

- Exclusively Persian cats.
- Subcutaneous nodules often together with superficial dermatophytosis.

Pathogenesis

Pseudomycetomas represent **subcutaneous infection caused by the dermatophyte, *Microsporum canis***.

They occur **exclusively in Persian** cats and immune incompetence has been suggested.

Clinical signs

Non-painful subcutaneous nodules that may **ulcerate and drain**.

Most occur on the dorsum.

The nodules may or may not be associated with obvious superficial dermatophyte infection.

Diagnosis

Diagnosis is based on signalment (Persian cats), signs and demonstration of organism.

On **histopathological examination** a Splendori-Hoepli reaction is evident, which consists of **fungal hyphae surrounded by amorphous eosinophilic material**, which represent antibody–antigen complexes. PAS stains show up the fungal hyphae.

Examine coat for signs of superficial infection using a Wood's lamp, and sterile coat collection using the toothbrush technique and **culture for *M. canis***.

Assess the immune status of the cat and determine if intercurrent disease is present using hematological, biochemistry, urinalysis, FeLV and FIV testing.

Differential diagnosis

Differential diagnoses that should be considered include bacterial, fungal and mycobacterial granulomas and neoplasia.

Treatment

If there is a single lesion, **surgical excision** is the treatment of choice.

Medical treatment using **itraconazole** (20 mg/kg daily) for several months may be effective. Anorexia may occur and reflect hepatopathy and require cessation of therapy.

SPOROTRICHOSIS

Classical signs

- Chain of subcutaneous nodules following the lymphatic tract, and extending away from primary wound.

Pathogenesis

Sporothrix schenckii is the causative organism, and is ubiquitous in **soil and organic debris**, especially in humid environs.

Infection occurs via **traumatic inoculation** via a **vegetable foreign body, cat claw**, or via wound contamination.

Clinical signs

The **cutaneous form** looks similar to a **cat bite abscess**.

The **cutaneolymphatic form** has corded **lymphatics with secondary ulcerations** occurring **along the lymph pathway**, extending away from the primary wound.

The disseminated form is rare.

Diagnosis

Diagnosis is based on identification of the organism.

Cytological examination shows numerous **pleomorphic yeasts**, which may be intra- or extracellular.

Histopathological examination reveals **oval, round or cigar-shaped organisms**. PAS and GMS stains facilitate identification.

Immunoperoxidase or fluorescent antibody techniques are useful if tissue numbers are low. This is usually not required in cats.

Culture from a **deep sinus tract swab or tissue biopsy** for definitive identification of organism.

Differential diagnosis

Differential diagnoses that should be considered include bacterial, mycobacterial, fungal granulomas, neoplasia, sterile panniculitis.

Treatment

Traditional therapy involved use of a saturated solution of **potassium iodide** (SSKI; 20 mg/kg PO q 12–24 h) administered for 30 days beyond clinical cure. Cats are **susceptible to iodism**, and many develop signs including anorexia, vomiting, depression, twitching, hypothermia and cardiovascular failure.

Ketaconazole (5–10 mg/kg twice daily) either singly or together with potassium iodide has been used successfully. Gastrointestinal, neurological signs and jaundice are reported associated with ketaconazole use.

Newer **imidazoles** may be useful, such as itraconazole (10 mg/kg/day PO).

Surgical excision is useful for the cutaneous form, where wide excision is possible.

Prognosis

Prognosis is guarded for all but the localized cutaneous forms.

Sporothrix is a serious zoonosis. In households with young children or immunosuppressed adults, it may be unwise to treat the cat because of the risk of infection.

Prevention

To prevent zoonotic infections, all discharging non-healing wounds in cats, especially where lymphatic cording is present, should be handled with great caution using gloves, careful cleaning after handling, etc.

PHEOHYPHOMYCOSIS

Classical signs

- Ulcerated nodule on the nose or limb.

Pathogenesis

Fungi reported in cats associated with pheochromocytosis include *Dresclera spicifera*, *Curvularia lunata* and *Exophiala jeanselmei*.

These are **saprophytic** fungi that produce dermataceous (dark) hyphal elements in tissues. They occur most commonly in **tropical or subtropical areas**.

Infection is by **traumatic implantation** via cat claw wounds or a plant foreign body.

Immunosuppression increases susceptibility.

Clinical signs

Pheohypomycosis occurs as a **solitary nodule**, usually on the **paw, nose, limb or trunk**.

The lesion may **ulcerate with sinus formation**.

Dissemination is rare.

Diagnosis

Diagnosis is based on **identification of the organism** associated with the lesion.

Cytological or histological examination can be used to identify **pigmented fungal elements**.

Definitive diagnosis is based on **culture** on SDA at 25–35°C, and identification of the organism.

Assess for concurrent immunosuppressive disease by testing for FIV and FeLV.

Differential diagnosis

Differential diagnoses that should be considered include bacterial, fungal and mycobacterial granulomas and neoplasia.

Treatment

Treatment of choice for the cutaneous form is **wide surgical excision**. Where wide surgical excision is not possible, amphotericin B combined with an imidazole such as itraconazole, and/or cryotherapy may be tried, although relapse is common.

Prognosis

Prognosis is good if surgical excision is possible, although relapse may occur. The disseminated form has a grave prognosis.

MULTICENTRIC SQUAMOUS CELL CARCINOMA IN SITU

Classical signs

- Multifocal, hyperkeratotic or ulcerated plaques.
- Occur on pigmented, thickly haired skin of older cats.

Pathogenesis

Papilloma virus antigen has been detected in some lesions.

Ultraviolet radiation and arsenicals are not thought to play a role.

Clinical signs

Lesions are found in **older cats** (> 10 years usually).

Multifocal lesions occur over the **head, neck, shoulders and forelimbs** on **pigmented, thickly haired skin**.

Begin as hyperkeratotic macules and evolve to **thick-crusted, ulcerated plaques**.

The neoplasia often have a long course **over a couple of years**, with **waxing and waning signs**.

Diagnosis

Diagnosis is based on **histopathological findings**.

Excise the lesion and submit for histopathology. Histologically, there is abrupt transition from normal to atypical epithelium. The **dermo-epidermal junction is not breached**.

Differential diagnosis

Differential diagnoses which should be considered include mycobacterial, fungal and bacterial granulomas and other neoplasia.

Treatment

Treatment of choice for **thin lesions** is **beta radiation**. Treatment does not prevent new lesions.

Etretinate and isotretinoin can be used in thicker lesions, but the response is variable.

Prognosis

Cats are often euthanized for cosmetic reasons and owner frustration at poor response to therapy.

Metastases have not been reported.

MELANOMA

Classical signs

- Ulcerated, pigmented nodule on head or neck.

See main references on page 1079 for details (The Cat With Skin Lumps and Bumps).

Clinical signs

Melanoma typically occurs in **older cats of any breed** (average age is 10 years).

Tumors usually occur as **solitary lesions** on the **head or neck**.

Size and shape are variable ranging from a **dome**, to a **plaque or polypoid shape**, and ulceration is frequent.

Diagnosis

Diagnosis is based on histopathological examination of an excisional biopsy. Characteristic findings are **atypical melanocytes in nests, sheets and cords**. Cells may exhibit epithelioid or spindle morphology or a combination of both.

BASAL CELL CARCINOMA (BCC)

Classical signs

- Pigmented, cystic tumor on head or neck of older cats.

See main references on page 1070 for details (The Cat With Skin Lumps and Bumps).

Clinical signs

Basal cell carcinoma occurs frequently as a **pigmented and/or cystic tumor of the head, neck, thorax, nasal planum or eyelids in older cats**.

Usually occur as a **solitary tumor** and are **frequently ulcerated**.

Diagnosis

Diagnosis is based on histopathology.

CUTANEOUS LYMPHOMA

Classical signs

- Alopecia and scale.
- Erythroderma.
- Hypopigmentation of hair or skin and mucocutaneous junctions.
- Nodules or plaques which often ulcerate.

See main references on page 1078 for details (The Cat With Skin Lumps and Bumps).

PATHOGENESIS

Cutaneous lymphoma is a **very rare tumor** in cats, and results when **malignant T or B lymphocytes infiltrate** the skin.

Most cases are **FeLV negative**.

Clinical signs

Signs of **epitheliotropic T cell tumors** (mycosis fungoides) include “non-inflammatory” alopecia, scaling, erythroderma (diffuse reddening of the skin), hypopigmentation of hair or skin, ulceration, plaques and nodules.

B cell neoplasia shows **dermal nodules** with or without ulceration, and with or without lymphadenopathy.

Systemic signs of weight loss, diarrhea and respiratory distress may be present.

Diagnosis

Diagnosis is based on clinical signs and histological examination of biopsied tissue.

Fine-needle aspirate and cytological identification of abundant malignant round cells is useful to establish a presumptive diagnosis.

Histopathological examination is required for a definitive diagnosis to demonstrate diffuse infiltrates of malignant, poorly differentiated lymphoid cells. The epitheliotropic form has Pautrier’s microabscesses, which are focal aggregates of neoplastic T cells in the epidermis.

Blood evaluation, radiographs, ultrasound, lymph node aspirates and bone marrow biopsy are important for clinical staging.

Differential diagnosis

Differential diagnoses for the **epitheliotropic form** include systemic lupus erythematosus, dermatophytosis, demodicosis, cutaneous flushing syndromes, drug eruption and hypersensitivities.

Differential diagnoses for the **nodular forms** include bacterial and fungal granulomas and other neoplasia.

Treatment

Retinoides (vitamin A analogs), such as isotretinoin (Accutane) or acitretin (Soriatane) can be used for palliative treatment of the epitheliotropic form (**mycosis fungoides**).

B cell lymphoma is treated with excision of solitary lesions and standard lymphoma protocols. Excisional surgery may be curative for solitary lesions. Small lesions may respond well to superficial radiation therapy. Results of chemotherapy for multiple lesions are often disappointing.

Prognosis

Prognosis is poor.

Cats with small solitary lesions may do well initially with surgical excision, but generalized disease is likely to occur within 12 months.

The epidermotropic form often has an insidious progression.

ACQUIRED CUTANEOUS FRAGILITY SYNDROME

Classical signs

- Large tears in paper-thin skin.
- Evidence of underlying disease, e.g. hyperadrenocorticism.

Pathogenesis

Dermal and epithelial atrophy occurs secondary to **hyperadrenocorticism**, **progestagen** administration or metabolic conditions and diseases such as **starvation**, **neoplastic cachexia**, **diabetes**, etc.

Clinical signs

Skin is **thin** (atrophic) and mechanically weak, and may **spontaneously tear**.

Skin is **fragile but not hyper-extensible**.

Diagnosis

Cutaneous signs are very characteristic.

Histopathological examination reveals **epidermal and dermal atrophy**.

Identification of the underlying pathology may require hematological and serum biochemistry examination, urinalysis, radiology, ultrasound and specific endocrine testing.

Differential diagnosis

The main differential diagnosis is **cutaneous asthenia**.

Treatment

Correct the underlying pathology.

Avoid trauma to the skin, or exerting tension on the skin while restraining the cat.

Prognosis

Prognosis is variable, and is dependent on the initiating cause.

XANTHOMA

Classical signs

- Yellowish, ulcerated nodules or plaques over bony points.
- Associated with hyperlipidemia.

See main references on page 570 for details (The Cat With Hyperlipidemia).

Clinical signs

Xanthoma appear as **alopecic nodules and plaques** which are **often ulcerated** on foot pads, lateral hocks, elbows, oral cavity or at sites of injury.

They often have a **whitish** or yellowish **waxy appearance**.

Cutaneous xanthomatosis has been described in cats with diabetes mellitus and is associated with hyperlipidemia.

Most common in cats associated with hyperlipidemia.

Diagnosis

Definitive diagnosis is based on histopathological evidence of **Touton giant cells**, which are considered pathognomonic.

History taking including drug history, physical examination and blood testing is required to differentiate primary and secondary hyperlipidemia.

Differential diagnosis

Differential diagnoses which should be considered include eosinophilic granuloma complex, bacterial and fungal granulomas and neoplasia.

METABOLIC EPIDERMAL NECROSIS (MEN)

Classical signs

- Crusting, erosions and erythema of mucocutaneous junctions and bony protuberances.
- Pad hyperkeratosis.

Pathogenesis

Metabolic epidermal necrosis is the **cutaneous manifestation of hepatic** and occasionally **pancreatic disease**.

- Other terms include superficial necrolytic dermatitis, necrolytic migratory erythema (NME) and hepatocutaneous syndrome.

Metabolic epidermal necrosis has been associated with **hepatic and pancreatic disease** in cats, but is poorly understood. It is possible that the pathological process causing the skin lesions is triggered by a variety of systemic metabolic derangements.

- Deficiencies in certain nutrients such as amino acids, zinc, essential fatty acids and biotin may cause keratinocyte degeneration.
- Because low plasma amino acid concentrations were found in dogs and high-quality protein diets or supplementation with egg leads to resolution of signs in some animals, it has been postulated to be associated with an **amino acid deficiency**.

In dogs and people it is associated with **glucagon-secreting tumors** and a variety of other diseases not associated with a hyperglucogonemia, especially hepatic disease. The role of glucagon is not understood, but it is postulated to affect catabolism of amino acids to glucose.

In cats it has been reported with pancreatic carcinoma, chronic hepatopathy and thymic amyloidosis.

Clinical signs

Alopecia, erythema, crusts, erosions and ulceration of the skin most frequently seen at mucocutaneous junctions and frictional areas of the skin. The skin can be thickened and may become fissured.

- The skin lesions are often **secondarily infected** with bacteria or yeast.

Footpads show marked hyperkeratosis and fissuring.

Diagnosis

Diagnosis is based on **histopathological examination** of the skin lesions and demonstration of **diffuse parakeratosis**, which includes follicles, epidermal pallor, basal cell hyperplasia (red, white and blue effect).

Measurement of **plasma glucagon** concentration is indicated to rule out a glucagonoma.

Diagnosis of the hepatic or pancreatic disease requires **serum biochemistry analysis** to demonstrate increased liver enzymes, and **ultrasound** to demonstrate liver or pancreas pathology.

Hepatic or pancreatic biopsy via ultrasound guidance or exploratory laparotomy is usually needed for definitive diagnosis of the underlying condition.

Differential diagnosis

Differential diagnoses include bacterial and fungal infections, neoplasia and pemphigus foliaceus.

Treatment

Treatment should be directed at controlling the underlying disease and nutritional support.

Amino acid supplements can be given by feeding a cooked egg yolk daily, and/or feeding a commercial

recovery diet containing high-quality protein and increased levels of amino acids.

- A slow IV **infusion of an amino acid** formulation designed for parenteral administration has been used successfully in some patients.

Supplementation with **zinc and essential fatty acids** may help some patients.

Anti-malassezial shampoos (miconazole containing) may help control the skin lesions.

Surgical resection of glucagonoma is indicated if present.

Prognosis

Prognosis is poor for long-term survival.

CUTANEOUS ASTHENIA

Classical signs

- Fragile, hyperextensible skin which tears easily.
- Focal necrosis and paperaceous scars.
- Patchy alopecia.

Pathogenesis

Cutaneous asthenia results from a **congenital defect of collagen I synthesis**.

Clinical signs

Cutaneous asthenia appears as **hyperextensible skin** and/or “**spontaneous**” **tearing of the skin**.

Focal necrosis of the skin (necrotic eschars), particularly involving the dorsal neck, may occur.

Numerous **paperaceous scars** and patchy alopecia may be evident.

Hematomas may occur.

Occasionally joint laxity and/or ophthalmic opacities are seen.

Diagnosis

Diagnosis is based on **clinical appearance** and **increased extensibility index** of the skin. An extensibility index of greater than 19% is considered abnormal.

- The extensibility index is measured by stretching the skin dorsally within pain limits. The vertical height of this skin fold is expressed as a percentage of the crown to rump length.

Histopathological examination with routine H&E is **not diagnostic**. Masson's trichrome stain, which is designed to stain dysplastic collagen red and normal collagen blue, has been reported to be a sensitive indicator of this disease. However, the author has not found this stain to be helpful in Burmese cats.

Electron microscopy is the definitive test and shows **irregular orientation of collagen fibrils**.

Differential diagnosis

The differential diagnosis which should be considered is acquired cutaneous fragility secondary to hyperadrenocorticism, progestagen administration, or other metabolic conditions. Importantly, the **skin is fragile but not hyperextensible** in acquired cutaneous fragility.

Treatment

Management involves **avoiding injury** by keeping the cat indoors, and taking care when handling the cat not to exert tension on the skin.

Suture tears rapidly to prevent further tearing.

Prognosis

Most cats can have a good-quality life if trauma is minimized.

EPIDERMOLYSIS BULLOSA

Classical signs

- Ulcerative lesions in young kittens.
- Nail shedding.

Pathogenesis

Epidermolysis bullosa results from a **congenital defect of the dermo-epidermal junction** of the skin.

The disease is classified as epidermolysis bullosa simplex, junctional epidermolysis bullosa and dystrophic epidermolysis bullosa, depending on the ultrastructural defect.

Clinical signs

Signs appear in **kittens often by 5–12 weeks of age**, at the time of increased activity and mechanical stress on the skin.

Signs include **nail shedding, foot pad ulceration, hard palate ulceration** or **skin ulceration** in frictional sites.

Diagnosis

Clinical signs in a young kitten are highly suggestive.

Histopathological examination of skin shows **dermo-epidermal separation** (cleft formation) without inflammation.

Electro microscopy together with immunolabeling is necessary to identify the ultrastructural level of the split, and the nature of the defect at that level, that is, the specific element that is missing.

Differential diagnoses

Differential diagnoses that should be considered include thermal injuries, chemical burns and vasculitis.

Treatment

There is **no specific treatment** for epidermolysis bullosa.

Avoid trauma and provide symptomatic wound care.

Onyectomy can be performed for pain relief, if the major sign is nail shedding.

Prognosis

Prognosis is guarded. Euthanasia is an option if the quality of life is not adequate.

CHEMICAL DERMATITIS

Classical signs

- Ulcers or crust-covered erosions at contact sites.
- Ptalism.

Pathogenesis

Strong alkalis, acids or cationic detergents can cause a chemical dermatitis if they are in contact with the skin.

Clinical signs

Ulceration or crust-covered erosions develop at contact sites.

Oral ulceration and ptalism may result from ingesting the chemicals while grooming.

Diagnosis

A tentative diagnosis is based on **clinical signs** consistent with chemical dermatitis, together with a **history** of possible exposure to irritant chemicals.

Differential diagnoses

Differential diagnoses that should be considered include thermal injuries, trauma and calicivirus infection.

Treatment

Remove chemical from skin using copious, gentle irrigation with saline or 0.05% chlorhexidine.

Use **prophylactic antibiotic** cover to minimize secondary bacterial infection.

Feed soft foods, or if oral ulceration is severe, use nasogastric or esophageal tubes for feeding.

Intravenous fluids may be required, so monitor carefully for dehydration and protein loss through the skin.

Wound care may require judicious debridement, and use of non-adherent bandages changed daily until the lesions re-epithelialize.

Prognosis

Prognosis is good if there is not extensive skin involvement.

TRAUMATIC PANNICULITIS

Classical signs

- Multiple fistulae with serosanguineous to gelatinous exudates.
- Inguinal or dorsolumbar area.
- History of prior blunt trauma to site.

Pathogenesis

Ischemia of individual lipocytes may occur following **trauma**, and the resultant release of triglycerides induces inflammation.

Clinical signs

Blunt trauma may cause **panniculitis**, which presents **2–3 weeks later** with signs.

Lesions are most common in the **inguinal or dorsolumbar** areas. There is **alopecia** of the **overlying skin**.

Sinus tracts or fistulae may form, with a resultant **serosanguineous to gelatinous exudate**.

Subcutaneous fibrosis occurs with healing.

Diagnosis

A **tentative diagnosis** is based clinical signs and a history of trauma.

No organisms are detected on cytology, biopsy or culture.

There is no response to antimicrobial therapy.

Differential diagnoses

Differential diagnoses that should be considered include infectious, immune-mediated and nutritional panniculitis.

Treatment

Treatment involves **surgical excision** of the involved fat pad.

Glucocorticoids (prednisolone at anti-inflammatory doses of 0.5–1 mg/kg q 24–48 h for 4–6 weeks) help reduce inflammation.

Vitamin E 200 IU/cat/day may help reduce inflammation.

Prognosis

Traumatic panniculitis is often frustrating to treat if surgical excision is not possible.

Prevention

Oxytetracycline (10 mg/kg q 12 h) and **vitamin E** (200 IU/cat q 24 h) immediately following trauma may help to improve tissue perfusion and stabilise cell membranes.

Early debridement of **necrotic fat** following trauma is indicated to reduce inflammation.

VASCULITIS AND MISCELLANEOUS ULCERATIVE DERMATOSES

Classical signs

- Ulcers and crusts (skin and/or mucocutaneous junctions).

Pathogenesis

Immune-mediated ulcerative dermatoses represent a heterogeneous group of diseases in which the primary lesion is cutaneous ulceration.

Vasculitis resulting in skin lesions is rare in cats. It may be associated with immune complexes secondary to infectious or neoplastic disease, drugs and as part of autoimmune syndromes, such as SLE or be idiopathic.

- Predisposed sites have minimal collateral circulation such as the pinnae, paws and tail tip.
- Ulceration and necrosis are typical.

Cold agglutinin disease is a rare disease where cold-reacting IgM erythrocyte antibodies cause autoagglutination in the cooler peripheral vasculature of the extremities resulting in ischemic necrosis of the ear and tail tips and foot pads.

Clinical signs

Typically there is **cutaneous ulceration**, which may be crust-covered.

Lesions often involve the **muco-cutaneous junctions**, **foot pads**, **nail-skin junction**, **oral cavity**, **inguinal and axillary** areas and extremities (ear and tail tips).

Vasculitis may be associated with **necrosis** particularly of pinnae, foot pads and tip of the tail.

Systemic signs such as fever and lethargy are not uncommon.

Diagnosis

Diagnosis is based on clinical signs and histological findings.

Early and late lesions should be examined **histopathologically**. For small ulcers, excise the entire ulcer together with the marginal skin. For large ulcers, an elliptical biopsy should be collected extending from grossly normal skin through the edge of the ulcer to the ulcerated skin.

An accurate drug history is important.

Diagnostic tests should be performed to rule-out concomitant neoplasia.

Differential diagnosis

Differential diagnoses which should be considered include bullous pemphigoid, systemic lupus erythematosus (SLE), discoid lupus erythematosus (DLE), vasculitis, cold agglutinin disease, erythema multiforme (EM), toxic epidermal necrolysis (TEN).

Treatment

Treat the underlying disease if possible, and stop drug treatment or change to a different class of drug if signs appeared during drug treatment.

Where an underlying trigger (drug or neoplasia) cannot be found, immunomodulation is recommended rather than immunosuppression.

Drugs commonly used include **pentoxifylline** (10 mg/kg q 12 h) which is a gastrointestinal tract irritant so should be given with food, **prednisolone** (2–4 mg/kg q 24 h or divided into twice daily and taper to response), chlorambucil or aurothioglucose.

Prognosis

Prognosis is guarded if the trigger cannot be found and resolved.

PANSTEATITIS/VITAMIN E DEFICIENCY

Classical signs

- Fever, lethargy and pain on cutaneous palpation.
- Cutaneous ulcerations with gelatinous exudate.

Pathogenesis

Vitamin E is an important natural antioxidant. A relative or absolute deficiency of vitamin E can result in peroxidation of bonds in unsaturated fat. This may occur with diets containing large amounts of **unsaturated fish oils**.

The unsaturated oils undergo oxidation, and release **reactive peroxides** in the body fat of the cat, causing painful inflammation of fat (pansteatitis).

Signs have been reported in cats that were fed mainly **oily fish such as red tuna**. Cats fed diets supplemented with cod-liver oil deficient in vitamin E are also at risk.

Clinical signs

Classical signs are lethargy, inappetence, fever, reluctance to move and pain on **cutaneous palpation**.

Subcutaneous fat has a generalized firm feeling on palpation.

Cutaneous ulcerations may form with a gelatinous exudate.

Diagnosis

Diagnosis is based on clinical signs and histological examination of biopsied fat.

- **Grossly**, affected fat may have a **brownish discolorization**.
- **Histopathological examination** shows **lobar and septal panniculitis** with characteristic ceroid deposition.

Differential diagnosis

Differential diagnoses which should be considered include infectious panniculitides, traumatic panniculitis and immune-mediated panniculitis.

Treatment

Treatment involves dietary correction and use of anti-inflammatory drugs such as prednisolone (1 mg/kg/day).

Prognosis

Prognosis is guarded to poor.

IDIOPATHIC FELINE ULCERATIVE DERMATOSIS

Classical signs

- Dorsal neck ulceration.

Pathogenesis

Pathogenesis is unknown and may be multifactorial.

Ulceration has been associated with use of **topical spot-on insecticidal agents** as an idiosyncratic reaction.

There is often a **history of vaccination** at the site within the last 12 weeks. This is a common site for vaccination, therefore a positive history does not equal causative role.

It has been associated with a variety of **allergies** including food allergy, and especially flea allergy, ectoparasites (demodex, notoedres, otodectes) and dermatophytosis.

Clinical signs

Chronic ulceration is usually present on the **dorsal neck area**, but may involve the face and base of ears.

Ulceration appears rapidly, and then follows a very insidious course.

The lesion **may spontaneously resolve** over 8–12 weeks **or persist**.

Pruritus varies from intensely itchy to not at all.

Diagnosis

Clinical signs are classical.

Check history of injections or application of insecticidal agents at the site.

Histological examination of a deep elliptical biopsy including the area affected with panniculus may show lymphocytic vasculitis/panniculitis, faded follicles and **linear subepidermal fibrosis**.

Differential diagnosis

Differential diagnoses that should be considered include trauma, cutaneous asthenia, necrotizing envenomation and thermal injury.

Treatment

Response to use of **glucocorticoids** is often **disappointing** because the pruritus is often steroid resistant.

A small number of cases treated by the author have responded (or spontaneously resolved) while on **pen-toxifylline** (10 mg/kg twice daily).

Keeping the **lesion wrapped** until it is completely healed, and using **Soft Paws** (Soft Paws Inc., Lafayette, LA, USA) on the hind feet may be successful in some cats. Soft Paws are vinyl caps that glue to the cat's claws and protect against skin damage from scratching.

A **hypoallergenic diet** may help some cats and a lime-sulfur dip every 5 days for 5–7 treatments has been suggested to rule out *Demodex gatoi*.

Wide surgical excision of the lesion and the use of Soft Paws on the claws of the hind feet are curative in some cats.

In cats resistant to treatment or where there is recurrence of the lesion after surgical excision, **declawing of the hind feet** has led to successful resolution of the lesion. However, Soft Paws should be trialed first and declawing used only as a last resort.

ERYTHEMA MULTIFORME (EM) AND TOXIC EPIDERMAL NECROLYSIS (TEN)

Classical signs

- Multifocal to confluent cutaneous ulceration.
- Muco-cutaneous junction ulceration.

Pathogenesis

Erythema multiforme and toxic epidermal necrolysis involve a **cytotoxic CD8+ T-cell response** against keratinocytes, which can be activated by drugs, viruses, neoplasia and foods.

Erythema multiforme is an **acute eruption of the skin and mucous membranes** and is most commonly associated with a drug sensitivity. Penicillin and aurothioglucose have been associated with erythema multiforme in cats.

Toxic epidermal necrolysis is an **acute disseminated disease** involving the mucous membranes and skin, and is associated with **systemic signs**.

- There is intracellular edema in the dermis and separation of the dermo–epidermal layers.

Clinical signs

Typically, onset of signs is **acute**.

In both conditions, lesions consist of **erythematous macules** (flat circumscribed red areas of skin ≤ 1 cm) and **ulceration**, which may be annular, arciform or serpiginous (snake-like).

Vesicles, blisters or bullae may be observed which ulcerate, ooze and crust over.

The ventral abdomen, peri-mammary area, ear pinnae, perioral and perineal areas are often affected.

Erosion or ulcers may be present on the **oral mucosa**.

Toxic epidermal necrolysis is associated with systemic signs including pyrexia, depression, anorexia.

Diagnosis

A **presumptive diagnosis** is based on the **clinical appearance of an acute ulcerative condition** involving the skin and mucous membranes, which is associated with a recent history of drug administration. Other differential diagnoses need to be excluded.

Histopathological examination of erythematous macules or ulcer margins reveals epidermal changes including hydropic degeneration, prominent single cell to apoptosis, lymphocyte and macrophage satellitosis and variable dermal edema (EM) to full thickness epidermal necrosis (TEN). Inflammatory changes in the dermis are mild to marked in EM but often absent in TEN.

Differential diagnosis

Other vesicular and pustular disorders, e.g. bacterial infections, pemphigus foliaceus, burns, chemical dermatitis need to be ruled out.

Treatment

Cyclosporin 5 mg/kg PO q 24 h. Not registered for use in cats.

Remove drug or diet triggers if identified.

Supportive treatment (intravenous fluids, warmth, avoidance of sepsis) needed where large amounts of epithelium are lost.

Prognosis

Prognosis is good if the trigger can be removed and the area affected is small, but is poor where large areas of epidermis have been lost.

53. The cat with paw or pad problems

Isobel Phebe Johnstone

KEY SIGNS

- Erythema, scaling, crusting, and/or pruritic lesions.
- Nodules, draining tracts, ulcers and/or abscesses.
- Distortion of the nails or deformity of the foot.

MECHANISM?

- A wide variety of diseases can have paw or pad problems as part of more generalized signs, or the lesions can be confined solely to the foot.

WHERE?

- Disease of the feet includes the paw, pads, digits and nails. Interdigital spaces are seldom affected in cats.
- It is rare for the disease to be confined solely to the feet. Usually the feet are affected in conjunction with other areas of the skin.

WHAT?

The most common problems seen in the paw are:

- Bacterial paronychia from a variety of causes.
- Immune-mediated diseases.
- Nodules or ulceration due to infections or neoplasia.

QUICK REFERENCE SUMMARY

Diseases causing paw or pad problems

ANOMALY

- **Variation in number of the digits* (p 1118)**

Hereditary variations in the number of digits, generally six toes, occur most commonly on the front feet.

- **Hypomelanosis (vitiligo) (p 1122)**

Loss of epidermal melanin is evidenced by non-pigmented patches in otherwise pigmented areas such as the nose, lips, mouth and paw pads.

continued

continued

- **Hyperpigmentation (lentigo simplex)** (p 1113)**

Dark pigmented patches (“freckles”) occur in the non-haired areas of orange cats older than 1 year of age.

- **Epidermolysis bullosa (p 1123)**

A hereditary claw-shedding disease seen in Siamese kittens causes the claws to shed easily with minor trauma.

METABOLIC

- **Hypothyroidism (p 1121)**

Erythematous, scaling lesions of the footpads occasionally occur with hypothyroidism. Seborrhea sicca and a dry lusterless hair coat, which is easily epilated, and has poor regrowth after clipping may be evident. It is very rare in cats, and occurs most commonly after bilateral thyroidectomy.

- **Hyperthyroidism** (p 1113)**

Unkempt hair coat and overgrown claws are commonly seen. Systemic signs include weight loss, polyphagia, polydipsia/polyuria and nervous/hyperactive temperament. Usually seen in cats older than 8 years.

- **Hyperadrenocorticism (p 1121)**

Rare condition in cats that results in very thin and easily torn skin, especially on the digits. Other systemic signs include polyphagia, polydipsia/polyuria, abdominal enlargement and skin infections.

- **Diabetes mellitus (p 1122)**

Whitish, waxy nodules in the paws are a rare complication of diabetes mellitus. Other systemic signs include polyuria/polydipsia, weight loss and polyphagia or anorexia.

- **Calcinosis cutis (p 1123)**

Metastatic calcification occasionally occurs in the pads of the feet secondary to renal failure. Affected pads are enlarged, firm and painful. A chalky white-to-pink material may be visible through the intact epidermis. Pads may ulcerate and exude a chalky, white, pasty material.

MECHANICAL

- **Foreign bodies (p 1120)**

Foreign bodies may result in nodules, abscesses or draining tracts in the interdigital web. Foreign bodies are much rarer in cats than dogs.

NEOPLASTIC

- **Primary and secondary neoplasia (p 1116)**

Neoplasia may cause swollen painful pads or digits that become ulcerated. Various neoplasms have been recorded as having a predilection for the feet; squamous cell carcinoma, metastatic ungual carcinoma, fibrosarcoma and malignant fibrous histiocytoma have been more commonly reported.

- **Cutaneous horns (p 1122)**

Cones of hard keratin growing out from the skin occasionally occur on the feet.

PHYSICAL

- **Irritant contact dermatitis or chemical burns* (p 1119)**

Erythema and ulceration of the footpads often occur together with salivation, mouth ulcers and anorexia.

- **Burns (thermal)* (p 1119)**

Superficial to deep ulceration on the footpads occurs, depending on the severity of the burn.

- **Frostbite (p 1120)**

Frostbite may result in erythema, edema, necrosis and sloughing of extremities.

INFECTIOUS (VIRAL)

- **Feline pox virus infection** (p 1113)**

Multiple papules, vesicles, plaques or crusts and ulcers may occur on the face, ears, limbs and paws associated with pox virus. Paronychia and sloughing of footpads may occur.

- **Infectious pododermatitis*** (p 1111)**

Viral, bacterial (most common), fungal and parasitic agents may cause pad and paw disease. Bacterial: Paronychia involving one or more claws, and more rarely pyoderma or fistulated interdigital abscesses are usually caused by the more common opportunistic bacterial infections such as *S. intermedius* and more rarely by the yeast *M. pachydermatitis*. Fungal: Single or multiple ulcerated nodules, or draining fistulated areas are usually associated with the rare opportunistic bacterial and fungal infections. Pheomycotic lesions are very darkly (black) pigmented. Non-pruritic, erythematous scaling, alopecic lesions are associated with dermatophytes and usually there are lesions elsewhere on the body as well. Kerion (nodular furunculosis) formation and onychomycosis (fungal claw infection) are rare. *Malassezia* causes brown staining at the base of the nails only, or a more generalized scaly erythematous dermatitis. Viral: Calici virus may produce footpad ulceration in association with oral ulceration, usually without the more classical respiratory signs of sneezing and nasal discharge. Parasitic: Erythematous, alopecic lesions may occur with *Demodex cati* infections, or pruritic crusting lesions with *Notoedres cati*. Usually there are lesions on other parts of the body.

INFLAMMATION (IMMUNE-MEDIATED)

- **Pemphigus* (p 1117)**

Pemphigus foliaceus is most common. A symmetrical pattern of lesions occurs on the face, ears, trunk, feet and mucocutaneous junctions consisting of erythema, oozing, crust, scales and alopecia. Some cats may present with only foot lesions.

- **Systemic lupus erythematosus (p 1121)**

SLE is a multi-systemic disease, which may involve the skin with ulcerative lesions of the feet and paronychia.

- **Plasma cell pododermatitis* (p 1115)**

Plasma cell pododermatitis results in swollen and very soft (“mushy”) footpads with normal pad symmetry. Normally it is non-painful, but the pads may become ulcerated.

- **Insect bite hypersensitivity** (p 1114)**

Symmetrical pattern of erythematous papules, ulcers and crusts occur on thinly haired areas, especially the bridge of the nose and/or ear tips. Sometimes the footpads are also affected. Lesions have a seasonal occurrence.

continued

*continued***ALLERGY**

- **Atopy and adverse food reaction*** (p 1116)

Atopy or adverse food reaction may just involve the feet with nail biting and chewing. More typically it manifests as skin lesions affecting the head, face, ears and inner thigh. These include non-inflammatory alopecia, miliary dermatitis and granulomatous ulcerated skin from licking and scratching, particularly of the face and neck.

TOXIC

- **Thallium poisoning** (p 1124)

Thallium-containing rodenticide toxicity results in hyperkeratosis and scaling of the footpads, as well as similar lesions elsewhere on the body.

TRAUMA

- **Shredded nail tips or avulsed nails (trauma)***** (p 1111)

Shredded nail tips or avulsed nails are typically evident in cats involved in road accidents.

- **Declawing complications** (p 1120)

Deformed claws, keratinaceous foreign bodies at the ends of the digits or draining tracts may result from imperfectly completed declawing procedures.

- **Arteriovenous fistulae** (p 1124)

An arteriovenous fistula is a very rare condition resulting in local edema and distinct, tortuous, pulsating blood vessels near the area.

INTRODUCTION**MECHANISM?**

Foot problems are less commonly seen in cats as a presenting complaint than in dogs.

The feet of cats can be affected, along with other areas of the body, in numerous feline dermatoses and systemic diseases.

Lesions confined primarily to the paw or pads are rarely seen.

Three categories of lesions are seen:

- **Scaling, crusting and pruritic** lesions, which usually result from immune-mediated and allergic diseases or infectious causes such as viral, fungal and parasitic.
- **Nodules, draining tracts, ulcers and abscesses**, which usually result from the more unusual bacterial and fungal infections or neoplasia.

- **Disorders of the claws and paronychia**, which usually result from trauma, bacterial paronychia or neoplasia.

WHERE?

Disorders of the feet including paws, pads, claws and ungual folds.

Careful history taking and a thorough physical examination are very important in establishing a list of differential diagnoses and for selection of appropriate laboratory tests.

For many of the diseases, definitive diagnosis is by histological evaluation of biopsy specimens.

WHAT?

The most common causes of foot problems are infectious agents, especially bacterial and fungal, and trauma.

Less common causes are tumors, immune-mediated diseases and endocrinopathies.

DISEASES CAUSING PAD OR PAW PROBLEMS

SHREDDED NAIL TIPS OR AVULSED NAILS (TRAUMA)***

Classical signs

- Broken or torn claws.
- Feathered ends to claws.

Clinical signs

Broken or torn claws.

Feathered ends to claws are classically seen in cats involved in a **road accident**, and result from dragging of the claws on the rough road surface.

- If the history of an injured cat is unknown, then feathered claw tips can be a clue to road trauma.

Diagnosis

Diagnosis is based on history and physical examination.

INFECTIOUS PODODERMATITIS***

Classical signs

- Paronychia involving one or more claws.
- Ulcerated nodules or fistulated areas.
- Non-pruritic, erythematous, scaling, alopecic lesions.

Pathogenesis

Common cause of foot problems in cats and is often **secondary** to factors such as **trauma or immune suppression** (FeLV, FIV, systemic disease).

Infectious agents can be bacterial, fungal or viral.

Bacterial.

- Various **opportunistic bacteria** have been reported, most commonly *Staphylococcus inter-*

medius, *Escherichia coli*, *Pseudomonas* sp., *Proteus* sp. or *Pasteurella* sp.

- More rarely other bacteria reported are *Mycobacterium* sp., *Listeria monocytogenes*, *Dermatophilus congolensis*, *Nocardia asteroides*.

Fungal.

- **Dermatophytes**, primarily *Microsporum canis*, *M. gypseum* and *Trichophyton mentagrophytes*, can be found on the paws but would rarely be found there as the only site on the body.
- Rare cases of **opportunistic saprophytic fungal infections** have been reported including:
 - Pheohyphomycosis caused by *Exophiala jeanselmei*, *Moniliella sauveolens*, *Cladosporium* sp., *Stemphyllium* sp. and *Scolecobasidium humicola*.
 - *Paecilomyces fumosoroseus* and *Sporothrix schenckii*.
- **Yeast infections** with *Cryptococcus neoformans*, *Rhodotorula mucilaginosa* and *Malassezia pachydermatis* usually also involve other areas of the body.

Viral.

- **Pox virus** causes foot lesions and is covered separately (see page 1113).
- Occasionally **Calici virus** may cause footpad ulceration, in addition to the more common clinical signs in other organs.

Parasitic.

- **Demodicosis** is reported to be a rare cause of claw disease.
- An opportunistic infection with *Leishmania braziliensis* has been reported causing a large vegetative lesion in the interdigital area.

Clinical signs

Bacterial.

- **Paronychia** involving one or more claws, and more rarely pyoderma or fistulated interdigital abscesses are usually caused by the more common opportunistic bacterial infections such as *S. intermedius*.
- **Single or multiple ulcerated nodules, or draining fistulated areas** are usually associated with the rare **opportunistic bacterial** (including *Nocardia*, *Listeria monocytogenes* *Dermatophilus congolensis*) and **fungal infections**.

Fungal.

- A variety of saprophytic fungi produce **draining tracts, ulcerated nodules and chronic non-healing wounds**. Pheomycotic lesions are very darkly (black) pigmented.
- Kerion (nodular furunculosis) formation and onychomycosis (fungal claw infection) are rare.
- *Malassezia pachydermatitis* is a yeast which is a secondary infectious agent, causing **brown staining at the base of the nails** only, or a more generalized scaly erythematous dermatitis. Rarely it causes paronychia involving one or more claws.
- Infection by **dermatophytes** causes hair loss and rarely infection of the nails (onychomycosis). Other areas of the body are usually also involved with irregular or circular alopecic patches, with or without scale, that are **non-pruritic and may be erythematous**.

Viral.

- **Pox virus** produces **multiple papules, vesicles, plaques or crusts** and ulcers, which may occur on the face, ears, limbs and paws. Paronychia and sloughing of footpads may occur.
- **Calici virus** infection may produce **footpad ulceration** in association with oral ulceration, usually without the more classical respiratory signs of sneezing and nasal discharge.

Parasitic.

- **Erythematous, alopecic** lesions may occur with *Demodex cati* infections, or pruritic crusting lesions with *Notoedres cati*. Usually there are lesions on other parts of the body.

Diagnosis

Wood's lamp examination or direct examination of hair and scales mounted in paraffin oil or KOH may detect dermatophytes.

Cytological examination of smears of the **exudate** from moist lesions, stained with Diff-Qik may reveal the primary organism present including *Malassezia*, *Cryptococcus* or bacteria.

Culture exudate to identify the organism, and obtain sensitivity for antibiotic treatment if bacterial.

Biopsy nodular or fistulous areas for histopathology, and culture tissue to identify the rarer opportunistic infections.

Serology to detect cryptococcal antibody is usually positive in cats with cryptococcosis.

Hair pluck/skin scrape to detect *Demodex*.

Differential diagnosis

Symmetrical bacterial paronychia can appear similar to **immune-mediated** disease such as pemphigus foliaceus.

Nodules and ulcerated areas can appear similar to **neoplastic lesions**.

Treatment**Bacterial infections.**

- Use **appropriate antibiotics** selected based on culture and sensitivity.
- Treatment for several weeks may be necessary for deep infections.
- If lesion recurs, **check immune status** (FeLV, FIV, systemic disease).

Fungal infections.

- **Griseofulvin** (50–100 mg/kg PO q 24 h, preferably with a fatty meal) is effective only for dermatophytes. Beware of adverse drug reactions including teratogenicity, gastrointestinal upsets and bone marrow suppression.
- **Ketoconazole** (5–10 mg/kg PO q 24 h) has been effective for most fungal and yeast infections but has more side effects than itraconazole. Adverse reactions include anorexia, fever, depression, vomiting, diarrhea and neurologic abnormalities. Lower doses or alternate day therapy may be necessary if reactions occur.
- **Itraconazole** (5–10 mg/kg PO q 24 h) may work better than ketoconazole, and has fewer side effects, but is more expensive.

Parasitic infections.**Demodex.**

- Feline demodicosis has responded to simple treatments such as three dips of **malathion or lime-sulfur** at weekly intervals.
- **Ivermectin** is very effective against mites, although its use in cats is off-label. For demodectic mange the dose rate is 0.6 mg/kg daily orally continued

for up to 30 days after negative skin scrapings. Stopping too early results in relapses.

- Similarly **Doramectin** at 0.6 mg/kg sc weekly can be used.

Leishmania.

- Successful treatment in cats has not been reported.

Prognosis

Prognosis varies depending on the type of infection and the underlying cause. The recurrence rate is high for bacterial paronychia if there is an underlying immune deficiency.

The prognosis is more guarded for the rarer opportunistic bacterial and fungal infections. Cures are reported with the use of the imidazole drugs (ketoconazole and itraconazole).

HYPERPIGMENTATION (LENTIGO SIMPLEX)**

Classical signs

- Black asymptomatic spots that gradually enlarge and become more numerous.
- Occur in cats with orange coat color.

Clinical signs

Hyperpigmented areas (“freckles”) in orange (ginger) cats are termed lentigo simplex.

Freckles usually appear **before 1 year of age** and increase in number with age.

There are multiple hypermelanotic macular lesions on the **nose, lips, eyelids and footpads**.

Lesions are **asymptomatic** and do not develop into melanomas.

Diagnosis

Diagnosis is based on the history of asymptomatic black spots developing in the poorly haired areas of cats with a ginger coat color.

HYPERTHYROIDISM**

Classical signs

- Weight loss with polyphagia.
- Unkempt hair coat.
- Nervous, hyperactive.

See main reference on page 304 for details (The Cat With Weight Loss and a Good Appetite).

Clinical signs

Most commonly there is **weight loss despite a ravenous appetite**. More rarely is appetite depressed.

Other signs may include tachycardia, polydipsia/polyuria, vomiting or diarrhea, and a heart murmur.

A **palpable thyroid nodule** in the neck is present in the majority of cats.

Restlessness and hyperexcitability are often evident.

An unkempt haircoat and **overgrown claws** are typical.

- The overlong claws catch in floor coverings or click on bare floors as the cat walks.

Usually occurs in cats older than 8 years of age.

Diagnosis

A tentative diagnosis is based on **history and physical examination**.

Increased total thyroxine (T₄) levels confirm the diagnosis. Cats with a high normal T₄ concentration and signs consistent with hyperthyroidism should either be retested several weeks later, or free T₄ concentration be measured by equilibrium dialysis, or a T₃ suppression test performed. Concurrent disease can decrease a high T₄ into the normal range.

FELINE POX VIRUS INFECTION**

Classical signs

- Multiple nodules, papules, crusts, and ulcerative plaques.
- Commonly on the face, limbs and paws.
- Pruritis, pain, fever, conjunctivitis and dyspnea may be present.

Pathogenesis

Infection is caused by a virus from the **orthopoxvirus** genus. The origin of the virus is unclear. It was attributed to the cow-pox virus, but now it is thought there could be a **feline pox virus**.

Reported infections are from **England and Europe**.

Clinical signs

Skin lesions occur on the **face, ears, limbs and paws** with **multiple papules, vesicles, plaques or crusts and ulcers**.

On the feet there can be **paronychia and sloughing of the footpads**.

Diagnosis

Biopsy and histologic examination of the crust or affected skin demonstrates **eosinophilic intracytoplasmic inclusion bodies** within keratinocytes.

Specialist tests that may be available also include a serologic test for virus-neutralizing antibodies, electron microscopy of crusts or affected skin to detect the virus, and virus isolation. **Virus isolation** is currently the only method for making a precise diagnosis.

Differential diagnosis

Bacterial and fungal infections, eosinophilic granuloma and neoplasia may all cause similar lesions but can be differentiated on biopsy and histological examination.

Treatment

Treatment is not thought to affect the outcome of the disease, and is not regarded as necessary as most cats **recover spontaneously within 1–2 months**.

Secondary bacterial infection should be treated with antibiotics.

Glucocorticoids are contraindicated.

Prognosis

Prognosis is good as cats recover spontaneously, however, there may be permanent scarring.

Transmission

The natural reservoir for infection is not known, but is thought to be **small wild animals** and the cat is infected whilst hunting them.

Transmission of cow pox virus from infected milk has also been blamed.

The pox virus can be **transmitted to in-contact cats, dogs and humans**; immunocompromised individuals are more at risk. Warn in-contact people of the **zoonotic potential**.

The virus is killed by most disinfectants, particularly chlorine-based ones.

Prevention

Prevent the cat from hunting or contact with an infected cat.

INSECT BITE HYPERSENSITIVITY**

Classical signs

- Erythematous, crusted, pruritic lesions.
- Symmetric lesions on ear tips, face, nose and footpads.

Pathogenesis

Hypersensitivity resulting in skin lesions is associated with **flying and biting insects**.

It is most often seen in cats that go **outdoors** when **mosquitoes or midges** (*Lasiohelix townsvillensis*) are present.

Clinical signs

Thinly haired areas are most commonly affected, especially the **bridge of the nose, ear tips and the junction of haired skin and the footpad** ("ears, nose and toes syndrome").

Lesions have a symmetrical pattern, and begin with **erythematous papules to plaques**.

Lesions are pruritic, and the cat traumatizes itself, so that the affected areas become **ulcerated and crusted**.

Chronic lesions develop **nodules, pigment changes (dark or pale patches), and alopecia.**

Footpads may be affected with swelling, scales or crusts, hyperkeratosis, fissures and pigment changes.

Diagnosis

Seasonal occurrence is evident coinciding with mosquito or midge season in cats allowed outdoors.

Tentative diagnosis can be confirmed by **keeping the cat indoors or hospitalized for 5 days** and demonstrating great improvement of lesions.

Biopsy and obtain small specimens (4-mm biopsy punch) carefully, as the **ears and nose bleed easily** and readily show scars. Histopathological changes are similar to those of cats with atopy, food and flea bite hypersensitivity.

Differential diagnosis

Food allergy commonly results in pruritis of the face, head, pinnae and neck, in contrast to just the nose and/or ears affected with insect hypersensitivity. Lesions are usually asymmetrical and very excoriated. Non-seasonal occurrence, and does not respond to the indoor confinement trial, but responds to an elimination dietary trial.

Autoimmune diseases such as pemphigus foliaceus/erythematosus and discoid lupus erythematosus typically also have a symmetric pattern, but usually there is extensive crusting and exudation of head and body. Depression and anorexia are often present. Pruritis is variable.

Treatment

Keep the cat indoors at the times of greatest insect activity, usually early morning and dusk.

Topical insect repellents applied to the affected area. Try a variety, as not many are well tolerated by cats; ointments or creams are best tolerated.

Petroleum jelly smeared on the ear tips and nose has also been used successfully.

Oral prednisolone (0.5–2 mg/kg on alternate days) or injectable glucocorticoids (repositol methyl prednisolone acetate, 20–40 mg/cat subcutaneously).

Prognosis and prevention

Good control of the problem is possible if the cat can be kept away from biting insects, or will tolerate insect repellent.

However, lesions may increase with severity over the years if exposure cannot be controlled.

PLASMA CELL PODODERMATITIS*

Classical signs

- Swollen, very soft footpads, generally non-painful.
- Normal pad symmetry.

Pathogenesis

Plasma cell pododermatitis is a **rare skin disease** affecting the footpads.

The cause is unknown, but is thought to be **immune-mediated or allergic.**

One study found 50% of cases to be feline immunodeficiency virus-positive.

Clinical signs

Typically, the **footpads are swollen, very soft and fluctuant (mushy).** Usually the larger metacarpal and metatarsal pads are the ones affected.

Normal pad symmetry is not disturbed by the swelling, but the stretching of the skin over the swollen pad results in a **white, silvery, cross-hatched appearance.**

Lesions involve one or more feet.

Normally, the **lesions are non-painful** and the cat is not lame, although cases of cats limping on the affected feet have been reported.

The pad may become **ulcerated**, and drain hemorrhagic fluid.

Some cats also have plasma cell stomatitis, immune-mediated glomerulonephritis or renal amyloidosis.

Diagnosis

Fine-needle aspirate of the lesion contains large numbers of uniform plasma cells with a few neutrophils and lymphocytes.

Deep wedge biopsy from a footpad near the pad margin is diagnostic. A punch biopsy may not go deep enough to be diagnostic.

- If a number of pads are affected choose a more mildly affected one to biopsy as a severely affected one may not heal well.

Differential diagnosis

Undifferentiated sarcoma may appear very similar and needs a biopsy to differentiate.

Treatment

This is not necessary if the cat is asymptomatic, as the disease may **spontaneously regress**.

Immunosuppressive doses of **prednisolone** (up to 4 mg/kg/day) have been recommended, but may not be effective.

Chrysotherapy (aurothioglucose; Solganol; 1–2 mg/kg IM weekly) may be effective.

Surgical excision of the footpad. A new footpad grows back. Reported to be the best therapy at present.

Prognosis

Prognosis is guarded as the recurrence rate is high, usually within 4–6 months.

ATOPY AND ADVERSE FOOD REACTION*

Classical signs

- Pruritis, which is manifested as scratching, licking or chewing.
- Skin lesions varying in severity from alopecia to miliary dermatitis to ulcerated plaques or granulomas.

Clinical signs

Atopy and adverse food reactions result in various **other dermatological manifestations** such as ulcerated plaques, miliary dermatitis, symmetrical alopecia and pruritis of the **face and neck**.

Pruritis is present but may not be obvious to the owner.

- Over-grooming results in non-inflammatory alopecia (“fur mowing”).

Foot or claw chewing may initially be the only presenting clinical sign.

- The cat drags the claws through the teeth with loud clicking noises, which brings the problem to the attention of the owner.
- **One or more ulcerated areas of the paws** (digits, periungual areas or interdigital spaces) may be present.
- Histologically these lesions are typical of eosinophilic granuloma complex.

Diagnosis

Rule out other causes of claw problems, especially **infectious pododermatitis and neoplasia**.

Control external parasites. A good choice is fipronil as this controls fleas, and anecdotally mites (*Cheyletiella*, *Sarcoptes*, *Otodectes* and *Notoedres*) and provides partial control of ticks.

Try a dietary trial using a food source that the cat has not been exposed to before. It may take ingenuity to find a new food that the cat is willing to eat. Duck, venison or rabbit (2/3 cup) with cooked rice or pasta (1/3 cup) are often tolerated. A trial period of a minimum of 9 weeks has been advocated for cats and up to 16 weeks preferably. Re-challenge the cat with the old diet to confirm the diagnosis, although owners may be unwilling to risk signs recurring.

Intradermal skin testing to test for atopy. This is technically more difficult in cats than dogs, as reactions are less intense and more transient.

PRIMARY AND SECONDARY NEOPLASIA*

Classical signs

- Swollen, painful digit(s) and/or paronychia.
- Ulcerative destructive lesion of the paw and digits.

Pathogenesis

Neoplasia involving the foot is rare in cats and is usually seen in older cats. The neoplasia may be primary

or secondary. Secondary neoplasia results from metastasis of primary neoplasia in other organs.

Squamous cell carcinoma.

- Rare primary tumor arising from the nail bed epithelium.
- Appears to be more aggressive than squamous cell carcinomas in other parts of the body.
- On clinical examination it may be mistaken for paronychia or pyoderma.

Metastatic digital (ungual) carcinoma.

- Usually presents as lameness associated with multi-centric digital carcinoma.
- Seen in aged cats (average age 13 years) with asymptomatic bronchogenic carcinoma or squamous cell carcinoma of the lung.
- Lesions can involve a number of digits and more than one paw. Typically there is swelling of the digit, ulceration of the skin or purulent discharge, and either fixed exsheathment, deviation or loss of the nail.

Fibrosarcoma.

- Seen in older cats and is not associated with feline sarcoma virus.
- Lesions are usually solitary and can involve the digits.
- The area is alopecic, ulcerated and the tumor has rapid infiltrative growth.

Undifferentiated sarcoma.

- Seen in older cats and involves the footpads of one or more feet.
- Affected pads are soft, mushy, painful and maybe ulcerated.

Malignant fibrous histiocytoma.

- Seen in older cats.
- The lesions are solitary, firm, poorly circumscribed, variable in size and shape and locally invasive.
- Legs, especially the paw, and shoulders are the most common sites.

Diagnosis

Biopsy of representative areas and histopathology.

Differential diagnosis

Plasma cell pododermatitis also has swollen mushy pads, which may be ulcerated.

Bacterial or fungal infections, especially the rarer opportunistic ones, can look very similar. Biopsy for histopathology and culture will distinguish between these.

Treatment

Radical surgical excision is the treatment of choice for tumors without evidence of metastasis.

Mean survival for metastatic digital carcinoma was 67 days.

PEMPHIGUS*

Classical signs

- Crust, scales, alopecia in a symmetrical pattern.
- Areas usually involved are face, ears, trunk, feet and mucocutaneous junctions.
- Occasionally have only foot lesions.

Pathogenesis

Pemphigus is an **immune-mediated disease**, with auto-antibodies directed against intercellular cement in the epidermis causing **loss of cohesion between keratinocytes** and resulting in the formation of bullae.

- Bullae are very transient in cat skin due to the thin epidermis, and may not be observed.

What initiates the auto-antibodies is unknown, but **drugs and chronic skin disease** have been implicated in some cases.

Different types of autoimmune dermatitis may involve cats' paws but the **most common** is *Pemphigus foliaceus*.

Clinical signs

Erythema, oozing, crusts, scales and alopecia occur with a **symmetrical pattern on the face, ears, trunk, feet and mucocutaneous junctions**.

Lesions commonly involve the **feet and footpads**, causing **hyperkeratosis and ulceration**. Some cats are presented with only footpad lesions and sometimes lameness.

Paronychia and **involvement of the nipples** are commonly seen in cats.

Diagnosis

Direct smears from intact vesicles or pustules may show numerous **acantholytic keratinocytes**; these are strongly suggestive of pemphigus.

Biopsy of primary lesions or at the periphery of the most recent lesions shows **subcorneal pustules** consisting of acantholytic keratinocytes and neutrophils.

Direct immunofluorescence of biopsies shows diffuse intercellular fluorescence.

Differential diagnosis

Systemic lupus erythematosus is rare and usually also has systemic signs.

Insect hypersensitivity is common, but lesions are usually confined to the bridge of the nose, tips of the ears, and occasionally footpads. Seasonal occurrence and history of biting insects being observed around the cat helps differentiate this from pemphigus.

Treatment

Therapy is often difficult as side effects from the drugs are common.

High doses of glucocorticoids (4–8 mg/kg daily) will induce remission in most cases (about 2 weeks). Once in remission, reduce to alternate day therapy and to the minimum dose which maintains remission.

Chlorambucil (0.1–0.2 mg/kg every 24–48 hours) can be added if glucocorticoids are insufficiently effective.

Chrysotherapy (gold salts; aurothioglucose: Solganal; Schering) has been useful in cats when other treatments have failed. Begin with 1 mg/kg IM weekly until remission, which may take up to 12 weeks to occur. If no response is evident after 12 weeks of therapy, increase dose to 1.5–2 mg/kg. Once the cat responds, give the dose every 2 weeks and then monthly for several months. Alternatively the dose can be started at 0.25 mg/kg IM for the first week, 0.5 mg/kg the second week, then 1 mg/kg weekly until remission and then a gradually decreasing dosage.

Prognosis

Prognosis is guarded, because the inciting cause is usually unknown, and the side effects of the therapy are often severe.

VARIATION IN NUMBER OF DIGITS*

Classical signs

- Abnormal number of toes (six most common).
- Agenesis or fusion of digits.

Clinical signs

Variation in the normal number of digits is present from birth.

Ectrodactyly is **agenesis** of all or part of a digit and is an inherited defect involving the fore-paws.

Polydactyly refers to **extra toes**.

- The mode of inheritance is dominant.
- There is considerable variation from animal to animal with the number of extra toes and how perfectly formed they are.
- Usually there are **six toes on each front foot**, but sometimes there can be seven toes on the front feet and six on the hind feet. The hind feet are not affected unless the front feet are involved.
- The **incidence varies** with it being common in some countries and not seen in others.

Syndactyly refers to **fusion of the digits**. It is also called “split-foot” or “lobster-claw”.

- Typically it manifests as a **central cleft** of either one or both front feet. However, there may be fusion of the bones of the foot to produce double claws.
- The evidence is for **dominant heredity**, possibly with variable expression, as the number of affected animals is less than expected, with some genetically affected animals appearing normal. The right side tends to be more severely affected than the left.

IRRITANT CONTACT DERMATITIS OR CHEMICAL BURNS*

Classical signs

- Variable erythema, ulceration, necrosis of the contact areas.
- Hyperkeratosis and scaling.
- Salivation and saliva staining around the mouth and paws with chemical burns.

Pathogenesis

Irritant contact dermatitis or chemical burns are commonly caused by chemicals used in the environment such as **herbicides, garden fertilizers, fuel oil** and other common household or cattery cleaning products and disinfectants including chlorine bleach (sodium hyperchlorite), strong alkalis, strong acids, pine oils, phenolic compounds and quaternary ammonium compounds.

Chemical burns with ulceration may occur if the product is incorrectly diluted.

- Typically this occurs if the product is applied undiluted and then water is used to dilute and wash the chemical away. Highly concentrated product may remain in less accessible areas, causing chemical burns to the feet and mouth.
- Signs develop when the cat inadvertently walks on them.

Most common in cats living outdoors.

Clinical signs

Typically, there is **erythema and ulceration of the footpads, interdigital spaces and around the nails**. Usually more than one paw is affected.

Pain and pruritis are sometimes evident.

Oral ulcers and salivation are often present, and result from the cat licking its feet. Regurgitation may result from chemical esophagitis.

Less toxic chemicals or concentrations may cause erythema, and excessive licking of the feet rather than ulceration.

Diagnosis

Diagnosis is based on history and physical examination.

Treatment

Bathe to remove traces of offending chemical.

Corticosteroids (prednisolone, 0.5–1 mg/kg PO q 24 h) to reduce inflammation.

Non-steroidal antiinflammatory drugs can be given for pain relief and to reduce inflammation. Ketoprofen is registered for use in cats (2 mg/kg SC or PO initially then 1 mg/kg PO daily). Meloxicam (0.2 mg/kg SC or PO initially then 0.025 mg/kg PO 2–3 times/week).

Antibiotics, if there is secondary infection.

Protective dressings may be necessary if ulceration is severe to promote healing.

BURNS (THERMAL)*

Classical signs

- Initially the skin may be dry and hard.
- Necrotic skin sloughs leaving large raw areas.
- Purulent discharge when secondarily infected.

Pathogenesis

Burns occur when cats walk or jump onto hot surfaces such as **barbecues or stove hot plates**, usually with the intent of stealing food.

More generalized burns occur in **cats trapped in house fires**.

Clinical signs

Signs depend on the severity of the burn, and include superficial to deep ulceration and sloughing of the burnt area.

Initially the skin may be dry and hard. Necrotic skin sloughs leaving **large raw areas**.

Purulent discharge occurs when the burnt area becomes secondarily infected.

Treatment

Silver sulfadiazine cream or **aloe vera gel** applied under a non-adherent dressing are excellent topical treatments for burns.

Burn healing is slow, taking weeks to months of treatment.

Very extensive or deep burns may heal with scarring that interferes with function, necessitating reconstructive surgical procedures.

DECLAWING COMPLICATIONS

Classical signs

- **Claw deformity or keratinaceous growths at the end of the digits.**
- **Swollen ends of digits and draining tracts.**

Clinical signs

Regrowth of claws may result from persistent germinative epithelium after incomplete removal during declawing.

Regrowth can vary from **deformed claws to keratinaceous foreign bodies** at the ends of the digits.

Swollen ends of digits and draining tracts may develop.

Diagnosis

A history of a declawing procedure having been performed.

Excisional biopsy of deformed ends of the digits is diagnostic and curative.

FROSTBITE

Classical signs

- **Frozen skin is pale and cool to the touch.**
- **Mild erythema, edema and pain after thawing.**
- **Necrosis and sloughing in severe cases.**

Clinical signs

Frostbite typically affects the **tips of the ears and the digits**, areas that are not well insulated.

Whilst frozen, the skin appears pale and cool to touch, and has decreased sensation.

After thawing, there may be **mild erythema, edema and pain.**

In severe cases, the skin becomes necrotic and sloughs.

Treatment

Rapidly thaw frozen area by the gentle application of warm (42–44°C) water.

Handle tissues gently to prevent further damage and pain.

Aloe vera gel applied topically helps to prevent vasoconstriction and tissue hypoxia.

Any resulting necrotic areas may need surgical debridement.

Antibiotics may be needed to control secondary infection, in cases where there is extensive tissue damage.

FOREIGN BODIES

Classical signs

- **Nodules, abscess and draining tracts.**

Clinical signs

Objects such as **plant awns, thorns** can become embedded in the interdigital space. This is much rarer in cats than in dogs.

Nodules, abscesses and draining tracts result.

Treatment

Surgical debridement and removal of foreign body.

Use antibiotics if secondary infection develops.

SYSTEMIC LUPUS ERYTHEMATOSUS

Classical signs

- Multi-systemic disease including the skin.
- Generalized or localized erythematous, scaly or crusted skin lesions.

Clinical signs

Dermatological signs occur in 20–30% of cases.

- Typically, there are generalized or localized **scaly or crusted lesions** on the face, ears and eyelids. Alternatively, **ulcerative lesions** may be present on the face, trunk and feet. Periocular leukotrichia may be evident.
- **Paronychia** and **oily seborrhea** may occur.

Systemic signs include intermittent pyrexia, anorexia, depression and weight loss.

Involvement of other organs may result in **immune-mediated anemia, thrombocytopenia, glomerulonephritis** and **polyarthritis**.

Diagnosis

Definitive diagnosis is very challenging, as the disease is so variable in its clinical presentation.

Skin biopsies show hydropic interface dermatitis.

A high positive **ANA titer** may occur in some cats.

Laboratory results demonstrating **multi-systemic disease** suggest a tentative diagnosis of SLE.

HYPOTHYROIDISM

Classical signs

- Lethargy, inappetence, obesity.
- Seborrhea sicca and a dry, lusterless hair coat, easily epilated with poor regrowth.

Clinical signs

Hypothyroidism may result in **erythematous, scaling and papular lesions**, which affect the **forehead, abdomen, tail and footpads**.

Often there is seborrhea sicca and a dry, lusterless hair coat, which is easily epilated, and has poor regrowth after clipping. The skin may be myxoedematous and thickened.

Other signs of hypothyroidism may be present including lethargy, inappetence, obesity, hypothermia and bradycardia.

Most commonly **occurs after bilateral thyroidectomy** for hyperthyroidism. Spontaneous hypothyroidism is very rare.

Diagnosis

If available, the **thyroid stimulation test** shows minimal to no stimulation.

Free T₄ or **free T₄ by equilibrium dialysis** are below the normal values for the laboratory.

Response to **trial therapy with thyroxine** (0.05–0.1 mg once daily) for 4 weeks results in improved clinical signs.

HYPERADRENOCORTICISM

Classical signs

- Pot-bellied appearance and muscle wasting.
- Unkempt hair coat with thin, easily torn skin.
- Polydipsia/polyuria and often associated diabetes mellitus (80% of cases).

See main reference on page 251 for details (The Cat With Polyuria and Polydipsia).

Clinical signs

Bilaterally symmetrical alopecia involving the face, flanks and limbs.

The **skin is often very thin** and **easily torn** especially **on the digits**.

Systemic signs of polydipsia, polyuria and weight loss are usually associated with diabetes mellitus.

Diagnosis

Low-dose dexamethasone test (0.1 mg/kg) or ACTH stimulation test is used for diagnosis.

Imaging the adrenals by abdominal ultrasound helps differentiate pituitary from adrenal-dependent hyperadrenocorticism.

DIABETES MELLITUS

Classical signs

- Polydypsia, polyuria, polyphagia and weight loss.

See main reference on page 236 for details (The Cat With Polyuria and Polydipsia).

Clinical signs

Cutaneous xanthomatosis has been described in cats with diabetes mellitus.

This may present as **whitish, waxy nodules in the paws**.

Typical signs include polydypsia, polyuria, polyphagia and weight loss.

Diagnosis

A tentative diagnosis is based on a history of polydypsia and polyuria with weight loss.

A definitive diagnosis is based on demonstrating **persistent hyperglycemia** > 12 mmol/L (> 216 mg/dl).

HYPOMELANOSIS (VITILIGO)

Classical signs

- Patches of complete lack of pigment.

Clinical signs

Loss of epidermal pigmentation (hypomelanosis) can be **primary** as with **vitaligo**, or **secondary** as in post-inflammatory change.

Vitaligo is a **hereditary lack of pigment** in the skin, and may have an autoimmune pathogenesis.

- Three affected Siamese cats had antimelanocyte antibodies, whereas four normal Siamese cats did not.
- There can be **symmetric macular depigmentation**, especially of the nose, lips, buccal mucosa and facial skin, also footpads and claws.
- Lesions are most noticeable in the dark coat colors where the normally dark footpads have pink patches.
- Onset of the condition is usually in young adulthood.

Diagnosis

Diagnosis is based on the history of a young age with patches of unpigmented skin in normally dark-pigmented areas.

In vitiligo there is no history of trauma or inflammation that could have damaged melanocytes.

CUTANEOUS HORNS

Classical signs

- Firm, horn-like protuberance on the skin.

Pathogenesis

The term cutaneous horn is used to describe a **keratotic mass** that is generally higher than it is wide, usually several millimeters in diameter and 1–2 cm high.

Cutaneous horn of the footpads in cats is a rare disorder. Affected cats have been **positive for FeLV** and the virus has been isolated from the horn material.

The viral-affected horns occur on the **footpads only**.

Clinical signs

Single or multiple firm horn-like formations arising from any area of skin. **Footpads** seem to be predisposed sites.

Diagnosis

Diagnosis is based on the typical clinical appearance and histopathology of dense laminated hyperkeratosis.

Biopsy may be necessary to **check for squamous cell carcinoma at the base**.

Check FeLV status.

Treatment

Surgical excision is the treatment of choice. Recurrences are frequent.

CALCINOSIS CUTIS

Classical signs

- Enlarged, painful and firm pads.
- The pads may be ulcerated and exuding a white paste of gritty material.
- Signs of chronic renal disease.

See main reference on page 245 (The Cat With Polyuria and Polydipsia).

Clinical signs

Calcinosis cutis is a rare complication of chronic renal disease.

Affected pads are **enlarged, firm and painful**.

A **chalky white-to-pink material** with feathery margins may be seen through the intact epidermis of non-ulcerated lesions.

Older lesions **may ulcerate** and extrude a chalky, white, pasty to gritty material.

Other signs associated with **chronic renal disease** such as polyuria/polydipsia, and weight loss.

Diagnosis

A **definitive diagnosis** is based on **biopsy** of the lesion that demonstrates metastatic calcium deposition in the tissues.

Clinical and laboratory findings are consistent with chronic renal failure.

EPIDERMOLYSIS BULLOSA

Classical signs

- Uncommon congenital disorder.
- Avulsion of the claws with minor trauma.
- Erosive lesions on the hard palate.

Pathogenesis

Separation of epidermal tissues from the dermis occurs after minor trauma because of **defective adherence** of the dermo–epidermal junction.

Epidermolysis bullosa is an uncommon congenital disorder, that has been reported in a line of Siamese cats.

Clinical signs

Nails are shed after minor trauma. The **entire claw is avulsed**, leaving the corium quick exposed. Regrown claws may be **deformed**.

There may also be **ulcers** on the **footpads and hard palate**.

The onset is noticed when kittens become ambulatory and start climbing.

Lesions may have secondary bacterial infection.

Diagnosis

A **definitive diagnosis is based on histopathology** of an amputated P3 which demonstrates dermo–epidermal separation without inflammation or basal cell injury.

Differential diagnosis

Bacterial paronychia can be very similar, but the history and histopathology will differentiate.

Immune-mediated disease affecting the claws, but generally there are severe dermatological signs elsewhere on the body.

Treatment

Curative treatment is not available, but **amputation of P3 of affected digits** will prevent recurrent claw loss with associated pain and infection.

Secondary infection should be managed with suitable antibiotics.

Avoid trauma.

ARTERIOVENOUS FISTULAE

Classical signs

- Localized persistent or recurrent edema.
- Distinct and tortuous blood vessels near the area.

Pathogenesis

Arteriovenous fistulae are **traumatically induced** from penetrating wounds, blunt trauma or post-surgical complications of onychectomy.

Clinical signs

Arteriovenous fistulae may be associated with **persistent or recurrent edema and bacterial paronychia** of one paw.

Pulsating blood vessels, palpable thrills and continuous machinery murmurs are present in the area of the fistula.

Diagnosis

A tentative diagnosis is based on the **clinical signs**.

Definitive diagnosis is by demonstration of the fistula by contrast radiography.

Treatment

Surgical removal of the fistula or amputation of the affected part.

THALLIUM POISONING

Classical signs

- Easily epilated hair.
- Cutaneous erythema, erosions, crusts, necrosis and alopecia.
- Lesions on ears, nose, abdomen.
- Marked redness of mucous membranes.

Pathogenesis

Thallium is a **cumulative rodenticide** rapidly absorbed through the mucosae and skin. Its use is now banned in many countries.

Clinical signs

Skin lesions are seen in association with chronic toxicity, and are characterized by **chronic dermatitis**. There is **severe redness of mucous membranes, cutaneous erythema, erosions, crusts, necrosis and alopecia**.

Lesions are usually present around **body orifices** and on the **nose, ears, abdomen** and **feet**. The footpads become hyperkeratotic and ulcerated.

Hair is easily epilated.

Diagnosis

Diagnosis is based on a **history of exposure** to thallium and **positive test for thallium in the urine**.

Skin biopsies demonstrate dermatitis consistent with thallium poisoning.

Differential diagnosis

A number of diseases can have a similar crusted and ulcerated appearance, and distribution to thallium toxicosis, and skin biopsies are needed to differentiate. These include:

- Autoimmune disorders.
- Drug eruptions.
- Erythema multiforme and toxic epidermal necrolysis.
- Lymphoreticular neoplasia.

Treatment

Prussian blue (100 mg/kg IV) given daily until urinary tests for thallium are negative has been used to treat thallium toxicosis, but is relatively ineffective when clinical signs are already present.

The recommendation at present is combination treatment with **charcoal for gastrointestinal trapping** of thallium and **potassium chloride supplementation**

(1–2 g q 8–12 h) to **promote renal excretion of thallium**.

Supportive care such as intravenous fluids and antibiotics for secondary infection.

Prognosis

Prognosis is very guarded, and **most cases die**.

PART 14

Queen and kitten with problems

54. The fading kitten

Julie Levy

KEY SIGNS

- Crying.
- Ineffective nursing.
- Weakness and inactivity.
- Hypothermia.

MECHANISM?

- **Kittens appear healthy and vigorous at birth.** The fading syndrome develops when an underlying medical problem results in poor nursing, hypoglycemia and hypothermia.

Signs of the fading syndrome include:

- Loss of suckling reflex.
- Weight loss.
- Weakness and inactivity.
- Bloated abdomen.
- Hypothermia.
- Crying.

WHERE?

- Polysystemic effects lead to generalized weakness, ineffective nursing and inactivity.

WHAT?

- Fading and death may result from the primary condition or from the debilitation that follows.

QUICK REFERENCE SUMMARY

Diseases causing a fading kitten and neonate

ANOMALY

- **Congenital defects* (p 1138)**

Most common life-threatening congenital anomalies are cleft palate (nasal reflux, sneezing and dyspnea), portosystemic vascular shunt (stunted growth, neurological signs), cardiac (heart murmur, cyanosis, dyspnea, palpable thrill and stunted growth), gastrointestinal defects including mega-esophagus (regurgitation), blind intestinal loops (vomiting) and atresia ani (abdominal distention).

METABOLIC

- **Neonatal isoerythrolysis (NI)** (p 1134)**

Acute hemolytic anemia in the first 2 days of life in kittens with blood type A who nurse on type B queens. Signs range from acute death on the first day of life to a fading syndrome over several days. Hemoglobinuria and anemia are highly suggestive.

- **Hypoglycemia*** (p 1133)**

Life-threatening complication of other conditions, including sepsis, malnutrition, hypothermia, parasitism. Signs usually occur in kittens up to 6 weeks of age, and include weakness and cessation of nursing or eating, ataxia, disorientation, agitation and in severe cases seizures, blindness, coma and death.

- **Prematurity* (p 1141)**

Respiratory distress due to immature pulmonary development is life threatening. Kittens also have no hair on ventrum or paws, ineffective sucking and MCV > 90 fl.

NUTRITIONAL

- **Nursing failure** (p 1135)**

May result from inadequate maternal milk supply due to agalactia or mastitis. Also ineffective nursing occurs due to weakness, competition or congenital anomaly. Occasionally, inappropriate milk replacer or feeding techniques are the problem. Signs usually occur in the first week of life and include weight loss, weakness and ineffective nursing.

- **Weaning stress* (p 1127)**

Transition to solid food may be affected by delayed physical development of unthrifty kittens or attachment to bottle feeding in hand-reared kittens. Kittens (6–8 weeks old) are reluctant to accept solid food but suckle well.

PSYCHOLOGICAL

- **Maternal neglect* (p 1135)**

Inexperienced queens, maternal illness or a distracting environment may cause queens to neglect their kittens. Queens may actively reject or attack sick kittens. Kittens may be agitated and crying or be small, weak and have little suckling activity. Usually occurs in the first week of life.

continued

continued

PHYSICAL

● Hypothermia*** (p 1131)

Hypothermia develops rapidly in neonatal kittens deprived of an external heat source or secondary to many other diseases. Hypothermia leads to gastrointestinal stasis, bradycardia, hypoglycemia and dehydration. Usually occurs in kittens <3 weeks of age but occurs as a secondary problem up to 6 weeks of age. Signs include cessation of nursing, inactivity and the kittens are cold to touch.

INFLAMMATION/INFECTIOUS

Viral:

● Feline leukemia virus infection (FeLV) (p 1142)

Systemic viral infections such as FeLV may cause fetal losses, fading neonates or illness of weanling kittens, but disease is most common in kittens 8 weeks and older. Likely to affect most or all of the litter.

● Feline infectious peritonitis infection (FIP) (p 1143)

FIP may cause fetal losses, fading neonates, or illness of weanling kittens, but disease is most common in kittens 8 weeks and older. Weight loss, ascites and cycles of unexplained fever may occur in kittens older than 8 weeks.

● Panleukopenia virus infection (p 1142)

Typically causes severe vomiting, diarrhea, dehydration and panleukopenia, most commonly in kittens older than 6 weeks of age. May cause peracute deaths without typical signs. Intrauterine infection may cause an intention tremor apparent when the kittens begin to walk.

● Upper respiratory infection (herpes virus**, calicivirus**) (p 1137)

Herpes and calicivirus typically cause upper respiratory infections from 2 weeks and older. Infected kittens are inactive, crying and have a poor appetite, lose weight and may be hypothermic or pyrexia. Sneezing, nasal discharge, oral ulcers, corneal ulcers, conjunctivitis are common.

BACTERIAL

● Bacterial sepsis*** (p 1128)

This is the most common cause of death in 1–6-week-old kittens. Pathogens are most likely to be acquired from the normal flora of the queen and the environment. Signs range from sudden death to a fading syndrome lasting a few hours to a few days. Signs include inactivity, weakness, crying and ineffective nursing. Abdominal bloating and dyspnea may also occur.

PARASITIC

● Intestinal parasitic infection (ascarids*, coccidia*, giardia, toxoplasmosis) (p 1141)

Diarrhea, dehydration and cachexia due to coccidia (common) and giardia (uncommon) occurs in kittens 5 weeks and older. Ascariasis (very common) causes weight loss, diarrhea, and intestinal obstruction in 8-week and older kittens if severe. Toxoplasmosis (uncommon) causes systemic illness in kittens of all ages.

● Flea anemia* (p 1140)

Severe anemia due to heavy flea infestation is common in all ages of kittens.

INTRODUCTION

MECHANISM?

Kittens appear **healthy and vigorous at birth**.

Infectious diseases, inadequate nutrition, congenital conditions or environmental extremes debilitate kittens.

The fading syndrome develops when the primary condition leads to poor nursing, hypoglycemia and hypothermia.

WHERE?

Regardless of the cause of illness, fading kittens frequently have a similar appearance: **generalized weakness, ineffective nursing, hypothermia and inactivity**.

The primary condition produces adverse effects on multiple organs, resulting in fading kitten syndrome.

WHAT?

The cause of fading kitten syndrome is frequently related to the age of the kitten.

Neonates succumb to **congenital defects, maternal neglect, nursing failure, neonatal isoerythrolysis and environmental stresses**.

Bacterial sepsis is the biggest threat to 1–6-week-old kittens.

Viruses, parasites, and weaning stress are more common in 4–8-week-old kittens.

Hypoglycemia occurs most commonly up to 6 weeks of age.

Hypothermia occurs most commonly up to 6 weeks of age.

DISEASES CAUSING THE FADING KITTEN OR NEONATE

BACTERIAL SEPSIS***

Classical signs

- Loss of suckling reflex.
- Hypothermia.

Classical signs—Cont'd

- Crying.
- Gastrointestinal stasis and bloating.
- Inactivity.
- Dyspnea.
- Kittens 1–6 weeks of age.

Pathogenesis

Sepsis is the leading cause of death in neonatal kittens in the 1–6-week age range.

In most cases, septic kittens have become systemically infected with organisms that are found among the normal cutaneous and intestinal flora of cats and not from exotic pathogens.

Kittens are born with an immature immune system and are largely dependent on passive immunity acquired from maternal colostrum to prevent bacterial infection.

- **Failure of passive transfer is an important cause of sepsis in kittens.**
- Other contributing factors are poor nutrition, environmental stress and concurrent debilitating illness.

Bacterial sepsis frequently affects entire litters, with kittens falling ill and perishing within a few hours or days of each other.

Clinical signs

Clinical signs range from sudden death to a fading syndrome that lasts a few hours to a few days.

Neonatal sepsis is **characterized by rapid deterioration and lack of response to therapy** in kittens that appeared to be healthy a few hours earlier.

Dyspnea may develop in the presence of bronchopneumonia.

External abscessation, particularly of the umbilical stump, may be present.

Hypothermia is common. Young kittens are unable to mount a febrile response to infection, so fevers are not present even in severe systemic infections.

Abdominal distension due to gastrointestinal stasis leading to gas accumulation is common.

Diagnosis

Sepsis is difficult to differentiate from other causes of fading kitten syndrome because there are rarely specific findings such as external abscesses.

Hypoglycemia is common.

Complete blood count often reveals leukocytosis with left shift and toxic changes. Leukopenia is a particularly grave finding.

Bacterial culture and sensitivity may be performed on blood, urine and exudates.

Complete necropsies with microbial culture and sensitivity of kittens that succumb to fading kitten syndrome are essential to prevent deaths of remaining littermates and to resolve recurrent problems in breeding programs and facilities that house kittens.

Necropsies often reveal widespread visceral abscessation in kittens that appeared to be thriving only hours before death.

Differential diagnosis

Hypoglycemia, hypothermia, and most causes of fading kitten syndrome mimic the clinical signs of bacterial sepsis.

Inflammatory leukogram changes in combination with clinical signs are highly suggestive of sepsis.

Because sepsis is so common in kittens aged 1–6 weeks, it should be the leading differential for fading kittens in this age group.

Treatment

Treatment for sepsis should begin as soon as the condition is suspected and should not be delayed for confirmation of the diagnosis.

Parenteral administration of fluids, medications and blood products can be challenging in neonatal kittens due to their small size.

- **Intravenous (IV) access can be achieved via the jugular vein** with a short 24- or 22-gauge catheter, even in very young kittens.
- If venous catheterization is not feasible, **the intraosseous (IO) route** may be used. After preparing the site aseptically, a 22-gauge hypodermic or spinal

needle is inserted in the proximal humerus or femur and can be bandaged in place for repeated or long-term use. Most fluids, medications and transfusions administered IV can also be given IO.

- **The peritoneum** provides a large surface area for absorption of fluids, blood products and drugs, but systemic blood levels following intraperitoneal (IP) administration may be delayed compared to IV and IO routes.
- The small muscle mass of neonatal kittens makes repeated intramuscular (IM) administration of medications impractical.
- Fluids and medications can also be administered subcutaneously (SC), although absorption may be poor if peripheral vasoconstriction is present.

Antibiotic therapy should cover the spectrum of the most commonly isolated agents of neonatal sepsis. These include *Streptococcus*, *Staphylococcus*, and **Gram-negative enteropathogens**. *Bordetella bronchiseptica* may cause life-threatening bronchopneumonia. Dose adjustments of antibiotics may be appropriate in neonatal kittens, but guidelines are largely empirical and based on other species.

- **Enrofloxacin** (5 mg/kg once daily, SC; current data suggest that absorption of enrofloxacin following oral dosing may be poor in neonatal kittens). Dose reduction of enrofloxacin is not required in kittens. It is effective against many agents of neonatal septicemia, but has poor activity against streptococcal species and anaerobes.
 - SC administration of enrofloxacin may result in permanent alopecia at the site of injection.
 - Cartilage erosions have not been reported in kittens treated with clinically relevant dosages.
 - Blindness due to retinal degeneration has been reported in adult cats, especially at higher doses.
- **Broad-spectrum parentally administered antibiotics** (e.g. enrofloxacin 5 mg/kg IV or SC q 24 h plus ampicillin 22 mg/kg IV or SC tid).
- **Amoxicillin-clavulanate** (22 mg/kg PO bid) provides extended coverage for kittens that do not require parenteral administration.
- **Initially, antibiotics are administered parenterally** to assure reliable absorption and adequate blood levels. As the kitten returns to health, oral administration may replace injection, although disruption of the normal intestinal flora and diarrhea may result.
- Treatment duration should be a minimum of 2 weeks.

Because **passive immunity is believed to be critical for protecting the neonate against bacterial pathogens**, it is essential to assure that affected kittens have adequate levels of immunoglobulin. This may be **confirmed by measuring serum IgG levels**. The delay in waiting for test results may put at-risk kittens in danger of illness however, so it may be warranted to **administer serum** empirically to provide protection for kittens at risk for septicemia. See page 1137 (maternal neglect and nursing failure) for details of serum administration.

Nutritional support is usually required because septic kittens fail to nurse. Even brief lapses in food intake can lead to hypoglycemia, immunosuppression and villus atrophy of the intestines, resulting in decreased defenses against pathogens. Some form of assisted-feeding is usually required. Nasogastric intubation (indwelling 3.5 or 5 French catheter) is a convenient route for feeding without the stress of forced hand-feeding or repeated orogastric intubation. Use a formula suitable for orphan kittens such as KMR (Kitten Milk Replacer). The recommended volume is 25 ml/100 g BW per day. Newborn kittens do not tolerate more than 2 ml at a feeding for the first 1–2 days, and should be fed every 2–4 hours. Thereafter, feeding volumes can be gradually increased to 5 ml/feed the first week, 10 ml/feed the second week, and 15 ml/feed the third week. After the first few days the kitten can be fed 4–6 times per 24 h. Weak kittens may not tolerate volumes this large without regurgitating and need to be fed smaller volumes more frequently.

Prognosis

Survival is low in kittens that are showing clinical signs of sepsis, particularly if dyspnea is present.

Prognosis for littermates that appear healthy at the time therapy is initiated is good.

Kittens from *Streptococcus canis*-infected queens that are treated empirically at birth have an excellent prognosis.

Transmission

Most bloodstream infections are acquired from the normal flora of the queen or from the environment. They invade the bloodstream via the umbilicus or from

colonization of the gastrointestinal, respiratory or urinary tracts.

***S. canis* is acquired from the vaginal mucosa of carrier queens during birth.** The organism is believed to invade via the umbilicus and the oronasal passages.

Prevention

***S. canis* transmission from carrier queens can be prevented** by routine use of penicillin at the time of birth. The queen is given a 1-ml SC injection of a product containing 150 000 IU benzathine penicillin and 150 000 IU procaine penicillin per ml. At birth, each newborn kitten receives 0.25 ml SC of a 1:6 dilution of the same product, and their navels are dipped in a 2% solution of tincture of iodine.

Passive transfer of maternal antibodies represents the strongest protection against bacterial sepsis. If there is any question about adequate colostrum intake by kittens, a serum IgG level can be determined. Alternatively, serum may be administered empirically as a source of immunoglobulin to kittens at risk for failure of passive transfer.

Because entire litters frequently succumb to bacterial infections, **littermates of kittens that have died of sepsis should be treated with antibiotics.**

If sepsis or failure of passive transfer is documented in one kitten of a litter, it is wise to prophylactically provide serum for the remaining kittens.

HYPOTHERMIA***

Classical signs

- Inactivity.
- Bradycardia.
- Respiratory depression.
- Intestinal gas accumulation.
- Kittens less than 6 weeks of age, but mostly less than 3 weeks.

Pathogenesis

During the first two weeks of life, normal body temperature is 35°C.

Neonatal kittens lack a shiver reflex and are **unable to raise their body temperature more than 7°C above ambient temperature.**

- Separation from the queen or littermates may result in rapid loss of body heat.

If the core temperature drops below 32°C, **the digestive tract becomes non-functional and nursing ceases.**

Severe hypothermia **depresses heart rate, respiration and metabolic functions.**

Although kittens living outdoors may develop primary hypothermia from environmental exposure, **most hypothermic kittens presented for veterinary care have a predisposing medical condition.**

Hypothermia is an almost universal sequella of all causes of fading kitten syndrome. **Concurrent hypoglycemia is very common.**

Primary hypothermia due solely to exposure is most common up to 3 weeks of age, whereas hypothermia secondary to other stressors such as cachexia, systemic illness and hypoglycemia may be seen in kittens as old as 6 weeks or more.

Clinical signs

Cessation of nursing.

Inactivity.

Cold to touch.

Diagnosis

Subnormal rectal body temperature.

- < 35°C in kittens under 2 weeks of age.
- < 37°C in kittens greater than 2 weeks of age.

Differential diagnosis

Any cause of fading kitten syndrome may result in hypothermia.

Treatment

First efforts should be directed at correcting hypothermia and hypoglycemia, if present.

Mildly hypothermic kittens can be rewarmed by external heat sources such as heating blankets, warm water bottles and heat lamps.

- Care should be taken to assure that recumbent kittens are not over-warmed or burned if they are too weak to move away from the heat source.

Severely hypothermic kittens (< 32.5°C) should be warmed at the core before surface warming is attempted. Heating the skin first causes peripheral vasodilation before the cardiopulmonary system is capable of supporting non-critical tissues.

- Core warming can be accomplished by administering **fluids warmed to 37°C (IV, IO or IP), warm water enemas, and heated inspired air.**
- Care should be taken not to warm the kitten too fast to avoid overtaxing the depressed cardiopulmonary system.

Simultaneously, blood glucose should be measured. If measurement is not available, the kitten should be **presumed to be hypoglycemic and treated empirically with dextrose** (see Hypoglycemia for details).

- If the body temperature is below 32°C, dextrose must be administered parentally since gastrointestinal dysfunction may prevent absorption of oral sugar solutions.

Once body temperature and blood glucose have been corrected, a search for a predisposing cause should be initiated if environmental conditions do not explain the hypothermia.

Debilitated kittens frequently relapse with hypothermia and hypoglycemia, so careful monitoring and preventive measures are important.

Prognosis

Prognosis for a full recovery is good if hypothermia and hypoglycemia were not too prolonged and if primary predisposing causes are correctable.

Prevention

Healthy kittens should thrive if they have access to the queen and littermates for warmth.

Neonatal kittens without a queen should be kept in warm quarters (≥ 27°C) or have access to a heat source such as a lamp or heating pad. To avoid overheating, kittens should be able to move to an unheated area of the nest.

HYPOGLYCEMIA***

Classical signs

- Weakness.
- Seizures.
- Blindness.
- Coma.
- Kittens up to 6 weeks of age, occasionally older.

Pathogenesis

Regardless of the cause of illness, sick neonates frequently stop nursing, dehydrate and become hypothermic, all of which contribute to hypoglycemia.

Neonates are especially susceptible to hypoglycemia because **energy requirements of neonates are 2–3 times higher than adults. Limited fat and glycogen stores** further predispose neonates to hypoglycemia if nutrition is inadequate.

Hypothermia is a common sequella to many diseases in neonates and contributes to hypoglycemia by several mechanisms:

- Mild to moderate hypothermia (< 34.5°C) suppresses nursing behavior.
- Severe hypothermia (< 32°C) results in gastrointestinal stasis and prevents absorption of glucose and other nutrients.
- Hypothermia reduces metabolic activity, including gluconeogenesis.

Parasitism and other intestinal diseases may disrupt nutrient absorption, leading to malnutrition and hypoglycemia.

Infection, inflammatory processes and stress increase utilization of glucose that may exceed the neonate's ability to replace it.

Hypoglycemia results in decreased metabolic functions, especially in the central nervous system.

- **Neurologic signs of hypoglycemia progress from weakness, lethargy and mental dullness to seizures, coma and death** if not corrected in time.

Clinical signs

Early signs of hypoglycemia are **weakness and cessation of nursing or eating**.

Neonatal kittens become **inactive**, whereas kittens older than 3 weeks may be **ataxic and appear disoriented or agitated**.

Severe hypoglycemia may **result in seizures, blindness, coma and death**.

Diagnosis

Hypoglycemia should be suspected in all fading kittens.

Home glucometers can be used to measure glucose quickly with a drop of blood.

Laboratory glucose results are the most accurate, but may take longer.

Blood glucose < 3.3 mmol/L (60 mg/dl) is consistent with clinical hypoglycemia.

If blood glucose measurement is not available, **response to treatment with IV dextrose or oral sugar solutions supports a diagnosis of hypoglycemia**.

Since hypoglycemia is frequently secondary to another medical condition, a thorough evaluation for a predisposing problem should be performed.

Differential diagnosis

Any cause of fading kitten syndrome may resemble hypoglycemia. **Although a low blood glucose level confirms hypoglycemia, concurrent conditions are also common.**

A normal blood glucose test differentiates hypoglycemia from **other causes of neurologic signs** such as head trauma, encephalitis, primary seizure disorder, portosystemic vascular shunt and inborn errors of metabolism.

Treatment

Emergency treatment for life-threatening hypoglycemia is **25% dextrose (1–2 ml/kg slowly IV)**. If venous access is not available, 10% dextrose may be administered IP or IO. Oral sugar solutions (e.g. 50% dextrose, corn syrup) can be given if body temperature is normal, but effect is slower and less predictable.

Clinical response to glucose replacement should be rapid. Delayed or partial response may occur if prolonged, severe hypoglycemia is present.

Continuous infusion of 5–10% dextrose or repeated bolus q 2–6 h may be required to maintain euglycemia until the underlying cause can be eliminated.

Hypothermia must be corrected before feeding is attempted.

Frequent small meals of high-protein diet supplemented with dextrose are given until euglycemia is maintained.

- Nasogastric or orogastric tube feeding may be required for neonatal or weak kittens with hypoglycemia.

Prognosis

If the underlying condition can be corrected, prognosis for full recovery is excellent.

In some cases, neurologic damage such as blindness from hypoglycemia may be irreversible.

Prevention

Good husbandry should assure against most causes of hypoglycemia.

- Neonates should be kept warm and be evaluated for nursing effectiveness.
- Older kittens should receive adequate high-quality nutrition and be free of parasites and gastrointestinal diseases.

Kittens should be evaluated daily for adequate food intake, weight gain and body composition.

NEONATAL ISOERYTHROLYSIS (NI)**

Classical signs

- Hemoglobinuria.
- Anemia.
- Acute death on first day of life or gradual decline over several days.

Pathogenesis

At this time, **the blood group system in cats is known to include: type A, type B and type AB**, but additional blood groups may emerge as more cats studied.

Type B cats produce natural anti-A antibodies, even prior to first transfusion or pregnancy. **Type B queens**

pass these antibodies to the newborn kittens in the colostrum.

When type A kittens (blood type inherited from type A stud) absorb the anti-A antibodies from the type B queen, the kittens' own red blood cells are lysed (neonatal isoerythrolysis), leading to **acute anemia, hemoglobinuria and organ failure.**

Because most mixed breed cats are type A, neonatal isoerythrolysis is uncommon.

- In the US, more than 95% of mixed breed cats are type A, < 5% are B, and AB is very rare.
- In other continents, B is more common in domestic shorthair cats. For example, in Australia 73% are type A, 26% are type B and AB < 1%.

Some breeds have up to 50% type B cats and are at high risk for neonatal isoerythrolysis. The breeds with the highest percentage of type B cats are Devon Rex, British shorthair, Cornish Rex, exotic shorthair, Sphinx, Scottish fold, Somali, Persian, Japanese bobtail, Birman and Abyssinian.

Clinical signs

Kittens are born healthy and nurse vigorously.

Dark red-brown urine (hemoglobinuria) appears soon after colostrum is ingested.

A fading syndrome develops in first few days of life. Death may also occur acutely without any prodromal signs.

Tail tip necrosis may occur in milder cases.

Diagnosis

The clinical history suggests kittens were healthy until colostrum was ingested.

Urinalysis and PCV reveal hemoglobinuria and hemolytic anemia.

Blood typing confirms incompatible parental blood types (type A stud, type B queen).

Differential diagnosis

Hemoglobinuria differentiates neonatal isoerythrolysis from other causes of early fading kitten syndrome.

Treatment

Remove kittens from queen during first day of life to prevent further colostrum ingestion.

If a transfusion is required in the first days of life, administer **washed type B red blood cells (available from the queen)** to the kitten.

- 3–5 ml donor blood is collected in CPD-A (citrate-phosphate-dextrose-adenine). A heparinized syringe can be used to collect donor blood in emergencies if CPD-A is not available.
- The blood is centrifuged for 10 minutes at 1500 rpm. The plasma (containing anti-A alloantibodies) is discarded. The red blood cells are reconstituted with saline (volume equal to discarded plasma), recentrifuged, and the saline discarded. A second saline wash is performed, and then the saline is discarded. A volume equal to half of the discarded plasma is added, yielding washed packed red blood cells ready for transfusion.
- Administer the packed red blood cells IV, IO or IP.
 - Avoid volume overload when using IV or IO routes.
 - Approximately 70% of RBCs administered IP reach the circulation by 72 h.

If transfusions are required **after 2 weeks of age, red blood cells of the kitten's own type A can be transfused**. However, **a major cross match** (donor cells + recipient plasma) **should be performed** to assure the period of incompatibility has passed).

Routine supportive care is essential during the hemolytic phase of neonatal isoerythrolysis.

Prognosis

Acute death without prodromal signs occurs in some severe cases.

Early recognition and treatment is expected to save many kittens with neonatal isoerythrolysis.

Some mildly affected kittens have only laboratory evidence of disease without clinical signs.

Kittens that survive the acute crisis generally recover to full health.

Prevention

Avoid incompatible breedings (type A stud, type B queen).

Breeders may choose to eliminate type B cats from the breeding pool entirely.

If incompatible breeding is unavoidable, **prevent nursing on maternal queen for the first 2 days of life**. Foster the litter on a type A queen or bottle feed during this time. **Administer serum from type A donor for passive immunity** in place of colostrum. Kittens can be returned to queen on day 3 because antibody absorption is complete by that time.

Rapid in-clinic blood typing of kittens by card test can be used to identify and segregate kittens at risk for neonatal isoerythrolysis.

NURSING FAILURE** AND MATERNAL NEGLECT*

Classical signs

- Ineffective nursing efforts.
- Crying.
- Loss of suckling reflex.
- Weight loss.
- Weakness.
- Usually present in first week of life.

Pathogenesis

Inadequate milk supply.

- Absent or inadequate milk production may be caused by premature delivery, delayed milk letdown, or maternal illness or malnutrition. Primiparous queens are more likely to have poor milk production.
- **Mastitis may result in milk that is toxic** or contains microbial pathogens. Uncomfortable queens may reject nursing attempts.
- **Large litters may overwhelm the queen's ability to produce enough milk**. Less-vigorous kittens may not compete well for access to nipples.
- **Poor maternal behavior** may result from difficult delivery that causes illness or exhaustion in the queen. Some queens simply fail to bond to their kittens and make no attempt to care for them.

Ineffective suckling.

- **Premature kittens** commonly lack a suckle reflex.
- **Hypothermia, hypoglycemia and weakness due to other illnesses may abolish the suckle reflex.**
- **Congenital anomalies** (e.g. cleft palate, mega-esophagus) may prevent effective suckling.

Failure of passive transfer.

- Colostrum is produced during the first 1–5 days of lactation. Colostrum has increased IgG, IgM and IgA compared to milk.
- **Kittens absorb virtually all of their maternal antibody from colostral milk in first day of life.** Less than 10% of antibodies are acquired before birth.
- **Failure to absorb adequate immunoglobulin leaves kittens susceptible to infection.** Kittens at the highest risk of failure of passive transfer are orphans, those with delayed nursing after birth (e.g. cesarean section delivery), and kittens nursing queens with poor colostrum quality.

Clinical signs**Inadequate milk supply.**

- Kittens are vigorous and show strong interest in suckling. **Hungry kittens are agitated and cry continuously.** Eventually, kittens may become weak from dehydration and malnutrition.

Ineffective suckling.

- Kittens may be **small, weak, inactive and show little suckling activity** in response to oral stimulation.
- Milk may leak from the nostrils (cleft palate, regurgitation).

Maternal neglect.

- **Queen is distracted and inattentive to kittens.** **Overt aggression** toward kittens is sometimes observed.
- Kittens are alert and agitated, crying and attempting to nurse.
- Some queens may not care for any kittens until the entire litter is delivered. First-born kittens may suffer from neglect during this time. Maternal neglect is **most common with inexperienced queens.**

Diagnosis

Examine the queen for general condition, mammary gland health and milk supply.

Observe maternal behavior.

Examine the kittens for congenital anomaly, general vigor, stomach fullness and suckling responses.

Failure of passive transfer is diagnosed by serum IgG concentration (normal >1000 mg/dl the day after colostrum ingestion).

Healthy kittens weigh approximately 100 g at birth and **should gain 10% body weight daily during the first week of life. Daily weight checks provide early detection of kittens that fail to thrive.**

Differential diagnosis

Any cause of fading kitten syndrome may lead to weakness and failure to nurse.

Queens that appear to be displaying poor or aggressive maternal behavior may be culling kittens with subclinical illnesses.

Treatment

Correct primary medical conditions of the queen or kittens that prevent effective nursing if possible.

Poor maternal behavior can often be corrected by **reducing stress and distraction in a quiet, safe environment free of human interference.**

- If the queen still neglects the litter, she should be **confined to a small space with kittens.** Resting benches and other alternatives to the nest box should be removed.
- If necessary, **the queen may be restrained to allow the kittens to nurse.** Queens often accept their litter after several nursing sessions.
- If the queen is highly distracted or agitated, **mild sedation may encourage maternal behavior.** Sedated queens should be monitored continuously for aberrant behavior.
- **Hand-rearing or transfer to a foster queen** may be required if bonding is unsuccessful.

Because inanition occurs quickly in undernourished kittens, **prompt nutritional intervention** is indicated for kittens with nursing failure.

- Feed kitten milk replacer by bottle or syringe if kitten will nurse.
- Transient forced feeding may be achieved by repeated orogastric intubation. **Prolonged feeding is less stressful if an indwelling nasogastric (3.5**

French catheter) tube is placed. See page 1131 (Bacterial sepsis) for details.

- If the **queen or a foster cat has good maternal behavior, she can be allowed to care for the kittens even if she is not lactating or if milk quality is poor**, as long as nutritional supplementation is provided. Kittens raised by queens frequently have better social development than hand-reared kittens.
- If kittens are to be reared completely by hand, **urination and defecation must be stimulated** by rubbing the perineum with a damp cotton ball. **Kittens develop the ability to urinate and defecate on their own by 3–4 weeks of age.**

Documented or suspected hypoglobulinemia due to **failure of passive transfer can be corrected by administration of donor serum.**

- The **best donor is a healthy, blood type A, vaccinated cat** free of FeLV, FIV and other infections. Cats that share the same environment as the kittens are most likely to have antibodies against pathogens the kittens may encounter. However, since most infections in kittens are due to ubiquitous normal flora and common feline viral pathogens, serum from any healthy, vaccinated cat is likely to be protective.
- **Serum is administered at a dose of 15 ml/100 g body weight SC or IP to achieve normal IgG concentration.**
 - The serum administration is divided into **3 doses of 5 ml** each administered **every 12 h** to avoid volume overload.
 - Catteries and facilities caring for large numbers of young kittens can prepare single-dose aliquots of donor serum for future use. Serum stored at -20°C remains adequate for immunoglobulin supplementation for more than a year after collection.

Prognosis

Prognosis is excellent when the underlying cause of nursing failure can be corrected.

Foster-rearing is time consuming, but can be performed by most pet owners. Healthy kittens that are free of underlying disease have an excellent prognosis if hand-reared.

Septicemia due to failure of passive transfer is one of the leading causes of death in neonatal kittens.

- Once signs of sepsis appear, prognosis for survival is poor. Administration of serum after clinical signs appear is less likely to affect outcome.
- Serum administered prior to the development of disease offers protection against sepsis.

Prevention

Breeding queens should be well-nourished and free of infectious disease. Vaccinations should be complete prior to breeding. **Queens with poor maternal behavior should be eliminated from breeding programs.**

Kittens should be kept warm and well-nourished.

Maternal behavior should be observed to ensure adequate access to milk by the kittens.

Queens and their litters should be kept in private, quiet quarters to avoid distracting or stressing the queen.

If ingestion of colostrum is uncertain, serum should be provided. Serum IgG can be measured in the kittens, but it is often more practical to administer serum empirically.

If sepsis or failure of passive transfer is documented in one kitten of a litter, it is wise to prophylactically provide serum and antibiotics for the remaining kittens.

UPPER RESPIRATORY INFECTION (HERPES VIRUS**, CALICIVIRUS*)

Classical signs

- Nasal discharge.
- Sneezing.
- Conjunctivitis.
- Oral ulceration.
- Corneal ulceration.
- Dyspnea.
- Kittens 2 weeks and older.

See main reference on page 7 for details (The Cat With Acute Sneezing).

Clinical signs

There is much overlap between the clinical signs caused by herpes- and calicivirus, so it is impossible to

definitively distinguish between the two viruses based on clinical signs alone. **Mixed infections are common.**

Neonatal kittens may develop severe viral respiratory disease as early as 2 weeks of age.

- At this age, kittens have nasal and ocular discharge and may become severely dyspneic.
- Conjunctivitis neonatorum may accompany upper respiratory infections in neonatal kittens that have not yet opened their eyes.
 - The eyelids are greatly distended by accumulation of fluid and purulent material in the conjunctival space behind the sealed lids. (See page 1212, The Cat With Ocular Discharge or Changed Conjunctival appearance).

Kittens (> 6 weeks) are less likely to become severely dyspneic.

- Kittens with calicivirus or herpes virus may have **oral ulcerations** that lead to salivation and refusal to eat.
- Older kittens with herpes virus may develop **corneal ulcers**.
- Some older kittens develop “febrile limping kitten syndrome” following natural exposure or vaccination with calicivirus.
 - High fevers (> 40°C) and severe joint pain are present.
 - Classical signs of upper respiratory infection may be absent.
 - The syndrome spontaneously resolves within a week with or without treatment.

Upper respiratory infection with *Bordetella bronchiseptica* may be complicated by dyspnea due to bronchopneumonia.

Diagnosis

Clinical signs are classical. In addition, there may be a history of upper respiratory infections in other household cats.

Viral culture of pharyngeal swabs can be used to differentiate herpes and calicivirus.

B. bronchiseptica is diagnosed by bacterial culture of pharyngeal swabs or tracheal wash specimens.

Bulging eyelids (conjunctivitis neonatorum) may occur in kittens prior to natural separation of the lids.

Thoracic radiography may reveal pneumonia.

Differential diagnosis

Bronchopneumonia, heart failure and oral ulceration due to caustic substances or electric shock can be differentiated from upper respiratory infection by careful physical examination ± thoracic radiography.

Treatment

Safe and effective systemic antiviral agents for herpes- and caliciviruses are not available.

Therapy is limited to **supportive care** including **fluid replacement, nutritional support** and **prevention of secondary bacterial infection** (amoxicillin/clavulanate 10–20 mg/kg PO bid, doxycycline 10 mg/kg PO q 24 h, or azithromycin 5–10 mg/kg PO q 24 h for 5–7 days).

Conjunctivitis and corneal ulceration are treated with topical antibiotic ointment (without corticosteroids).

- Severe ocular herpes infection may benefit from topical antiviral compounds.
- Lysine has been shown to inhibit herpes virus in cats at 100 mg/kg orally once daily.

Although *B. bronchiseptica* may be susceptible to amoxicillin/clavulanate, some strains are resistant to penicillins and cephalosporins. Fluoroquinolones, doxycycline, and azithromycin are effective against most isolates.

In kittens with **conjunctivitis neonatorum, the eyelids should be gently separated** and the **purulent material flushed out**, followed by topical antibiotics and frequent cleansing of the eyes.

- Despite a dramatic clinical appearance at the time of diagnosis, most kittens fully recover with normal vision.

Intranasal vaccination against viral upper respiratory infection (**not panleukopenia virus**) beginning **as early as 3–4 weeks of age has ameliorated upper respiratory outbreaks** in some catteries with endemic infections.

CONGENITAL DEFECTS*

Classical signs

- Cleft palate: milk from nostrils during nursing.
- Cardiac defect: heart murmur, dyspnea, cyanosis.

Classical signs—Cont'd

- **Gastrointestinal defect: vomiting, regurgitation, constipation.**
- **Portosystemic vascular shunt: salivation, neurologic signs.**

Pathogenesis

Drug administration (e.g. cleft palate from griseofulvin), vaccination (e.g. cerebellar hypoplasia from modified live virus panleukopenia), and infection (e.g. thymic atrophy from FeLV) during pregnancy may cause congenital defects.

Genetic predisposition for specific deformities occurs in some breeds (e.g. cleft palate in Siamese, craniofacial deformity in Burmese).

Spontaneous defects are the most common.

Clinical signs

Signs are dependent on type of defect.

- In **cleft palate, milk leaks from nostrils during nursing**. Rhinitis, sneezing and dyspnea may be present.
- **Cardiac defects** may be accompanied by heart murmur, cyanosis, dyspnea, palpable thrill and stunted growth. Many kittens may be asymptomatic until they are older.
- Kittens with **megaesophagus** (primary or secondary to vascular ring anomaly) have regurgitation from the time of birth. Other gastrointestinal defects such as blind intestinal loops, motility disorders and atresia ani also have signs from the time of birth including vomiting, abdominal distension, crying and constipation.
- **Signs in kittens with portosystemic vascular shunt (PSS) are usually delayed** until weaning or later.
 - Intermittent salivation and neurologic signs (ataxia, seizures, disorientation, blindness) are common and **may** be associated with meals.
 - Signs of cystitis may occur if urate calculi form in bladder.
- Cerebellar hypoplasia is accompanied by intention tremor and ataxia, which is observed when kittens begin to walk.

Diagnosis

Thorough physical examination (cleft palate, cardiac defect, atresia ani) is essential.

Radiography ± contrast and ultrasonography (cardiac defect, megaesophagus, intestinal defect, PSS) may characterize the specific anatomic defect.

Post-prandial bile acids or plasma ammonia are elevated in kittens with PSS.

Nuclear scintigraphy is helpful for confirming diagnosis of PSS.

Differential diagnosis

Transient innocent murmurs are common during the first weeks of life but **usually cease by 8 weeks of age**. A patent ductus arteriosus (PDA) may close spontaneously during the perinatal period.

Anemic kittens may develop a flow murmur that resolves with correction of the anemia.

Treatment

Surgical correction is often the ideal treatment (cleft palate, vascular ring anomaly, patent ductus arteriosus, PSS).

Affected neonates may require aggressive nutritional support via nasogastric or esophagostomy tube feeding until they are large enough for surgical correction.

Prognosis

Prognosis is good to excellent for surgically correctable defects (e.g. PDA, PSS).

Cleft palate repair is often complicated by post-operative healing problems and may require multiple surgeries.

Early correction of vascular ring anomalies usually improves regurgitation, but not all cases return to normal.

Megaesophagus may occasionally resolve spontaneously. Aspiration pneumonia is a common complication of megaesophagus and may lead to euthanasia.

Cardiac defects in some cats may remain asymptomatic for years without treatment (e.g. ventricular septal defect, tetralogy of Fallot).

Congenital gastrointestinal defects carry a poor prognosis for normal function following surgery.

Prevention

Avoid drug administration, especially known teratogens, during pregnancy.

Avoid modified live virus vaccination during pregnancy.

Select breeding stock that is free of inherited diseases.

WEANING STRESS*

Classical signs

- Reluctance to accept solid food in kittens 6–8 weeks old.
- Crying, agitation.

Clinical signs

Reluctance to accept solid food in kittens 6–8 weeks old. **Kittens suckle well on queen or bottle.**

Inability to compete with larger littermates around the food bowl.

Kittens may have a withdrawn or anxious personality.

Crying, agitation.

Diagnosis

Good suckle reflex.

Thrives with queen or littermates of similar size and maturity.

Differential diagnosis

Medical causes of failure to thrive can appear similar.

Excessive competition from littermates.

Treatment

Extend nursing or hand-rearing of kittens with delayed maturation.

Hand-feed gruel (food–milk mixture) to assist transition to solid food.

House with other kittens of similar maturity.

Hand-reared kittens with “bottle addiction” may require **increasing time intervals between feedings and formula offered in a dish** before they will accept solid food.

FLEA ANEMIA*

Classical signs

- Inactivity.
- Inappetence.
- Pale mucous membranes.
- Heavy flea infestation.
- Kittens 2–8 weeks old.

Clinical signs

Progressive weakness and inactivity.

Pale or white mucous membranes.

Heavy flea infestation or marked accumulation of flea feces in hair-coat.

May develop systolic heart murmur secondary to anemia.

Affects entire groups of cats with young kittens developing the most severe anemia.

Diagnosis

Clinical signs are classic.

CBC reveals anemia and hypoproteinemia due to blood loss. The anemia is usually regenerative unless concurrent iron deficiency develops.

Differential diagnosis

Anemia secondary to hookworm infection is differentiated by fecal examination.

Severe anemia secondary to FeLV infection is uncommon in young kittens and is excluded by testing for the virus.

Severe anemia in mixed breed, Burmese and Siamese kittens associated with transient hyperlipidemia at 4–5 weeks of age is eliminated based on lack of severely lipemic plasma found in hyperlipidemia.

Treatment

Remove fleas with a kitten-safe flea adulticide (imidacloprid, fipronil). Treat the other household pets and the environment to prevent reinfestation. Selamectin can be used from 6 weeks of age, but debilitated kittens may have adverse reactions.

If anemia is severe, **whole blood or packed red blood cell transfusion** may be required. If intravenous catheterization is not possible, blood may be administered IO or IP. Approximately **70% of red blood cells administered IP reach the circulation within 72 hours.**

INTESTINAL PARASITIC INFECTION (ASCARIDS*, COCCIDIA*, GIARDIA, TOXOPLASMOSIS)

Classical signs

- Weight loss.
- Diarrhea.
- Dehydration.
- Abdominal distention.
- Kittens 4 weeks and older.

Clinical signs

Diarrhea, weight loss and abdominal distention are common findings of intestinal parasitism.

Severe coccidial diarrhea may cause dehydration and hypoglycemia.

Vomiting occurs uncommonly.

Diagnosis

Fecal flotation and direct smear.

Response to treatment.

Differential diagnosis

Bacterial or viral gastroenteritis and malnutrition cause similar signs and may occur concurrently with intestinal parasitism.

Treatment

Supportive care (e.g. fluid replacement, nutritional supplementation) as needed.

Coccidia: sulfadimethoxine (50 mg/kg PO first day, then 25 mg/kg PO q day for 10–20 days until asymptomatic and fecal flotation negative). All exposed kittens should be treated, and environmental contamination should be controlled. Some kittens may have persistent or recurrent infections.

Ascariasis: pyrantel pamoate (10 mg/kg PO, repeat in 2–4 weeks) or selamectin (administered topically to the skin can be used monthly for fleas and ascarids from 6 weeks of age). Because ascariasis is very common, all kittens should be routinely treated regardless of fecal test results.

Giardia: fenbendazole (50 mg/kg PO q day for 5 days).

PREMATURITY*

Classical signs

- Incomplete hair-coat.
- Low birth weight.
- Ineffective suckling reflex.
- Dyspnea.
- Kittens in first days of life.

Clinical signs

Lack of hair on ventrum and paws.

Low birth weight (< 80 g).

Absent or ineffective suckling efforts.

Dyspnea if pulmonary development is inadequate.

Diagnosis

Physical examination.

Breeding date known.

Immature fetal hematology (mean corpuscular volume > 90 fl, increased nucleated red blood cells).

Differential diagnosis

None.

Treatment

Tube feeding.

Oxygen supplementation.

If dyspneic or more than a few days premature, prognosis for survival is poor.

FELINE LEUKEMIA VIRUS (FeLV) INFECTION

Classical signs

- Loss of suckling reflex or appetite.
- Weight loss.
- Hypothermia.
- Inactivity.
- Crying.
- Kittens 4 weeks and older.

Clinical signs

Perinatal infection may result in abortions, stillbirths, and fading kittens, although **most clinical illness is seen in weaned kittens and adolescents.**

Poor appetite.

Weight loss.

Hypothermia if kittens are less than 6 weeks old.

Crying and inactivity.

Perinatal FeLV is likely to affect most or all of the litter.

Abortions and stillbirths.

Kittens in apparently healthy litters individually fade and die over several weeks to months.

Some infected kittens are long-term survivors.

Diagnosis

Test queen and each kitten for FeLV antigen.

It is **common for infected kittens to have delayed seroconversion for FeLV antigen for several weeks to**

months, leading to false-negative tests in litters of fading kittens at the time of initial testing.

Delayed seroconversion and inconsistent infection within litters makes it inappropriate to test only representative littermates.

- **All kittens should be tested, and serial testing may be required** to confirm infection status.
- **The probability that an infected queen will transmit FeLV to her kittens is high.**

Some individuals in an affected litter may escape infection.

DIFFERENTIAL DIAGNOSIS

Any cause of fading kitten syndrome may mimic FeLV infection. Losses from FeLV occur more commonly in older kittens (> 4 weeks) than in neonates.

Treatment

Treatment is largely supportive, although specific antiviral therapy may have added benefit by reducing viral burden. **Claims for clinical benefits of immune modulator therapy have not yet been substantiated** in controlled clinical trials.

Recombinant feline interferon omega (antiviral dose: 1 MU/kg SC \times 5 days at day 0, day 14, day 60).

AZT (antiviral dose: 5–15 mg/kg PO or SC bid).

Treated cats had improved one-year survival compared to cats receiving placebo.

Recombinant human interferon alpha (antiviral dose: 100 000–1000 000 IU/kg SC q day).

Recombinant human interferon alpha (immune modulator dose: 30 IU/cat PO q 24 h alternate weeks).

Staphylococcus protein A (immune modulator dose: 10 μ g/kg IP twice weekly).

Provide supportive care with fluid replacement, antibiotics and blood products if indicated.

Although aggressive therapy may improve the condition of clinically ill kittens, **seroconversion to negative status is uncommon.**

PANLEUKOPENIA VIRUS INFECTION

Classical signs

- Intention tremor (evident about 5 weeks of age).

Classical signs—Cont'd

- Severe vomiting and diarrhea (usually ≥ 7 weeks old).
- Hypothermia or fever.
- Severe dehydration.

Clinical signs

Intrauterine infection may result in intention tremor (cerebellar hypoplasia), which becomes apparent when kittens begin to walk. This condition is **non-progressive** and does not affect health unless tremor severity prevents adequate food intake or leads to injury.

Postnatal infection causes necrosis of intestinal mucosa and hematopoietic progenitor cells resulting in **severe vomiting, diarrhea, dehydration and panleukopenia**.

- Most common in kittens ≥ 7 weeks old when protection from maternal antibodies is lost.

Hypothermia occurs in **kittens < 6 weeks old** or older kittens in endotoxic shock. **Fever** is common in **kittens > 7 weeks old**.

Panleukopenia commonly affects entire litters, but some kittens may escape infection if passive immunity is protective.

Peracute deaths may occur without typical signs in some kittens.

Diagnosis

Clinical signs of gastroenteritis in the presence of severe panleukopenia are classical findings.

Non-regenerative anemia and hypoproteinemia are common.

Detection of parvovirus antigen in feces by point-of-care tests for canine parvovirus appears to be useful, although the test accuracy of these tests in cats is unknown. Cats recently vaccinated against panleukopenia may also shed virus and test positive.

Necropsy and histopathology findings are diagnostic.

Differential diagnosis

Panleukopenia virus can be differentiated from other causes of gastroenteritis such as sepsis, FeLV and enteric bacterial infections by identifying parvovirus in the feces. In addition, the degree of leukopenia is

usually much more severe in panleukopenia virus infection.

Treatment

Aggressive intravenous fluid replacement is essential. IO fluid administration may substitute if venous access is limited. IP SC or oral fluid administration is less likely to provide adequate fluid support for the duration of illness (5–10 days). Fluids should be supplemented with potassium, dextrose and water-soluble vitamins as needed.

Parenteral broad spectrum antibiotics (e.g. enrofloxacin 5 mg/kg IV or SC q 24 h plus ampicillin 22 mg/kg IV or SC tid) are administered due to the severity of the leukopenia. Anti-emetics may be required if nausea is severe.

Blood transfusions may be required to treat anemia, hypoproteinemia and to provide passive humoral immunity.

Nothing is offered orally until vomiting has ceased.

Mortality is high in untreated kittens, but most aggressively treated patients should survive.

FELINE INFECTIOUS PERITONITIS VIRUS (FIP) INFECTION

Classical signs

- Abortions, stillbirths, fading kittens.
- Recurrent fever.
- Weight loss.
- Ascites.
- Kittens 4 weeks and older.

Clinical signs

Perinatal infection may result in abortions, stillbirths and fading kittens, although **most clinical illness is seen in weaned kittens and young adults**.

Cycles of unexplained fever and weight loss are common in older kittens (> 8 weeks).

Ascites, pleural effusion or uveitis may be present in older kittens (> 8 weeks).

FIP is **more likely to affect individual kittens** or litters than to cause widespread outbreaks of disease.

Diagnosis

Biopsy and necropsy tissues contain **pyogranulomatous inflammation and vasculitis**.

Serum coronavirus antibody titers are unreliable for diagnosis of FIP, but very high titers tend to correlate with clinical FIP.

- Although a high percentage of kittens within the household are likely to have positive coronavirus titers, only a few are expected to develop the disease.

Coronavirus PCR is unreliable for confirmation of FIP.

Hyperproteinemia (polyclonal gammopathy), often accompanied by non-regenerative anemia and lymphopenia, is consistent with FIP.

High-protein, pyogranulomatous effusion in the peritoneal, thoracic or pericardial cavity is highly suggestive of FIP.

The Rivalta test on serum or effusions may be the most reliable diagnostic test for FIP.

Differential diagnosis

FIP can be difficult to differentiate from other causes of fading kitten syndrome. Cyclic fevers and modified transudates are strong evidence for FIP.

Treatment

Medical treatment is usually ineffective for FIP, especially for fading kittens. Transient palliation of clinical signs may sometimes be possible with corticosteroid treatment.

55. The infertile queen

Isobel Phebe Johnstone

KEY SIGNS

- Normal estrus cycles and failure to produce a litter.
- Failure to cycle.
- Prolonged interestrus intervals.

MECHANISM?

- Infertility is the failure of a queen to produce a litter. It is the result of abnormalities in the **female** (e.g. infection, congenital abnormalities) or **male** or **environmental management practices** which prevent successful mating and pregnancy.

Signs of infertility include:

- Normal estrus cycles and failure to produce a litter.
- Failure to cycle.
- Prolonged interestrus intervals.

WHERE?

- **Reproductive tract** (ovaries, uterus, vagina and vulva).

WHAT?

- The **most common problems** associated with infertility are:
- **Environmental** and **management** practices.
- **Viral** or **bacterial** infections.

QUICK REFERENCE SUMMARY

Diseases causing an infertile queen

ANOMALY

- Congenital abnormalities (p 1156)

The queen appears physically normal but there is a structural abnormality in the reproductive tract that is a barrier to intromission or to the movement of sperm. Chromosomal abnormalities can present as phenotypically normal females that do not exhibit estrus.

continued

continued

METABOLIC

- **Ovarian cysts (cystic follicles)** (p 1151)**

Either prolonged anestrus or persistent estrus if the cysts are hormonally active. A possible problem in queens held back from breeding or the use of progestogen contraception products.

- **Cystic endometrial hyperplasia** (p 1152)**

Failure to produce kittens despite normal mating. Usually seen when queens have many estrus cycles without being mated or after the use of progestogen contraception products.

NUTRITIONAL

- **Hypovitaminosis A (p 1158)**

Anorexia, weight loss, hyperkeratosis, corneal infections, night blindness and reproductive problems of anestrus, fetal resorption, abortion or kittens with birth defects. Can be a problem in queens fed poor-quality food.

- **Taurine deficiency (p 1159)**

Retinal degeneration, cardiomyopathy and reproductive problems such as fetal resorption, stillborn kittens or live kittens of low birth weight with brain and limb deformities. Rare now that the problem has been recognized and commercial diets are appropriately supplemented.

NEOPLASTIC

- **Neoplasia (p 1157)**

Maybe a palpable abdominal mass (unusual) or ascites from metastases. Irregular estrus cycles occur with hormonally active ovarian tumors. Usually seen in older queens (9 years and over).

PHYSICAL/ENVIRONMENTAL

- **Physical and environmental factors (female/queen)*** (p 1148)**

A diverse range of causes producing signs ranging from anestrus, to prolonged interestrous intervals to normal estrus but refusal to mate to normal mating but no pregnancy.

- **Physical and environmental factors (male/tom)** (p 1150)**

A variety of problems that can prevent successful mating or male infertility which will present as normal mating but no ensuing pregnancy.

- **Inadequate photoperiod* (p 1153)**

The queen fails to exhibit estrus behavior and is housed in an area with inadequate lighting.

INFLAMMATION/INFECTIOUS

Viral:

- **Feline panleukopenia (p 1154)**

Fetal death, mummified fetuses or kittens born with neurological signs. The natural infection is now rare, but vaccination of a pregnant queen with live virus vaccines can produce the same problems.

- **Feline leukemia virus* (p 1153)**

Reproductive failure due to resorption or abortion. A common cause of reproductive failure in some countries unless vaccination programs are in place.

- Feline herpes virus (p 1154)

Pregnant queens may abort after a severe bout of respiratory disease. Now a much rarer cause of reproductive failure due to effective vaccines.

BACTERIAL/RICKETTSIAL

- *Bartonella henselae* (p 1155)

Infection has resulted in reproductive failure in experimentally infected cats.

- *Chlamydomphila felis* (p 1155)

Causes acute respiratory disease and sometimes fatal pneumonia in 6–12-week-old kittens. It is poorly documented whether it is a cause of poor reproductive performance, especially abortion in cats.

INTRODUCTION

MECHANISM?

Infertility can be defined as the **failure from any cause, of a female cat (queen) to produce a litter**. It is not a specific diagnosis but a **sign of a problem**. The problems encountered that can result in infertility can be subdivided into three categories.

Normal estrus cycle but failure to produce a litter.

- Evaluate the **general health of the queen**.
 - A queen may be infertile due to dysfunction of other organ systems such as the kidneys or liver.
 - Ensure the queen is vaccinated and free of diseases known to affect fertility, such as feline leukemia virus and *Chlamydomphila felis*.
- **Problems within the reproductive tract** can cause infertility.
 - Developmental defects or neoplastic masses can block the passage of sperm.
 - There can be implantation failure or abortion of fetuses due to problems with the uterine wall such as cystic endometrial hyperplasia or neoplasia.
- Evaluate the **fertility of the male cat (tom)**.
 - Review the breeding history of the male, particularly his ability to sire litters in the previous 6–12 months.
 - Use a proven sire who works well with any queen.
- Review breeding **management practices**.
 - Ensure the queen is allowed adequate time with the male for sufficient matings to stimulate ovulation.

- She should be housed with the male for as long as she is in estrus as the queen is an induced ovulator and needs a number of matings to stimulate a sufficient hormonal surge for ovulation.
- The stud cat owner should observe matings to ensure that normal matings and mating behavior are happening.

Failure to cycle.

- Previous ovariectomy should be ruled out.
- The **general health of the queen** may be compromised to such an extent that her estrus cycles cease.
 - Factors such as poor nutrition, overcrowding, stress of cat shows and debilitating illness can suppress estrus cycles.
- **Inadequate photoperiod**.
 - **Adequate light exposure** is essential for normal polyestrous cycles.
 - Cats are seasonally polyestrous, commencing estrus cycles with increasing day length.
 - At least 12–14 hours of light per day are necessary for normal estrus cycles.
- **Disorders of sexual development**.
 - Chromosomal abnormalities can result in a lack of fully functional ovaries and/or interfere with the normal development of the reproductive tract.

Prolonged interestrus intervals.

- **Pseudopregnancy** produced by **spontaneous ovulation** will produce a prolonged interestrus interval.
- **Hormonal dysfunction of the ovaries**.
 - **Polycystic ovaries** or **ovarian neoplasia** can halt the normal functioning of the ovaries.

WHERE?

Ovaries, uterus, vagina and vulva.

WHAT?

Environmental and management practices are a common cause of infertility in the cat.

In the cat there are **many infectious diseases** that can cause infertility.

DISEASES CAUSING SIGNS OF INFERTILITY IN THE QUEEN

PHYSICAL AND ENVIRONMENTAL FACTORS (FEMALE/QUEEN)***

Classical signs

- Failure to exhibit estrus behavior.
- Failure to permit breeding.
- Normal mating but no pregnancy.
- Prolonged interestrus intervals.

Pathogenesis

Age of puberty varies markedly between breeds.

- It may be as early as **4.5 months of age in Burmese and Siamese** to as long as **18 months of age in Persians**.
- Failure to exhibit estrus can be as simple as insufficient time to reach puberty.

Cats **need to reach a body weight of 2.3–2.5 kg** before normal estrus cycling commences. Although a cat may be of a sufficiently mature age it may be underweight.

Previous ovariohysterectomy. A new owner may be unaware of the previous history of the queen.

Environmental stress such as the show circuit, overcrowding, travel or unfamiliar locations can suppress estrus cycles or estrus behavior (silent heat).

Male preference; the queen may aggressively reject a certain male.

Spontaneous ovulation.

- Cats are **normally induced ovulators** but it is now known that spontaneous ovulation in cats is more frequent than once thought.
- If the queen has already ovulated then she may not permit mating.
- Pseudopregnancies from serial spontaneous ovulations, especially if the queen is a quiet caller, may be interpreted as pathological prolonged interestrus intervals.

Insufficient matings to induce ovulation. A certain level of luteinizing hormone is required to trigger ovulation. Normally this is only attained after several matings over a number of days.

Clinical signs

An apparently normal, healthy cat with a history of failing to show estrus.

An **underweight** cat.

A **nervous, highly strung** cat.

Normal matings but failure to become pregnant.

Diagnosis

History, especially of the cattery environment and management practices such as:

- **Cattery mating practices** and observations of mating behavior.
 - Inexperienced queens and studs should be paired with experienced ones.
 - The stud owner should remain in attendance during mating as foreplay, mating and separation can be quite violent. Some studs can become very rough and frighten a queen, especially an inexperienced one, and she may refuse to mate. Conversely a queen can be too aggressive for the stud and mating may be unsuccessful.
 - The stud owner needs to watch closely to ensure that successful mating has actually taken place.
 - A queen should be allowed at least three observed matings and the queen and stud should run together for at least 2 days, mating at will.
 - A queen usually needs 4–12 matings before there is a sufficient luteinizing hormone (LH)

surge for ovulation. The more matings the higher the LH surge.

- **Quality and quantity of the food being fed.** Poor-quality, incomplete diets or insufficient food can cause reproductive failure.
- The **housing with respect to the amount of light**, overcrowding and other possible “stresses”.
- The **show history of the queen**, for example, if she was held back from breeding for a show career.
- **Physical examination**, noting weight and condition of the cat as well as general health, especially the condition of the teeth is important for detecting physical causes of infertility.
- Severe dental disease is debilitating to general health.
 - The cat may be reluctant to eat and be below minimum weight for estrus cycles.
 - Circulating bacteria and toxins can damage other organs such as the heart, liver and kidneys, which in turn affect the health of the cat.

Vaginal smears obtained once or twice per week for 1–2 months during the breeding season **can reveal if the queen is silently calling.**

- Cornified epithelial cells (superficial and anuclear) predominate during the follicular phase and estrus coincides with the end of the follicular phase.

Progesterone levels measured 1–2 weeks after suspected estrus, detected either by vaginal cytology or behavior, will diagnose pseudopregnancy. A level > 6.36 nmol/L (2 ng/ml) indicates ovulation has occurred and by 1–2 weeks the level has risen to between 31.8–63.6 nmol/L (10–20 ng/ml) whether pregnant or pseudopregnant.

Differential diagnosis

If mating occurred but there is failure to produce a litter, or there is failure to cycle, or prolonged interestrus intervals are occurring, see other causes of female infertility in this chapter.

Chromosomal abnormalities can produce a small, non-cycling queen. Karyotyping is necessary to definitively distinguish this from a problem due to poor nutrition. However, ensuring proper feeding practices will solve the latter problem in time.

Treatment

Correct housing conditions and management problems such that the queen is living in the least stressful environment that can be devised.

Ensure **good nutrition** and that the **cat is actually eating** the food.

For a **queen that is aggressive** towards a male:

- Try a **more gentle introduction** such as removing the male from his pen and housing the queen there for a few days to get used to the smell and new surroundings and then reintroduce the male.
- Select a **different, experienced male** and see if the queen will accept him, if not try another.
 - Some queens are aggressive to all males despite being on full call, this is very unusual and it is possible that these have a subtle hormonal problem affecting their mating behavior.

For a **queen that spontaneously ovulates, house her long-term with a male** so that he can mate her immediately he detects she is in estrus so that sperm are there ready to fertilize the eggs.

For queens that appear healthy and no problem can be found to account for the lack of estrus, try **housing these with calling queens and/or close to a tom cat**, so that pheromones may stimulate ovarian activity.

Anestrus queens with normal ovaries can be induced to cycle by **exogenous hormones**.

- 2 mg follicle-stimulating hormone (FSH) IM once daily until onset of estrus (3–7 days).
- Then follow with either natural mating or 250 IU of human chorionic gonadotropin (hCG) to induce ovulation.

Prognosis

The prognosis is good for problems that can be solved by adjusting cattery conditions and practices.

Prevention

Ensure cattery conditions and management are always of the highest standard.

Do not breed from a line of cats if breeding problems are encountered in more than one female from that line.

PHYSICAL AND ENVIRONMENTAL FACTORS (MALE/TOM)**

Classical signs

- No mating behavior.
- Inability to mate.
- Unsuccessful mating (copulation failure).

Pathogenesis

Physical problems with the male such as:

- Congenital or acquired phimosis or bands of tissue connecting the penis to the prepuce.
 - There will be an inability to extrude the penis properly.
- **Preputial hair ring.**
 - A mat of hair becomes wrapped around the shaft of the penis, particularly long-haired cats, interfering with penile penetration.
- **Dental disease.**
 - Tooth pain or lack of teeth can prevent the male from making the important neck grip during mating, and he cannot keep the female still and remain mounted for intromission.

Behavioral and psychological problems with the male.

- He may be **timid and submissive.**
 - This could be a basic genetic behavioral trait or be due to insufficient testosterone.
- The male has **not reached puberty yet.**
 - Age at which males show mating behavior varies markedly. Some have been known to sire litters at 7 months of age, others do not start working until about 2 years of age.
 - Spraying behavior can start months before mating behavior.
- The male may have started working but is **still very inexperienced** and may not be able to manage certain queens.

Mismatched body size.

- The male and female must be of similar body size/length as the male has to have a firm neck grip at the front and yet be able to reach the vulva with his penis at the rear.

Changes to the male's territory may interrupt his mating behavior.

- Tom cats are very territorial and usually will only mate successfully in their own familiar territory.

- Normally the tom is housed in a stud cage, around which he sprays frequently to make it his territory, and the queens are brought to him.
- New housing or too vigorous cleaning of his cage will interfere with his familiarity with his territory.

Male infertility. Lack of sperm, abnormal sperm or retrograde ejaculation into the bladder cause male infertility.

Clinical signs

Disinclination to mate or aggressive behavior towards the queen.

Attempts to mate are unsuccessful.

Normal mating but the queen does not become pregnant.

Diagnosis

Ask questions regarding the **housing of the tom and mating practices** at the stud cat's establishment.

- Are the stud quarters adequate for introducing the queen, and for mating behavior?
- Are the stud and queen allowed to live together for unlimited matings?

Ask questions regarding the **mating behavior and ability of the tom.**

- Are normal matings observed?
- Are the tom and queen evenly matched in size?

Physical examination of the tom for general health and especially:

- The presence of two apparently normal testes.
- Check teeth for dental problems.
- Extrude penis and examine for problems that would prevent intromission.
- **Measure serum testosterone to check for inadequate production.** Normal levels range from non-detectable to 17.3 nmol/L (5 ng/ml) or more and so a stimulation test is necessary to document adequate testosterone production.
 - Give 25 µg GnRH IM and measure serum testosterone 1 h later; normal range 17.3–41.6 nmol/L (5–12 ng/ml).
 - Or give 250 IU hCG and measure serum testosterone 4 h later; normal range 10.4–31.2 nmol/L (3–9 ng/ml).

- **Assess if the tom is fertile.**

- Find out the reproductive success of queens mated at around the same time as the queen in question.
- Swab the vagina of the mated queen to look for sperm.
- Check the urine of the tom after mating for evidence of sperm. Their presence will at least confirm production of sperm, however, the infertility problem may be retrograde ejaculation into the bladder.
- Electro-ejaculation of the tom to assess sperm quality. This technique is likely to be only available in specialist practices.
- Tom cats can be trained to an artificial vagina but this takes time and patience.

Treatment

Ensure adequate tom cat housing and allow the tom to mark his territory adequately so that he is happy to work there.

- The stud quarters should be of a sufficient size to allow free movement for mating, at least 2.5×1.8 m (8×6 ft), with sleeping quarters and shelves for observation, exercise and escape from the queen.

Ensure the health of the tom including provision of **adequate nutrition**, especially vitamin A for functioning testes and maintenance of dental health.

Remove physical obstructions to normal penile function.

Allow adequate time for puberty, and match an inexperienced tom with an experienced queen.

Timid or submissive males could be given testosterone (50–150 mg SC or IM monthly) to see if this improves their performance, however, it may be inadvisable to persevere with them in case there is a hereditary basis to their inadequacy.

Prognosis

Problems that can be solved by adjusting management practices or attending to physical problems such as dental disease or preputial hair rings hold a good prognosis for future successful matings.

However, if there is male infertility, insurmountable psychological problems or other unsolvable problems, then it is best to choose a new stud.

- If a pregnancy is desired from this particular stud then artificial insemination (AI) is successful in cats.
 - Either train the male to use an artificial vagina or find a specialist center with electro-ejaculation facilities.
 - Allow the queen to come into a natural estrus preferably, or estrus can be induced as per above (page 1149), then give 500 IU of hCG IM at the time of AI to induce ovulation.

OVARIAN CYSTS (CYSTIC FOLLICLES)**

Classical signs

- Prolonged estrus behavior.
- Alternatively, prolonged interestrus interval or anestrus.

Pathogenesis

Cystic follicles may be hormonally active producing estrogen and hence persistent estrus.

Non-functional follicles can interfere with normal ovarian function and produce prolonged interestrus intervals or anestrus.

Clinical signs

Prolonged estrus behavior.

Alternatively, prolonged interestrus intervals or anestrus.

Diagnosis

Abdominal ultrasonography is a reliable means of identifying cystic structures.

Persistently **increased plasma estrogen levels** (> 20 pg/ml; 73 pmol/L) supports a diagnosis of cystic ovaries.

Exploratory laparotomy and visualizing the ovaries. This allows surgical treatment if the diagnosis is confirmed.

Differential diagnosis

Ovarian granulosa cell tumors can be hormonally active and also result in persistent estrus. These are usually seen in cats older than 5 years and are rare.

Treatment

Mate the queen to see if breeding can ovulate the cysts.

Try to **induce follicular rupture with hCG** (predominantly LH); 250 IU IM daily for 2 days.

Surgical removal of the cyst(s). Cysts can be ruptured mechanically, or if only one ovary is involved then remove the ovary if the cyst is large.

Prognosis

Prognosis is good for future pregnancies if the cysts can be ruptured by one of the methods above.

Prevention

Do not allow a young queen frequent estrus cycles without mating. Breed queens frequently, long periods of estrus without mating are conducive to the formation of cystic ovaries. The statement “Queens should be pregnant, lactating or both” is often quoted as being the ideal for good reproductive health.

CYSTIC ENDOMETRIAL HYPERPLASIA**

Classical signs

- Normal estrus cycles and mating but failure to produce a litter.

Pathogenesis

Cystic endometrial hyperplasia involves chronic hyperplasia and cystic glandular development of the endometrium.

In the dog, these changes have been produced by prolonged exposure to progesterone.

This mechanism may be possible in those cats that undergo serial spontaneous ovulations and hence prolonged exposure of the uterus to progesterone. However, spontaneous ovulation is an uncommon occurrence in cats.

Usually intact non-pregnant females undergo waves of follicular development and then atresia. Therefore, in cats the changes in the endometrium are likely caused by estrogens.

Cystic endometrial hyperplasia is associated with **infertility from implantation failure or early embryonic death.**

The incidence of cystic endometrial hyperplasia increases with age. It can be seen as early as 5–6 years but is more likely from 10 years of age. It is more common in nulliparous queens than in multiparous queens.

Clinical signs

The queen is apparently healthy, with normal estrus cycles. Mating behavior is normal but no litter eventuates.

Diagnosis

Abdominal ultrasound may be able to visualize the cysts in the uterine wall and is a non-invasive way of detecting the condition.

Exploratory laparotomy and biopsy of the uterus provide a definitive diagnosis.

Differential diagnosis

Other causes of normal mating but failure to produce a litter.

- Poor general health of the queen. A history and physical examination should detect any problems.
- Fertility and mating problems of the male cat. A history of recently siring litters and observations of normal mating are reassuring of fertility of the stud.
- Management practices should be checked to ensure that they allow an adequate number of matings to produce ovulation.
- Reproductive tract abnormalities. Ultrasonography may reveal neoplasia. An exploratory laparotomy will be necessary to detect developmental abnormalities, and biopsy of the uterus to detect abnormal conditions such as cystic endometrial hyperplasia or neoplasia. Cystic endometrial hyperplasia is a relatively common cause of the problem.

Treatment

Once the endometrium has undergone cystic change, there does not seem to be a treatment that reverses the changes.

Prognosis

Prognosis for producing a litter is poor, as the cystic endometrium interferes with implantation.

Prevention

Pregnancy protects the queen against pathologic changes in the uterus that interfere with fertility.

INADEQUATE PHOTOPERIOD*

Classical signs

- Failure to exhibit estrus behavior.

Pathogenesis

Cats are seasonal breeders, commencing estrus cycles with increasing day length.

A day length (photoperiod) of 14–16 hours of bright light per day is necessary for normal estrus cycling.

Clinical signs

A queen of apparently good health, normal body weight and not “stressed” that **fails to commence estrus cycles in the breeding season**.

Diagnosis

History and clinical examination to ensure a normal healthy cat.

Question the owner on housing arrangements and access to light.

Differential diagnosis

Other causes of anestrus.

- Poor nutrition. These cats have poor body condition and are below the minimum weight of 2.3–2.5 kg for commencing estrus cycles.
- Overcrowding. There is a history of a number of queens living together in small quarters and poor cattery conditions.
 - Each adult cat should have a minimum of 2.5 square feet of floor space and no more than 12 adult cats should be housed in the same pen.

- Stress of the show circuit. Obtain a history of the frequency of showing, the amount of travel and the cat’s reaction to showing.
- Poor health of the queen. A history and physical examination should detect this problem.
- Disorders of sexual development. These are detected by karyotyping for chromosomal abnormalities and exploratory laparotomy for physical defects of the reproductive tract.

History and physical examination will help to rank the possible causes into order of likelihood for the particular case.

Treatment

Ensure access to adequate environmental light in the breeding season.

- Maintain cats with a minimum of 12 hours of artificial light per day equivalent to a 100 watt bulb in a 4 × 4 meter room.

In the non-breeding season altering the hours of light can be used to induce estrus.

- If the hours of exposure to light can be controlled, then house the queen for 2 months at short days of 9 h of light followed by 1 month of 14 h days of light. There is a stimulant effect on estrus within 10 days.

Prognosis

Prognosis is excellent for normal reproductive function once an appropriate photoperiod is arranged.

Prevention

House cats with good access to natural lighting, either via windows or housed in outside catteries.

- If lighting in the cattery can be controlled, then the largest number of litters produced per year is when a regular 12 h light/dark cycle is maintained.

FELINE LEUKEMIA VIRUS*

Classical signs

- Fever, malaise, generalized lymphadenopathy.

continued

Classical signs—Cont'd

- Leukopenia, thrombocytopenia and anemia.
- FeLV-related disease such as lymphoid and myeloid neoplasms and reproductive failure.

See main reference on page 540 for details.

Clinical signs

Reproductive signs associated with FeLV infection may include effects on the fetus or uterus.

- Fetal effects include:
 - Unobserved **early embryonal deaths**.
 - **Resorption** of fetuses.
 - **Abortion** of normal-appearing fetuses.
 - Live-born **kittens who then fail to nurse**, become dehydrated and die in the first few weeks of life.
- **Possibly pyometra** due to immunosuppression, with consequent affect on fertility.

Diagnosis

Diagnosis is by demonstrating a positive **viral antigen test**; a variety of commercial test kits are available. See page 543 for details.

Viral isolation in the laboratory.

FELINE HERPES VIRUS**Classical signs**

- Acute and chronic respiratory disease.
- Abortion and neonatal mortality.

See main reference on page 583 for details.

Clinical signs

Acute upper respiratory tract signs with **paroxysms of sneezing** and **mucopurulent oculonasal discharge**, or chronic conjunctivitis and sinusitis.

Abortion occurs in infected queens, either as a direct effect of the virus on the placenta, or due to the debilitating effects of the disease on the queen.

- Now a much rarer cause of reproductive failure due to effective vaccines.

Diagnosis

Diagnosis is based on **history and physical examination** with signs typical of herpes virus infection.

Virus isolation in tissue culture from nasal, conjunctival or oropharyngeal swabs is available at some laboratories.

Herpes virus intranuclear inclusion bodies in hematoxylin and eosin-stained sections of inflamed mucous membranes.

DNA probes with **PCR** (polymerase chain reaction) **amplification is a very sensitive test** for detecting herpes virus infections and this is now the preferred test in a clinical situation.

- Moisten well a clean dry bacteriology swab with tears or exudate, place the swab in a sterile container (no transport medium) and refrigerate at 4°C until submission. Local anesthetic may be used in the eye before firmly swabbing the conjunctival sac.

FELINE PANLEUKOPENIA**Classical signs**

- Peracute disease characterized by sudden death.
- Subacute disease manifested by mild depression and diarrhea.
- Fetal infection resulting in fetal death or live kittens with neurological problems.

See main reference on page 650 for details.

Clinical signs

Signs of fetal infection depend on the gestational age of the fetus at the time of exposure.

- There may be **infertility** due to **inapparent loss of embryos**.
- There may be **abortion of mummified or macerated fetuses**.
- Kittens born alive often have **cerebellar hypoplasia** with consequent ataxia, and they may also be blind due to **retinal degeneration**.

Diagnosis

In the cat with reproductive failure but without illness, diagnosis of panleukopenia as being the cause is difficult.

Vaccination produces strong immunity and a history of regular vaccination generally rules out natural infection. However, vaccination of a pregnant queen with live virus can produce the same signs in the fetus as natural infection.

BARTONELLA HENSELAE

Classical signs

- Cats have shown fever, mild neurologic signs and reproductive disorders.

See main reference on page 390 (The Pyrexia Cat) for further details.

Clinical signs

Bartonella spp. are emerging **vector-borne pathogens** that cause persistent, often asymptomatic, bacteremia in their natural hosts.

Chronic infection may predispose the host to mild insidious non-specific manifestations.

Cats have shown fever, mild neurologic signs and **reproductive disorders**.

Bartonella henselae infection in experimentally inoculated cats resulted in **reproductive failure**, with females either **not becoming pregnant despite repeated breedings or only becoming pregnant after repeated breedings**.

It is not transmitted transplacentally, in colostrum or milk, or venereally.

Male cats bred with infected cats did not become infected.

Diagnosis

Diagnosis is based on detection of *Bartonella* in **whole blood by culture or PCR**.

Detection of *Bartonella* antibodies in serum can be used, but there is poor correlation with blood culture and PCR.

Treatment

Treatment involves use of **antibiotics** active against *Bartonella*.

To date no optimal protocol has been established. Suggested antibiotics for bartonellosis in the cat are:

- Azithromycin 10 mg/kg PO q 24 h for 4 weeks. Dose rate in cats is currently empiric.
- Doxycycline 10 mg/kg PO q 12 h for 2–4 weeks.
- Enrofloxacin 22.7 mg total PO q 12 h for 2–4 weeks. Retinal pathology may be induced at this high dose.
- Rifampin 10 mg/kg PO q 24 h for 2 weeks is effective alone, but should be given in combination with doxycycline to reduce bacterial resistance.

It is likely **prolonged administration may be necessary** to eliminate infection. Dosing for 4 weeks appears more efficacious than 2 weeks.

Post-treatment serology may be useful to determine elimination of *Bartonella* infection.

Prevention

With **rigorous flea and tick control measures** it is highly probable that transmission of *Bartonella* species will be greatly reduced or eliminated.

Zoonosis

Bartonella species are associated with several clinical syndromes in people. Immunocompromised people are particularly at risk.

CHLAMYDOPHILA FELIS

Classical signs

- Acute and chronic respiratory disease.
- Ophthalmitis, conjunctivitis and pneumonia in kittens.
- Possible infertility.

See main reference on page 13 for details.

Clinical signs

Chlamydomphila felis causes **neonatal conjunctivitis and conjunctivitis** of 6–12 week-old kittens, and sometimes fatal neonatal pneumonia.

It is currently poorly understood whether *Chlamydomphila* causes abortion, stillbirths and infertility.

- **Abortion** has been associated with outbreaks of *Chlamydomphila* conjunctivitis in catteries, however it has not been well documented that it was the cause of the abortion.
- The mechanism by which *Chlamydomphila* could cause abortion or infertility in cats is not known. It may be similar to that in people and some live-stock species, or it could be secondary to systemic inflammation and pyrexia.

Diagnosis

Diagnosis is based on history and physical examination with **signs typical of *Chlamydomphila* infection**.

The **PCR test** is a very sensitive test for detecting *Chlamydomphila felis* infection and is now the preferred test in the clinical situation. The method of specimen collections is described above for herpes virus.

CONGENITAL ABNORMALITIES

Classical signs

- Failure to exhibit estrus behavior.
- Failure to permit mating.
- Normal mating but no pregnancy.

Pathogenesis

A variety of congenital abnormalities, resulting in different signs, can result in infertility.

A **structural abnormality** of the female reproductive tract **may prevent normal intromission**.

Structural abnormalities may result in a **barrier to the movement of sperm up the tract**, although there is normal mating.

- Missing or non-patent portions of the tract have been reported.

Chromosomal abnormalities such as X-monosomy (37,XO), which has been associated with small stature and small non-functional ovaries (ovarian dysgenesis) and 38,XX/57,XXY, which has produced hermaphroditism.

Clinical signs

A **failure to exhibit estrus** behavior despite all circumstances appearing to be normal. Stature of the queen may be small.

Normal estrus behavior but the **queen will not permit intromission**.

Normal estrus and mating behavior but there is **no resulting pregnancy**.

Diagnosis

Diagnosis is based on history, especially regarding signs of estrus and attempts at mating, and physical examination to determine if there is a barrier to intromission.

Contrast radiography of the reproductive tract.

- This is **best done at estrus** as at this time the cervix is open and the contrast is able to travel up the uterine horns to test their patency.

Karyotyping to check for chromosomal abnormalities. Usually 10 ml of heparinized blood at room temperature sent within 24 hours of collection is required, but check with the nearest cytogenetics laboratory for their sample requirements.

A **laparotomy to examine the reproductive tract may be required**. It is useful to take biopsies of the ovaries and uterus at this time.

Differential diagnosis

Causes of anestrus such as:

- Inadequate photoperiod. See if the queen comes into estrus after ensuring at least 14 hours of bright light per day. The queen should start estrus cycles after about 1–2 months.
- Environmental stress-induced suppression of estrus. Over-crowding causes a higher frequency of aberrant social behavior, lowers resistance to disease and there may be poor nutrition resulting from food competition. If such problems are suspected, plus there is anestrus, then check conditions at the cattery.

Treatment

Chromosomal abnormalities are not treatable.

Laparotomy and inspection of the reproductive tract would indicate if the abnormalities could be corrected surgically. However, as the abnormalities may be heritable, it would be unwise to breed from the queen.

Prognosis

Chromosomal abnormalities causing bilateral ovarian dysgenesis would not be fertile.

- Cases of chromosomal abnormalities and only unilateral ovarian dysgenesis have been reported with successful pregnancies.

Very rarely is there a structural abnormality that could be surgically corrected, so that the reproductive tract could carry a litter to term.

Prevention

Chromosomal and structural abnormalities are usually unfortunate congenital defects of development, and it is not known how to prevent them.

- If they frequently happen in a line of cats then do not breed from that line.

NEOPLASIA

Classical signs

- Irregular estrus cycles and/or aggressive behavior.
- Swollen abdomen, and possibly a palpable abdominal mass.
- Cystic endometrial hyperplasia and pyometra may occur.

Pathogenesis

Neoplasia involving the reproductive tract in the female cat is uncommon, and is usually seen in older cats.

- **Ovarian neoplasia.**
 - **Granulosa cell tumors** account for about half of the ovarian tumors.
 - In the queen, these are usually malignant tumors.

- They may be hormonally functional, producing either androgenic or estrogenic hormones.
- Cystic endometrial hyperplasia and pyometra may occur secondary to hormonally active tumors.
- Reported age range is 6 months to 20 years, with an average of 9 years.

Adenoma and adenocarcinoma are seen less commonly.

- They are frequently bilateral.
- The malignant form may spread to the peritoneal cavity.
- **Fibroma/sarcoma, leiomyosarcoma, teratoma and dysgerminoma** are rare.
- **Uterine and vaginal neoplasia** is extremely rare in cats.
- **Leiomyoma** and **fibroma** are the commonest types of tumor.
 - The tumors may be single or multiple and are usually in the body of the uterus.
 - Usually the cats are 9 years of age or older.
 - These tumors may be hormonally influenced, and are most likely to be seen in association with ovarian cysts or cystic endometrial hyperplasia.
- **Adenocarcinomas** are even less common and are malignant.
- **Lymphoma** has been described in association with multicentric disease.
- Vaginal tumors are less common than uterine tumors but are of the same types.

Clinical signs

The tumors may be large enough to present as a palpable abdominal mass, especially granulosa cell tumors and dysgerminomas.

If **granulosa cell tumors** are hormonally functional there may be:

- **Irregular estrus.**
- **Cystic endometrial hyperplasia and pyometra.**
- Gynecomastia and bilateral alopecia.
- Abnormal aggressive behavior.

Ovarian adenocarcinoma may metastasize to the abdominal cavity, producing an effusion, and **present as ascites.**

Uterine leiomyomas may develop rapidly following estrus, the mass **may block the uterine lumen**, and the queen may present with dystocia or pyometra.

Diagnosis

Ovarian tumors may be large enough to be seen on plain radiographs. They displace coils of the small intestine in the cranial and mid-abdomen. Retrograde vaginography using a positive contrast agent may be used to demonstrate vaginal masses. At estrus the cervix will be open and allow the contrast agent into lumen of the uterus and this may demonstrate uterine neoplasia.

Abdominal ultrasound and biopsy are invaluable to diagnose the primary tumor and detect metastases to abdominal organs.

As some tumors have been reported to metastasize to the lungs, **thoracic radiographs** should be done prior to treatment.

- Exploratory surgery and biopsy or tumor removal provide a definitive diagnosis, and are the best method of checking for metastases.

Differential diagnosis

Ovarian cysts can appear very similar to ovarian tumors.

- They occur frequently in older queens.
- **Ultrasound may be able to differentiate these.**
 - Ovarian cysts have thin walls with anechoic contents. Acoustic enhancement is a feature.
 - Ovarian neoplasia can be recognized as a mass lesion of varying size and echo-texture, maybe multicystic, but usually with irregular margins and irregular septae.
- Surgical removal and **histopathology give a definitive diagnosis.**

Treatment

Surgical removal of the ovary(ies) affected by tumor.

- A complete ovariectomy is the treatment of choice as there may be uterine pathology associated with hormonally active tumors. Only leave the uterus if one ovary is unaffected and there is to be an attempt at gaining a litter from an important queen.
- Chemotherapy treatment for these tumors has not been reported. Cisplatin has been used in human and canine ovarian carcinomatosis, but this drug is contraindicated in cats.

Ovariectomy should be curative for benign tumors.

Prognosis

Prognosis is guarded for ovarian tumors in cats, as **most are malignant**, and they are the most common type of tumor to metastasize.

Uterine tumors have a much better prognosis as the **most common types are benign.**

Prevention

Ovariectomy at a young age eliminates the chance of these tumors occurring. In a queen required for breeding this is not an option. However, she should undergo ovariectomy as soon as she is no longer required for breeding.

HYPOVITAMINOSIS A

Classical signs

- Weight loss, anorexia, hyperkeratosis of epithelial tissues, failure of glandular secretions, corneal infections, night blindness and retinal atrophy.
- Lack of estrus cycles.
- Fetal resorption or abortion.
- A high proportion of the kittens with defects.

Pathogenesis

Inadequate vitamin A in the diet. **Cats require pre-formed vitamin A in the diet** as they are unable to process carotene into vitamin A.

- With the ready availability of good-quality commercial diets, a deficiency should be a rare occurrence.
 - There is a possibility of deficiency where a **poor-quality commercial diet** or **inadequate home-prepared food** is fed.

Clinical signs

Failure of implantation may occur. This presents as a queen with normal mating but fails to produce kittens.

There is a high proportion of kittens with **cleft palates, spina bifida, hydrocephaly and defects of the diaphragm.**

Diagnosis

Measure the vitamin A levels of the queen. Normal plasma vitamin A levels are 2866 ± 2390 IU (960 ± 770 mg/ml).

Differential diagnosis

Any of the causes of anestrus, fetal resorption or abortion.

Treatment

Feed a **good-quality commercial diet**.

Feed liver (good source of vitamin A) no more than once a week if the cat is on an imbalanced diet and the owner does not want to change to a balanced commercial diet. If liver is fed too frequently, cats can become addicted to liver and refuse to eat anything else.

Vitamin A supplementation. The amount needed for normal reproduction has been reported to be at least 2000 IU/day ($670 \mu\text{g/day}$). The NRC recommended daily requirement for cats is 5000 IU/kg.

Beware of over-dosing with vitamin A and producing skeletal exostoses.

Prognosis

Prognosis is excellent for normal reproduction once the deficiency has been rectified and the diet continues to be adequate in vitamin A.

Prevention

The best prevention is to **feed a good-quality commercial diet**. If the owner wishes to feed home-prepared

food, then give good nutritional counseling so that the fundamentals of cat nutrition are understood.

TAURINE DEFICIENCY

Classical signs

- Central retinal degeneration.
- Cardiomyopathy.
- Reproductive failure.

See main reference on page 1181 for details.

Clinical signs

Taurine-deprived queens maintain normal weight and appetite and come into estrus, however, they commonly **reabsorb fetuses, or produce stillborn or low-birth-weight kittens.**

- Kittens may be born with **brain deformities, limb deformities, and grow slowly.**

Diagnosis

Measure plasma taurine levels. Whole blood levels of 250 nmol/ml have been suggested as representing a satisfactory taurine status.

Treatment

A requirement of 400 mg of taurine for growth, and 500 mg for reproduction, per kilogram (5000 kcal) of diet has been suggested by the National Research Council. This means approximately 25 mg of taurine per day.

56. The cat with vaginal discharge

Isobel Phebe Johnstone

KEY SIGNS

- Vaginal discharge \pm systemic signs.

MECHANISM?

- Bacterial invasion of the uterus via the vagina.

WHERE?

- Uterus, vagina and vulva.

WHAT?

- Most cats with a vaginal discharge have pyometra.

QUICK REFERENCE SUMMARY

Diseases causing vaginal discharge

INFLAMMATION/INFECTIOUS

Bacterial:

- **Metritis* (p 1162)**
Causes fever, septicemia, shock and a vaginal discharge.
- **Cystic endometrial hyperplasia/pyometra complex*** (p 1161)**
Causes nephrogenic diabetes insipidus, vaginal discharge, inappetence, weight loss.

INTRODUCTION

MECHANISM?

Metritis and pyometra are caused by **opportunistic bacterial invasion of the uterus via the vagina** whilst the cervix is open. The bacteria are able to colonize in the uterus when the endometrium or uterine contents are abnormal.

- **Acute bacterial infection** can follow queening (kittening), if there has been **trauma to the reproductive tract**, and especially **if there has been abortion or retained fetuses or placental tissue**.
- **Chronic bacterial infection** is usually a **sequel of cystic endometrial hyperplasia** where, under the influence of excessive hormonal stimulation, there is endometrial growth and excessive glandular secre-

tions, which are an excellent medium for bacterial growth.

WHERE?

Uterus, vagina and vulva.

WHAT?

Most cats with a vaginal discharge have bacterial infection of the uterus.

DISEASES CAUSING VAGINAL DISCHARGE

CHRONIC CYSTIC ENDOMETRIAL HYPERPLASIA/PYOMETRA COMPLEX***

Classical signs

- Low-grade inappetence and lethargy.
- Vaginal discharge, or distended uterus palpable.
- Fever.
- Polyuria, polydypsia.

Pathogenesis

Chronic cystic endometrial hyperplasia/pyometra complex presents with **vaginal discharge**, and cats may have **polyuria and polydypsia** as a presenting sign. **Pyrexia is rare.**

Chronic cystic endometrial hyperplasia/pyometra complex occurs in intact cats of **any age, regardless of whether they have previously had kittens.**

Cystic endometrial hyperplasia (CEH) is thought to occur from an exaggerated and abnormal response to chronic and **repeated progesterone stimulation.**

- Use of progestagen products to prevent estrus has resulted in CEH.

CEH predisposes the uterus to develop infection.

- *E. coli* is the most common bacterium causing the infection, although numerous other bacteria have been isolated.

In cats, **susceptibility to overgrowth of bacteria** causing pyometra is increased when the uterus is under both **progesterone (diestrus) and estrogen (estrous)** influence. This situation occurs **after coital stimulation** causing ovulation and formation of corpora lutea, or after spontaneous ovulation, which can occur in cats.

Increased **uterine secretion during diestrus is an excellent medium for bacterial overgrowth.**

Stump pyometra can occur if the uterine body is not totally removed at ovariohysterectomy, but this is very rare.

It is a possibility with long-term use of progestogen products because of their potential to produce CEH.

- If remnant ovarian tissue is left, allowing ovarian cycles, then CEH can develop.
- The caudal position of the site allows easy colonization by ascending infection from the vagina.

Clinical signs

Copious vaginal discharge (**serosanguineous to mucopurulent**) is most common.

Closed-cervix pyometra with no discharge is less common; these cats often have significant **uterine distention**, which may cause abdominal enlargement.

Low-grade inappetence that may be present for weeks or months.

Weight loss.

Depression, listlessness, \pm dehydration.

Usually not pyrexia.

Unkempt appearance.

Polyuria, polydypsia.

Diagnosis

Clinical signs (vaginal discharge, listlessness) plus **distended uterus on radiograph** (can only be distinguished from pregnant uterus after 47 days when calcification of fetal skeleton is visible).

Ultrasonography readily distinguishes between pregnancy and pyometra 21 days after the last breeding date.

Increased white cell count and/or left shift is found in most, but not all cats with pyometra.

Differential diagnosis

Pregnancy. Some cases of pyometra palpate as separate uterine swellings, very similar to a 3–4-week pregnancy.

A **uterine tumor** may block the lumen, producing a build up of uterine secretions and a distended uterus, similar to pyometra. The contents may be sterile (mucometra) or become infected, which will then become a pyometra. Ultrasound may reveal the tumor.

Other causes of chronically sick, inappetent cat (see page 330).

Treatment

Antibiotics should be selected on the results of culture and sensitivity. Whilst awaiting the results start the cat on a broad-spectrum antibiotic with activity against *E. coli*, as this is likely to be the pathogen.

- Penicillins, cephalosporins or quinolones are good first-choice antibiotics whilst awaiting culture and sensitivity results.
 - Amoxycillin (4–11 mg/kg 12 h PO, IV); amoxycillin-clavulanate (12.5 mg/kg 12 h PO, 24 h SC).
 - Cephalosporins (15 mg/kg 12 h PO, 6–8 h IV).
 - Enrofloxacin (5 mg/kg 24 h PO, SC); orbifloxacin (2.5 mg/kg 24 h PO).
- Antibiotics alone are unlikely to be successful in clearing the uterus of infection, and prostaglandin adjunct therapy is usually needed. Continue antibiotics for 14 days after the prostaglandin treatment.

Prostaglandin therapy.

- This is usually only used in queens required for future breeding and, combined with antibiotics, **is very successful in treating pyometra** by physically expelling the uterine contents.
- Warn the owner that there is likely to be underlying uterine pathology, and the prognosis for a future successful pregnancy is guarded.
 - Give the prostaglandin F2 α , dinoprost tromethamine (Lutalyse; 0.1 mg/kg SC q 12 h) for 5 days.

- Recheck 1 and 2 weeks after the last injection; a clear serous vagina discharge at this time suggests successful treatment of the pyometra.
- If a purulent vaginal discharge is present, then consider a second 5-day course of injection.
- Breed the queen on the first estrus post-treatment.

Ovariohysterectomy is the treatment of choice, especially if the queen is not required for future breeding, or if there is evidence of peritonitis.

Fluid therapy is necessary to support a sick queen.

Prognosis

With early institution of appropriate treatment (antibiotics, fluid and electrolyte support) and ovariohysterectomy **the prognosis for full recovery is good.**

The **prognosis for future fertility is not good**, as there is usually underlying uterine pathology that will interfere with carrying a litter to term.

Prevention

If a female cat is not required for breeding, then **ovariohysterectomy at a young age** will eliminate the possibility of pyometra.

A breeding queen having frequent litters is unlikely to develop cystic endometrial hyperplasia.

Queens that are held back from breeding, and allowed frequent cycles without pregnancy have an increased likelihood of cystic endometrial hyperplasia.

Be aware that the long-term use of **progestagen products** to prevent estrus **can result in cystic endometrial hyperplasia/pyometra**, and so minimize the use of these products.

METRITIS*

Classical signs

- Fever, anorexia and vaginal discharge.
- Septicemia and shock.
- Neglected, distressed, crying kittens.

See main reference on page 269 for details of acute pyometra/metritis (The Cat With Depression, Anorexia or Dehydration).

Pathogenesis

Metritis is an **acute bacterial infection** of the post-partum uterus.

- It may follow normal parturition, but especially **after abortion, dystocia and retention of placental or fetal tissues**.

Bacteria invade the uterus from the vagina and are able to establish in the uterine contents.

- Bacteria commonly involved include *E. coli*, beta-hemolytic streptococci, staphylococci, *Pasteurella* spp. and various species of anaerobic bacteria.

Clinical signs

The queen has a **fever, anorexia** and a purulent, **usually foul-smelling, vulvar discharge**.

Dehydration, septicemia, endotoxemia and/or shock can follow.

The owner may first be alerted to a problem by **neglected, distressed, crying kittens**.

Diagnosis

The diagnosis is based on a **history of recent parturition or litter loss**, and physical examination.

Abdominal ultrasound is useful to assess the uterine contents, especially for evidence of retained fetus(es) or fetal membranes.

Differential diagnosis

Bacterial infection of the uterus is the only likely cause of these clinical signs.

Treatment

Bacterial culture and sensitivity of the discharge is important to ensure appropriate antibiotic therapy. Type of antibiotic must be carefully chosen to avoid effects on any suckling kittens.

- Penicillins and cephalosporins are good choices until culture and sensitivity results are known, because these antibiotics are considered safe for neonates.
 - Amoxycillin (10–20 mg/kg 12 h PO, 5–10 mg/kg 12 h IV), amoxycillin-clavulanate (12.5 mg/kg

PO 12 h, SC 24 h), cephalosporins (15 mg/kg 12 h PO, 6–8 h IV).

- Do not use chloramphenicol (may adversely affect bone marrow), tetracyclines (may cause bone and teeth defects) or quinolones (may affect developing cartilage).

Intravenous fluids for circulatory support. Feline plasma, if available, is useful for treating toxic shock.

- Consider using subcutaneous fluids if kittens are suckling, as an IV line may unduly distress the queen as she tries to suckle the kittens and the kittens may become entangled in it as the queen moves around.

Ovariohysterectomy should be performed if the queen is no longer required for breeding, and especially if there is evidence of uterine rupture or peritonitis.

Ecbolic agents to promote expulsion of the uterine contents are useful, especially if the queen is required for future breeding.

- **Oxytocin** (5 units IM q 12–24 h) for several days, but this is only useful in the very early post-partum period, as the uterus is only sensitized to it for about 2 days post-partum.
- **Prostaglandin PGF_{2α}** (Lutalyse; 0.1 mg/kg SC twice daily) for several (3–5) days.

Prognosis

With aggressive initial therapy, the prognosis is good for recovery of the queen, and for the continued nursing of any live kittens.

Prostaglandin therapy, combined with antibiotic therapy, is usually successful in clearing the uterus and the prognosis is good for a future successful pregnancy.

Prevention

Cleanliness of the queen and her surroundings will reduce bacterial contamination of the perineum. However, bacteria are always present in the vagina and can gain entry via an open cervix, and so metritis is always a possibility.

If there is evidence a queen has aborted, then **prompt investigation to check for retained fetus(es) or fetal membranes** is advised, and their removal via ecbolic agents or surgery so that they are not niduses for infection is recommended.

PART 15

Cat with eye problems

57. The blind cat or cat with retinal disease

Richard IE Smith

KEY SIGNS

- Dilated pupils and loss of vision.
- Cloudy, or red eye with loss of transparency.
- Retinal changes such as hyper- or hyporeflectivity, hemorrhage, haziness and pigment changes.

MECHANISM?

- Blindness may be caused by a change in transparency of the ocular media (cornea, anterior chamber, lens and vitreous), inflammation of the uvea (uveitis) causing retinal detachment, retinal disease or problems that affect the central visual system. Sudden loss of vision is usually caused by retinal detachment or a central visual disturbance.

WHERE?

Structures in the visual system that may be involved in blindness include:

- The ocular media (cornea, anterior chamber, lens and vitreous).
- Retina.
- Optic nerve.
- Midbrain.
- Visual cortex.

continued

continued

WHAT?

- Blindness caused by opacity of the ocular media is discussed in the chapters headed “The Cat With a Cloudy Eye” and “The Cat With a Red Eye”.
- Blindness in cats usually occurs secondary to systemic disease. Toxoplasmosis, cryptococcosis and systemic hypertension are the most common causes. Less common causes include glaucoma, taurine deficiency and central nervous disease.

QUICK REFERENCE SUMMARY

Diseases causing retinal disease

WHERE?

RETINA

DEGENERATIVE

- Hereditary retinal degeneration in Abyssinian cats (p 1183)

This is a genetically determined progressive retinal degeneration that is rare in other breeds of cats. Young cats (< 4 years) present with loss of vision. Fundoscopy reveals a hyper-reflective tapetum and attenuated retinal blood vessels.

- Feline central retinal degeneration (p 1181)

This is likely to be an early stage of taurine deficiency retinopathy. See Taurine deficiency below.

METABOLIC

- **Hypertensive retinopathy*** (p 1171)**

Relatively common in older cats. Cats present with sudden blindness, and may have a dilated pupil(s) (usually bilateral) with a red vitreous, resulting from retinal hemorrhage. Retinal detachment is common. Early cases may show hemorrhage along the larger retinal blood vessels. Check renal function, thyroid function and the heart for cardiomegaly.

- Anemic retinopathy (p 1186)

Loss of pupil light reflexes and pale retinal vessels and small hemorrhages throughout the retina. Occurs in severely anemic cats with PCV < 10% or hemoglobin levels below 5 g/dl. Other signs of severe anemia are present.

- Hyperviscosity syndrome (p 1186)

Cats with marked hyperproteinemia may show retinal hemorrhage, optic disc swelling and partial retinal detachment secondary to retinal hypoxia. Most commonly occurs associated with multiple myeloma.

- Lipemia retinalis (p 1185)

Rare in cats. Retinal blood vessels appear enlarged, with a yellow to orange hue. Although most are idiopathic, it is also seen in cats with diabetes mellitus, inherited hyperchylomicronemia and following high doses of corticosteroid administration.

MECHANICAL

- Glaucoma causing retinal degeneration (p 1178)

Cats that have advanced glaucomatous retinal changes usually have buphthalmos (enlarged globe). There is a high intra-ocular pressure above 30 mmHg. The retina may be hyper-reflective with

attenuated retinal blood vessels and optic disc cupping. There may be evidence of the primary cause, e.g. chronic uveitis or neoplasia.

NEOPLASTIC

- **Metastatic intra-retinal neoplasia (p 1184)**

Adenocarcinoma and lymphosarcoma are the most reported metastatic neoplasias in the eye. They usually present as uveitis, but choroidal lesions can be seen causing swelling underneath the retina, which has a brownish appearance or retinal detachment.

- **Trauma-associated ocular sarcoma (p 1184)**

Affected cats range from 7–15 years of age, and have a history of prior ocular trauma. Cats present with signs of anterior uveitis, and may show glaucoma, and white to pink masses in the vitreous, if it can be visualized.

Nutritional

- **Taurine deficiency retinopathy (feline central retinal degeneration – FRCD) (p 1181)**

Usually seen in cats that are fed dog food or vegetarian diets. Early appearance is of a focal hyper-reflective area in the area centralis. As the disease progresses, this coalesces to form a broad hyper-reflective band superior to the disc. Eventually there is irreversible blindness, with a hyper-reflective tapetum and attenuated retinal blood vessels.

INFLAMMATION/INFECTIOUS

Viral:

- **Feline leukemia virus (p 1179)**

More commonly presents as a uveitis with changes to the iris appearance, and abnormal pupil size and shape. Retinal detachment may occur if the neoplasia involves the choroid.

- **Feline infectious peritonitis virus (FIP) (p 1179)**

Cats with ocular signs are typically less than 1 year of age, and initially do not have systemic signs of FIP. Ocular disease usually presents as anterior uveitis and hypopyon. Advanced cases show serous retinal detachment and may have neurological signs. Other systemic signs develop as the disease becomes chronic.

Fungal:

- **Chorioretinitis caused by other fungi (p 1176)**

Blastomyces dermatitidis, *Coccidioides immitis*, *Histoplasma capsulatum*. Usually presents as anterior uveitis. Examination of the retina shows focal granulomas with a cloudy vitreous. Blindness occurs in advanced cases.

- ***Cryptococcus neoformans** (p 1174)**

Presenting ocular signs are usually anterior uveitis. Examination of the retina shows focal granulomas, with a cloudy vitreous. Blindness occurs in advanced cases. Mucopurulent nasal discharge and nasal swelling, or skin nodules may be present.

Protozoal:

- **Chorioretinitis caused by *Toxoplasma gondii*** (p 1172)**

The most common ocular presentation is anterior uveitis. The retinal change is chorioretinitis. Blindness occurs in cats with retinal detachment and optic neuritis. Other systemic signs of

continued

continued

toxoplasmosis may or may not be present, and include fever, inappetence, lethargy, dyspnea, muscle pain, CNS signs, and jaundice or increased liver enzymes.

Parasitic:

- Fly larval migration (ophthalmomyiasis) (p 1182)

Typically presents with a unilateral blindness. Examination of the fundus shows a cloudy vitreous, and linear track marks in the retina, which appear as linear areas of pigment change, and hemorrhage in early cases.

Toxic:

- Toxic retinal degeneration (p 1185)

Sudden blindness after drug administration. Fluoroquinolones, particularly enrofloxacin, may rarely cause blindness, especially at high doses. This syndrome has also been described after concurrent administration of methylnitrosurea and ketamine hydrochloride. Cortical blindness can occur following hypoxia associated with anesthesia.

Trauma:

- Traumatic retinal detachment (p 1177)

There will be a history of trauma. Usually presents acutely as a painful, red eye caused by intra-ocular hemorrhage (hyphema), and usually unilateral. Scleral and conjunctival hemorrhage may also be present. Ocular ultrasound is very useful to assess the state of the retina, lens and posterior sclera.

WHERE?

OPTIC NERVE

ANOMALY

- Optic nerve coloboma (p 1187)

Rare in cats. It may be present in cats with eyelid coloboma (agenesis). Optic disc has dark, hollow appearance (inverted funnel shape).

WHERE?

MIDBRAIN AND VISUAL CORTEX

ACCIDENT

- Ischemic encephalopathy (p 1188)

Ischemic encephalopathy results from several disease processes including embolism (feline ischemic encephalopathy), and hypotension, which is usually associated with anesthesia. Hypoxia during anesthesia may result in cortical blindness. It most often occurs after resuscitation from cardiac arrest, or following an anesthetic protocol that predisposes to hypoxia. Feline ischemic encephalopathy presents as sudden onset of unilateral thalamocortical neurological signs including mental depression and confusion, compulsive circling, and hemiparesis and rarely, severe cluster seizures or status epilepticus. Occasionally, it is bilateral and associated with blindness.

NEOPLASTIC

- Intracranial neoplasia (p 1189)

Blindness is associated with neurological signs. Blindness is caused by lesions affecting the optic chiasm (dilated pupils) or cerebral cortex (slow to normal pupils). The retina appears normal.

INFLAMMATION/INFECTIOUS:

Viral:

- **Feline infectious peritonitis virus (p 1179)**

Typically presents as young cats (7–9 months) with anterior uveitis. It may progress to blindness with retinal detachment and/or central blindness and neurological signs. Other systemic signs develop as the disease becomes chronic, such as weight loss, inappetence, lethargy and fever.

Fungal:

- ***Cryptococcus neoformans** (p 1174)**

Blindness may be central in origin or caused by extensive chorioretinitis and retinal detachment. Cats with this presentation usually have multi-organ disease.

Protozoal:

- ***Toxoplasma gondii** (p 1172)**

These cats may have anterior uveitis, chorioretinitis and optic neuritis. Cats with CNS disease may have central blindness and neurological signs.

INTRODUCTION

MECHANISM?

The **ocular media** are the transparent parts of the eye, through which light passes to the retina. They consist of the cornea, anterior chamber, lens and vitreous. Any mechanism that causes loss of clarity in these media will cause loss of vision.

- **Corneal diseases that cause loss of transparency** will affect vision, and are described in the chapter “The Cat With Diseases Confined to the Cornea” (page 1233).
- A **cloudy anterior chamber** may affect vision. This is usually seen in cases that have uveitis (inflammation of the vascular coat of the eye). Problems that cause a cloudy anterior chamber are discussed in the chapter “The Cat With a Cloudy Eye” (page 1254).
- **Hemorrhage in the anterior chamber** will cause vision loss. This is called hyphema and is discussed in the chapter “The Cat With a Red Eye” (page 1196).
- A **cloudy lens** is called a **cataract** and will cause vision loss. See the chapter “The Cat With a Cloudy Eye” (page 1254).
- **Inflammation or hemorrhage** in the vitreous will cause a vision defect. See the chapter “The Cat With a Cloudy Eye” (page 1254) or “The Cat With a Red Eye” (page 1191).

The **retina** is complex neural tissue that **transforms photic energy into electrical energy**. This energy

transformation occurs in cells known as rods and cones. These cells form the outer layer of the neural retina.

The **cones are used for day vision and color**, and the **rods for night vision and movement**. Cats have rod-dominated retinas. The rods and cones are supported metabolically by the **retinal pigment epithelium**, which lies internally to the choroid (vascular tunic of the eye).

The rods and cones communicate with bipolar, horizontal, amacrine and Mueller cells in the inner nuclear layer of the retina. These **cells modify and integrate the stimulus** produced in the rods and cones and transfer this information to the ganglion cells, which lie in the inner retina. **Axons from ganglion cells join to form the optic nerve**.

Information from the rods and cones is thus passed via the inner nuclear layer cells and ganglion cells, to the visual cortex, where it is processed as vision.

The most common cause of blindness in cats is secondary to problems associated with this complex tissue and includes:

- **Genetic disorders** that effect metabolism of the rods and cones such as progressive retinal atrophy in the Abyssinian cat.
- **Metabolic toxins and deficiencies** may cause retinal cell death. Examples include toxic retinal degeneration, and taurine deficiency retinopathy.
- **Systemic fungal, protozoal, viral, bacterial and neoplastic conditions** pass through the retinal pigment

epithelium from the rich vascular supply of the choroid, to cause retinitis and retinal detachment.

- **Systemic conditions that affect the vascular system** can cause changes in the retina. Systemic hypertension causes inner retinal hemorrhage and detachment. Anemia, polycythemia vera and hyperviscosity syndromes can cause vision problems.
- **Glaucoma** (increased intra-ocular pressure) causes retinal degeneration by complex mechanisms that are not well understood, but include retinal vascular ischemia, and pressure-related changes in the axoplasmic flow of optic nerve fibers.

The **optic nerve connects the eye to the midbrain.**

Inflammation of the optic nerve and conditions that affect the anterior brain and/or midbrain will cause vision loss, by preventing stimuli from the ganglion cells from reaching the central processing area of the visual cortex. Efferent nerve fibers controlling pupil function will usually be affected causing **changes in pupillary light reflexes**. See the main references on page 1279 “The Cat With Abnormal Pupil Size, Shape or Response” and optic neuritis is a rare condition in the cat. Causes of optic nerve disease in cats are usually confined to:

- **Inflammation or neoplasia affecting the optic chiasm.**
- **Inflammation or neoplasia of the mid-brain.**

Midbrain and visual cortex lesions can present with **blindness and normal-appearing eyes.**

Sometimes ocular lesions are present, but do not account for the blindness.

Pupil size and pupillary light reflexes help **localize the site of the lesion causing blindness.**

- If the lesion is at the **cortical level**, there will usually be a normal to slow pupil light reflex.
- If the lesion is anterior and involves the **optic chiasm**, there will be a loss of pupillary light reflex.
- If the lesion is in the **mid-brain**, there will be anisocoria (uneven-sized pupils).

The **visual cortex** occupies approximately one third of the cerebrum. Vision is an extremely complex process that is not fully understood. The ocular structures may be perfectly normal, but if the brain cannot process the information sent from the eye, the animal will appear to

be blind. **Animals with central blindness generally have normal pupil reflexes**, although they may be slow.

Conditions that affect the visual cortex include:

- **Ischemia** from oxygen starvation or trauma.
- **Vascular accidents** causing ischemia.
- **Inflammation** of brain or meninges.
- **Neoplasia** of cerebral or meningeal tissue, causing pressure-related cell degeneration.

Usually other neurological signs are present suggesting there is a central lesion such as seizures, proprioceptive deficits, ataxia and weakness.

WHERE?

Structures that may be involved in blindness include:

- **The ocular media** (cornea, anterior chamber, lens and vitreous).
- **Retina.**
- **Optic nerve.**
- **Mid-brain.**
- **Visual cerebral cortex.**

WHAT?

Changes to the ocular media appear as a cloudy eye. See the main reference on pages 1254, 1233 “The Cat With a Cloudy Eye” and “The Cat With Abnormalities Confined to the Cornea”.

Most cats with sudden blindness have a retinal detachment caused by infectious agents or hypertension.

Cats that have blindness associated with **abnormal pupil reflexes** and normal retinas generally have **optic nerve or mid-brain** disease.

Blind cats with normal retinas and normal pupil reflexes usually have central blindness, with lesions involving the **visual cortex.**

Pupillary light reflexes form an important part of eye examinations, and help determine the part of the visual system that is causing blindness.

The summation of retinal electrical responses to light can be measured electrophysiologically using a procedure known as **electroretinography (ERG).**

DISEASES CAUSING A BLIND CAT OR CAT WITH RETINAL DISEASE AND BLINDNESS ASSOCIATED WITH RETINAL PROBLEMS

HYPERTENSIVE RETINOPATHY***

Classical signs

- Acute onset of vision loss in an old cat, usually bilateral.
- Dilated pupils, non-responsive or poorly responsive to light.
- Cloudy vitreous with red areas of hemorrhage.

Pathogenesis

Hypertension causes **vasoconstriction of pre-capillary retinal arterioles**. **Hypoxia** of the arteriole causes smooth muscle necrosis, which leads to **vascular dilatation**, and leakage of serum and blood.

Leakage from vessels causes **serous retinal detachment**, and subretinal, intra-retinal or preretinal **hemorrhage**.

Retinal blood vessels may rupture, causing hemorrhage into the vitreous.

Hypertensive retinopathy occurs most commonly secondary to **chronic renal disease**, **hyperthyroidism** and **cardiac disease**.

Clinical signs

Classical signs are **acute onset of vision loss** in an **old cat**, which is **usually bilateral**. The cat suddenly starts to bump into things, appears to be lost, and has very cautious movements.

The **pupils** are usually **dilated**, and non-responsive or **poorly responsive to light**.

Affected **eyes appear slightly cloudy**, and there may be focal red areas visible through the pupil, as a result of retinal hemorrhage. The vitreous may appear red. Early cases may show hemorrhage along the larger retinal blood vessels.

Hyphema may be seen in the anterior chamber.

It is difficult to visualize the **retina** on fundoscopic examination, as it **appears out of focus**. This is caused by retinal detachment, with the retina ballooning into the vitreous, and **appears as a thin veil of pale tissue**.

These cats may have **cardiomegaly**, and left ventricular hypertrophy.

There may be other signs suggestive of hypertension, for example, a **bounding cardiac apex beat**.

Systolic arterial blood pressure is usually **greater than 160 mmHg**.

Other signs suggestive of renal and/or thyroid disease, such as progressive weight loss, polydipsia, polyuria and azotemia may be present.

Diagnosis

Clinicians should suspect this problem in any old cat that has suddenly gone blind.

Ophthalmoscopy will demonstrate **vitreal hemorrhage**. The retina will appear out of focus, and hemorrhage adjacent to the major retinal blood vessels is visible.

Complete retinal detachment is common.

Blood pressure is most commonly measured in the cat using Doppler technology. Arterial blood pressure greater than 160 mmHg confirms a diagnosis of hypertensive retinopathy. Most cats with clinical signs have a blood pressure of **greater than 200 mmHg**.

BUN, creatinine and urine protein:creatinine ratios are useful clinical pathology parameters to check renal function.

Thyroid function should be checked by measuring **plasma thyroxine (T4) concentration**.

Further useful procedures include **cardiac ultrasound**, and in some cases, imaging of the thyroid with radioisotopes.

Treatment

Amlodipine (Norvasc, Pfizer) is a **calcium channel blocker**, which has a greater effect on vascular smooth muscle cells than on cardiac muscle cells. The dose is

approximately 0.625 mg/cat per day, i.e. 1/4 of a 2.5 mg tablet (USA) or 1/8 of a 5 mg tablet (Australia).

The use of corticosteroids is controversial.

If hypertension is associated with **hypertrophic cardiomyopathy**, then calcium channel blockers such as **diltiazem** may be used. For more detail see main reference on page 130 for details (The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

β-blockers such as propranolol (Inderal) can also be used in the management of the cardiac disease at 1/4 of a 10 mg tablet q 8 h.

Hyperthyroidism when present, should be treated using surgery, radioactive iodine (131-I) or anti-thyroid drugs such as carbimazole or methimazole. For more detail see main reference on page 306 (The Cat With Weight Loss and a Good Appetite).

Cats with renal disease should be placed on appropriate medical and dietary management. For more details see the main reference on page 337 (The Thin, Inappetent Cat).

CHORIORETINITIS CAUSED BY *TOXOPLASMA GONDII***

Classical signs

- Anterior uveitis (cloudy eye) is the most common sign.
- +/- Lymphocytic plasmacytic uveitis – gray to tan-colored nodules on the iris surface.
- Chorioretinitis and optic neuritis that may cause blindness.
- Rarely, systemic signs may be seen concurrently with ocular signs. These include fever, weight loss, +/- muscular pain, +/- signs of respiratory or neurological disease.

See the main reference on page 375 (The Pyrexia Cat).

Pathogenesis

Infection with *Toxoplasma gondii* occurs by three mechanisms.

- **Ingestion of tissue cysts (bradyzoites)** from an intermediate host such as cockroaches, earthworms, rodents, reptiles and birds (most common) is the common route of infection in cats, and occurs in

kittens once they start to hunt. Infection may occur from eating uncooked meat from cattle, sheep, chickens and pigs, which consumed food or water contaminated by cat feces.

- **Ingestion of sporulated oocysts** from food or water contaminated by cat feces (far less common).
- **Transplacental transmission** occurs, but is less common.

After ingestion, a **gut replication cycle occurs**. The cat is the definitive host and is the only species in which this occurs. This results in the production of **unsporulated (non-infective) oocysts**, which are passed in feces. These become infective after 1–5 days, by sporulation (this requires aeration) in the environment. The spores formed are called sporocysts, and are filled with sporozoites.

The **extra-intestinal** development of *T. gondii* is similar in all species. Upon ingestion, sporozoites and bradyzoites transform into **tachyzoites**, which is the rapidly multiplying form of *T. gondii*. These may replicate in any cell type, and are disseminated to various organs in the body. Tachyzoites multiply intracellularly for a period of time, and then become **tissue cysts containing numerous bradyzoites**, which is the slowly replicating form of *T. gondii*. Release of bradyzoites from these cysts restarts the intracellular replication in cells.

Cysts may develop in the **CNS, muscles, visceral organs (particularly lungs and liver) and ocular tissues**. They may persist in a dormant state for life. Biologically they are a resting state, waiting for ingestion by a predator. Following ingestion by a mammal or bird they form tachyzoites.

Activation of bradyzoites in tissue cysts may occur associated with other disease states, such as FIV, FeLV, hemobartonellosis and FIP, which act as stressors or immunosuppressors. High-dose corticosteroid use has been known to activate dormant *T. gondii* infections.

When **bradyzoites are activated**, they undergo **rapid replication, causing destruction of tissue**. This incites an inflammatory response in various tissues, notably the **central nervous system, uveal tract of the eye, muscle, liver and lungs**. This also causes a host of immune responses, including hypersensitivity, antibody and immune-complex reactions.

It is unclear whether the inflammation in ocular toxoplasmosis is caused by cellular destruction, and the

resultant local hypersensitivity, antibody, and immune-complex reactions, or whether the eye is secondarily involved from reactions occurring in tissues outside the eye.

Ocular toxoplasmosis in humans causes a posterior uveitis, with a necrotizing chorio-retinitis. In cats, the most common presenting sign is **anterior uveitis**, and in cases with disseminated disease, **chorioretinitis and optic neuritis** may be seen.

Histologically, ocular lesions in cats appear as granulomatous to lymphocytic/plasmocytic, multifocal chorioretinitis and/or iridocyclitis.

Clinical signs

The **most common ocular presenting sign** is **anterior uveitis, appearing as a cloudy eye**. This may be **unilateral or bilateral**.

- Affected eyes appear cloudy in acute cases, and may show **hypopyon** (pus in the anterior chamber) and **keratic precipitates**, which are focal accumulations of protein, and white blood cells on the corneal endothelium.

Cats that present with **lymphocytic, plasmocytic nodules on the iris**, seen as **diffuse focal grayish nodules** protruding from the anterior iris surface, may have ocular toxoplasmosis.

Blind cats with toxoplasmosis have **chorioretinitis**. This is seen as **small, multifocal, raised areas in the retina** that have pigment changes. These cats may also have **optic neuritis**, with an inflamed optic disc that is hyperemic and raised.

Systemic signs of toxoplasmosis in cats include:

- Fever, weight loss and muscle pain.
- Respiratory disease, especially pneumonia.
- Multifocal neurologic disease.
- Liver disease.
- Systemic signs of toxoplasmosis are very rare in adult cats. They are most common in perinatal kittens.

Diagnosis

It is very difficult to make a definitive diagnosis with demonstration of the organism in cases with *T. gondii* infection. A tentative diagnosis is usually made based on the clinical signs, supported with laboratory tests.

The **classical ocular sign** suggesting toxoplasmosis is anterior uveitis. The eye(s) may appear cloudy with hypopyon and keratic precipitates, or have evidence of mild uveitis with lymphocytic/plasmocytic nodules in the iris.

Serological tests have varying degrees of sensitivity and specificity:

- Measurement of antibodies may be via indirect fluorescent antibody tests (**IFA**), indirect hemagglutination tests (**IHA**), or enzyme-linked immunosorbent assay (**ELISA**). The ELISA test is available in kit form, which is a quantitative test and does not yield a titer.
- **Demonstration of a rise in IgM titers** (often measured by IFA) from paired samples taken 2–4 weeks apart, indicates a recent active infection. However, some cats do not develop detectable IgM titers, and in other cats, positive IgM titers can persist for months to years after infection.

Polymerase chain reaction (PCR) testing for parasite DNA in tissue or fluid samples. The specificity for active infection is improved when combined with the IgM titer.

Comparison of levels of aqueous humor *T. gondii* antibody levels with serum levels (Goldman–Witmer coefficient or C-value) has been advocated to determine that anterior uveitis has been caused by *T. gondii*, although the use of C-values is still controversial. The Goldman–Witmer coefficient compares the *T. gondii*-specific immunoglobulin concentration with the total immunoglobulin concentration in serum and aqueous humor. A *T. gondii*-specific antibody C-value > 1 in aqueous humor indicates possible local production, rather than leakage from the serum through a faulty blood–ocular barrier. ***T. gondii*-specific C values > 3 are advocated as criteria for evidence of local antibody production.**

Differential diagnosis

Differential diagnoses include other conditions that present as anterior uveitis.

- Cats with **FIP** present with **anterior uveitis (hypopyon and keratic precipitates)**. This is not as common in many geographical areas, and most commonly occurs in young cats from 6 months to 1 year of age. Currently, there is no definitive test

for FIP. Serology is confused by intestinal coronavirus infections. Cats with FIP often have increased total protein and IgG concentrations in response to viral antigen, and also from cell damage resulting from the intense tissue inflammation. It is not pathognomonic for FIP, and reflects the chronic inflammatory nature of the disease.

- **FIV uveitis** can cause a mild anterior uveitis, and anterior chamber flare. The condition can be diagnosed with serology using an ELISA test.
- **FeLV uveitis** can cause signs similar to acute *T. gondii* infection, with an inflamed swollen iris and hypopyon. The retina may be infiltrated with tumor cells, and the retina may occasionally be detached from neoplasia infiltrating the choroid.

Other inflammatory conditions that present with chorioretinitis include:

- **Fungal diseases** especially **cryptococcosis, blastomycosis, histoplasmosis, candidiasis and coccidioidomycosis**. These diseases present with signs of uveitis and multifocal granulomatous chorioretinitis that appears as small brownish nodules in the retina, and may cause blindness. Systemic signs of fever, inappetence, weight loss and dyspnea are often present. Serological tests are available to differentiate these infections.

Treatment

A combination of drugs that inhibit the production of folinic acid necessary for *T. gondii* proliferation has been the mainstay of treatment in people. The most common combination is pyrimethamine, a dihydrofolate reductase inhibitor, and a sulfonamide, which inhibits production of folic acid. Unfortunately, cats do not tolerate sulfa drugs as well as people, and often develop gastrointestinal side effects.

Trimethoprim/sulfadiazine (30 mg/kg PO q 12 h) may be given alone, or with pyrimethamine (0.5 mg/kg PO q 24 h). Supplement with folinic acid (1 mg/kg PO q 24 h).

Other antimicrobial drugs that are used to control *T. gondii* infection include **tetracyclines, clindamycin, clarithromycin and atovaquone**.

Clindamycin (Antirobe, Upjohn) at a dose rate of 12.5 mg/kg q 12 h for 3–4 weeks is the most common treatment used in cats.

Concurrent anti-inflammatory therapy for anterior uveitis, e.g. **topical 0.5% prednisolone** acetate drops applied q 6–12 h are used to suppress the inflammation associated with the infection, and prevent secondary complications such as glaucoma.

CRYPTOCOCCUS NEOFORMANS*

Classical signs

- **Sudden blindness with retinal detachment.** Vitreous flare may be present making the retina difficult to examine.
- **Anterior uveitis** (anterior chamber flare, miosis, inflamed discolored iris).
- **Exophthalmos** (eye bulging forward).
- **+/- mucopurulent discharge with sneezing and a swollen nose.**
- **Neurological signs.**
- **Chronic skin granulomas.**

See the main references on page 25 (The Cat With Signs of Chronic Nasal Disease).

Pathogenesis

Cryptococcosis is the most common fungal infection affecting cats which **occurs throughout the world**.

Cryptococcus neoformans is a budding, capsulated yeast-like fungus found in **soil or in avian excreta**. In Australia, there is an association of the organism *C. neoformans* var. *gatti* with the **bark of a Eucalypt tree**, the River Red Gum (River and Forest varieties), which has been **exported world wide** as a timber tree.

In general, all deep fungal infections enter the body by the inhalation of aerosolized spores leading to either fungal rhinitis (e.g. *Cryptococcus*) or pneumonia (e.g. blastomycosis, histoplasmosis), with subsequent dissemination to other parts of the body, including the eye, by hematogenous or lymphatic spread.

The initial ocular site for establishment of infection is usually the **choroid**, and the **anterior uveal tract** is often involved later in the course of the infection.

Clinical signs

Cats may present with **sudden blindness** caused by **multifocal granulomatous chorioretinitis** with varying degrees of **retinal detachment**.

- **Vitreous flare (cloudy vitreous)** is present, and makes the retina difficult to examine in cases with severe inflammation.
- If the retina can be visualized, the granulomas appear as small **swollen brownish discolored areas** in the tapetal and non-tapetal retina.

There is usually **anterior uveitis with corneal edema, anterior chamber flare** (with or without hypopyon and keratic precipitates), **swollen iris with varying degrees of posterior synechia** causing a **distorted pupil**, and in chronic cases, new vascular growth on the anterior surface of the iris (pre-iridal fibrovascular membrane formation).

Complications include **secondary cataract and glaucoma**.

Some cats present with **exophthalmos** (eye bulging forward), where there has been an extension of the disease from the sinuses and nasal cavity into the orbital tissues.

In cases with nasal infection, there may be a **mucopurulent discharge with sneezing**. **Distortion and swelling** over the **bridge of the nose**, or a **polyp-like mass** projecting from the nasal cavity are present in 70% of cats with the respiratory form.

Chronic skin granulomas may be present. Skin lesions consist of **papules or nodules** varying from 0.1–1 cm in diameter. Lesions may **ulcerate and exude serous fluid, or remain as intact nodules**.

Cats with disseminated disease may show neurological signs.

Cats may **present with chronic nasal or skin disease**, and the ocular involvement is identified secondarily on physical examination. Cats may also be presented **primarily for the ocular signs**, where the owner has seen the development of a cloudy eye and the cat has gone blind.

Diagnosis

A **tentative diagnosis is based on typical clinical signs** of nasal or skin disease and concurrent ocular

signs. The presence of small swollen brownish discolored areas in the retina suggests fungal disease. The frequency of occurrence of individual fungal diseases in the geographical area helps establish a tentative diagnosis.

Cytology can be very useful in the diagnosis of *C. neoformans*. Demonstration of the organism can be made via **anterior chamber centesis** or by fine-needle biopsy (using a 25 gauge needle) taken from the sub-retinal space. The sample is best stained with **new methylene blue, Indian ink or Diff-Quick**.

Serology to detect **capsule antigen** is sensitive using serum, CSF fluid or urine.

Histopathology from tissue biopsies demonstrates the organism.

Radiology of the nasal cavity, sinuses and chest may be useful in cases that do not demonstrate nasal or skin signs.

Ocular ultrasound can be used to **detect retinal detachment** when anterior chamber flare, cataract or vitreal flare prevents ophthalmoscopic examination of the fundus. It is also used in cases of exophthalmos to examine, and do ultrasound-guided biopsies of the orbital tissue.

Differential diagnosis

Other fungal diseases such as **blastomycosis, histoplasmosis, candidiasis and coccidioidomycosis** can cause similar signs. They also present with signs of uveitis and multifocal granulomatous chorioretinitis that appear as small brownish nodules in the retina, and may cause blindness. Consideration of individual fungal diseases as differential diagnoses will depend on which diseases are found in the geographical region. Serological tests are available to differentiate these infections.

Ocular toxoplasmosis. Cats present with similar signs of anterior uveitis, blindness and chorioretinitis, although the ocular inflammation is not usually as severe. Laboratory tests may be needed to differentiate these diseases. Tests for toxoplasmosis can be confusing to interpret, but serological tests for *Cryptococcus* antigen are sensitive and specific.

Ocular manifestations of FIV, FIP and FeLV are usually signs of anterior uveitis, rather than sudden blindness from retinal involvement. However, retinal disease and sudden blindness can be an uncommon presenting sign with these viruses. FIP is difficult to confirm with diagnostic tests, and is diagnosed by a process of elimination. FIV and FeLV can be diagnosed with serological tests, although these diseases can occur concurrently with cryptococcosis.

Treatment

See the main reference on page 26 (The Cat With Signs of Chronic Nasal Disease).

Cats with multifocal chorioretinitis usually have disseminated cryptococcosis, and have a very poor prognosis for treatment.

Prolonged treatment with constant monitoring of antigen titers and renal function is required.

Combinations of anti-fungal drugs appear to give the best results and include:

- **Amphotericin B.** Drug can be given IV (see standard texts) or SC (0.5–0.8 mg/kg) in 400 ml of 0.45% saline containing 2.5% dextrose. Administer subcutaneously two or three times a week for 1–3 months, until a total cumulative dose of 8–26 mg/kg is reached. Monitor serum creatinine, urea (more sensitive, but influenced by many non-renal factors) and urine specific gravity and sediment for casts. If azotemia develops, discontinue amphotericin until it resolves and reduce dose.
- 5-fluorocytosine 50 mg/kg q 8 h PO used combined with amphotericin.
- **Fluconazole** 2.5–10 mg/kg PO q 12 h may be the best of the imidazole drugs for CNS and ocular cryptococcosis, and is used after the course of amphotericin for as long as 2 years.

CHORIORETINITIS CAUSED BY OTHER FUNGI

Classical signs

- Chorioretinitis progressing to anterior uveitis (cloudy eye) and endophthalmitis, in a geographical area where fungal infections occur.

Classical signs—Cont'd

- Vision loss and reduced pupil light reflexes.
- Other organ system disease, e.g. renal, CNS, nasal cavity.

See main references on page 25 for details (The Cat With Signs of Chronic Nasal Disease) for cryptococcosis and pages 387, 379, 371 (The Pyrexia Cat) for other fungi.

Pathogenesis

Other fungi that cause intra-ocular infections vary in their geographical distribution:

- **Blastomycosis** is a dimorphic fungus, which grows as a yeast in mammalian tissue, and as a mycelial form in the environment. It is found in the USA in the midwestern and southeastern states along the Mississippi, Ohio and Missouri Rivers and occasionally mid-Atlantic states, and in Central America, parts of Asia, Africa, Europe and Israel. Close proximity to water is a factor in its distribution.
- **Histoplasmosis** is a dimorphic fungus, which exists as a free-living mycelial form, and yeast-like organisms in mammalian tissues. It is found in central USA, especially in the Ohio, Mississippi and Missouri River basins, and in Central and South America. There is an association with moist humid conditions and nitrogen-rich soils, bat and bird excrement.
- **Coccidioidomycosis** a soil mycelial organism with a natural reservoir in desert soils, and around animal burrows. It is found in southwestern USA, Mexico, Central and South America. Animal infection occurs by inhalation of arthrospores, which can transform into spherules and then endospores in lung tissue.

Clinical signs

Most intra-ocular fungal infections cause similar ocular signs.

- **Choroidal granulomas** are the most characteristic sign on fundoscopy, and appear as a raised area of tapetal hyporeflexivity, or small swollen brownish discolored areas in the retina.
- A **generalized chorioretinitis** and **secondary retinal detachments**, with ballooning of the retina into the vitreous.

- **Optic neuritis** may be present, seen as a red, swollen optic nerve that is hyperemic.
- **Anterior uveitis** seen as cloudy, red eye with corneal edema, hypopyon and inflamed conjunctiva.

Affected cats show **varying degrees of blindness**, depending on the severity of the ocular infection.

Systemic signs can involve many other organs, especially the lungs, brain, nasal cavity, as well as the peri-orbital tissues, lymph nodes, bones, toenails and skin.

Diagnosis

A tentative diagnosis is based on the presenting signs of a cat with rapidly progressive, usually bilateral **chorioretinitis, progressing to anterior uveitis**, with signs of other systemic disease, and occurring in a geographic area where such fungal disease is known to occur.

Imaging techniques can be used to obtain more supportive evidence of a deep fungal infection:

- Thoracic radiography to demonstrate pulmonary granulomas.
- Nasal cavity radiography.
- Ocular ultrasound; signs of retinal detachment.

Confirmation of the diagnosis is based on the **demonstration of the respective organism** in:

- Cerebrospinal fluid.
- Samples taken by centesis of vitreous or subretinal exudate.
- Histopathology of enucleated globes.
- Bone marrow biopsy samples (histoplasmosis).

Serological tests can be performed, looking for elevated antibodies (blastomycosis, histoplasmosis, coccidioidomycosis).

Treatment

Antifungal medications are the cornerstone of therapy. Drugs chosen should be based on results of fungal culture and sensitivity, where possible. Treatment may need to be prolonged, depending on response.

Itraconazole 100 mg PO q 24 h with food, or 10 mg/kg q 24 h, or 5 mg/kg q 12 h PO.

Fluconazole 50 mg PO q 8 h.

Amphotericin B. This drug can be administered in a subcutaneous infusion of glucose and sodium chloride to reduce the renal toxicity (see The Cat With Signs of Chronic Nasal Discharge, page 26).

Avoid use of systemic corticosteroids.

Topical steroids or NSAIDs may be used to control the anterior uveitis.

Supportive therapy such as fluids and nutritional support.

Enucleation of the eye is recommended if endophthalmitis and/or secondary glaucoma develop.

Prognosis

Prognosis is guarded to grave in most cases where there is systemic involvement.

TRAUMATIC RETINAL DETACHMENT

Classical signs

- **Acutely painful eye with hyphema.**
- **+/- Scleral and conjunctival hemorrhage.**
- **Usually unilateral.**

See the main reference on page 1200 (The Cat With a Red Coloration of the globe).

Clinical signs

The typical presentation of **traumatic retinal detachment** is an **acutely painful eye**, which is usually **unilateral**.

Exophthalmos may be present from retrobulbar hemorrhage and swelling.

Most traumatic eye injuries will exhibit **some degree of ocular hemorrhage**. This may present as:

- Scleral and/or subconjunctival hemorrhage.
- A red eye with hyphema. The anterior chamber may be filled with blood, or there may be a loose clot.
- If the vitreous is visible, there may be focal areas of hemorrhage, or the vitreous may be filled with blood.

Try to visualize the pupil and pupillary light reflex. A blind eye will usually have a dilated pupil.

The retina may not be visible due to the hyphema. If there is hemorrhage in the inter-retinal space between the retinal pigment epithelium and the rods and cones, the retina will bulge forward with a red appearance.

Loss of vision may be caused by **trauma to the optic nerve**. It is not possible to visualize this part of the nerve, but hemorrhages may be present on the optic disc.

Beware of **secondary glaucoma**. Initially, traumatized eyes are very soft. Glaucoma may follow acutely from obstruction of the iridocorneal angle by hemorrhage, lens luxation or rupture, and inflammation. Cases with chronic retinal detachment may form vascular membranes, which obstruct the drainage angle.

Diagnosis

Diagnosis is based on clinical signs of a cat presented with an acutely painful, red eye. **Carefully examine the eye to determine the extent of the injury**. If the fundus is visible ophthalmoscopically, the retina will be able to be examined, and areas with hemorrhage and detachment will be visible.

Ocular ultrasound using a 10-megahertz stand-off probe, is a very useful diagnostic tool when the fundus cannot be visualized because of severe hyphema. Retinal detachment will show as a bulging hypoechoic line. Pay particular attention to the shape of the globe, as severely traumatized eyes may also have a rupture of the sclera posteriorly, and this will have a very poor prognosis. Try to visualize the muscle cone and optic nerve for swelling.

Use **tonometry** to monitor intra-ocular pressure.

Treatment

Treatment is usually conservative, and includes antibiotics and anti-inflammatory drugs.

- **Systemic broad-spectrum antibiotic** cover to prevent hematogenous infection.
- **Systemic anti-inflammatory drugs** to reduce inflammation and prevent secondary complications in the eye, such as prednisolone 1 mg/kg bid or a NSAID like ketaprofen, cartrophen or metacam.

In cases with exophthalmos, do a **temporary tarsorrhaphy** to protect the cornea.

GLAUCOMA CAUSING RETINAL DEGENERATION

Classical signs

- Buphthalmos (an enlarged globe).
- Increased intra-ocular pressure.
- Dilated pupil, poorly or non-responsive to light.
- Hyper-reflective tapetum.
- Luxated lens or cataract.

See the main reference on page 1232 (The Cat With Ocular Discharge or Changed Conjunctival Appearance).

Clinical signs

Cats blinded from glaucoma will have an **enlarged globe (buphthalmos)**, and the condition will be chronic.

Deep episcleral vessel injection is seen in eyes with a high intra-ocular pressure (above 30 mmHg). Compared to superficial episcleral vessels, the **deep vessels** are usually **straighter and larger**, do not move when the overlying bulbar conjunctiva is moved, and do not blanch with the topical application of 1:1000 epinephrine.

The **pupil is dilated or semidilated**, with either absent or poor pupillary light reflex.

There may be signs of chronic anterior uveitis, especially abnormalities in the appearance of the iris surface for example:

- **Pinkish discoloration** associated with **fibrovascular membrane formation**.
- **Grayish nodules** on the iris surface.

There may be **signs of lens instability** including:

- An aphakic crescent (crescent shape produced by the clear space between the edge of the displaced lens and the adjacent pupillary margin).
- Anterior or posterior luxation (dislocation).
- Iridodonesis (wobbling of the iris).

There may be signs of **intra-ocular neoplasia**.

Prolonged increased intra-ocular pressure results in **collapse of the cribriform plate**. This causes obstruction to retinal vascular flow at the level of the optic disc, and obstruction to the axoplasmic flow in the optic

nerves fibers. The resulting **retinal degeneration** results in the following ophthalmoscopic signs:

- A hyper-reflective tapetum.
- Attenuation (thinning) of the retinal blood vessels.
- Optic disc cupping (the optic disc is pushed backward).

Diagnosis

Diagnosis is based on the clinical appearance of buphthalmos, with any or all of the other related signs of glaucoma, such as chronic anterior uveitis and lens instability.

- Tonometry is used to measure intra-ocular pressure (IOP). Normal range for IOP in the cat is 15–25 mmHg. Readings **over 30 mmHg are supportive of a diagnosis of glaucoma.**

FELINE LEUKEMIA VIRUS

Classical signs

- Discrete iris or ciliary body masses (FeLV-associated lymphosarcoma).
- Anterior uveitis.
- Intermittent asymmetric changes in pupil size, shape or response.
- Other FeLV-associated signs, e.g. anemia.
- Retinal detachment.

See the main reference on page 1300 (The Cat With Abnormal Iris Appearance).

Clinical signs

FeLV may cause **ocular lymphosarcoma**, which appears as **discrete iris or ciliary body masses**, usually bilateral, which may cause gross distortion of the iris structure.

FeLV more commonly presents as a uveitis, with changes to iris appearance, and abnormal pupil size and shape. The **anterior chamber** may contain **fibrin and/or blood**. Anterior uveitis may occur in the absence of discernible intra-ocular neoplasia.

Some cats develop **spastic pupil syndrome**, which presents as otherwise unexplainable intermittent

asymmetric **changes in pupil size, shape or response**. For more detail see main reference on page 1278 (The Cat With Abnormal Pupil Size, Shape or Response).

It is possible to see **retinal detachment** when the neoplastic process involves the choroid.

There may be other signs of FeLV-associated disease, e.g. anemia or multicentric lymphosarcoma.

Diagnosis

Diagnosis is based on the clinical signs observed in the eye, in association with other signs suggestive of FeLV, e.g. multicentric lymphoma, FeLV-associated anemia.

Diagnosis is confirmed on **clinical pathology**, for example on cytology of lymph nodes or aqueous centesis samples, or occasionally on hematology.

A positive serological test using an **antigen-based test for FeLV** is supportive evidence of the disease. For more detail see main reference on page 543 (The Anemic Cat).

Treatment

For more detail see main reference on pages 1292 and 544 (The Cat With Abnormal Iris Appearance and The Anemic Cat).

Treatment of the ocular condition, in conjunction with systemic chemotherapy, might include **topical corticosteroids** such as 0.5% prednisolone acetate drops given q 6–12 h.

Prognosis for the eye will be poor to guarded, if secondary glaucoma has occurred.

FELINE INFECTIOUS PERITONITIS VIRUS

Classical signs

- Young cats 6–12 months of age.
- Anterior uveitis with large fibrin clots (hypopyon).
- Keratic precipitates (“mutton fat deposits”) on the cornea.
- Chorioretinitis causing variable vision loss and/or abnormal pupil reflexes.

(continued)

Classical signs—Cont'd

- **Neurological signs, including behavioral changes, cranial nerve abnormalities, seizures and head tremor.**

See the main reference on page 372 (The Pyrexia Cat).

Pathogenesis

FIP is caused by a coronavirus that causes a **disseminated, pyogranulomatous vasculitis**. There are two forms of the disease that are recognized:

- An **effusive (wet) form**, that causes a fibrin-rich exudation in the peritoneal cavity.
- A **non-effusive (dry) form**, that usually manifests with ocular and neurological signs including anterior uveitis, chorioretinitis and meningitis, respectively.

There is evidence to suggest that FIP is caused by a mutation of enteric coronavirus (FECV) which occurs within about 18 months of infection.

Clinical signs

The **ocular form of the disease** is usually seen in **young cats from 6 months to a year of age**.

The **main presenting sign is uveitis**. Large fibrin clots mixed with exudated white and red blood cells form a **hypopyon** (cloudy eye). **Keratic precipitates** are common, and appear as large pinkish, brown spots (“mutton fat deposits”) on the inferior endothelial surface of the cornea.

The **vitreous may be hazy**, because of similar exudation of cells from the ciliary body.

The retina may show a focal or total exudative **retinal detachment**. It is common to see an inflammatory exudate sheathing the major retinal blood vessels, which appears as a **cloudy sheath around the vessels**.

Blindness may be seen with **abnormal pupil reflexes** (miotic in the early stages with uveitis, followed by a dilated pupil in blind cats), and **abnormal pupil size (anisocoria)**.

Cats with ocular signs frequently **develop neurological signs weeks or months later**, and are euthanized or die

because of **meningoencephalitis**, and its associated signs, such as seizures. Most common signs in addition to seizures, are **central vestibular signs**, which include head tilt, loss of balance, nystagmus, mental depression, and postural reaction deficits, and **cerebellar signs** such as intentional tremors, and hypermetria. Behavioral changes often occur.

Cats with ocular signs of FIP rarely show systemic signs of illness such as fever, inappetence and weight loss **at initial presentation**. As the disease becomes chronic, weight loss and neurological signs develop (seizures are most common).

Diagnosis

There is no definitive diagnostic test for the FIP virus.

A tentative diagnosis is initially based on the suspicious clinical signs of a young cat with uveitis showing hypopyon and keratic precipitates.

Serology is usually regarded as being of dubious benefit in the diagnosis, as the FIP organism cross-reacts with enteric forms of coronavirus.

Diagnosis can only be confirmed on characteristic histopathology of affected tissues on biopsy or necropsy examination. The typical change is described as a **pyogranulomatous vasculitis**. Necrosis and a fibrinoid response are seen in some cases. The ocular cellular response includes neutrophils, lymphocytes, plasma cells, macrophages and large, spindle-shaped histiocytes.

Cats often have a **large increase in plasma total protein, globulin** and IgG concentration, because of the chronic nature of the inflammatory disease process. The polyclonal increase in gammaglobulins is caused by virus antigen and cell destruction from the intense inflammation associated with the infection.

Differential diagnosis

Toxoplasmosis is the main differential diagnosis. Toxoplasmosis occurs in cats of all ages. The exudative response in the eye is not usually as pronounced. Laboratory tests can be used to differentiate (see above).

All other **ocular diseases that cause anterior uveitis and chorioretinitis** should be excluded with diagnostic

tests, particularly fungal infections such as cryptococcosis (see page 1268).

Treatment

There is no specific treatment for FIP, and once signs develop the disease is almost uniformly fatal.

Topical and systemic corticosteroids will initially reduce the signs of uveitis and chorioretinitis, but recurrence is common.

Supportive medical management including fluids and nutrition can be attempted. Interferon-alpha and cyclophosphamide or chlorambucil may temporarily reduce clinical signs.

Cats which are anorexic and depressed, and do not respond to supportive therapy, should be euthanized.

TAURINE DEFICIENCY RETINOPATHY (INCLUDING FELINE CENTRAL RETINAL DEGENERATION – FRCD)

Classical signs

- Vision loss in advanced cases.
- Hyper-reflective tapetal retina, beginning as an elliptical lesion in the area centralis and progressing to include the entire retina.
- Attenuated (thin) retinal blood vessels in advanced cases.
- History of inadequate diet especially cats fed commercial dog foods.
- All breeds at any age.
- Affected cats may have a cardiomyopathy.

Pathogenesis

The syndromes feline central retinal degeneration (FCRD) and taurine deficiency retinopathy are regarded by many authors as being the **same disease**. The disease is still occasionally seen in cats that appear to have adequate levels of dietary taurine, but the overall incidence of the disease throughout the world appears to have declined as the taurine content of commercial diets has been increased.

Taurine is a sulfur-containing amino acid, which is metabolized in the liver from cysteine. **Cats are**

deficient in the enzyme cysteinesulfinic acid decarboxylase that is **necessary for the production of taurine**, and therefore need diets that contain a high level of taurine.

In cats, taurine is used almost exclusively for **bile acid conjugation**.

Taurine is dissolved in the cytosolic fluids of cells, particularly in excitable tissues. It is found in high concentrations in the retina, heart, central nervous system and skeletal muscle.

Taurine is essential for photoreceptor survival, and is found in high concentrations in inner and outer segments. It is thought to **protect the retina from light and chemical damage, regulate calcium ion transport and regulate signal transduction**.

Taurine deficiency causes a loss of photoreceptor outer segment and photoreceptor nuclei, and underlying hypertrophy and disorganization of the underlying retinal pigment epithelial cells. It is not clear why the area centralis is affected more than the outer retina, but it may be associated with increased cone density and higher levels of rhodopsin pigment in cone cells in this area. Cone cells are affected more than rods.

Ophthalmoscopically the initial lesion develops in the area centralis. **The area centralis (temporal to the optic disc) at first develops a granular appearance, then becomes hyper-reflective**. As the degeneration advances, a second hyper-reflective lesion develops nasal to the optic disc, which eventually coalesces with the area centralis lesion to form a broad hyper-reflective band, dorsal to the optic disc. Finally, generalized retinal degeneration develops, with generalized tapetal hyper-reflectivity, and retinal vessel attenuation.

Taurine deficiency also causes dilated cardiomyopathy. See main references on page 151 for details (The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

Clinical signs

Taurine deficiency may be seen in all breeds of cats, at any age, although it is less common now that functional taurine is in all commercial cat food. It is most commonly seen in cats fed **dog food or vegetarian diets**.

Initially, cats are presented with **vision loss**. In later stages, this is associated with **poor pupillary light reflexes**.

There are **five stages of the disease** described on clinical ophthalmoscopy:

- Stage 1. There is an increased granularity of the area centralis, adjacent to the optic disc. Cats are visual at this stage.
- Stage 2. The area centralis develops an ellipsoidal hyper-reflective appearance. Vision is starting to deteriorate.
- Stage 3. A second hyper-reflective lesion develops nasal to the optic disc. Vision deteriorates further.
- Stage 4. The two hyper-reflective lesions join to form a broad band of hyper-reflective tapetum. Vision is noticeably poor at this stage.
- Stage 5. There is generalized retinal degeneration, with severely attenuated retinal blood vessels. The cat is blind.

Diagnosis

Diagnosis is based on clinical signs, in particular observation of the typical retinal lesions, and a **history of inappropriate diet**.

Electroretinography (ERG) can be performed to identify altered photoreceptor function. **Cones appear to be affected more than rods**, so these cats will have reduced b waves in photopic (light) conditions, and better responses in scotopic (dark adapted) conditions.

Measurement of plasma taurine levels is the best way to diagnose the condition. Cats with plasma taurine levels below 40 nmol/ml are regarded as deficient.

Treatment

Provide taurine supplementation.

- 250–500 mg PO q 12 h.
- In the early stages, retinal damage can be reversed, but ophthalmoscopic signs remain unchanged.
- The effects of prolonged deficiency are only partially reversible.
- The ERG signs associated with rod degeneration may reverse, but **cone degeneration never totally recovers**.

Advanced cases will remain **irreversibly blind**, despite treatment.

FLY LARVAL MIGRATION (OPHTHALMOMYIASIS)

Classical signs

- Vision loss, usually unilateral.
- Cloudy posterior segment with linear track-like lesions on fundoscopy.
- Anterior uveitis associated with larva in the anterior chamber.
- Rare condition.

Clinical signs

Larval migration of the *Cuterebra* fly causes vision loss, usually unilateral, associated with chorioretinitis. Typically the cat is presented with a cloudy painful eye.

There are usually **poor pupillary light reflexes** in that eye, and **anisocoria**, if the condition is unilateral.

The characteristic fundoscopy signs are linear **hyper-reflective “tracks” in the tapetal fundus**, and linear light gray areas of reduced pigmentation in the non-tapetum. Hemorrhage may be evident in the early stages. Sometimes the white **body of a fly larva** is seen associated with one of the tracks.

Rarely, the larva is seen in the anterior chamber, with associated signs of anterior uveitis.

Diagnosis

Diagnosis is based on appearance of the fundoscopic lesions, or observation of the parasite in the anterior chamber and associated uveitis.

Treatment

There is no specific treatment.

Do not kill the parasite, as this may cause a severe immune reaction to the parasite proteins.

Topical and systemic corticosteroid therapy is used to minimize the inflammation in the affected eye.

A free-moving parasite in the anterior chamber or vitreous should be surgically removed.

HEREDITARY RETINAL DEGENERATION IN ABYSSINIAN CATS

Classical signs

- Progressive loss of vision occurs in young Abyssinian cats.
- Loss of pupil light reflexes in advanced cases.
- Tapetal hyper-reflectivity and retinal vessel attenuation.
- Relatively rare disease.

Pathogenesis

Two forms of hereditary retinal degeneration have been described in Abyssinian cats.

- **Rod-cone dysplasia.**
 - Inheritance is **autosomal dominant**.
 - Rods and cones degenerate at the same rate.
 - Degeneration begins centrally, with progressive loss of the photoreceptor layer.
 - The photoreceptor inner segments remain rudimentary, and the outer segments fail to elongate.
- **Rod-cone degeneration.**
 - Inheritance is **autosomal recessive**.
 - Rods degenerate rapidly, but cones are spared until the late stage of the disease.
 - Degeneration begins in the mid-peripheral regions of the retina.
 - Histological changes begin at approximately 35 days post-natally, with immature rod outer segment discs. The cones appear normal at this stage. The rod outer segments begin to form vacuoles, and the disc material clumps with subsequent drop out of the cells. Two to three years later, the cones start to degenerate and drop out. Rhodopsin levels are reduced in affected cats. Cats may also have plasma lipid abnormalities.

Clinical signs

Inherited retinal degeneration is a **rare disease** causing blindness in **young** (≤ 4 years) **Abyssinian cats**. It occurs very rarely in other breeds of cats.

Rod-cone dysplasia.

- Retinal degeneration begins at 4 weeks of age, and cats are blind by 1 year of age. The typical history is of a **young cat that goes rapidly blind**.

- Nystagmus may be present.
- Loss of vision occurs rapidly, and **mydriasis**, **hyper-reflective tapetum** and **attenuated retinal blood vessels** are evident.
- There is loss of pupillary light reflexes in advanced cases.

Rod-cone degeneration.

- Retinal degeneration does not begin until 1.5–2 years of age, and blindness follows over the next 2–4 years. The typical history is of **older cats that go slowly blind**.
- The **retina** on either side of the optic disc begins to develop a **subtle gray discoloration**. A more diffuse grayness of the tapetal area follows. The tapetal area then becomes **hyper-reflective** and the retinal blood vessels attenuate.
- The non-tapetal fundus may show pale areas mixed with heavily pigmented areas.
- There is loss of pupillary light reflexes in advanced cases.
- **Electroretinography (ERG)** shows a progressive reduction of the B-wave amplitude which correlates to the loss of rhodopsin.

Diagnosis

Initially, diagnosis is made on the breed and age of the cat, and the clinical presentation of vision loss. Pupils may become dilated, and the tapetum will be hyper-reflective in the advanced stage of the disease.

Histopathology will help to confirm the disease if cats can be sacrificed.

ERG with reduced B-wave amplitude is useful in the early stages of the disease.

Differential diagnosis

Taurine deficiency will present with loss of pupillary light reflexes, hyper-reflective tapetum and retinal vessel attenuation. This may affect cats of all ages and all breeds. Dietary history and plasma taurine levels should help to differentiate this disease.

Hypertensive retinopathy usually occurs in older cats. There is always hemorrhage present around retinal blood vessels, or there is focal areas of hemorrhage present in the vitreous. There will be varying degrees of

retinal detachment. Check these cats for renal disease and hyper-thyroidism.

Inflammatory chorioretinitis is always appears as cloudy eyes that have uveitis. Laboratory tests are useful to confirm diagnoses.

Treatment

There is **no treatment** for this form of retinal degeneration. Breeders need to be made aware of the mode of inheritance.

TRAUMA-ASSOCIATED OCULAR SARCOMA

Classical signs

- Rare, primary neoplasia that occurs in older cats (7–15 years).
- History of previous severe trauma to eye.
- Anterior uveitis, keratitis (corneal edema and pigmentation) and glaucoma.
- White to pinkish masses may be visible in the vitreous.

Clinical signs

Trauma-associated ocular sarcoma is a rare primary neoplasia reported only in cats.

It occurs in older cats, typically **7–15 years of age** that have had a history of **ocular trauma 3–10 years previously**.

Signs of anterior **uveitis and keratitis** may be evident, as edema and pigmentation of the cornea, and a cloudy eye. These changes may prevent visualization of the intra-ocular structures.

Secondary glaucoma is common at this stage of the disease. The eye will show buphthalmos (enlarged globe) with engorged scleral vessels.

If the posterior segment can be visualized, **white to pink masses** may be seen.

The condition is thought to occur **after lens trauma**, which triggers the **lens epithelial cells** to undergo **metaplasia**.

The neoplasia rapidly extends through the choroid, and infiltrates the optic nerve. Metastasis has been reported.

Survival rate is very low.

Diagnosis

Old cats that have a prior history of trauma, and present with glaucoma and signs of uveitis and keratitis, are candidates for this rare condition.

Fine-needle biopsy may be done, but may not yield a diagnostic sample if the tumor contains fibrous and cartilaginous tissue.

Histopathology of enucleated globes provides a definitive diagnosis, and will show changes that may include granulation tissue, fibrosarcoma, osteosarcoma and anaplastic spindle cell sarcoma.

Treatment

All blind globes with chronic uveitis should be watched for the development of this condition.

Early enucleation with histopathology should be done on all globes where there is a **prior history of trauma**, and there are **changes in the size and shape of the globe**, or **changes in the anterior chamber** and cornea, that are indicative of intra-ocular disease.

Severely traumatized blind eyes in cats should be enucleated, to prevent the occurrence of this condition, particularly if there has been lens rupture.

In confirmed cases, check for metastases to regional lymph nodes, and other organs such as lungs and liver.

METASTATIC INTRA-RETINAL NEOPLASIA

Classical signs

- Rare in cats.
- Uveitis with corneal edema, cloudy aqueous and distorted pupil.
- Swelling and pigment changes in the retina.

Clinical signs

This is a rare condition in cats.

Most cases present as **anterior uveitis with corneal edema and a cloudy aqueous**, and have some form of **swelling seen in the iris**, which may cause distortion of the pupil (dyscoria).

Fundoscopy may show a **bulging of the retina**, and **some pigment change** such as a **brownish appearance**. **Retinal detachment** may occur as the neoplasia extends through the choroid into the intra-retinal space.

The most common metastatic neoplasia in the eye include **lymphosarcoma**, and **adenocarcinoma from lung, uterus and undetermined origin**.

Diagnosis

An **initial tentative diagnosis** is based on the most common presentation of iris swelling, distortion of the retina and signs of uveitis.

Fine-needle biopsies may help to obtain a diagnosis.

Chest and abdominal radiology should be done to find primary adenocarcinomas.

Examination of the buffy coat for abnormal lymphocytes can be done in cases with lymphosarcoma.

Fine-needle biopsies of enlarged lymph nodes may be diagnostic.

TOXIC RETINAL DEGENERATION

Classical signs

- Rapid loss of vision within 5 days with dilated pupils.
- History of administration of methylnitrosurea in combination with ketamine hydrochloride.
- High doses of fluoroquinolones, particularly enrofloxacin, may cause blindness in cats.

Clinical signs

There are **few cases reported** of toxic retinal degeneration in the cat.

There is **rapid loss of vision** over **approximately 5 days**, usually in cats that have been administered specific drugs. This syndrome is associated with **high doses of fluoroquinolones**, particularly enrofloxacin, although it has also occurred as an idiosyncratic reaction in cats given less than the recommended dose of 5 mg/kg q 24 h. Methylnitrosurea, in combination with

ketamine hydrochloride, has also been associated with this syndrome.

- **Ketamine** also increases cerebral oxygen demand, and the visual cortex is the most sensitive area of the brain to hypoxia. Hypotension associated with acepromazine especially intravenous administration, and high doses of isoflurane, or other anesthetic agents, and mask delivery of anesthetic agents all exacerbate the hypoxia. Hypoxia of the visual cortex can result in cortical blindness following anesthesia.

Pupils become **dilated and unresponsive to light**.

Pathology is characterized by photoreceptor and outer nuclear layer degeneration.

Diagnosis

A tentative diagnosis is **based on clinical signs and history** of either:

- Sudden blindness after administration of methylnitrosurea and ketamine.
- Sudden blindness after administration of enrofloxacin, especially at a higher dose (20 mg/kg q 24 h) than the recommended rate of 5 mg/kg q 24 h.

LIPEMIA RETINALIS

Classical signs

- Retinal blood vessels appear enlarged, and may have a yellow to orange hue.
- Rare in cats.

See main reference on page 569 (The Cat With Hyperlipidemia).

Clinical signs

Cats **do not show visual impairment** with lipemia retinalis, so this condition is usually seen as an incidental finding.

Ophthalmoscopic examination reveals **enlarged retinal blood vessels**, which have a **yellow to orange coloration**. There may be some haziness surrounding the major vessels from lipid leakage, and this may cause a local inflammation.

Lipemia retinalis is seen in cats that have **increased fasting triglycerides**, which is most commonly

idiopathic in origin, but may be associated with **diabetes mellitus or hereditary hyperchylomicronemia**. Post-prandial lipidemia may be seen in normal cats, especially after a high-fat diet, and obese cats. It can occur after administration of corticosteroids.

Diagnosis

The **clinical signs** of large retinal blood vessels that have a yellow to orange hue should alert the clinician to lipidemia. Blood cholesterol and triglyceride levels should be checked.

Diagnosis is based on clinical signs and **increased plasma triglycerides**.

Blood glucose levels should be checked for diabetes mellitus.

There may be a history of corticosteroid use, particularly megestrol acetate.

ANEMIC RETINOPATHY

Classical signs

- Blind, weak cat with profound anaemia (PCV < 10% or hemoglobin < 5 g/dl).
- Retinal hemorrhages and attenuated, pale retinal vessels.
- Partial to complete loss of pupillary light reflex.

Clinical signs

Typically the cat presents as **blind and weak, with profound anemia** (PCV < 10%). The severe anemia is thought to cause a **hypoxic retinopathy**.

On fundoscopy there are **focal retinal hemorrhages** associated with anoxia of the retinal blood vessel cell wall. The **vessels appear pale and are attenuated** (thinned).

Partial to complete loss of the pupillary light reflex is present as a result of retinal hypoxia.

Other signs of severe anemia are present including pale mucous membranes, increased respiratory rate, lethargy and weakness.

Diagnosis

Diagnosis is based **initially on the clinical signs** of a severely anemic cat with poor pupillary light reflexes and multiple small retinal hemorrhages.

Diagnosis is confirmed on **hematology**, and **ruling out coagulopathy** as a cause of retinal hemorrhage. Anemia must be **profound** for this syndrome to occur, i.e. usually the PCV is less than 10% or hemoglobin less than 5 g/dl.

The cause of the anemia should be identified. Common causes of profound anemia are chronic and include FeLV-associated anemia or *Mycoplasma hemofelis* (*Hemobartonella felis*) infection. FeLV-associated anemia may also be accompanied by thrombocytopenia, which may contribute to the retinal hemorrhages.

HYPERVISCOSITY SYNDROME

Classical signs

- Blindness and loss of pupil reflexes.
- Dilated tortuous retinal vessels, retinal hemorrhages, retinal detachment.
- Monoclonal globulin spike on plasma electrophoresis.

Clinical signs

Severe plasma hyperviscosity causes **blindness and loss of pupillary reflexes**.

Markedly increased plasma proteins cause increased viscosity of blood. This results in sluggish blood flow to the retina and retinal **hypoxia**.

On fundoscopy, there are **extremely dilated, tortuous retinal vessels, retinal hemorrhages, retinal detachment**, perivascular effusion and optic disc edema may be evident.

A **variety of other clinical signs** may be present associated with the primary disease causing the hyperproteinemia, including lethargy, pale mucous membranes, neurologic signs and lameness.

Diagnosis

Diagnosis is initially based on the suspicious signs seen on fundoscopy, especially the presence of **bizarre dilated, tortuous retinal vessels**.

Diagnosis is confirmed by demonstration of a monoclonal globulin spike on protein electrophoresis of plasma.

Multiple myeloma is the most frequent cause of a monoclonal globulin spike.

BLINDNESS CAUSED BY OPTIC NERVE PROBLEMS

OPTIC NERVE COLOBOMA

Classical signs

- Rare condition that occasionally affects vision.
- Inverted funnel or black hole appearance in optic disc.
- Associated with eyelid agenesis.
- Retinal dysplasia also occurs (dark lines on tapetal fundus).

Clinical signs

Optic nerve coloboma is a **rare lesion** in cats.

It is usually seen as an **incidental finding** on ophthalmoscopic examination of cats with **eyelid agenesis (coloboma)**.

Both **hereditary and in utero infections** have been suggested as causes.

The coloboma appears as a **dark area associated with the optic disc**, and has the **appearance of an inverted funnel or black hole**.

Vision is rarely affected.

Retinal dysplasia may occur concurrently, and appears as a dark streak or depigmented rosette in the tapetal fundus.

Diagnosis

Diagnosis is based on the fundoscopic findings of an optic disc with a dark hollow appearance. Retinal dysplasia appears as dark lines in the tapetal fundus.

BLINDNESS ASSOCIATED WITH MIDBRAIN AND VISUAL CORTEX PROBLEMS

*TOXOPLASMA GONDII**

Classical signs

- Blindness with a normal PLR.
- Anterior uveitis and chorioretinitis.
- Other neurological signs of CNS involvement.

See the main reference on page 375 (The Pyrexia Cat).

Clinical signs

Cats with CNS involvement may show blindness, with normal to slow pupillary light reflexes, if the lesions involve the cerebral visual cortex.

Uveitis and chorioretinitis may be present. See above (page 1173).

Blindness may be caused by extensive chorioretinitis and/or CNS disease involving the visual cortex.

Diagnosis

See the main reference above under chorioretinitis (page 1173).

*CRYPTOCOCCUS NEOFORMANS**

Classical signs

- Cats of all ages.
- Uveitis with hypopyon and keratic precipitates.
- Blindness with or without CNS signs.

See the main reference on page 25 (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Cryptococcosis affects cats of all ages.

Blindness may occur with or without CNS signs. **Blindness may be central** or associated with **retinal**

detachment and optic neuritis. Cats with CNS signs may show seizures, ataxia and/or depression.

Uveitis with hypopyon and keratic precipitates is a common presenting sign.

Affected cats often show **other signs** that may include one or all of the following: **chronic nasal discharge** with swollen bridge of the nose or polyp-like mass protruding from nostril, skin lesions, swollen lymph nodes, anorexia and weight loss.

Treatment of the ocular disease may alleviate signs, only to be followed by **blindness with or without CNS signs** such as seizure and ataxia.

Diagnosis

CSF tap may confirm the presence of typical yeast-like organisms visible either directly, or found on culture.

Serology may support the diagnosis.

ISCHEMIC ENCEPHALOPATHY

Classical signs

- Young adult to middle-aged cats.
- Sudden-onset blindness.
- Normal, slow or absent pupillary light reflexes.
- Seizures, ataxia and/or motor defects.

See the main reference on page 800 (The Cat With Seizures, Circling and/or Changed Behavior).

Clinical signs

Ischemic encephalopathy can result from several disease processes including embolism (feline ischemic encephalopathy), and hypotension, which is usually associated with anesthesia.

Feline ischemic encephalopathy is a syndrome more common in **young adult to middle-aged cats**. The pathogenesis is unknown, but is thought to be an associated embolic event resulting in cerebral ischemia.

- In contrast, cerebrovascular accidents resulting in hemorrhage into the brain, are rare in cats, and older animals are more at risk, especially if hypertensive from renal failure or hyperthyroidism.

Ischemic encephalopathy may also occur as a **complication of anesthesia**, particularly in cats resuscitated

after cardiac arrest. The **visual cortex is the most sensitive area of the brain to hypoxia**. Hypoxia of the visual cortex can result in cortical blindness.

- **Hypotension** associated with **acepromazine**, especially intravenous administration, and **high doses of isoflurane, or other anesthetic agents**, and **mask delivery** of anesthetic agents (which combines high doses of inhalant agents and poor airway maintenance), all exacerbate anesthesia-associated hypoxia. **Ketamine** also increases cerebral oxygen demand and has been associated with cortical blindness.
- Cortical blindness associated with anesthesia is evident once the cat wakes up. Other neurological signs may be evident such as paresis, ataxia, proprioceptive deficits, circling and seizures.
- Typically, there is **blindness** with dilated pupils, and normal to slow pupillary light reflexes.

In **feline ischemic encephalopathy** typically there is a **peracute onset of unilateral forebrain signs** (mental depression and confusion, compulsive circling, hemiparesis and ataxia) and rarely, severe cluster seizures or status epilepticus. Vision defects including **loss of menace response** may be present. Blindness does not occur unless the infarction involves both hemispheres, which is uncommon.

Diagnosis

A tentative diagnosis is based on clinical signs of a sudden onset of neurological problems in an adult cat unassociated with anesthesia (feline ischemic encephalopathy), or on recovery from anesthesia.

CT scan or MRI using dyes may help to localize and diagnose the problem, if feline ischemic encephalopathy is suspected. A CSF tap may show red blood cells, or hemosiderin in more chronic cases.

FELINE INFECTIOUS PERITONITIS VIRUS (FIP)

Classical signs

- Typically, young cats 6–12 months of age.
- Central blindness with normal PLR or anisocoria.
- Central vestibular and cerebellar signs.

See the main reference on page 372 (The Pyrexia Cat).

Clinical signs

Feline infectious peritonitis is an infrequent disease causing **central blindness**, and most often occurs in young cats that were in **multi-cat households or obtained from breeders** within the previous 18 months.

Cats with central blindness have the **dry form of FIP**, and usually have a history of **uveitis and the classical signs of hypopyon and keratic precipitates**.

The choroid of the eye is homologous embryologically with the meninges, so cases with meningitis often also show chorioretinitis.

Central blindness is associated with **normal to slow pupillary light reflexes** for cortical lesions, or anisocoria if the midbrain is involved. Concurrent involvement of the eyes may result in abnormal reflexes.

FIP is usually a protracted disease, often with **vague systemic signs such as inappetence, weight loss, lethargy** and pyrexia.

Central vestibular and cerebellar signs may be seen. Affected cats often develop seizures.

Ocular disease may initially respond to corticosteroid therapy, with the cat then developing CNS signs and blindness weeks or months later.

Diagnosis

There is **no definitive diagnosis for FIP**.

Diagnosis is initially based on the suspicious **clinical signs of a young cat with uveitis**, showing hypopyon and keratic precipitates, **followed up to months later with neurological signs**.

Serology is usually regarded as being of dubious benefit in the diagnosis, as the FIP organism cross-reacts with enteric forms of coronavirus.

Diagnosis can only be confirmed on characteristic histopathology of affected tissues on biopsy or necropsy. The typical change is described as a **pyogranulomatous vasculitis**. Necrosis and a fibrinoid response are seen in some cases. The ocular cellular response includes neu-

trophils, lymphocytes, plasma cells, macrophages and large, spindle-shaped histiocytes.

Cases usually show a large increase in IgG due to the chronic nature of the disease, seen as **increased plasma total protein and globulin concentration**. There is a polyclonal increase in gammaglobulins caused by virus antigen, and cell destruction from the intense inflammation associated with the infection.

INTRACRANIAL NEOPLASIA

Classical signs

- Slowly progressive unilateral or bilateral vision loss.
- Older cats.
- Normal pupillary light reflex or anisocoria.
- May show neurological signs.

See the main reference on page 881 (The Cat With Anisocoria or Abnormally Dilated or Constricted Pupils).

Clinical signs

Intracranial neoplasia causing blindness usually presents as an **older cat with a loss of vision**, which may be unilateral or bilateral.

- If the lesion affects the **optic chiasm**, the **pupils will be dilated and non-responsive to light**. Meningiomas and pituitary tumors have been reported in this area.

Mid-brain masses may cause anisocoria, but vision defects will not be as apparent. Meningioma has been reported in this area.

Meningiomas in the region of the **visual cortex** may cause blindness. The pupil should have a **normal to slow response to light**.

Diagnosis

The **clinical presentation** of vision loss in an older cat with a normal fundus and abnormal PLRs increases the index of suspicion for an intracranial mass.

CT scan and MRI are useful tools to diagnose and localize the lesion.

58. The cat with a red coloration of the globe

Richard IE Smith

KEY SIGNS

- Hemorrhage in any part of the eye.
- Engorged scleral vessels.
- Erythema of conjunctiva.
- Red appearance through pupil.

MECHANISM?

- In this chapter, the globe refers to the eyeball, and does not include the supporting structures such as eyelids, third eyelid and orbital structures.
- The globe appears red on the exterior when the conjunctival vessels are inflamed, or the scleral vessels are engorged, or there is diffuse conjunctival hemorrhage.
- The interior of the globe appears red due to hemorrhage in the anterior chamber, vitreous or retina.
- In animals with color-diluted genes, the fundus (that part of the retina that can be examined through the pupil) may have a red reflection from the so-called “tigroid retina”.

WHERE?

- Conjunctiva, choroid.
- Iris.
- Anterior chamber.
- Vitreous.
- Retina.

WHAT?

- Trauma is a common cause of a red globe and this involves hemorrhage in the conjunctiva, sclera, anterior chamber (hyphema) or vitreous.
- Inflammation of the iris and ciliary body (anterior uveitis) may cause hyphema.
- Retinal hemorrhage from trauma, inflammation or hypertension may cause hemorrhage in the vitreous.

QUICK REFERENCE SUMMARY

Diseases causing a red coloration of the globe

WHERE?

BULBAR CONJUNCTIVA (THE CONJUNCTIVA COVERING THE GLOBE)

METABOLIC

- Hemorrhage associated with bleeding disorders (p 1197)
Bleeding disorders can cause echymoses in the conjunctiva, and in severe cases hyphema. Other signs such as oral hemorrhages, skin hemorrhages and melena may be present.

INFLAMMATION

- Uveitis*** (p 1198)
Appears uni- or bilaterally as a cloudy eye with a red appearance from inflamed, congested conjunctiva. Signs of inflammation are present within the eye, including hypopyon (cloudy anterior chamber), and swelling and color change of the iris. Pupils will be miotic, and the eye is soft. Sometimes there is anisocoria (unequal-sized pupils) and dyscoria (abnormal-shaped pupil).

- Glaucoma* (p 1199)
A red globe caused by engorged episcleral vessels. In chronic cases the globe is enlarged (buphthalmos). Other changes may be present in the eye such as cloudy cornea, uveitis and cataract formation.

INFECTIOUS

- Acute infectious conjunctivitis*** (p 1197)
Occurs most frequently in young cats. Herpesvirus and *Chlamydomydia felis* may cause unilateral or bilateral signs, with chemotic (edema) and red (hyperemic) conjunctiva. Ocular discharge is first serous then rapidly mucopurulent. In *Chlamydomydia felis* infection, the redness (hyperemia) is not as intense and the respiratory signs milder than in herpetic conjunctivitis. Mycoplasma produces mild inflammation and serous discharge, and is readily responsive to most antibiotics topically.

TRAUMA

- Hemorrhage associated with trauma*** (p 1197)
Ocular trauma frequently results in conjunctival, subconjunctival or retrobulbar hemorrhage. There is usually a history of trauma to the head or eye. Focal or diffuse hemorrhage may be evident between the conjunctiva and sclera (subconjunctival).

WHERE?

ANTERIOR CHAMBER

INFLAMMATION

- Hyphema associated with inflammation* (p 1200)
Hemorrhage in the anterior chamber may occur secondary to trauma, anterior uveitis, neoplasia or bleeding disorders. Usually accumulations of blood and protein occur within the anterior chamber, and may be attached to the iris or free within the aqueous.

TRAUMA

- **Hyphema associated with trauma* (p 1200)**

Anterior chamber may be filled with blood so the eye appears completely red. Owners often describe the eye as “black” in color. May be hemorrhage in the conjunctiva as well.

WHERE?

IRIS

NEOPLASTIC

- **Iris neoplasia* (p 1202)**

Lymphosarcoma infiltrating the iris causes iris swelling, distortion, a “creamy” color change and hemorrhage on the anterior iris surface. The pupil may be distorted (dyscoria). Hyphema and hypopyon are present in varying degrees.

INFLAMMATION/INFECTIOUS

- **Uveitis*** (p 1201)**

FIV, FeLV, FIP, *Blastomyces dermatitidis*, *Candida albicans*, *Coccidioides immitis*, *Cryptococcus neoformans*, *Histoplasma capsulatum* are all associated with uveitis, which may result in a pink- or red-appearing iris or hemorrhage into the anterior chamber. Systemic signs associated with the agent are usually present. Anterior uveitis with pre-iridal fibrovascular membranes (PFIM) are the main presenting signs in chronic uveitis. Hemorrhage is associated with the PFIMs. Retinal hemorrhage is seen occasionally in areas of granuloma formation. Often there is no obvious cause and the uveitis is idiopathic.

IMMUNE

- **Pre-iridal fibrovascular membranes (PIFMs)* (p 1201)**

New blood vessel growth seen on the anterior surface of the iris that gives the iris an injected pink discoloration. Vessels are fragile and easily hemorrhage into the anterior chamber, causing hyphema. Usually seen in eyes with chronic inflammatory disease, total retinal detachment or neoplasia.

TRAUMA

- **Trauma, blunt or penetrating* (p 1299)**

Bleeding into the eye is caused by an injury to the iris root or ciliary body. In penetrating injuries, especially from cat claws, hemorrhage is directly associated with an injury to the iris.

WHERE?

VITREOUS

METABOLIC

- **Hypertensive retinopathy*** (p 1202)**

Typically presents as an older cat with a history of sudden blindness. Usually bilateral, affected eyes appear cloudy, and the vitreous has focal red areas visible through the pupil. The retina appears out of focus. Common secondary to chronic renal disease or hyperthyroidism and cardiomyopathy.

continued

continued

TRAUMA

- **Traumatic hyphema* (p 1203)**

Blunt or penetrating trauma to the head and eye or may cause hemorrhage in the vitreous. The eye appears red through the pupil. There may or may not be hemorrhage in the anterior chamber or conjunctival hemorrhage.

WHERE?

RETINA

ANOMALY

- **Tigroid fundus*** (p 1204)**

The appearance of a red fundus reflection can be normal in color-dilute cats such as Siamese and Color Points. This is due to lack of pigment in the retinal pigment epithelium and consequent red reflection from choroidal blood vessels (tigroid fundus). Where there is no tapetum the whole of the fundus will appear red. Where there is a tapetum, then only the non-tapetum will appear red.

METABOLIC

- **Hypertensive retinopathy*** (p 1204)**

Usually occurs in older cats with a history of sudden blindness. The eye seen through the pupil may appear red from hemorrhages in the pre-retina. Focal hemorrhages are seen along the major blood vessels. The retina may look cloudy and is difficult to focus with an ophthalmoscope because of retinal detachment.

INFLAMMATION/INFECTIOUS

- **Inflammatory retinal disease* (p 1205)**

Inflammatory retinal disease, especially caused by fungal infections or ocular visceral larva migrans, may cause retinal hemorrhage. Fungal infections cause anterior uveitis with inflamed conjunctiva, pre-iridal fibrovascular membranes and occasional hemorrhage in the anterior chamber (hyphema). Less commonly, hemorrhagic lesions are seen in the retina. Rarely, retinal hemorrhage is caused by larvae migrating along blood vessels causing localized damage to the retina and hemorrhage from injuries to the blood vessel they are migrating in or move through.

TRAUMA

- **Blunt or penetrating trauma* (p 1206)**

The eye appears red through the pupil if there is retinal hemorrhage. Hemorrhage may be focal or diffuse depending on the degree of trauma. If the retina is not visible, ocular ultrasound will be needed to assess the posterior eye for retinal detachment or scleral rupture. Other parts of the eye may also have hemorrhage.

INTRODUCTION

MECHANISM?

Any mechanism that gives the appearance of a red globe is included in this chapter. This may involve trauma or a disease process. Single or multiple ocular tissues may be involved. Diseases primarily affecting supporting structures such as eyelids, third eyelid and orbital structures are not included in the chapter, and the reader is referred to those specific chapters.

Conjunctivitis

In conjunctivitis, the **soft tissues surrounding the eye may be red and/or swollen** (chemosis). This usually involves trauma or diseases of the conjunctiva and nictitating membrane.

Diseases of the conjunctiva are usually seen in young animals.

Cases with a red swollen conjunctiva and exophthalmos usually have **orbital inflammation** (see “The Cat With Abnormal Globe Position or Size”, page 1309).

Trauma is common in all ages, and usually shows focal or diffuse hemorrhage in the bulbar conjunctiva.

Cats with **bleeding disorders** may show echymoses of the conjunctiva (see “The Bleeding Cat, page 481).

Uveitis

Uveitis is a common cause of a red eye.

In **anterior uveitis**, the conjunctiva, anterior uvea (iris and ciliary body), and the appearance of the anterior chamber will be altered, which may give the **appearance of a cloudy and red eye**.

The conjunctiva will usually be inflamed. The redness is caused by **hyperemia of the conjunctival blood vessels**.

There may be a **diffuse corneal edema** caused by disruption to the endothelium and leakage of plasma, which occurs secondary to inflammation associated with the uveal tract.

Keratic precipitates (KPs) may be visible through the cornea. They appear as gray to tan, dot-like or sometimes

coalescing opacities on the endothelial surface of the cornea, and represent focal accumulations of white blood cells and protein on the lower surface of the endothelium.

The **anterior chamber** will show **flare** which is a diffuse cloudiness caused by protein and white blood cells floating in the aqueous humor, and there may be **hypopyon** (a dense accumulation of protein and blood cells within the anterior chamber).

The **intra-ocular pressure (IOP) is low** (usually below 10 mmHg – normal 12– 25 mmHg). When the ciliary body is inflamed, the production of aqueous is reduced.

In chronic uveitis, the **iris may show new blood vessel growth** on the surface. These are called pre-iridal fibrovascular membranes (PIFMs). This also occurs in cases that have ciliary body neoplasia, and in chronic retinal disease.

The **pupil is usually miotic** (constricted) and **may be distorted** from adhesion onto the anterior lens capsule (posterior synechia).

The **lens may have an altered appearance** with iris pigment and protein on the anterior lens capsule. The lens fibers may be cloudy from cataract formation.

In cases of **posterior uveitis** (inflammation of the choroid), the **vitreous may be cloudy** due to the presence of white blood cells and protein dispersed within the vitreous. This is caused by leakage of protein and cells from the ciliary body and choroidal blood vessels. If the retina is visible there may be changes in its appearance. A serous detachment occurs when protein and blood cells leak from the choroidal vessels and push the retina forward, off the retinal pigment epithelium. This may be seen as a **fold in the retina** or it may be difficult to focus on the retina with an ophthalmoscope. Focal areas of inflammation appear as color changes in the tapetal and non-tapetal retina. There may be decrease or increase in the appearance of the pigment.

Glaucoma

In glaucoma, the conjunctival vessels have mild inflammation. **The redness is caused by the deeper, engorged, episcleral vessels** resulting from interrupted venous drainage. Engorgement is much more subtle than occurs in dogs.

The **intra-ocular pressure** is **increased** above 25 mmHg.

The cornea may show **mild diffuse (blotchy) edema** from disruption to the endothelial physiology.

The globe may be enlarged (**buphthalmos**) due to stretching of the sclera.

The **lens may be subluxated or luxated**, because the zonules rupture when the sclera stretches.

The **retinal blood vessels may be thinned** (attenuated), caused by increased pressure at the cribriform plate when it collapses.

The optic disc may be pushed inwards (**optic disc cupping**). It appears deeper and darker, and the blood vessels curve over the outer rim and plunge deeply into the depressed disc. This happens because the cribriform plate is the weakest point in the sclera.

Blindness is a sequela, as the nerve bundles in the optic nerve become damaged by the disruption to their axoplasmic flow when the disc collapses. There are likely to be other adverse effects on nerves at a cellular level, but they are not well defined at present.

Hyphema

Hyphema is **hemorrhage within the eye**.

When **diffuse** in the anterior chamber, the iris and pupil will not be visible.

There may be **focal areas of blood**, seen as free accumulations of redness in the anterior chamber or overlying the iris.

If the anterior chamber is clear, and the iris is visible but the eye appears red through the pupil space, this will be due to either **hemorrhage in the vitreous or retina**, or a **normal red reflection seen in the color-diluted fundus**.

The appearance of a **red fundus reflection** can be **normal in a color-dilute cat**. This is due to lack of pigment in the retinal pigment epithelium and consequent red reflection from choroidal blood vessels (tigroid fundus). Where there is no tapetum, the whole of the fundus will appear red. Where there is a tapetum, then only the non-tapetum will appear red.

Neoplasia

Lymphosarcoma occasionally occurs as a secondary infiltration of the conjunctiva with neoplastic lymphoid cells. The **conjunctiva** appears **swollen and thickened with a pink appearance**, which may be confused with chemosis and inflammation, because it looks like an inflammatory conjunctivitis. The surface usually appears to be dry, and may be covered with a dry mucoid discharge. It is not a common disease.

WHERE?

The most common areas of the eye that appear as a red eye include:

- The conjunctiva and nictitating membrane in cats with **conjunctivitis**.
- The conjunctiva, cornea, anterior chamber, iris and vitreous where there is **anterior uveitis**.
- The conjunctiva and scleral blood vessels in cats with **glaucoma**.
- The conjunctiva, nictitating membrane, cornea, anterior chamber, iris, lens, vitreous and retina in eyes that have had **trauma**.

One or more of these processes may be involved in a cat with red eye.

- For example, an eye with **uveitis** may have **secondary glaucoma** caused by a disruption to the outflow of aqueous humor, occurring somewhere between the ciliary body, the pupil and the drainage mechanism in the irido-corneal angle.

WHAT?

Most processes involving reddening of the ocular structures are **inflammatory or traumatic**, and involve either **frank hemorrhage, hyperemia or vascular infiltration of tissue**.

Vascular neoplasia and immune-mediated diseases can cause hemorrhage.

Determine which ocular tissue is affected and, initially go to that chapter in the book for more detailed information.

DISEASES CAUSING A RED GLOBE: THE RED BULBAR CONJUNCTIVA

ACUTE INFECTIOUS CONJUNCTIVITIS***

Classical signs

- Usually occurs in young animals.
- Intense inflammation and chemosis with mucopurulent discharge (*Chlamydomydia felis* infection).
- Less intense inflammation but very injected vessels and serous discharge (herpesvirus conjunctivitis).
- Mild inflammation and serous to mucoid discharge (*Mycoplasma* infection).

See the main reference on page 1212 for details (The Cat With Ocular Discharge or Changed Conjunctival Appearance) and page 13 (The Cat With Acute Sneezing or Nasal Discharge).

Clinical signs

Young cats with *Chlamydomydia felis* conjunctivitis show **intense chemosis and redness of the conjunctiva**, and a mucopurulent discharge usually develops. There may be **signs of respiratory disease**, with sneezing and nasal discharge.

The inflammation in **herpesvirus (FHV-1) infection** is less intense, but the conjunctiva can become quite red. Respiratory signs are more marked. Discharge is usually serous.

A mild inflammation is seen with *Mycoplasma conjunctivitis*, and the discharge is more serous to mucoid in nature.

Diagnosis

For more details on diagnosis of conjunctival infections see page 1213 (The Cat With Ocular Discharge or Changed Conjunctival Appearance).

Chlamydomydia felis conjunctivitis.

- Commonly occurs **initially as unilateral** signs, followed days later as bilateral disease.

- **Serous to mucopurulent discharge**, which may be more copious than FHV-1 conjunctivitis.
- **Conjunctival follicles** form in chronic cases.
- **Conjunctival swabs or scrapings** taken with a spatula may be positive on a fluorescent antibody test.
- **Cytology specimens** may demonstrate the presence of intracytoplasmic inclusion bodies, which are present in the first 2 weeks of infection.
- **Culture is very difficult** and requires the use of specific growth media sent to specialized laboratories.

Herpes conjunctivitis.

- The **conjunctiva is less inflamed** in acute FHV-1 infections compared to *Chlamydomydia felis* infection.
- **Respiratory signs** are more pronounced with sneezing, serous discharge, anorexia, pyrexia and depression.
- Young cats are more commonly infected with acute signs.
- Severe cases may form a pseudomembrane, and later develop conjunctival adhesions (symblepharon).
- **Laboratory diagnosis** is based on PCR, virus isolation or fluorescent antibody may be supportive.

Mycoplasma felis and *M. gatae*.

- Mycoplasma usually causes a **mild form of conjunctivitis**
- Ocular discharge remains **serous**.
- A **conjunctival pseudomembrane** occasionally forms with a thick white discharge.
- **Cytology** may reveal small basophilic inclusion bodies at the level of the basement membrane.
- The organism can be **readily cultured**.

HEMORRHAGE ASSOCIATED WITH TRAUMA*** OR BLEEDING DISORDERS

Classical signs

- **Bright red sclera** (diffuse hemorrhage) and a history of blunt trauma.
- Conjunctiva may be swollen and bulging, and the eye may be prominent.
- **Ecchymoses** (small areas of hemorrhage) or **petechia** in bleeding states, and no history of trauma.

See the main reference on page 1223 for details (The Cat With Ocular Discharge or Changed Conjunctival Appearance).

Clinical signs

Sub-conjunctival hemorrhage is common after blunt trauma to the eye, especially from motor vehicle accidents.

The most common presentation is a **diffuse reddening of the conjunctiva** over the sclera, with very little swelling. This may be **focal or diffuse** over the entire sclera.

In severe cases, there may be **frank hemorrhage** with swelling of the conjunctiva. This may be present after orbital trauma, and frank orbital hemorrhage may cause severe bulging of the conjunctiva around the globe, and bulging of the eye forward (exophthalmos).

The hemorrhage may be seen as a **diffuse redness between the conjunctiva and sclera**, or as a **frank bleed** under the conjunctiva.

Petechia (multiple small red spots) or ecchymotic hemorrhage (larger patches of red color) may be seen in blood clotting disorders, e.g. rodenticide toxicity and thrombocytopenia.

Diagnosis

The **clinical signs** of diffuse or focal redness with a **history** of trauma are diagnostic. There is frequently no other associated problem.

If in doubt, **fine-needle aspirates** may be beneficial.

It is important to differentiate between hemorrhage caused by trauma and bleeding disorders (See “The Bleeding page 485).

If there is no history of trauma, laboratory tests should be done to check for **clotting or platelet disorders** (page 488).

Orbital radiology may be needed in cats with severe peri-orbital trauma to check for orbital fractures.

Orbital ultrasound (10-MHz probe) is useful to check the posterior sclera, optic nerve and the muscle cone.

UVEITIS***

Classical signs

- Any age of cat.
- Usually seen as a cloudy, red eye.

Classical signs—Cont'd

- The cornea is cloudy.
- The eye is obviously painful with blepharospasm (closed eyelids) and photophobia (squinting).
- Usually is unilateral, and may become bilateral.

See the main reference on page 1294 for details (The Cat With Abnormal Iris Appearance).

Clinical signs

Any age of cat may be affected.

Uveitis is **commonly seen unilaterally**, but may become bilateral.

The **bulbar conjunctiva can appear very red** with uveitis. This is caused by **congestion of the deep episcleral and conjunctival vessels** secondary to inflammation within the eye.

There may be hemorrhage in the anterior chamber (**hyphema**), with bleeding originating from inflammation in the iris and ciliary body.

The eye has a **cloudy appearance** (anterior chamber flare) from the accumulation of protein and white blood cells that leak from the inflamed iris and ciliary body blood vessels (hypopyon).

The inferior surface of the cornea may show **keratic precipitates**, commonly called “mutton fat deposits”. They are accumulations of protein and white blood cells that have adhered to the endothelium in focal spots. The **cornea may be edematous**. Corneal changes also cause a cloudy appearance to the eye.

The **pupil is miotic (constricted)** because the iris sphincter muscles are stimulated by a prostaglandin-induced inflammation. Sometimes there is anisocoria (unequal-sized pupils) and dyscoria (abnormal-shaped pupil). There is often **swelling and color change of the iris**.

Cats with uveitis **show pain by keeping the eye closed** (blepharospasm), and it is very sensitive to light (photophobia).

Cats may be **anorexic and lethargic**, as it is usually secondary to systemic disease.

Affected eyes are hypotonic (**low intra-ocular pressure – below 100 mmHg**), because inflammation in the ciliary body reduces aqueous humor production.

Diagnosis

Diagnosis is based on clinical signs. Congested, red conjunctiva with a cloudy anterior chamber, miotic pupil, and very soft eye are almost pathognomonic for uveitis.

All cases should have a thorough clinical examination, and a minimum data base obtained through laboratory tests.

Common causes of uveitis which need to be ruled out based on diagnostic tests are FIV, FeLV, FIP, cryptococcosis, other fungal infections and toxoplasmosis.

Candida albicans is a rare cause of uveitis in cats. Ocular lesions consist of conjunctival hyperemia and chemosis, fibrin and flocculent material in all ocular chambers, and small nodular lesions in the fundus. On histological examination, organisms are evident that are free and phagocytized in the vitreal and retinal exudates.

Any problem causing a bacteremia may cause uveitis.

Many cases of uveitis are idiopathic, and no obvious cause is found.

GLAUCOMA*

Classical signs

- Red eye caused by deep episcleral vessel injection.
- Increased IOP above 25 mmHg.
- ± Enlarged globe (buphthalmos).
- Cornea may be cloudy.
- Pupil mid-dilated to dilated and poorly responsive to light.
- ± Signs of chronic uveitis (changes in the appearance of the iris surface).
- ± Uveal neoplasia (change in iris color, size, shape and/or thickness).
- ± Lens instability or dislocation.

See the main reference on page 1312 for details (The Cat With Abnormal Globe Position or Size).

Clinical signs

Glaucoma causes **deep episcleral vessel injection**. Deep vessels are usually straighter and larger, do not move when the overlying bulbar conjunctiva is moved, and do not blanch with the topical application of 1:1000 epinephrine. The signs of glaucoma are more subtle in cats than in dogs.

The intra-ocular pressure (IOP) is high. In most cats with signs of glaucoma the **IOP will be above 30 mmHg** (normal 10–25 mmHg).

An **enlarged globe (buphthalmos)** may or may not be present, depending on the chronicity of the increased IOP.

The **pupil will be dilated or semi-dilated**, with either absent or poor pupillary light reflexes. The increased IOP causes paralysis of the iris sphincter muscle, retinal damage, and often blindness within days.

The **cornea may be slightly cloudy** because of pressure changes in the endothelium. The cloudiness may have a mottled appearance.

Signs of chronic anterior uveitis may be present, especially abnormalities in the appearance of the iris surface including pinkish discoloration associated with fibrovascular membranes, or grayish discoloration of the iris surface with iris melanoma.

Signs of **lens instability** may be present including:

- Aphakic crescent (crescent shape produced by the clear space between the edge of the displaced lens and the adjacent pupillary margin).
- Anterior or posterior luxation (dislocation).
- Iridonesis (wobbling of the iris).

Signs of **intra-ocular neoplasia** are occasionally present, seen as a change in the shape, thickness, color and/or contour of the iris. Diffuse black irises may be seen in older cats with melanosis and iris melanoma.

Diagnosis

Initial diagnosis is based on the appearance of buphthalmos with any or all of the other related signs of glaucoma, chronic anterior uveitis and lens instability.

Measurement of intra-ocular pressure (IOP) with tonometry. Normal range for IOP in the cat is 10–25 mmHg. **Readings over 30 mmHg are supportive of a diagnosis of glaucoma.**

DISEASES CAUSING A RED GLOBE: THE RED ANTERIOR CHAMBER

HYPHEMA ASSOCIATED WITH TRAUMA* OR INFLAMMATION*

Classical signs

- The anterior chamber may be full of blood and bright red in color.
- The eye may appear black, if bleeding is very severe.
- Signs of trauma with scleral and subconjunctival hemorrhage may be present.
- Bleeding disorders may have signs of hemorrhage on mucous membranes and skin.

Pathogenesis

HypHEMA (blood in the anterior chamber) occurs because of **trauma to the iris and/or ciliary body**.

The blood may be **diffuse, filling the anterior chamber**, which appears **bright red**, or consist of a **focal** accumulation of red cells. If focal, the eye may also appear cloudy because of leakage of protein and white cells (hypopyon).

Any inflammatory disease of the iris can cause leakage of blood products into the anterior chamber. This can range from fibrin without significant numbers of accompanying red cells, to frank hemorrhage (hypHEMA).

HypHEMA may also occur secondary to **chronic uveitis**, when **pre-iridal fibrovascular membranes (new blood vessels)** develop on the iris surface. These are **fragile and may hemorrhage**.

HypHEMA may occasionally occur **secondary to systemic neoplasia**, particularly lymphosarcoma, as the blood vessel endothelial walls are disrupted.

In **bleeding states** such as rodenticide poisoning or thrombocytopenia, the anterior chamber may fill with blood.

Clinical signs

HypHEMA may appear as a **focal accumulation of red cells** attached to the iris or free within the aqueous.

Protein and white cells (**hypopyon**) may also be present in the anterior chamber.

HypHEMA may appear as a **diffuse reddish discoloration** of the anterior chamber from free red cells. **Fibrin** may be present as a result of hemorrhage, resulting in straw-colored strands or masses in the anterior chamber, or there may be a combination of free red cells and fibrin.

The anterior chamber may **appear black** when there has been a **severe bleed**.

The **adnexa may show signs of trauma**, including scleral and sub-conjunctival hemorrhage.

If bleeding disorders are present, mucous membranes and skin may have small hemorrhages (petechia) or blotchy hemorrhages (echymoses).

Diagnosis

Diagnosis is based on the appearance of the anterior chamber.

Ocular ultrasound is useful as an adjunct where the anterior chamber cannot be visualized. Check that the spatial arrangements within the eye are normal, such as depth of the anterior chamber, position and thickness of the iris, position and density of the lens, density of the vitreous. Also check for signs of retinal detachment and the integrity of the scleral wall.

If there are no signs of trauma, uveitis or neoplasia, assess **platelet number and function, and clotting times**.

Treatment

In severe cases of hemorrhage, some veterinary ophthalmologists inject **tissue plasminogen activator** (TPA 0.1 mg usually diluted in 0.3 ml of diluent) into the anterior chamber, as it breaks down fibrin which helps to disperse the clot. Its use is controversial, and should not be used where there is trauma to the iris root, as this may cause a re-bleed.

Topical 1% prednisolone acetate drops (q 8 h) are used to reduce inflammation and minimize iris adhesions (synechia).

Systemic corticosteroids such as prednisolone (1 mg/kg q 12–24 h), are also used to minimize inflammation

and adhesion formation, particularly in cases with uveitis.

In acute cases, **systemic NSAIDs** at recommended doses are used to reduce prostaglandin-induced inflammation. Do not use in combination with corticosteroids.

The use of **drugs to manipulate the pupil** is commonly recommended in the older texts, but this is now **controversial**. Dilating the pupil with atropine reduces the iris surface area, which decreases absorption and may also predispose to glaucoma by compromising the drainage angle. Constricting the pupil with pilocarpine increases the chance of synechia formation, which may lead to iris bombé and secondary glaucoma. Manipulating the iris may also cause further bleeding.

THE RED EYE CAUSED BY CHANGES IN THE IRIS

UVEITIS***

Classical signs

- Red blood cells may be free floating (hyphema) or adhered to the anterior surface of the iris.
- Other signs of uveitis such as red conjunctiva, ocular pain, miotic pupil.
- Color change in iris (lighter or darker) and be thickened.

See the main reference on page 1294 for details (The Cat With Abnormal Iris Appearance).

Clinical signs

Uveitis is associated with changes of iris color. Darker irises may become lighter in color during the inflammatory change, but in chronic cases they often become darker with a blotchy appearance. In lighter irises, the color change is more subtle. If **pre-iridal fibrovascular membranes** form, the iris may take on a **congested, pink appearance**. The iris surface may show **areas of red**, with blood cells attached to the anterior surface, or free in the anterior chamber. Compare the abnormal iris to the opposite eye.

Changes in iris contour also occur with uveitis. The iris may appear **thickened and distorted** when it is

infiltrated with a lot of inflammatory cells, and the surface may become uneven.

Red congested conjunctiva, miotic pupil, ocular pain, and a soft eye are other signs that will be present in uveitis.

Retinal hemorrhage is seen occasionally in areas of fungal granuloma formation, giving the pupil a red appearance.

FIV, FeLV, FIP, *Blastomyces dermatitidis*, *Candida albicans*, *Coccidioides immitis*, *Cryptococcus neoformans*, *Histoplasma capsulatum* are all associated with uveitis, and systemic signs associated with the agent are usually present. Often no cause is found and it is classed as idiopathic uveitis.

Diagnosis

Clinical signs of a red conjunctiva with cloudy anterior chamber, miotic pupil and very soft eye are almost pathognomonic for uveitis.

All cases should have a thorough clinical examination, and a minimum data base obtained through laboratory tests.

Common causes of uveitis are **FIV, FeLV, FIP, toxoplasmosis, cryptococcosis and other fungal infections**, and these should be ruled out using appropriate diagnostic tests.

Any problem causing a bacteremia may cause uveitis.

Many cases of uveitis are idiopathic with no obvious cause.

PRE-IRIDAL FIBROVASCULAR MEMBRANES (“PIFMS”)*

Classical signs

- Iris has a pink injected appearance from new vessels growing across the anterior surface.
- Intra-ocular neoplasm or a detached retina may be evident.
- Secondary hyphema or glaucoma may occur.

See the main reference on page 1303 for details (The Cat With Abnormal Iris Appearance).

Clinical signs

New blood vessels growing across the **anterior surface of the iris** give the **iris an injected pink discoloration**.

The vessels are fragile, and are often associated with **hyphema**.

Pre-iridal fibrovascular membrane (PIFM) formation is associated with angiogenic factors released by proliferating intra-ocular neoplasms, retinal hypoxia associated with retinal detachment, or chronic ocular inflammation. These abnormalities may be evident on careful examination of the eye.

Secondary glaucoma may occur.

Diagnosis

Diagnosis is based on the characteristic appearance of the fibrovascular membranes on the anterior stromal surface of the iris.

Occasionally an underlying cause may be apparent, such as a **ciliary body epithelial tumor** at the pupil space, or a **total retinal detachment**.

IRIS NEOPLASIA*

Classical signs

- Iris tinged with blood +/- free red cells in the anterior chamber.
- Iris is pale and thickened.
- Pupil may be distorted.

See the main reference on page 1297 for details (The Cat With Abnormal Iris Appearance and The Cat With Abnormal Pupil Size, Shape or Response).

Clinical signs

Ocular neoplasia causing **hemorrhage** is **usually associated with lymphosarcoma**. It is rare for other forms of neoplasia such as melanoma to cause hemorrhage in the eye.

Lymphosarcoma may be associated with **FeLV infection**, although often it occurs in negative cats.

The iris is infiltrated with neoplastic cells, and appears **thickened with a pale fleshy color change**.

The **iris may have red cells on the surface** mixed with protein and white blood cells. Leakage of cells and protein occurs because of disruption of the endothelial cells on the blood vessel walls, and results in **varying degrees of hyphema and hypopyon**. Lymphosarcoma does not usually cause frank hemorrhage.

The **pupil will be distorted (dyscoria)** if the iris is grossly distorted with infiltrated cells.

Glaucoma is often an associated complication.

Regional lymph nodes may be enlarged, or other signs of multicentric lymphosarcoma present.

Diagnosis

A tentative diagnosis is based on the **appearance of the iris**, which is typically thickened, with a fleshy color change, and may have focal hemorrhage on the surface.

Serology for FeLV may support the diagnosis.

White blood cell cytology looking for abnormal plump-shaped lymphocytes with large prominent nucleoli in the peripheral blood is useful in cases with lymphosarcoma.

Biopsy of regional lymph nodes is indicated if there is lymphomegaly. Fine-needle biopsy of the liver or spleen should be performed if there is organomegaly.

An **anterior chamber paracentesis** using cytology to demonstrate neoplastic lymphocytes can be done, but is not usually necessary, as the above tests usually will confirm the diagnosis.

THE RED VITREOUS

HYPERTENSIVE RETINOPATHY***

Classical signs

- Acute onset of vision loss in an old cat, usually bilateral.
- Dilated pupils, non-responsive or poorly responsive to light.
- Cloudy vitreous with red areas of hemorrhage.

See the main reference on page 1171 for details (The Blind Cat or Cat With Retinal Disease).

Clinical signs

Hypertension causes leakage of fluid and red blood cells into the retina, and rupture of retinal blood vessels.

Vitreous hemorrhage caused by **hypertensive retinopathy** appears as **acute-onset vision loss** in an old cat, and is usually bilateral. The cat suddenly starts to bump into things, appears to be lost, and has very cautious movements.

The **pupils are usually dilated**, and non-responsive or poorly responsive to light.

Affected eyes appear **slightly cloudy**, and there may be **focal red areas visible through the pupil**.

It is **difficult to visualize the retina** on fundoscopic examination, as it appears out of focus. This is caused by **retinal detachment** and the retina ballooning into the vitreous.

Hypertensive cats may have **cardiomegaly and left ventricular hypertrophy**. There may be other signs suggestive of hypertension such as a **bounding cardiac apex beat**.

Systolic arterial blood pressure is usually greater than 160 mmHg.

Other signs suggestive of **chronic renal failure or hyperthyroidism** may be present, such as progressive weight loss, polydipsia, polyuria, azotemia, inappetence or polyphasia, or a palpable thyroid nodule.

Diagnosis

Clinicians should suspect this problem in any **old cat that has suddenly gone blind**.

Ophthalmoscopy will demonstrate **vitreous hemorrhage**. The retina will be hard to focus showing hemorrhage adjacent to the major retinal blood vessels.

Blood pressure is most commonly measured in cats using Doppler technology. Arterial blood pressure **greater than 160 mmHg confirms a diagnosis of hypertension**. Most cats with clinical signs of retinopathy have a blood pressure of greater than 200 mmHg.

Blood urea nitrogen (BUN), creatinine and a urine protein:creatinine ratio are useful clinical pathology parameters to **check renal function**.

Thyroid function should be checked using thyroxine (T4) concentrations. (See page 301, The Cat With Weight Loss and a Good appetite, for details of diagnosis).

Cardiac ultrasound may be used to confirm thyrotoxic cardiac hypertrophy.

TRAUMATIC HYPHEMA*

Classical signs

- Uniform red color is seen through the pupil.
- Pupil may be dilated.
- ± Hemorrhage in the anterior chamber.
- Signs of trauma such as sub-conjunctival hemorrhage and adnexal injuries.

Clinical signs

Blunt or penetrating trauma may cause hemorrhage into the vitreous.

Hemorrhage in the vitreous appears as a **uniform red color visible through the pupil**. The eye may have a red glow caused by free red blood cells in the vitreous. Hemorrhage may also be present in the anterior chamber.

The pupil may be dilated.

On ophthalmoscopic examination, **no detail will be visible in the fundus**. The retina will not be able to be visualized because of the intense red color of the vitreous infiltrated with red blood cells.

Other **signs of trauma to the eye**, such as conjunctival and sub-conjunctival injury and hemorrhage, and adnexal injuries may be present, or there is a history of trauma.

Diagnosis

Diagnosis is based on the clinical signs of a red color visible through the pupil, and the reflection of the retina and tapetal is obscured. There is usually a history of trauma.

Ocular ultrasound using a 10-Hz probe is a very useful adjunct to diagnosis. This will show problems

associated with the retina such as detachment, and rupture of the sclera, as well as hemorrhage in the orbit.

Radiology may be useful to check the orbital bones for signs of fracture.

THE RED EYE CAUSED BY RED REFLECTION FROM THE RETINA

THE TIGROID FUNDUS***

Classical signs

- A red fundus reflex is seen frequently in color-diluted cats.
- Seen in cats with a blue iris such as Siamese and Color Points.

Clinical signs

The red reflex is often seen by owners using flash photography as a “red eye”.

In cats the red reflex is frequently **misdiagnosed as retinal hemorrhage**.

The appearance of a red fundus reflection can be normal in a color-dilute cat. Cats with **color dilution have no pigment in the retinal pigment epithelial cells**. As a result, the blood vessels of the choroid are seen clearly against the white background of the sclera. The blood vessels appear in a tigroid pattern (**called tigroid fundus**), and can give a striking red reflex when seen through the pupil in certain light. Where there is no tapetum, the whole of the fundus will appear red. Where there is a tapetum, then only the non-tapetum will appear red.

Occurs in **cats with a blue iris such as Siamese and Color Points**.

Diagnosis

Diagnosis is based on signs. On ophthalmic examination the eyes are normal, with the typical tigroid vascular pattern. The **breed and blue iris color** are indicators of a tigroid fundus.

HYPERTENSIVE RETINOPATHY***

Classical signs

- Sudden blindness in an old cat.
- Dilated pupils, non-responsive or poorly responsive to light.
- Retinal hemorrhages mainly along the major blood vessels with hemorrhage in the vitreous.
- The retina may be detached and difficult to visualize clearly.

See the main reference on page 1171 for details (The Blind Cat or Cat With Retinal Disease) and also page 1202 (The red vitreous).

Clinical signs

Typically appears as **acute-onset vision loss in an old cat**.

Pupils are dilated, and non-responsive or **poorly responsive to light**. Signs are usually bilateral.

Affected eyes appear slightly cloudy and focal red areas of hemorrhage are visible through the pupils.

Retinal hemorrhages occur mainly along the major blood vessels, with hemorrhage in the vitreous.

When the retina is detached, the **retinal blood vessels are not clearly in focus** with an ophthalmoscope. The retina can be seen ballooning into the vitreous, and appears as a thin veil of pale tissue.

Diagnosis

Diagnosis is based on the clinical presentation of **acute vision loss in an older cat**, the finding of **hemorrhage** adjacent to major vessels in the retina, and **systolic blood pressure > 160 mmHg**.

Blind cats usually have a total retinal detachment in both eyes. The retina cannot be visualized through the pupil with an ophthalmoscope, and a thin veil of pale tissue can be seen bulging into the vitreous.

Hyperthyroidism and chronic renal disease need to be ruled out with diagnostic tests, and thoracic radiographs or cardiac ultrasound may be useful to detect cardio-megaly.

INFLAMMATORY RETINAL DISEASE*

Classical signs

- Main sign is uveitis (red conjunctiva, cloudy aqueous, swollen iris and corneal edema in acute cases).
- Focal red areas may be seen through the pupil.
- Retina may be out of focus, or have small focal brownish-colored areas within the tapetum when looked at with an ophthalmoscope.
- Small hemorrhages may be seen along the major retinal blood vessels.

See the main reference on page 1167 for details (The Blind Cat or Cat With Retinal Disease).

Clinical signs

Any inflammatory disease of the retina may cause **pre-retinal or retinal hemorrhage**.

Hemorrhage is rarely obvious to the naked eye, but is seen on ophthalmoscopic examination in an eye that shows signs of uveitis.

In cases with **systemic fungal infection** (*Blastomyces dermatitidis*, *Candida albicans*, *Coccidioides immitis*, *Cryptococcus neoformans*, *Histoplasma capsulatum*), the eye or eyes are usually inflamed with signs of uveitis including red conjunctiva, cloudy aqueous from hypopyon, corneal edema, swollen iris, iris hemorrhage from pre-iridal fibrovascular membranes and miotic pupils.

The hemorrhage is usually related to **changes in retinal appearance** such as focal changes in tapetal or non-tapetal color. Usually there is **hyper-reflectivity in the tapetum**, and loss of black coloration in the non-tapetum.

The retina may show signs of **focal granulomas**, which appear as raised areas with a muddy brown color. These areas may have small foci of hemorrhage on the surface.

The major retinal blood vessels may have small hemorrhages close to the arteries.

There may be hemorrhage in the vitreous if there is pre-retinal hemorrhage.

Rarely, retinal hemorrhage is caused by larva (*Cuterebra* or *Metastrongylid*) migrating along blood vessels causing localized damage to the retina and hemorrhage from injuries to the blood vessel they are migrating in or move through.

In cases with **ocular larval migrans**, the characteristic funduscopy signs are **linear hyper-reflective “tracks”** in the tapetal fundus, and linear light-gray areas of reduced pigmentation in the non-tapetum. Sometimes the white body of a fly larva might be seen associated with one of the tracks. Hemorrhage may be seen in these tracks.

Rarely, the larva might be seen in the anterior chamber with associated signs of anterior uveitis.

Diagnosis

Ocular fungi

Diagnosis is initially based on the presentation of a cat with a **rapidly progressive, usually bilateral chorio-retinitis progressing to anterior uveitis**, with **signs of other systemic disease**, occurring in a geographic area where such fungal disease is known to occur.

Imaging techniques can be used to obtain more supportive evidence of a deep fungal infection:

- **Thoracic radiography** to demonstrate pulmonary granulomas.
- **Nasal cavity radiography** to demonstrate a soft tissue density and bone lysis consistent with fungal rhinitis.
- **Ocular ultrasound** to look for signs of retinal detachment when the fundus cannot be clearly visualized through the pupil.

Serological tests can be performed, looking for increased serum antibodies (cryptococcosis, blastomycosis, histoplasmosis, coccidioidomycosis).

Confirmation of the diagnosis is based on the **demonstration of the causative organism** in:

- Nasal swabs or biopsy.
- Cerebrospinal fluid.
- Samples taken by centesis of vitreous or subretinal exudate.
- Histopathology of enucleated globes.
- Bone marrow biopsy samples (histoplasmosis).
- Fine-needle aspirates of lung lesions.

Ocular larval migrans

Diagnosis is based on appearance of the suspicious fundoscopic lesions, or by observation of the parasite in the anterior chamber.

BLUNT OR PENETRATING TRAUMA*

Classical signs

- History of trauma to the head and/or eye.
- A focal or diffuse red coloration seen through the pupil.
- Varying degrees of vision loss will occur depending on the severity of the injury.
- The conjunctiva and adnexal tissue may show hemorrhage.

Clinical signs

When **blunt or penetrating trauma causes retinal hemorrhage**, there is usually a history of trauma to the head or eye, and a red appearance behind the pupil. The conjunctiva and adnexal tissue may show hemorrhage.

There may be **hyphema** causing diffuse redness of the anterior chamber, **vitreal hemorrhage** or **retinal hemorrhage** seen as a red eye through the pupil. The red color through the pupil may be diffuse through the posterior chamber (vitreal hemorrhage) or seen as retinal hemorrhage. When the red color is obvious, it is usually caused by hemorrhage from the retina into the vitreous.

The **degree of hemorrhage varies** from focal areas of blood in the vitreous or on the retina, to frank bleeding throughout the vitreous and retina.

Severe cases may have a dilated pupil.

Vision loss will be determined by the extent of the injury and the degree of hemorrhage within the eye.

Diagnosis

Diagnosis is based on a history of trauma, and signs of hemorrhage in the eye.

It is important to try to visualize the fundus, to determine if there is detachment or tears of the retina.

Ocular ultrasound is a very useful tool to determine the state of the retina when it cannot be visualized through the pupil. Retinal detachments are seen as a bulging line away from the sclera. The integrity of the scleral coat can be checked, and also the state of the orbit behind the globe. In some cases the sclera may be ruptured, and if this is the case, this will give a grave prognosis for vision in an affected eye.

In severe ocular trauma, **radiology of the orbit** is indicated to check for fractures.

CT scan and MRI are other tools that may be useful in difficult cases. The shape, size and position of the globe within the orbit can be compared to the other eye. Orbital fractures can be demonstrated.

59. The cat with ocular discharge or changed conjunctival appearance

Richard IE Smith

KEY SIGNS

- Serous to mucopurulent ocular discharge.
- Chemosis, hyperema.
- Follicles.
- Diffuse or focal mass.

MECHANISM

Basic pathophysiological mechanisms of ocular discharge can include:

- Reflex lacrimation due to irritation of the corneal surface.
- Effects of infectious micro-organisms on conjunctival tissues.
- Allergic conditions causing increased tearing.
- Effects of inflammatory conditions of the orbit and adnexal tissues on conjunctival tissues.
- Reduced drainage of the tear film.

Ocular discharges can be serous, mucoid or mucopurulent.

WHERE?

A changed conjunctival appearance with ocular discharge may result from diseases of:

- Eyelid.
- Conjunctiva.
- Cornea.
- Orbit.
- Tear duct.

WHAT?

- Infectious causes of conjunctivitis such as *Chlamydomphila felis* and feline herpesvirus-1 are the most common cause of increased ocular discharge in cats.

QUICK REFERENCE SUMMARY

Diseases causing ocular discharge or changed conjunctival appearance

WHERE?

CONJUNCTIVA

NEOPLASTIC

- **Squamous cell carcinoma*** (p 1217)**

Occurs in cats with non-pigmented eyelids. The conjunctival neoplasia is seen as an extension of the eyelid lesion, which will appear red and ulcerated.

- **Conjunctival hemangiosarcoma/hemangioma (p 1225)**

Rare in cats. Seen occasionally as a red raised lesion at the lateral limbal conjunctiva and on the leading edge of the third eyelid conjunctiva.

- **Conjunctival lymphosarcoma (p 1224)**

A rare condition seen as focal or diffuse swelling of the conjunctiva. Usually occurs as an extension of orbital lymphosarcoma, and secondary to systemic lymphosarcoma.

INFLAMMATION/INFECTIOUS

Viral:

- **Herpes virus conjunctivitis*** (p 1212)**

Acute conjunctivitis with hyperemia, chemosis and initially a serous discharge. Rapid progression to a mucopurulent discharge, which is usually bilateral. In young cats, respiratory signs, including paroxysms of sneezing occur. Severe cases form symblepharon (conjunctival adhesions), which can occlude tear duct puncta producing chronic epiphora. Chronic serous ocular discharge can occur in older cats.

Bacterial:

- ***Chlamydomphila (Chlamydia) keratoconjunctivitis*** (p 1215)***

In acute cases in young cats, there is conjunctival chemosis (edema) and intense hyperemia, with a serous to mucopurulent discharge. Often begins unilaterally and progresses to bilateral. Respiratory signs such as sneezing tend to be mild or absent. Chronic cases develop follicular conjunctivitis accompanied by a serous discharge.

Protozoal:

- ***Mycoplasma conjunctivitis** (p 1218)***

A mild conjunctivitis with serous discharge, unilateral or bilateral. A serous nasal discharge may be present.

INFLAMMATION/NON-INFECTIOUS

- **Chemosis and/or hyperemia secondary to orbital disease (p 1211)**

The globe will show exophthalmos (bulging forward) and the conjunctiva will be swollen with a mucopurulent discharge. The third eyelid may be prominent and inflamed. The cat may have dental disease or sneezing with nasal discharge.

Immune-mediated:

- **Eosinophilic keratoconjunctivitis* (p 1221)**

Proliferative white/pink plaques appear on the conjunctiva and/or cornea. The conjunctiva is inflamed with a mucopurulent discharge. The cornea may be intensely vascularized.

- **Allergic conjunctivitis* (p 1222)**

A **serous ocular discharge** with **very little inflammation** of the conjunctiva is seen in cats with allergic disorders. May be associated with atopy, food allergy or insect bites.

Trauma:

- **Trauma of conjunctival and peri-adnexial tissue** (p 1220)**

Conjunctival wounds from trauma, plant thorns and cat fights may result in conjunctival tears, chemosis, hyperemia, hemorrhage and mucopurulent discharges.

- **Sub-conjunctival hemorrhage* (p 1223)**

Blunt trauma may result in focal or diffuse subconjunctival hemorrhage, with no associated inflammation or discharge. Retrobulbar trauma may result in exophthalmos with swollen conjunctiva. There may be superficial hemorrhage on the conjunctiva, or subconjunctival hemorrhage.

WHERE?

EYELID

ANOMALY

- **Eyelid agenesis (coloboma) (p 1227)**

Usually the upper lateral eyelid margin is missing (abnormal) causing exposure of the conjunctiva and trichiasis (normal eyelid hair rubbing on the cornea). This results in chronic conjunctivitis, keratitis and chronic serous or mucoid discharge.

MECHANICAL

- **Lower lid entropion (p 1228)**

Rare in cats but seen in cases with enophthalmos (globe shrunken into the orbit), which causes the lower lid to turn inwards. The trichiasis that results may cause a chronic mucopurulent discharge and corneal ulceration. Surgical correction can be frustrating.

- **Symblepharon occluding the lower nasolacrimal puncta (p 1213)**

Seen as a tearing down the medial canthus and nose. Tear staining is present. Check to see if the lower puncta is present and patent. Conjunctiva appears abnormally thickened and distorted. The cornea may appear cloudy and covered by a thin membrane. There is a history of cat flu as a kitten.

NEOPLASTIC

- **Squamous cell carcinoma*** (p 1217)**

Common in white cats and cats with non-pigmented eyelids. The area is red and ulcerated.

- **Meibomian gland adenocarcinoma (p 1229)**

Rare in cats. The eyelid margin has a **raised rough area often in the form of a papilla**. The conjunctival surface will be swollen and discolored over the area of the meibomian gland in the tarsal plate.

INFLAMMATION/INFECTIOUS:

- **Meibomian gland inflammation** (p 1225)**

The cat presents with a history of irritated eyes, and a mucoid to mucopurulent discharge. Under the eyelid is a row of red inflamed meibomian glands. Inspissated pus and lipid material can accumulate in the glands, and is seen as raised whitish lesions. The condition can cause a lot of discomfort, seen as blepharospasm and rubbing.

continued

continued

Trauma:

- **Eyelid trauma** (p 1226)**

Trauma may result in lacerations, hemorrhage and a mucoid to mucopurulent discharge as the lesion heals. The wound should be obvious. Healed eyelid wounds may result in cicatricial distortion of the lids, and trichiasis or ectropion.

WHERE?

CORNEA

DEGENERATIVE

- **Corneal sequestrum** (p 1231)**

There may be a serous or mucopurulent discharge, with a brown or black stained area on the cornea. Ulceration and corneal vascularization may or may not be present.

MECHANICAL

- **Ulcerative keratitis** (p 1230)**

Causes a serous ocular discharge with blepharospasm and photophobia. Corneal cloudiness is present, and corneal erosion is evident on close examination, or with fluorescein stain.

INFLAMMATORY/INFECTIOUS

- **Herpetic keratitis*** (p 1229)**

Early cases seen as dendritic lesions (faint linear changes). Chronic cases develop geographic keratitis (irregular-shaped lesions) associated with superficial ulceration and scarring. All have a serous ocular discharge. History of prior cat flu with signs consistent with feline herpes virus-1 infection.

Inflammatory/immune-mediated:

- **Eosinophilic keratoconjunctivitis* (p 1221)**

A mucopurulent discharge with proliferative inflammatory lesion of the cornea and conjunctiva. Associated with allergic conditions.

Trauma:

- **Corneal trauma*** (p 1230)**

Serous to mucopurulent discharge is commonly seen in corneal injury. Fibrin tags or clots may be seen attached to the injured area of the cornea. If the cornea has been penetrated, a continuous clear discharge may be present caused by leakage of aqueous humor. The cat will show severe ocular pain, guarding the eye, blepharospasm and photophobia.

WHERE?

ORBIT

INFLAMMATORY

- **Retrobulbar infection (p 1231)**

Retrobulbar infection may result in exophthalmos, and swollen conjunctiva with injected blood vessels, and a mucopurulent discharge. The third eyelid may be prominent, and there may be pain on opening the mouth. Rare.

INTRODUCTION

MECHANISM?

Ocular discharge is a sign that the **eye is irritated, inflamed** or there is an **obstruction to tear drainage**.

Ocular discharges vary in type.

- A **serous (watery) discharge** is present when there is excess tear stimulation. Excessive tearing is known as “**epiphora**”.
- A **mucoid (jelly-like) discharge** is seen when the conjunctiva is inflamed and the conjunctival goblet cells produce excess mucus secretion.
- A **mucopurulent (pus) discharge** is found when the conjunctiva is inflamed, and there is a mixture of mucus secretion and inflammatory cells.

Common causes of ocular discharge include diseases affecting the **conjunctiva, cornea, eyelid, orbit or tear duct**.

- Diseases affecting the **conjunctiva** include:
 - Infectious diseases are the most common causes of ocular discharge.
 - Allergic conditions.
- Problems associated with the **cornea** include:
 - Ulcerative keratitis (inflammation of the cornea).
 - Infectious agents causing keratitis.
 - Traumatic keratitis.
- **Obstruction to tear drainage**.
 - In cats **symblepharon** (adhesion of conjunctiva to conjunctiva or conjunctiva to cornea) is the most common cause of puncta occlusion.
- **Eyelid problems causing irritation of the cornea** include:
 - Eyelid **agenesis** (coloboma) is the term used when there is a congenital absence of all or part of the normal eyelid margin. It causes **trichiasis** (normal eyelid or facial hair irritating the conjunctiva or cornea) and exposure and drying of the adjacent conjunctiva and cornea.
 - Eyelid **trauma** may cause trichiasis because the eyelid margin is damaged or missing.
 - Eyelid **neoplasia** may cause irritation of the corneal surface.
- **Orbital inflammation** (retrobulbar disease) may cause **chemosis** (conjunctival edema) and ocular discharge. The eye may show **exophthalmos** (bulging outwards).

- **Dental disease** is the most common cause of orbital inflammation.
- **Orbital neoplasia**, particularly lymphosarcoma, is another disease that may cause exophthalmos and chemosis.
- Orbital disease may also be caused by an extension of **chronic sinus and nasal inflammation or neoplasia**, where the bony orbit has been breached adjacent to the frontal sinus or posterior nasal cavity.

Changed appearance of the conjunctiva is seen clinically as:

- **Ocular discharge**, which may be serous, mucoid or mucopurulent.
- **Chemosis** (edema), which causes the conjunctiva to swell and bulge under the eyelids.
- **Hyperemia** (redness) can be intense as the conjunctiva has a rich blood supply.
- **Follicle formation** occurs because the conjunctiva is very rich in lymphoid tissue. Antigenic stimulation in chronic inflammation or allergic states is the most common cause of follicle formation.
- **Hemorrhage**.
 - **Echymoses** (focal hemorrhage) and **petechia** (pin point hemorrhages) may be a sign of a bleeding disorder associated with a systemic disease causing thrombo-cytopenia.
 - **Coagulopathies** may show signs of conjunctival hemorrhage.
 - Sub-conjunctival hemorrhage is seen in cases of trauma.
- **Peri-ocular pruritis** (skin irritation) may be a sign of underlying conjunctival irritation.⁴⁵
- **Emphysema** (accumulation of air within tissue) of the conjunctiva may be seen as a rare entity after facial trauma, when air leaks under the skin and conjunctiva to produce swelling that may be confused with chemosis. Crepitus (a crackling feeling of the tissue) will be present to help differentiate this from chemosis.

WHERE?

History and physical examination will help determine the cause of ocular discharge, and changed conjunctival appearance. It is important to determine whether it is an **acute or chronic problem**.

Look at the **conjunctiva** for changed appearance.

Examine the associated tissues as problems may arise from the **eyelids, cornea, orbit or teeth**.

Check the summary table for diseases arising from these tissues.

WHAT?

The appearance of the discharge will help localize the problem.

Serous discharge is usually associated with eyelid agenesis, corneal disease, allergic conditions or blocked tear ducts.

Mucoid and mucopurulent discharge is more common with infections of the conjunctiva, eyelid or orbit.

Infectious diseases are the most common cause of ocular discharge and changed conjunctival appearance.

Diagnosis is based on the history, clinical examination, cytology, biopsy, laboratory tests for infectious diseases and radiology of teeth, sinuses and nasal cavity in cases with orbital disease.

DISEASES CAUSING OCULAR DISCHARGE OR CHANGED CONJUNCTIVAL APPEARANCE: CONJUNCTIVAL CAUSES OF OCULAR DISCHARGE AND CHANGED CONJUNCTIVAL APPEARANCE

HERPES VIRUS CONJUNCTIVITIS***

Classical signs

- Paroxysms of sneezing or salivation.
- Hyperemia and chemosis of the conjunctiva, usually bilateral.
- Serous to mucopurulent ocular and nasal discharge.
- Conjunctival adhesions obstructing puncta of tear duct.

See main reference on pages 7, 1237 for details (The Cat With Acute Sneezing or Nasal Discharge and The Cat With Abnormalities Confined to the Cornea).

Pathogenesis

Herpesvirus is one of the most common causes of acute and chronic ocular discharge in cats.

Infection is caused by **feline herpes virus-1 (FHV-1)**, a member of the subfamily Alphaherpesviridae. Serologically distinct varieties have been isolated from non-domestic cats. The virus is also commonly called **feline rhinotracheitis virus (FVR)**.

The disease is **more frequent in kittens**, particularly those from **catteries with carrier cats, pet shops and shelters**.

The course of the disease is usually 10–14 days.

Histologically, **complete epithelial necrosis occurs**, accompanied by a polymorphonuclear cell infiltrate.

A chronic carrier state may persist in older cats and recurrence of viral shedding and/or signs is common. This may be because the FHV-1 virus does not stimulate effective local immunity.

Clinical signs

The earliest sign of classical herpesvirus infection is **paroxysms of sneezing or salivation**. This is usually seen in kittens and cats that have not been immunized.

In young cats, **systemic signs of upper respiratory disease** with **anorexia, pyrexia and depression** are common.

Tracheal and bronchial inflammation may result in coughing and dyspnea, and occasionally bacterial pneumonia occurs in kittens.

Acute conjunctivitis manifested by hyperemia and chemosis is seen at the same time as the respiratory signs.

Prolapse of the third eyelid may occur as part of the inflammatory process in the eye.

Serous ocular discharge is seen in the acute phase and this **rapidly progresses to a seromucous and mucopurulent discharge**.

In young cats, **ulceration** may occur in the buccal mucosa and on the tongue.

The ocular changes are usually **bilateral**, but may be unilateral initially or in older cats.

In severe cases, **symblepharon** is a complication (adhesion of conjunctiva to conjunctiva or conjunctiva to cornea), and the **puncta may be occluded** causing chronic epiphora.

In severe infections, the conjunctiva may be covered in a **gray pseudomembrane (diphtheritic)**.

In older cats with a **carrier status**, **mild signs of herpesvirus infection** may be seen after some form of stress. In these cases, the inflammation is less intense and often only a serous discharge is present. These cats may have a history of respiratory infection as a kitten.

Chronic serous ocular discharge can occur in older cats.

Corneal involvement (keratitis) may occur 1–2 weeks after initial signs. Keratitis is visible as **corneal cloudiness** (edema and inflammation), and **punctate or branching ulcers**, which may **coalesce to large ulcers**.

- Corneal perforation and secondary bacterial infection may result in destruction of the eye; this occurs more often in young kittens (ophthalmia neonatorum).
- **Herpesvirus keratitis often occurs in the absence of active upper respiratory infection.**

Diagnosis

Acute ocular and respiratory signs in a young cat suggest an infection with herpesvirus or calicivirus infection. **Herpesvirus** tends to produce **more severe conjunctivitis and mucopurulent ocular discharge** than calicivirus.

Diagnosis is usually based on clinical signs, as it is often not cost effective to establish a definitive diagnosis. Obtaining a definitive diagnosis is useful in chronic cases, or when there is a persistent cattery problem.

Definitive diagnosis is based on a variety of techniques, of which polymerase chain reaction is the most sensitive.

- **Cytology.** Intranuclear inclusions in epithelial cells can be demonstrated with immunoperoxidase stains in some acute primary infections. This is not very reliable or cost effective.
- **Immunofluorescence.** Direct or indirect fluorescent-antibody techniques can be applied to corneal or conjunctival smears or tissue sections, but it has poor sensitivity.
- **Virus isolation** by demonstration of **cytopathic effects in cell culture**. This is the gold standard for

detection of herpesvirus, but is not often used because of logistical difficulties in getting rapid results.

- **Serology** is of limited usefulness. Antibody titers tend to be of low magnitude after primary infection, sometimes reaching only 1:64 at 60 days after infection. High titers are rarely seen after recrudescence infection.
- **Polymerase chain reaction (PCR)** testing: DNA amplification of an amino acid sequence of the thymidine kinase gene is perhaps the most sensitive test available. Theoretically, the test could pick up one strand of viral DNA. The high sensitivity of nested PCR tests may reduce specificity, because non-viral DNA contaminants may be detected.
 - Conjunctival swabs and/or biopsies are used for laboratory diagnosis using PCR or virus isolation. Not all laboratories are equipped to do this work. Check with your laboratory, as you may have to send samples interstate or overseas for results.

Differential diagnosis

Calicivirus.

- Tends to produce milder respiratory signs and less severe conjunctivitis and mucopurulent ocular discharge. Ulceration of the tongue is classical.

Chlamydophila felis conjunctivitis.

- Commonly only unilateral, followed days later as bilateral disease.
- Serous to mucopurulent discharge, which may be more copious than FHV-1 conjunctivitis.
- Conjunctival follicles form in chronic cases.
- Conjunctival swabs or scrapings taken with a spatula may be positive to a fluorescent antibody test.
- Cytology specimens may demonstrate the presence of intracytoplasmic inclusion bodies, which are present in the first 2 weeks of infection.
- Culture is very difficult, and requires the use of specific growth media sent to specialized laboratories.

Mycoplasma felis and *M. gatae*.

- It usually causes a mild form of conjunctivitis
- Ocular discharge remains serous in nature.
- It has been reported to occasionally form a conjunctival pseudomembrane with a thick white discharge.

- Cytology may reveal small basophilic inclusion bodies at the level of the basement membrane.
- The organism can be readily cultured.

Neoplasia.

- Squamous cell carcinoma, particularly of the lower lid in depigmented eyelids, may present with swollen red eyelids and a mucopurulent discharge.
- Cytology or fine-needle biopsy will confirm this condition.
- Lesions are frequently ulcerated.

Bacterial conjunctivitis.

- Not common as a primary ocular disease, but is seen secondary to viral infection.
- The inflammation is less intense than the acute herpesvirus presentation, but in chronic herpesvirus cases, bacterial infection is frequently misdiagnosed as the cause of conjunctivitis and ocular discharge.
- Bacterial conjunctivitis causes a mucopurulent discharge.

Hemorrhage.

- Hemorrhage may be seen as a diffuse or focal area of redness, but there is usually little hyperemia or no inflammation.
- It is not common to have an ocular discharge with conjunctival hemorrhage.

Treatment

Topical and probably systemic **corticosteroids are contraindicated** in all cases of ocular herpesvirus infections. The effect of topical NSAIDs has produced equivocal results experimentally.

A variety of topical ocular antiviral agents are available. However, not all treatments are commercially available worldwide.

- **Idoxuridine** inhibits DNA synthesis by competing with thymidine for incorporation into viral DNA. It is no longer in production, but has been the most commonly used topical agent for treating FHV-1 infection. **Check with your “compounding pharmacist”**, as topical drops are frequently made to order. **Idoxuridine 0.1% drops most commonly used**, and produce excellent results. Drops need to be used at least three to four times daily.
- **Vidarabine** (adenine arabinoside. Vira-A, Parke-Davis) interferes with DNA polymerase and may be effective in cases that are resistant to idoxuridine. Use q 6–8 h.

- **Trifluorothymidine** (Viroptic, Glaxo Wellcome) has the best in vitro effect of all available topical agents. Use q 6–8 h.
- **Acyclovir** (Zovirax ophthalmic ointment, Glaxo-SmithKline) may be the only commercially available drug in some countries. The efficacy against FHV-1 has been reported as poor. Use q 6–8 h.
- **Dilute povidine iodine** (diluted 50% in saline) has been used, but there is only anecdotal evidence of its efficacy in clinical situations, and at this strength can be very irritating to eyes.

Oral antiviral agents include:

- **Acyclovir** (Zovirax) appears very effective, even at doses far below the in vitro ED₅₀. The usual dose is 50 mg/kg q 6–12 h, but watch for toxic signs of bone marrow suppression even at this dose. Often used in conjunction with oral α interferon, and the resulting synergism significantly reduces ED₅₀ of acyclovir.
- **Valacyclovir** (Valtrex, GlaxoSmithKline) is an acyclovir prodrug but rapid absorption of this drug in cats appears to make it more readily able to cause toxicity, especially in sick, acutely infected cats.
- **Interferon α :** α interferon is a cytokine produced naturally by leukocytes. It may prevent spread if given in the very early stages of infection in acutely infected cats. There are no specific dosage recommendations but commonly used dosage is 30 IU daily. This dose is made up in 1ml syringes and frozen. Each day, one syringe is thawed and two drops placed topically in the eye, the remainder given orally for absorption across oronasal mucus membranes. The dose is commonly given for 7 days on 7 days off.

Other therapies that are used include:

- **Oral lysine:** Lysine has been used in human medicine to suppress clinical signs of herpes simplex infections. Lysine competes with arginine for incorporation in the viral genome. Arginine is necessary for the replication of the FHV-1 virus, and incorporation of lysine produces a non-infective virus particle. It may be more effective in cats with corneal disease than those with conjunctivitis alone. The recommended dose is 250 mg daily.
- **Topical and/or systemic tetracycline** antibacterials are commonly used because of their specific effect on *Chlamydophila felis* and *Mycoplasma* organisms, which may be present together with herpesvirus infections.
 - **Tetracyclines have a mild anti-inflammatory effect** on ocular tissue. They suppress antibody

production and chemotaxis of neutrophils, and inhibit lipases, collagenases and prostaglandin synthesis. Research also shows that tetracyclines exert other pleiotrophic properties independent of their antimicrobial activity, which include inhibition of metalloproteases, blockade of nitrous oxide synthetase (a potent mediator of inflammatory activity), suppression of tumor progression, bone resorption and angiogenesis.

Improving **ocular hygiene** is beneficial.

- Regular cleaning of infected eyes with polyionic eye wash solutions will make the cat feel more comfortable, and suppress secondary bacterial infection.

Prognosis

The prognosis for a full and uneventful recovery in young cats is **very good**.

In young cats with very severe inflammation, symblepharon formation will create chronic eye problems that may include:

- Poor eyelid and nictitating membrane function caused by **conjunctival adhesions**.
- Disruption to the corneal limbal stem cells, which may result in permanent **scarring and abnormality of the cornea**.
- **Epiphora** results from scarring and occlusion of the puncta.
- **Keratoconjunctivitis sicca** (KCS) may be seen on rare occasions.

In adult cats, a chronic recurrent state may develop, and in these cases the prognosis for permanent recovery is guarded.

Virus replication occurs in the cornea, and although not clinically obvious at the time of infection, this will manifest in older cats as a chronic dendritic (geographic) keratitis, sometimes years after the initial infection. See The Cat With Eye Problems Confined to the Cornea (page 1238).

Transmission

FHV-1 is a ubiquitous viral organism found all over the world and is highly infectious.

Infection of kittens may occur through direct contact with a carrier queen. Virus is shed 4–6 weeks after queening.

Infection is via contamination of mucous membranes (ocular, oral or inhalation of virus).

Prevention

Vaccination with live modified or killed vaccines (see page 10, The Cat With Acute Sneezing or Nasal Discharge).

Elimination of carrier cats from catteries. Remove queens that repeatedly have infected litters, or wean kittens early.

CHLAMYDOPHILA (CHLAMYDIAL) KERATOCONJUNCTIVITIS***

Classical signs

- In kittens, intense hyperemia and chemosis, usually unilateral, followed by bilateral conjunctivitis.
- Serous ocular discharge changing to a copious mucopurulent discharge after a few days.
- Mild respiratory signs with sneezing and a seromucoid nasal discharge.
- Diffuse conjunctival follicle formation with serous discharge in older cats with chronic infection.

See main reference on page 13 for details (The Cat With Acute Sneezing or Nasal Discharge).

Pathogenesis

Chlamydomphila felis psittaci is responsible for disease in about **20% of cats with respiratory tract signs**. Sneezing with a seromucoid nasal discharge may be seen.

Chlamydomphila felis psittaci infections in cats **primarily affect the conjunctiva**. The organism can be found experimentally in other tissues of the urogenital and gastrointestinal tract.

The **course of the disease is 7–21 days**.

Conjunctival epithelial cells are infected, and have intracytoplasmic inclusion bodies typical of this organism.

Histologically, neutrophils predominate early, followed by infiltration with macrophages, lymphocytes and plasma cells.

Recently a new chlamydial agent, *Neochlamydia hartmannellae*, an amebic endosymbiont, has been identified in cats. In a study of 226 samples from cats with keratitis or conjunctivitis and 30 healthy cats, 12% were found to have *Chlamydophila felis* (*Chlamydia psittaci*) and 39% *N. hartmannellae*. Both organisms were found to be significantly associated with disease.

Clinical signs

Initially, there is unilateral conjunctivitis, with the signs spreading to involve the other eye several days later.

Acute infections have **intense conjunctival hyperemia**, with **chemosis** and a serous ocular discharge. This progresses to a copious purulent discharge over a few days.

Chemosis can be so severe that the cornea and intra-ocular structures are difficult to examine. Signs tend to be more severe in kittens than adult cats.

Conjunctival lymphoid follicles are often seen in chronic cases of the disease, and older cats. The surface of the conjunctiva may have a few, or be covered with lymphoid follicles, and this is accompanied by a serous discharge.

Respiratory signs such as sneezing are absent, or very minor compared to ocular signs.

Chlamydial keratoconjunctivitis occurs in cats of all ages.

Diagnosis

Typically, there is a history of **acute conjunctivitis**, which may be accompanied by sneezing and a mild nasal discharge. The conjunctivitis can be quite dramatic, with an intensely red swollen conjunctiva in acute cases. Chronic cases may have an obvious follicular conjunctivitis.

Conjunctival cytology may show presence of **intra-cytoplasmic inclusion bodies**. These are seen as **pale pink granular clusters** that may indent the nucleus.

There are **ELISA and latex agglutination tests** available to support a diagnosis. Discharges should be cleaned from the eye, and then a **dry swab or scraping** used to obtain conjunctival cells for the tests. False-

positive results occur in the presence of secondary bacterial infections.

Fluorescent antibody tests can also be done on conjunctival scrapings.

Culture is very difficult and requires specific growth media (usually embryonated eggs), and specialized laboratories.

Differential diagnosis

Herpes conjunctivitis.

- The conjunctiva is less inflamed in acute FHV-1 infections.
- Chronic cases have a serous ocular discharge with hardly any sign of conjunctivitis.
- In the acute form, respiratory signs are more pronounced, with sneezing, serous discharge progressing to mucopurulence, anorexia, pyrexia and depression.
- Young cats are more commonly infected with acute signs.
- Laboratory diagnosis based on PCR, virus isolation or fluorescent antibody may be supportive.

Mycoplasma conjunctivitis.

- A mild disease with serous discharge.
- Mild respiratory signs, unless co-infected with FHV-1.
- A pseudomembrane may develop composed of a thick white exudate.
- It responds rapidly to a wide range of antibiotics.
- Cytology may reveal small basophilic inclusion bodies, which are coccoid or coccobacillary, and are seen in the periphery of the cytoplasm of the epithelial cells.
- Culture of organism can be done in most laboratories.

Neoplasia: squamous cell carcinoma.

- Typically involves lower lid in depigmented eyelids.
- Cytology and fine-needle biopsy should confirm this diagnosis.
- Lesions are usually red, raised and ulcerated.

Primary bacterial conjunctivitis.

- This is not common in cats.
- There will be less inflammation and discharge compared to *Chlamydophila felis* and FHV-1 conjunctivitis.
- The discharge is more likely to be mucopurulent.

Hemorrhage.

- There may be diffuse or focal areas of redness, usually with little hyperemia or inflammation.
- There will be very little discharge associated with the hemorrhage.

Treatment

Topical **tetracycline** ointment applied four times daily. (may no longer be available)

Topical fluoroquinolone (particularly ofloxacin) seems to have very good results in this author's experience using tid/qid.

Oral tetracycline, for example, doxycycline 5 mg/kg PO q 12 h for 3–4 weeks.

Oral **Azithromycin (Zithromax, Pfizer)** 5 mg/kg q 24 h PO for 14 days as an alternative treatment to tetracycline.

Some chronic cases may require long-term systemic therapy.

Prognosis

Generally prognosis is very favorable with few damaging sequelae.

Recurrent infections and latent carrier state are believed to occur.

Transmission

Transmission is thought to occur by **direct contact** of susceptible cats with ocular and nasal secretions from affected cats. A chronic latent carrier state probably occurs.

Prevention

Vaccination has produced conflicting results and is not widely used.

SQUAMOUS CELL CARCINOMA OF THE EYELID AND CONJUNCTIVA*****Classical signs**

- Red, slightly swollen eyelid margin with inflamed adjacent conjunctiva (early lesion).

Classical signs—Cont'd

- Red and ulcerated lesion with dry crusty surface (later).
- Deep erosions may develop at medial canthus.
- Eyelid and conjunctiva eroded away (advanced lesion).

See the main reference on pages 1321, 1334, 1069, 1089 for details (The Cat With Abnormal Eyelid Appearance or The Cat With an Abnormal Third Eyelid, The Cat With Skin Lumps and Bumps and The Cat With Non-healing Wounds).

Clinical signs

Squamous cell carcinoma usually **secondarily involves the conjunctiva** from a primary eyelid lesion.

Redness and mild swelling of the eyelid is seen in the **pre-cancerous stage**. The affected area may be small initially, but later spreads to include the entire eyelid margin. It is more common on the medial part of the lower eyelid. The **adjacent conjunctiva is inflamed**.

In advanced cases, **the epithelial surface erodes to form an ulcer that may have a dry crusty surface**. **The adjacent conjunctiva may become ulcerated and red**, and can have a crusty mucopurulent discharge.

The entire lid margin including conjunctiva, can be eroded away in advanced cases.

Deep erosions may develop in the medial canthus. When lesions occur at the medial canthus, the normal canthal contour is missing. In advanced cases, it is common for **secondary bone involvement of orbital and nasal bones**.

Usually seen in cats with **non-pigmented eyelids**, and **is usually on the lower lid**, as this is more exposed to sunlight and ultraviolet light damage.

Diagnosis

The **lesion is fairly typical**, and consists of an ulcerated area, usually involving the lower eyelid and conjunctiva, on a poorly pigmented eyelid.

Cytology is very useful, as samples can easily be taken with a little local anesthetic. The surface of the lesion

should be cleaned with saline, or an irrigating eye wash. A small scalpel blade or spatula is then used to scrape the surface of the lesion. Carefully wipe the tissue on the blade over a glass microscope slide, and stain with a cellular stain. **Neoplastic epithelial cells are large and often clumped, with large dark staining nuclei and prominent nucleoli with very small cytoplasm.** Normal epithelial cells have a large amount of pink cytoplasm, and a central small round nucleus.

Fine-needle biopsy will demonstrate similar pathology to cytology specimens. Use a 22-gauge hypodermic needle and a 5-ml syringe. Push the needle into the lesion, and suck hard on the syringe. Let the plunger go, and remove the needle from the lesion. Remove the needle from the syringe, and pull the plunger back so that the syringe is full of air. Replace the needle on the syringe, and blow the needle contents onto a microscope slide. Spread this carefully with another slide, and stain with a cellular stain. A similar pattern of cells will be seen as in the cytology sample.

Histopathology is more definitive but requires more invasive surgical techniques to remove a block of affected tissue. Place tissue in 10% buffered formalin, and send to a laboratory for sectioning and examination.

Radiology of adjacent bones is important in cases involving the medial canthal tissue and skin over the nose. Any secondary involvement of bony tissue gives a very poor prognosis.

Differential diagnosis

Granulating wounds can have a similar appearance. Use cytology and fine-needle biopsy to differentiate if needed. Granulating wounds appear healthy, with uniform redness and a smooth, moist cellular surface.

Treatment

The lesion may be excised if it is in a small focal area. If the lesion is in the medial canthus, care should be taken to try to preserve the lower puncta and nasolacrimal duct.

Radiation therapy, either with direct beta-radiation, or radioactive gold implants.

Cryosurgery is the **most common** method of treatment. There are many types of cryogens that are used.

Two or three freeze–thaw cycles using liquid nitrogen will produce the best results. The eyelid and conjunctiva has a very rich blood supply, and heals rapidly after cryo-destruction of tissue. Supportive therapy using broad-spectrum ointments or drops, and regular, gentle cleaning helps the healing process, by preventing secondary bacterial infection. (See page 1070, The Cat With Lumps and Bumps.)

Intralesional chemotherapy using cisplatin in oil adjuvant, or in plastic rods, has been used with some success. Refer such cases to a trained oncologist. (See page 1346).

MYCOPLASMA CONJUNCTIVITIS**

Classical signs

- Usually mild conjunctivitis, unilateral or bilateral.
- Serous ocular discharge becoming mucopurulent.
- Mild respiratory signs such as mild serous nasal discharge.
- Occasionally, thick white discharge across conjunctiva (pseudomembrane).

See the main reference on page 14 for details (The Cat With Acute Sneezing or Nasal Discharge).

Pathogenesis

Mycoplasma felis and *Mycoplasma gatae* are thought to cause conjunctivitis in cats.

They may only be pathogenic when **potentiated by other organisms**, for example *Chlamydomydia felis*, and viruses such as herpes or calicivirus.

Infection causes a polymorphonuclear leukocyte response in the conjunctiva.

Cytology may reveal **small basophilic inclusion bodies**, which are coccoid or coccobacillary, and are seen in the periphery of the cytoplasm of the epithelial cells.

Mycoplasma organisms can be cultured in the laboratory.

Clinical signs

Usually, there is a **unilateral or bilateral conjunctivitis**, with a **serous discharge becoming mucopurulent**.

The conjunctiva may appear normal, or there may be a mild hyperemia and chemosis.

In more chronic cases, the **conjunctiva may be thickened with the formation of follicles**, which develop from focal areas of lymphoid cell stimulation.

Rarely, a **pseudomembrane** is formed, which consists of a thick white exudate covering the conjunctiva.

Respiratory signs consist of sneezing with a serous nasal discharge.

Diagnosis

Initial diagnosis is usually based on typical clinical signs of mild sneezing, with serous nasal, and mild serous ocular discharge. Chronic cases develop conjunctival follicles and on rare occasions a thick tenacious white pseudomembrane forms.

Cytology may reveal **small basophilic inclusion bodies**, which are coccoid or coccobacillary, and are seen in the periphery of the cytoplasm of the epithelial cells. There is a predominantly polymorphonuclear cell response.

Isolation of the organism can be done in most laboratories from clean conjunctival swabs. It is important to remove the discharges from the eye with sterile normal saline solution or eye washes, prior to taking the sample, as this reduces the contamination from secondary bacterial infections.

Differential diagnosis

Allergic conjunctivitis will have a similar appearance to mild cases of mycoplasma infection. There is usually a poor response to antibiotic treatments. Most cases have an allergy to insect bites, food, or the cats are atopic. The best approach for control of the ocular signs is by referral to a dermatologist or medical internist, so that the cause of the allergy can be established and the correct management instigated.

Herpetic keratitis usually presents with acute respiratory signs, including sneezing, nasal discharge, pyrexia, depression and anorexia. The conjunctiva shows chemosis and hyperemia, and the ocular discharge is more pronounced. Viral isolation and PCR tests may be helpful to differentiate herpesvirus from mycoplasma infection, and there is usually an equivocal response to antibiotic treatment.

Chlamydial conjunctivitis shows mild respiratory signs of sneezing and nasal discharge. In acute cases, the conjunctiva may show severe chemosis and hyperemia, with a serous discharge rapidly changing to a mucopurulent discharge. Chronic cases show follicle formation in the conjunctiva. Cytology, fluorescent antibody, and ELISA tests can be used to differentiate chlamydial infections from mycoplasma.

Eosinophilic keratoconjunctivitis presents with a mucopurulent discharge, and there is a proliferative inflammatory response of the conjunctiva and cornea. The presence of eosinophils in a cytological preparation of the conjunctiva and cornea is supportive for this diagnosis. The condition responds to topical and systemic corticosteroids.

Treatment

Mycoplasma conjunctivitis **responds rapidly to a wide range of antibiotics particularly tetracycline and chloramphenicol**. Tetracycline is more commonly used because this organism is frequently seen in association with *Chlamydomydia felis* infection.

Respiratory and ocular signs will be suppressed by topical and systemic corticosteroids, but are not indicated for treatment.

Prognosis

The prognosis is good as complications are rare. Cases that are complicated by concomitant infection with *Chlamydomydia felis* or viruses may have a complicated prognosis.

Transmission

Direct contact with affected animals. Infection is more prevalent in catteries and pet shops.

Airborne transmission occurs in confined spaces such as catteries and pet shops.

Prevention

There is no effective vaccine.

Good hygiene and separation of animals at risk from infected animals will reduce the incidence of infection.

TRAUMA OF CONJUNCTIVITIS AND PERIADNEXIAL TISSUE**

Classical signs

- Small to large conjunctival tears.
- Seromucoid or mucopurulent discharge.
- Chemosis with hemorrhage in acute cases.
- Blepharospasm, photophobia and ocular guarding reflecting ocular pain.

Clinical signs

Conjunctival wounds may present as **small to large tears**. Common causes are **cat claw wounds**, **plant injuries** from **thorns**, or associated with other blunt ocular trauma, commonly from **motor vehicle accidents**.

In acute cases, there is chemosis (edema) of affected conjunctiva with hemorrhage.

Ocular discharge may be serous when there are small scratches, to mucoid or purulent when large infected wounds are present in the conjunctive or peri-adnexial tissue.

There may be hemorrhage and evidence of trauma in surrounding tissue.

Ocular pain is frequently present, manifested by **blepharospasm**, photophobia and ocular guarding.

Diagnosis

If the eye is very painful, **apply a little topical anesthesia**. Proxymetacaine products are less irritating to the tissues). The cat may then open the eye making it easier to visualize the conjunctival surfaces and cornea.

Close examination should reveal any conjunctival wounds, but may be difficult in cases with chemosis.

Check for foreign bodies such as grass seeds, which may be lodged under the third eyelid, or in the upper or lower conjunctival fornix.

Differential diagnosis

Chronic cases may show healing by granulation, and have a mucopurulent discharge similar in appearance to **eosinophilic keratoconjunctivitis**. Differentiate using a **conjunctival smear**, which should have eosinophils present in eosinophilic conjunctivitis, and in a healing wound, will show predominantly neutrophils. Eosinophilic conjunctivitis usually has a history of a chronic condition that has not responded to antibiotic treatment.

Cats with **orbital cellulitis** will often have an inflamed conjunctiva, chemosis and a mucopurulent discharge. This condition may occur secondary to a conjunctival wound deep in the fornix, which has become infected with bacteria. Ocular ultrasound may be very helpful to diagnose orbital disease, where conjunctival injuries have been complicated with secondary orbital infections.

Malar abscesses caused by periodontal disease may cause chronic discharging sinuses in the lower conjunctival fornix. Check the mouth when chronic mucopurulent discharges are seen, and there is no history of ocular trauma. Dental radiology will be helpful to diagnose this condition.

Treatment

It may be necessary to use a local anesthetic and heavy sedation to **clean the eye**. Use normal saline (0.9%) or ocular irrigating solutions to gently remove discharges. Discharges are very uncomfortable for the cat, and harbor unwanted bacteria.

If the wound in the conjunctiva is very large, **suture it with fine absorbable sutures**, preferably buried underneath the conjunctiva. Sutures should be made from polygacton or polyglycolic acid using 6/0 to 8/0 sizes.

If the wound is infected, treat with **broad-spectrum topical antibiotic** drops or ointment. Common antibacterials include triple sulfonamides, neomycin/bacitracin, fucidic acid, chloramphenicol, gentamycin and framycetin. It may be prudent to take a clean swab for bacterial isolation and sensitivity, prior to starting antibiotic therapy.

Systemic drugs may be used in conjunction with topical medications, because the conjunctiva has a very rich blood supply.

EOSINOPHILIC KERATOCONJUNCTIVITIS*

Classical signs

- Proliferative white to pink inflammatory tissue on cornea with adjacent conjunctiva sometimes involved.
- The cornea may be intensely vascularized.
- Mucopurulent discharge is usually present.
- Eosinophils in cytology of affected cornea and/or conjunctiva are diagnostic.

See the main reference on page 1245 for details (The Cat With Abnormalities Confined to the Cornea).

Pathogenesis

The disease is thought to be **immune-mediated** or an allergic response.

Histologically, there is a **granulomatous response**, with a mixed population of leukocytes including lymphocytes, plasma cells, eosinophils and occasional mast cells and histiocytes. The presence of eosinophils is regarded as diagnostic.

Peripheral eosinophilia is present in about 15% of cases.

Insect bites and food allergies have been documented as causes of this condition. It has also been suggested that this response may be an ocular form of the feline eosinophilic granuloma complex, particularly the linear granuloma response. (See The Cat With a Cloudy Eye, page 1262).

Clinical signs

Signs **begin unilaterally**, but may become bilateral.

Eosinophilic keratoconjunctivitis is a **proliferative** (not ulcerative) **lesion producing plaque-like white to pink tissue**, that may be covered by a thick white discharge.

The cornea is involved primarily, and the adjacent conjunctiva is sometimes involved secondary to corneal involvement.

The **cornea may be ulcerated**, and have intense neovascularization in chronic cases.

The third eyelid may also show proliferative lesions.

Mucopurulent discharge is usually present.

Frequently, there is a history of poor response to antibiotic treatment.

Diagnosis

Initial diagnosis is based on a history of poor response to antibiotic treatment, together with signs of a **proliferative keratitis** and/or conjunctivitis, and a mucopurulent discharge.

Cytology or histopathology that demonstrates eosinophils is regarded as diagnostic.

Affected animals may have signs of skin disease or a history of digestive problems.

In tropical climates, check the ears for signs of insect bites (mosquitoes and midges).

Differential diagnosis

Chronic chlamydial conjunctivitis may look similar when there is inflamed conjunctiva and follicle formation. Differentiate with histology or cytology, and look for the presence of eosinophils typically seen in eosinophilic keratoconjunctivitis.

Treatment

The condition will rapidly respond to **systemic corticosteroids** dosed at 1 mg/kg daily. Once the inflammatory response is controlled, then alternate day therapy at 0.5 mg/kg can be used until all signs have disappeared.

Topical corticosteroids alone, using 1% **prednisolone acetate drops or dexamethasone 0.1% drops q 8 h** will control some cases, or be useful as a maintenance treatment for long-term control.

If the tips of the ears show alopecia, pruritis and crusting, the condition may be caused by biting insects. Such cases have been documented in Queensland, Australia. In such cases, the cats must be housed in conditions that are insect free for long-term resolution.

Allergic states caused by diet have been implicated. Dietary exclusion tests may be useful to eliminate this as a cause. (See The Cat With Miliary Dermatitis, page 1029).

ALLERGIC CONJUNCTIVITIS*

Classical signs

- Mild serous discharge that may be intermittent and seasonal.
- Very little pathology is evident in the conjunctiva.
- Cats may sneeze.

See the main reference on page 17 for details (The Cat With Acute Sneezing or Nasal Discharge).

Pathogenesis

Allergic conjunctivitis is an uncommon problem in cats, and may be associated with an **insect bite allergy** (fleas and biting insects such as mosquitoes and midges), **food allergy** or **atopy** (usually caused by pollens).

Clinical signs

Signs may be intermittent and seasonal, depending on the allergen.

There is a **mild serous discharge**, and the cat may show signs of irritation by rubbing its eyes.

There is usually very little conjunctival inflammation associated with this condition.

There may be concurrent sneezing, dermatitis and/or gastrointestinal signs.

Diagnosis

There are **no specific diagnostic tests** for allergic conjunctivitis. It is usually diagnosed by eliminating other causes of conjunctivitis, and on the presence of a mild serous discharge with very little inflammation in the conjunctiva.

Allergy testing done by a dermatologist may help identify the allergen in cases with atopy. (See The Cat With Miliary Dermatitis, page 1031.)

An **elimination diet** that changes the source of protein may identify a food allergy. Protein sources such as venison, duck, turkey, rabbit, kangaroo mixed with carbohydrate (rice, potato or pasta) are frequently used for periods of up to 1 month for diagnosis of food allergy, but a balanced commercial hypoallergenic diet is best for maintenance. **WARNING: Vegetarian diets will rapidly cause blindness** by depleting taurine, and should never be used in cats. They cause retinal degeneration and blindness as well cardiac problems (see The Cat With Signs Of Large Bowel Disease, page 766).

Differential diagnosis

Mycoplasma conjunctivitis can produce mild inflammation with serous discharge. However, it usually responds very well to a wide variety of antibiotics, compared with a poor response in allergic conjunctivitis.

Chronic feline herpes virus-1 conjunctivitis may produce chronic serous discharge with very little conjunctival inflammation similar to allergic conjunctivitis. Use laboratory tests to differentiate, particularly PCR or virus isolation.

Treatment

Topical corticosteroid drops used twice daily will usually control most cases with allergic conjunctivitis. The range of drops used can vary according to the severity of the signs. Very mild cases will respond to 0.1% **hydrocortisone drops**, while more acute cases will respond better to drops containing 0.5–1% **prednisolone** acetate.

If a food allergy is diagnosed based on response to an elimination diet, and reoccurrence of signs when challenged with the original diet, the cat should be transitioned from the homemade elimination diet to a **complete commercial hypoallergenic diet for maintenance**. Most homemade single protein and carbohydrate source diets are not balanced, and are suitable only for a limited diagnostic trial, and not for maintenance. Vegetarian diets will rapidly cause blindness by depleting taurine and should never be used in cats.

Where there is a confirmed allergy caused by atopy, food allergy or insect bites, exposure to allergens needs to be controlled as much as practicable. **Prevent insect**

bites by housing affected cats in insect-free conditions, for example, by confining inside.

Densensitisation for some forms of atopy may be possible when the cat has a positive skin test (see The Cat With Miliary Dermatitis, page 1031).

Prognosis

Prognosis is excellent if there is a confirmed allergy caused by atopy, food allergy or insect bites, and exposure to allergens can be controlled.

Typically this is a chronic condition that requires intermittent treatment with **topical corticosteroids** when epiphora is present.

SUB-CONJUNCTIVAL HEMORRHAGE*

Classical signs

- Mild cases of trauma show focal red areas of bleeding under the conjunctiva.
- Severe cases of trauma show diffuse reddening of the conjunctiva which may be quite swollen.
- Petechial to echymoses hemorrhages may be seen in bleeding states.

Clinical signs

Sub-conjunctival hemorrhage is common after blunt trauma to the eye, especially from motor vehicle accidents.

The most common presentation is **diffuse reddening of the conjunctiva** over the sclera, with very little swelling. This may be focal, or diffuse over the entire sclera.

In severe cases, there may be frank hemorrhage with swelling of the conjunctiva. This may be present after orbital trauma results in frank orbital hemorrhage, causing severe bulging of the conjunctiva around the globe.

Retrobulbar trauma may result in exophthalmos with swollen conjunctiva. There may be superficial hemorrhage on the conjunctiva, or subconjunctival hemorrhage.

Ecchymotic hemorrhage may be seen with blood clotting disorders, e.g. rodenticide toxicity. **Petechia and ecchymotic hemorrhages (larger areas of hemorrhage)** may be seen with thrombocytopenia. In these cases there is no history of trauma.

Diagnosis

The **clinical signs** of diffuse or focal redness with a **history** of trauma are diagnostic. There is frequently no other associated problem.

If in doubt, fine-needle aspirates of the abnormal area may be beneficial.

If there is no history of trauma, laboratory tests should be done to check for clotting or platelet disorders. (See The Bleeding Cat, page 488).

Orbital radiology, CT scan and ocular ultrasound may be needed in cases with severe peri-orbital trauma. Look for interruption of the normal scleral contour for signs of a ruptured globe using ultrasound. Check for the state of the bony orbit with radiology and CT scan.

Differential diagnosis

It is important to differentiate between hemorrhage caused by trauma and bleeding disorders (see The Bleeding Cat, page 485).

Treatment

In cases of trauma, treatment is palliative. Irrigation, hot and cold compresses, and corneal lubrication are important if swelling is present.

If swelling prevents a normal blink, and the cornea is exposed, the eyelids should be closed with a temporary **tarsorrhaphy or third eyelid flap**, otherwise corneal ulceration will rapidly develop. A temporary tarsorrhaphy is done using 4/0 or 5/0 monofilament nylon in a mattress pattern through the midpoint of the eyelid margins.

Treat bleeding disorders with appropriate drugs, and blood transfusions if needed (see The Bleeding Cat, pages 502, 511, 513, 514).

CONJUNCTIVAL LYMPHOSARCOMA

Classical signs

- Swollen, thickened conjunctiva covered with dry crusty discharge.
- Very little redness (hyperemia).
- Globe may be prominent caused by involvement of orbital tissue.
- Third eyelid may be swollen and prominent.

See the main reference on pages 1078, 1311 (The Cat With Lumps and Bumps and The Cat With Abnormal Globe Position or Size).

Pathogenesis

The conjunctiva has a rich supply of lymphoid tissue, but it usually becomes affected **secondary to orbital or systemic lymphosarcoma**.

The condition may **appear acutely**, and frequently the cat will show no other systemic signs such as swollen lymph nodes or enlarged spleen.

Focal and diffuse lesions have been reported. Infiltration of the conjunctiva with neoplastic cells causes **swelling**.

There may be a mild mucopurulent discharge. The discharge crusts on the conjunctival surface as it becomes dry and inflamed, which results from lack of tear lubrication caused by the swelling and poor ability to blink.

Clinical signs

This is a rare condition in cats.

Focal or diffuse swelling of the conjunctiva is seen. The **swelling has the same appearance as chemosis**, however, the conjunctiva is not edematous, but infiltrated by neoplastic lymphoid cells. There is **very little redness (hyperemia)** present.

The **swollen conjunctiva may be dry**, and have a **crusty mucopurulent discharge** on the surface,

because the eyelids cannot close, and the tear film cannot cover the surface.

The third eyelid may be involved. **Swelling and partial prolapse** may result in abnormal prominence of the third eyelid.

There may be involvement of the orbital tissues. This will cause swelling of the conjunctiva and a prominent globe (exophthalmos).

Diagnosis

Cytology from a **fine-needle biopsy** should reveal large numbers of **plump lymphoid cells** with a large dark staining nucleus, and prominent nucleoli.

Fine-needle aspirates from enlarged lymph nodes will help to support a diagnosis. (See page 1075.)

Histopathology will show a similar infiltration of neoplastic cells in the conjunctiva.

Serology for FeLV is positive in many cases. (See page 1142.)

Hematology may be useful to support a diagnosis. Occasionally neoplastic lymphoid cells are prominent in the blood smear, especially if there are greatly increased numbers of lymphocytes.

Ocular ultrasound using a 10-MHz probe will help identify focal lesions in the orbit. Ultrasound-guided biopsies can be done by guiding a Tru-cut biopsy probe into the affected area.

Treatment

Eye lubricants and artificial tears are required to lubricate swollen and dry conjunctiva, and help to prevent secondary complications such as corneal ulceration.

Topical corticosteroid drops may be indicated as an adjunct to systemic therapy. Prednisolone acetate 1% or dexamethasone 0.1% drops instilled into the eye three to four times a day will help reduce swelling associated with neoplastic infiltration.

Chemotherapy may be effective in achieving remission in some cats. (See The Cat With Signs of Chronic Small Bowel Diarrhea, page 742.)

CONJUNCTIVAL HEMANGIOMA/HEMANGIOSARCOMA

Classical signs

- Focal raised red lesion in the lateral conjunctiva or on the outer surface of the third eyelid.
- Often described by the owner as a small blood blister on the eye.
- Red cornea adjacent to lateral conjunctival lesions in advanced cases.

See the main reference on page 1075 for details (The Cat With Skin Lumps and Bumps).

Pathogenesis

Lesions in this area are usually primary, and probably caused by UV radiation. However, it is prudent to check for systemic signs of hemangiosarcoma.

This is a rare condition in cats.

Clinical signs

Conjunctival hemangioma or hemangiosarcoma appears as a **small raised red area**, most commonly in the conjunctiva at the **lateral limbus**.

The **cornea** may become **infiltrated** with bright red tissue in chronic cases. An intense red infiltration will appear extending from the lateral limbus adjacent to the conjunctival lesion.

Hemangioma or hemangiosarcoma may also occur on the conjunctival surface at the **leading edge of the third eyelid**. A red raised focal lesion on the leading surface of the third eyelid can occur as a separate problem, not associated with lesions near the limbus.

Very little change occurs in the surrounding tissue.

Diagnosis

Biopsy is essential to differentiate hemangioma from hemangiosarcoma.

Differential diagnosis

Healing wounds with granulating tissue have a very similar appearance to hemangiosarcoma. A history of trauma may help to differentiate granulation tissue

from neoplasia, but a biopsy may be required for differentiation.

Treatment

Wide surgical excision with cryosurgery of the base of the wound will usually be curative. Regular checks need to be made for regrowth.

Beta radiation may be used if available.

EYELID CONDITIONS CAUSING OCULAR DISCHARGE

MEIBOMIAN GLAND INFLAMMATION**

Classical signs

- Serous ocular discharge.
- Blepharospasm and rubbing of eyes with front paws.
- Inner surface of eyelids are bright red.
- Raised cream-colored lesions on the eyelid margin.

See the main reference on page 1324 for details. (The Cat With Abnormal Eyelid Appearance).

Pathogenesis

Meibomian gland inflammation may be caused by an infection of the glands, usually with *Staphylococcus* or *Streptococcus* spp.

In some cases, the infectious agent may cause a hypersensitivity reaction. This is more common with *Staphylococcus* spp.

The inflammation and hypersensitivity reaction may **change the ocular pH** on the eyelid surface, which further exacerbates the problem.

Individual glands swell with **inspissated lipid secretions**.

Clinical signs

The cat presents with a history of **irritated eyes**, and has a **serous to mucopurulent discharge** around the eyelid margins.

The condition can cause a lot of discomfort, seen as **blepharospasm and rubbing**. Ocular pain with squinting may or may not be present.

If the inner surface of the eyelids is examined, there will be an obvious redness and swelling of the meibomian glands within the tarsal plate.

There may be redness of the eyelid and conjunctiva. The inner surface of eyelids is often bright red.

It is usually a **chronic condition**, and can be frustrating to manage.

Raised cream-colored lesions with cheesy appearance represent inspissated cells swollen with accumulated lipid material, which is highly inflammatory to surrounding tissue.

Diagnosis

Careful examination of inner lid margins will show a very red inflamed row of glands.

There is usually a mucopurulent discharge.

Culture and sensitivity of meibomian secretions may be helpful. Sensitivity will often show resistance to a wide variety of antibacterial agents.

Several small punch biopsies, 2 mm in size, with histopathology, culture and sensitivity may help identify the cause.

Differential diagnosis

Eosinophilic conjunctivitis may appear similar, but has eosinophils present on cytology.

Peri-ocular skin conditions causing blepharitis such as malassezia, ringworm and immune-mediated conditions like pemphigus foliaceus.

Treatment

Hygiene is very important in these cases, and **regular cleansing and massage** of the eyelid margins is beneficial, if the cat is amenable.

Topical anti-inflammatory drugs are useful in chronic cases. **Prednisolone acetate** 0.5% instilled into the eyes two to three times daily is sufficient.

Topical antibiotics are indicated, particularly those that will treat *Staphylococcus* and *Streptococcus* spp.

Systemic tetracyclines, particularly doxycycline, have been widely used to suppress similar inflammation in human medicine. In cats, use an oral dose of 5 mg/kg PO q 24 h for 1–3 months. **Tetracyclines have a mild anti-inflammatory effect** on ocular tissue. They suppress antibody production and chemotaxis of neutrophils, and inhibit lipases, collagenases and prostaglandin synthesis. Research also shows that tetracyclines exert other pleiotropic properties independent of their antimicrobial activity which include inhibition of metalloproteases, blockade of nitrous oxide synthetase (a potent mediator of inflammatory activity), suppression of tumor progression, bone resorption and angiogenesis.

EYELID TRAUMA**

Classical signs

- Small wounds present as tears on the margin of the eyelid or skin surface.
- Lacerated margins cause distortion with globe more prominent.

See the main reference on page 1326 for details (The Cat With Abnormal Eyelid Appearance).

Clinical signs

Eyelid lacerations are common following fights. They present with a typical wound through the eyelid margin. In severe cases, the wounds gape open exposing the globe.

Healed eyelid wounds may result in cicatricial distortion of the lids, that leads to trichiasis. Hair from the surrounding eyelid skin may rub on the eye (trichiasis), causing epiphora and keratitis.

If the eyelid margins are not apposed correctly, the lid will be distorted and chronic conjunctivitis and keratitis are common sequelae. This will result in a mucoid to mucopurulent discharge.

Cicatricial ectropion, when the lower eyelid hangs open exposing the conjunctiva, is the most common complication after lower eyelid wounds.

If the wound occurs in the area of the lower puncta, scarring may result in epiphora, as tear drainage is affected.

Diagnosis

Eyelid wounds are obvious on clinical examination. There will usually be a history of trauma.

EYELID AGENESIS (COLOBOMA)

Classical signs

- Unilateral or bilateral abnormality of upper outer lid margin.
- Seromucoid ocular discharge.
- Vascularized adjacent upper cornea with or without ulceration.
- Most common in Persians but any breed can be affected.

See main reference on page 1323 for details. (The Cat With Abnormal Eyelid Appearance).

Pathogenesis

Eyelid agenesis is a **congenital anomaly**, and strictly speaking is a coloboma of the eyelid. The eyes should be checked for other signs of defects, as some cases also have a coloboma of the optic disc.

Clinical signs

Occurs in **all breeds of cats** including domestic short-hair cats, but is more common in **Persians**.

The agenesis is **usually bilateral**, but may be unilateral.

It mainly affects the upper eyelid, and the lateral half to one third of the eyelid margin is missing or abnormal.

Where the eyelid margin is missing, the eyelid hair directly rubs on the cornea, causing **trichiasis, keratitis and tearing**.

The conjunctiva is exposed adjacent to the area of the agenesis, causing desiccation and mucoid discharge.

Most cases present with **tearing, corneal vascularization and ulceration as kittens**.

Diagnosis

There will be a history of **chronic epiphora** with keratitis and obvious ocular irritation.

Careful examination will show that a portion of the upper eyelid margin is missing or abnormal.

Differential diagnosis

Eyelid wounds that have healed with a section of lid margin missing appear similar. Age and a history of trauma usually differentiate.

Treatment

Surgical correction is the only curative solution. There are many surgical techniques that involve **rotational or advancement flaps**. For details the reader should go to texts that have details of ophthalmic surgical techniques or refer the cat to an ophthalmologist.

SYMBLEPHARON OCCLUDING THE LOWER NASOLACRIMAL PUNCTA

Classical signs

- Chronic epiphora with tearing down the face causing brown staining. Unilateral or bilateral.
- History of cat flu as a kitten.
- Abnormal appearance of conjunctiva, and occasionally a cloudy cornea.

See the main reference on page 1212 for details (Herpesvirus conjunctivitis).

Pathogenesis

Symblepharon is the **adhesion of any part of the conjunctiva to itself or to the cornea**. It includes:

- Adhesion of conjunctiva from bulbar conjunctiva to eyelid conjunctiva.
- Adhesion of bulbar conjunctiva to cornea.
- Adhesion between third eyelid conjunctiva and eyelid or bulbar conjunctiva.

Symblepharon **occurs after severe inflammation**, following destruction of large portions of the conjunctival epithelium.

The entire corneal surface may be reduced to a thin conjunctival membrane, when the infection is so severe that it destroys the corneal stem cells at the level of the limbus. The normal corneal epithelium is absent, and is replaced with a thin conjunctival membrane.

It is seen most commonly **after acute herpesvirus-1 infection** in kittens.

Clinical signs

The **conjunctiva can be distorted, thickened**, and cover part or all of the cornea. Symblepharon may be **unilateral or bilateral**.

The eyelids may be distorted in severe cases, and the adhesion between bulbar and lid conjunctiva may cause poor eyelid function.

The **third eyelid may be thickened and distorted**, and have poor movement across the globe.

Poor eyelid function and puncta occlusion cause **chronic ocular discharges**. If the puncta is occluded, the discharges will be serous, but when the condition is severe and eyelid function is disturbed, the discharges may become mucopurulent. The chronic epiphora with tearing down the face may cause **brown staining of the fur**.

The **entire cornea may appear cloudy**, covered by a thin vascular membrane. Surprisingly, some of these cats have limited vision.

Diagnosis

There is usually a **history of acute respiratory disease as a kitten**, followed by chronic ocular inflammation and discharge.

Close examination will reveal an abnormal conjunctiva with adhesion to eyelids, cornea and/or third eyelid.

Examine the eyelid with magnification to see if the puncta has been occluded causing epiphora.

Differential diagnosis

Healed wounds with eyelid damage around the puncta area may appear similar, but there is no history of acute inflammation or respiratory disease.

Healed wounds of the third eyelid usually have some form of deformity to the contour of the margin, and the third eyelid is rarely adhered to surrounding tissues.

In **ulcerative keratitis** with a large corneal deficit, conjunctiva or third eyelid conjunctiva may have adhered to the healing cornea, but this will usually occur near the limbus, and not centrally over the entire cornea.

Treatment

The need for treatment depends on the severity of the condition.

Specialized surgical techniques to reposition the conjunctiva are required, but even in experienced hands the results are not rewarding, as the adhesions invariably reform.

Surgery to re-establish tear drainage is rarely successful because of severe damage to the nasolacrimal ducts, and occlusion of the puncta.

Conjunctivo-rhinostomy techniques have been described to establish tear drainage to the nose.

Prevention

Try to prevent formation of symblepharon in kittens with acute conjunctival inflammation using appropriate treatment.

- Treat kittens with severe ocular inflammation with **broad-spectrum antibiotics and anti-viral** agents (see Herpes conjunctivitis, page 1214). **Tetracycline** antibiotic ointment is best, because *Chlamydomydia felis* or mycoplasma infection may complicate herpesvirus infection.
- **Hourly lubrication with artificial tears** appears to be very beneficial.

LOWER LID ENTROPION**

Classical signs

- Lower eyelid is curled inwards.
- Chronic ulcerative keratitis caused by eyelid hair rubbing on the cornea.
- Mucoïd to mucopurulent discharge.

See main reference on page 1320 for details (The Cat With Abnormal Eyelid Appearance).

Clinical signs

Usually the central portion of the lower eyelid margin rolls inwards towards the globe. **Lid hair adjacent to the margin may appear moist or be coated in conjunctival mucus.**

Enophthalmos is often present as the underlying cause, or chronic blepharospasm **caused by painful corneal diseases.**

Corneal surface disease **is present from the eyelid hair rubbing on the cornea.** This can include **superficial ulceration, sequestrum formation, and a vascular response from the limbus adjacent to the area of lid irritation.**

Chronic discharge occurs **ranging from mucoid to mucopurulent.**

Diagnosis

Diagnosis is based on the characteristic sign of an inward rolling eyelid margin with secondary corneal changes and chronic ocular discharge.

MEIBOMIAN GLAND ADENOCARCINOMA

Classical signs

- Localized or diffuse eyelid swelling.
- \pm Surface ulceration.

See main reference on page 1324 for details. (The Cat With Abnormal Eyelid Appearance).

Clinical signs

Meibomian gland adenomas or carcinomas are seen as a **nodular or diffuse mass causing localized thickening of the eyelid.** The tumor may have an ulcerated surface.

Diagnosis

Tentative diagnosis is based on the appearance of the eyelid lesion.

Exfoliative cytology is useful in some cases that show ulceration.

Fine-needle biopsy can be useful in cases where there is discreet swelling.

Definitive diagnosis is based on histopathological examination of affected tissue.

CORNEAL DISEASE CAUSING OCULAR DISCHARGE

HERPETIC KERATITIS***

Classical signs

- Ocular pain seen as blepharospasm and photophobia.
- Mild serous ocular discharge. Superficial corneal ulceration in a dendritic or geographic distribution.
- Superficial vascularization and scarring, if chronic.

See main reference on page 1237 (The Cat With Abnormalities Confined to the Cornea).

Clinical signs

Cats present with signs of ocular pain, seen as blepharospasm and photophobia.

A mild serous discharge is common.

Superficial ulceration in an irregular (geographic) or linear (dendritic) pattern is seen when the cornea is examined under magnification, or with a slit lamp biomicroscope. The corneal lesion is in the epithelium or superficial stroma.

There may be varying degrees of **superficial vascularization and scarring.**

There is often a history of **quiescent phases, followed by recurrence** of serous discharge, and eye discomfort after stress.

A **history of prior cat flu, often as a kitten**, with signs consistent with feline herpesvirus-1 infection, may be present. **Corneal involvement** (keratitis) may first occur 1–2 weeks after upper respiratory signs, or may be unassociated with respiratory signs.

Diagnosis

A **history** of respiratory infection as a kitten, followed by chronic episodes of ocular discharge and pain, indicates

a tentative diagnosis of herpetic keratitis. **Close examination** will show dendritic lesions or geographical ulceration.

Laboratory tests such as PCR may support a diagnosis of FHV-1 infection. See Herpetic conjunctivitis, page 1213.

CORNEAL TRAUMA***

Classical signs

- Blepharospasm and photophobia with ocular guarding.
- Initially a serous ocular discharge becoming mucopurulent.
- +/- Copious watery discharge from constant leakage of aqueous humor if cornea is perforated.
- Blue or cloudy cornea.
- Retention of fluorescein stain.
- Black appearance to the corneal deficit, if iris is prolapsed through wound.

See main reference on page 1249 (The Cat With Abnormalities Confined to the Cornea).

Clinical signs

Ocular pain is evident as **blepharospasm and photophobia**.

There will be an **ocular discharge**, which is serous at first and becomes mucopurulent.

In cases where the **cornea is perforated**, there may be a copious watery discharge from constant leakage of aqueous humor out of the wound.

The surrounding cornea will have **corneal edema** seen as a blue or cloudy eye.

There will be **retention of fluorescein** stain where there is a large deficit of epithelium. If the wound is leaking aqueous, the fluorescein will wash off the cornea away from the perforation.

Fibrin tags or clots may be seen attached to the injured area of the cornea, plugging the wound.

In large perforations, **iris tissue may be prolapsed** (iris prolapse) through the wound giving a black appearance to the corneal deficit.

Diagnosis

Diagnosis is based on the clinical signs of severe ocular pain with a serous discharge, and evidence of corneal trauma, such as a tear in the cornea, which may be plugged with fibrin, or have an iris prolapse.

Ocular discharge which will vary from serous to very watery, if aqueous is leaking.

ULCERATIVE KERATITIS**

Classical signs

- Painful closed eye with a serous discharge.
- Focal or diffuse corneal cloudiness.
- Conjunctival inflammation.
- Corneal erosion.
- Positive green stain with fluorescein dye.
- Red appearance of cornea in chronic cases.

See main reference on page 1246 for details. (The Cat With Abnormalities Confined to the Cornea).

Clinical signs

Serous ocular discharge is often the presenting sign.

Signs of ocular pain with **blepharospasm (resulting in a closed eye)**, and **photophobia** are present.

Focal or diffuse corneal edema (cloudiness) occurs, depending on the amount of epithelial loss.

Erosion of epithelium and stroma is present, depending on severity of the ulceration.

There will be **retention of fluorescein stain** by the exposed corneal stroma.

Chronic cases may show **varying degrees of vascularization**.

Large ulcers usually develop **corneal vascularization**, which may be superficial or deep, and result in a red appearance of the cornea. This depends on how long the ulcer has been present, and what the cause is.

The eye may be red because of conjunctival inflammation.

Diagnosis

Diagnosis is based on **signs of ocular pain** with a serous discharge, and the presence a **corneal deficit** on examination of the cornea.

The ulcerated area of cornea will retain fluorescein dye (staining yellow-green).

CORNEAL SEQUESTRUM**

Classical signs

- A serous or mucopurulent ocular discharge.
- Brown staining of the cornea.
- +/- Signs of ocular discomfort.

See main reference on page 1233 for details (The Cat With Abnormalities Confined to the Cornea).

Clinical signs

Corneal sequestrum is more common in **brachycephalic breeds** such as Persians and color-points, but can occur in any breed.

The classical presentation is an area of **brown or black staining of the cornea**, which may be superficial, or involve deep layers of the stroma. The lesion rarely absorbs fluorescein dye, except in cases where the periphery is ulcerated.

A **serous ocular discharge** is present in non-ulcerated cases.

Chronic cases may have **ulceration around the diseased area of cornea**. These often have secondary bacterial infection, and a mucopurulent ocular discharge.

Cats may or may not show signs of ocular discomfort.

There may be a **history of herpesvirus infection** as a kitten. However, there are probably other causes, such as **medial entropion** in brachycephalic cats and **corneal ulceration**.

Diagnosis

Clinical signs of ocular discharge associated with brown staining of the cornea.

Sequestrum may be associated with FHV-1 infection, which can be confirmed with laboratory tests.

ORBITAL DISEASE CAUSING OCULAR DISCHARGE AND CHANGED CONJUNCTIVAL APPEARANCE

RETROBULBAR INFECTION

Classical signs

- Prominent globe (exophthalmos).
- Chemosis of the conjunctiva, with injected blood vessels and a mucopurulent discharge.
- The third eyelid may be prominent or swollen.
- Pain and reluctance to open the mouth.
- Rare.

See main reference on page 1310 (The Cat With an Abnormal Globe Position or Size).

Clinical signs

Cats will have **varying degrees of exophthalmos**, depending on the extent of the orbital inflammation.

In acute cases, there is usually a **mucopurulent discharge**, that may be copious if there is orbital cellulitis.

The **conjunctiva may be red** with injected blood vessels, and show chemosis (edema).

The **third eyelid is prominent and may be swollen**, when the swelling is outside the muscle cone in the orbit.

Acute cases show severe pain, and **resist opening the mouth**.

It may be difficult to retropulse the globe into the orbit.

Retrobulbar infection may be **hematogenous**, associated with **foreign body penetration**, or from extension of **dental or sinus disease**. Check the cat for signs of dental disease, especially molar root disease, or nasal discharge.

It is **rare** in cats compared to dogs.

Diagnosis

Initial diagnosis is based on the classical signs of exophthalmos, with chemosis and inflammation of the

conjunctiva, and a mucopurulent discharge. Pain when the mouth is opened supports the diagnosis.

Check the teeth for dental disease, and the nose for nasal discharges suggesting sinus problems.

Ocular ultrasound is very useful. The orbit is examined for changes in echodensity. **Abscesses** appear as **focal hyper-echoic areas**. If the inflammation is diffuse, the normal muscular cone will be hard to visualize.

Dental radiology is used to check the roots of the molar teeth for periodontal disease.

Radiology of the orbit and sinuses is useful if one suspects the infection has extended from these areas. The orbital rim is examined for signs of erosion adjacent to the frontal and nasal sinus.

CT or MRI of the nose and sinuses is used to rule out an extension of disease from these areas to the orbit. There will usually be an erosion of the bony orbit, and signs of disease in the nose or sinuses.

60. The cat with abnormalities confined to the cornea

Richard IE Smith

KEY SIGNS

- Cloudy cornea.
- Redness from vascularization.
- Pink or white plaque.
- Coffee to black staining lesion.
- Ocular pain (blepharospasm, photophobia).

MECHANISM?

- Superficial damage to the epithelial surface causes an erosion (superficial ulcer). Loss of epithelium and stromal tissue results in a deep ulcer with a loss of transparency of the cornea because of edema of the stromal tissue.
- Cats with uveitis secondary to systemic disease may show changes in the inner endothelial cell layer. This will be seen as corneal edema (diffuse grayish appearance) and there may be “keratic precipitates” (focal deposits consisting of white blood cells and fibrin) present on the endothelium.
- The cat has some unique degenerative and immune-mediated corneal diseases.

WHERE?

- Cornea (epithelium, stroma, endothelium).

WHAT?

- Trauma and infectious diseases affecting the upper respiratory system are the main causes of corneal disease in cats.
- The cat cornea develops a unique degenerative disease, which forms a corneal sequestrum.
- An immune-mediated disease called eosinophilic keratitis is seen associated with allergic states.
- Corneal edema and keratic precipitates are seen in cats with uveitis, usually secondary to systemic disease.

QUICK REFERENCE SUMMARY

Diseases causing abnormalities confined to the cornea

DEGENERATIVE

- **Calcific degeneration (p 1252)**

Rare in cats. Seen as a band of gritty white material in the anterior stroma, usually secondary to chronic herpetic keratitis. Known as a band keratopathy.

- **Corneal sequestrum (feline keratitis nigrum)** (p 1241)**

Presents with an axial (central) area of staining (light brown to black) in the cornea, usually unilateral. Most common in brachycephalic breeds such as Persians and Himalayans. Approximately 80% are associated with herpetic keratitis. In the early stages there is no ulceration, but chronic lesions may have ulcerated borders, and there may be intense deep stromal vascularization associated with these ulcerated lesions. It is a focal area of stromal degeneration surrounded by an inflammatory zone.

ANOMALY

- **Stromal dystrophy of Manx cats (p 1252)**

A rare condition in young Manx cats that starts with axial stromal edema and progresses to a diffuse corneal edema with a thickened stroma full of bullae (fluid-filled vesicles). A blinding corneal disease with no treatment possible.

- **Endothelial dystrophy (p 1252)**

Seen in Domestic Short Hair cats. A very rare condition seen in young cats evident as a cloudy blue cornea caused by diffuse corneal edema secondary to an endothelial dystrophy. There is no specific cause, and no treatment is possible.

METABOLIC

- **Lysosomal storage diseases with ophthalmic manifestations (p 1253)**

GM 1 gangliosidosis, GM 2 gangliosidosis, mannosidosis, mucopolysaccharidosis 1 (MPS1). Mucopolysaccharidosis 2 (MPS2) may be associated with corneal changes. The cornea shows opacity caused by vacuoles in the keratocytes and endothelial cells. Seen in young animals that also have neurologic signs of ataxia, muscular tremors and paralysis.

INFLAMMATION/INFECTIOUS

- **Feline herpes virus 1 (FHV-1) keratitis*** (p 1237)**

Cats may have a history of FHV-1 infection as kittens, with acute upper respiratory tract signs, salivation, sneezing, pyrexia, lethargy and anorexia. Often appears as a unilateral disease in older cats. The epithelium may show dendritic lesions (finger-like projections of thickened epithelium that stain with rose bengal stain) in early cases. Chronic cases show irregular (geographic) ulceration to the level of the superficial stroma. Scarring and vascularization of the cornea follows after repeated inflammatory episodes.

- **Bacterial ulcerative keratitis* (p 1248)**

Usually secondary to corneal trauma. Ulcers stain positive with fluorescein dye. There is a variable presentation depending on the depth of the ulcer and the type of infection. *Pseudomonas* infection may cause a “melting ulcer” (keratomalacia) with digestion of stromal tissue by bacteria and cellular enzymes.

- Florida keratopathy (“Florida spots”)/mycobacterial keratitis (p 1251)

Focal grayish opacities seen in the stroma caused by a mycobacterium. Only seen in the southeast USA.

Inflammation:

- **Keratitis secondary to uveitis** (p 1251)**

Usually seen as a diffuse blue eye caused by corneal edema from a compromised corneal endothelium. The eye may have an associated red injected conjunctiva. The anterior chamber may have a hypopyon (accumulation of protein and white blood cells) and the inferior endothelium may have keratic precipitates (focal accumulations of white blood cells and protein). Frequently associated with systemic diseases such as cryptococcosis, toxoplasmosis, FeLV, FIV, FIP (young cats) and systemic mycoses (USA).

Immune-mediated:

- **Eosinophilic keratitis* (p 1245)**

Seen as a cloudy, red cornea, sometimes with a muco-purulent discharge. A proliferative white to pinkish plaque develops on the cornea, with superficial and in chronic cases, deep vascularization. Usually a history of poor response to antibiotic therapy. Eosinophils demonstrated on cytology from corneal scrapings are diagnostic.

Trauma:

- **Neurotropic keratitis (p 1250)**

Ulcerative keratitis results from denervation of the cornea or paralysis of the eyelids. The cornea has a dry lusterless appearance, often with superficial ulceration and vascularization. The cat cannot blink the eye, or there is no corneal reflex when the cornea is touched with a thread. Usually seen after accidents that affect the facial and/or trigeminal nerve.

- **Ulcerative keratitis (not associated with specific corneal disease or corneal perforation)* (p 1246)**

Appears as a very painful, cloudy eye with serous discharge. Edema, blepharospasm and ulceration, or a penetrating wound are typical. Usually occur secondary to corneal trauma. Foreign bodies such as grass seeds and thorns or blunt trauma from motor vehicle accidents are the most common causes of corneal trauma. Trauma may cause a superficial ulcer, deep ulcer or penetrating wound. Melting ulcers appear as a very cloudy cornea with a soft gelatinous appearance. A black area within the ulcer and a thin bulging membrane indicate a descemetocoele.

- **Ulcerative keratitis caused by corneal perforation (cat fight wounds)** (p 1242)**

Very painful, closed eye with serous discharge and sometimes bleeding. Anterior chamber may be full of blood and protein. Cats commonly attack their opponent's eyes, usually causing a penetrating corneal wound with a claw. An iris prolapse is a common complication, and is seen as a light to dark brown bulge in the center of the corneal wound (and distorted pupil if visible). Lens rupture is a devastating complication that causes an acute uveitis, glaucoma and blindness.

- **Blunt trauma* (p 1249)**

Painful, cloudy and red eye. Cornea may have superficial ulcer or be ruptured (usually around the limbus). The anterior chamber may be filled with blood (hyphema). Conjunctiva may be red from subconjunctival hemorrhage. Eye may be bulging (exophthalmos) from edema and hemorrhage in the orbit.

INTRODUCTION

MECHANISM?

The main supportive tissue of the cornea is the **stroma**, which consists of cells that stretch from one side to the other, known as **keratocytes**, and an intercellular matrix that contains collagen fibers and glycosaminoglycans. The outer surface is covered by an **epithelial layer**, about six cells deep, that has a very thin basement membrane. The inner surface has a cell monolayer called the **endothelium**, which has a very thick basement membrane called **Descemet's membrane**.

The **cornea is transparent** because it does not have a blood supply, contains no pigmented cells, the collagen fibers are laid down in very specific planes and the hydration of the intercellular matrix is controlled.

The epithelium and endothelium have properties that prevent fluid from entering the stroma. If the epithelium is eroded, the stromal matrix will absorb fluid, swell and become cloudy. This is known as **corneal edema**. Similarly, if the endothelium is compromised, aqueous humor will enter the stroma and cause corneal edema.

Very simply, the cornea is kept alive by the tear film, which provides nutrients for the cells and immune mechanisms to protect the eye from disease. **Oxygen enters the cornea by diffusion through the tear film.**

The cornea is the main refractive tissue for the optical mechanism of the eye.

Diseases of the cornea in cats are generally confined to the outer epithelium and the supportive stromal tissue.

The cat cornea heals very well with limited scarring and melanin pigment deposition compared to other species.

Inflammation of the cornea is known as "keratitis". Keratitis may be acute or chronic, and ulcerative or infectious. Inflammation is associated with erosions and edema.

When the epithelium is damaged, a corneal ulcer develops. The ulcer may be **superficial** if only the

epithelium is missing, or **deep** if the epithelium and stroma are eroded. When the epithelium and entire stroma are eroded as far as Descemet's membrane, the condition is called a **Descemetocoele**. Descemet's membrane is very elastic in the cat. When there is a large stromal deficit, the Descemetocoele will be seen as a large bulge of transparent tissue.

The integrity of the epithelium is tested with a water-soluble dye called fluorescein. The epithelium prevents water-soluble substances from entering the stroma. If the epithelium is disrupted, the dye will be absorbed by the stroma and remain temporarily as a yellow green stain. The dye coloration can be enhanced by using ultraviolet light (the blue filter on direct and indirect ophthalmoscopes). **Rose bengal** is another stain that is used to show minor changes in the epithelial layer. It may be useful to show the dendritic lesions seen in feline herpesvirus-1 keratitis.

Corneal ulcers may be caused by trauma, infectious diseases, immune processes that affect the epithelium and stroma, and by any mechanism that prevents the normal tear film from covering the eye.

Endothelial disruption may be caused by trauma or inflammation within the eye, usually secondary to uveitis (an inflammation of the vascular tissue in the eye). An inherited form of endothelial dystrophy has been described in the Manx cat.

The cornea has a very rich nerve supply emanating from the trigeminal nerve. Nerve endings are found throughout the cornea up to the level of the basal epithelial cells. Any disruption of the epithelium causes severe ocular pain, which is manifested by blepharospasm (eyelid spasm), photophobia (pain from light) and ocular guarding. The pain will stimulate excessive tear production causing a serous ocular discharge.

The cat cornea has some unique diseases caused by degeneration of the stroma, and proliferative lesions, which develop from immune mechanisms associated with systemic reactions to allergic disease.

Chronic superficial corneal disease will stimulate vascular in-growth from the limbus (the area where the cornea merges with the sclera) known as **corneal**

vascularization. Superficial blood vessels grow in a branching pattern and may bring melanin cells with them, causing pigmentation and loss of transparency.

Acute inflammation within the eye (uveitis) will cause an intense, deep stromal vascular infiltration around the periphery (limbus) known as a “**brush border**”. Corneal edema and keratic precipitates are seen in eyes that have uveitis. The epithelium is usually intact, but the endothelium is disrupted.

Corneal pigmentation develops secondary to corneal vascularization as melanin cells from the limbal melanocytes are dragged into the stroma with the blood vessels. This is not as common a reaction in the cat compared to other species.

Corneal edema can be seen in cases with glaucoma, because the increased intra-ocular pressure disrupts the endothelium, allowing aqueous to enter the stroma. The epithelium is usually intact.

WHERE?

Corneal epithelium stroma (keratocytes and matrix) and endothelium.

WHAT?

Most superficial corneal epithelial problems are caused by **trauma or infections, specifically herpesvirus-1**.

Corneal stromal problems are caused by trauma, herpesvirus or degeneration associated with corneal sequestrum. Cloudiness of the cornea is caused by edema or scarring.

Proliferative corneal lesions are usually caused by an immune-mediated reaction known as **eosinophilic keratoconjunctivitis**.

Corneal endothelial problems are caused by **trauma, uveitis, glaucoma**, and very rarely, endothelial dystrophy.

Non-specific reactions that cause edema and chronic keratitis can be seen with glaucoma.

Congenital diseases of the cornea are rare in cats.

DISEASES CAUSING ABNORMALITIES CONFINED TO THE CORNEA

FELINE HERPESVIRUS-1 (FHV-1) KERATITIS***

Classical signs

- Kittens may have swollen red eyes with a serous discharge. In very severe cases this may be followed by a cloudy appearance of the cornea. The cornea is covered by a conjunctival membrane and has a dull gray appearance, sometimes with superficial vascularization.
- Young cats may present with signs of ocular pain (blepharospasm and photophobia) and serous discharge. Microscopic examination of the cornea may show dendritic lesions seen as a faint branching within the epithelium. They may stain positive with rose bengal stain.
- Older cats develop chronic painful eyes that may have a slightly cloudy cornea with some faint blood vessels present. This is caused by shallow irregular ulceration (geographic ulcer) often with faint superficial vascularization.
- Older cats frequently have a history of acute episodes followed by quiescent periods, but close examination will reveal a slightly cloudy, scarred cornea.
- The condition is frequently unilateral but may be bilateral.

See main reference on page 1212 for details (The Cat With Ocular Discharge or Changed Conjunctival Appearance) and The Cat With Acute Sneezing or Nasal Discharge (page 7).

Pathogenesis

Herpesvirus infection is one of the most common causes of acute and chronic corneal disease in older cats

The condition is caused by infection with feline herpes virus-1 (FHV-1), a subfamily of Herpesvirinae. FHV-1

has poor tropism for corneal tissue. Corneal disease is usually the consequence of conjunctival infection in young cats.

FHV-1 affects the cornea through two different mechanisms.

Firstly, the virus has a **direct cytopathic effect on corneal epithelium** and produces the typical linear or branching (dendritic) lesions. The lesions rarely reach the depth of the epithelial basement membrane, and can therefore be difficult to detect. Staining the epithelium with rose bengal may reveal these pink branching lesions.

Secondly, **an immune response to viral antigen** causes a prolonged absence of epithelium. This is seen clinically as a “**geographic ulcer**”, that is, a large ulcer with an irregular shape that appears to look like a continent or land mass. There may be some fine superficial blood vessels within the anterior stroma in the area that is affected.

The virus is able to replicate and become latent in nerve tissue, most likely in trigeminal nerve sensory ganglia. Virus reactivation occurs after stress and after the administration of corticosteroids. Vaccination with live virus vaccines may exacerbate the condition in affected cases.

Clinical signs

The **earliest sign of classical** herpesvirus infection is paroxysms of sneezing or salivation. This is usually seen in kittens and cats that have not been immunized.

Systemic signs of upper respiratory disease are common and include anorexia, pyrexia and depression.

Acute conjunctivitis manifested by hyperemia and chemosis is seen at the same time as the respiratory signs. Prolapse of the third eyelid may occur as part of the inflammatory process in the eye.

Serous ocular discharge is seen in the acute phase and this progresses to a **mucopurulent discharge**.

In young cats, ulceration may occur in the buccal mucosa and on the tongue.

The ocular changes are **usually bilateral**, but may be unilateral in older cats.

The cornea may be affected in acute infections by formation of **symblepharon**. Necrosis of the epithelium, probably with stem cell damage, allows the conjunctiva to permanently adhere to the corneal stroma. The cornea then heals with a dull gray appearance, covered by a thin membrane of conjunctiva.

In older cats with a carrier status, **mild signs of herpesvirus** infection may be seen **after some form of stress**. In these cases, the inflammation is less intense and only a serous discharge is present. These cats may have a history of respiratory infection as a kitten.

The classical corneal lesions in **early infections** appear as **dendritic (branching) epithelial lesions** that can be very subtle in appearance and may require magnification to visualize. They usually occur after the primary conjunctival inflammation has decreased in intensity. The epithelium may be swollen in affected areas, and these branching lesions may stain pink with rose bengal stain. There may be a mild conjunctivitis with a serous ocular discharge

In chronic cases, a **stromal keratitis** develops. The condition is frequently unilateral. The epithelium is eroded and there may be mild edema with some superficial vascularization. The cornea develops an **irregular surface with scarring** that is obvious on clinical examination and this is known as a geographic ulcer. This is the classical form of FHV-1 keratitis seen in older cats. It is **frequently only unilateral**, and may appear years after initial infection in cats with no previous history of eye disease.

Chronic stromal FHV-1 keratitis has a history of quiescent periods followed by signs of ocular pain with blepharitis, photophobia and corneal erosions. There is rarely conjunctivitis or ocular discharge.

A black staining color may develop in the center of the cornea known as a **corneal sequestrum** (keratitis nigrum). This is caused by a stromal coagulative necrosis, and it has been suggested that FHV-1 infection may be the cause of 80% of these lesions.

Diagnosis

Diagnosis is based on a **history of repeat ocular problems with subtle corneal changes**. It is difficult to establish a definitive diagnosis.

Cytology: intranuclear inclusions in epithelial cells can be demonstrated with immunoperoxidase stains in some acute primary infections. This is not very reliable.

Immunofluorescence: direct or indirect fluorescent antibody techniques on corneal/conjunctival smears or tissue sections. This has poor sensitivity.

Virus isolation by demonstration of cytopathic effects in cell culture. This is the gold standard for detection of herpesvirus, but is not often used because of logistical difficulties in getting rapid results.

Serology: antibody titers tend to be of low magnitude after primary infection, sometimes reaching only 1:64 at 60 days after infection. High titers are rarely seen after recrudescence infection.

Polymerase chain reaction (PCR) testing: DNA amplification of an amino acid sequence of the thymidine kinase gene is perhaps the most sensitive test available. Theoretically the test could pick up one strand of viral DNA. High sensitivity in nested PCR tests may reduce specificity by the detection of non-viral DNA contaminants. Although this test was initially heralded as an excellent diagnostic tool, in practice the results have been very disappointing. It would appear that sample collection and individual laboratories have a great influence on specificity.

- Conjunctival swabs and/or biopsies are used for PCR or virus isolation. Not all laboratories are equipped to do this work. Check with your laboratory, as you may have to send samples interstate or overseas for results.

Differential diagnosis

Ulcerative keratitis.

- Not common as a primary ocular disease, but is seen secondary to viral infection.
- It usually follows ocular trauma.

- The inflammation is more intense than herpesvirus keratitis with greater destruction of stromal tissue and more intense edema. Keratomalacia (melting cornea) can develop in cases with pseudomonas infections.
- Bacterial keratitis causes a mucopurulent discharge.
- Cytology from clean scrapings taken from the edge of the ulcer may demonstrate bacteria. Culture and sensitivity can be done from scrapings taken from the edge of the ulcerated cornea.
- Ulcers heal without recurrence.

Eosinophilic keratoconjunctivitis.

- This is a proliferative lesion that is usually accompanied by inflammation and a mucopurulent discharge.
- The presence of eosinophils on cytology is regarded as diagnostic.

Neoplasia.

- Squamous cell carcinoma of the cornea is reported, but it is a very rare condition in cats. The lesion is proliferative but there is little ocular discharge.
- Cytology or fine-needle biopsy will confirm this condition.

Treatment

Not all treatments useful for ocular herpesvirus infection are commercially available throughout the world.

Topical and probably systemic **corticosteroids are contraindicated** in all cases of ocular herpesvirus infections. The effect of topical NSAIDs has produced equivocal results experimentally. However, some cases of herpesvirus keratitis may only respond if corticosteroids are used in conjunction with antiviral agents.

Topical ocular antiviral agents include:

- **Idoxuridine** inhibits DNA synthesis by competing with thymidine for incorporation into viral DNA. It is no longer in production, but has been the most commonly used topical agent for treating FHV-1 infection. Topical drops are frequently made to order by a **compounding pharmacist** and produce excellent results. **Idoxuridine 0.1% drops are**

most commonly used. Drops need to be used at least three to four times daily.

- **Vidarabine** (adenine arabinoside, Vira-A, Parke-Davis) interferes with DNA polymerase and may be effective in cases that are resistant to idoxuridine. Use q 6–8 h.
- **Trifluorothymidine** (Viroptic, Glaxo Wellcome) has the best in vitro effect of all available topical agents. Use q 6–8 h.
- **Acyclovir** (Zovirax ophthalmic ointment, Glaxo-SmithKline) may be the only commercially available drug in some countries. The efficacy against FHV-1 has been reported as poor. Use q 6–8 h.
- **Dilute povidine iodine** (diluted 50% in saline) has been used, but there is only anecdotal evidence of its efficacy in clinical situations, and at this strength can be very irritating to eyes.

Oral antiviral agents include:

- **Acyclovir** (Zovirax) seems very effective, even at doses far below the in vitro ED_{50} . The usual dose is 50 mg/kg, q 6–12 h, but watch for toxic signs of bone marrow suppression even at this dose. Often used in conjunction with oral α interferon and synergism significantly reduces ED_{50} of acyclovir.
- **Valaciclovir** (Valtrex, GlaxoSmithKline) is an acyclovir prodrug, but rapid absorption of this drug in cats appears to make it more readily able to cause toxicity, especially in sick acutely infected cats.
- **Interferon α :** α interferon is a cytokine produced naturally by leukocytes. It may prevent viral spread if given in the very early stages of infection in acutely infected cats. Most common regimen is a 7-day on/7-day off oral course, which is believed to work by absorption through the oral mucosa and tonsils. Treatment with this drug is controversial and dosages vary widely. Systemic courses are also used by giving 10 000 IU SC twice weekly in conjunction with topical idoxuridine or acyclovir.

Other therapies that are used:

- **Oral lysine:** Lysine has been used in human medicine to suppress clinical signs of herpes simplex infections. Lysine competes with arginine for incorporation in the viral genome. Arginine is necessary for the replication of the FHV-1 virus and incorporation of lysine produces a non-infective virus particle. It may be more effective in cats with corneal disease

than conjunctivitis alone. The recommended dose is 250 mg daily.

- **Topical and/or systemic tetracycline** antibacterials are commonly used because of their specific effect on chlamydial and mycoplasmal organisms which may be present together with herpesvirus infections.
 - Tetracyclines have a mild anti-inflammatory effect on ocular tissue. They suppress antibody production and chemotaxis of neutrophils, and inhibit lipases, collagenases and prostaglandin synthesis. Research also shows that tetracyclines exert other pleiotropic properties independent of their antimicrobial activity which include inhibition of metalloproteases, blockade of nitrous oxide synthetase (a potent mediator of inflammatory activity), suppression of tumor progression, bone resorption and angiogenesis.

Ocular hygiene is important. Regular cleaning of infected eyes with poly-ionic eye wash solutions will make the cat feel more comfortable and suppress secondary bacterial infection.

Prognosis

The prognosis for a full and uneventful recovery of herpetic keratitis is **very guarded**.

In young cats with very severe corneal symblepharon formation it is nearly impossible to create a normal cornea. These cases will have permanent scarring and opacity of the cornea with virtually no vision.

In adult cats, a chronic recurrent state may develop, and in these cases the prognosis for permanent recovery is guarded.

Virus replication occurs in the cornea, and although not clinically obvious at the time of infection, this will manifest in older cats as a chronic geographic keratitis, sometimes years after the initial infection.

Transmission

FHV-1 is a ubiquitous viral organism found all over the world and is highly infectious.

Infection of kittens may occur through direct contact from a carrier state present in queens. Virus is shed 4–6 weeks after queening.

Infection is via contamination of mucous membranes (ocular, oral or inhalation of virus).

Prevention

Vaccination with live modified or killed vaccines (see page 10).

Elimination of carrier states in catteries.

Only use killed vaccines on clinically affected animals.

CORNEAL SEQUESTRUM (FELINE KERATITIS NIGRUM)**

Classical signs

- Area of pigmented cornea varying from a very light coffee-colored stain to an intense thick black plaque.
- +/- Blepharospasm and photophobia.
- Predominantly in brachycephalic breeds such as Persians and Himalayans.
- Usually unilateral.

Pathogenesis

This disease is unique to cats and has an unknown cause.

Recent research suggests that **FHV-1 keratitis may play a role** in about 80% of cases.

Other causes include corneal ulceration, chronic corneal trauma from medial entropion, and disruption of the tear film on exposed globes.

It is a corneal stromal disease characterized by **degeneration of collagen and fibro-blasts**. The surrounding stroma is usually infiltrated with a mixed population of white blood cells including neutrophils, lymphocytes, plasma cells, and less commonly macrophages and giant cells. The degree of pigmentation varies with the degree of stromal degeneration.

Lesions vary in depth from superficial stromal degeneration to full-thickness degeneration as deep as Descemet's membrane.

The source of pigmentation has not been established, but is probably absorbed by the damaged stroma from the tear film pigments, particularly porphyrins.

Clinical signs

Clinical signs vary from a faint **coffee-colored staining** of the axial (central) super-ficial cornea to a **dense black plaque**.

There may be a history of previous infection with FHV-1 as a kitten, or later in life, herpetic keratitis.

The disease is **initially seen unilaterally**, but eventually both eyes may become involved.

Initially the cat may not show any signs of discomfort, but as the lesion progresses **blepharospasm and photophobia** develop.

Early, light-staining lesions have an intact epithelium and do not stain with fluorescein. Lesions that have developed a dense plaque may have a **fine ring of ulceration surrounding the lesion** which may stain positive with fluorescein.

The surrounding cornea will not show signs of edema or vascularization in mild cases, but as the degree of degeneration progresses, corneal edema with marked deep stromal vascularization may be prominent.

Eyes that have a faint stain usually do not have any ocular discharge. Eyes that have a dark plaque with surrounding ulceration and intense corneal vascularization often have a mucopurulent ocular discharge.

The disease is seen predominantly in **Persians and Himalayans**, but any breed can be affected.

There is no sex or age predilection, but it is more common in adults.

Diagnosis

Diagnosis is based on the clinical signs of a mild brown-staining cornea to a dense black plaque with keratitis.

Histopathology of resected cornea will show a typical pattern of degenerated stroma surrounded by a ring of inflammatory cells.

PCR tests on resected cornea may confirm the presence of FHV-1 infection but results are usually unequivocal.

Differential diagnosis

There are no other ocular presentations that present with a brown discoloration.

Herpetic keratitis.

- Very chronic cases may have a dense white superficial scar with degrees of corneal vascularization. This scarred area may slowly develop a faint stain and progress to a dense black plaque, typical of corneal sequestrum. The initial changes in corneal sequestration are subtle and may be missed.
- PCR tests may help to associate this disease with corneal sequestrum.

Eosinophilic keratitis.

- The lesion is proliferative with an intense corneal edema and vascularization. There is no brown staining.
- Cytology shows the presence of eosinophils.

Ulcerative keratitis.

- There is a positive stain to fluorescein in the initial stages.
- Chronic healing ulcers may be vascularized and have edema (white). There is no brown pigment, but occasionally ulcers may progress to form a corneal sequestrum.

Treatment

Try to identify the cause and eliminate this. **Medial entropion and FHV-1 keratitis** are the two most common causes that need to be addressed. Surgically correct medial entropion and treat FHV-1 keratitis with an anti-viral agent (see Herpes keratitis, page 1239).

Conservative management is encouraged by some ophthalmologists, as some lesions may spontaneously slough and the cornea heals with a scar. **Broad-spectrum antibiotic ointments** such as neomycin and polymyxin, chloramphenicol or fucidic acid are used to lubricate the eye and guard against bacterial infection. **Antiviral agents** are often used to suppress the effects of herpetic keratitis. **Artificial tear solutions** may provide some relief from irritation and corneal drying.

Surgical management is the preferred option by the majority of ophthalmologists. The diseased stroma is resected by lamellar keratectomy, and the stromal defect closed with either a pedicle conjunctival graft or a sliding corneo-scleral graft. Partial- or full-thickness keratoplasty (corneal graft) has been used in an attempt to minimize corneal scarring, but results have not been very encouraging as the cornea vascularizes and scars. For surgical techniques readers should refer to an

ophthalmology text which describes the surgery in detail (see references).

Prognosis

The prognosis in cases that slough after medical management is reasonable. Some of these lesions may recur, and scarring will be intense causing vision impairment. However, cats with axial scarring seem to be able to lead a reasonably normal lifestyle.

Healing after pedicle grafts or cornea-scleral grafts is good, but scarring is present. Scarring is less intense after a sliding corneo-scleral graft as the opaque grafted scleral tissue is confined to the outer cornea.

Keratoplasty has not been widely embraced by veterinary ophthalmologists because rejection, vascularization and scarring of grafts occurs in other animal species. However, the cat cornea reacts more like human cornea to grafting than other animals, and therefore, is supposed to be amenable to full-thickness keratoplasty.

Transmission

Apart from FHV-1 infection, there is no known transmission of this disease from one cat to another. Cases with herpetic keratitis have the same etiopathogenesis as is described under this heading.

Prevention

There is no known prevention, apart from palliative treatment of corneal ulcers and herpetic keratitis. Cases associated with medial entropion should have surgical correction of the eyelid problem.

ULCERATIVE KERATITIS CAUSED BY CORNEAL PERFORATION (CAT FIGHT WOUNDS)**

Classical signs

- Acute very painful eye guarded with blepharospasm. Serous discharge, often containing blood.
- Very cloudy cornea usually with a linear wound or triangular tear that is plugged with fibrin.

Classical signs—Cont'd

- Collapsed anterior chamber with varying degrees of hyphema (blood) and protein.
- Iris prolapse may be seen as black bulge in the wound.
- If the wound has not sealed and is leaking aqueous humor, there will appear to be excessive amounts of tearing and the face will be wet.

Pathogenesis

Cat claw wounds are the most common cause of corneal perforation.

When the cornea is perforated the anterior chamber collapses. If the wound is large enough, the iris comes forward to plug the defect causing an **iris prolapse**.

An immediate prostaglandin reaction is set up within the eye, **causing leakage of protein** from the iris and ciliary body blood vessels.

The sudden decompression of the globe causes **hemorrhage in the anterior chamber**. The hemorrhage may also be caused by an injury to the iris by the penetrating claw.

The anterior lens capsule may be torn, causing **lens rupture**. This causes a severe antigenic reaction to the released lens proteins within the globe.

The wound is plugged by fibrin in cases where there is no iris prolapse. This forms a platform for fibroblasts to develop and the healing process in the wound is begun.

Secondary complications are common with anterior synechia (adhesion of iris to cornea) and posterior synechia (adhesion of iris to anterior lens capsule). This causes distortion of the pupil (dyscoria).

Secondary glaucoma may develop if the iridocorneal angle becomes obstructed.

Cats with ruptured lenses are at risk for developing an **intra-ocular sarcoma** (see The Cat With a Cloudy Eye, page 1276).

Clinical signs

Corneal perforations are severe corneal injuries that present as **ocular emergencies**. Cat claw injuries are

the most common cause of corneal perforation, and there may be other evidence of skin wounds from the fight.

The perforated corneal lesion is usually with a **linear wound or triangular tear that is plugged with fibrin** surrounded by a **dense area of edema**. The injured cornea may be covered with a layer of fibrin.

The **eye is held tightly closed**, and cats with this injury will resist any handling of the eye.

There will be a **serous discharge** often tinged with fresh blood.

The **anterior chamber may be very shallow and the globe very soft**.

If the wound has not sealed and is leaking aqueous humor, the face will be wet and there will appear to be excessive amounts of tearing.

A black, bulging area in the wound is a sign of an **iris prolapse**. In lightly pigmented irises, the bulge may be brown in color.

Another sign of iris prolapse is a distorted pupil with the affected iris leaflet presenting towards the wound. This can only be visualized if the anterior chamber is not filled with blood.

Cats that have a penetrating corneal lesion should be **examined carefully for signs of lens rupture**. This can be very difficult to ascertain. An obvious tear in the anterior capsule may be seen in the pupil space if the pupil is not miotic, and the anterior chamber is not very cloudy or full of blood. Sometimes leakage of lens protein seen as **thick transparent jelly-like material** can be seen in the anterior chamber. However, if the tear in the lens capsule is under a small wound in the peripheral iris, it may be impossible to see. In such cases, watch for **intense uveitis that will not respond to therapy**. A cataract will form in the injured lens.

These cases need to be referred to a veterinary ophthalmologist whenever possible.

Iris prolapse may be difficult to differentiate from a descemetocoele in cases that have a very painful eye.

Differential diagnosis

Keratomalacia (melting ulcer).

- A very cloudy cornea with soft gelatinous stroma covering a large area.

- Usually with history of previous ulcer, and is therefore not an acute injury.
- May be some hypopyon (protein and cells in the anterior chamber) present.

Descemetocoele.

- Usually history of ulceration.
- The lesion is mostly axial (central) and there is rarely blood or protein in the anterior chamber.
- The globe is not soft and maintains normal to slightly lower IOP.
- The surrounding cornea is frequently quite healthy.

Treatment

If the corneal tear is small, near the limbus, and is well sealed with a fibrin plug, **conservative treatment** can be used.

- **Protect the cornea** with a third eyelid flap or temporary tarsorrhaphy.
- **Dilate the pupil with topical 1% atropine.**
- Use a **topical broad-spectrum antibiotic** drop and protect the eye from infection with **systemic broad-spectrum antibiotics**. **NEVER use an ointment** when there has been a penetrating corneal injury, as ointment bases that enter the anterior chamber will cause an intense and chronic foreign body uveitis.
- Cats with acute eye injuries should be given **systemic NSAIDs** to minimize the effects of an intra-ocular prostaglandin reaction.

Do not use topical corticosteroids when the cornea is ulcerated as this will predispose keratomalacia.

When there is a large tear or there is an iris prolapse, microsurgery is required to suture the cornea. The iris needs to be gently teased back into the anterior chamber, which should be flushed to remove blood and fibrin. Viscoelastic solutions are then used to space the anterior chamber, and the corneal deficit is sutured with interrupted 8/0 to 10/0 nylon or absorbable suture material. This is very specialized surgery that requires specialist training, magnification and specialized instrumentation.

- The pupil is then dilated with atropine, infection prevented with broad-spectrum topical and systemic antibiotics, and NSAIDs given to minimize inflammation.

If the lens has been ruptured, a **lensectomy** has to be performed. Remember that these cases may develop

intra-ocular sarcoma at a later date, so owners must be warned of the danger.

Prognosis

Cases with no damage to the iris or lens have a good prognosis.

Cases with iris tears, prolapsed iris and ruptured lenses have a favorable to poor prognosis.

Glaucoma may be a sequela in cases with complications.

KERATITIS SECONDARY TO UVEITIS**

Classical signs

- Cloudy blue cornea and a red sclera/conjunctiva.
- +/- Keratic precipitates (mutton fat deposits) on cornea.
- A hypopyon (cloudiness) in the anterior chamber.

See the main reference on page 1259 for details (The Cat With a Cloudy Eye).

Clinical signs

The cat presents with a **cloudy blue cornea and injected red sclera and conjunctiva**.

The corneal cloudiness is caused by edema from compromised endothelial function.

Keratic precipitates (mutton fat deposits) may be present on the inferior endothelium of the cornea.

A **hypopyon (protein and white blood cells)** may be present in the anterior chamber, and evident as a cloudiness of the aqueous fluid.

The pupil will usually be **miotic** (constricted).

The cat will usually have a systemic disease such as **toxoplasmosis, cryptococcosis, FeLV, FIV or FIP or systemic mycoses**.

Diagnosis

A **tentative diagnosis is based on signs** of a red, cloudy eye and other classic signs of uveitis such as hypopyon and keratic precipitates.

Cats with acute uveitis need to be worked up for systemic diseases. The most common rule outs are toxoplasmosis, cryptococcosis, FeLV, FIV, FIP (in young cats) and systemic mycoses in North America.

EOSINOPHILIC KERATITIS*

Classical signs

- Irregular white to pinkish plaque on the cornea.
- Corneal edema and vascularization.
- +/- Similar conjunctival lesion.
- Unilateral or bilateral.
- Poor response to a variety of antibacterial agents.

Pathogenesis

The disease is thought to be **immune-mediated or an allergic response** peculiar to cats.

There is no age, sex or breed predisposition.

Eosinophilic keratitis is a **proliferative lesion** with an intense infiltration of inflammatory cells including plasma cells, lymphocytes, eosinophils and occasional histiocytes and mast cells. The corneal stroma shows edema and intense vascularization, both superficial and deep.

Insect bites from (insects) and food allergies have been documented as causes of this condition. It has also been suggested that this response may be an ocular form of the “Eosinophilic granuloma disease complex”, particularly the linear granuloma response. See The Cat With Salivation (page 586).

Clinical signs

Signs **begin unilaterally**, but may become bilateral.

Seen as a cloudy, red cornea. This is a proliferative lesion producing **whitish to pink, plaque-like tissue** that may be covered by a thick white discharge.

The corneal epithelium is usually intact, but may show **patchy staining with fluorescein**. There is usually an **intense neovascularization** (superficial and deep) in chronic cases. There is varying degrees of edema, usually involving the entire cornea.

The conjunctiva is usually involved secondary to the cornea, and may present with a **similar white, proliferative plaque** and mucopurulent ocular discharge.

The third eyelid may also show proliferative lesions.

There is often a history of a **poor response to a variety of antibacterial agents**.

Diagnosis

There is usually a history of an **edematous, vascularized** cornea that will **not respond to antibiotic therapy**.

Clean the eye with saline or eye wash, and take a scraping of the lesion using a scalpel blade, spatula or cytology brush. Gently spread the tissue onto a glass microscope slide and stain with a Wright or Romanofski stain. The presence of **eosinophils is diagnostic**. If conjunctival lesions are present, preferably take a sample from the conjunctiva.

The use of cytology brushes on the cornea and conjunctiva will give the best results for examination of cell structure.

Small conjunctival biopsies can be submitted in formalin for histopathology. The presence of eosinophils is diagnostic. These may be easily taken by applying local anesthetic (preferably proxymetacaine) in the eye, and removing a small snip of conjunctiva from under the upper or lower eyelid with a fine pair of forceps and scissors.

Hematology may reveal a peripheral eosinophilia.

Differential diagnosis

Chronic ulcerative conjunctivitis.

- Ulcers that heal with proliferative granulation tissue are rare in the cat. However, chronic ulcers may present with intense vascularization and granulation of the stroma.
- Eosinophils will not be present in cytology of such lesions.

Keratomalacia (melting cornea).

- This is usually an acute corneal problem with severe edema and loss of stromal tissue forming a deep extensive ulcer. There is rarely vascularization. These lesions may be infected with

Pseudomonas aeruginosa, which can be cultured from the edge of the ulcer with a swab moistened in sterile saline.

Chronic herpetic keratitis.

- Chronic herpetic keratitis may present with a large irregular area of corneal scarring and mild superficial corneal vascularization, but the lesion usually has superficial ulceration and is not proliferative. The cornea rarely shows the same intense vascularization and edema seen in eosinophilic keratitis.
- There will be a history of poor response to antibiotic therapy.
- Cytology will not reveal eosinophils.
- PCR tests on conjunctival and corneal tissue may help to differentiate.

Neoplasia.

- Squamous cell carcinoma of the cornea has been seen, but it is a very rare condition in cats. The lesion is proliferative but there will not be much ocular discharge.
- Cytology or fine-needle biopsy will confirm this condition.

Treatment

The condition will rapidly respond to systemic corticosteroids dosed at 1 mg/kg q 12 h PO.

Topical prednisolone acetate 0.5 or 1% drops applied q 8–12 h are excellent providing there is no ulceration of the cornea.

If tips of the ears show alopecia, pruritis and crusting the condition may be caused by biting insects. Such cases have been documented in Queensland, Australia. These cats should be housed in conditions that are insect free to prevent reoccurrence.

Allergic states caused by diet have been implicated.

Dietary exclusion tests may be useful to eliminate this as a cause. See “The Cat With Signs of Chronic Small Bowel Diarrhea” (page 739).

Prognosis

The prognosis is very favorable in cases that respond to corticosteroids. Corneal scarring may be a sequela after chronic keratitis.

The prognosis is improved if the cause of the allergic state can be found and controlled.

ULCERATIVE KERATITIS (NOT ASSOCIATED WITH SPECIFIC CORNEAL DISEASE OR CORNEAL PERFORATION)*

Classical signs

- Ocular pain with serous discharge, blepharospasm and photophobia.
- Varying degrees of corneal cloudiness.
- Very cloudy cornea with a soft gelatinous appearance (melting ulcers or keratomalacia).
- Black area within a cloudy cornea, and a thin, bulging membrane at the center (Descemetocoele).
- Positive staining of the stroma with fluorescein dye, except where a Descemetocoele is present.

Pathogenesis

Most ulcers that are not associated with a specific corneal disease state are caused by **corneal trauma**. Foreign bodies such as **grass seeds and thorns**, or **blunt trauma from motor vehicle** accidents are the most common causes of corneal trauma. Trauma may cause a superficial ulcer, a deep ulcer or penetrating wound.

Ulcers may **vary from a superficial loss of epithelium to a deep stromal defect**.

Corneal edema develops when there is loss of epithelium, because the stroma absorbs fluid causing the stromal matrix to swell.

A **Descemetocoele** forms when there is **no stromal tissue present**, but Descemet's membrane is intact. In cats, Descemet's membrane is very elastic and can bulge considerably within the corneal defect.

Melting ulcers (keratomalacia) develop when the stromal tissue undergoes some form of **autolysis**. This may occur from **proteolytic enzymes** present in **damaged epithelial cells**, from enzymes produced by **neutrophils and macrophages** in the tear film, and from

bacteria especially *Pseudomonas* spp., which produce proteolytic enzymes.

Clinical signs

Eyes with ulceration are **invariably very painful**. Cats show serous ocular discharge, blepharospasm, photophobia and ocular guarding in severe injuries.

Ulcers stain **positive with fluorescein dye**. A very deep ulcer that has formed a **Descemetocoele may not show any staining** because Descemet's membrane will not hold dye.

Examination of the cornea with magnification will show a deficit in the corneal surface due to loss of epithelium and stroma.

Corneal edema will be present in cases that have loss of epithelium, because fluid will be absorbed by the stromal matrix. This will show as a **cloudy cornea**. Edema may be focal, around the ulcer or diffuse when large ulcers are present.

A **Descemetocoele** usually looks like a **thin, bulging membrane** in an area where there is a very deep ulcer. It may have a **black appearance** caused by a reflection from the pupil behind. It is usually a more **chronic condition** in the cat where there has been an ulcer for some time.

Cats with chronic ulcers often **do not show much inflammatory reaction** in the cornea. It is common to see chronic ulceration in cats with **no sign of neovascularization**.

Ulcers that develop into a **melting cornea** are devastating conditions that appear with a **rapidly developing cloudy edematous cornea that has a gelatinous soft appearance**. The eye is extremely painful and the threat of rupture is very high. They are often infected with *Pseudomonas* spp.

Diagnosis

There may be a **history of trauma or a cat fight**. The **diagnosis is made on clinical examination** by finding a painful eye showing a stromal deficit.

The ulcer will stain with fluorescein except in the case of a Descemetocoele.

If the center of the ulcer is dark, and the area bulges, there may be a Descemetocoele. Descemet's membrane

is very elastic in cats and can bulge forward quite noticeably.

Where the cornea is soft and gelatinous, a **swab should be taken from the lesion** and sent to the laboratory for culture and sensitivity.

Perforating injuries are very painful, and show changes in the anterior chamber such as hyphema and protein leakage with fibrin, whereas non-perforating ulcers such as descemetocoele rarely show changes in the anterior chamber.

Differential diagnosis

Herpetic keratitis.

- Usually appears as a superficial ulcer with an irregular appearance.
- PCR tests may be helpful to differentiate from chronic superficial ulceration.

Eosinophilic keratitis.

- This is a proliferative lesion, but the epithelium may be eroded with a positive fluorescein stain.
- Cytology should show the presence of eosinophils.

Iris prolapse (differential for descemetocoele).

- An acute, very painful eye with cloudy cornea and usually hemorrhage in the anterior chamber. The eye will be soft and the anterior chamber shallow. The prolapsed iris tissue may be black or brownish in color depending on the degree of pigmentation in the iris. There may be a fibrin clot present over the iris, plugging the wound. The wound is usually linear in shape rather than oval to round as seen in ulcers.

Treatment

As a general rule, **eliminate the cause of the ulcer** and provide **protection for the cornea** using lubrication, appropriate antibiotics where necessary and surgical techniques to close and protect the eye.

Superficial epithelial erosions heal rapidly with minimal treatment. The use of antibiotics is not encouraged as they are rarely infected. **Support with artificial tear solutions** will make the eye more comfortable.

Corneas with deep ulcers that have stromal loss **need to be protected with surgical techniques** such as third eyelid flaps or temporary tarsorrhaphies (see references for texts that show details of these surgical techniques).

- **Antibiotics** are often used topically to prevent secondary infection. If the ulcer is infected, then appropriate antibiotics should be used after culture of a swab taken from the edge of the ulcer.
- **Artificial tear solutions** will lubricate the eye and make the cat feel more comfortable.
- **Atropine ophthalmic drops** (most commonly 1%) are used to dilate the pupil and to prevent ciliary muscle spasm. They should be used two to three times daily until the pupil is dilated, and daily thereafter (NOTE: atropine drops are very bitter and often make cats salivate profusely). For this reason 1% atropine ointment is often used, as the drug does not run down the tear duct as fast.

NEVER use topical corticosteroids when a corneal ulcer is present, as this will predispose to keratomalacia (melting ulcer).

BACTERIAL ULCERATIVE KERATITIS*

Classical signs

- Painful, edematous eye.
- Mucopurulent discharge.
- Cornea may have a soft gelatinous appearance (melting ulcer/keratomalacia).
- Ulcers are not as well defined.
- Anterior chamber, where visible may be cloudy.
- Positive staining of the stroma with fluorescein dye, except where a descemetocoe is present.

Pathogenesis

There are no specific primary bacterial conditions that affect the cornea in cats. **Infections are secondary to injury.**

Ulcers become infected secondarily, usually with *Streptococcus* spp. or *Staphylococcus* spp., which are the common pathogens associated with eye infections.

Pseudomonas infection may cause a “melting ulcer” (keratomalacia). The cornea loses definition and becomes quite soft and jelly-like. This is caused by **protease enzymes** secreted by the bacteria, and by self-digestion of stroma by enzymes secreted from dying

epithelial cells and neutrophils and macrophages present in the ocular discharges.

Clinical signs

Signs are the same as for **ulcerative keratitis**

Eyes with bacterial ulceration may be much **more painful** than an eye with an uninfected ulcer. The **discharge** is likely to be **mucopurulent** rather than serous, and can be quite copious as there may be concurrent conjunctivitis.

Eyes are **photophobic** and there is guarding of the affected eye. Cats will resist handling of the eye.

Ulcers stain **positive with fluorescein dye**, except where a descemetocoe is present.

Corneal edema will be much more obvious and intense when there is infection. The entire cornea may be quite cloudy and look very soft and jelly-like when there is a melting ulcer or keratomalacia. Ulcers are not as well defined.

When visible, **the anterior chamber may be cloudy**. Often there is **secondary uveitis** causing cloudiness of the anterior chamber, because protein and cells are excreted from the iris and ciliary body.

Ulcers that develop into a **melting cornea** are devastating conditions. They appear as a **rapidly developing cloudy edematous cornea that has a gelatinous soft appearance**. The eye is extremely painful, and the threat of rupture is very high. They are often infected with *Pseudomonas* spp.

Diagnosis

There may be a **history of trauma or a cat fight**. The **diagnosis is made on clinical examination** by finding a painful eye showing a stromal deficit.

The ulcer will stain with **fluorescein**, except in the case of a descemetocoe.

Where the cornea is soft and gelatinous, a **swab should be taken from the lesion**, and sent to the laboratory for culture and sensitivity.

Cytology is useful to help choose immediate treatment. Using a Wrights stain, *Streptococcus* spp. and *Staphylococcus* spp. appear as single **cocci** or bunches of round,

purple-staining cocci, free or in cells. One slide should also be stained with a Gram stain. *Pseudomonas* bacteria are seen as **rods**, and stain positively with a Gram stain.

Treatment

Infected ulcers need aggressive treatment.

As a general rule, **frequent use of appropriate antibiotic drops** is required every 15 min to hourly for at least 24 hours, followed by drops every 4 hours. Ointments can be used where there is no keratomalacia, and do not need to be used as frequently. **Superficial ulcers** heal rapidly and need less-frequent treatment.

- When an ulcer is infected, appropriate **antibiotics should be used based on culture** of a swab taken from the edge of the ulcer. If in doubt, use a broad-spectrum antibiotic that will control both Gram-positive and Gram-negative bacteria.
- Where a ***Pseudomonas* infection** is suspected or confirmed by laboratory analysis, the cat must be treated vigorously with **aminoglycoside** (commonly gentomycin or tobramycin in gentomycin-resistant cases) or **fluoroquinolone** (some generations such as flucloxacillin are effective) antibiotics **topically every 15 minutes to 1 hour** until the infection is controlled. They may also be used systemically but particular care should be used with aminoglycosides in cats, as they are ototoxic and nephrotoxic. Toxicity may occur from frequent topical use, so monitor cases carefully.

Corneas with deep ulcers that have stromal loss **need to be protected with surgical techniques** such as **third eyelid flaps or temporary tarsorrhaphies** (see references for texts that show details of these surgical techniques).

Artificial tear solutions will lubricate the eye and make the cat feel more comfortable.

Atropine ophthalmic drops (most commonly 1%) are used to dilate the pupil and to prevent ciliary muscle spasm. They should be used two to three times daily until the pupil is dilated, and daily thereafter (NOTE: atropine drops are very bitter and often make cats salivate profusely). For this reason 1% atropine ointment is often used, as the drug does not run down the tear duct as fast.

In cases where secondary uveitis is present, systemic treatment with NSAIDs at appropriate doses and systemic antibiotics are recommended.

NEVER use topical corticosteroids when a corneal ulcer is present, as this will predispose to keratomalacia (melting ulcer).

Prognosis

Prognosis is good in cases with simple superficial ulcers.

Prognosis is guarded if the entire cornea has keratomalacia, or if there is hypopyon and secondary uveitis.

BLUNT TRAUMA

Classical signs

- Painful, cloudy and red eye.
- Cornea may have superficial ulcer or be ruptured (usually around the limbus).
- Conjunctiva may be red from subconjunctival hemorrhage.
- The anterior chamber may be filled with blood (hyphema).
- Eye may be bulging (exophthalmos) from edema and hemorrhage in the orbit.

Pathogenesis

Blunt trauma causing corneal damage is usually the result of a **motor vehicle accident**.

Clinical signs

The blunt trauma may cause an **abrasion on the surface of the cornea**, usually with loss of epithelium. This is evident as positive staining with **fluorescein dye**.

Rupture of the cornea may be evident, and is **usually at the limbus** because this appears to be the area that is weakest and absorbs most of the force when the cornea is flattened inwards. The **iris may protrude from the wound** and is seen as **brownish pigmented tissue**.

Hemorrhage from iris root tears and ciliary body trauma is common with this type of injury, and is seen as **hyphema**.

Subcutaneous and scleral hemorrhage may also be present.

In cats with **orbital hemorrhage**, the eye will bulge forward (**exophthalmos**) and the cat may have difficulty closing the eye. **Rapid drying of the cornea** then occurs causing further loss of epithelium, which results in **severe ulceration**.

Diagnosis

Diagnosis is based on a **history of trauma**, and the **clinical appearance**. Typically there is a corneal ulcer or rupture, and hyphema with subcutaneous hemorrhage, with or without exophthalmos.

Ocular ultrasound is a useful tool when the anterior chamber cannot be visualized because of hyphema. Look for lens displacement and check if there is a normal scleral contour at the back of the eye. Vitreous hemorrhage is seen as a dark hyperechoic area between the lens and scleral contour.

Treatment

Superficial ulcers can be treated with lubrication using artificial tear solutions. If infection is present, a topical antibiotic drop or ointment may be used.

In cats with **limbal rupture**, treatment depends on whether there is iris prolapse or not. If there is a **simple tear without complication**, then the condition may be treated conservatively with **antibiotic drops, systemic NSAIDs and systemic broad-spectrum antibiotics**. **Do not use ointment** in cats with **corneal rupture**, as the ointment base may enter the eye and cause **severe uveitis**.

In cats with **limbal rupture complicated with iris prolapse, microsurgery** needs to be done to correct the iris prolapse and suture the corneo-scleral wound. If possible, referral to an ophthalmologist is encouraged. **Topical and systemic antibiotics** should be used in conjunction with a **systemic NSAID**.

Where **exophthalmos** is present, the eye must be closed with a **third eyelid flap** or preferably a **tarsorrhaphy**. Use nylon sutures in a mattress (preferably) or interrupted pattern through the middle of the eyelids.

Prognosis

For eyes with **superficial ulceration** and mild hyphema, the prognosis is very good.

Eyes with a **limbal rupture** have a good prognosis if the lesion is not very large and is not complicated with iris prolapse.

Eyes with **severe trauma** and hyphema, complicated by lens luxation or rupture and vitreous hemorrhage, have a poor prognosis.

Eyes with exophthalmos from orbital swelling and corneal desiccation, can develop **very deep and complicated ulcers** if not treated correctly.

NEUROTROPIC KERATITIS

Classical signs

- Chronic mild keratitis with superficial ulceration and superficial vascularization.
- Cornea looks dry and lusterless.
- Poor blink reflex or poor corneal reflex or both.

Pathogenesis

Cats that have **facial nerve damage** may have a **poor to absent blink reflex**. This results in drying of the cornea, as the tear film is not distributed over the cornea. The consequence is poor **epithelial health and superficial ulceration**.

Some cats cope well with paralyzed lids, as the third eyelid acts as a sweep to distribute tears over the cornea.

Cats with injury or infection affecting the **trigeminal nerve** may show complete **lack of corneal sensation** (reflex). When the cornea has no innervation, chronic keratitis may develop producing **superficial ulceration and neovascularization**.

Clinical signs

Neurotropic keratitis appears as a **chronically sore eye with poor blink reflex**. To test for this condition, gently touch the eyelids and they should automatically close if normal.

A **dry and lusterless cornea** with **superficial ulceration** and superficial neovascularization is typically seen.

Lack of eyelid closure or corneal sensation is evident. To test corneal sensation, use a thin piece of rolled cotton wool or a thread of cotton, and touch the cornea from the side of the eye. Try not to allow easy visualization of the test material, otherwise the animal will respond to the visual stimulus and not the touch stimulus. In a normal cornea, the eyelids should close immediately the cornea is touched.

Cases with corneal denervation have the same signs as those with lack of blink reflex. Even when the blink reflex is normal, and the tear film is normal, **if the cornea has no innervation** it will develop a **neurotropic keratitis**.

Diagnosis

A diagnosis is based on history and signs of **trauma or ear infection affecting the facial or trigeminal nerve**. Lack of corneal reflex or blink reflex is definitive.

Chronic keratitis which is usually mild, and accompanied by varying degrees of **superficial ulceration and vascularization**.

Differential diagnosis

Herpetic keratitis.

- These cases have superficial ulcers with neovascularization of varying degrees, but the blink and corneal reflex remains intact.

Treatment

Topical treatment with artificial tear solutions is of great benefit. The eyes need to be treated frequently for best results.

Temporary closure of the eyelids with a tarsorrhaphy is useful short term.

In chronic cases, the **eyelids may be permanently closed centrally to protect the cornea**. Refer to ophthalmology texts for surgical techniques.

Prognosis

Signs often **improve after a period of 3–6 months** when nerve function is improved or restored. Other cases need to be managed for life.

FLORIDA KERATOPATHY (“FLORIDA SPOTS”)/MYCOBACTERIAL KERATITIS

Classical signs

- **Focal gray-white opacities in the anterior stroma of the cornea.**
- **Usually affects both eyes.**
- **Only recognized in the southeastern USA.**

Clinical signs

One, or more commonly both, **corneas have focal white to gray opacities** in the anterior stroma, varying in diameter from 1–8 mm in size.

The **condition is asymptomatic** as cats show no signs of ocular pain or irritation, and there is no associated inflammation in the cornea.

The condition has **only been described in the USA**, and is suspected to be **associated with infection**.

- **Rhinosporidium** was initially diagnosed from histological samples. However, ultrastructural examination of affected cornea showed vacuoles with amorphous material and **rod-like organisms characteristic of mycobacteria** that stain positively with Ziehl–Neelsen carbolfuchsin stain.

Diagnosis

A **tentative diagnosis is based on geographical location and signs** of a cornea with multiple focal opacities in the anterior stroma and the cat shows no irritation or inflammation.

A **definitive diagnosis is based on histological findings**.

Differential diagnosis

A focal lesion with **acid-fast bacilli** that progresses to form a fleshy white lesion has been described in the **northwest USA**.

Histology shows an inflammatory response with infiltration of neutrophils and mononuclear cells.

This lesion is said to resemble the skin lesion in **cat leprosy**, and is thought to be a different disease to “Florida spots”.

Treatment

Treatment with antibiotics and corticosteroids does not alter the appearance of the lesions.

STROMAL DYSTROPHY OF MANX CATS

Classical signs

- Young Manx cats.
- Begins with stromal edema that progresses to a cornea filled with large bullae.

Clinical signs

Rare disease of young Manx cats. Cats present with an axial (central) **stromal edema** which progresses to diffuse corneal edema and a **thickened corneal stroma filled with bullae** (fluid-filled vesicles).

Affected cats become blind.

Histology demonstrates progressive disintegration of stromal collagen fibers which are replaced with fluid-filled vesicles. Eventually the epithelium separates from its basement membrane and ulceration occurs.

Diagnosis

A tentative diagnosis is based on the presentation of a young Manx cat with corneal edema.

A **definitive diagnosis** is based on **histopathology**.

Differential diagnosis

There is no similar condition seen in Manx cats.

Treatment

There is **no definitive treatment**, and cats will become blind.

If ulceration occurs, methods used to **protect the cornea** such as third eyelid flaps and tarsorrhaphies may keep the cat comfortable. Resolution of ulceration will be difficult, and conjunctival grafts may have to be used to seal the corneal defects.

ENDOTHELIAL DYSTROPHY

Classical signs

- Progressive corneal edema that eventually leads to blindness.

Clinical signs

Rare condition in **young (4-month-old) Domestic Shorthair cats**.

Endothelial dystrophy results in **progressive corneal edema seen as a cloudy blue cornea, which leads to blindness**.

The corneal **epithelium is intact**, and there is no staining with fluorescein dye.

If the anterior chamber can be examined, there is no sign of inflammation such as flare or hypopyon indicating the presence of protein and white blood cells.

The cause of the condition is not known, and no treatment is possible.

Diagnosis

A **tentative diagnosis is based on the signs** in a young cat of progressive corneal edema, no staining with fluorescein dye, and no history of trauma to the eye or inflammation.

There is **no definitive diagnosis**.

CALCIFIC DEGENERATION

Classical signs

- Linear deposit of calcium in the anterior stroma with a shiny, gritty appearance that may be vascularized.
- Rare condition associated with chronic herpetic keratitis.

Clinical signs

Calcific degeneration is seen as a **linear deposit of calcium in the anterior stroma**, known as a **band keratopathy**. The affected area has a shiny, gritty appearance and may be vascularized.

There will be a **history of herpes keratitis** with chronic ulceration and scarring of the cornea.

This is a rare condition in the cat.

Diagnosis

A **tentative diagnosis is based on signs** of a focal shiny, gritty lesion on the cornea associated with a chronic herpetic keratitis.

LYSOSOMAL STORAGE DISEASES WITH OPHTHALMIC MANIFESTATIONS

Classical signs

- A very rare condition in the cat.
- Young cats that develop progressive corneal opacity with a “ground glass” appearance.
- Usually neurological signs such as ataxia, muscular tremor and paralysis.

See the main reference on page 935 for details (The Cat With Ataxia Without Weakness).

Clinical signs

Signs begin in **young cats** around 3–6 months of age.

The **cornea develops a ground-glass appearance** that is seen as a corneal opacity. This is caused by vacuole formation in keratocytes and endothelial cells.

Affected cats usually have **neurological signs**, which include ataxia, muscular and head tremors, paralysis and hypermetria.

The retinal ganglion cells and cells in the inner nuclear layer can be affected with vacuole formation.

Diagnosis

A **tentative diagnosis is based** on the **clinical presentation** in a young cat with neurological signs and ocular signs such as corneal opacity.

A **definitive diagnosis** is made based on **histopathological examination** of neural tissue using specific staining techniques usually from tissues obtained at post mortem. A specialist pathologist will be needed to make the diagnosis.

Lysosomal storage diseases with ophthalmic manifestations include:

- GM 1 gangliosidosis.
- GM 2 gangliosidosis.
- Alpha mannosidosis.
- Mucopolysaccharidosis 1 (MPS1).
- Mucopolysaccharidosis 2 (MPS2).

61. The cat with a cloudy eye

Richard IE Smith

KEY SIGNS

- Cloudiness of the cornea, anterior chamber, lens or vitreous.

MECHANISM

- A cloudy eye is usually caused by a change in the transparency of the clear structures of the eye.

WHERE?

- Cornea.
- Anterior chamber.
- Lens.
- Vitreous.

WHAT?

- The most common causes of a cloudy eye are diseases that cause edema or scarring of the cornea, and uveitis, which causes cloudiness in the aqueous humor and/or vitreous as a result of protein and cells leaking through inflamed uveal blood vessels. Hereditary cataract (opacity of the lens) is rare in cats, but cataracts may develop secondary to uveitis. Nuclear sclerosis is a common cause of lens cloudiness in old cats.

QUICK REFERENCE SUMMARY

Diseases causing a cloudy eye

WHERE?

CORNEA

DEGENERATIVE

- **Corneal sequestrum (feline keratitis nigrum)** (p 1260)**

Presents with an axial (central) area of staining (light brown to black) in the cornea, and is usually unilateral. Most common in brachycephalic breeds such as Persians and Himalayans. Approximately 80% are associated with herpetic keratitis. In the early stages there is no ulceration, but chronic lesions may have ulcerated borders surrounded by an inflammatory zone with intense vascularization.

ANOMALY

- **Corneal (stromal) dystrophy of Manx cats (p 1264)**

A rare condition in young Manx cats that starts with axial stromal edema and progresses to a diffuse corneal edema with a thickened stroma full of bullae (fluid-filled vesicles). It is a blinding corneal disease with no treatment possible.

INFLAMMATION/INFECTIOUS

- **Feline herpesvirus-1 keratitis*** (p 1259)**

Cats may have a history of FHV-1 infection as kittens. Often appears as a unilateral disease in older cats. The epithelium may show dendritic lesions (finger-like projections of thickened epithelium that stain with rose bengal stain) in early cases. Chronic cases show irregular (geographic) ulceration to the level of the superficial stroma. Scarring and vascularization of the cornea follows after repeated inflammatory episodes.

- **Mycobacterial keratitis ("Florida spots") (p 1264)**

Focal grayish opacities seen in the stroma caused by a mycobacterium. Only seen in the southeast USA.

INFLAMMATORY/NON-INFECTIOUS

- **Ulcerative keratitis* (p 1262)**

A very painful, cloudy eye with serous discharge, blepharospasm and photophobia. Usually occurs secondary to corneal trauma. Superficial ulcers have loss of epithelium, which is seen as an erosion of the surface, and stains green with fluorescein dye. Deeper ulcers have a hollow caused by loss of stroma.

Immune-mediated:

- **Eosinophilic keratitis* (p 1261)**

Seen as a cloudy, red cornea, sometimes with a muco-purulent discharge. A proliferative white to pinkish plaque develops on the cornea, with superficial and in chronic cases, deep vascularization. Usually a history of poor response to antibiotic therapy. Eosinophils demonstrated on cytology from corneal scrapings are diagnostic.

Trauma:

- **Cornea scarring from injury* (p 1263)**

Opaque areas on cornea, which vary in size and intensity. There is no pain or discharge associated with these opacities, and usually there is a history of previous severe ocular inflammation or trauma.

WHERE?

ANTERIOR CHAMBER

METABOLIC

- **Lipemic aqueous (p 1270)**

The anterior chamber looks milky, but intra-ocular architecture can be visualized. Signs may be unilateral or bilateral, and may have a sudden onset. Occurs secondary to anterior uveitis in cats on a high-fat diet, or is associated with hyperlipidemia. Idiopathic in Burmese cats.

continued

continued

NEOPLASTIC

- **Ocular neoplasia* (p 1267)**

Most cases present as anterior uveitis with corneal edema and a cloudy aqueous, and have some form of swelling seen in the iris, which may cause distortion of the pupil (dyscoria). The retina may be distorted and have a color change. Lymphosarcoma is the most common tumor and often presents as bilateral iris swelling with a “creamy” color change, and anterior chamber hypopyon and/or hemorrhage in a young cat, with or without other signs suggesting multicentric neoplasia. The pupil may be distorted (dyscoria).

INFLAMMATION/INFECTIOUS

- **Feline leukemia virus* (p 1266)**

FeLV may present as a cloudy aqueous associated with white cells and fibrin in the eye caused by a uveitis. Changes to iris appearance and abnormal pupil size and shape occur. It may or may not be associated with lymphosarcoma.

- **Feline infectious peritonitis (p 1266)**

Ocular form usually occurs in cats 6–12 months old. Ocular signs may be unilateral or bilateral. Typically there is fibrinous anterior uveitis and hypopyon, and initially no systemic signs. Advanced cases show serous retinal detachment and may have neurological signs.

- ***Toxoplasma gondii* (toxoplasmosis)** (p 1265)**

Most common sign is a cloudy anterior chamber from anterior uveitis and hypopyon. Older cats may develop small translucent nodules in the iris from lymphocytic–plasmocytic uveitis. Advanced cases may develop serous retinal detachment. Occasionally systemic signs are present including fever, weight loss, and respiratory, neurological and hepatic signs.

- ***Cryptococcus neoformans* (cryptococcosis) (p 1268)**

Usually presents as anterior uveitis with a cloudy aqueous secondary to leakage of white cells and protein. Examination of the retina shows focal granulomas with a cloudy vitreous. Blindness occurs in advanced cases.

- **Other systemic fungal infections (*Blastomyces dermatitidis*, *Candida albicans*, *Coccidioides immitis*, *Histoplasma capsulatum*) (p 1268)**

Typically there is a cloudy aqueous secondary to white cells and protein leaking into eye from anterior uveitis. Pre-iridal fibrovascular membranes are seen in chronic cases. Hemorrhage is associated with the PFIMs. Retinal hemorrhage is seen occasionally in areas of granuloma formation and appears as focal cloudy swelling in the retina.

WHERE?

LENS

DEGENERATIVE

- **Nuclear sclerosis and senile cataract** (p 1271)**

In nuclear sclerosis, the central part of the lens (nucleus) becomes slightly cloudy but the cat is still visual. Sclerosis is a normal aging process that starts from 8 years and becomes progressively cloudier with age. Senile cataract is seen in much older cats from 12–20 years of age. Nuclear

cells finally break down so the nucleus becomes very cloudy and vision deteriorates. The lens cortex may also start to degenerate resulting in cortical changes in addition to nuclear changes.

METABOLIC

- **Diabetic cataract (p 1273)**

Rare finding in aged diabetic cats. Lens is cloudy with an immature to mature cataract and impaired vision.

INFLAMMATION/INFECTIOUS

- **Cataract secondary to infectious uveitis** (p 1271)**

The lens becomes very cloudy because of a cortical cataract developing from poor nutrition and toxic states within the eye. Signs of uveitis are present such as a cloudy eye due to aqueous flare and fibrovascular membranes on the iris (PFIMs).

INFLAMMATION/NON-INFECTIOUS

- **Cataract secondary to non-infectious uveitis (p 1273)**

Nuclear cataract in a young healthy cat with no evidence of ocular inflammation. Rare.

Trauma:

- **Cataract secondary to lens trauma* (p 1272)**

Penetrating injuries that rupture the lens capsule will disrupt normal lens physiology and cause cataract development. This causes an acute uveitis from the released lens proteins within the eye (lens-induced uveitis). Blunt trauma to the eye may also rupture the lens. A tentative diagnosis is based on a history or signs of eye trauma and the presence of a mature or immature cataract.

WHERE?

VITREOUS

METABOLIC

- **Cloudy vitreous associated with systemic hypertension*** (p 1274)**

Vitreous may appear cloudy due to detached retina bulging into vitreous. Hemorrhage occurs into the vitreous from ruptured retinal blood vessels. Seen in older cats with a history of sudden blindness. Common secondary to chronic renal disease or hyperthyroidism.

NEOPLASTIC

- **Feline intra-ocular sarcoma (p 1276)**

Affected cats range from 7–15 years of age and have a history of prior ocular trauma. Cats present with signs of anterior uveitis and may show glaucoma and white to pink masses in the vitreous, if it can be visualized.

INFLAMMATION/INFECTIOUS

- **Feline immune deficiency virus* (p 1275)**

FIV infection causes pars planitis which is a “Snowbank” inflammation of the pars plana and thought to be almost pathognomonic for FIV infection. It results in a cloudy vitreous.

INTRODUCTION

MECHANISM?

The eye is an organ with various media that normally maintain **clarity for transmission of light** by very specialized means.

- The **corneal stroma** maintains optical clarity by the highly organized structure of the collagen fibrils, lack of blood vessels and lack of pigment.
- The **lens fibers** (cells) are also laid down in a very orderly fashion and contain soluble lens proteins known as crystallins.
- The **aqueous humor** is a clear fluid secreted by the ciliary body to maintain the anterior chamber.
- The **vitreous is a complex, transparent living tissue** made mainly from complex carbohydrates.

Cloudiness of the eye results from changes in structure and composition of the cornea, aqueous (anterior chamber), lens or vitreous (posterior chamber).

Cloudy cornea

For details on the structure and function of the cornea see “The Cat With Abnormalities Confined to the Cornea” (page 1236).

The **cornea becomes cloudy from edema** when the surface develops an **ulcer (ulcerative keratitis)**. Loss of epithelial cells allows the stroma to absorb fluid. This causes the intercellular matrix to swell, which in turn, disrupts the normal pattern of the keratocytes and the cornea becomes cloudy.

Corneal edema is also seen in cases of glaucoma and uveitis where the endothelial pump mechanism is disturbed, so that aqueous enters the stroma from the anterior chamber.

Inflammatory conditions in the cornea cause cloudiness by disrupting the normal cellular matrix, either with cellular infiltrates or by changing the normal cellular structure, such as scar tissue formation.

Cloudy anterior chamber

The anterior chamber is a **fluid-filled compartment bounded by the cornea anteriorly and the lens and ciliary body posteriorly**.

The fluid is called aqueous humor and is produced by a process of ultrafiltration and active secretion in the ciliary body. Aqueous exits the anterior chamber through the trabecular meshwork in the iridocorneal angle to reach the vascular system via the scleral vessels. The dynamics of aqueous humor production and drainage is very complex, but simply, it keeps the eye inflated at a predetermined pressure known as the intra-ocular pressure (IOP). **Interference of aqueous drainage causes glaucoma.** The increased intra-ocular pressure disturbs the corneal physiology resulting in corneal edema and a cloudy eye. See “The Cat with Abnormal Globe Position or Size” (page 1312).

Aqueous is a clear fluid that also supplies nutrients to the inner structures of the eye. When the anterior uveal tract (ciliary body and iris) becomes inflamed this is called **anterior uveitis**. Inflammation of the vascular-rich uveal tract causes the blood vessels to leak protein and white blood cells into the aqueous causing “**aqueous flare**”. Accumulations of protein and white blood cells may form opaque clots known as “**hypopyon**”. This causes a cloudy anterior chamber. See “The Cat With Abnormal Iris Appearance” (page 1294).

At the same time, anterior uveitis disturbs the endothelial pump mechanism, allowing aqueous to enter the stroma. This causes edema of the cornea seen as a cloudy eye.

Cloudy lens

A **cloudy lens** is seen when the lens develops a **cataract**.

A cataract is defined as an opacity of the lens. Lens fibers become opaque when they are no longer viable. A cataract is classified according to the position in the lens, and according to whether it is immature or mature.

The lens consists of an anterior and posterior capsule on the outer surface of the cortex. The central part of the lens is known as the nucleus. The lens is suspended by fibers known as zonules, which extend from the equator (outer circumference) of the lens to the ciliary processes. Lens cells are known as lens fibers and are continually produced from the lens epithelium, which is most active at the equator.

The lens has no blood supply, and therefore relies on the nutrients in the aqueous humor and the vitreous for

its nutritional requirements. Disturbance to the nutrition of the lens will result in death of lens fibers and development of a cataract.

Genetic cataract is rare in the cat.

Most cataracts in cats are secondary to disease processes within the eye such as uveitis or neoplasia.

Lens fibers in the nucleus become slightly opaque with age. This is known as **nuclear sclerosis** and may be seen from about 8 years of age. This is not a true cataract as the fibers are viable and the eye is usually visual. With age, the nuclear fibers may die, so nuclear sclerosis may develop into a nuclear cataract.

Cloudy vitreous

The vitreous is a living tissue (mainly mucopolysaccharide; also called glycosaminoglycans) that fills the space between the retina, ciliary body and lens.

Inflammation or hypertension of the inner retinal blood vessels will allow protein and white/red blood cells to leak into the vitreous causing “**vitreous flare**”. This may present as a cloudy eye behind the pupil.

Inflammation of the choroid (posterior uvea) leads to leakage of protein and blood cells into the outer retinal space leading to a serous retinal detachment. **Retinal detachment** can present as a cloudy eye behind the pupil.

Vitreous degeneration is rare in the cat.

WHERE?

Disease affecting the **cornea, anterior chamber, lens or vitreous** may result in a cloudy eye.

Decide which of the media have become cloudy and go to that part of the text for greater detail.

WHAT?

Cloudiness of cornea, anterior chamber, lens or vitreous may be caused by:

- **Infiltrates of inflammatory cells** or infusion of **tissue fluid** (edema), which produces swelling of the corneal stroma, will result in a cloudy cornea.
- **Alteration of the cellular matrix in the cornea and lens** causes a change in the refractive index, because of changed chemical properties of these

structures. For example, the change in the structure of the crystallins in the lens results in cataract formation.

- **Accumulation of protein and cells** in the aqueous humor causes a cloudy aqueous called hypopyon.
- On rare occasions **lipid** may be seen in the **aqueous (aqueous lipid)** forming a very cloudy eye.
- **Leakage of cells and protein** into the vitreous from inflammation of the ciliary body and/or choroid causes a cloudy vitreous.

The most common causes of corneal cloudiness are from **inflammation** associated with herpesvirus keratitis or eosinophilic keratitis, or from **trauma** resulting in edema, cellular infiltrates, ulcerative keratitis, and/or scarring or corneal sequestrum.

The most common causes of anterior chamber cloudiness are **inflammation** from **infectious agents** such as *Toxoplasma gondii*, *Cryptococcus*, other systemic fungi, feline infectious peritonitis virus, feline leukemia virus or from **neoplasia**.

The most common causes of lens cloudiness are from **nuclear sclerosis** or **cataract** secondary to **infectious uveitis or trauma**.

The most common cause of posterior chamber cloudiness is from systemic hypertension.

DISEASES CAUSING A CLOUDY CORNEA

FELINE HERPESVIRUS-1 KERATITIS***

Classical signs

- FHV-1 keratitis is primarily a disease of older cats.
- Frequently unilateral but may be bilateral.
- Shallow irregular ulceration (geographic ulcer) often with superficial vascularization and edema.
- History of acute episodes followed by quiescent periods.

See main references on pages 1212, 1237 for details (The Cat With Ocular Discharge or Changed Conjunctival Appearance, The Cat With Abnormalities Confined to the Cornea) and page 7 (The Cat With Acute Sneezing or Nasal Discharge).

Clinical signs

Herpesvirus is one of the most common causes of acute and chronic corneal disease in older cats.

Acute primary infection with herpesvirus may result in the following signs:

- **Conjunctival hyperemia** and serous ocular discharge that becomes purulent by days 5–7 of infection.
- Mild to moderate **chemosis and blepharospasm**.
- Non-specific **upper respiratory signs** such as sneezing and serous nasal discharge.
- Fine-branching (microdendritic) **corneal lesions** may be seen, especially if the cornea is stained with rose bengal. They result from the direct cytopathic effect of the virus, and are finger-like projections of epithelium.

Symblepharon formation with adhesion of conjunctiva to conjunctiva and conjunctiva to cornea may follow severe inflammation especially in young kittens.

Recrudescence infections may show any of the following signs:

- Dendritic ulcers.
- Corneal sequestrum.
- Superficial indolent epithelial ulcers.
- Serous ocular discharge.
- Stromal edema and scarring.

FHV-1 keratitis is primarily a disease of older cats.

Frequently unilateral but may be bilateral.

A **large shallow ulcer** with an irregular shape that appears to look like a continent or land mass (**geographic ulcer**) may be evident, and is often associated with superficial vascularization. It is the result of an immune response to viral antigen. There may be edema and in chronic cases scarring with calcific degeneration (calcium deposition in the anterior stroma).

Typically there is a history of **acute episodes followed by quiescent periods**, but close examination will reveal a slightly cloudy, scarred cornea.

Diagnosis

A **tentative diagnosis** is usually based on the **clinical signs**.

A **definitive diagnosis** requires specific techniques, which are available from some laboratories. These are

used infrequently and vary in their sensitivity. PCR is the most useful of these.

- **Cytological examination** of corneal/conjunctival smears stained with immunoperoxidase may demonstrate intranuclear inclusions in epithelial cells in some acute primary infections, but is not very reliable.
- **Immunofluorescence** using direct or indirect fluorescent antibody techniques on corneal/conjunctival smears or tissue sections may demonstrate the virus, but has poor sensitivity.
- **Virus isolation** is the gold standard for detection, but is not often used because of logistical difficulties in getting rapid results. It depends on demonstration of cytopathic effects of the virus in cell culture.
- **Serological techniques** are not very useful because antibody titers tend to be of low magnitude after primary infection sometimes reaching only 1:64 at 60 days after infection. High titers are rarely seen after recrudescence infection.
- **Polymerase chain reaction (PCR)** testing depends on DNA amplification of an amino acid sequence of the thymidine kinase gene, and is perhaps the most sensitive test available. Theoretically the test could pick up one strand of viral DNA. High sensitivity in nested PCR tests may reduce specificity by the detection of non-viral DNA contaminants.

CORNEAL SEQUESTRUM (FELINE KERATITIS NIGRUM)**

Classical signs

- **Area of pigmented cornea** varying from a very light coffee-colored stain to an intense thick black plaque.
- +/- **Blepharospasm and photophobia**.
- **Predominantly in brachycephalic breeds** such as Persians and Himalayans.
- **Usually unilateral**.

See the main reference on page 1234 (The Cat With Abnormalities Confined to the Cornea).

Clinical signs

The classic presentation is an **area of pigmented cornea**. The degree of pigmentation varies from a very

light **coffee-colored stain to an intense thick black plaque.**

Approximately 80% are associated with herpetic keratitis. There may be a **history of previous infection with FHV-1** as a kitten, or later in life, with herpetic keratitis. However, cases may develop after corneal ulceration or from medial entropion.

The disease is initially seen **unilaterally**, but eventually both eyes may become involved.

Initially the cat may not show any signs of discomfort, but as the lesion progresses **blepharospasm and photophobia develop.**

Early, light-staining lesions have an intact epithelium and do not stain with fluorescein. Lesions that have developed a dense plaque may have a **fine ring of ulceration** surrounding the lesion, which may stain positive with fluorescein.

In mild cases, the surrounding cornea will not show signs of edema or vascularization, but as the degree of degeneration progresses, **corneal edema with marked deep stromal vascularization** may be prominent.

Eyes that have a faint stain usually do not have any ocular discharge. Eyes that have a dark plaque with surrounding ulceration and intense corneal vascularization often have a **mucopurulent ocular discharge.**

The condition is seen in any breed of cat, but it occurs predominantly in **brachycephalic breeds such as Persians and Himalayans.** There is no sex or age predilection.

Diagnosis

A tentative diagnosis is based on the **signalment and clinical signs.** Typically there is a mild brown-staining cornea to a dense black plaque with keratitis.

A definitive diagnosis is based on **histopathological examination of resected cornea.** There is a typical pattern of degenerated stroma surrounded by a ring of inflammatory cells.

PCR tests on resected cornea may confirm the presence of FHV-1 infection.

EOSINOPHILIC KERATITIS*

Classical signs

- Irregular white to pinkish plaque on the cornea.
- Corneal edema and vascularization.
- +/- Similar conjunctival lesion.
- Unilateral or bilateral.
- Poor response to a variety of antibacterial agents.

See the main reference on page 1245 (The Cat With Abnormalities Confined to the Cornea).

Clinical signs

Signs **begin unilaterally**, but may become **bilateral.**

Seen as a **cloudy, red cornea.** This is a **proliferative lesion** producing **whitish to pink, plaque-like tissue** that may be covered by a thick white discharge.

The corneal epithelium is usually intact, but may show **patchy staining with fluorescein.** There is usually an **intense neovascularization** (superficial and deep) in chronic cases. There are varying degrees of edema, usually involving the entire cornea.

The **conjunctiva** is usually involved secondary to the cornea, and may present with a **similar white, proliferative plaque** and mucopurulent ocular discharge.

The third eyelid may also show proliferative lesions.

There is often a history of a **poor response to a variety of antibacterial agents.**

Diagnosis

A tentative diagnosis is based on the history of an **edematous, vascularized cornea** that will not respond to antibiotic therapy.

Clean the eye with saline or eye wash and take a scraping of the lesion using a scalpel blade, spatula or cytology brush. Gently spread the tissue onto a glass microscope slide and stain with a Wright or Romanofski stain. **The presence of eosinophils is diagnostic.** If conjunctival lesions are present, preferably take a sample from the conjunctiva.

Small conjunctival biopsies can be submitted in formalin for histopathology. The presence of eosinophils is diagnostic.

Hematology may reveal a peripheral eosinophilia.

Treatment

The condition will **rapidly respond to systemic corticosteroids** dosed at 1 mg/kg daily.

If the tips of the ears show alopecia, pruritis and crusting, the condition may be caused by biting insects. Such cases have been documented in Queensland, Australia. In such cases the cats must be housed in conditions that are insect free.

Allergic states caused by diet have been implicated. Dietary elimination tests may be useful to exclude this as a cause (see The Cat With Signs of Large Bowel Disease (page 766), The Cat With Abnormalities Confined to the Cornea (page 1246), The Cat With Miliary Dermatitis (page 1030), The Pruritic Cat Without Miliary Dermatitis (page 1046).

Try to minimize known causes of allergy such as insect bites by fleas and mosquitoes. Where there is a dietary component involved maintain cat on a **low-antigen diet**.

ULCERATIVE KERATITIS*

Classical signs

- Severe pain with serous discharge, blepharospasm and photobia.
- Variable severity from a superficial epithelial erosion to a deep stromal ulcer followed by a Descemetocoele.
- Positive staining of the stroma with fluorescein dye, except where a Descemetocoele is present.
- Varying degrees of corneal edema seen as a cloudy cornea. Corneal perforation is surrounded by a dense area of edema with a dark brown or black center if the iris has prolapsed into the corneal wound. A layer of fibrin may cover the injured cornea.

See the main reference on page 1242 (The Cat With Abnormalities Confined to the Cornea).

Clinical signs

There may be **evidence of the underlying cause**. Most ulcers that are not associated with a specific corneal disease are caused by **corneal trauma**. **Foreign bodies such as grass seeds and thorns**, or blunt trauma from **motor vehicle accidents** are the most common causes of corneal trauma. Trauma may cause a superficial ulcer, a deep ulcer or penetrating wound.

Eyes with ulceration are invariably **very painful**. Cats show serous **ocular discharge**, **blepharospasm**, photophobia and ocular guarding in severe injuries.

Ulcers stain positive with fluorescein dye. A very deep ulcer that has formed a Descemetocoele may not show any staining because **Descemet's membrane will not stain with fluorescein**.

Examination of the cornea with magnification will show a deficit in the corneal surface because of loss of epithelium and stroma.

Corneal edema will be present in cases that have loss of epithelium, because fluid will be absorbed by the stromal matrix. This will show as a cloudy cornea. Edema may be focal around the ulcer, or diffuse when large ulcers are present.

Penetrating injuries are common after **cat fights**. They present with a perforation of the cornea surrounded by a dense area of edema and swelling. A **fibrin plug** may be present in the corneal wound. If the iris has prolapsed into the wound, the center of the perforation will be dark brown or black in color. The anterior chamber may be collapsed and contain blood (hyphema) and fibrin.

Perforating injuries that are not sealed by fibrin and/or iris, will **leak aqueous** so the cat will have a very wet eye and face.

Diagnosis

There may be a **history of trauma** or a **cat fight**. The diagnosis of ulcerative keratitis is based on clinical signs of a painful eye showing a stromal deficit.

The ulcer will **stain with fluorescein** except in the case of a Descemetocoele. If the center of the ulcer is dark, and the area bulges, there may be a Descemetocoele. Descemet's membrane is very elastic in cats and can bulge forward quite noticeably.

Perforating injuries are very painful and show **changes in the anterior chamber** such as hyphema and protein leakage with fibrin.

Treatment

As a general rule, **eliminate the cause of the ulcer** and provide **protection for the cornea** using lubrication, appropriate antibiotics where necessary and surgical techniques to close and protect the eye.

Superficial epithelial erosions heal rapidly with minimal treatment. The use of antibiotics is not encouraged as they are rarely infected. **Support with artificial tear solutions** will make the eye more comfortable.

Corneas with deep ulcers that have stromal loss **need to be protected with surgical techniques** such as third eyelid flaps or temporary tarsorrhaphies (see references for texts that show details of these surgical techniques).

- **Antibiotics** are often used topically to prevent secondary infection. If the ulcer is infected, then appropriate antibiotics should be used after culture of a swab taken from the edge of the ulcer.
- **Artificial tear solutions** will lubricate the eye and make the cat feel more comfortable.
- **Atropine ophthalmic drops** (most commonly 1%) are used to dilate the pupil and to prevent ciliary muscle spasm. They should be used two to three times daily until the pupil is dilated, and daily thereafter (NOTE: atropine drops are very bitter and often make cats salivate profusely). For this reason 1% atropine ointment is often used, as the drug does not run down the tear duct as fast.

Where a ***Pseudomonas* infection** is suspected or confirmed by laboratory analysis, the cat must be treated vigorously with **aminoglycoside** (commonly gentomycin or tobramycin in gentomycin-resistant cases) or fluoroquinolone (some generations such as flucloxacillin are effective) antibiotics **topically every 15 minutes to 1 hour** until the infection is controlled. They may also be used systemically but particular care should be used with aminoglycosides in cats as they are ototoxic and nephrotoxic. Toxicity may occur from frequent topical use, so monitor cases carefully.

NEVER use topical corticosteroids when a corneal ulcer is present, as this will predispose to keratomalacia (melting ulcer).

If there is a **penetrating corneal lesion**, examine the eye carefully for signs of **iris prolapse and lens rupture**. These cases need to be referred to a veterinary ophthalmologist whenever possible.

- If there is a **corneal tear that is well sealed with a fibrin plug**, protect the cornea with a third eyelid flap or **temporary tarsorrhaphy**. **Dilate the pupil with atropine** and use a **topical broad-spectrum antibiotic drop**. **NEVER use an ointment** when there has been a penetrating corneal injury, because ointment bases that enter the anterior chamber will cause an intense and chronic foreign body uveitis. Animals with acute eye injuries should be given **systemic NSAIDs** to minimize the effects of an intra-ocular prostaglandin reaction. The eye should also be protected from infection with **systemic broad-spectrum antibiotics**.

When there is an **iris prolapse**, **microsurgery is required** to suture the cornea. The iris needs to be gently teased back into the anterior chamber, and the chamber flushed to remove blood and fibrin. **Viscoelastic solutions** are then used to space the anterior chamber, and the corneal deficit is sutured with interrupted 8/0 to 10/0 nylon or absorbable suture material. This is very specialized surgery that requires specialist training, magnification and specialized instrumentation. The pupil is then dilated with atropine, infection prevented with broad-spectrum topical and systemic antibiotics and NSAIDs given to minimize inflammation.

CORNEAL SCARRING FROM INJURY*

Classical signs

- Range from faint cloudiness of the superficial stroma to dense opacity.
- Variable position, size, shape and density of scar.
- History of previous severe inflammation or trauma.

Pathogenesis

Scarring may be secondary to **disease processes or trauma**.

Scars form secondary to stromal damage. When stroma is infected or lost from ulceration, **keratocytes metamorphose into fibrocytes**.

Corneal healing is achieved by **epithelial regeneration and stromal repair**.

Epithelial regeneration occurs by:

- Sliding of cells to cover the surface.
- Mitosis to reconstruct the layers.

Stromal repair occurs via **avascular and vascular healing**.

- A **vascular healing** occurs in small uncomplicated wounds and involves:
 - Infiltration of neutrophils from the tear film and limbal blood vessels.
 - Macrophages invade, and digest the cellular debris.
 - Keratocytes transform to fibrocytes that migrate into the damaged area.
 - Collagen fibrils are laid down in an irregular pattern that disrupts the corneal transparency.
- **Vascular healing** occurs when there is extensive stromal loss.
 - Cellular infiltration is more extensive.
 - Blood vessels invade from the limbus.
 - **Granulation tissue forms** and this heals in a dense scar.

Clinical signs

Scars present as **cloudy areas on the cornea**. Superficial scarring of the cornea is seen as a faint cloudiness of the superficial stroma. Dense opacity is seen with deep scars that involve the deep layers of the cornea.

Scars **vary considerably in position, size, shape and density** depending on the depth and area of corneal stroma that has been damaged.

Usually there is **no inflammation in the affected eye**.

Vision is always affected by corneal scarring.

Diagnosis

A diagnosis is based on **clinical findings and history**. Typically the cornea has cloudy areas of varying density, there is no positive staining with fluorescein, and the eye has no sign of inflammation, pain or discharge.

Usually, there is **a history of previous severe inflammation or trauma**, with healing of the cornea.

MYCOBACTERIAL KERATITIS (FLORIDA SPOTS)

Classical signs

- An asymptomatic keratitis recognized in the southeastern USA.
- The cornea has focal gray-white opacities in the anterior stroma, varying in diameter from 1–8 mm in size.
- The lesions usually affect both eyes.

See the main reference on page 1251 (The Cat With Abnormalities Confined to the Cornea).

Clinical signs

One, or more commonly, both **corneas have focal white to gray opacities** in the anterior stroma.

The **condition is asymptomatic**, as cats show no signs of ocular pain or irritation, and there is no associated inflammation in the cornea.

The condition has only been described in the USA.

Diagnosis

A **tentative diagnosis** is based on **clinical signs** – multiple focal opacities in the anterior stroma of the cornea, not associated with irritation or inflammation.

Rhinosporidium was initially diagnosed from histological samples. However, ultrastructural examination of affected cornea showed vacuoles with amorphous material and **rod-like organisms** characteristic of **mycobacteria** that stain positively with Ziehl–Neelsen carbolfuchsin stain.

CORNEAL (STROMAL) DYSTROPHY OF MANX CATS

Classical signs

- Young Manx cats.
- Begins with stromal edema that progresses to a cornea filled with large bullae.
- Eventually causes blindness.

See the main reference on page 1252 (The Cat With Abnormalities Confined to the Cornea).

Clinical signs

Rare disease of young Manx cats. Cats present with an axial (central) **stromal edema** which progresses to diffuse corneal edema and a thickened corneal stroma filled with **bullae (fluid-filled vesicles)**.

Affected cats become **blind**.

Diagnosis

A tentative diagnosis is based on the presentation of a **young Manx cat with corneal edema**.

A **definitive diagnosis** is based on histopathology.

- **Histology** demonstrates **progressive disintegration of stromal collagen fibers**, which are replaced with fluid-filled vesicles. Eventually the epithelium separates from its basement membrane and ulceration occurs.

DISEASES CAUSING A CLOUDY ANTERIOR CHAMBER

TOXOPLASMA GONDII (TOXOPLASMOSIS)**

Classical signs

- Cloudy anterior chamber from anterior uveitis is the most common sign.
- +/- Gray to tan-colored nodules on the iris surface (lymphocytic-plasmacytic uveitis).
- Cloudy vitreous (chorioretinitis and optic neuritis).
- Rarely, systemic signs may be seen concurrently with ocular signs.
- These include fever, weight loss, +/- muscular pain, +/- signs of respiratory or neurological disease.

See the main reference on pages 1296, 1169 (The Cat With Abnormal Iris Appearance and The Blind Cat or Cat With Retinal Disease).

Clinical signs

Systemic signs are rare but may include:

- **Fever, weight loss and muscle pain.**
- **Respiratory** signs associated with pneumonia.

- Signs of **multifocal neurologic** disease.
- Liver disease.

Ocular signs are more common, and may include one or all of the following signs:

- **Anterior uveitis** is the **most common sign** and is seen as a **cloudy anterior chamber**. This is caused by leakage of protein and white blood cells from inflamed iris and ciliary body blood vessels into the aqueous humor. It is also known as hypopyon.
- In severe cases of uveitis, the **cornea may be cloudy due to edema** caused by aqueous leakage through a compromised endothelium.
- **Keratic precipitates** may be seen on the surface of the endothelium. These are the so-called “mutton fat” deposits that consist of white cells and protein attached to the endothelium. They are more common in the inferior cornea.
- **Cloudy vitreous** caused by chorioretinitis; white cells and protein leak into the vitreous through inflamed retinal and choroidal blood vessels.
- **Lymphocytic plasmocytic uveitis** is seen as pale nodules on the iris surface.
- **Secondary cataract formation** is common in chronic cases, and will be seen as a cloudy eye within the pupil space.
- Glaucoma is a sequel to chronic uveitis.
- Signs may be **unilateral or bilateral**.

Diagnosis

A tentative diagnosis may be based on the **clinical signs**.

A **definitive diagnosis** requires supportive laboratory data which may include:

- **Serology.**
 - Demonstration of a **rise in IgM titers** indicates a recent active infection.
 - **Comparison of** levels of **aqueous humor** *T. gondii* antibody levels with **serum levels** (Goldman–Witmer coefficient or C-value) has been advocated, with higher aqueous levels suggesting the anterior uveitis was caused by *T. gondii*. The use of C-values is still controversial.
- **Polymerase chain reaction (PCR)** testing for parasite DNA in tissue or fluid samples.

FELINE INFECTIOUS PERITONITIS

Classical signs

- Young cats 6–12 months of age.
- Anterior uveitis with large fibrin clots (hypopyon).
- Large brownish to pink keratic precipitates on the inferior endothelial surface of the cornea.
- Chorioretinitis causing variable vision loss and/or abnormal pupil reflexes.
- Neurological signs, including behavioral changes, cranial nerve abnormalities, seizures and head tremor.

See the main reference on page 1179 (The Blind Cat or Cat With Retinal Disease).

Clinical signs

The ocular form of the disease is usually seen in young cats from **6 months to 1 year of age**.

Ocular signs may be **unilateral or bilateral**.

The **main presenting sign is uveitis**. **Large fibrin clots** mixed with exudated white and red blood cells form a **hypopyon**. **Keratic precipitates** are common and appear as large pinkish, brown spots on the inferior endothelial surface of the cornea (“mutton fat deposits”).

The vitreous may be hazy due to a similar exudation of cells from the ciliary body.

The retina may show a **focal or total exudative retinal detachment**. It is common to see an inflammatory exudate sheathing the major retinal blood vessels, which form a **cloudy sheath around the vessels**.

Blindness may be seen with **abnormal pupil reflexes** (miotic in early stages with uveitis, followed by dilation in blind cases) and abnormal pupil size (anisocoria).

Cats with ocular signs frequently develop **neurological signs**, and die or are euthanized as a result of meningoencephalitis and its associated signs, which include behavioral changes, cranial nerve abnormalities, seizures and head tremor (seizures most common).

Cats with ocular signs of FIP **rarely show systemic signs** of illness such as fever, inappetence and weight loss **at the initial presentation**. As the disease becomes chronic, weight loss and neurological signs develop.

Diagnosis

There is no definitive diagnosis for FIP.

A tentative diagnosis is initially based on clinical signs; **a young cat with uveitis showing hypopyon and keratic precipitates**.

Serology is usually regarded as being of dubious benefit in the diagnosis, as the FIP organism cross-reacts with enteric forms of coronavirus.

Diagnosis can only be confirmed on **characteristic histopathology** of affected tissues on biopsy or necropsy examination. The typical change is described as a **pyogranulomatous vasculitis**. Necrosis and a fibrinoid response are seen in some cases. The ocular cellular response includes neutrophils, lymphocytes, plasma cells, macrophages and large, spindle-shaped histiocytes.

Cats often have a **large increase in plasma total protein, globulin and IgG** concentration, because of the chronic nature of the inflammatory disease process. The polyclonal increase in gammaglobulins is caused by virus antigen and cell destruction from the intense inflammation associated with the infection.

FELINE LEUKEMIA VIRUS*

Classical signs

- Discrete iris or ciliary body masses (FeLV-associated lymphosarcoma).
- Anterior uveitis.
- Intermittent asymmetric changes in pupil size, shape or response.
- Other FeLV-associated signs, e.g. anemia.
- Retinal detachment.

See the main reference on page 1300 (The Cat With Abnormal Iris Appearance).

Clinical signs

FeLV may cause **ocular lymphosarcoma**, which appears as **discrete iris or ciliary body masses**, usually bilateral, which may cause gross distortion of the iris structure.

FeLV more commonly presents as a uveitis, with changes to iris appearance, and abnormal pupil size and shape. The **anterior chamber** may contain **fibrin and/or blood**. Anterior uveitis may occur in the absence of discernible intra-ocular neoplasia.

Some cats develop **spastic pupil syndrome**, which presents as otherwise unexplainable intermittent asymmetric **changes in pupil size, shape or response**. For more detail see page 1300 (The Cat With Abnormal Iris Appearance).

It is possible to see **retinal detachment** when the neoplastic process involves the choroid.

There may be other signs of FeLV-associated disease, e.g. anemia or multicentric lymphosarcoma.

Diagnosis

Diagnosis is based on the clinical signs observed in the eye, in association with other signs suggestive of FeLV, e.g. multicentric lymphoma, FeLV-associated anemia.

Diagnosis is confirmed on **clinical pathology**, for example on cytology of lymph nodes or aqueous centesis samples, or occasionally on hematology.

A positive serological test using an **antigen-based test for FeLV** is supportive evidence of the disease. For more detail see page 543 (The Anemic Cat).

OCULAR NEOPLASIA*

Classical signs

- Diffuse pigmentary change across the anterior iris surface, most often a pale fleshy change.
- Mass lesions bulging forward from the anterior iris stroma or distorting normal pupil shape, or causing generalized iris thickening.

Classical signs—Cont'd

- Cloudy anterior chamber filled with white blood cells and protein.
- Varying degrees of hyphema.

See the main reference on pages 1184, 1297 for details (The Blind Cat or Cat With Retinal Disease, The Cat With Abnormal Iris Appearance).

Clinical signs

Most cases present as **anterior uveitis with corneal edema and a cloudy aqueous**, and have some form of **swelling seen in the iris**, which may cause distortion of the pupil (dyscoria).

Various tumors occur in the eye. They may **arise from the iris** such as melanoma, lymphosarcoma, sarcoma and ciliary body tumors or **arise from the retina** including **lymphosarcoma and adenocarcinoma from lung, uterus and undetermined origin**.

Lymphosarcoma is the most common ocular neoplasm, and may be FeLV-associated, although more commonly does not appear to be associated with FeLV.

Lymphosarcoma often presents as bilateral iris swelling, and anterior chamber hypopyon and/or hemorrhage in a young cat, with or without other signs suggesting multicentric neoplasia.

Signs of lymphosarcoma typically include:

- The **anterior chamber is cloudy** from white blood cells and proteins that have leaked from diseased iris blood vessels.
- The **iris may have red cells on the surface** mixed with protein and white blood cells caused by disruption of the endothelial cells on the blood vessel walls. Lymphosarcoma does not usually cause frank hemorrhage. Varying degrees of hyphema are present.
- The **iris appears thickened** with a pale fleshy color change, and may be tinged with blood.
- The pupil is distorted (dyscoria) if the iris is grossly distorted with infiltrated cells.
- Glaucoma is often an associated complication.
- Corneal edema may be present.
- Regional lymph nodes may be increased in size.

Diffuse iris melanoma typically appears as an enlarging area over months to years of light tan to dark brown pigmentation on the iris surface. Usually the neoplasm does not form an obvious discrete mass, but the iris may become diffusely thickened. The disease is usually unilateral and typically occurs in older cats.

- Presentation may more resemble uveal inflammation than neoplasia.
- Sometimes the disease may present in an advanced state with secondary glaucoma.
- Amelanotic diffuse iris melanomas have also been reported. These are difficult to diagnose unless the effects of the tumor on angle obstruction and resultant glaucoma are observed.

Post-traumatic sarcoma more commonly forms **discrete masses** within the eye.

Ciliary body adenoma is a rare slow-growing neoplasm, which appears as a whitish to cream mass behind the pupil margin.

Metastatic neoplasia from an extra-ocular primary tumor appears as an intra-ocular neoplasm involving the iris, and is associated with a similar neoplasm remote from the eye, e.g. mammary or uterine adenocarcinoma.

Diagnosis

A tentative diagnosis is based initially on the **appearance of the eye (uveitis, iris swelling and/or distortion of the retina)** and consideration of the history.

Examination of the buffy coat is useful for diagnosis of lymphosarcoma. The presence of abnormal plump lymphocytes with large prominent nucleoli is highly suggestive.

Biopsy of **regional lymph nodes** is useful if there is lymphomegaly.

Definitive diagnosis may be obtained by **fine-needle aspirate biopsies** or anterior chamber centesis and cytology.

Serology for FeLV may support the diagnosis of lymphosarcoma.

Chest and abdominal radiology and/or ultrasound may be indicated.

CRYPTOCOCCUS NEOFORMANS

Classical signs

- **Sudden blindness with retinal detachment.**
- **Vitreous flare** may be present making the retina difficult to examine.
- **Anterior uveitis** (anterior chamber flare, miosis, inflamed discolored iris).
- **Exophthalmos** (eye bulging forward).
- **+/- Mucopurulent discharge with sneezing and a swollen nose.**
- **Neurological signs.**
- **Chronic skin granulomas.**

See the main reference on pages 1174, 16, and 1089 (The Blind Cat or Cat With Retinal Disease, The Cat With Signs of Chronic Nasal Disease and The Cat With Non-healing Wounds).

Clinical signs

Cryptococcosis is the most common fungal infection affecting cats, and **occurs throughout the world.**

The initial ocular site for establishment of infection is usually the **choroid**, and the **anterior uveal tract** is often involved later in the course of the infection.

Cats may present with **sudden blindness** caused by **multifocal granulomatous chorioretinitis** with varying degrees of **retinal detachment**.

- **Vitreous flare (cloudy vitreous)** is present, and makes the retina difficult to examine in cases with severe inflammation.
- If the retina can be visualized, the granulomas appear as small swollen brownish discolored areas in the tapetal and non-tapetal retina.

There is usually **anterior uveitis with corneal edema, anterior chamber flare** (with or without hypopyon and keratic precipitates), **swollen iris with varying degrees of posterior synechia** causing a **distorted pupil**, and in chronic cases, new vascular growth on the anterior surface of the iris (pre-iridal fibrovascular membrane formation).

Complications include **secondary cataract and glaucoma.**

Some cats present with **exophthalmos** (eye bulging forward), where there has been an extension of the disease from the sinuses and nasal cavity into the orbital tissues.

In cases with nasal infection, there may be a **mucopurulent discharge with sneezing**. **Distortion and swelling** over the **bridge of nose**, or a **polyp-like mass** projecting from the nasal cavity are present in 70% of cats with the respiratory form.

Chronic skin granulomas may be present. Skin lesions consist of **papules or nodules** varying from 0.1–1 cm in diameter. Lesions may **ulcerate and exude serous fluid**, or **remain as intact nodules**.

Cats with disseminated disease may show neurological signs.

Cats may **present** with **chronic nasal or skin disease**, and the ocular involvement is identified secondarily on physical examination. Cats may also be presented **primarily for the ocular signs**, where the owner has seen the development of a cloudy eye and the cat has gone blind.

Diagnosis

A **tentative diagnosis is based on typical clinical signs** of nasal or skin disease and concurrent ocular signs. The presence of small swollen brownish discolored areas in the retina suggests fungal disease. The frequency of occurrence of individual fungal diseases in the geographical area helps establish a tentative diagnosis.

Cytology can be very useful in the diagnosis of *C. neoformans*. Demonstration of the organism can be made via **anterior chamber centesis** or by fine-needle biopsy (using a 25-gauge needle) taken from the sub-retinal space. The sample is best stained with **new methylene blue**, **Indian ink** or **Diff-Quick**.

Serology to detect **capsule antigen** is sensitive using serum, CSF fluid or urine.

Histopathology from tissue biopsies demonstrates the organism.

Radiology of the nasal cavity, sinuses and chest may be useful in cases that do not demonstrate nasal or skin signs.

Ocular ultrasound can be used to **detect retinal detachment** when anterior chamber flare, cataract or vitreal flare prevents ophthalmoscopic examination of the fundus. It is also used in cases of exophthalmos to examine, and do ultrasound-guided biopsies of the orbital tissue.

OTHER SYSTEMIC FUNGAL INFECTIONS (BLASTOMYCES DERMATITIDIS, CANDIDA ALBICANS, COCCIDIODES IMMITIS, HISTOPLASMA CAPSULATUM)

Classical signs

- **Chorioretinitis progressing to anterior uveitis (cloudy eye) and endophthalmitis**, in a geographical area where fungal infections occur.
- **Vision loss and reduced pupil light reflexes.**
- **Other organ system disease**, e.g. renal, CNS, nasal cavity.

See the main references on pages 1176, 1300 and 1283 for details (The Blind Cat or Cat With Retinal Disease, The Cat With Abnormal Iris Appearance and The Cat With Abnormal Pupil Size, Shape or Response).

Clinical signs

Most intra-ocular fungal infections cause similar ocular signs.

- **Choroidal granulomas** are the most characteristic sign on fundoscopy, and appear as a raised area of tapetal hyporeflexivity, or small swollen brownish discolored areas in the retina.
- A **generalized chorioretinitis and secondary retinal detachments**, with ballooning of the retina into the vitreous.
- **Optic neuritis** may be present, seen as a red, swollen optic nerve that is hyperemic.
- **Anterior uveitis** seen as cloudy, red eye with corneal edema, hypopyon and inflamed conjunctiva.

Affected cats show **varying degrees of blindness**, depending on the severity of the ocular infection.

Systemic signs can involve many other organs, especially the lungs, brain, nasal cavity, as well as the peri-orbital tissues, lymph nodes, bones, toenails and skin.

Diagnosis

A tentative diagnosis is based on the presenting signs of a cat with rapidly progressive, usually bilateral **chorioretinitis, progressing to anterior uveitis**, with signs of other systemic disease, and occurring in a geographic area where such fungal disease is known to occur.

Imaging techniques can be used to obtain more supportive evidence of a deep fungal infection:

- Thoracic radiography to demonstrate pulmonary granulomas.
- Nasal cavity radiography.
- Ocular ultrasound; signs of retinal detachment.

Confirmation of the diagnosis is based on the **demonstration of the respective organism** in:

- Cerebrospinal fluid.
- Samples taken by centesis of vitreous or subretinal exudate.
- Histopathology of enucleated globes.
- Bone marrow biopsy samples (histoplasmosis).

Serological tests can be performed, looking for elevated antibodies (blastomycosis, histoplasmosis, coccidioidomycosis).

LIPEMIC AQUEOUS

Classical signs

- Eye may suddenly become very cloudy with a “milky appearance”.
- Unilateral or bilateral.
- Idiopathic in Burmese cats associated with hyperlipidemia.
- May occur in cats with uveitis that are on a high-fat diet.

Pathogenesis

High concentrations of lipid can enter the anterior chamber **from the uveal vessels** if there is either:

- Breakdown of the blood–aqueous barrier in **anterior uveitis**.
- Abnormally high concentrations of serum lipids, which can be secondary or primary **hyperlipidemia**.

Lipemic aqueous is **idiopathic in Burmese cats** associated with hyperlipidemia.

Clinical signs

Typically there is a **diffusely and uniformly cloudy anterior chamber**. The aqueous appears as if it is full of milk.

Usually the iris, pupil and tapetal reflex can still be visualized.

Lipemic aqueous is **often unilateral** and may be **sudden in onset**.

Occasionally it is associated with cats that have **uveitis** caused by systemic diseases such as **toxoplasmosis, FIP, fungal infections**, when they have hyperlipidemia caused by a **high-fat content in the diet**.

Diagnosis

A tentative diagnosis is based on **clinical signs**.

A definitive diagnosis is based on **biochemical analysis of aqueous centesis** samples and demonstration of high serum lipid concentrations. Lipid electrophoretograms may be performed on the sample.

Diagnosis of the underlying cause should be pursued, if lipemic aqueous is not in a predisposed breed such as the Burmese. If it is the result of a systemic disease combined with a high-fat diet, the underlying disease should be identified (see The Cat With Abnormal Iris Appearance, page 1294 and With Retinal Disease, page 1186).

Treatment

Reduce plasma lipid concentrations using a **low-fat diet**.

Treat other underlying medical problems, which are associated with hyperlipidemia such as diabetes mellitus, and systemic diseases causing uveitis (see The Cat With Abnormal Iris Appearance, page 1294).

DISEASES CAUSING A CLOUDY LENS

CATARACT SECONDARY TO INFECTIOUS UVEITIS**

Classical signs

- Cloudy lens, unilateral or bilateral.
- Frequently only unilateral.
- Poor vision if bilateral. Iris may be distorted from posterior synechia.
- Iris may show fibrovascular membranes on surface.
- History of chronic uveitis caused by infectious agent such as toxoplasmosis or fungal disease.

Pathogenesis

Inflammation in the eye results in changes to the lens nutrition and accumulation of toxic products in the eye which results in death of cells. This will cause a cloudy lens (cataract).

Cataract is often associated with chronic uveitis caused by infectious agent such as toxoplasmosis or fungal disease.

Clinical signs

The lens appears cloudy due to the formation of a cortical cataract.

The cataract may be **unilateral or bilateral**, but is more often unilateral. Vision is poor if bilateral.

Other **signs of uveitis** will be present such as aqueous flare and fibrovascular membrane growth on the iris. The iris may have a darker color than the opposite eye, or have changes in contour due to adhesions of the iris to the anterior lens capsule (posterior synechia).

There may be **changes in the cornea such as edema or scarring**, with or without superficial vascularization.

Hypopyon or keratic precipitates may be evident.

Some cats develop **secondary glaucoma**.

Diagnosis

A **tentative diagnosis** is based on the signs of a cloudy lens or cataract.

Signs of uveitis or history of past uveitis indicate the origin of the cataract. See page 1303 (The Cat With Abnormal Iris Appearance).

The eye should be checked for glaucoma by measuring the intra-ocular pressure.

Treatment

Cataract surgery can be done if the inflammation has been controlled.

- It is prudent to do a diagnostic work-up for systemic diseases that cause uveitis prior to doing surgery. See page 1199 (The Blind Cat or Cat With Retinal Disease) and page 1304 (The Cat With Abnormal Iris Appearance).
- Check the eye for retinal detachment with ultrasound prior to surgery.
- An **electroretinogram** is indicated to ensure that the eye has normal retinal function prior to surgery.

NUCLEAR SCLEROSIS AND SENILE CATARACT**

Classical signs

- Milky appearance of lens in cats older than 10 years of age.
- Cats are usually visual and leading a normal lifestyle.
- The fundus can be seen clearly with an ophthalmoscope.

Pathogenesis

Nuclear sclerosis is a **normal aging process** in the lens which starts in animals from about 8 years of age and is evident by 10 years.

Lens fibers are produced throughout life, but the lens does not increase in size. Therefore, the fibers in the center become **thinner and pack closer together** causing a slight opacity, termed **sclerosis**. As the lens ages further some of these fibers may **break-down** and then a **nuclear cataract** develops. In very old cats, the nuclear cataract may become quite dense with secondary changes in the surrounding cortex leading to a **mature cataract**.

Clinical signs

The **center of the lens** becomes **slightly cloudy**, but the cat will be able to see quite well until the changes are advanced and become a cataract.

Nuclear sclerosis is seen from **10 years of age** and **cataracts** typically occur in cats **12–20 years of age**.

On ophthalmoscopic examination, the fundus will be clearly visible until a true cataract forms.

Diagnosis

Diagnosis of nuclear sclerosis is **based on clinical signs** of a slightly cloudy lens in an older cat, with vision intact. The fundus can be clearly seen with an ophthalmoscope.

Diagnosis of senile cataract is **based on clinical signs** of a cloudy lens in an older cat, with no history or signs of preceding ocular trauma or inflammation.

Treatment

There is **no definitive treatment** for this aging change.

If a cataract develops and the cat is healthy, **cataract surgery** can be performed. Because senile cataract occurs in aged cats, it is important to check renal function and blood pressure before proceeding with surgery.

CATARACT SECONDARY TO LENS TRAUMA*

Classical signs

- History of previous eye injury, frequently caused by a cat claw.
- Cornea has scar from old wound.
- ± Anterior or posterior synechia (iris adhesions to cornea or lens).
- Lens may be partially or completely cloudy.
- ± Chronic inflammation (uveitis) caused by lens protein outside the capsule.

Pathogenesis

Any injury to the lens fibers will **disrupt the normal lens metabolism**, and cause death of lens fibers leading to cataract formation.

The **most common cause of lens injury** in cats is from **cat fights** when a cat claw penetrates the globe and tears the anterior lens capsule. This may be obvious when the tear is visible through the pupil, but some injuries occur under the iris root in the equator of the lens and are not possible to visualize.

Other causes of injury are **blunt trauma**, which is frequently associated with motor vehicle accidents. With blunt trauma, the sudden compression of the eye followed by rapid decompression causes rupture of the lens capsule.

Once the nutrition of the lens fibers is disturbed, the **cells will start to die and become opaque**, resulting in typical cloudy lens and cataract formation.

An injured lens in a cat can lead to **sarcoma formation** due to metaplasia of the lens epithelial cells. See pages 1276 (Feline intra-ocular sarcoma).

Clinical signs

Typically, there is a **history or signs of eye trauma**, usually a cat-fight claw injury or blunt trauma. The cornea may have a scar from an old wound.

Lens may be partially or completely cloudy because of an **immature or mature cataract**.

In anterior capsule tears, **lens material** can be seen in the anterior chamber as a **cloudy flocculent material**. There is intense inflammation associated with leakage of lens material, and it may be difficult to see through a very cloudy cornea.

Tears in the equatorial region of the lens may often be sealed by the ciliary body and iris root, and only develop a **local cataract**. Generally, an injury to the lens fibers will lead to a mature cataract.

Where the eye has hyphema (red eye), the lens will not be able to be seen ophthalmoscopically.

Often the tear in the lens capsule has **iris pigment adhered** to it, visible as a black area. Anterior or posterior synechia (iris adhesions to cornea or lens) may be evident.

Be aware that cats with **chronic inflammation after trauma** often have a ruptured lens causing chronic lens-induced uveitis.

Diagnosis

A tentative diagnosis is based on a **history or signs of eye trauma** and the presence of a **mature or immature cataract**.

In acute cases, lens material is visible in the anterior chamber.

In chronic cases, chronic uveitis is evident after an eye injury.

Ocular ultrasound is a very useful tool for detecting lens rupture. Look for the normal position of the lens as seen by the anterior and posterior hyperechoic line defining the anterior and posterior lens capsule. In high-quality machines with a 10-MHz probe, the lens shape and position can be visualized quite easily. Any change to the appearance or lack of hyperechoic lines is suspicious for lens rupture.

Treatment

If there is corneal edema and the anterior chamber is filled with blood and protein, treat the eye with **broad-spectrum antibiotics** topically and systemically. Inflammation should be controlled initially with **NSAIDs**. If the lens is ruptured, **corticosteroids systemically** will be needed to control the lens-induced uveitis, which is an immune reaction in the eye against the exposed lens fibers.

If the injury has recently occurred, and the cornea and anterior chamber allows visualization of the lens, a **lens-tectomy** should be performed immediately. This treatment is controversial because of the danger of sarcoma formation later in life.

Cataract surgery can be performed later if a mature cataract develops.

Cats with an injured lens have a high risk of developing ocular sarcoma, and enucleation should be considered.

CATARACT SECONDARY TO NON-INFECTIOUS UVEITIS

Classical signs

- Nuclear cataract in a young healthy cat that with no evidence of ocular inflammation.

Pathogenesis

In contrast to dogs, genetic cataract is rare in cats, but has been reported.

Congenital cataract is seen when the lens development is disrupted or altered in the early embryonic development of the eye.

As the nucleus is the first part of the lens to develop, this is the usual area of cataract development seen in young cats (**nuclear cataract**). As the cat ages, the lens cortex may become cataractous and the eye develops a mature cataract.

Clinical signs

Cloudy lens in a young cat with no history of illness and no sign of inflammation in the eye.

Vision is reduced or absent if both eyes are affected.

Diagnosis

Diagnosis is based on the classical appearance of a cloudy lens in a young healthy cat, which has no evidence of ocular inflammation.

Treatment

Cataract surgery can be done by a trained ophthalmologist if the globe and retina is normal.

- **Ocular ultrasound** should be done to determine whether the retina is detached. A 10-MHz probe should be used. Detached retinas are seen as faint lines bulging into the vitreous between the optic disc and ora serrata.
- **Electroretinography** can be done to determine whether the retina has normal rod and cone function.

DIABETIC CATARACT

Classical signs

- Rare finding in older cat with diabetes mellitus.
- Cloudy lens with immature to mature cataract.

Pathogenesis

Diabetic cataract forms because the lens is bathed in a solution that is very high in glucose. The lens cells cannot metabolize the excess glucose by normal anaerobic glycolysis, and therefore uses aerobic glycolysis using the **sorbitol pathway** and the enzyme **aldose reductase** as the catalyst. The by-product of this process is **sugar alcohol (sorbitol), which kills the cell**. The sugar alcohol is a large molecule that cannot escape through the cell wall, and results in a more concentrated intracellular fluid than the surrounding fluid. Water is therefore imbibed into the cell, which causes it to swell and rupture. This in turn causes an immune reaction within the eye called **lens-induced uveitis**.

Diabetic cataracts are **rare in cats**. This is thought to be due to **low levels of the enzyme aldose reductase** in old cats, which prevents the lens cells from using the sorbitol pathway to the same degree as other animals.

Clinical signs

Cloudy lens and poor vision in a cat with diabetes mellitus.

Diagnosis

A tentative diagnosis is based on the signs of a cloudy lens consistent with an immature to mature cataract in a cat with diabetes mellitus.

Treatment

Cataract surgery can be done successfully by a trained ophthalmologist.

DISEASES CAUSING A CLOUDY VITREOUS

CLOUDY VITREOUS ASSOCIATED WITH SYSTEMIC HYPERTENSION***

Classical signs

- Acute onset of vision loss in an old cat, usually bilateral.
- Dilated pupils, non-responsive or poorly responsive to light.

Classical signs—Cont'd

- Cloudy vitreous with red areas of hemorrhage.

See the main reference on page 1171 (The Blind Cat or Cat With Retinal Disease).

Pathogenesis

Hypertension causes **vasoconstriction of pre-capillary retinal arterioles**. **Hypoxia** of the arteriole causes smooth muscle necrosis, which leads to **vascular dilation**, and leakage of serum and blood.

Leakage from vessels causes **serous retinal detachment**, and subretinal, intraretinal or preretinal **hemorrhage**.

Retinal blood vessels may rupture, causing hemorrhage into the vitreous.

Hypertensive retinopathy occurs most commonly secondary to **chronic renal disease** and **hyperthyroidism**.

Clinical signs

Classical signs are **acute onset of vision loss** in an **old cat**, which is usually **bilateral**. The cat suddenly starts to bump into things, appears to be lost, and has very cautious movements.

The **pupils** are usually **dilated**, and non-responsive or **poorly responsive light**.

Affected **eyes appear slightly cloudy**, and there may be focal red areas visible through the pupil, as a result of retinal hemorrhage. The vitreous may appear red. Early cases may show hemorrhage along the larger retinal blood vessels.

It is difficult to visualize the **retina** on fundoscopic examination, as it **appears out of focus**. This is caused by retinal detachment, with the retina ballooning into the vitreous, **and appears as a thin veil of pale tissue**.

These cats may have **cardiomegaly**, and left ventricular hypertrophy.

There may be other signs suggestive of hypertension, for example, a **bounding cardiac apex beat**.

Systolic arterial blood pressure is usually **greater than 160 mmHg**.

Other signs suggestive of renal and/or thyroid disease, such as progressive weight loss, polydipsia, polyuria and azotemia may be present.

Diagnosis

Clinicians should suspect this problem in **any old cat that has suddenly gone blind**.

Ophthalmoscopy will demonstrate **vitreal hemorrhage**. The retina will appear out of focus, and hemorrhage adjacent to the major retinal blood vessels is visible.

Blood pressure is most commonly measured in the cat using Doppler technology. Arterial blood pressure greater than 160 mmHg confirms a diagnosis of hypertensive retinopathy. Most cats with clinical signs have a blood pressure of **greater than 200 mmHg**.

BUN, creatinine and urine protein:creatinine ratios are useful clinical pathology parameters to check renal function.

Thyroid function should be checked by measuring **plasma thyroxine (T4) concentration**.

Further useful procedures include **cardiac ultrasound**, and in some cases, imaging of the thyroid with radioisotopes.

Treatment

Amlodipine (Norvasc, Pfizer) is a **calcium channel blocker**, which has a greater effect on vascular smooth muscle cells than on cardiac muscle cells. The dose is approximately 0.625 mg/cat/day, i.e. 1/4 of a 2.5 mg tablet (USA) or 1/8 of a 5 mg tablet (Australia).

The use of corticosteroids is controversial.

If hypertension is associated with **hypertrophic cardiomyopathy**, then calcium channel blockers such as **diltiazem** may be used. For more detail see main reference on page 162 for details (The Cat With Tachycardia, Bradycardia or an Irregular Rhythm).

β-blockers such as propranolol (Inderal) can also be used in the management of the cardiac disease at 1/4 of a 10 mg tablet q 8 h.

Hyperthyroidism when present, should be treated using surgery, radioactive iodine (131-I) or anti-thyroid drugs such as carbimazole or methimazole. For more detail see main reference on page 305 (The Cat With Weight Loss and a Good Appetite).

Cats with renal disease should be placed on appropriate medical and dietary management. For more details see the main reference on page 337 (The Thin, Inappetent Cat).

FELINE IMMUNODEFICIENCY VIRUS*

Classical signs

- Show signs of mild uveitis.
- “Snowbank” inflammation of the pars plana seen through dilated pupil. Appears as cloudy outer vitreous in this area.
- May be other systemic signs such as loss of weight, inappetence and fever.

Pathogenesis

Infection with the virus usually occurs as a result of a bite from another FIV-positive cat. Transmission in saliva by grooming is thought possible, but rare.

After infection a viremic phase occurs, which may be associated with a transient fever, generalized lymphadenopathy and neutropenia. An asymptomatic carrier state or chronic disease then follows.

Clinical signs

Cats that develop signs of FIV may have evidence of generalized systemic disease such as weight loss, and poor body and coat condition. Pyrexia, lymphadenopathy and infections of the oral cavity, respiratory tract, skin and other sites may occur.

In the eye, **pars planitis** or “snow bank” inflammation of the pars plana resulting in **vitreous cloudiness** is thought to be almost pathognomonic for FIV infection. Other signs of uveitis can also be seen, such as cloudy aqueous and iris inflammation.

Diagnosis

A tentative diagnosis is based on the **clinical signs of vitreous cloudiness** described as “snow bank” inflammation, in a FIV-positive cat.

Treatment

Supportive treatment is indicated, and depends on the organ system affected.

The use of steroid anti-inflammatory drugs for the ocular lesion has to be weighed against the potential immunosuppressive effects.

FELINE INTRA-OCULAR SARCOMA

Classical signs

- Rare, primary neoplasia that occurs in older cats (7–15 years).
- History of previous severe trauma to eye.
- Anterior uveitis, keratitis (corneal edema and pigmentation) and glaucoma.
- White to pinkish masses may be visible in the vitreous.

Clinical signs

Intra-ocular sarcoma is a **rare primary neoplasia** reported only in cats.

It occurs in **older cats 7–15 years of age**, that have had a **history of ocular trauma 3–10 years** previously.

There may be signs of **anterior uveitis** with **keratitis**, with edema and pigmentation of the cornea. These changes may prevent visualization of the intra-ocular structures.

Secondary glaucoma is common at this stage of the disease. The eye will show **buphthalmos (enlarged globe)** with engorged scleral vessels.

If the posterior segment of the eye can be visualized, **white to pink masses** may be seen in the vitreous.

The condition is thought to occur after lens trauma, which triggers the lens **epithelial cells to undergo metaplasia**.

The neoplasia rapidly extends through the choroid and **infiltrates the optic nerve**. Metastasis has been reported.

Survival rate is very low.

Diagnosis

A tentative diagnosis is based on the **signalment, history and signs** of an old cat with a prior history of trauma and signs of glaucoma, uveitis and keratitis.

A definitive diagnosis is based on **histological examination** of tissue.

- **Fine-needle biopsy** can be attempted, but may not yield a diagnostic sample if the tumor contains fibrous and cartilaginous tissue.
- **Histopathology of enucleated globes** shows changes that may include **granulation tissue, fibrosarcoma, osteosarcoma and anaplastic spindle cell sarcoma**.

All blind globes with chronic uveitis should be watched for the development of this condition.

Treatment

Early enucleation with histopathology should be done on all globes with a prior history of trauma whenever there are changes in the size and shape of the globe, or changes in the anterior chamber and cornea indicative of intra-ocular disease.

Severely traumatized blind eyes in cats should be enucleated to prevent the occurrence of this condition, particularly if there has been lens rupture.

Check for metastases to regional lymph nodes and other organs such as lungs and liver prior to surgery.

62. The cat with abnormal pupil size, shape or response

Michael E. Bernays

KEY SIGNS

- Slow or absent pupillary light reflex.
- Unequal pupil size or abnormal pupil shape.

MECHANISM

Abnormal pupil sizes or responses are usually due to processes which affect either the:

- Retina: inflammatory, degenerative or hypertensive retinopathies.
- Afferent or efferent nervous pathways involved in the pupillary light reflex or dilation of the pupil, particularly cranial nerve II and autonomic nerves, i.e. neuropathies.
- Iris: inflammatory or occasionally degenerative diseases.

WHERE?

Pathways involved in the pupillary light reflex.

- Retina, optic nerve, optic chiasm, optic tracts, midbrain, oculomotor nucleus parasympathetic preganglionic fibers, ciliary ganglion, parasympathetic fibers in long ciliary nerve, iris pupillary sphincter muscle.

Pathways involved in sympathetic dilation of the pupil.

- Thalamus, cervical spinal cord long tracts, T1–T3 spinal nerves, sympathetic preganglionic fibers, cranial cervical ganglion, sympathetic postganglionic fibers (middle ear**, orbit), iris dilator muscle.

WHAT?

- The most common diseases causing abnormalities of pupil response include hypertensive retinopathy and infectious diseases of the retina and central nervous system.

QUICK REFERENCE SUMMARY

Diseases causing abnormal pupil size, shape or response

RETINA AND OPTIC NERVE

DEGENERATIVE

- Hereditary progressive retinal photoreceptor dysplasia or degeneration (p 1290)
Young to middle-aged cat with a history of gradual onset vision loss, especially in Abyssinian cats, but also described in Persians and Siamese. Rare.
- Feline central retinal degeneration (FRCD) (p 1285)
Slow onset of vision loss and loss of normal papillary light reflex. Possible history of a diet poor in taurine.

METABOLIC

- Hypertensive retinopathy*** (p 1282)
Old cat with sudden onset of vision loss, dilated and poorly or non-responsive pupils. Fundoscopic signs ranging from retinal hemorrhage and localized subretinal exudate to extensive bullous retinal detachment.
- Anemic retinopathy (p 1288)
Blind, weak cat with profound anemia and retinal hemorrhages and partial to complete loss of papillary light reflexes.
- Hyperviscosity retinopathy (p 1288)
Rare condition causing blindness and loss of pupil reflexes due to retinal damage. Extremely dilated tortuous retinal vessels with monoclonal globulin spike on protein electrophoresis.

NUTRITIONAL

- Taurine deficiency retinopathy* (p 1285)
Slow onset of vision loss and loss of normal papillary light reflex. History of a diet poor in taurine, e.g. dry dog food diet, or a diet high in plant fiber.

INFECTION

- Infectious chorioretinitis** (p 1283)
Caused by protozoa (*Toxoplasma gondii*), fungi (*Cryptococcus neoformans*, blastomycosis, histoplasmosis, coccidioidomycosis), parasites (ophthalmomyiasis (fly larval migration)). Abnormal pupil responses result from retinopathy or central nervous system involvement. Variable signs occur including retinal detachments, retinal hemorrhages, subretinal exudates, subretinal granulomas, pre-retinal hemorrhages, together with systemic signs of infection such as fever, depression, inappetence and weight loss.
- Feline infectious peritonitis (FIP) virus** (p 1284)
Fibrinous peritonitis, CNS disease or fibrinous uveitis in a young cat with variable vision loss and/or abnormal pupil reflexes. Anorexia and/or pyrexia.

TOXIC

- Drug toxicity to fluoroquinolones*-** (p 1284)
Sudden-onset blindness and absent papillary light reflexes associated with recent administration of a fluoroquinolone, e.g. enrofloxacin.

continued

continued

IRIS

DEGENERATIVE

- **Iris atrophy* (p 1287)**

Dilated pupil with sluggish pupillary light reflex in an old cat with normal vision. Visible defects around the pupil margin may occur with atrophy.

- **Feline dysautonomia (p 1289)**

Variable ocular signs, including reduced lacrimation, dilated non-responsive pupils, anisocoria, prolapsed third eyelids, photophobia in conjunction with other systemic signs such as constipation, vomiting and regurgitation, dry mouth or dry nostrils.

ANOMALY

- **Iris coloboma (p 1290)**

Wedge-like or radial sectorial defect in appearance of the iris.

- **Persistent pupillary membranes (PPM) (p 1289)**

Small strand-like structures going from one part of the iris collarette to another, to the anterior lens capsule or to the posterior corneal surface.

- **Anisocoria associated with blue irides and deafness in white cats* (p 1287)**

Uneven-sized pupils in a white cat, with the larger pupil on the same side as a unilateral blue iris.

INFECTION

- **Infectious anterior uveitis – protozoal, fungal or parastic (*Toxoplasma*, *Cryptococcus neoformans*, blastomycosis, coccidioidomycosis, histoplasma capsulatum, ophthalmomyiasis)** (p 1283)**

These infectious organisms may cause chorioretinitis with variable pupil responses, vision loss and retinal changes, which typically include retinal detachment, subretinal exudates or granulomas. Signs of anterior uveitis may also be present such as flare, hyperemia of the iris surface, keratic precipitates and fibrin. Systemic illness is present, typically with pyrexia, inappetence, weight loss and malaise, and often with dyspnea.

- **Feline leukemia virus infection/feline spastic pupil syndrome* (p 1286)**

History of variable pupil behavior with pupils alternating between miotic or dilated, in one or both eyes, over weeks to months. Intervening periods of normality with equal pupils and/or neoplastic disease affecting the iris, iris thickening and inflammation.

- **Feline infectious peritonitis (FIP) virus* (p 1284)**

Fibrinous peritonitis, CNS disease or fibrinous uveitis in a young cat with variable vision loss and/or abnormal pupil reflexes. Anorexia, malaise and/or pyrexia are typically present.

IATROGENIC

- **Use of parasympatholytic drugs** (p 1284)**

Dilated non-responsive pupil associated with a history of recent use of a drug such as atropine or tropicamide in the same eye.

TRAUMA

- **Dyscoria associated with iris synechia or prolapse into a corneal wound* (p 1286)**

Pear- or tear-shaped pupil, with adhesion of the acute angle of the tear to the lens capsule or to a traumatic defect in the cornea.

- **Feline hemidilated pupil syndrome* (p 1287)**

D shape (left eye) or reverse D (right eye) shaped pupil, which becomes accentuated on stimulation of the pupil with bright light.

INTRODUCTION

This chapter refers only to diseases within the globe causing an abnormal pupil size, shape or response.

For other disease processes occurring remotely from the eye see main reference on page 1282 for details (The Cat With Anisocoria or Abnormally Dilated or Constricted Pupils).

For infectious conditions affecting the iris and therefore pupil size or response see main reference on page 1295 for details (The Cat With Abnormal Iris Appearance).

MECHANISM?

Disease processes affecting pupil size or response can generally be divided into:

- Those which affect **afferent** pathways, i.e. going towards the central nervous system (CNS) from the retina.
- Those which affect **efferent** pathways, i.e. going away from the CNS towards the effector organ, in this case the dilator and constrictor muscles of the iris.
- Those which affect the **effector organ**, the **iris** (these diseases are largely covered in The Cat With Changed Iris Appearance).

The term **anisocoria** refers to a difference in pupil size between the two eyes of the same animal.

The term **dyscoria** refers to an abnormality in shape.

The terms **mydriasis** and **miosis** refers to the states of pupil dilation and pupil constriction, respectively.

To demonstrate complete normality of pupil function, the pupil must be shown to dilate in a dark environment and to constrict after stimulation by bright light.

Dynamic contraction anisocoria, where the direct response of an eye to light stimulation is greater than

the indirect response in the opposite eye is regarded as normal in cats. Only static anisocoria (i.e. where one eye is not being stimulated by a light source) is regarded as abnormal.

Disease processes therefore either involve the retina, afferent and efferent nerve pathways or iris and are most often **degenerative, hypertensive, infectious or toxic** in nature.

WHERE?

Abnormalities in pupil size or response can originate from lesions or dysfunction in any of the following regions:

- **Retina, optic nerve, optic chiasm, optic tracts or midbrain** which form the **afferent arm for reflexes** which regulate pupillary responses, i.e. they detect the amount of light getting into the system and transmit information about the light levels to the midbrain.
- **Parasympathetic nervous system.** The efferent arm for pupillary constriction consists of the parasympathetic nucleus of the oculomotor nerve, parasympathetic fibers in cranial nerve III (oculomotor nerve), ciliary ganglion and long ciliary nerves.
- **Sympathetic nervous system.** The efferent arm for pupillary dilation consists of the thalamus, cervical spinal cord long tracts, T1–T3 spinal nerves, pre-ganglionic fibers in the cervical region, cranial cervical ganglion and postganglionic fibers especially as they course through the middle ear.
- **Iris.** Diseases which affect pupil size or response can affect either the dilator or constrictor muscles.

WHAT?

The most common causes of abnormalities of pupil size or response are:

- Diseases of the retina.
- Diseases of the central nervous system.

Less frequent causes of abnormal size or response are:

- **Neuropathy** of the **parasympathetic fibers** within cranial nerve III, which supply the pupillary constrictor muscle, or disease confined to the iris involving the **constrictor muscle**.
- **Injury** to the **sympathetic fibers** supplying the iris dilator, most commonly trauma in the cranial thoracic or cervical region, disease of the middle ear or disease confined to the iris affecting the dilator muscle.
- **Hypertensive retinopathy, fungal or *Toxoplasma* infection causing chorioretinitis or anterior uveitis, feline infectious peritonitis (FIP) and retinal degeneration from inherited or nutritional (taurine deficiency) causes** are the most common intra-ocular causes of abnormal pupil size, shape or response.

DISEASES CAUSING SIGNS OF ABNORMAL PUPIL SIZE, SHAPE OR RESPONSE

HYPERTENSIVE RETINOPATHY***

Classical signs

- Acute-onset vision loss in an old cat.
- Acute onset, usually bilateral, dilated pupils non-responsive or poorly responsive to light.

Pathogenesis

Hypertension causes vasoconstriction of pre-capillary retinal arterioles. Hypoxia of the arteriole causes **smooth muscle necrosis**, eventually leading to **vascular dilatation and leakage of serum and blood**.

Leakage from vessels causes **serous retinal detachment**, subretinal, intraretinal or preretinal **hemorrhage**.

Hypertension is most commonly the result of **hyperthyroidism, renal disease or is idiopathic**.

Clinical signs

Typical history is of **acute onset of vision loss in an old cat, or acute onset of bilaterally (usually) dilated pupils that are non-responsive or poorly responsive to light**.

Fundoscopic findings range from **retinal hemorrhage and localized subretinal exudates**, to extensive bullous retinal detachment.

Other signs suggestive of hypertension such as a **bounding cardiac apex beat** may be evident.

Other signs suggestive of **renal and/or thyroid disease** such as progressive weight loss, polydipsia, polyuria or azotemic breath may be detected from the history or physical examination.

Diagnosis

Diagnosis is initially based on the **characteristic clinical signs**.

Confirmation of the diagnosis is based on a workup involving:

- Blood pressure measurement.
- Clinical pathology suggestive of renal and/or thyroid disease.
- Other procedures such as imaging of the thyroid with radio-isotopes or cardiac ultrasound.

Treatment

Amlodipine (Norvasc, Pfizer) is a **calcium channel blocker** which has a greater effect on vascular smooth muscle cells than on cardiac muscle cells. Dose is approx 0.625 mg/cat/day, i.e. $\frac{1}{4}$ of a 2.5 mg tablet (USA) or $\frac{1}{8}$ of a 5 mg tablet (Australia) q 24 h.

If hypertension is associated with hypertrophic cardiomyopathy then calcium channel blockers such as **Diltiazem** may be used. For more detail see main reference on page 162 for details (The Cat With Tachycardia, Bradycardia or An Irregular Rhythm).

β -blockers such as propranolol (Inderal) can also be used in the management of the cardiac disease at $\frac{1}{4}$ of a 10 mg tablet q 8 h.

Hyperthyroidism, when present, should be treated by surgery, radioactive iodine (^{131}I) or anti-thyroid drugs

such as carbimazole or methimazole. For more details see main reference on page 305 (The Cat With Weight Loss and a Good Appetite).

INFECTIOUS CHORIORETINITIS**

ANTERIOR UVEITIS** (PROTOZOAL, FUNGAL OR PARASITIC) (*TOXOPLASMA*, *CRYPTOCOCCUS NEOFORMANS*, BLASTOMYCOSIS, COCCIDIOIDOMYCOSIS, HISTOPLASMA CAPSULATUM, OPHTHALMOMYIASIS)

Classical signs

- Abnormal pupil light reflexes.
- Variable degrees of vision loss.
- Variable signs on fundoscopy including retinal detachments, retinal hemorrhages, subretinal exudates, subretinal granulomas, pre-retinal hemorrhages.
- Signs of anterior uveitis.

For more details see main reference on page 1300 (The Cat With Abnormal Iris Appearance) or page 1172 (The Blind Cat or Cat With Retinal Disease).

Clinical signs

Organisms that may produce signs of chorioretinitis or uveitis include protozoa (*Toxoplasma gondii*), fungi (*Cryptococcus neoformans*, blastomycosis, histoplasmosis, coccidioidomycosis), parasites (ophthalmomyiasis (fly larval migration)).

Systemic clinical signs of fever, dyspnea, gastrointestinal disease, upper respiratory disease or other organ involvement suggest infection with *Toxoplasma* or any of the systemic fungal diseases.

Abnormal pupil responses occur due to retinopathy or to central nervous system involvement.

Variable degrees of vision loss result, depending on degree of retinal or central nervous tissue injury.

Variable signs on fundoscopy including retinal detachments, retinal hemorrhages, subretinal exudates, subretinal granulomas, and pre-retinal hemorrhages consistent with chorioretinitis.

Signs of **anterior uveitis** such as flare, hyperemia of the iris surface, keratic precipitates, and/or fibrin.

Diagnosis

Diagnosis is based initially on the identification of suspicious signs on careful examination of the fundus and the anterior segment.

Diagnosis is confirmed by serology, or identification of the characteristic morphology of a pathogen from the subretinal exudate or anterior chamber fluid, or from another site such as lymph node, bone marrow, liver or lung aspirate.

- **Technique of anterior chamber aqueous centesis:** Prepare the eye using a 1:20 Povidine solution. Under sedation using topical anesthesia and using illumination and magnification, pass a 30-G needle obliquely into the anterior chamber. It is important to visualize the needle passing into the anterior chamber anterior to the iris. Drain approximately $\frac{1}{2}$ a needle hub, then withdraw the needle.
- **Technique of subretinal fluid centesis:** Under general anesthesia, prepare the conjunctival surfaces with 1:20 Povidone iodine and with the pupil dilated (if possible), rotate the globe ventrally and immobilize with Colibri forceps. Insert a 27-G needle perpendicularly, and if possible, visualize the needle passing through the sclera and choroid into the subretinal space, and aspirate 0.1–0.2 ml of fluid.

Many infectious agents may not actually be present within the eye to cause ocular disease, but cause pathology by the presence of immunocompetent cells within the uveal tissue, which have been stimulated by antigens in sites remote from the eye. *Toxoplasma gondii* is thought to cause uveitis in this way.

An important differential diagnosis is hypertensive retinopathy. This is usually a very acute disease occurring mainly in old cats, which have other signs such as weight loss, and renal or cardiac disease. It is not associated with anterior uveitis, and is not usually associated with other CNS signs, although seizures may occur.

FELINE INFECTIOUS PERITONITIS (FIP) VIRUS**

Classical signs

- Fibrinous peritonitis, central nervous system disease or fibrinous uveitis in a young cat.
- Variable vision loss and/or abnormal pupil reflexes.
- Systemic signs including anorexia, lethargy and fever.

For more detail see main reference on page 1295 for details (The Cat With Abnormal Iris Appearance) and page 352 (The Thin, Inappetent Cat).

Clinical signs

FIP typically causes fibrinous peritonitis and/or signs of central nervous system disease and/or fibrinous uveitis in a young cat.

Anorexia, pyrexia, weight loss and malaise are usually present. Other signs including icterus, abdominal distention, dyspnea and multifocal neurological signs are variably present.

In the eye, the most common presenting sign is a **fibrinous uveitis**. Fibrinous exudation results in cream to **red-colored solid opacities** in the anterior chamber, or over the surface of the iris.

Other signs of **anterior uveitis** such as blood or cloudiness in the anterior chamber, miosis, general reddening or thickening of the iris, and injection of deep episcleral vessels may be evident.

Variable vision loss and/or abnormal pupil reflexes may be present.

Usually occurs in a cat less than 3 years of age, which has been **housed with other cats in the previous 18 months**, for example, in a cattery or multi-cat household.

Diagnosis

Diagnosis is based initially on the **suspicious clinical signs**. The “wet” forms (fibrinous peritonitis) and “dry” forms of the disease usually occur separately.

Serology is usually regarded as being of dubious benefit in the diagnosis, as the FIP organism cross-reacts with enteric forms of coronavirus.

Diagnosis can only be **confirmed on characteristic histopathology** of affected tissues on biopsy or necropsy examination. Typical change is described as a pyogranulomatous vasculitis. Necrosis and a fibrinoid response are seen in some cases.

USE OF PARASYMPATHOLYTIC DRUGS**

Classical signs

- Dilated non-responsive pupil associated with normal vision.
- History of recent use of one of these drugs in the same eye.

Clinical signs

Dilated non-responsive pupil(s) associated with normal vision.

History of use of eye drops containing a parasympatholytic drug such as atropine or tropicamide in the previous 1–2 weeks.

Diagnosis

Diagnosis is based purely on the clinical signs, and the history of recent use of one of these drugs in the same eye.

Diagnosis is usually confirmed by the **return of normal pupil reflexes within 1–2 weeks** of cessation of use of the drug in the eye.

DRUG TOXICITY TO FLUOROQUINOLONES***

Classical signs

- Acute onset of bilaterally dilated pupils, non-responsive to light.
- Acute onset vision loss.
- History of recent use of a fluoroquinolone, especially at higher than recommended dose.

Clinical signs

Acute onset of bilaterally dilated pupils that are non-responsive to light.

Acute onset of **vision loss**.

There is a history of **recent use of a fluoroquinolone**, especially at higher than recommended dose rate. Blindness may also occur at the recommended dose, and appears to be an idiosyncratic reaction to the drug.

- Anecdotal personal communication suggests that the problem is seen frequently when Enrofloxacin is given at a daily dose rate of 20 mg/kg (the standard recommended dose rate is 5 mg/kg q 24 h).

The retina has a normal appearance on fundoscopy.

Diagnosis

Diagnosis is based on the **acute onset of the clinical signs** and the history of recent use of a **fluoroquinolone**, especially at a higher than recommended dose.

Prognosis

Prognosis for vision is **usually guarded**, but may be improved if the toxicity is recognized in the early stages and the drug withdrawn immediately.

TAURINE DEFICIENCY RETINOPATHY*

FELINE CENTRAL RETINAL DEGENERATION (FCRD)

Classical signs

- Vision loss in advanced cases.
- Typical ophthalmoscopic signs starting in the area centralis progressing to involve the whole of the retina.
- History of inadequate diet.

Pathogenesis

The disease occurs in **cats fed an inadequate diet**, especially cats fed commercial dog foods, or a diet high in plant fiber.

Taurine deficiency is regarded as being the primary factor leading to **photoreceptor degeneration**.

The syndromes feline central retinal degeneration (FCRD) and taurine deficiency retinopathy are regarded by many authors as being the same disease. The disease is still **occasionally seen in cats which appear to have adequate levels of dietary taurine**, but the overall incidence of the disease throughout the world appears to have declined as the taurine content of commercial diets has been increased.

Taurine deficiency also causes **dilated cardiomyopathy**. See main references on page 151 for details (The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

Clinical signs

Vision loss occurs in the **later stages** of the disease, and is associated with a poor pupil light reflex.

Characteristic retinal lesions are evident on fundoscopy.

- **Focal degeneration** occurs in the **area centralis at first**. The area centralis at first develops a granular appearance, then becomes hyper-reflective.
- A second hyper-reflective lesion then develops nasal to the optic disc, which eventually coalesces with the area centralis lesion to form a broad hyper-reflective band dorsal to the optic disc.
- **Finally, generalized retinal degeneration develops**, with generalized tapetal hyper-reflectivity and retinal vessel attenuation.

Diagnosis

Diagnosis is based on clinical signs, in particular observation of the typical retinal lesions.

Electroretinography (ERG) can be performed to identify altered photoreceptor function. **Cones appear to be affected more than rods**, so these cats will have reduced b waves in photopic (light) conditions and better responses in scotopic (dark-adapted) conditions.

Treatment

Administer taurine supplementation. A minimum intake of **110 mg/kg body weight per day** is needed for maintenance of normal retinal function.

Prognosis

Effects of prolonged deficiency are **only partially reversible**, and supplementation is of no value where there is advanced retinal degeneration with blindness. The appearance of the lesions evident at time of diagnosis will remain the same, even though the ERG signs associated with rod degeneration may reverse.

DYSCORIA ASSOCIATED WITH IRIS SYNECHIA OR PROLAPSE INTO A CORNEAL WOUND*

Classical signs

- Pear- or tear-shaped pupil, with adhesion of the acute angle of the tear to the lens capsule or to a traumatic defect in the cornea.

Clinical signs

Pear- or tear-shaped pupil, with the acute angle of the tear **sticking to either the lens capsule**, or to a traumatic defect in the **cornea**.

The abnormal shape is often accentuated by stimulating the papillary light reflex with a bright light.

Diagnosis

Diagnosis is based purely on **careful examination of the eye** by focal light examination or slit lamp biomicroscopy.

Treatment

Treatment is usually either medical or surgical.

- **Medical treatment with mydriatics** such as atropine, mydriacyl or 10% phenylephrine will sometimes pull the iris away from the lens or cornea, if used in the very early stages.
- **Surgical repair** by a veterinary ophthalmic surgeon is recommended. Repair the corneal laceration and replace the iris and tamponade away from the corneal wound, using viscoelastics.

FELINE LEUKEMIA VIRUS INFECTION/FELINE SPASTIC PUPIL SYNDROME*

Classical signs

- History of variable pupil behavior with pupils at different times alternating between miotic or dilated, in one or both eyes, over weeks to months. Intervening periods of normality with equal pupils.
- Normal vision.
- Pupils may fail to dilate or incompletely dilate in semi-darkness.

Pathogenesis

Viral neuritis is caused by feline leukemia virus (FeLV) and affects the parasympathetic and/or sympathetic efferent fibers to the iris.

Clinical signs

Cats retain vision, but the **pupils fail to dilate**, or incompletely dilate in semi-darkness.

The history often reveals **paradoxically varying pupil behavior**, with pupils alternating between miotic or dilated, in one or both eyes in the weeks to months prior to presentation. There may have been intervening periods of normality with equal pupils.

Other ocular signs may be seen, for example, FeLV-associated **lymphoma** involving the iris, may cause swelling and hemorrhage of the iris surface. See main reference on page 1300 for more details (The Cat With Abnormal Iris Appearance).

Diagnosis

Diagnosis is based on the history of an intermittent, **bizarre, inexplicable variation in pupil response**.

Supportive evidence is based on positive testing for FeLV.

Treatment

There is no treatment for this condition. This syndrome is thought to have a very poor prognosis with

most cats dying within 2 years from other manifestations of the feline leukemia complex.

FELINE HEMIDILATED PUPIL SYNDROME*

Classical signs

- D-shaped pupil in the left eye or reverse D-shaped pupil in the right eye.

Pathogenesis

Cats have two short ciliary nerves carrying only parasympathetic fibers from the ciliary ganglion, referred to as the malar (lateral) and nasal (medial) nerves. The **malar nerve innervates the lateral half of the iris sphincter**, while the **nasal nerve innervates the medial half**. The dog in contrast has 5–8 short ciliary nerves which contain both sympathetic and parasympathetic fibers.

Damage to the malar nerve results in constriction of only the medial half of the pupillary constrictor muscle, while **damage to the nasal nerve** will cause constriction of only the lateral half of the muscle during miosis.

Clinical signs

Pupil appears as **D shaped in the left eye or reverse D shaped in the right eye**. The D shape is accentuated by stimulating the pupillary light reflex with a bright light.

Diagnosis

Based entirely on the observation of a D- or reverse D-shaped pupil.

Treatment

No specific treatment is indicated. Some will reverse over time, provided the nerve has not been completely transected.

ANISOCORIA ASSOCIATED WITH BLUE IRIDES AND DEAFNESS IN WHITE CATS*

Classical signs

- White cat with behavioral signs suggesting deafness.
- With a unilateral blue iris, pupils are uneven sized (anisocoria) with a larger pupil on side of blue iris.

Clinical signs

Reduced pigmentation of the iris causes blue iris coloration in a white cat. These cats also have **reduced pigment in the retinal pigment epithelium and choroid, and have no tapetum**. Where the lack of pigment is unilateral, there will always be an anisocoria, with the **non-pigmented side having a larger pupil**. This is thought to be the result of an **abnormality of the pupillary light reflex**, caused by the effect of lack of pigment on the development of the afferent pathways to the lateral geniculate nucleus and pretectal nucleus.

White cat with behavioral signs suggesting **deafness**.

Diagnosis

Diagnosis is based purely on the clinical signs occurring in a white cat.

IRIS ATROPHY*

Classical signs

- Loss of normal iris color associated with increased transparency of the iris in an old cat.
- Dilated pupil with sluggish pupillary light reflex (PLR).

Pathogenesis

Age-related atrophy and thinning of iris structures occur, especially involving the anterior stroma, pupil margin and associated pupillary constrictor muscle.

Clinical signs

Cat is **older than 10 years of age**.

There is **loss of normal coloration** because of **loss of pigment** in the anterior iris stroma. This may be especially obvious in old Siamese or other color-dilute cats with blue irides (e.g. Himalayan). The iris can become so thin, that it may take on a transparent appearance. Vision is normal.

Loss of normal pupillary light reflex is associated with atrophy of the pupillary sphincter. This sign is less commonly seen in the cat than in the dog, as the pupillary sphincter shape is more often conserved in feline iris atrophy, resulting in a **sluggish pupillary light reflex** rather than a dilated non-responsive pupil. Visible defects may occur around the pupil margin with atrophy.

Diagnosis

Diagnosis is based purely on consideration of the **age and breed of the cat**, that is, an old color-dilute cat greater than 10 years of age, and on the **clinical signs** of a sluggish pupillary light reflex, and loss of iris pigmentation.

Treatment

No treatment is possible for iris atrophy.

ANEMIC RETINOPATHY

Classical signs

- Blind, weak cat with profound anemia.
- Retinal hemorrhages and attenuated, pale retinal vessels.
- Partial to complete loss of pupil light reflex.

See main reference on page 1186 (The Blind Cat or The Cat With Retinal Disease).

Clinical signs

Blind cat with partial to complete loss of pupil light reflex.

Retinal hemorrhages and attenuated, pale retinal vessels.

Other **signs of severe anemia**, e.g. pale mucous membranes, increased respiratory rate and lethargy. Anemia must be **profound** for this syndrome to occur, i.e. **usually the PCV is less than 10%** or hemoglobin less than 5 g/dl.

Diagnosis

Diagnosis is based initially on the clinical signs of a severely anemic cat with poor papillary light reflexes and multiple small retinal hemorrhages.

Diagnosis is confirmed on hematology. The cause of the anemia should be identified. Common causes of profound anemia include FeLV-associated anemia or *Mycoplasma haemofelis* infection. FeLV-associated anemia may also be accompanied by thrombocytopenia which may contribute to the retinal hemorrhages.

HYPERVISCOSITY RETINOPATHY

Classical signs

- Blindness and loss of pupil reflexes.
- Extremely dilated tortuous retinal vessels, retinal hemorrhages, retinal detachment, perivascular effusion, optic disc edema.
- Monoclonal globulin spike on protein electrophoresis.

Clinical signs

Blindness and loss of pupil reflexes occur due to retinal damage.

Extremely dilated, tortuous retinal vessels, retinal hemorrhages, retinal detachment, perivascular effusion and optic disc edema are evident on fundoscopy.

A variety of **other clinical signs** including lethargy, weight loss, inappetence, pale mucous membranes, neurological signs and lameness may be exhibited.

Rare condition in cats.

Diagnosis

Diagnosis is initially based on the suspicious signs seen on fundoscopy, especially the presence of **bizarre, dilated, tortuous retinal vessels**.

Diagnosis is confirmed by demonstration of a **monoclonal globulin spike** on protein electrophoresis.

FELINE DYSAUTONOMIA

Classical signs

- Variable ocular signs, including reduced lacrimation, dilated non-responsive pupils, anisocoria, prolapsed third eyelids, photophobia.
- Other systemic signs such as constipation, vomiting and regurgitation, dry mouth or dry nostrils.

AU:
Data
missing

For more details see main reference on page 792 (The Constipated or Straining Cat) or page 203 (The Incontinent Cat).

Clinical signs

Ocular signs are due to abnormalities of autonomic innervation to eye structures and can include reduced lacrimation, **dilated non-responsive pupils, anisocoria, prolapsed third eyelids** and photophobia in a cat with vision.

Other systemic signs such as **constipation, vomiting and regurgitation, dry mouth or dry nostrils** are related to effects of the disease on autonomic nerves supplying secretory glands or the gastrointestinal system.

Typically, the onset of signs is **acute over 48 h and associated with depression and anorexia**.

Rare disease, and most common in the United Kingdom.

Diagnosis

The disease can be suspected in any cat showing combinations of the clinical signs.

Definitive diagnosis is based on histopathology of autonomic ganglia at necropsy.

PERSISTENT PUPILLARY MEMBRANE (PPM)

Classical signs

- Strands of iris-like tissue arising from the iris collarette and crossing the pupil space, or attaching to the cornea or lens.

Classical signs—Cont'd

- Dot-like opacities on the endothelial surface of the cornea or the anterior capsule of the lens.
- Thin strands of iris tissue crossing the pupil space.

Pathogenesis

The pupillary membrane is a mesodermal embryonic structure, which, until regression, forms a solid sheet of tissue bridging the pupil space and the anterior chamber.

The **pupillary membrane arises from the iris collarette**.

In adult cats, the collarette appears as a slightly raised region halfway between the pupil margin and the iris root.

The pupillary membrane remains as **persistent strands of tissue** in the anterior segment of the eye, **if it fails to rarify in late fetal life**.

Clinical signs

Fibrous strands of iris-like tissue extend **from the iris collarette** (raised area approximately half way between the iris root and the pupillary margin) to either another region of the collarette, the anterior capsule of the lens, or the **posterior corneal surface** (most commonly). The strands can be very thin, and magnification may be required to visualize them.

Dot-like gray to black opacities may be visible on the endothelial surface of the cornea or the anterior capsule of the lens, and are associated with strands attaching the opacity to the iris. The opacities are unassociated with a history of previous inflammation within the eye.

The condition is **rare in cats** compared to the frequency with which it is seen in dogs, and rarely seems to affect the pupillary light reflex or pupil shape.

Diagnosis

Diagnosis is based on the **characteristic appearance** of the persistent pupillary membranes on careful ocular examination.

Differential diagnosis

The gray opacities formed by persistent pupillary membranes, which attach to the corneal endothelium should

be differentiated from **keratic precipitates (KPs)**, formed as a result of anterior uveitis. A strand of tissue attaching the opacity to the iris, and the absence of other signs of anterior uveitis is diagnostic of a persistent pupillary membrane.

Treatment

No treatment is indicated.

IRIS COLOBOMA

Classical signs

- Wedge-like or radial sectorial defect in the iris.

Clinical signs

Wedge-like or radial sectorial defect in the iris.

Occurs as a **congenital anomaly**, but can be first noticed in a cat of any age.

The defect may enable structures behind the iris, for example the lens equator or lens zonules, to be visualized more readily in the affected sector.

Diagnosis

The condition is quite rare in cats, and should be differentiated from **iris atrophy** seen in old color-dilute (Himalayan or Siamese) type cats.

HEREDITARY PROGRESSIVE RETINAL PHOTORECEPTOR DYSPLASIA OR DEGENERATION

Classical signs

- Progressive vision loss especially in a young Abyssinian cat.
- Slow loss of pupillary light reflexes.
- Fundoscopic signs of tapetal hyper-reflectivity and retinal vessel attenuation.

Pathogenesis

Although rare, genetically determined **progressive retinal rod-cone degeneration** has been described in Abyssinian, Siamese and Persian cats.

The best-described degeneration occurs in the **Abyssinian cat**. In this breed, both autosomal dominant rod-cone dysplasia (onset 2–3 months of age), and autosomal recessive rod-cone degeneration (onset 1–2 years of age) modes of inheritance have been described. The disease in Abyssinians is now seen rarely.

Clinical signs

Typically there is a history of **progressive vision loss**.

Slow loss of pupillary light reflexes progresses to dilated pupils non-responsive to light.

Occasionally other signs, such as variable or intermittent **nystagmus**, are seen, especially in the rod-cone dysplasia in Abyssinian kittens.

In the adult-onset form, the fundoscopic signs start as a **subtle grayish discoloration in the central retina** on each side of the optic nerve head. The lesion progresses to a more diffuse gray tapetal discoloration with early retinal vessel attenuation. Later, hyper-reflective areas start to appear within the discolored tapetum. Finally, there is extensive tapetal hyper-reflectivity with severe attenuation of retinal vessels.

In the early-onset form there is tapetal fundus dullness and loss of detail evident at 8–12 weeks of age. Progression of the disease is fairly rapid, with development of tapetal hyper-reflectivity, loss of pigmentation in the non-tapetum and vessel attenuation. There is end-stage degeneration by 12 months of age.

Diagnosis

Diagnosis is based on the history of a **slow onset of vision loss**, with slow deterioration of the pupillary light reflex and characteristic fundoscopic changes in an Abyssinian cat.

Diagnosis can be confirmed by demonstration of progressive reductions in b-wave amplitude on electroretinography.

Differential diagnosis

Other retinal diseases can usually be differentiated by age and breed of the cat, other systemic signs and the fundoscopic changes.

- **Taurine deficiency retinopathy** may also produce the signs associated with dilated cardiomyopathy.
- **Hypertensive retinopathy** is usually sudden in onset in an old cat, and typically there is retinal detachment and associated renal and/or thyroid disease.

- **Feline infectious peritonitis** usually causes signs in young cats. Typically systemic signs of anorexia, lethargy and fever are also seen.

Treatment

There is no treatment for progressive retinal degeneration.

63. The cat with abnormal iris appearance

Michael E. Bernays

KEY SIGNS

- Abnormal iris shape.
- Abnormal iris coloration.

MECHANISM?

- Inflammatory processes, either idiopathic or associated with infectious agents, are the most common cause of changed iris appearance. Neoplasia, immune-mediated inflammation and degeneration are less frequent mechanisms for change.

WHERE?

- Iris.
- Other organ systems.

WHAT?

- Most diseases which alter iris appearance are inflammatory associated with infectious agents such as FIP, FIV, FeLV and *Toxoplasma*, or are idiopathic. Iris neoplasia from melanoma or lymphosarcoma are less common. Iris atrophy associated with age-related degeneration is common in old cats.

QUICK REFERENCE SUMMARY

Diseases causing abnormal iris appearance

DEGENERATIVE

- **Iris atrophy* (p 1299)**

Thinning of the iris with loss of normal iris color. Loss of normal pupillary constrictor function resulting in sluggish pupil light reflex in an old cat.

ANOMALY

- **Iris coloboma (p 1304)**

Notch-like or sectorial defect in structure of the iris. Unusual.

- **Persistent pupillary membranes (p 1304)**

Small strand-like structures going from one part of the iris collarette to another, to the anterior lens capsule or to the posterior corneal surface. Rare.

- Iris cyst (p 1305)

Small brown to black cyst-like structures commonly found at the pupil margin which may become more obvious with pupil dilation. May be semi-transparent.

METABOLIC

- **Pre-iridal fibrovascular membranes* (p 1303)**

New vessels growing across the anterior surface of the iris giving the iris a pink injected appearance. An intra-ocular neoplasm, a retinal detachment or signs of chronic inflammation may be evident. There may be secondary hyphema or glaucoma.

NEOPLASTIC

- **Iris neoplasia*** (p 1297)**

Diffuse iris melanoma appears as a brown to light tan discoloration, which is rapidly progressive over the iris surface over weeks to months. It usually occurs in older cats, and is usually unilateral. Lymphosarcoma appears as bilateral iris swelling, and anterior chamber hemorrhage, in a young cat with or without other signs suggesting a multicentric location. Ciliary body adenoma is rare, and appears as a slow-growing whitish to cream mass behind the pupil margin. Metastatic neoplasia from an extra-ocular primary tumor is an intra-ocular neoplasm involving the iris, and is associated with a similar neoplasm remote from the eye, e.g. mammary or uterine adenocarcinoma.

INFECTIOUS

Viral:

- **Feline leukemia virus (FeLV)** (p 1300)**

Signs of anterior uveitis such as blood, fibrin or cloudiness in the anterior chamber, miosis, or general reddening or thickening of the iris in a FeLV-positive cat. Bilateral iris swelling from lymphosarcoma may be present.

- **Feline immunodeficiency virus (FIV)** (p 1302)**

Signs of anterior uveitis such as blood, fibrin or cloudiness in the anterior chamber, miosis, or general reddening or thickening of the iris and/or swelling associated with lymphosarcoma in a FIV-positive cat.

- **Feline infectious peritonitis (FIP) virus*** (p 1295)**

Severe anterior fibrinous uveitis, usually bilateral, in a young cat. Other signs of FIP such as anorexia, weight loss, depression, pyrexia, abdominal or chest effusions and/or multifocal neurological disease.

Bacterial:

- *Bartonella henselae* (cat-scratch fever) (p 1305)

Typically, naturally infected cats only develop subclinical disease, although anterior uveitis has been reported.

Protozoal:

- *Toxoplasma gondii**** (p 1296)

Signs may be acute, or chronic and intermittent. Fever, lethargy and anorexia with various combinations of respiratory, hepatic, ocular and neurological signs.

continued

continued

Fungal:

- **Fungal infections (*Cryptococcus neoformans*, blastomycosis, coccidioidomycosis, *Histoplasma capsulatum*)** (p 1302)**

Fever, depression, anorexia and weight loss combined with signs of other organ disease such as involvement of lung, liver, bone marrow, lymph nodes, CNS and/or eyes. Typically there is chorioretinitis progressing to anterior uveitis and endophthalmitis associated with positive serological evidence of an infectious cause, or identification of an organism in anterior chamber fluid. Fungal uveitis has a geographic distribution.

Parasitic:

- **Cuterebra larval migration (ophthalmomyiasis) (p 1305)**

Vision loss, poor PLR and characteristic track-like lesions in the tapetal fundus, with or without anterior uveitis.

- **Ocular dirofilariasis (p 1305)**

Uveitis occurs associated with presence of adult filaria in the eye. Rare.

Immune:

- **Lymphocytic-plasmacytic uveitis* (p 1302)**

Chronic gray to slightly tan nodules in the anterior stromal surface of the iris.

Idiopathic:

- **Idiopathic uveitis* (p 1302)**

Uveitis in a cat where extensive investigation does not reveal a possible etiology.

Trauma:

- **Penetrating injuries to the iris** (p 1299)**

Changes may occur in the iris appearance associated with trauma, including fibrinous adhesions to adjacent structures, tears in the iris proper or iris prolapse through the outer ocular coats, i.e. the cornea and sclera. Penetrating foreign bodies may or may not be obvious.

INTRODUCTION**MECHANISM?**

The most common cause of changed iris appearance is inflammation, most commonly associated with infectious agents, although inflammation secondary to neoplasia and immune-mediated disease may also occur.

Important pathophysiologic processes involved in iris inflammation (anterior uveitis) include breakdown of the blood–aqueous barrier associated with increased vessel permeability, release of chemical mediators following tissue damage, and chemotaxis of polymorphonuclear and mononuclear leukocytes.

The most important chemical mediators are probably the **arachidonic acid derivatives** released from damaged cell membranes, which then participate in the cyclo-oxygenase and the lipoxygenase pathways. Prostaglandins produced by the cyclo-oxygenase pathway are regarded as the most important chemical mediators. Oxygen free radicals may also be important.

While most types of immunologic responses are thought to occur in the eye, types II (antibody-mediated cytotoxic responses), III (immune-complex deposition and complement activation) and IV (cell-mediated cytotoxic responses) are thought to be the most important. Monocytes and macrophages are important in

phagocytosis, antigen processing and presentation to T cells.

Immune-mediated responses to retinal or lens antigens may be important in immune-mediated uveitis where no infectious cause is identified.

Some neoplastic diseases, e.g. intra-ocular lymphosarcoma can look very inflammatory, whereas others (e.g. diffuse iris melanoma) tend to cause gross pigment changes without necessarily causing an inflammatory response until the disease becomes very advanced.

Changes which can be seen in association with inflammation of the iris (anterior uveitis) include:

- **Generalized reddening** (hyperemia) and thickening of the iris.
- **Frank hemorrhage** from the iris surface.
- Fibrinous exudation resulting in **cream to red-colored solid opacities** in the anterior chamber, or over the surface of the iris.
- **Miosis.**
- **Grayish nodules** on the iris surface which represent localized aggregations of lymphoid cells.
- Gray to tan, dot-like, or sometimes coalescing opacities on the endothelial surface of the cornea (called **keratic precipitates**).
- **Cloudiness** of the aqueous fluid (called aqueous flare).
- Deposits of pigment or inflammatory cell debris on the anterior lens capsule. Adhesions of the pupil margin to the lens may occur (called **posterior synechiae**). If synechia are extensive, there may be anterior bowing of the iris (called iris bombé) and a shallow anterior chamber.
- Anterior cortical **cataract**.
- **Iris cysts**, either attached to the pupillary margin or free floating in the anterior chamber.
- **Anterior vitreous opacity** due to inflammation of the pars plana of the ciliary body (“pars planitis”). This change is especially associated with feline immunodeficiency virus (FIV) infection.
- **Corneal vascularization.**
- Engorgement of the deep episcleral vessels.
- **Lens subluxation or luxation.** This is usually due to inflammatory destruction of ciliary zonules, but may result from secondary glaucoma, which causes globe enlargement and zonule stretching.

WHERE?

Diseases which alter iris appearance can arise in and be confined to the iris, they can result from disease processes involving other parts of the eye, or they can be a localized manifestation of systemic disease.

WHAT?

Most diseases which alter iris appearance are inflammatory. Investigation of many cases of anterior uveitis for a possible infectious cause may not identify an etiologic agent, and so **many cases of uveitis in the cat are regarded as “idiopathic”**. Most cases of idiopathic uveitis probably involve an autoimmune response to an unidentified endogenous antigen.

Severe inflammation in a young cat is more likely to have an infectious etiology and **feline infectious peritonitis (FIP)** should be considered as one of the more likely possibilities.

A change in pigmentation in an older cat is more likely to be due to **neoplasia**.

Iris atrophy secondary to degenerative changes is a common incidental finding in may old cats.

Congenital abnormalities such as persistent pupillary membranes or iris colobomas are seen far less commonly.

DISEASES CAUSING ABNORMAL IRIS APPEARANCE

FELINE INFECTIOUS PERITONITIS VIRUS***

Classical signs

- Severe anterior fibrinous uveitis, usually bilateral, in a young cat.
- Other signs of FIP such as anorexia, weight loss, pyrexia, abdominal or chest effusions, multifocal neurological disease.

See main references on page 372 for details (The Pyrexia Cat).

Pathogenesis

Infection is thought to be acquired by inhalation or ingestion.

The virus replicates in the tonsils, epithelial cells of pharynx, respiratory mucosa and small intestine then infects monocytes, which disseminate the virus throughout the body.

The effusive form of the disease is thought to occur in cats with poor cell-mediated immune (CMI) responses, and the non-effusive form in cats with partial cell-mediated immunity.

The effusive form is associated with **immune complex-mediated vasculitis**.

The non-effusive form is characterized by **pyogranulomatous and granulomatous lesions in many organs** in particular eyes, brain, liver and kidney.

Clinical signs

Initially mild upper respiratory tract signs may occur, but usually go unnoticed.

Generally the disease is seen in young cats less than 1–2 years of age.

Anorexia, pyrexia, weight loss and malaise are typical. Other signs including icterus, abdominal distention, dyspnea and multifocal neurological signs are variably present.

In the eye, the most common presenting sign is a fibrinous uveitis. Fibrinous exudation results in **cream to red-colored solid opacities** in the anterior chamber, or over the surface of the iris.

Other signs of anterior uveitis such as blood or cloudiness in the anterior chamber, miosis, general reddening or thickening of the iris, and injection of deep episcleral vessels may be evident.

Diagnosis

A presumptive diagnosis is initially based on a combination of the clinical signs and laboratory findings. FIP should be **suspected especially when a bilateral fibrinous uveitis occurs in a young cat**.

Hematology and biochemistry may be helpful but are not definitive. Changes typical of FIP include a mild normocytic, normochromic anemia, neutrophilic leukocytosis and lymphopaenia, elevated total serum proteins, and a **polyclonal gammopathy** due to elevated alpha-2 globulins and gamma globulins.

Serology is usually regarded as being of dubious benefit in the diagnosis, as the FIP coronavirus cross-reacts with enteric forms of coronavirus.

Diagnosis can only be confirmed on characteristic histopathology of affected tissues on biopsy or necropsy examination. Typical change is described as a pyogranulomatous vasculitis. Necrosis and a fibrinoid response are seen in some cases.

Treatment

No treatment will cure the disease, which is invariably fatal. There is no prognosis for long-term survival, especially for cases with the effusive form. Cases with uveitis only may have a slightly better long-term prognosis.

Recent interest has been shown in the use of recombinant **alpha interferon** at doses ranging between 10 000–30 000 IU/kg given SQ daily for **short-term remission of signs**.

Palliative therapy traditionally has included the use of corticosteroids, including **topical 0.5% prednisolone acetate** applied to the eyes q 6–8 h for cases with uveitis.

Cats which are anorexic and depressed, and do not respond to supportive therapy, should be euthanized.

TOXOPLASMA GONDII INFECTION***

Classical signs

- Fever, weight loss, inappetence, malaise.
- +/- Muscle or joint pain.
- +/- Signs of respiratory, hepatic and/or neurological disease.
- Typical signs of anterior uveitis.

See main references on page 375 for details (The Pyrexia Cat) and page 958 (The Cat With Generalized Weakness).

Pathogenesis

Infection occurs by:

- Ingestion of tissue cysts (bradyzoites) from an intermediate host (most common) or
- Ingestion of sporulated oocysts from soil or water (far less common) or
- Transplacental transmission (rare).

After ingestion a **gut replication cycle occurs**. The cat is the definitive host and is the only species in which this occurs. This results in the production of unsporulated (non-infective) oocysts which are passed in feces. The oocysts **sporulate in the environment after 1–5 days** and become **infective**. Intestinal replication will also result in the formation of **tachyzoites (active acute infection)** or **bradyzoites (inactive latent infection)**.

Activation of bradyzoites, typically found in muscle, brain and liver, may occur because of other disease states such as FIV, which act as stressors or immunosuppressors. High-dose corticosteroid use has been known to activate dormant *T. gondii* infections.

When bradyzoites are activated, they undergo rapid replication causing destruction of tissue and inciting an inflammatory response in various tissues, notably the **central nervous system, uveal tract of the eye, liver and lungs**.

Clinical signs

Signs may be acute, or chronic and intermittent. The acute fatal form occurs mostly in kittens.

Fever, anorexia, depression, weight loss.

Muscle or joint pain may be evident.

Dyspnea is common in kittens and cats with the acute form, and is associated with pneumonia.

Multifocal neurologic signs.

Signs of liver disease such as jaundice, enlarged liver, ascites or elevated liver enzymes.

Ocular signs, especially anterior uveitis, chorioretinitis and optic neuritis. The organism may cause a lymphocytic-plasmacytic uveitis evidenced by gray to tan-colored nodules on the iris surface.

Diagnosis

Diagnosis may be based initially on the clinical signs, but obtaining supportive laboratory data is essential in making a definitive diagnosis.

Serology.

- Demonstration of a **rise in IgM titers** indicates a recent active infection.
- **Comparison of levels of aqueous humor *T. gondii* antibody levels with serum levels** (Goldman–Witmer coefficient or C-value) has been advocated to determine that anterior uveitis has been caused by *T. gondii*, although the use of C-values is still controversial.

Definitive diagnosis requires demonstration of the organism **in inflamed tissues or fluid samples by histology, immunohistochemistry, or polymerase chain reaction (PCR) techniques**.

Treatment

Clindamycin (Antirobe, Upjohn) at a dose rate of 12.5 mg/kg twice daily for 3–4 weeks is usually effective against the organism. If no response is evident after 3 weeks of antibiotic therapy, reconsider the diagnosis.

Concurrent anti-inflammatory therapy decreases the anterior uveitis, e.g. topical 0.5% **prednisolone acetate** drops applied bid–qid.

IRIS NEOPLASIA***

Classical signs

- Diffuse pigmentary change across the anterior iris surface.
- Mass lesions bulging forward from the anterior iris stroma or distorting normal pupil shape.

Pathogenesis

Various tumors occur in the iris such as melanoma, lymphosarcoma, sarcoma and ciliary body tumors.

Diffuse iris melanoma arises as a primary neoplasia of the iris stroma, and is the most common primary intra-ocular neoplasm seen in cats.

Lymphosarcoma results from invasion of neoplastic lymphocytes from the peripheral circulation.

Intra-ocular sarcoma usually occurs as a sequel after (usually years) trauma causing penetrating injury to the lens. It is believed that the sarcoma arises from transformed lens epithelium. This neoplasm forms solid masses within the eye, which metastasize rapidly, usually via the optic nerve.

Ciliary body tumors may represent primary neoplasia or metastatic neoplasia from an extra-ocular site.

Clinical signs

Diffuse iris melanoma typically appears as an enlarging area over months to years of light tan to dark brown pigmentation on the iris surface. Usually the neoplasm does not form an obvious discrete mass, but the iris may become diffusely thickened. The disease is usually unilateral and typically occurs in older cats.

- Presentation may more resemble uveal inflammation than neoplasia.
- Sometimes the disease may present in an advanced state with secondary glaucoma.
- Amelanotic diffuse iris melanomas have also been reported.

Lymphosarcoma and post-traumatic sarcoma more commonly form **discrete masses** within the eye. Lymphosarcoma often presents as bilateral iris swelling, and anterior chamber hemorrhage in a young cat, with or without other signs suggesting multicentric neoplasia.

Ciliary body adenoma is a rare, slow-growing neoplasm, which appears as a whitish to cream mass behind the pupil margin.

Metastatic neoplasia from an extra-ocular primary tumor appears as an intra-ocular neoplasm involving the iris, and is associated with a similar neoplasm remote from the eye, e.g. mammary or uterine adenocarcinoma.

Diagnosis

Diagnosis is based initially on the appearance of the iris and consideration of the history.

Amelanotic diffuse iris melanomas are difficult to diagnose unless the effects of the tumor on angle obstruction and resultant glaucoma are observed.

Definitive diagnosis may be obtained by **fine-needle aspirate biopsies** or anterior chamber centesis and cytology.

Differential diagnosis

Diffuse iris melanoma needs to be differentiated from other causes of pigmentation of the iris and can look similar to:

- **A benign pigmented nevus**, which appears as a flat pigment spot in the iris. A nevus will be observed not to have changed in size with serial examination.
- **Post-inflammatory pigmentation**. A detailed history may reveal previous bouts of anterior uveitis within the eye. This pigmentation will not be progressive.

Treatment

Enucleation of an eye with diffuse iris melanoma is recommended if:

- There is evidence of rapid spread of a diffuse iris melanoma. The eye should be reassessed frequently to determine if the pigmentary change is progressive.
- Pigmentary change is seen near or in the irido-corneal angle on gonioscopy.
- A change in pupil shape or mobility occurs.
- Secondary glaucoma develops.

Evidence of metastasis may still occur as late as 2–3 years after enucleation.

If there is a high suspicion or confirmation of an **intra-ocular sarcoma** it requires **immediate enucleation** with exenteration of orbital tissue. Prognosis is still guarded and most cats will eventually die from metastatic disease within months.

Systemic chemotherapy for lymphosarcoma can be attempted unless the eye is already affected by secondary glaucoma. For more detail see main reference on page 432 (The Yellow Cat or Cat With Elevated Liver Enzymes).

PENETRATING INJURIES TO THE IRIS**

Classical signs

- Corneal lacerations.
- Mis-shapen pupil margin and bulging of iris tissue into the corneal defect.
- Visible iris tear.
- Blood and fibrin in the anterior chamber.

Pathogenesis

Injuries to the iris usually occur in conjunction with injuries to the adjacent cornea or sclera.

If the corneal injury is large, the iris may prolapse through the cornea and plug the defect.

Clinical signs

Trauma to the eye may result in a variety of changes to the iris including:

- **Visible iris tears.**
- **Iris prolapse through the corneal wound.**
A black, bulging membrane will be seen with associated fibrin. The pupil margin is mis-shapen associated with the iris moving forward into the corneal defect.
- **Fibrinous adhesions** to adjacent structures.

Fibrin and blood in the anterior chamber (hyphema) are often present with trauma.

Associated **lens injury may occur**, which may be difficult to appreciate without removing fibrin from the anterior chamber and dilating the pupil.

A penetrating foreign body may or may not be evident.

Diagnosis

Diagnosis is based purely on the appearance of the iris on careful examination.

Treatment

Surgical repair is recommended. This might include replacement of iris tissue into the anterior chamber with suturing of the corneal defect. Viscoelastic substances

and mydriatics can be used to push the iris away from the cornea.

Partial iridectomy may be necessary if a prolapsed section of iris is badly damaged or atonic.

Intra-ocular surgery may be required to **remove a damaged lens** to prevent destruction of the eye by severe lens-induced intra-ocular inflammation. If the lens is severely traumatized then eye ablation would be recommended to reduce the possibility of later post-traumatic intra-ocular sarcoma development.

IRIS ATROPHY**

Classical signs

- Loss of normal iris color and increased transparency of the iris in an old cat.
- Sluggish pupillary light reflex (PLR).

Pathogenesis

Iris atrophy is an **age-related atrophy and thinning of iris structures**, especially the anterior stroma, pupil margin and associated pupillary constrictor muscle.

Clinical signs

Iris atrophy occurs in old cats, and appears as **loss of normal coloration and increased transparency of the iris because of loss of pigment** in the anterior iris stroma. This may be **especially obvious in old Siamese cats or other color-dilute cats** with blue irides. The iris can become so thin that it may take on a transparent appearance.

There may be **some loss of normal pupillary light reflex** (PLR) associated with atrophy of the pupillary sphincter. In old cats with iris atrophy, pupil shape is often retained, but the PLR is not as brisk as in a younger cat. It is unusual to see atrophy to the degree sometimes seen in old dogs, where notch-like defects occur, with thin connecting strands across the defect.

If the pupil becomes very dilated, the equator of the lens may become visible.

Diagnosis

Diagnosis is based principally on a consideration of age and clinical signs.

Treatment

There is no treatment for iris atrophy.

FELINE LEUKEMIA VIRUS (FeLV)**

Classical signs

- Discrete iris or ciliary body masses (FeLV-associated lymphosarcoma).
- Anterior uveitis, fibrin and blood in the anterior chamber.
- Otherwise unexplainable intermittent asymmetric changes in pupil size, shape or response.
- Other FeLV-associated signs, e.g. anemia.

See main references on page 540 for details (The Anemic Cat) and page 350 (The Thin, Inappetent Cat).

Pathogenesis

Following oral or nasal exposure to the virus, there is viral **replication in oropharyngeal lymphoid tissue**. If the immune response to the virus is ineffective in eliminating it, there is **replication of virus in bone marrow**, which leads to viremia, FeLV-related diseases or latent infection.

Infection with the virus is known to **cause a number of neoplasms**, including alimentary, mediastinal, renal, spinal, retrobulbar or lymph node forms as well as a number of hematologic lymphoid malignancies involving different bone marrow precursors.

Malignant lymphoid cells can invade intra-ocular uveal structures, generally as part of a wider syndrome of multicentric lymphosarcoma.

A **viral neuritis** can also be caused by FeLV, and affect parasympathetic or sympathetic efferent fibers to the iris in feline spastic pupil syndrome.

FeLV is also associated with uveitis.

Clinical signs

Discrete iris or ciliary body masses, which cause gross distortion of iris structure, and are usually bilateral.

Fibrin and/or blood may be evident in the anterior chamber indicating the presence of anterior uveitis.

Spastic pupil syndrome is associated with FeLV neuritis. Vision is retained, but one or both pupils are intermittently miotic or dilated over weeks or months, and they do not dilate appropriately with darkness. For more detail see main reference on page 878 (The Cat With Anisocoria or Abnormally Dilated or Constricted Pupils).

Diagnosis

Diagnosis is based on the clinical signs observed in the eye, in association with other signs suggestive of FeLV, e.g. multicentric lymphoma, FeLV-associated anemia.

Diagnosis is confirmed on **clinical pathology** including hematology and cytology of lymph nodes or aqueous centesis samples which demonstrate neoplasia.

A **positive serological test for FeLV antigen** suggests association of the neoplasm or spastic pupil syndrome with FeLV infection. For more details of testing see main reference on page 543 (The Anemic Cat).

Treatment

For more detail see main reference on page 544 (The Anemic Cat)

Treatment of the ocular condition in conjunction with systemic chemotherapy might include topical corticosteroids such as **0.5% prednisolone acetate drops** given q 6–12 h. Prognosis for the eye will be poor to guarded if secondary glaucoma has occurred.

FUNGAL INFECTIONS** (CRYPTOCOCCUS NEOFORMANS, BLASTOMYCOSIS, COCCIDIOIDOMYCOSIS, HISTOPLASMA CAPSULATUM)

Classical signs

- Chorioretinitis progressing to anterior uveitis and endophthalmitis, occurring in a geographical area where fungal infections are known to occur.
- Vision loss and reduced pupil light reflexes in affected eyes.
- Signs of other organ system disease, e.g. renal, CNS, nasal cavity.

See main references on page 16 for details (The Cat With Signs of Chronic Nasal Disease) for cryptococcosis and pages 371, 379, 387 (The Pyrexia Cat) for other fungi.

Pathogenesis

In general, all deep fungal infections enter the body by the **inhalation of aerosolized spores** leading to either **fungal rhinitis** (e.g. *Cryptococcus*) or **pneumonia** (e.g. blastomycosis, histoplasmosis) with subsequent dissemination to other parts of the body, including the eye, by hematogenous or lymphatic spread.

The initial ocular site for establishment of infection is usually the choroid, while the anterior uveal tract is often involved later in the course of the infection.

The different intra-ocular fungi vary in their geographical distribution.

- **Blastomycosis** is caused by a dimorphic fungus, which grows as a yeast in mammalian tissue and as a mycelial form in the environment. Found in the USA (in the midwestern and southeastern states along the Mississippi, Ohio and Missouri Rivers and occasionally mid Atlantic states), Central America, parts of Asia, Africa, Europe and Israel. Close proximity to water may be a factor in its geographical distribution.
- **Cryptococcosis** is caused by a budding capsulated yeast-like fungus with more worldwide distribution. *C. neoformans* is shed in pigeon feces and can be found in soil or in avian excreta. *C. neoformans* var. *gatti* is found in the developing flower of some Australian Eucalypt trees (red river gums and forest red gums). High concentrations of organisms are found in the bark and the accumulated debris surrounding the base of the tree. These trees have been widely exported around the world from Australia.
- **Histoplasmosis** is caused by a dimorphic fungus which forms a free-living mycelial form and yeast-like organisms in mammalian tissues. Found in central USA especially in Ohio, Mississippi and Missouri River basins and in Central and South America. There is association with moist humid conditions, nitrogen-rich soils, and bat and bird excrement.
- **Coccidioidomycosis** is caused by a soil mycelial organism with a natural reservoir in desert soils and around animal burrows. Found in Southwestern USA, Mexico, Central and South America. Animal infection occurs by inhalation of arthrospores, which can transform into spherules and then endospores in lung tissue.

Clinical signs

Typically, there is **anorexia, depression, fever and weight loss** combined with other systemic signs which can involve many other organs, especially the **lungs, brain, nasal cavity but also the orbital tissues, lymph nodes, bones, toenails and skin.**

Most **intra-ocular fungal infections** cause either:

- **Choroidal granulomas** which are typically evident on fundoscopy as a raised area of tapetal hypoflectivity, or **small swollen brownish discolored areas** in the tapetal and non-tapetal retina.
- **Generalized chorioretinitis** and secondary retinal detachments. This may progress to anterior uveitis and endophthalmitis.
- **Optic neuritis**, which is seen as a red, swollen optic nerve that is hyperemic.
- **Anterior uveitis**, which appears as anterior chamber flare, miosis and an inflamed discolored iris.
- Vision loss and **reduced pupil light reflexes** in affected eyes.

Diagnosis

Initial diagnosis is based on the clinical presentation of a cat with a rapidly progressive, usually bilateral chorioretinitis progressing to anterior uveitis, with signs of other systemic disease, and occurring in a geographic area where such fungal disease is known to occur.

Imaging techniques can be used to obtain more supportive evidence of a deep fungal infection:

- Thoracic radiography for pulmonary granulomas.
- Nasal cavity radiography.
- Ocular ultrasound for signs of retinal detachment.

Confirmation of the diagnosis is based on the demonstration of the organism in:

- Cerebrospinal fluid.
- Samples taken by centesis of vitreous or subretinal exudate.
- Histopathology of enucleated globes.
- Bone marrow biopsy samples (histoplasmosis).
- Lung or lymph node aspirates or draining tracts.

Serological tests can be performed, looking for elevated:

- Antibodies (blastomycosis, histoplasmosis, coccidioidomycosis).
- Antigen – Cryptococcal capsular antigen in blood, CSF, or urine is sensitive and specific.

Treatment

Antifungal medications. Drug chosen should be based on results of fungal culture and sensitivity where possible. Treatment may need to be prolonged, depending on response.

- Itraconazole 100 mg PO daily with food.
- Fluconazole 50 mg PO q 8 hours.
- Amphotericin B. See page 26 (The Cat With Signs of Chronic Nasal Disease) for description of administration in a subcutaneous infusion of glucose and sodium chloride to reduce the renal toxicity.

Avoid use of systemic corticosteroids in systemic fungal disease.

Topical steroids or non-steroidals may be used to control the anterior uveitis.

Supportive therapy is important until anti-fungal medication is effective.

Enucleation of the eye is recommended if endophthalmitis and/or secondary glaucoma develop.

Prognosis

Guarded to grave in most cases where there is systemic involvement.

FELINE IMMUNODEFICIENCY VIRUS (FIV) INFECTION**

Classical signs

- Signs of uveitis.
- Bilateral iris swelling associated with neoplasia.

See main references on page 330 for details (The Thin, Inappetent Cat) and page 399 (The Cat With Enlarged Lymph Nodes).

Pathogenesis

Ocular disease including uveitis, glaucoma, infiltration of inflammatory cells in the posterior chamber (pars planitis), focal retinal chorioretinitis and retinal hemorrhages have been reported associated with FIV infection.

Neoplasia including lymphoma (often extra-nodal) have been associated with the terminal stage of the disease, although the exact role of FIV in the neoplastic process is unclear.

Clinical signs

Signs of anterior uveitis, e.g. miosis, injected iris surface, anterior chamber flare, fibrin.

Discrete iris or ciliary body masses causing iris swelling, which is associated with lymphosarcoma.

Diagnosis

Diagnosis is based on the clinical signs of uveitis or lymphosarcoma in a FIV-positive cat, and failure to identify any other possible cause.

LYMPHOCYTIC-PLASMOCYTIC UVEITIS*

Classical signs

- Gray to tan nodules on the anterior surface of the iris.
- Keratic precipitates.

PATHOGENESIS

Lymphocytic-plasmocytic uveitis stems from an **immune-mediated process**, which results in the formation of **numerous lymphoid nodules within the anterior uveal tract**. It is probably a response to endogenous antigens, and in some cats, *Toxoplasma* is regarded as a possible cause.

Clinical signs

Typically there are **gray to tan nodules on the anterior surface of the iris**.

Opacities occur on the **endothelial surface of the cornea** (keratic precipitates)

Aqueous flare (cloudiness of the anterior chamber due to suspended proteins and cells)

Pre-iridal fibrovascular membranes occur in the chronic stages.

Secondary glaucoma, lens luxation and globe enlargement occur in the chronic stages.

Diagnosis

Diagnosis is based principally on the appearance of the iris.

Cytology of aqueous humor usually reveals lymphocytes and occasional plasma cells.

Treatment

There is no cure for this disease. Once the nodules have been formed they will never go away completely with therapy, however treatment will control the inflammation and reduce the incidence of the secondary sequelae.

Topical corticosteroids.

- **Prednisolone** acetate
Prednefrin Forte (Allergan - 1%) applied q 8–12 h.
Sterofrin (Alcon - 0.5%) q 6–8 h reducing to effect.

Topical NSAIDs.

- **Flurbiprofen** (Ocufen 0.03%) applied q 8–12 h.

Mydriatics such as atropine are rarely indicated because of the side effects of salivation seen in cats and the chronic nature of the disease.

Treat glaucoma with:

- Continuing steroid or NSAID therapy.
- Topical carbonic anhydrase inhibitors (Dorzolamide 2% topically tid).
- Topical beta-blockers, e.g. timolol maleate 0.5% applied bid–tid.

Laser cyclo-photo-coagulation in chronic cases non-responsive to medical treatment.

Glaucoma will often be refractory to treatment.

PRE-IRIDAL FIBROVASCULAR MEMBRANES*

Classical signs

- New vessels growing across the anterior surface of the iris giving the iris a pink injected appearance.
- \pm Intra-ocular neoplasm, detached retina and/or uveitis.

Pathogenesis

Pre-iridal fibrovascular membrane (PIFM) formation is associated with angiogenic factors released by proliferating intra-ocular neoplasms, retinal hypoxia or chronic inflammation.

Clinical signs

PIFMs appear as **new vessels growing across the anterior surface of the iris**, giving the iris a pink discoloration.

Because PIFM formation is associated with **intra-ocular neoplasms, retinal detachment or chronic inflammation**, these abnormalities may be evident on careful examination of the eye.

PIFMs may be associated with secondary **hyphema or glaucoma**.

Occasionally the vessels in PIFMs may be visible leaving the pupil margin and migrating across the anterior lens capsule.

Diagnosis

Diagnosis is based on the characteristic appearance of the fibrovascular membranes on the anterior stromal surface of the iris.

Occasionally an underlying cause may be apparent, e.g. a ciliary body epithelial tumor at the pupil space or a total retinal detachment.

Differential diagnosis

Iris neoplasia, especially secondary neoplasms of the iris arising in some other part of the body, e.g. lymphosarcoma resulting in hyphema.

Acute inflammation resulting in pinkish injection of the anterior iris surface.

Treatment

There is no treatment for PIFMs except for treatment of the underlying chronic diseases, which may be associated with the condition. Once formed the PIFMs will remain permanently on the iris surface.

IDIOPATHIC UVEITIS*

Classical signs

- Signs of uveitis.
- Extensive laboratory investigations fail to identify possible etiology.

Clinical signs

Idiopathic uveitis is characterized by any signs of anterior uveitis such as miosis, injected iris surface, anterior chamber flare, and fibrin, where **extensive laboratory investigations fails to identify a possible etiology**.

One study showed there may be a significant positive association of idiopathic anterior uveitis with **high aqueous titers to herpesvirus**.

Diagnosis

Diagnosis is based on the clinical signs of uveitis with failure to identify a possible cause.

PERSISTENT PUPILLARY MEMBRANES

Classical signs

- Strands of iris-like tissue arising from the iris collarette and crossing the pupil space, or attaching to the cornea or lens.
- Dot-like gray to black opacities on the endothelial surface of the cornea or the anterior capsule of the lens unassociated with history of previous inflammation within the eye.
- Rare in cats.

Pathogenesis

Persistent papillary membrane is an embryonic structure, and results from **failure of the pupillary membrane to rarify in late fetal life**.

The pupillary membrane is formed from mesoderm, which, until regression, forms a solid sheet of tissue bridging the pupil space from the iris collarette. In normal adult cats, the collarette appears as a slightly raised region halfway between the pupil margin and the iris root.

The condition is seen rarely in cats compared to the frequency with which it is seen in dogs, and rarely seems to affect the pupil light response or pupil shape.

Clinical signs

Persistent papillary membrane appears as **fibrous strands of iris-like tissue** running from the:

- Iris collarette to another region of the iris collarette. The iris collarette is a raised area approximately half way between the iris root and the pupillary margin.
- Iris to anterior capsule.
- Iris to posterior corneal surface (most common).

The strands can be very thin and magnification may be required to visualize them.

Persistent papillary membrane may also appear as **dot-like gray to black opacities on the endothelial surface of the cornea** or the anterior capsule of the lens, unassociated with history of previous inflammation within the eye.

Diagnosis

Diagnosis is based on the characteristic appearance of the PPMs on careful ocular examination.

Differential diagnosis

The gray opacities formed by PPMs which attach to the corneal endothelium should be differentiated from **kera-tic precipitates**, formed as a result of anterior uveitis. A strand of tissue attaching the opacity to the iris and the absence of other signs of anterior uveitis is diagnostic of a PPM.

Treatment

No treatment is indicated for PPMs.

IRIS COLOBOMA

Classical signs

- Segmental full-thickness defect of the iris with lens visible behind the defect.
- Remaining iris is normal.
- May also cause an abnormal pupil shape.
- Rare in cats.

Clinical signs

The defect is a **rare anomaly** that may be detected in a young cat, and results in a **notch-like or sectorial defect in the iris**.

Iris coloboma appears as **thinned to absent iris stroma in a radial sector of the iris**. The remaining iris appears normal.

Small strands, which are remnants of the iris dilator muscle, may be seen **bridging the space** formed by the defect.

Abnormal pupil shape (dyscoria) may be present.

Diagnosis

Diagnosis is based on the **characteristic appearance** of iris coloboma on ocular examination.

IRIS CYST

Classical signs

- Pigmented cyst-like structures, translucent on illumination, in the anterior chamber or attached to the pupil margin.
- Rare in cats.

Clinical signs

Iris cysts appear as **brown- or black-pigmented cyst-like structures** freely floating in the anterior chamber, or attached to the posterior pigmented epithelium of the iris at the pupil margin. They may be more obvious with pupil dilation.

Iris cysts occur as a congenital abnormality, or occur as a result of inflammation, and are uncommon in cats.

Iris cysts are usually **partly translucent** on focal light illumination.

Diagnosis

Diagnosis is based purely on the characteristic appearance of iris cysts on ocular examination.

CUTEREBRA LARVAL MIGRATION (OPHTHALMOMYIASIS)

Classical signs

- Vision loss.
- Cloudy posterior segment with linear track-like lesions on funduscopy.

Classical signs—Cont'd

- Typical signs of anterior uveitis associated with larva in the anterior chamber.

Clinical signs

Migration of cuterebra larva through the eye causes vision loss and poor pupillary light reflexes.

Characteristic signs on funduscopy include **linear hyper-reflective “tracks” in the tapetal fundus**, linear light gray areas of **reduced pigmentation in the non-tapetum** and cloudy posterior segment. The white body of a fly larva is sometimes seen associated with one of the tracks.

Sometimes the larva is seen in the anterior chamber with associated signs of anterior uveitis.

Diagnosis

Diagnosis is based on **appearance of the suspicious fundoscopic lesions**, or on the observation of the parasite in the anterior chamber with the associated uveitis.

OCULAR DIROFILARIASIS

Classical signs

- White filarial worm in the anterior chamber associated with typical signs of anterior uveitis.

Clinical signs

Immature adult dirofilaria are rarely found in the anterior chamber, and are associated with signs of **corneal edema and/or anterior uveitis**.

Diagnosis

Diagnosis is on observation of a filarial-like parasite within the anterior chamber on ocular examination.

***BARTONELLA HENSELA* (CAT-SCRATCH FEVER)**

Classical signs

- Subclinical or mild fever.
- Occasionally ocular signs associated with anterior uveitis.

See main reference on page 366 (The Pyrexia Cat) for more details.

Clinical signs

Naturally infected cats **usually only develop subclinical infection.**

Mild, self-limiting fever lasting 48–72 hours has been documented in some experimentally infected cats.

Anterior uveitis was documented in one naturally exposed cat.

Diagnosis

Diagnosis is based on a positive blood culture, however, intermittent bacteremia may occur for longer than 1 year following infection.

The organism is present within erythrocytes, therefore, hemolyzing red blood cells increases the sensitivity of the culture.

64. The cat with abnormal globe position or size

Michael E. Bernays

KEY SIGNS

- Increased globe prominence.
- Increased globe size.
- Reduced globe prominence.
- Reduced globe size.

MECHANISM?

- A globe which is more prominent may be either enlarged (buphthalmic) or a normal-sized globe which is abnormally positioned, usually displaced cranially (exophthalmic).
- A globe which is less prominent may be shrunk (ptthisis), or it may be a normal-sized globe which is positioned more caudally or deeper in the orbit (enophthalmic).

WHERE?

- Globe.
- Orbit.

WHAT?

- The most common causes of abnormal globe positioning or size in the cat are:
- Increased prominence: orbital cellulitis or orbital neoplasia.
- Increased size: chronic glaucoma causing enlargement.
- Reduced prominence: shrinkage of orbital tissue related to loss of orbital fat.
- Reduced size: pthisis (shrinkage) due to intractable inflammation causing low intra-ocular pressure or globe leakage due to a persistent corneal or scleral defect.

QUICK REFERENCE SUMMARY

Diseases causing abnormal globe position or size

INCREASED GLOBE SIZE OR PROMINENCE

WHERE?

GLOBE

INFLAMMATION

- **Buphthalmos associated with glaucoma** (p 1312)**

Enlarged globe results from glaucoma, which occurs as a sequel to chronic anterior uveitis. Usually unilateral.

TRAUMA

- **Traumatic globe proptosis** (p 1313)**

Globe is located external to eyelids and is usually associated with evidence of severe trauma.

WHERE?

ORBIT

NEOPLASTIC

- **Orbital neoplasia*** (p 1310)**

Lymphosarcoma usually results in bilateral globe prominence and peri-ocular tissue swelling. Sometimes it is associated with anterior uveitis evidenced by intra-ocular fibrin, hemorrhage and/or iris masses. It may occur in conjunction with other signs of multicentric lymphoma. Squamous cell carcinoma more often causes unilateral globe prominence, and there is evidence of co-existent neoplasia involving oral or nasal mucous membranes or pre-existent eyelid or conjunctival neoplasia in a cat with non-pigmented eyelid margins. Fibrosarcoma or osteosarcoma typically produce a unilateral, slow-onset increase in globe prominence or globe displacement, and peri-ocular swelling.

INFECTION

- **Bacterial orbital cellulitis*** (p 1310)**

Exophthalmos, peri-ocular swelling, conjunctival chemosis, and pain on palpation, retropulsion or opening of the mouth occurs secondary to periodontal disease of the caudal maxillary teeth, penetrating injury caudal to the upper M1 tooth, or blood-borne infection.

IATROGENIC

- **Non-septic orbital cellulitis or hemorrhage (p 1310)**

Exophthalmos and peri-ocular swelling which becomes more pronounced following blind surgical orbital exploration procedures.

TRAUMA

- **Fractures of bones around the orbit or orbital emphysema* (p 1314)**

Severe peri-ocular swelling, abnormalities in outline of the skull and/or proptosis of varying degrees may occur as a sequel to trauma. Palpable zygomatic arch, vertical ramus of the mandible and/or frontal bone fractures are often evident. Orbital emphysema may occur with trauma, and appears as peri-orbital swelling which has a crepitant or “puffy” sensation on palpation.

DECREASED GLOBE SIZE OR PROMINENCE

WHERE?

GLOBE

DEGENERATIVE

- Pthisis (p 1315)

Reduced globe size occurs secondary to a known history of severe trauma, chronic intra-ocular inflammation or hemorrhage. Unusual in cats.

ANOMALY

- Microphthalmos (p 1316)

Rare in cats. Appears as small eye with small corneal dimensions sometimes and associated with other ocular defects, e.g. cataract.

TRAUMA

- **Collapse of the globe* (p 1315)**

Small globe and signs of aqueous leakage (wetting of the skin and haircoat around the eye), which occurs in association with rupture of the cornea or sclera.

WHERE:

ORBIT

DEGENERATIVE

- **Enophthalmos secondary to orbital fat loss or muscle wastage** (p 1314)**

Bilateral, non-painful, caudal displacement of the globe occurs associated with generalized muscle wastage and weight loss. The third eyelid is prominent.

INTRODUCTION

MECHANISM?

A globe which appears to be more prominent may be either enlarged (buphthalmic) or a normal-sized globe which is abnormally positioned, usually displaced cranially (exophthalmic). Likewise a globe which is less prominent may be so because it is shrunken (pthisis) or it may be a normal-sized globe which is positioned more caudally or deeper in the orbit (enophthalmic).

WHERE?

Globe.

Orbit.

WHAT?

The **most common causes of abnormal globe positioning or size in the cat** are:

- **Cranial displacement (exophthalmos)** from orbital cellulitis or orbital neoplasia.
- **Increased size (buphthalmos)** from chronic glaucoma.
- **Caudal displacement (enophthalmos)** as a result of shrinkage of orbital tissue related to loss of orbital fat.
- **Reduced size (pthisis)** from shrinkage of the globe due to intractable inflammation causing low intra-ocular pressure or leakage due to a persistent corneal or scleral defect.

Unilateral prominence or enlargement can best be appreciated by comparing with the opposite eye especially from the dorsal aspect.

Bilateral abnormalities are more likely to be **associated with systemic disease**, whereas unilateral problems are more likely to reflect local phenomena, for example, lymphoma involving the orbit will usually cause bilateral exophthalmos.

The final decision as to whether there is a change in size or a change in position might lie with a consideration of the associated ocular signs, for example:

- If **buphthalmos rather than an exophthalmos** is suspected, then look for associated signs which one might expect to see with glaucoma and buphthalmos, that is, dilated to mid-dilated non-responsive pupil, deep episcleral vessel injection, high intra-ocular pressure measured with a tonometer, vision loss, and fundoscopic suggestion of retinal degeneration.
- If **exophthalmos is suspected rather than buphthalmos**, then look for pain on opening the mouth, poor retropulsion, signs of ventral orbital swelling behind the last upper molar teeth, and swelling of peri-ocular tissue.
- If **enophthalmos is suspected rather than ptosis**, look for a prominent but not swollen third eyelid.
- If **reduced size** is suspected, look for signs of chronic intra-ocular inflammation, low intra-ocular pressure on tonometry and/or possible signs of globe rupture and aqueous leakage.

DISEASES CAUSING INCREASED GLOBE SIZE OR PROMINENCE

BACTERIAL ORBITAL CELLULITIS*** OR NON-SEPTIC CELLULITIS OR HEMORRHAGE

Classical signs

- Acute in onset over a few days.
- Exophthalmos.
- Pain on opening mouth.
- Prominent nictitating membrane.
- \pm Fever.
- Occasionally bulging of oral mucosa caudal to upper M1 tooth.
- Chemosis.

Pathogenesis

Cellulitis is induced by bacterial infection of the orbital soft tissue. Bacteria are introduced into the tissue by several routes:

- Blood-borne via vessels within the orbit.
- Traumatic inoculation through the oral mucous membranes caudal to the upper molar tooth from sharp foreign bodies such as a bone, or by iatrogenic introduction during orbital exploration.
- Spread of infection associated with periodontal disease of caudal maxillary teeth.
- Spread from an area of osteomyelitis involving bone around the orbit.

Iatrogenic non-septic cellulitis can occur by trauma of orbital tissues during surgical exploration behind the upper M1 tooth with serrated cutting devices such as hemostats.

Clinical signs

Typically there is a very acute onset of signs over a few days.

Pain is evident, especially on opening the mouth.

A normal-sized globe is pushed cranially (exophthalmos).

Prominent nictitating membrane.

Fever is variably present.

Peri-orbital swelling causes swelling of conjunctival tissue around the globe (chemosis), and conjunctiva become exposed and dry.

Occasionally bulging of oral mucosa caudal to upper M1 may be evident.

If the cellulitis, hemorrhage and/or edema are associated with blind surgical orbital exploration, signs of exophthalmos and peri-ocular swelling become more pronounced following the procedure.

Diagnosis

History is usually of a rapid onset of signs over a few days.

Classical signs are exophthalmos, chemosis, third eyelid prominence, and peri-ocular swelling, which are usually associated with pain on palpation, retropulsion or opening of the mouth.

Imaging techniques which are useful include:

- **Ultrasound:** anechoic or hypo-echoic regions are suggestive of a fluid-filled cavity while complex echogenicity is more suggestive of cellulitis.
- **Plain radiographs** of the maxilla and zygomatic arch may demonstrate signs suggestive of osteomyelitis such as proliferation or lysis of bone. A frontal sinus view may be helpful.
- **Dental radiography** might demonstrate a rarified area of alveolar bone around the tooth root apical region.
- **CT or MRI** in special circumstances might be helpful for demonstrating soft tissue detail.

Laboratory examination of aspirates or swabs of orbital contents are valuable. Look for neutrophils, macrophages, signs of bacterial lysis.

Differential diagnosis

Orbital neoplasia usually causes more slowly progressive onset of signs with less acute pain.

Treatment

Treatment involves careful surgical drainage via a small incision caudal to upper molar tooth. Blunt probes are preferable to hemostats, which cause more trauma to orbital tissue.

Use oral antibiotics based on culture and sensitivity of aspirates, or treat empirically with antibiotics directed particularly at anaerobes, such as clindamycin (5.5 mg/kg q 12 h). Administer for 7–10 days, but for severe infections use for up to 28 days.

Anti-inflammatory drugs help to reduce inflammation and achieve more rapid reduction of peri-orbital swelling.

- Oral prednisolone 1 mg/kg q 24 h for the first 7 days or
- NSAIDs.
 - Ketoprofen: Ketofen 2 mg/kg SC continuing 1 mg/kg orally q 24 hourly for up to 5 days.
 - Carprofen: Rimadyl 4 mg/kg SC or IV. Oral dose not approved for use in cats.
 - Meloxicam: Metacam 0.1 mg/kg (one drop/kg) PO as an initial loading dose then 1–2 drops q 24 hourly for up to 3 days.

ORBITAL NEOPLASIA***

Classical signs

- Usually slow in onset over weeks to months. Lymphosarcoma of the orbit can however progress more rapidly.
- Not usually associated with pain on opening the mouth except in advanced stages.
- Exophthalmos with a prominent nictitating membrane.

Pathogenesis

Lymphosarcoma can localize in the orbit in multicentric disease, and is often bilateral when it involves the orbit.

Squamous cell carcinoma invades from the oral mucous membrane, the nasal cavity or from the frontal sinus into the medial orbit.

Fibrosarcoma is a primary neoplastic disease originating from the periosteum of the bone surrounding orbit.

Clinical signs

Clinical signs are usually slow in onset over weeks to months. Lymphosarcoma of the orbit can however progress more rapidly.

Exophthalmos is present and the severity is dependent on the degree of proliferation of the neoplasm.

A **prominent nictitating membrane** might be seen especially in the later stages.

Chemosis of the conjunctiva occurs with subsequent exposure and drying.

Bulging of oral mucosa caudal to the upper M1 tooth is occasionally seen, especially in the later stages of the disease.

Pain on opening mouth is variable, and the majority of cases do not show signs of pain. Neoplastic disease may become more painful if the affected tissue becomes inflamed. If pain does occur, it is more likely to occur in the later stages of the disease, when there is more gross disruption of normal tissue architecture.

Blindness or abnormality of the pupillary light reflex occurs if the optic nerve or CN III is affected by the neoplastic process but this is uncommon.

Lymphosarcoma usually results in bilateral globe prominence and peri-ocular tissue swelling. Sometimes it is associated with anterior uveitis evidenced by intra-ocular fibrin, hemorrhage and/or iris masses. It may occur in conjunction with other signs of multicentric lymphoma.

Squamous cell carcinoma more often causes unilateral globe prominence, and there is evidence of co-existent neoplasia involving oral or nasal mucous membranes or pre-existent eyelid or conjunctival neoplasia in a cat with non-pigmented eyelid margins.

Fibrosarcoma or osteosarcoma typically produce a unilateral, slow-onset increase in globe prominence or globe displacement and peri-ocular swelling.

Diagnosis

Orbital neoplasia should be suspected in any case of non-painful or mildly painful exophthalmos with a slow onset and progression of signs.

Ultrasound is a particularly useful imaging technique. Plain radiographs of the maxilla, frontal bone and zygomatic arch may be useful, and CT or MRI may be needed in special circumstances.

Differential diagnosis

Orbital cellulitis usually causes a more painful exophthalmos of more rapid onset.

Treatment

Chemotherapy is used for treatment of **lymphosarcoma**. See main reference on page 432 for details (The Cat With Enlarged Lymph Nodes).

Squamous cell carcinoma and fibrosarcoma can be treated by surgery with or without irradiation.

- Radical surgical excision is required, and aim to remove 1–2 planes of normal tissue with the affected tissue.
- Megavoltage or orthovoltage irradiation of the orbit can be used to attempt prevention of regrowth of invasive neoplasms where surgical excision does not achieve clean margins.

Prognosis

Prognosis is poor for invasive orbital fibrosarcoma or squamous cell carcinoma.

Orbital lymphosarcoma has a guarded prognosis.

BUPHTHALMOS ASSOCIATED WITH GLAUCOMA**

Classical signs

- Enlarged globe.
- Deep episcleral vessel injection.
- Associated with signs of chronic anterior uveitis, uveal neoplasia and secondary glaucoma.

Pathogenesis

Buphthalmos occurs from stretching of the fibrous outer tunic of the eye associated with elevated intra-ocular pressure. In the cat, most cases of glaucoma are secondary to chronic anterior uveitis or iris neoplasia.

Primary glaucoma has been described in **Burmese** cats in Australia, which appears to be familial. In this condition there appears to be a genetically determined narrowing of the irido-corneal angle resulting eventually in reduced aqueous outflow and increased intra-ocular pressure.

Clinical signs

The globe is more prominent because it is enlarged (buphthalmos).

Deep episcleral vessels are injected secondary to increased intra-ocular pressure. Deep vessels are usually straighter and larger, do not move when the overlying bulbar conjunctiva is moved, and do not blanch with the topical application of 1:1000 epinephrine.

The **pupil is dilated or semi-dilated**, and the pupillary light response is either absent or poor.

Signs of chronic anterior uveitis are often present, especially abnormalities in the appearance of the iris surface. The iris may have a pinkish discoloration associated with fibrovascular membranes or grayish nodules.

The **anterior chamber** may appear to be very **shallow** in **aqueous misdirection glaucoma**, which is a poorly

understood syndrome where the lens is positioned more anteriorly along the axis of the eye as a result of aqueous being diverted into the vitreous.

Signs of lens instability are typically present and include:

- Aphakic crescent (crescent shape produced by the clear space between the edge of the displaced lens and the adjacent pupillary margin).
- Anterior or posterior luxation (dislocation).
- Iridonesis (wobbling of the iris).

Signs of intra-ocular neoplasia such as mass lesions or discoloration of the iris may be present.

Diagnosis

Diagnosis is based on the appearance of buphthalmos with any or all of the other related signs of glaucoma, chronic anterior uveitis, intraocular neoplasia or lens instability.

Measurement of intra-ocular pressure by tonometry confirms the diagnosis. Normal range for intra-ocular pressure in the cat is 15–25 mmHg. Readings over 30 mmHg are supportive of a diagnosis of glaucoma.

Treatment

There are **no consistently reliable therapeutic protocols** which will lower intra-ocular pressure in all cats. Monitoring is necessary to confirm that chosen treatment is working. Type of therapy chosen and its predicted success will depend on several factors. These include:

- **Whether the angle is opened or closed.** When the angle is closed or obstructed, treatment regimes involving cyclo-destruction to reduce production of aqueous within the eye may not work as well as aqueous shunting procedures.
- **Whether the glaucoma is primary or secondary to other pathology.** If glaucoma occurs secondary to chronic anterior uveitis it is often more responsive to simple treatment with anti-inflammatories alone, without the use of other ocular hypotensive treatments.

Medical therapy includes:

- **Carbonic anhydrase inhibitors.**
 - Dorzolamide 2% (Trusopt): one drop q 8 h topically.

- **Anti-inflammatories** can be used, especially where the glaucoma has been secondary to chronic anterior uveitis.

- Topical prednisolone acetate 1% (Prednefrin Forte, Allergan) 1 drop q 12–24 h.
- Oral prednisolone up to 1 mg/kg q 12 h.

Surgical therapy.

- **Cyclo-destructive procedures** are used to selectively destroy parts of the ciliary body to reduce aqueous production to match reduced outflow.
- Transcleral diode laser cyclo-photo-coagulation only works well where the ciliary body is well pigmented, and so tends not to work well for color dilute cats, e.g. Burmese, Siamese, Himalayans.
 - Transcleral cyclo-cryo-ablation. This is the original technique described for cyclo-destruction, and is a suitable alternative for use in cats where laser surgery does not work well, i.e. Color Point cats with minimal pigmentation of the uveal tract.
- **Lens removal** is suggested wherever the lens is unstable because of chronic anterior uveitis. Inflammation is sometimes easier to control by removing the lens.

TRAUMATIC GLOBE PROPTOSIS**

Classical signs

- Globe located cranially to eyelid margins.
- Subconjunctival hemorrhage.
- Extra-ocular muscle tearing.

Pathogenesis

Proptosis occurs through **excessive blunt trauma to the globe or lateral orbit**. The condition is uncommon in cats because of skull shape. The globe is located deeper in the orbit with more protection laterally than in dogs, except in brachycephalic cats. Occasionally however, cats can be seen with this condition following motor vehicle trauma. Prognosis for the eye is usually poor because the forces required to proptose a feline globe are often so severe that severe globe trauma occurs with resultant permanent loss of normal globe structure and function.

Clinical signs

Proptosis of the eye, with eyelid margins located behind the globe.

Subconjunctival **hemorrhage**.

Extra-ocular muscle tearing.

Intra-ocular signs are variable. The pupil can be dilated or constricted, but is more commonly dilated after severe trauma, because of damage to the optic nerve and or the long ciliary nerves. Hyphema may be present.

Diagnosis

Diagnosis is obvious based on clinical signs.

Treatment

Irrigate the globe with a balanced electrolyte solution to remove debris.

Lubricate the cornea and bulbar conjunctiva with solutions containing hypromellose, polyvinyl alcohol or carboxymethyl cellulose.

Surgically attempt to replace the globe by manipulation of the eyelid margins. Often orbital soft tissue swelling makes this difficult. A technique using pre-placed tarsorrhaphy sutures has been described:

- 4/0 or 5/0 polypropylene or nylon sutures are inserted by passing through the dorsal and ventral eyelid.
- A flat object (e.g. scalpel handle) is placed on the corneal surface under the row of pre-placed sutures with sufficient lubricant to protect the cornea.
- The sutures are tightened over the scalpel handle to force the globe back into the orbit, at the same time, the eyelids are brought together and the sutures are tied to effect a temporary tarsorrhaphy, which can be left in place for 1–2 weeks, until peri-ocular and orbital swelling is resolved.

FRACTURES OF THE BONES AROUND THE ORBIT OR ORBITAL EMPHYSEMA*

Classical signs

- Orbital swelling.
- Fluctuant, puffy or crepitant feel on palpation.

Clinical signs

Peri-orbital edema, hemorrhage and/or emphysema associated with blunt trauma or surgery may result in exophthalmos and increased globe prominence.

Severe peri-ocular swelling, abnormalities in outline of the skull and/or proptosis of varying degrees may occur as a sequel to trauma. Palpable zygomatic arch, vertical ramus of the mandible and/or frontal bone fractures often evident.

Orbital emphysema may be present associated with trauma from a fall or motor car accident or following surgery. Emphysema is most commonly caused by a fracture of a bone lining one of the paranasal sinuses, in particular the frontal sinus. **Swelling** is evident and there is a **fluctuant, “puffy” or crepitant feel on palpation** of peri-ocular tissues.

Diagnosis

Diagnosis is usually based on the **characteristic clinical signs**, and a history of possible frontal bone fracture.

Plain skull radiography may show soft tissues dissected by air-containing compartments.

THE CAT WITH REDUCED GLOBE SIZE OR PROMINENCE

ENOPHTHALMOS SECONDARY TO ORBITAL FAT LOSS OR MUSCLE WASTAGE**

Classical signs

- Globe is caudally displaced into the orbit.
- ± Entropion especially of the lower lid.
- Generalized atrophy of facial muscles and prominence of zygomatic arch.
- Associated generalized poor body condition.

Pathogenesis

Loss of orbital fat caudal to the globe secondary to **weight loss**, or **generalized muscle wastage** causes caudal movement of a normal-sized globe.

Clinical signs

Globe is caudally displaced into the orbit (**enophthalmos**).

Generalized atrophy of the muscles of mastication and/or facial expression is evident, and the zygomatic arch is prominent.

Lower lid entropion is sometimes seen.

Ocular signs are usually **always bilateral** because they relate to systemic illness.

Generalized poor body condition is evident, and atrophy of other muscle groups and bony prominences are more obvious. There may also be associated loss of hydration of connective tissue, if the weight loss is secondary to chronic renal disease.

Diagnosis

Diagnosis is based on the appearance of a **normal-sized globe, which is sunken into the orbit, and a thin emaciated cat**.

Laboratory investigation is required to determine the cause of the weight loss. Common causes include hyperthyroidism and chronic renal disease.

- Hyperthyroidism is associated with increased thyroxine concentrations, and often increased alanine-amino-transferase (ALT) activity.
- Chronic renal disease is associated with variable increases in BUN, creatinine and serum phosphate and poorly concentrated urine (<1.030). Serum potassium may be low in the early stages, and high in the late stages of the disease.

Treatment

Treatment involves correcting or controlling the medical condition causing weight loss.

COLLAPSE OF THE GLOBE*

Classical signs

- Small globe size compared to the opposite side.
- Painful closed eye.
- Serous discharge from leaking aqueous.

See the main reference for details in “The Cat With Abnormalities Confined to the Cornea” on page 1243,

“Ulcerative keratitis caused by corneal perforation (cat fight wounds)” and on page 1246 “Blunt trauma”.

Clinical signs

Painful, closed eye with serous discharge and sometimes bleeding.

Cornea is cloudy and anterior chamber may be full of blood and protein.

Globe appears small compared with the ipsilateral eye, and there are **signs of aqueous leakage** with wetting of the skin and haircoat around the eye, which occurs in association with rupture of the cornea or sclera.

Diagnosis

A presumptive diagnosis is based on clinical signs and history.

PTHSIS

Classical signs

- Small globe size compared to the opposite side.
- Globe is covered by the third eyelid.
- Signs of previous inflammation within the eye.
- Intra-ocular pressure is usually low.
- Rare in cats.

Clinical signs

The **globe size is small** compared with the ipsilateral eye.

There is unusual coverage of the globe by the nictitating membrane because of small size.

Pthisis occurs secondary to chronic uveal inflammation or severe penetrating trauma. **Signs of chronic uveal inflammation** are evident, for example:

- Abnormal pupil shape.
- Changes in iris color due to fibrovascular membranes on the anterior surface of the iris.
- Keratic precipitates, which are gray to tan-colored opacities on the posterior surface of the cornea, and are usually located ventrally.
- Synechia, which are visible as adhesions of the iris to the anterior lens capsule, and may cause irregularity

in pupil shape. Pigment deposition on the anterior capsule may be seen.

- Pupillary membranes, which are membranous structures spanning the pupil space. Immobility of the pupil often results.

Diagnosis

Diagnosis is **based on the appearance of a small globe with low intra-ocular pressure** and signs of previous inflammation.

Tonometry will usually reveal unusually low intraocular pressure (usually < 10 mmHg).

MICROPHTHALMOS

Classical signs

- Small globe unassociated with signs of previous inflammation.
- \pm Other ocular abnormalities such as congenital cataract or persistent pupillary membranes.
- Rare in cats.

Clinical signs

Rare in cats.

The **globe is small, and there is no history or signs of previous inflammation**. The corneal diameter is usu-

ally obviously smaller than the opposite side, but the cornea does not have a significantly smaller radius of curvature than the scleral coat. In contrast, a pthisical globe will usually have an obviously smaller corneal radius of curvature than the scleral coat, causing the appearance of a bulging cornea.

There is unusual coverage of the globe by the nictitating membrane because of the small globe size.

Other ocular abnormalities are sometimes present, for example:

- Persistent pupillary membranes (PPM), which are small strands of tissue arising from the iris surface. They connect either to other points on the iris surface, the posterior surface of the cornea where they form gray focal opacities, or the anterior lens capsule. Persistent pupillary membranes are unassociated with other signs of intra-ocular inflammation.
- Congenital cataract resulting in opacity of the lens. Congenital cataracts are more likely to be nuclear in location, with the surrounding cortex clear.

Diagnosis

Diagnosis is **based on the clinical signs** of a small, but relatively normal looking eye.

If intra-ocular pressure can be measured, is usually normal (15–25 mmHg). In contrast, pressure is usually low in a pthisical globe.

65. The cat with abnormal eyelid appearance

Michael E. Bernays

KEY SIGNS

- Misshapen or abnormal alignment of eyelid(s).
- Eyelid swelling or mass.
- Alopecia, erythema, crusting, discharge.
- Eyelid lacerations.

MECHANISM?

- Abnormal eyelid appearance can result from congenital abnormalities, inflammation, neoplasia, trauma or neurological disease.

WHERE?

- Eyelid skin.
- Eyelid margin.
- Conjunctiva.

WHAT?

- The most common causes of altered eyelid appearance include neoplasia, inflammation and trauma.

QUICK REFERENCE SUMMARY

Diseases causing abnormal eyelid appearance

ANOMALY

- **Eyelid agenesis/eyelid coloboma** (p 1323)**

Absence of an identifiable eyelid margin, usually bilateral and involving the upper lateral lid. Gradual transition from haired skin to conjunctiva, and often causing keratitis, corneal vascularization, ulceration and increased lacrimation with wetting of the irritating hairs. Usually first noticed in a young cat.

- **Distichiasis (p 1329)**

Cilia extending from meibomian gland openings at the eyelid margin. Rare.

continued

continued

MECHANICAL

- **Entropion* (p 1320)**

Lower eyelid margin rolled inwards, causing corneal irritation and serous to mucopurulent ocular discharge. Seen occasionally.

- **Ectropion (p 1328)**

Eyelid rolled outwards due to former injury associated with cicatricial scarring.

- **Upper lid ptosis* (p 1324)**

Upper eyelid droops or fails to be elevated. Usually from sympathetic neuropathy (Horner's syndrome) and associated with ipsilateral miosis, enophthalmos and third eyelid prominence. Less often from cranial nerve III paresis, and occasionally in associated with a dilated pupil unresponsive to light (internal ophthalmoplegia), or inability to elevate the eyeball during outward turning.

NEOPLASTIC

- **Squamous cell carcinoma*** (p 1321)**

Ulceration and crusting affecting the lid margins and non-haired skin or conjunctiva. Localized or diffuse eyelid swelling may be present. Only occurs on non-pigmented skin.

- **Basal cell carcinoma** (p 1321)**

Flat to slightly raised areas of red to dark brown discoloration with irregular edges.

- **Mast cell tumor* (p 1321)**

Rapidly growing nodular tumor often with poorly defined borders, with variable surface ulceration.

- **Fibrosarcoma* (p 1321)**

Usually rapidly growing diffuse swelling with involvement of adjacent facial or orbital tissues.

- **Sebaceous gland adenoma or adenocarcinoma (p 1321)**

Nodular or diffuse mass causing localized thickening of the eyelid. Tumor may have an ulcerated surface.

INFLAMMATION/INFECTIOUS

Bacterial:

- **Bacterial blepharitis, meibomitis, chalazion or hordoleum* (p 1324)**

Bacterial blepharitis causes eyelid swelling, erythema and ulceration. Lesions seen more commonly at the medial canthus. Meibomitis, chalazion and hordoleum are associated with acute or chronic swelling of single or multiple meibomian glands, causing erythema of lid conjunctiva, and eyelid swelling. In acute cases (hordoleum) the lids are painful and inflamed with inflammation around the glands. In chronic cases, inflammation may organize into large mass of caseous material with a tendency to be walled off in fibrous capsules within eyelid (chalazion). Only individual glands may be swollen (meibomitis). Mucoïd to mucopurulent ocular discharge occurs.

Fungal:

- **Dermatophytosis** (p 1322)**

Alopecia and crusting or scaling of peri-ocular eyelid skin. Other similar lesions on the face or ears.

- Malassezia (p 1327)

Alopecia and crusting of peri-ocular skin.

Parasitic:

- Demodecosis (p 1327)

Peri-ocular alopecia, erythema, scaling with variable pruritis.

- **Notoedres cati*** (p 1327)

Alopecia with pronounced pruritis, crusting and excoriation of the ears, eyelids face and neck.

- Parasitic myiasis (p @)

Fistulous opening with larvae visible in wound.

Inflammation/non-infectious:

- **Solar dermatitis**** (p 1329)

Erythema and crusting, with or without hemorrhage usually involving non-pigmented eyelid skin.

- **Allergic blepharitis**** (p 1325)

Associated with food allergy, atopy, insect bite hypersensitivity, staphylococcal allergy, or contact allergy to topical drugs. Variable erythema, swelling, pruritis, excoriation, exudation and crusting of eyelid skin.

Immune-mediated:

- Pemphigus foliaceus, pemphigus erythematosus, systemic lupus erythematosus (p 1328)

Alopecia, erythema, scaling and crusting of the eyelids additionally affecting nailbeds, nipples (foliaceus) and ears, muzzle and nose (erythematosus). Uncommon. Other immune-mediated disease (e.g. immune-mediated polyarthritis, glomerulo-nephritis) is present in SLE.

Trauma:

- **Eyelid trauma/wounds*** (p 1326)

Visible tears in the eyelid skin or discontinuities at the eyelid margin with loss of normal function. Discharge ranges from hemorrhagic, serous or purulent, depending on duration.

INTRODUCTION

MECHANISM?

Basic pathological mechanisms underlying an abnormal eyelid appearance include failure of embryonic tissues to differentiate or rarify, inflammation, neoplasia, trauma and neurological disease.

WHERE?

The location of disease processes within the eyelid can often be simply described according to whether the

process affects the eyelid skin, the eyelid margin or the palpebral conjunctiva. Sometimes multiple tissues may be affected within the eyelid. Occasionally an eyelid may appear abnormal because of a neurological process occurring distant to the eye.

Altered eyelid function or structure may affect adjacent or remote structures, for example:

- Entropion or eyelid agenesis may cause corneal disease due to lack of a normal anatomical relationship between the eyelid and the cornea.
- Immune-mediated, allergic or parasitic skin disease may affect skin remote from the eyelid.

WHAT?

The most common causes of altered eyelid appearance include:

- **Failure of embryonic tissues to differentiate or rarify** resulting in eyelid agenesis or abnormal cilia. These conditions will commonly be first recognized in a young cat.
- **Inflammation of infectious or non-infectious etiology.**
 - Infectious causes include bacteria, dermatophyte fungi or external parasites.
 - Non-infectious causes include **allergic** causes such as food allergy, inhalant allergy, bacterial hypersensitivity, insect bite hypersensitivity or contact allergy to topical drugs; **immune-mediated responses to components of the skin around the eyelids** occur in pemphigus erythematosus or pemphigus foliaceus.
- **Neoplasia.**
 - **Squamous cell carcinoma** occurring in non-pigmented skin is the most common neoplastic disease seen in the eyelid.
 - Basal cell carcinomas, mast cell tumors or fibrosarcomas are less common, while sebaceous gland tumors occur rarely.
- **Neurological disease.**
 - **Sympathetic ptosis** or **ptosis due to injury to the dorsal branch of the oculomotor nerve** may occur with trauma, inflammation or neoplasia involving the nervous system.
- **Trauma.**
 - Cats are renowned for injuries caused by claws inflicted during fighting with other cats.

DISEASES CAUSING AN ABNORMAL EYELID APPEARANCE

ENTROPION**

Classical signs

- Lower eyelid is curled inwards.
- Chronic ulcerative keratitis caused by eyelid hair rubbing on the cornea.
- Mucoid to mucopurulent discharge.

Pathogenesis

The condition **appears to occur secondary to enophthalmos in cats**. Enophthalmos can be caused by loss of fat or reduction in masseter muscle mass within the orbit.

The defect can also occur **secondary to chronic blepharospasm** caused by painful corneal diseases.

Clinical signs

Usually the **central portion of the lower eyelid margin rolls inwards towards the globe**. Lid hair adjacent to the margin may appear moist or be coated in conjunctival mucus.

Corneal surface disease is present from the eyelid hair rubbing on the cornea. This can include superficial ulceration, sequestrum formation, and a vascular response from the limbus adjacent to the area of lid irritation.

Chronic discharge occurs ranging from mucoid to mucopurulent.

Diagnosis

Diagnosis is based on the characteristic sign of an inward rolling eyelid margin with secondary corneal changes and chronic ocular discharge.

Treatment

Surgical procedures such as the modified Hotz–Celsus procedure involving **removal of a strip of skin and orbicularis muscle adjacent to the area of entropion** seem to work adequately for cats. Some cats seem to have an oversized palpebral fissure, resulting in inadequate tension of the lower eyelid. Occasionally a permanent lateral canthal closure in addition to the Hotz–Celsus procedure is recommended to reduce palpebral fissure size.

The **condition will recur if the inciting cause is not corrected**.

EYELID NEOPLASIA (SQUAMOUS CELL CARCINOMA, BASAL CELL CARCINOMA, MAST CELL TUMOR, FIBROSARCOMA, AND SEBACEOUS GLAND ADENOMA OR CARCINOMA)****

Classical signs

- Localized or diffuse eyelid swelling.
- Ulceration, excoriation or discharging sinuses.
- Altered tissue color.

Pathogenesis

Squamous cell carcinoma is thought to be induced by prolonged exposure to solar radiation. This causes dysplastic changes in the surface squamous cells of lid epithelium, with eventual progression of the dysplasia to invasive carcinoma. **This neoplasm almost exclusively affects non-pigmented skin**, so is more common in white cats. It is the most common feline eyelid neoplasm.

Basal cell carcinoma arises from the basal cells of the epithelium. Solar radiation is a possible etiology. The tumor is less common.

Mast cell tumor is a neoplastic proliferation of mast cells in tissue. Inciting factors are unknown. Less common.

Fibrosarcomas arise from connective tissue fibroblasts of the dermis or subcutis. Feline sarcoma virus (FeSV) is implicated as a cause of multicentric fibrosarcoma in young cats. Less common.

Sebaceous gland adenomas or carcinomas are rare.

Clinical signs

Any of the following typical signs might be seen including **localized or diffuse areas of eyelid swelling, erosion, crusting, discharging sinuses (+/- necrotic material forming a core), or alterations in tissue color.**

Squamous cell carcinoma can have a flattened verrucous (cauliflower-like) appearance or can look erosive without swelling. Often there is ulceration and crusting affecting the lid margins and non-haired skin or conjunctiva. Localized or diffuse eyelid swelling

may be present. The lesion may invade into adjacent palpebral conjunctiva. These neoplasms generally only occur in **non-pigmented skin**.

Basal cell carcinomas are usually round and well circumscribed, but can become ulcerated. Appear as flat to slightly raised areas of red to dark brown discoloration with irregular edges.

Mast cell tumors can form either well or poorly circumscribed areas of swelling in the eyelid. They appear as rapidly growing nodular tumor, often with poorly defined borders, and variable surface ulceration.

Fibrosarcomas are generally focal nodular neoplasms in the subcutis, but can become ulcerated. Usually appear as a rapidly growing diffuse swelling, and involve adjacent facial or orbital tissues.

Sebaceous gland adenomas or carcinomas are seen as a nodular or diffuse mass causing localized thickening of the eyelid. The tumor may have an ulcerated surface.

Diagnosis

Tentative diagnosis is based on the appearance of the eyelid lesion.

Exfoliative cytology is useful in some cases that show ulceration.

- **Squamous cell carcinomas** typically appear as undifferentiated, single or grouped, round to square cells with large amounts of light basophilic cytoplasm and pleomorphic nucleolated nuclei. Sometimes more squamous, partly or fully keratinized cells can be seen.
- **Basal cell carcinomas** are usually more basophilic staining than SCC. Cells are more round to square than SCC, and have small amounts of basophilic cytoplasm, and relatively uniform round to oval, non-nucleolated nuclei.
- **Mast cell tumors** can be poor- to well-differentiated with intensely basophilic staining cytoplasmic granules, and small, round, centrally located nuclei. Accompanying eosinophils are usually seen.

Fine-needle biopsy can be useful in cases where there is discreet swelling.

Definitive diagnosis is based on histopathological examination of affected tissue.

Differential diagnosis

Autoimmune skin disease causes peri-ocular inflammation, alopecia and crusting with sites remote from the eyelid affected as well, for example, ear pinna, muzzle, nasal planum, nailbeds.

Allergic skin disease causes swollen inflamed lids, sometimes with conjunctival chemosis and ocular discharge. May respond rapidly to topical anti-inflammatory treatment or identification and removal of an offending antigen from the environment, e.g. stopping feeding of an allergenic food or reduce exposure to insects by enclosure in a gauzed cat house.

Infectious eyelid skin diseases respond to treatment with antibiotics, antifungals or antiparasitics.

Any lesion appearing in pigmented eyelid skin is very unlikely to be squamous cell carcinoma.

Treatment

Wide surgical excision is the treatment of choice for most neoplastic lesions. Wide excision is especially important in the treatment of mast cell tumor and squamous cell carcinomas as the borders between the neoplasm and normal tissue can be ill-defined. Large excisions may require plastic surgery procedures to replace removed sections of eyelid. As the lower lid is more frequently involved, lip-to-lid subdermal plexus flaps can be used. Lid-splitting techniques can be used for smaller defects.

Adjunctive modalities can include:

- **Squamous cell carcinoma:** cryosurgery, β irradiation.
- Basal cell carcinoma: cryosurgery.
- Mast cell tumor: chemotherapy with oral and intralesional steroids. Intralesional injections with hypotonic solutions (sterile distilled water) have also been used as an adjunctive therapy. See reference on page 1075 for more details (The Cat With Skin Lumps and Bumps).

Prognosis

Varies depending on the type and stage of the neoplasia, degree of local tissue and/or systemic involvement.

The prognosis is grave for cats affected by FeSV-induced fibrosarcoma.

SOLAR DERMATITIS**

Classical signs

- Erythema and crusting, with or without hemorrhage.
- Almost always involves non-pigmented eyelid skin only.

Clinical signs

Erythema and crusting is usually seen, occasionally associated with hemorrhage under the crusts. The lesion is regarded as a **precursor to the development of squamous cell carcinoma.**

Non-pigmented areas only are affected almost **without exception.**

The lesions are more **commonly seen on the lower lid** rather than the upper lid because of the more direct exposure to UV light.

Associated lesions may be seen on the nasal planum or the tips of the ears.

Diagnosis

Tentative diagnosis is based on the appearance of the lesions and location in non-pigmented areas of eyelid skin.

Definitive diagnosis is made on the histopathological examination of affected eyelid skin.

DERMATOPHYTOSIS**

Classical signs

- Alopecia and crusting or scaling of peri-ocular eyelid skin.
- Other similar lesions on the face or ears.

Clinical signs

Typical lesions include alopecia and crusting or scaling of peri-ocular eyelid skin.

Other similar lesions might be seen on the face or ears.

Diagnosis

Tentative diagnosis is based on appearance of the skin lesions, and the clinical history of exposure to other cats with similar lesions or a suspected carrier cat.

Some organisms (*Microsporum canis*) demonstrate **fluorescence under UV light**. Negative findings under UV light examination should not be used to rule out dermatophyte infection. “False” fluorescence of epidermal scales can sometimes be interpreted as a positive result.

Definitive diagnosis is made by **microscopic examination of hair shafts and by culture of the organism**. Microscopic examination may reveal the presence of small ectothrix, or endothrix spores on or in the keratin at the base of the hair shaft. *Microsporum canis* is the most common cause. *Microsporum gypseum* is identified less commonly, while *Trichophyton* species are rarely implicated in feline dermatophyte infections.

Differential diagnosis

Autoimmune skin disease can be ruled out by histopathological examination of affected skin.

Treatment

Many different treatments are recommended in the literature but more common ones include:

- **Griseofulvin** 12.5 mg/kg PO q 12 h for 4–6 weeks. Drug should be given with a fatty meal to enhance absorption. The drug is teratogenic if given to pregnant queens.
- **Ketoconazole** 10 mg/kg PO q 24 h.
- Topical treatments containing compounds such as miconazole or povidine iodine are also effective. Some other compounds such as chlorine may be irritant when used around the eye.

EYELID AGENESIS/EYELID COLOBOMA*

Classical signs

- Absence of normal eyelid margin, with transition from haired skin to conjunctiva.
- Often bilateral, usually involving lateral upper lids in a young cat.

Classical signs—Cont'd

- Trichiasis with secondary keratitis and corneal vascularization.

Pathogenesis

There is an abnormality in development and differentiation of surface ectoderm and possibly neural crest mesenchyme.

Breed predisposition may occur, as the disease appears to be seen more commonly in Persian kittens.

Clinical signs

Often seen as a bilateral abnormality, usually of the **upper lateral eyelid**. **There is gradual transition from haired skin to conjunctiva, with absence of a normal lid margin**.

Corneal disease occurs because of trichiasis (hair rubbing on the cornea) associated with the absence of a normal margin, which results in corneal ulceration and vascularization.

Diagnosis

Diagnosis is based on the characteristic appearance of the deficient eyelid margin in a young cat, with secondary keratitis caused by irritation of the trichiasis.

Treatment

Surgical techniques are aimed at removing the abnormal area of eyelid and joining normal lid margins together. The method depends on the size and position of the defect.

If the eyelid defect is small, a V-shaped wedge of the abnormal eyelid may be resected and the normal lid sutured together using a figure-of-eight suture to appose the margins.

If there are **larger, lateral upper lid defects**, the lower lid margin at the lateral canthus may be joined to the medial aspect of the upper lid defect, making a new lateral canthus.

Larger defects involve surgical correction by transposition of a strip of skin and associated orbicularis muscle from the lower eyelid to the upper defect. The

conjunctiva is dissected from the upper defect and sutured to the edge of the transposition flap. Cryosurgery of hairs near the new conjunctiva–skin margin may be needed later to correct the remaining upper lid trichiasis.

More recently a new technique has been described involving injection of subdermal collagen into the colobomatous region, and use of a modified Stades technique to create a hairless scar in the region of the reconstructed margin. This technique overcomes the traditional problem of trichiasis and continuing irritation of the cornea by eyelid hairs in the reconstructed region.

UPPER LID PTOSIS*

Classical signs

- Upper lid droops over the globe and ocular fissure appears smaller.
- Poor performance of blink response in tests for palpebral or corneal blink.

See main reference on page 1335 for details (The Cat With an Abnormal Third Eyelid: sympathetic neuropathy of the third eyelid).

Pathogenesis

Sympathetic neuropathy causing denervation of Müller's muscle results in upper lid ptosis. Sympathetic neuropathies can be associated with pathology involving pre- or post-ganglionic fibers.

- **Pre-ganglionic fibers** can be damaged at a number of locations including the descending sympathetic fibers in the spinal cord (rare), thoracic spinal cord segments or nerve roots of T1–T3 (nerve root avulsion, brachial plexus injuries or anterior mediastinal disease) or the ascending fibers in the cervical region (e.g. abscess or cellulitis).
- **Post-ganglionic fibers** are most commonly damaged by middle ear disease.

Cranial nerve III (oculomotor nerve) dysfunction affecting the superior palpebral levator.

Clinical signs

The upper lid does not elevate properly compared to the opposite side, and the upper lid droops over the globe. The ocular fissure appears smaller than the other eye.

There is poor performance of the blink response in tests for palpebral or corneal blink.

Diagnosis

Diagnosis is usually based on the observation of clinical signs in association with other manifestations of either:

- **Sympathetic dysfunction – miosis, prominent nictitating membrane, enophthalmos.**
- **CN III dysfunction: internal ophthalmoplegia** occurs due to effects on parasympathetic fibers to the pupillary constrictor. Dysfunction will result in a **dilated pupil non-responsive to direct or indirect light**, but the **opposite eye will show a normal indirect response to light in the affected eye**. External ophthalmoplegia can result in lateral strabismus or inability to elevate the eyeball during outward turning, along with the upper lid ptosis.

Use of topical 10% epinephrine will help to differentiate between oculomotor and sympathetic ptosis. Oculomotor ptosis would not be expected to be reversed by application of this drug whereas sympathetic ptosis will disappear transiently.

Treatment

Identify and correct (if possible) the problem causing the neuropathy.

BACTERIAL BLEPHARITIS, MEIBOMITIS, CHALAZION OR HORDOLEUM*

Classical signs

- Eyelid swelling, erythema and ulceration.
- Mucoïd to mucopurulent ocular discharge.
- ± Chronic meibomian gland swelling with caseous material or acute abscessation.

Pathogenesis

Bacterial infection is mostly by pathogenic staphylococci. The most common region of the eyelid involved is the **meibomian gland**.

Pyodermas involving the sebaceous glands of the skin and associated staphylococcal hypersensitivity are also seen.

Clinical signs

Eyelid swelling, erythema and ulceration occur with **bacterial blepharitis**. Lesions are seen more commonly at the medial canthus with staphylococcal hypersensitivity.

Meibomitis, chalazion or hordoleum involve **acute or chronic swelling of single or multiple meibomian glands**.

In acute cases (hordoleum), the lids are painful and inflamed with inflammation around the glands. The infection in the meibomian gland may organize into discrete abscesses containing purulent material. Occasionally sinuses form which discharge onto the skin. Chronic cases may organize into large masses of caseous material with a tendency to be walled off in a fibrous capsule within the eyelid (chalazion). In meibomitis, only individual glands are swollen.

Mucoid to mucopurulent ocular discharge occurs.

Diagnosis

Diagnosis is usually based on the appearance of the eyelid and response to treatment.

Samples of material drained from abscessed meibomian glands can be cultured to determine etiology and sensitivity to antibiotics.

Histopathology might be performed on eyelid skin where allergy or autoimmune disease is suspected in the differential diagnosis.

Differential diagnosis

Allergic skin disease must be ruled out by appropriate consideration of possible antigens, e.g. food proteins, insect bites, inhalant or contact allergens.

Immune-mediated skin disease can be ruled out by demonstration of characteristic histopathology.

Neoplasia can be differentiated from chronic meibomian gland swelling with caseous material or acute abscessation by cytology or histopathology.

Treatment

Use **systemic antibiotics** based on results of culture and sensitivity or empirically:

- Amoxil–clavulanic acid combinations at 12.5 mg/kg q 12 hourly.
- Doxycycline at 5 mg/kg q 12 hourly. There is now some suggestion in the literature that doxycycline may act as an immune-modulator by altering immune responses to meibomian or sebaceous lipid.
- Cephalexin 15 mg/kg q 12 hourly.

Topical antibiotics.

- Fusidic acid is not available in North America but is used in Australia and Europe. Apply topically q 12 hourly.
- Terramycin ophthalmic ointment q 12 hourly.

Surgical drainage and/or curettage of lesions may sometimes be necessary to control chalazia. This is best done via a caudal approach through bulbar conjunctiva. A chalazion clamp will help to immobilize the lid during drainage.

ALLERGIC BLEPHARITIS*

Classical signs

- Variable eyelid erythema, swelling and pruritis.
- Excoriation and exudation, with crusting of eyelid skin.
- ± Skin lesions involving other parts of the body.

See main reference on page 1025 for details (The Cat With Miliary Dermatitis).

Pathogenesis

Allergic skin disease affecting eyelid skin can be due to any of the following:

- Food allergy.
- Staphylococcal allergy.
- Insect bite hypersensitivity.
- Atopy.
- Contact allergy (to topical drugs).

Clinical signs

Clinical signs are variable and can include combinations of erythema, swelling, pruritis, excoriation, exudation and crusting of eyelid skin.

Lesions may be seen at other sites on the skin, e.g. neck and face, ears, ventral abdomen.

Diagnosis

A tentative diagnosis is based on the appearance of the erythematous, crusting and/or pruritic lesions around the eyelids, and the appearance of lesions on other parts of the body, e.g. ears, for insect bite hypersensitivity.

Confirmation of the diagnosis is based on the use of appropriate tests or trials.

- **Food allergy** diagnosis requires careful **questioning about dietary history, followed by an appropriate food elimination trial** using a single novel protein (1/3 cup) with potato or rice (2/3 cup), and demonstration of an improvement in the appearance of the skin. Dietary trials should be performed for at least one month.
- **Staphylococcal allergy** is indicated by **demonstration of an improvement after a trial course of antibiotics**, e.g. amoxicillin–clavulanic acid combination at a dose rate of 12.5 mg/kg q 12 hourly for at least 2 weeks.
- **Insect bite hypersensitivity** is diagnosed by **demonstration of an improvement after enclosing the cat in an insect-proof enclosure** for at least 2–3 weeks.
- **Atopy requires intradermal skin testing** to help identify the allergen.
- **Contact allergy** should be suspected when **withdrawal of the suspected offending drug from topical use** for 2–3 weeks results in resolution of signs.

Differential diagnosis

Immune-mediated skin disease can be ruled out on the basis of histopathology of skin biopsies by a competent dermatohistopathologist.

Treatment

Treatment is variable depending on the type of allergy:

- Food allergy: withdraw offending food protein from the diet.
- Staphylococcal allergy: continue antibiotic treatment for at least 4 weeks.
- Insect bite hypersensitivity: use insect repellants on or around the cat, or attempt to reduce insects by environmental control, e.g. use of mosquito coils,

electrical insect destruction appliances, reducing local mosquito or midge breeding grounds.

- Inhalant allergy: hyposensitization by a competent dermatologist. Judicious use of oral corticosteroids to control pruritis.
- Contact allergy (to topical drugs): Withdraw offending drug from use on the eye.

EYELID TRAUMA/WOUNDS*

Classical signs

- Linear defects or discontinuities.
- Puncture wounds with secondary cellulitis and abscessation.
- Abrasions, excoriations, hemorrhage and crusting.
- Swelling with purple to red discoloration (bruising).

Pathogenesis

Trauma can be variable in its effect on eyelid structure.

- **Sharp lacerating trauma** tends to create linear defects or discontinuities.
- **Puncturing trauma** may not be readily obvious unless infectious organisms introduced by the puncture wound later cause cellulites.
- **Abrading trauma** causes surface excoriation, hemorrhage and crusting.
- **Traumatic contusion** (bruising trauma) will cause significant swelling and purple to red discoloration of the eyelid tissue.

Clinical signs

Trauma to the eyelids should be suspected whenever any of the following are observed:

- Linear defects or discontinuities of the eyelid margin or skin surface.
- Swelling.
- Surface ulceration or excoriation.
- Surface hemorrhage or bruising.
- Serous ocular discharge and/or crusting.
- Associated trauma to the conjunctiva and/or globe.

Diagnosis

Diagnosis is based on the history of a known traumatic episode, and on the appearance of the eyelids suggesting trauma.

Treatment

Initial debridement is recommended to remove excessively traumatized tissue.

Accurate surgical apposition of wounds using 5/0 or 6/0 polypropylene or nylon sutures should be performed whenever there are sharp discontinuities of tissue. Debridement without suturing, followed by secondary intention healing (granulation) may be used whenever accurate apposition is not possible, however primary healing of eyelid structures is always preferable.

Antimicrobial therapy with antibiotics should be specifically directed against known common skin flora. Antibiotics should be considered whenever there is severe devitalization of tissue, loss of normal tissue perfusion due to disruption of arterial supply, or venous or lymphatic drainage. Appropriate empirical antibiotics selections include:

- Amoxicillin–clavulanic acid combinations at 12.5 mg/kg q 12 hourly.
- Cephalexin 15 mg/kg q 12 hourly.

Anti-inflammatory therapy with NSAIDs to reduce inflammation and swelling: Ketoprofen 1 mg/kg orally q 24 hours.

NOTOEDRES CATI INFECTION*

Classical signs

- Alopecia of the ears, eyelids, face and neck.
- Crusting and excoriation.
- Usually pronounced pruritis.

Clinical signs

Alopecia, crusting and excoriation of the ears, eyelids, face and neck.

Usually pronounced pruritis.

Diagnosis

If *Notoedres* infection is suspected, a tentative diagnosis is often made on the basis of the appearance of the lesions and the pruritis.

Other diseases which cause scaling and crusting such as **dermatophytosis** and **autoimmune skin diseases** are **usually not pruritic**.

Definitive diagnosis is based on the identification of the parasite in skin scrapings.

DEMODECOSIS

Classical signs

- Peri-ocular alopecia, erythema and scaling.
- Variably pruritic.
- Rare in cats.

Clinical signs

Typically there is alopecia, sometimes associated with scaling, erythema, crusting or alterations in pigmentation of the peri-ocular skin.

Often demodecosis is associated with other systemic disease such as FIV, FeLV, diabetes mellitus.

Diagnosis

Tentative diagnosis is based on suspicious skin lesions.

Definitive diagnosis is made on identification of mites in scrapings and/or histopathologic examination of affected eyelid skin.

MALASEZZIA

Classical signs

- Peri-ocular alopecia, and crusting.
- Variably pruritic.
- Rare in cats.

Pathogenesis

Rare in cats, and appears to be associated with **genetic factors in young cats**, for example Rex cats.

Adult-onset disease may be **allergy-associated**, and in aged cats *Malassezia* has been associated with **thymomas and carcinomas** of the pancreas and liver.

Clinical signs

Typically there is **alopecia**, sometimes associated with **crusting** or pruritis, erythema and scaling.

Diagnosis

Diagnosis is made on **identification of yeast** organisms on cytological examination of a Diff-Quik-stained specimen obtained by adhesive tape or touching a cotton bud or slide to the affected area.

Because the organism is a normal commensal of the skin, diagnosis is based on identifying the organism associated with a typical skin lesion, and resolution of the lesion in response to treatment.

Treatment

Malassezia is responsive to topical therapy such as **creams or lotions containing imidazoles**, but application is difficult because of the location.

Systemic antifungal therapy using **ketoconazole** or other **imidazole** may be better tolerated.

IMMUNE-MEDIATED BLEPHARITIS (PEMPHIGUS FOLIACEOUS, PEMPHIGUS ERYTHEMATOSUS, SYSTEMIC LUPUS ERYTHEMATOSUS)

Classical signs

- Alopecia, erythema, scaling and crusting of eyelids.
- Lesions on ears, muzzle, temporal skin and nose (pemphigus erythematosus), or nailbeds, nipples and other mucocutaneous junctions (pemphigus foliaceus).
- Other immune-mediated disease (e.g. immune-mediated polyarthritis, glomerulonephritis) in SLE.
- Uncommon.

Clinical signs

Uncommon disease in cats.

Alopecia, erythema, scaling and crusting of eyelids. Blisters are rarely seen as these are usually transient.

Additional areas affected are the **nailbeds, nipples and other mucocutaneous junctions** (foliaceus) and **ears, muzzle, temporal skin and nose** (erythematosus).

Systemic lupus erythematosus (SLE) is a very rare disease. It is more commonly seen in young cats with a

reported higher incidence in Persian and Siamese breeds. Immune-mediated disease of other tissues is usually present by definition in SLE, for example:

- Immune-mediated polyarthritis: painful arthritic joints, lameness.
- Glomerulo-nephritis: chronic progressive signs of polydipsia/polyuria and azotemia.
- Cats usually have other systemic signs such as fever, lymphadenopathy.

Diagnosis

A provisional diagnosis is made on the appearance and location of the skin lesions.

Definitive diagnosis is made on histopathology of skin biopsies.

High ANA titers are usually seen in SLE.

Differential diagnosis

Similar eyelid lesions can be seen in allergic blepharitis, and in both conditions other lesions may also be seen on the face, but these cases can usually be differentiated from pemphigus and SLE on biopsy.

Dermatophyte infections can be identified by microscopic examination of hair shafts and culture.

Squamous cell carcinoma in the pre-cancerous stage ("solar dermatitis") can look similar to immune-mediated skin disease, but can be ruled out by biopsy of affected skin.

Treatment

Immunosuppressive doses of corticosteroids, e.g. prednisolone up to 2.5 mg/kg PO q 12 h, reducing as signs of disease abate.

In more aggressive immune-mediated skin disorders such as pemphigus foliaceus, other immune-modulating drugs may have to be used to achieve control, e.g. chlorambucil 0.1 mg/kg q 24 h.

ECTROPION

Classical signs

- Eyelid rolled outwards, making bulbar conjunctiva more visible.

Classical signs—Cont'd

- Cicatricial scarring from previous injury.
- Rare.

Clinical signs

Rare in cats.

Eyelid margin is rolled outwards, making bulbar conjunctiva more visible.

Usually it is caused by former injury. If the eyelid is examined carefully, signs of previous injury will be identified by cicatricial scarring causing the roll-out. This will make manual correction of the ectropion by lid tensioning at the time of examination difficult.

Diagnosis

Diagnosis is based on the characteristic appearance of a fixed ectropion with scarring.

DISTICHIASIS**Classical signs**

- Cilia extending from meibomian gland openings at the eyelid margin.
- ± Ocular irritation with lacrimation.
- Rare in cats.

Clinical signs

Cilia are present extending from meibomian gland openings at the eyelid margin.

Irritation from the cilia may cause increased lacrimation and occasionally signs of corneal irritation, such as ulcerative or non-ulcerative keratitis, vascularization of the cornea or even corneal sequestration.

Rare in cats.

Diagnosis

Diagnosis is based on the detection of the fine cilia extending from the meibomian gland openings. Magnification and bright illumination will facilitate detection against a white scleral background.

PARASITIC MYIASIS**Classical signs**

- Discharging fistulous opening onto the face.
- Fly larvae visible in wound.

Clinical signs

Discharging wound which may involve the eyelid. Usually fly larvae are visible inside a discharging fistulous opening.

Diagnosis

Diagnosis is based on the appearance of the fly larvae (maggots) in a discharging wound.

66. The cat with an abnormal third eyelid

Michael E. Bernays

KEY SIGNS

- Abnormal prominence of third eyelid.
- Focal or generalized swelling of third eyelid.
- Erythema, chemosis.
- Eyelid lacerations.
- Ocular discharge.

MECHANISM?

- Abnormalities of third eyelid appearance usually result from abnormalities in eyelid innervation, especially of the autonomic sympathetic nerves, or inflammation or neoplasia involving the conjunctiva of the third eyelid.

WHERE?

- Third eyelid cartilage.
Conjunctiva covering the third eyelid.
Gland of the third eyelid.

WHAT?

- The most common cause of altered third eyelid appearance is autonomic nervous system disease especially sympathetic neuropathy. Neoplasia and inflammatory disease is occasionally seen.

QUICK REFERENCE SUMMARY

Diseases causing an abnormal third eyelid

WHERE?

THIRD EYELID

METABOLIC

- **Third eyelid prominence related to severe weight loss* (p 1137)**
Occurs secondary to loss of orbital fat and enophthalmos (caudal globe retraction).

NEOPLASTIC

- **Squamous cell carcinoma*** (p 1134)**

Proliferative pink mass growing from the third eyelid with verrucous or ulcerated surface.

- **Other neoplastic disease of the third eyelid (adenoma, adenocarcinoma, mast cell tumor, lymphoma, hemangioma)* (p 1138)**

Tumors result in generalized swelling, a localized mass lesion, or erosion on the third eyelid.

Hemangioma may form a discrete mass on the third eyelid, usually red to purple in color, which may hemorrhage.

PHYSICAL

- **Prolapsed gland of the third eyelid (p 1340)**

Pink to red mass protruding from behind the leading edge of the third eyelid (rare).

- **Everted nictitans cartilage (p 1331)**

Folded edge of third eyelid margin, without fleshy mass suggestive of gland prolapse (rare).

- **Third eyelid prominence related to ocular pain* (p @)**

Occurs secondary to enophthalmos (globe retraction) due to the pain.

INFECTIOUS

- **Infectious disease involving the conjunctiva of third eyelid (feline herpesvirus-1**, *Chlamydophila felis*** *Mycoplasma**) (p 1337)**

Signs include acute onset of hyperemia and chemosis of conjunctival surfaces and serous or mucopurulent ocular discharge, often together with concurrent upper respiratory tract signs. Chlamydial and mycoplasmal conjunctivitis may involve one or both eyes initially, and herpesvirus causes bilateral involvement.

- **Tetanus (p 1339)**

Bilateral third eyelid prominence in association with contraction of facial muscles, and increased tone in muscles of mastication (“lockjaw”). Rare in cats.

IMMUNE

- **Eosinophilic keratoconjunctivitis** (p 1335)**

Pink to whitish plaque-like thickening of the third eyelid, sometimes associated with similar lesions on the cornea.

IDIOPATHIC

- **Third eyelid dysautonomia (“Haws”)** (p 1338)**

Acute onset of bilateral third eyelid prominence, which is non-painful, and resolves over days to weeks without treatment.

- **Feline dysautonomia (p 1338)**

Third eyelid prominence, in association with any of a range of other systemic signs, e.g. keratoconjunctivitis sicca, dilated non-responsive pupils, anisocoria, dry nose and/or mouth, bradycardia, constipation megaesophagus and urinary or fecal incontinence. Onset of signs is over 48 h, and is associated with depression and anorexia.

continued

continued

TRAUMA

● Trauma to the third eyelid* (p 1330)

Asymmetric notch-like defects in the third eyelid margin due to claw injury from fighting with other cat(s).

● Sympathetic neuropathy of the third eyelid (Horner's syndrome)** (p 1335)

Prominent third eyelid, usually unilateral, in association with any combination of enophthalmos, upper lid ptosis or miosis, in association with or without other localizing signs such as ipsilateral forelimb lameness, cervical lesions (e.g. abscess, cellulitis) or middle ear disease.

INTRODUCTION

MECHANISM?

The most common cause of change in third eyelid appearance is an abnormality in innervation, especially involving the autonomic sympathetic nerves.

The abnormal third eyelid is most often noticed because it is prominent.

Prominence or **protrusion of the third eyelid is a passive phenomenon** in most animal species. Protrusion is usually facilitated by active contraction of muscle in adjacent orbital structures, and occurs because either:

- The globe is retracted caudally into the orbit by the action of the rectus and retractor bulbi muscles (the normal position of the globe tends to push the third eyelid into its retracted position at the medial aspect of the globe) or
- Sympathetically innervated smooth muscle at the base of the third eyelid (arising from deep in the orbit around facial coverings of the medial and ventral rectus muscles) is not contracting, causing a failure of retraction of the third eyelid.

In the cat, the third eyelid may become actively protruded, independent of globe movement, by the action of skeletal muscle fibers, which are extensions of the levator palpebrae superioris and the lateral rectus muscles, innervated by the oculomotor (CN III) and abducens (CN VI), respectively.

Because the third eyelid is covered by conjunctiva on both its posterior and anterior surface, any disease which affects the conjunctiva (see The Cat With Ocular Discharge or Changed Conjunctival Appearance,

page 1212) can also involve the surface of the third eyelid. Such conjunctival diseases are either:

- Inflammatory disease due to:
 - Infectious agents such as FHV1, *Chlamydomydia felis*, *Mycoplasma*.
 - Non-infectious, allergic or other immune-mediated etiologies, e.g. eosinophilic keratoconjunctivitis or follicular conjunctivitis.
- Neoplastic disease, especially squamous cell carcinoma.

WHERE?

Disease anywhere along the **sympathetic neural pathways** (i.e. thalamus, cervical spinal cord long tracts, T1–T3 spinal nerves, ascending pre-ganglionic fibers, cranial cervical ganglion, sympathetic post-ganglionic fibers in middle ear or orbit), and the smooth muscle fibers innervated by them, may cause protrusion of the third eyelid.

Conjunctival surface diseases cause abnormal appearance of the third eyelid.

Cartilage of the third eyelid may fold causing an everted appearance.

WHAT?

The most common cause of altered third eyelid appearance is autonomic nervous system disease especially **primary third eyelid dysautonomia** ("haws"). Horner's syndrome is associated **with other clinical signs** such as enophthalmos, miosis and upper lid ptosis. Primary third eyelid dysautonomia is associated **with prominence of the third eyelid with lack of other signs** of sympathetic denervation.

Inflammatory disease is occasionally seen, and can be of infectious or non-infectious, immune-mediated or allergic etiology.

Neoplasia involving the conjunctiva of the third eyelid occurs infrequently.

DISEASES CAUSING ABNORMAL THIRD EYELID APPEARANCE

INFECTIOUS DISEASE INVOLVING CONJUNCTIVA OF THE THIRD EYELID*** (FELINE HERPESVIRUS-1**, *CHLAMYDOPHILA FELIS*** AND *MYCOPLASMA** INFECTION)

Classical signs

- Inflammation and chemosis (swelling) specifically involving the conjunctiva of the third eyelid.
- Discharge varies from serous or mucoid to mucopurulent.

See main references on feline herpesvirus, chlamydial and mycoplasmal infection on pages 1212, 1218 for details (The Cat With Ocular Discharge or Changed Conjunctival Appearance).

Clinical signs

Typically there is **inflammation and chemosis (swelling)** specifically involving the conjunctiva of the third eyelid. Usually the associated bulbar and palpebral conjunctivae are also affected.

There may be **signs of upper respiratory tract disease** in the early stages, although all these organisms may also cause conjunctivitis unassociated with typical upper respiratory tract signs. Conjunctivitis alone may occur in cats with previous exposure that have developed immunity, or it may represent recrudescence of signs in carrier cats.

Discharge varies from serous or mucoid to mucopurulent. The type of discharge seen is dependent on the stage of the infection, for example, FHV-1 herpesvirus infections usually cause a serous discharge in the early stages, which progresses to a mucopurulent discharge secondary to bacterial infection.

Although herpesvirus, *Chlamydomphila felis* and *Mycoplasma* infection may be difficult to distinguish clinically in some cats, in other cats signs may be suggestive of the causative agent.

- **Herpesvirus** typically causes bilateral serous conjunctivitis in conjunction with other upper respiratory signs (sneezing, nasal discharge). Discharge rapidly becomes mucopurulent and the cat is depressed, anorexic and febrile. In some cats, dendritic ulcerative keratitis may occur initially. Non-ulcerative stromal keratitis and/or corneal sequestration may occur several weeks to a few months after the initial infection, which may have been unnoticed. Symblepharon may be seen as a sequel in young cats.
- **Chlamydial conjunctivitis** typically appears as severe hyperemia and chemosis of conjunctival surfaces. It is associated with mucopurulent discharge, usually starting in one eye and later progressing to involve the contralateral eye.
- **Mycoplasmal conjunctivitis** appears as unilateral or bilateral conjunctivitis, associated with epiphora, papillary hypertrophy of conjunctiva, conjunctival follicles, chemosis, and occasionally thick white pseudomembrane.

Diagnosis

A tentative diagnosis is often made on the signs of inflammation, chemosis and discharge associated with upper respiratory tract signs.

A **definitive diagnosis** requires identification of the organism on conjunctival cytologic preparations stained with **Wright–Giemsa**, e.g.

- Membrane-bound basophilic intracytoplasmic inclusions indicate chlamydial infection.
- Small basophilic-staining pleomorphic organisms closely associated with the cell membrane surface indicate mycoplasmal infection.

Specific tests are available for the diagnosis of infectious disease especially in the early stages, e.g.

- Herpesvirus: immunofluorescent antibody (IFA), virus isolation (VI) and polymerase chain reaction (PCR).
- *Chlamydomphila felis*: IFA and PCR.

Differential diagnosis

Infectious conjunctivitis is usually distinctive and differentiation between the infectious agents needs to be made. The chronic forms of infection may appear similar to **eosinophilic keratoconjunctivitis**, which can be differentiated based on cytological examination of deep scrapings or on histopathology.

Treatment

See The Cat With Ocular Discharge or Changed Conjunctival Appearance (page 1207) for more details.

Herpesvirus: topical trifluorothymidine, Idoxuridine, Vidarabine, topical or oral Acyclovir, topical or oral alpha interferon, oral lysine.

Chlamydomphila felis: topical tetracycline, oral doxycycline, oral azithromycin.

Mycoplasma: topical tetracycline or chloramphenicol.

THIRD EYELID DYSAUTONOMIA (“HAWS”)^{***}

Classical signs

- Bilateral non-painful third eyelid prominence.
- Usually acute onset, and often resolves rapidly without treatment within days to weeks.
- Unassociated with other signs of sympathetic denervation.

Clinical signs

Bilateral, non-painful third eyelid prominence, usually acute in onset and resolves rapidly within days to weeks. Not associated with other signs of sympathetic denervation such as ptosis and a miotic pupil.

Sometimes seen in association with acute gastrointestinal signs, e.g. diarrhea. One report in the literature found an association with torovirus infection.

Diagnosis

Diagnosis is usually based solely on the clinical signs.

Differential diagnosis

Horner’s syndrome results in acute onset of unilateral prominence of the third eyelid whereas Haws is bilateral. Horner’s syndrome is associated with other signs such as ptosis and a miotic pupil.

Treatment

No treatment is necessary. All cases will resolve with time.

SQUAMOUS CELL CARCINOMA^{***}

Classical signs

- Verrucous, raised mass usually arising from non-pigmented conjunctival surface.
- Erosion and mucopurulent discharge.

Clinical signs

Pink, proliferative mass with a cauliflower-like (verrucous) or ulcerated surface usually arising from the non-pigmented conjunctival surface of the third eyelid. Typically the lesion is associated with erosion, loss of normal tissue architecture and mucopurulent discharge.

Diagnosis

Initial diagnosis is based on the appearance of the lesion.

Cytology and/or histopathology are required for a definitive diagnosis. Typical cytological appearance includes large clumps of eosinophilic keratinized epithelial cells, and sometimes loss of normal architecture is visible in the form of whorls or keratin “pearls”.

Differential diagnosis

Eosinophilic keratitis is an uncommon proliferative disease of the third eyelid. It may also be associated with corneal disease and cytology is characteristically in the form of eosinophilic infiltrates.

Other neoplastic disease. Hemangiomas are not as common, have a smoother surface, and appear as a darker red to purple-colored mass.

Treatment

Surgical excision with good margins is required to ensure complete removal. The lesions can sometimes invade deep into the extra-ocular tissues by the time the lesion is recognized.

Cryosurgery using liquid nitrogen or nitrous oxide with double freeze thaws and slow controlled thawing can be effective for small tumors less than 0.5 cm diameter. Maximal destruction of tumor cells occurs when temperatures of between -20°C to -40°C are achieved at the center of the tumor.

β -irradiation with strontium 90 can be effective if available.

EOSINOPHILIC KERATOCONJUNCTIVITIS**

Classical signs

- Pink to whitish plaque-like thickening of the third eyelid.
- \pm Similar lesions on the cornea.

Clinical signs

Appears as **pink to whitish plaque-like thickening of the third eyelid**. Similar lesions may appear on the cornea in some cats.

The pathogenesis is unknown, but is postulated to involve insect bite hypersensitivity or herpesvirus infection in some cats. Generally there is not a strong association with the presence of other feline eosinophilic disease.

Diagnosis

Tentative diagnosis is based on the presence of typical lesions on the third eyelid and cornea.

Cytological examination of deep scrapings of the lesion or histopathology of a biopsy specimen demonstrate an **infiltrate of plasma cells and lymphocytes** with variable numbers of eosinophils. Eosinophils may not always be the most numerous cell type.

Tests for herpesvirus infection, e.g. in situ PCR and (see The Cat With Ocular Discharge or Changed Conjunctival Appearance, page 1213, for more details).

Differential diagnosis

Squamous cell carcinoma usually causes more disfigurement of the third eyelid due to proliferation and ulceration.

Other neoplasms such as hemangioma have a characteristic appearance.

Chronic *Mycoplasma* and *Chlamydophila felis* infection may appear similar in some cats, but can be differentiated on cytological examination of Wright–Giemsa-stained slides, immunofluorescent antibody and PCR.

Treatment

Oral corticosteroids: Prednisolone 5 mg orally q 12–24 h, with dose reducing as effect is achieved.

Oral progestagens at a low dose (e.g. megestrol acetate 5 mg twice weekly) should be used only in cases refractory to oral prednisolone. Beware of possible side effects such as insulin resistance, diabetes and obesity.

Topical corticosteroids are usually contraindicated because of an underlying association with ocular herpesvirus infection. These drugs may potentiate the herpesvirus infection by local immunosuppression.

Treat the underlying cause if identified, e.g. treat the ocular herpesvirus infection.

SYMPATHETIC NEUROPATHY OF THE THIRD EYELID (HORNER'S SYNDROME)**

Classical signs

- Usually unilateral.
- Non-painful prominence of the third eyelid.
- Miosis of the ipsilateral pupil.
- Upper lid ptosis.
- Enophthalmos.

Pathogenesis

Protrusion of the third eyelid occurs where there is disruption of the sympathetic neural pathways innervating the smooth muscle of the third eyelid (Horner's syndrome). Disruption may occur anywhere along the pathway including in the thalamus, cervical spinal cord

long tracts, T1–T3 spinal nerves or nerve roots, ascending pre-ganglionic fibers, cranial cervical ganglion and sympathetic post-ganglionic fibers in middle ear or orbit. Less commonly protrusion is the result of dysfunction of the smooth muscle fibers innervated by the sympathetic nerve.

More common causes in the cat include:

- **Middle ear disease** especially nasopharyngeal polyps. Nasopharyngeal polyps arise in the middle ear and emerge into the external ear canal or nasopharynx. Typically they occur in young cats (< 5 years), but any age can be affected.
- **Disruption of ascending sympathetic pathways** in the neck due to **injury or inflammation** associated with fight wounds.
- **Injury to nerve roots of T1–T3** associated with forelimb trauma, usually from motor vehicle accidents.
- **Anterior thoracic cavity disease**, e.g. mediastinal lymphoma.

Rarely, is third eyelid protrusion the result of nerve damage within the brain or spinal cord, or smooth muscle disease.

Clinical signs

Usually there is a **unilateral, non-painful prominence of the third eyelid**, together with other signs of sympathetic denervation, i.e. miosis, upper lid ptosis (“drooping”), enophthalmos.

Other signs may be present in some cases, which may enable further localization of the lesion, e.g.

- An **abscess or cellulitis of cervical soft tissue** structures suggests disruption of ascending preganglionic fibers.
- **Signs of middle or inner ear disease** such as a head tilt or circling. Nasopharyngeal polyp may be seen as a fibrous mass emerging into the external ear canal, or cause noisy breathing, dyspnea with or without nasal discharge, sneezing or coughing and gagging.
- **Ipsilateral forelimb lameness** may occur from damage to nerve roots or nerves innervating the leg. **Radial nerve paresis or paralysis** may occur concurrently with avulsion of T1–T3 nerve roots if C8 or T1 nerve roots are injured. If the **musculo-cutaneous nerve** roots (C5–7) are also injured, the

elbow cannot be flexed or the paw picked up, resulting in excoriation of the dorsum of the paw. Muscle atrophy is apparent within 5–7 days of injury to the motor nerve roots. Damage to C7–T1 may also result in loss of the **ipsilateral cutaneous trunci (panniculus)** reflex.

Diagnosis

Any cat with an apparently non-painful, non-inflamed prominent third eyelid, which also has miosis, upper lid ptosis and enophthalmos should be suspected as having Horner’s syndrome.

Pharmacological testing with sympathomimetics is controversial, and the indirect-acting sympathomimetic hydroxyamfetamine is no longer available in some countries. Reliable diagnostic protocols are not available, however a rapid (within 5–8 minutes) reversal of signs following the administration of one drop of 10% phenylephrine is suggestive of post-ganglionic denervation hypersensitivity, indicating that the lesion is somewhere rostral to the cranial cervical ganglion. Anatomically this corresponds to localization of the lesion in the middle ear or orbital structures rostral to the middle ear. The response should always be compared with that in the contralateral normal eye.

Lesion localization will not be possible in many cases, and many cases seem to be idiopathic.

Differential diagnosis

Third eyelid dysautonomia (Haw’s) is always bilateral, and is not associated with other signs of sympathetic denervation. Horner’s syndrome is almost always unilateral.

Treatment

Where possible, treatment should be directed at the associated problems which may be causing interruption of sympathetic pathways.

The disfigurement created by Horner’s syndrome can be reversed by frequent (at least 2–3 times daily) application of one drop of 10% phenylephrine in the affected eye. This treatment only alters the appearance of the eye and does nothing else for the cat’s well-being,

except that vision might be improved where the third eyelid prominence and enophthalmos is extreme, causing most of the globe to be covered by nictitans.

Prognosis

Depending on the cause many cases may resolve over time as denervated smooth muscle re-innervates, provided that oculosympathetic fibers are not totally destroyed.

TRAUMA TO THE THIRD EYELID MARGIN*

Classical signs

- Notch-like or linear tears arising from the third eyelid margin.
- Usually unilateral, with the contralateral eye unaffected.

Clinical signs

Trauma to the third eyelid may result in notch-like or linear tears starting at the margin of the third eyelid. These occur most commonly from cat fights.

Third eyelid trauma may be associated with other ocular signs, when seen in the acute stages, e.g. conjunctival chemosis and ocular discharge (see *The Cat With Ocular Discharge or Changed Conjunctival Appearance*, page 1211).

Diagnosis

Diagnosis is based on the clinical signs, and the history of unilateral third eyelid notch or tear occurring after a possible fight with another cat.

THIRD EYELID PROMINENCE RELATED TO OCULAR PAIN*

Classical signs

- Third eyelid prominence.
- Associated with other ipsilateral signs of ocular pain, e.g. enophthalmos, blepharospasm, corneal disease, pupil miosis.

Clinical signs

The third eyelid is prominent because of **retraction of the globe, associated with ocular pain**.

It is associated with **ipsilateral signs of ocular pain**, for example, enophthalmos, blepharospasm, corneal disease, pupil miosis or anterior uveitis.

Diagnosis

Diagnosis is based on signs of ocular pain together with prominence of a normal-appearing third eyelid.

Differential diagnosis

Horner's syndrome and **Haws** are usually non-painful.

Horner's syndrome, tetanus and feline dysautonomia each have their own specific associated clinical signs, which are more suggestive of that particular condition.

Treatment

Treat the cause of the ocular pain as indicated.

THIRD EYELID PROMINENCE RELATED TO SEVERE WEIGHT LOSS*

Classical signs

- Signs of generalized muscle wasting associated with chronic disease.
- Thin face with signs of muscle wastage around the lateral aspects of the orbit.
- Bilaterally symmetrical third eyelid prominence without miosis or upper lid ptosis.

Clinical signs

Typically these cats have a bilaterally symmetrical third eyelid prominence due to marked enophthalmos, and there are no other signs normally associated with other causes of third eyelid prominence such as miosis or upper lid ptosis.

Generalized whole-body muscle wasting is present in association with signs of other organ system disease,

e.g. chronic renal failure, inflammatory bowel disease or hyperthyroidism.

Third eyelid prominence occurs secondary to loss of orbital fat and enophthalmos.

Diagnosis

Diagnosis is based on the generalized body muscle and fat loss, in association with the pronounced enophthalmos and third eyelid prominence.

OTHER NEOPLASTIC DISEASE OF THE THIRD EYELID* (ADENOMA, ADENOCARCINOMA, MAST CELL TUMOR, LYMPHOMA, HEMANGIOMA)

Classical signs

- Mass or erosive lesion involving the third eyelid.
- Ocular discharge.

Clinical signs

Tumors of the third eyelid **appear as a mass or erosive lesion** involving the third eyelid. Appearance depends on the type of tumor, which includes lymphoma, hemangioma, mast cell tumor, adenoma and adenocarcinoma.

- **Hemangiomas** are rare, are usually dark red to purple in color, and are fragile with a tendency to hemorrhage.
- **Lymphoma** will usually cause more generalized swelling of the third eyelid and the peri-orbital tissues, and may be associated with other systemic signs of multicentric lymphoma.
- **Mast cell tumors** can form either well- or poorly circumscribed areas of swelling in the eyelid. They appear as rapidly growing nodular tumor, often with poorly defined borders, and variable surface ulceration.
- **Adenomas or carcinomas** are seen as a nodular or diffuse mass causing localized thickening of the eyelid. The tumor may have an ulcerated surface.

The neoplastic mass may cause increased **ocular discharge** because of third eyelid dysfunction. The normal distribution of the precorneal tear film across

the cornea is impaired because of an uneven eyelid margin.

Diagnosis

Diagnosis is initially based on the **appearance of the lesion**, which varies according to the type of tumor.

Definitive diagnosis is by cytological and histological examination.

FELINE DYSAUTONOMIA

Classical signs

- Unilateral or bilateral third eyelid prominence.
- Acute onset of anorexia and depression.
- Other signs of autonomic dysfunction such as keratoconjunctivitis sicca, mydriasis, anisocoria, dry nose or mouth, bradycardia, constipation, megaesophagus, urinary or fecal incontinence.

See main references on page 792 for details (The Constipated or Straining Cat).

Clinical signs

Third eyelid prominence, in association with any of a range of **other systemic signs suggestive of autonomic dysfunction** including keratoconjunctivitis sicca, dilated non-responsive pupils, anisocoria, dry nose and/or mouth, bradycardia, constipation, megaesophagus and urinary or fecal incontinence.

Typically, the onset of signs is **acute over 48 h and associated with depression and anorexia**.

Diagnosis

Diagnosis is based on signs of generalized autonomic dysfunction.

Condition is rare or at least uncommon, and most frequent in UK.

Definitive diagnosis is based on the demonstration of **characteristic ultrastructural lesions within cell bodies** in autonomic ganglia at post mortem.

Differential diagnosis

Abnormality of the third eyelid without the presence of other signs of autonomic dysfunction would suggest localized sympathetic dysfunction such as **Horner's or Haws syndrome**.

Treatment

No definitive treatment is available. Prognosis is generally guarded to poor, however supportive treatment is reported to be variably effective.

TETANUS

Classical signs

- Bilateral third eyelid prominence.
- Contraction of facial muscles, increased tone in muscles of mastication ("lockjaw").
- Stiffness of one or more limbs which worsens with stimulation.

Pathogenesis

Signs of tetanus result from the toxin produced by *Clostridium tetani*, a spore-forming, Gram-positive rod. *C. tetani* is found in the soil, and also occurs as part of the normal gastrointestinal tract flora of some animals.

Spores of the *Clostridium tetani* bacillus enter the body commonly via surface wounds. The toxin, **tetanospasmin**, is produced during cell growth, sporulation and lysis, if there is a suitable anaerobic environment for the bacteria. The toxin migrates along nerve axons from a local wound, to sites of action in the central nervous system, where it initially binds to presynaptic inhibitory motor nerve endings. The effect of the toxin is to block the release of inhibitory neurotransmitters (glycine and gamma-amino butyric acid) across the synaptic cleft. This results in uninhibited muscle contraction.

The **incubation period** for signs to develop varies from **3–21 days after an injury**, depending on the proximity of the injury to the CNS, the ability of the local tis-

sue environment to support toxin production, and the number of organisms present.

Tetanus is **rare in cats**, because they are more **resistant to the toxin** than humans and horses. This innate resistance is related to the **inability of the toxin to penetrate and bind to nervous tissue**, and likely accounts for the frequency of localized signs in cats.

Tetanus has occurred after routine surgery (such as ovariohysterectomy), fetal death during pregnancy, and trauma.

Tetanus may occur in young cats associated with a gum wound secondary to losing a deciduous tooth.

Clinical signs

Signs of tetanus may be localized or generalized, or may begin with localized signs and progressively involve more muscle groups over a week or more, and become generalized. Generalization is more likely if there is inadequate wound management, or inadequate antibiotic therapy.

Diagnosis may be difficult in the early stages of the disease when characteristic signs of generalized tetanus are absent.

Classical signs of generalized tetanus include bilateral third eyelid prominence in association with **contraction of the facial muscles** giving the appearance of a "**sardonic smile**", and increased tone in the muscles of mastication ("lockjaw"). The cat may have a "startled" appearance.

Focal tetanus results in **stiffness of the muscles in closest proximity to the wound**, and is often evident as stiffness of one or two limbs.

In many cats, **a neglected wound with necrotic tissue** is found, suggesting a site for toxin production.

Tetanus may be associated with infection of the female reproductive tract, and may produce local signs in the pelvic limbs.

The history of a penetrating or neglected wound, and the **presence of persistent involuntary muscle rigidity in a mentally alert cat** is highly suggestive of tetanus.

If there is generalized muscle stiffness, the cat may have an **increased temperature** associated with the muscle contraction.

Diagnosis

Diagnosis is based on the characteristic clinical signs.

EMG testing of affected muscles is strongly suggestive of tetanus if it demonstrates **persistent spontaneous motor unit potentials**.

Differential diagnosis

Any condition which causes **bilateral third eyelid prominence** such as **haws** or **dysautonomia** should be considered. However, facial muscle or limb rigidity is not seen with these conditions.

Mild hypocalcemia in late pregnancy or following whelping could be confused with tetanus, especially as the reproductive tract may be a site of infection and toxin production. Rapid response to intravenous calcium in pregnancy-associated hypocalcemia will rule out tetanus.

Meningoencephalitis or **encephalopathy** including thiamine deficiency may occasionally have tetanic spasms worsened with touch or sound. In these animals mentation is usually depressed and other neurological signs are evident.

Treatment

Treatment involves appropriate **antibiotic therapy**, **wound care**, **supportive treatment**, and use of **tetanus antitoxin**.

It is important to **debride necrotic tissue**, so the tissue environment is less attractive for persistence of the organism and toxin production.

Antibiotics with anaerobic activity especially **metronidazole** (**10 mg/kg, q 8 h**), and those belonging to the penicillin group, e.g. amoxicillin or **amoxycillin/clavulanate** are indicated to prevent further proliferation of bacteria in the wound.

- Metronidazole has been shown to be superior to penicillin G and tetracycline. It is bactericidal against most anaerobes and achieves effective therapeutic concentrations even in anaerobic tissues.

Tetanus antitoxin binds to circulating toxin, and cannot dislodge toxin within peripheral nerves. Its main purpose is to neutralize circulating toxin outside the nervous system. If the signs are localized and non-progressive, administering tetanus antitoxin systemically is not likely to be beneficial, and is associated with a risk of anaphylaxis.

- The dose of antitoxin is usually about 1000 U/kg IV administered slowly over 5–10 minutes, with some (1000 U) injected locally in the wound. As most tetanus antisera are generally prepared in equines, consideration should be given to the pre-emptive use of corticosteroids and antihistamine to prevent possible anaphylaxis. Give a test dose (0.1–0.2 ml) intradermally or subcutaneously 15–20 minutes before IV administration and check for a wheal.

Muscle relaxants such as **diazepam** can be used to control the muscle rigidity and make the cat more comfortable. Efficacy of the drug varies between individual cats. Alternatively, small doses of **acepromazine** (1.25–2.5 mg/cat PO q 6 hours as required), **chlorpromazine** (IV) or **phenobarbital** may be effective in reducing muscle stiffness.

Other **supportive treatment** should be given as indicated, e.g. **alimentation**, **intravenous fluids**.

Keep the cat in a **quiet, dark area** to reduce the muscle spasms, which are stimulated by touch or sound

Difficulty urinating or defecating may occur, and needs to be managed.

Prognosis

The **prognosis is generally good** with appropriate treatment, and full resolution of signs usually occurs within 2–3 months.

Prognosis is poorer if signs develop very rapidly.

PROLAPSED GLAND OF THE THIRD EYELID

Classical signs

- Pink to red mass protruding from behind the third eyelid.
- Variable inflammation and discharge.
- Rare and only reported in Burmese cats.

Clinical signs

Pink to reddish mass with a smooth conjunctival surface protrudes from behind the leading edge of the third eyelid margin.

Prolapse may be accompanied by **variable degrees of inflammation and discharge**, ranging from mucoid to mucopurulent.

Rare in cats compared with dogs, and reported only in Burmese cats.

Diagnosis

Diagnosis is based on the appearance of the mass. Differential diagnosis would be a tumor or a folded (everted or inverted) third eyelid cartilage, also rarely reported, and only in Burmese cats.

EVERTED NICTITANS CARTILAGE

Classical signs

- Folded everted third eyelid margin.
- Rare and only reported in Burmese cats.

Clinical signs

Everted third eyelid margin occurs because of **fold-ing of the cartilage** of the third eyelid. This condition should be distinguished from a prolapsed gland of the nictitans.

Rare in cats. Reported only in Burmese cats.

Diagnosis

Diagnosis is based on the appearance of the third eyelid margin. Usually there is no sign of a fleshy mass protruding from behind the third eyelid.

Treatment

Resection of the folded section of cartilage will enable straightening of the third eyelid.

PART 16

Drugs

67. Special considerations related to drug use in cats

Jill Elizabeth Maddison

KEY SIGNS

- Differences in dosing recommendations between dogs and cats are usually because of differences in drug metabolism.
- Cats are deficient in some glucuronyl transferases resulting in very prolonged half lives for some drugs such as aspirin.
- Feline hemoglobin is more susceptible to oxidation forming methemoglobin; oxidation occurs with drugs such as benzocaine.
- Some receptor sites for drug binding are more sensitive, for example with morphine.

Drugs not recommended for use in cats

Acetaminophen (paracetamol)	Methemoglobinemia and Heinz body anemia.
Apomorphine	Significant CNS depression.
Azathioprine	Bone marrow suppression.
Benzocaine	Methemoglobinemia. Laryngeal edema.
Cisplatin	Fatal, acute pulmonary edema.

continued

continued

Phenytoin	Sedation. Ataxia. Anorexia. Dermal atrophy.
Propylthiouracil	Lethargy. Weakness. Anorexia. Bleeding diathesis.
Scopolamine	Tendency to cause behavioral changes.
Sodium phosphate enemas	Depression. Ataxia. Vomiting. Bloody diarrhea.

Drugs which are therapeutically useful in cats but which may have different toxicity/activity profiles than in dogs

Aspirin	Hypernea. Hypersensitivity. Hyperthermia.
Chloramphenicol	Anemia.
Digoxin	Vomiting. Anorexia. Bradycardia. Arrhythmias.
Doxorubicin	Renal failure.
Enrofloxacin	Blindness.
Furosemide	Dehydration. Hypokalemia.
Griseofulvin	Leukopenia and thrombocytopenia. Non-reversible ataxia.
Ketoconazole	Dry hair coat. Weight loss.
Lignocaine	Myocardial and CNS depression.
Megestrol acetate	Mammary hypertrophy and neoplasia. Cystic endometritis. Diabetes mellitus.
Methimazole, carbimazole	Anorexia. Vomiting. Self-induced facial excoriation. Bleeding diathesis. Hepatopathy. Serious hematological side effects.

continued

continued

Metronidazole	Disorientation. Ataxia. Seizures. Blindness.
Opioids: morphine derivatives (excluding meperidine [pethidine], butorphanol and buprenorphine)	Inconsistent sedation. Increased risk of excitation.
Organophosphates	Acute toxicity – hypersalivation, vomiting, diarrhea, muscle tremors. Chronic or delayed toxicity – paresis or paralysis which may or may not be reversible.
Potassium bromide	Depression. Severe coughing.
Tetracyclines	Hepatic lipidosis. Increased ALT activity. Ptyalism. Anorexia.
Thiacetarsamide	Drug fever. Respiratory distress. Fulminant pulmonary edema.

INTRODUCTION

SPECIAL CONSIDERATIONS RELATED TO DRUG USE IN CATS

Why are cats different?

There are some important differences in drug disposition between dogs and cats that can have a profound influence on dosing recommendations for cats.

The majority of the difference in drug disposition between cats and dogs **relates to differences in drug metabolism**.

DRUG METABOLISM – GENERAL

Water-soluble drugs can be **excreted in urine** without being metabolized.

Drugs that are **lipid soluble** must be **converted to water-soluble metabolites** that can be excreted, usually by the kidney.

Drug metabolism occurs in the liver in two phases (I and II).

Most differences between dogs and cats in drug disposition relate to **differences in Phase II metabolism**, although deficiencies in Phase I metabolism may be involved in some drug toxicities in cats including chloramphenicol toxicity.

During Phase II metabolism, parent drugs or Phase I metabolites are bound (conjugated) to large molecules such as **glucuronide, glutathione, sulfate and acetyl groups, and amino acids** (e.g. glycine and taurine) resulting in a water-soluble, inactive compound.

FELINE DRUG METABOLISM

Cats are **deficient in some glucuronyl transferases** which are important for glucuronidation.

- Drugs that are excreted as glucuronide conjugates in other species such as aspirin, benzoic acid, acetaminophen (paracetamol) and hexachlorophene may have a **prolonged half-life in cats**.
- Increased half-life **increases the risk of toxicity** due to drug accumulation.

Not all drugs that are glucuronidated are a problem in cats. **Cats are only deficient in certain families of glucuronyl transferases**.

- The drug may have a wide safety margin and drugs may be metabolized by a different route in cats (although this can result in toxicity for some drugs).
- For example, **sulfation is well developed in cats** compared to dogs and **acetylation**, which is deficient in dogs, appears to be **well developed in cats**.

FELINE HEMOGLOBIN AND DRUGS

Feline hemoglobin is more susceptible to oxidation, and therefore methemoglobinemia formation, than in dogs. This increases the risk of adverse drug reactions.

There are a number of possible mechanisms including the different structure of feline hemoglobin, lower concentrations or activities of intracellular repair enzyme and differences in intracellular concentrations of glutathione-conjugating enzymes.

OTHER PHYSIOLOGIC FACTORS THAT INFLUENCE DRUG DISPOSITION

Other physiologic factors that may influence drug disposition are similar in dogs and cats.

Age-related differences should always be considered. **Pediatric and geriatric animals** are potentially more susceptible to adverse drug effects due to:

- **Alterations in drug distribution.**
 - Greater volume of distribution in pediatric animals.
 - Reduced lean body mass and total body water in geriatric animals.
 - Lower plasma protein in young and old animals.
- **Drug metabolism.**
 - Reduced hepatic metabolism in neonates.
 - Reduced hepatic blood flow and reduced hepatocyte mass and function in geriatric animals.
- **Drug elimination.**
 - Glomerular and tubular function are reduced in neonates and old animals.

Drug interactions and disease factors that influence drug disposition such as **hepatic, cardiac and renal pathology** have a similar importance in cats and dogs.

The effect of **inappetence in diseased cats is important** as dietary protein is an important source of sulfate and other compounds used in Phase II drug metabolism in cats. Taurine may also be important. Anorexic cats therefore may be more susceptible to adverse drug reactions because of reduced drug metabolism.

DRUGS NOT RECOMMENDED FOR USE IN CATS

ACETAMINOPHEN (PARACETAMOL)

Clinical action

Non-steroidal analgesic.

Why shouldn't it be used in cats?

Glucuronidation is the major pathway for metabolism of acetaminophen in most species, but **cats have a low concentration of glucuronyl transferase**.

Sulfation is the major metabolic pathway in the cat, but its capacity is limited.

As the dose is increased, a greater percentage of the drug is oxidized, which results in toxic metabolites.

The metabolites are normally conjugated with glutathione, but **when hepatic glutathione is depleted**, the metabolite binds covalently to amino acid residues of protein in the liver **resulting in centrilobular hepatic necrosis**.

Glutathione is easily depleted in cats as the reserves are limited.

APOMORPHINE

Clinical action

Anti-emetic.

Why shouldn't it be used in cats?

Higher doses are required for anti-emetic action than in dogs.

Significant CNS depression is associated with its use.

AZATHIOPRINE

Clinical action

Cytotoxic.

Why shouldn't it be used in cats?

Although azathioprine has been used successfully to treat immune-mediated disease in cats, serious **bone marrow suppression** has been reported in cats treated

with doses used in dogs (2.2 mg/kg and 1.1 mg/kg on alternate days).

In addition to dose-related marrow toxicity, idiosyncratic severe, irreversible, fatal leukopenia and thrombocytopenia has also been reported in cats.

They may lack thiopurine methyl transferase (TPMT), the enzyme necessary to degrade the 6-mercaptopurine active metabolite of azathioprine although this is not proven.

The recommended dose in cats (0.3 mg/kg) and the single size tablet of 25 mg means that reformulation is necessary as clients must not split the coating of cytotoxic drugs.

Chlorambucil is a better alternative in cats.

BENZOCAINE

Clinical action

Topical local anesthetic.

Why shouldn't it be used in cats?

Topical application can cause **methemoglobinemia**, laryngeal application can cause **laryngeal edema**.

CISPLATIN

Clinical action

Cytotoxic.

Why shouldn't it be used in cats?

Cisplatin causes **fatal, acute pulmonary edema** in cats and should not be used in this species.

PHENYTOIN

Clinical action

Anti-convulsant.

Why shouldn't it be used in cats?

Prolonged half life (>40 hours) compared to dogs resulting in rapid accumulation and development of adverse signs such as sedation, ataxia and anorexia.

Dermal atrophy has also been reported in a cat treated with phenytoin.

PROPYLTHIOURACIL

Clinical action

Anti-thyroid.

Why shouldn't it be used in cats?

Adverse effects from PTU include lethargy, weakness, anorexia and bleeding diathesis due to induction of immune-mediated disease.

Nine of 105 cats developed serious side effects in a study of cats with hyperthyroidism.

Methimazole or carbimazole are the preferred drugs of choice for treating feline hyperthyroidism.

SCOPOLAMINE

Clinical action

Anti-emetic.

Why shouldn't it be used in cats?

Short half life.

Tendency to cause **behavioral changes**.

SODIUM PHOSPHATE

Clinical action

Retention enemas.

Why shouldn't it be used in cats?

Active ingredients can be rapidly absorbed through the rectal mucosa resulting in potentially **fatal hyperphosphatemia**, hypocalcemia, hypernatremia, hyperosmolality and metabolic acidosis.

Clinical signs observed include **depression, ataxia, vomiting and bloody diarrhea**.

Dehydrated or debilitated cats are particularly susceptible.

DRUGS WHICH ARE THERAPEUTICALLY USEFUL IN CATS BUT WHICH MAY HAVE DIFFERENT TOXICITY/ACTIVITY PROFILES THAN IN DOGS

ASPIRIN

Clinical action

Non-steroidal anti-inflammatory.

Adverse effects

The **half life of aspirin** in the cat is approximately four times longer (**38 hours** vs 9 hours) than in dogs because clearance depends on glucuronidation.

The dose should be reduced and the dosing interval extended when using aspirin in cats.

Clinical signs of toxicity include **hypernea, hypersensitivity and hyperthermia**.

Recommended dose

10–20 mg/kg q 48–72 h.

CHLORAMPHENICOL

Clinical action

Anti-microbial.

Adverse effects

Reversible non-regenerative anemia can occur in both dogs and cats.

Cats may be more susceptible, but the increased incidence is probably related to overdosing of cats by using the dog-dosing schedule, which is approximately five times higher per kg than what is recommended here. Note, many texts still recommend higher doses than 50 mg/cat bid.

Recommended dose

50 mg/cat bid.

DIGOXIN

Clinical action

Positive inotropic, negative chronotropic.

Adverse effects

Cats are **more sensitive to digitalis-induced toxicosis** than dogs and the dosage should be reduced compared to dogs and further reduced if given concurrently with aspirin and furosemide.

The elixir form is not as well tolerated as the tablet form.

Dose

Cat 2–3 kg 0.0312 mg q 48 h.

Cat 4–5 kg 0.0312 mg q 24–48 h.

Cat > 6 kg 0.0312 mg q 12 h.

DOXORUBICIN

Clinical action

Cytotoxic.

Adverse effects

Doxorubicin when used at the “dog dose” of 30 mg/m² has been associated with induction of **renal failure in cats**. Therefore, it is used at a lower dose in cats.

Recommended dose

25 mg/m².

ENROFLOXACIN

Clinical action

Fluoroquinolone anti-microbial agent.

Adverse effects

An apparent species-specific toxicity is acute retinal degeneration recently reported in cats.

Blindness often results, but some cats may regain vision.

In a recent study of affected cats, the daily and total doses of enrofloxacin administered and the duration of treatment were highly variable.

Recommended dose

5 mg/kg sid.

FUROSEMIDE

Clinical action

Diuretic.

Adverse effects

Cats appear to be **more sensitive** to the effects of furosemide than dogs.

Dose

1–2 mg/kg bid.

GRISPEOFULVIN

Clinical action

Anti-fungal.

Adverse effects

Bone marrow hypoplasia manifested as leukopenia and thrombocytopenia. This is believed to be an idiosyncratic reaction. Cats with FIV infection appear to be at an increased risk.

Non-reversible ataxia has also been reported in a kitten treated with the drug.

Recommended dose

50 mg/kg/day PO (may be given in divided doses and should be administered with a fatty meal to enhance absorption).

KETOCONAZOLE

Clinical action

Anti-fungal.

Adverse effects

In contrast to dogs, ketoconazole does not alter production of steroid hormones such as cortisol, testosterone

and progesterone. Adverse effects appear to be minimal, and limited to **dry hair coat and weight loss**.

Recommended dose

5–10 mg/kg q 8–12 h PO.

LIGNOCAINE

Clinical action

Anti-arrhythmic.

Adverse effects

Toxicosis results in **myocardial depression** and **CNS signs** including drowsiness, depression, ataxia and muscle tremors, and occurs more commonly in cats.

Dose

0.25–0.75 mg/kg IV slowly.

MEGESTROL ACETATE

Clinical action

Synthetic progestagen used for reproductive, behavioral and dermatologic disorders.

Adverse effects

The most serious side effects associated with megestrol acetate include **mammary hypertrophy and neoplasia**, **cystic endometritis** and **diabetes mellitus**.

The mechanism for diabetes mellitus appears to be different than in the dog (where it relates to increased growth hormone production).

Megestrol-induced diabetes in the cat may be transient or permanent. Megestrol acetate also causes adrenal suppression in the cat.

Recommended dose

Megestrol acetate is not recommended for the treatment of behavioral or dermatologic disorders due to the risk of serious side effects.

Control of estrus can be achieved by using 5 mg/cat for 3 days then 2.5–5 mg once/week for 10 weeks.

METHIMAZOLE, CARBIMAZOLE

Clinical action

Anti-thyroid.

Adverse effects

Side effects observed in about 18% of cats treated with methimazole (or its metabolite, carbimazole) include **anorexia, vomiting, self-induced facial excoriation, bleeding diathesis and hepatopathy.**

About 4% will develop serious hematological side effects.

Although about 20% develop autoantibodies, this does not appear to be associated with clinical immune-mediated disease.

Recommended dose

5 mg/cat q 8–12 h induction then 2.5–5 mg/cat q 8–12 h for maintenance.

METRONIDAZOLE

Clinical action

Antibiotic.

Adverse effects

Reversible CNS toxicity has been reported in cats resulting in disorientation, ataxia, seizures and blindness.

Dose

10–25 mg/kg q 24 h or 10–25 mg/kg q 12 h (for Giardia).

OPIOIDS

Some morphine derivatives (excluding meperidine [pethidine], butorphanol and buprenorphine).

Clinical action

Analgesia.

Adverse effects

Inconsistent sedation.

Increased risk of excitation.

This may reflect differences in the type or concentration of opioid receptors in cats or a relative overdosage.

Dose

Meperidine 3–5 mg/kg IM, IV.

Morphine 0.1 mg/kg SC, IM.

Butorphanol 0.4 mg/kg q 6 h SC or 0.2 mg/kg q 6 h IV.

Buprenorphine 0.01 mg/kg SC, IM q 8–12 h.

ORGANOPHOSPHATES

Clinical action

Insecticide.

Adverse effects

Cats are more sensitive to the effects of organophosphates than dogs although the mechanism for this is unknown.

It is not related to different hepatic metabolizing capacity as organophosphates are metabolized by cholinesterases located at nerve endings.

Toxicity may be acute (similar signs to dogs) or chronic or delayed.

Chronic or delayed toxicity manifests as **paresis or paralysis** which may or may not be reversible.

Toxic epidermal necrolysis has been reported in cats treated topically with organophosphate based flea rinses.

A survey of the effects of flea collars in cats revealed a high number of adverse reactions ranging from **dermatitis to death.**

POTASSIUM BROMIDE

Clinical action

Anti-convulsant.

Adverse effects

There appears to be a greater prevalence of adverse effects in cats compared to dogs (50%) in one study.

Coughing of sufficient severity to lead to euthanasia or discontinuation of medication has been reported.

Dose

30 mg/kg/day.

TETRACYCLINES

Clinical action

Antibiotic.

Adverse effects

Hepatic lipidosis, increased ALT activity, ptyalism and anorexia have been reported in a cat treated with tetracycline.

It has been speculated that cats may be more susceptible to tetracycline-induced **hepatotoxicosis** than other

species due to their unique protein metabolism and requirements.

THIACETARSAMIDE

Clinical action

Adulticide (dirofilariasis).

Adverse effects

Cats appear to be relatively susceptible to the acute toxic effects of thiacetarsamide.

Drug fever and respiratory distress may develop.

In one study 25% of cats treated died from fulminant pulmonary edema.

Recommended dose

2.2 mg/kg q 12 h for 2 days.

68. Drug therapy in cats

A comprehensive list of recommended dosing regimens

Dawn Merton Boothe

The following index represents a compilation of doses recommended for the treatment or prevention of diseases in the cat. The information has been retrieved from multiple sources, including but not limited to: *Boothe's Formulary*, published by the American Animal Hospital Association (2nd printing 1997); *Kirk's Current Veterinary Therapy XIII* (John D. Bonagura (ed), published by WB Saunders Company, Philadelphia, USA), and the *Veterinary Drug Handbook* (Donald C Plumb, published by PharmaVet Publishing, White Bear Lake, MN).

Inclusion of a drug in the index should not be interpreted as an indication of safety of the drug. Most drugs are likely to be associated with adverse effects if used in excess. It is assumed that the reader is familiar with significant adverse effects, which may occur with drugs that are commonly used, regardless of the species. Many of the drugs tend to be uniquely associated with adverse effects in cats and the reader should refer to the text regarding the use of these drugs. Several drugs which have been effectively and safely used in the cat no doubt are missing from the table. Exclusion of a particular drug from the table may reflect a contraindication for the use of the drug in cats (e.g., acetaminophen). Also not addressed in the accompanying dosing index are drug interactions. Again, the reader is strongly encouraged to review the risks associated with drugs when administered simultaneously in a patient.

Of the drugs listed, 5% are approved for use in the cat in the United States. More specific information regarding the use of these drugs, or drugs approved for use in the dog but not the cat, may be obtained through *Veterinary Pharmaceuticals and Biologicals*, the Veterinarian's PDR, published by Veterinary Medicine Publishing Group, a subsidiary of Medical Economics Company, Inc, Oradell, New Jersey, USA. The remaining drugs are approved for use in humans; further information regarding these drugs can be obtained from the *Physician's Desk Reference* (PDR), published by Medical Economics. Comparable European resources are available for use.

The source of the dosing regimen recommended in the index varies with the drug. If an original source which referenced use of the drug in cats could not be found in the literature, the dose was obtained from either personal communication (noted as such), the manufacturer's drug packaging or from the above identified sources. In instances when recommended dosing regimens for a drug varied with the source, either a range or several doses were listed for the drug in the index. Doses which varied with the therapeutic intent of a drug were also listed as either a range or as separate subheadings for each intent. Dosing regimens for anticancer drugs have not been well established in the cat and vary with each author. Although a dosing regimen is offered for most anticancer drugs in the index, the reader is encouraged to refer to

alternative and recent literature sources for more detailed discussion. For all drugs, an attempt should be made to titrate the drug to the individual animal's response. This approach is critical for avoiding

adverse reactions to some drugs (e.g., insulin, dihydrotachysterol and others). Again, the reader is encouraged to review literature which addresses the use of these drugs more in depth.

Drug index

Drug	Indications	Dose	Route ^a	Frequency (h) ^b
Acarbose	Hyperglycemia (diabetes mellitus)	12.5–20 mg	PO	with each meal
Acemannan	Immunomodulation	2 mg, 1–2 mg/kg	intralesional, IP, or SC	weekly
Acepromazine	Restraint, sedation Arterial thromboembolism Amphetamine toxicosis	0.05–0.1 mg/kg, max 1 mg 0.05–2.25 mg/kg 0.15–0.3 mg/kg 0.05–1.00 mg/kg	IV IM, SC, IV, PO SC IV, IM, SC	8–12
Acetazolamide	Glaucoma	5–10 mg/kg	PO	8–12
Acetylcysteine	Acetaminophen toxicosis	140 mg/kg 70 mg/kg	IV PO	loading dose 4–6×5–7 treatments
Acetylsalicylic acid	Antipyretic Antithrombotic Anti-inflammatory Hypertrophic cardiomyopathy Analgesia	6–10 mg/kg 80 mg/cat or 25 mg/kg 10–20 mg/kg 162 mg/cat 10 mg/kg	PO PO PO PO PO	48–72 2 times/wk 48 2 times/wk 48
Activated charcoal	Gastrointestinal adsorbent	1 g/5 ml water: give 10 ml of slurry/kg 1–4 gm/kg (granules) 6–10 ml/kg (suspension)	PO PO	
Actinomycin-D	Anticancer	0.5–0.9 mg/m ²	IV	
Acyclovir	Feline herpes	200 mg	PO	6
Albendazole	Lung worms	50 mg/kg	PO	24×21 days
Albuterol	Bronchodilation	20–50 (up to 100);µ/kg	PO	6–8
Allopurinol	Urate urolithiasis	10 mg/kg	PO	8–12 for 30 days then every 24 h
Aloe vera cream	Burns	thickness of 1/8–1/4 inch	topically	6× several days then 12–24
Alpha-Keri		1 capful to 1–2 quarts of water for final rinse or spray aerosol onto wet coat and rub well		

Alprazolam	Elimination behavioral problems	0.125–0.25 mg/cat	P0	12
Aluminum carbonate gel	Phosphate binder	10–30 mg/kg	P0 w/meals	8
Aluminum hydroxide	Antacid	21–30 ml	P0	2–4
	Phosphate binder	30–90 mg/kg	P0 w/meals	8–24
Aluminum magnesium hydroxide		2–10 ml	P0	2–4
Amantadine	Analgesia for chronic pain, e.g. DJD, used as combination therapy			
Amikacin	Susceptible infections	3–5 mg/kg	P0	24 for 7–14 days
Aminopentamide	Antidiarrheal	15–22 mg/kg	IM, SC, IV	24
Aminophylline	Bronchodilator	0.1 mg/cat	SC, IM, P0	8–12
		4–6.6 mg/kg	P0	8–12
		2–5 mg/kg	IV infusion	12
Aminopromazine	Smooth muscle relaxant	2.0–4.5 mg/kg	P0	12
6-aminosalicylic acid	Chronic inflammatory bowel disease see mesalamine, olsalazine			
Amitraz	Ear mites	Mix 1 ml amitraz in 10–20 ml mineral oil	apply topically	48 h for 3 wk
Amirtryptiline	Behavior, urine spraying	2 mg/kg or 5–10 mg/cat	P0	24
Amtodipine besylate	Systemic hypertension	0.625 mg up to 1.25mg/cat	P0	24
Ammonium chloride	(Struvite dissolution)	800 mg/cat (approx 1/4tsp) or 1.5% of diet	P0	24, mixed with food
		20 mg/kg	P0	12
Amoxicillin	Susceptible infections	10 mg/kg	P0, SC, IV	8–12
	Cholangiohepatitis	20 mg/kg	P0, SC, IV, IM	6–12
	Cellulitis	22 mg/kg	P0, SC	12
		11.1 mg/kg	IM, SC	12
Amoxicillin/clavulanic acid	Resistant, serious infection	10–20 mg/kg	P0	8–12
		62.5 mg/cat	P0	12
Amfetamine SO ₄	CNS stimulation during certain toxicoses, chlorpromazine toxicosis	5 mg/cat	P0	12
		5 mg	P0	24 × 4 days

Drug	Indications	Dose	Route^a	Frequency (h)^b
Amphotericin B	Systemic mycoses	0.25 mg/kg test dose 0.15–1 mg/kg in 5% dextrose	IV over 6–8 h	48 to a total cumulative dose of 10 mg/kg
	Leishmaniasis	0.5–0.8 mg/kg	IV	48 to cumulative dose of 8–16 mg/kg
liposomal	Leishmaniasis	1–2.5 mg/kg	IV	48 × 4 weeks
	Mycoses	3.0–3.3 mg/kg	IV	72–96 to cumulative dose of 15 mg/kg
lipid complex solution	Mycoses	1–2.5 mg/kg	IV	48 for 4 weeks
		0.5 mg/kg test dose then 1–2.5 mg/kg	IV	48 for 4 weeks to a cumulative dose of 12 mg
	Resistant filamentous fungi	2–2.5 mg/kg	IV	48 for a total cumulative dose
Ampicillin	Susceptible bacteria	20–60 mg/kg	PO	8–12
Ampicillin trihydrate	Susceptible bacteria	5.5–50 mg/kg	IM, SC	6–8
Ampicillin sodium salt		5.5–22 mg/kg	IV	6–8
Ampicillin-sulbactam	Susceptible bacteria	10–50 mg/kg	IV, IM	6–8
Amprolium	Coccidiosis	60–100 mg/kg 300–400 mg/kg on food 1.5 tsp/gallon or 3.8 liter water 150 mg/kg	PO PO PO PO	24 × 5 24 × 5 24 × 14 24 × 14
	with sulfadimethoxine (25 mg/kg)			
Antazoline 0.5%	Allergic conjunctivitis		Topically	24
Aprotinin	Protease inhibitor (pancreatitis)	5000 KUI (kallikrein inhibitor units)/kg	IV, IP (preferred)	6–8
Ascorbic acid	Feline infectious peritonitis Acetaminophen toxicosis	25–125 mg/kg/day 30 mg/kg 100 mg/cat	PO PO, SC PO	24 6 × 7 treatments 24–8
Asparaginase	Lymphosarcoma	10,000 U/m ²	IV	weekly as part of a protocol

Aspirin	see acetylsalicylic acid				
Atenolol	Hypertension	2 mg/kg or 6.25–12.5 mg/cat	P0	24	
Atipamezole	Metadomidine reversal	volume equivalent to medetomidine volume	IV	As needed	
Atovaquone	Antiprotozoal (pneumocystosis)	13.3 mg/kg with fatty meal	P0	8 × 21 days	
Atracurium besylate	Paralytic agent	0.1–0.25 mg/kg 0.15 mg/kg	IV IV	initially, then 30 min later	
Atropine	Sinus bradycardia	0.022–0.044 mg/kg 0.04 mg/kg	IM, SC, IV P0	PRN or 6–8	
	Atropine response test	0.044 mg/kg	IV	Preanesthetic	
	Hypersialism	0.02–0.045 mg/kg	SC, IM, IV		
	Cholinergic toxins	0.02 mg/kg	SC	PRN	
	Pemphigus complex, plasmacytic stomatitis and podomatitis	0.2–2 mg/kg	1/4 dose IV, the rest SC, IM		
Aurothioglucose		2 mg	IM	then,	
		1 mg/kg	IM	once weekly decreasing to once monthly	
Azathioprine	Enteritis	0.2–0.3 mg/kg	P0	24–48	
	Immune hemolytic anemia	1.0 mg/kg	P0	24–48	
	Immune thrombocytopenia				
	Immunosuppression	1.1 mg/kg	P0	48	
Azithromycin	Susceptible infection	5 mg/kg	P0	24–48	
Aztreonam	Susceptible bacteria	12–25 mg/kg	IV, IM	8–12	
BAL	Chelator	see dimercaprol			
Baquelprim-sulfa methoxine or sulfadimidine					
	Coccidiosis	30 mg/kg	P0	48 × 2	
	Susceptible infections	30 mg/kg	P0	24 × 2 then 48 × 10 to 21 days	
Beclomethasone dipropionate	Anti-inflammatory	200 mg	Inhalant	PRN	
Benazepril	Afterload reduction	0.25–0.5 mg/kg	P0	24

Drug	Indications	Dose	Route^a	Frequency (h)^b
Benzimidazole	Trypanosomiasis	5 mg/kg	PO	24 for 2 months
Benzocaine	Local anesthetic		Topical	
Benzoyl peroxide	Seborrheic, antibacterial	leave on skin for 10 min and rinse		every 3–4 days to once every 1–2 wk
Betamethasone	Antiinflammatory	0.1–0.2 mg/kg	PO	12–24
Bethanechol	Bladder atony, dysautonomia	1.25–5.0 mg	PO	12–8
Bisacodyl	Stool softener	2–5 mg/cat 1–3 suppositories 1–2 ml enema	PO rectal rectal	24, PRN PRN PRN
Bismuth subcarbonate	GI tract protectant	0.3–3.0 gm	PO	4
Bismuth subsalicylate	Antidiarrheal, antiemetic	1–3 ml/kg	PO	divided every 4–6
Bleomycin	Chemotherapy	10 μ /m ²	IV, SC	24 for 4 days, then weekly; max dose 200 mg/m ²
Bran	Stool softener	1–2 TBS/400 g food	PO	PRN
Brewer's yeast	Source of B vitamins	0.2 μ /kg	PO	24–96
Bromide; Potassium or sodium	Anticonvulsant	30–60 mg/kg	PO	divided every 12 h; monitor to adjust dose
Bromocriptine mesylate	Hyperadrenocorticism, pseudo-pregnancy	10–30 μ /kg	PO	24 for 10–16 days
Bunamidine	Taenia, dipylidium	20–50 mg/kg	PO	after 3 h fast
Bupivacaine hydrochloride		0.22–0.3 ml 5–10 μ /kg 2.5–15.0 mg	Epidural IM PO	12 12–8
Buprenorphine	Analgesia	0.005–0.01 mg/kg	IV, IM	4–8
Buspiron	Behavioral therapy	2.5–5 mg/cat	PO	12–24
Busulfan	Chronic myelocytic leukemia	3–4 mg/m ² or 0.1 mg/kg	PO	24

Butamisolol	Hookworm, whipworms	2.2 mg/kg (0.22 ml/kg)	SC	repeat in 21 days
Butorphanol	Prae-anesthetic	0.05–0.4 mg/kg w/ acepromazine	IV, IM, SC	
	Antiemetic prior to cancer chemo.	0.2–0.6 mg/kg	SC, IM, IV	
	Analgesia	0.1–0.8 mg/kg	IM, SC, IV	6–12
		0.55–1.1 mg/kg	PO	6–12
Calcitriol	Hypoparathyroidism	2.5–3 mg/kg (0.0025–0.003(g/kg)	PO	24
Calcium carbonate	Nutritional supplement	1/2 tsp	with each meal	
	Phosphate binder	60–100 mg/kg		24
Calcium chloride 10%	Ventricular asystole	1 ml/9 kg or 0.1–0.3 ml/kg	IV (slowly)	
	Hypocalcemia	0.1–0.3 ml/kg	IV (slowly)	
Calcium citrate	Calcium replacement Urothiliasis	10–30 mg/kg	PO	8 (with meals)
Calcium EDTA	Lead poisoning	100 mg/kg/day = total dose make solution of 1 g Versenate/ 100 ml D ₅ W divide total quantity mls into 20 aliquots, 1 dose	SC	5 days
	Ventricular asystole	0.5–1.5 ml/kg	IV (slowly)	6 for 5 days
Calcium gluconate 10%	Hypocalcemia, hyperkalemia	0.5–1.5 ml/kg	IV in 5% D/W over 20–30 min	PRN
		10–15 ml	IV infusion	6–8 intervals
		50–150 mg/kg		24
		150–250 mg/kg	PO (tab)	8–12
		0.2–0.5 g	PO	
Calcium lactate	Calcium replacement	0.2–0.5 g/cat	PO	24
Captan powder 50%	Dermatomycoses	2 tbsp/gal water	topically, do not rinse	2–3 times/wk
Captopril	Vasodilator	2–3 mg/cat	PO	8–12
		3–6.25 mg/cat	PO	12
Carbenicillin	Susceptible bacterial infection	15–30mg/kg	IV	8

Drug	Indications	Dose	Route^a	Frequency (h)^b
	Anticancer and immunosuppressive therapy	6.25–12.5 mg/cat	P0	24 h 4 days/wk
Cyclosporine	Immune thrombocytopenia, SLE, sebaceous adenitis	4–6 mg/kg 3–7 mg/kg 10 mg/kg	4 hour IV infusion P0 P0	24 (avoid extravasation) 12 (adjust dose based on monitoring) 12
Cyclosporine ophthalmic	Keratoconjunctivitis sicca, pigmentary keratitis plasmoma of third eyelid	1–2% solution	drop in eye	12
Cyclothiazide	Diuretic	0.5–1 mg/kg	P0	24
Cyproheptidine	Appetite stimulant	2–4 mg/cat	P0	12–24
Cytarabine	Anticancer	30–50 mg/kg 100 mg/m ² 20 mg/m ²	IV, IM, SC IV, IM, SC Intrathecal	once a wk 24h for 4 days then 24 for 1–5 days
Cythioate	Tick prevention	1.5–3.3 mg/kg 0.22 ml/kg	P0 liquid (15 mg/ml)	72 or 2x wk 72 or 2 wk
Dacarbazine	Lymphoreticular neoplasms Soft tissue sarcomas	200–250 mg/m ² 1000 mg/m ²	IV IV drip	24 for 5 days, every 21 days over 6–8 h, every 21 days
Dactinomycin	Anticancer	0.015 mg/kg 0.7–1.5 mg/m ²	IV IV	24 for 3–5 days; wait 3 wks weekly
Dalteparin (LMW heparin)	DIC, thrombosis	70 IU/kg	SC	24
Danazolol	Immune-mediated disorders	5–10 mg/kg	P0	12
Dapsone	Mycobacteriosis Brown recluse spider bite	1.1 mg/kg 0.7–1 mg/kg	P0 P0	12 for 4–6 wks 8
Deferoxamine mesylate	Iron chelator	10 mg/kg	IV, IM, SC	2 h for 2 doses then, 8 h for day

	Repertusion injuries	10 mg/kg 50 mg/kg	IV, IM IV	over 5 min
Demeclocycline	Innappropriate ADH secretion	3–12 mg/kg	PO	6–12
Deprenyl	Hyperadrenocorticism, Cognitive dysfunction	see selegiline		
Derm caps	Skin disorders	1 capsule per 9 kg	PO	24
Derm caps (liquid)	Skin disorders	to 4.5 kg give 0.35 ml		
Desmopressin acetate	Central diabetes insipidus	0.3 : µ/kg (diluted in 50 ml saline)	IN, conjunctival	infused over 15–30 min; repeat as needed 12–24 12–24 12–24
Desoxycorticosterone acetate	Hypoadrenocorticism	2–4 drops 0.1 mg 1–2 drops 0.2–0.4 mg/kg	conjunctivally PO IN, conjunctival conjunctivally	24, max 5 mg
Desoxycorticosterone pivalate	Hypoadrenocorticism	25 mg	IM = 1mg/day	DOCA released for 25 days
Dexamethasone	Cerebral edema, spinal cord trauma, fibrocartilaginous disk disease, other CNS trauma	2 mg/kg 1 mg/kg 0.1 mg/kg 0.25 mg/kg 4–6 mg/kg 0.25–1.25 mg/kg 0.10–0.15 mg/kg	IV IV, SC IV, SC, PO IV, PO, IM IV (slowly) PO SC, PO	then, 8–12, then 8–12 6–8 12–24 12 for 5–7 days, then taper dose with mineralocorticoids then 8–24
	Hydrocephalus Shock, anaphylaxis Immune-mediated disease	0.1–0.5 mg/kg 1 mg/kg 0.25–1.0 mg/cat	SC, IV IV PO	15 minutes before doxorubicin
Adrenocortico collapse Feline bronchial asthma				
Iron chelation for doxorubicin Induced cardiotoxicity		25 mg/kg (ratio of 10–20:1 Dexrazoxane: doxorubicin)	IV

Drug	Indications	Dose	Route^a	Frequency (h)^b
Physostigmine	Muscarinic mushroom intoxication	0.25–0.50 mg/cat 0.02 mg/kg	IM IV	12, over 5 min period
Physostigmine 0.5% o.o	Dysautonomia	apply 1/8 inch or 0.3 cm	topically	8
Phytomenadione (phytonadione)	See Vitamin K1			
Pilocarpine 1% ophthalmic soln	Dysauronomia	1 drop	topically	6
Piperacillin sodium	Susceptible bacterial infections	25–50 mg/kg	IV, IM	8–12
Piperacillin-tazobactam	Susceptible bacterial infections	25–50 mg/kg (based on piperacillin)	IV	6–8
Piperazine	Roundworms	44–66 mg/kg	PO	repeat in 3 wks
Piroxicam	Anaesthetic, anticancer	0.3 mg/kg	PO	24–72
Plicamycin	see Mithramycin			
Polyethylene glycol electrolyte solution	Cathartic	25 ml/kg	PO, stomach tube	then repeat in 2–4 before lower GI exam
Polyethylene glycol electrolyte solution	Electrolyte replacement	25 ml/kg	PO	repeat in 2–4 hours
Polysulfated glycosam- inoglycans	Degenerative joint disease	2–5 mg/kg	IM	3–5 days
Potassium chloride	Potassium supplementation Hypokalemia	0.10–0.25 ml/kg 0.5 mEq/kg	PO IV	8; dilute 1:1 w/water not to exceed 0.5 mEq/kg/h
Potassium citrate	Calcium oxalate urolithiasis	1–3 mEq 10–40 mEq/500 ml of fluid, depending on serum potassium	PO, IV IV, SC	24
Potassium gluconate	Hypokalemic polymyopathy	50–75 mg/kg	PO	12
Kaon elixer		5–8 mEq/cat	PO	12–24
Tumil-K		2.2 mEq/100 kal of energy 1/4 tsp/4.5 kg	PO	24
				12–24

Potassium iodide	Sporotrichosis, pythiosis	30–100 mg/cat	daily (in single or divided doses) for 10–14 days
Potassium permanganate (1:2000)	Strychnine toxicosis	5 mL/kg in gastric lavage	
Potassium phosphate	See phosphate		
Povidone-iodine	Burns	Apply light coating	12–24
Pralidoxime Cl (2-PAM)	Organophosphate toxicosis	20 mg/kg	12, initial dose IV slow
Praziquantel	Antiparasiticide	<1.8 kg: 6.3 mg/kg >1.8 kg: 5 mg/kg 5 mg/kg 25 mg/kg	once once IM, SC PO
	Paragonimiasis		8–12 for 2 days
Prazosin	After load reductions Urethral obstruction	0.5 and 2 mg/cat 0.5–2 mg/cat; 0.07 mg/kg	8–12 8–12
Prednisolone/prednisone	Eosinophilic ulcers, plasma cell gingivitis	1–2 mg/kg 0.5–1.5 mg/kg	24 24 divided daily, taper over 3 months
	Plasmacytic/lymphocytic enteritis	1–2 mg/kg	12, then taper dose weekly
	Urethritis, persistent hematuria	2.5–5.0 mg	24–48
	Anti-inflammatory	2.2 mg/kg	12–24, then taper to every 2 days
	Hypoadrenocorticism	1 mg/kg	12
	Hypoglycemia	0.25–3.00 mg/kg	12
	Chronic therapy	2–4 mg/kg	48
	Hypercalcemia		
	Immune skin diseases, systemic lupus erythematosus	1.1–2.2 mg/kg	12 until remission, then taper
	SLE, rheumatoid arthritis	1.5–2.0 mg/kg <1 mg/kg	12–24, then taper to 48
	Immune polymyositis, masticatory myositis	2 mg/kg	24
	Blepharitis, episcleritis uveitis,	0.5–2.0 mg/kg	12

Drug	Indications	Dose	Route ^a	Frequency (h) ^b
		to be antagonized	IV	over 10 min, then reduce dose by 50% decrease dose by 50% for each hour since heparin administration
Pseudoephedrine	Nasal decongestant Urinary incontinence	15-30 mg/cat 0.2-0.4 mg/kg	P0 P0	8-12 8-12
Psyllium	Bulk laxative	1-3 tsp 3-10 g	P0 P0	8-12 in food w/food
Pyrantel pamoate	Round-, hookworms	10 mg/kg	P0	once, repeat in 2 wks
Pyridostigmine bromide	Myasthenia gravis/acquired	1-5 mg 0.25 mg/kg	P0 P0	24
	Antidote (curariform)	0.15-0.30 mg/kg	IM, IV	
Pyrilamine maleate	Antihistamine	12.5-25.0 mg	P0	6
Pyrimethamine	Neosporosis With trimethoprim/sulfonamide	0.25-1 mg/kg 15 mg/kg	P0 P0 P0	24 24 12
	Toxoplasmosis	0.5-2.0 mg/kg	P0	12 for 14-28 days
	Enteropithelial cycle	2 mg/kg	P0	24 for 14-28 days
Quinacrine	Giardia, coccidiosis	11 mg/kg	P0	24 for 5 days
Racemethionine	Urinary acidifier	see DL Methionine		
Ranitidine	Chronic gastritis, GI tract ulceration, gastrinoma Hypergastrinemia from chronic renal failure	0.5 mg/kg 3.5 mg/kg 2.5 mg/kg	IV, P0, SC P0 IV	12 12 12
Retinol (Vitamin A)	Dermatologic lesions	625-800 IU/kg	P0	24
Ribavirin	Susceptible viral infections	11 mg/kg	P0, IM, IV	24 x 7 days
Riboflavin (Vitamin B ₁₂)	Bartonellosis (with doxycycline)	5-10 mg/kg	P0	24 x 14 days
Rifampin	Susceptible infections	10-20 mg/kg	P0	24
Ringer's solution		40-50 ml/kg/day	IV, SC, IP	for maintenance
Roxithromycin	Susceptible infections	15 mg/kg	P0	24

Rutin	Chylothorax, limb lymphedema	50 mg/kg	P0	8
Selegiline	Cognitive disorders	0.5 mg/kg	P0	24
	Hyperadrenocorticism	1-2 mg/kg	P0	24
Selamectin	Parasiticide	6 mg/kg	topical	30 days (fleas, ticks [<i>Dermacentor variabilis</i> , Heartworm preventative] 1-2 x 30 days apart (<i>Otodectes</i> , <i>Sarcoptic scabiei</i>). Once (<i>Ancylostoma tubaeforme</i> , <i>Tanai cati</i>).
Selenious acid, sodium selenite	Supplementation	0.3 mg/kg	P0	
Selenium	Pancreatitis	0.1 mg/kg	IV infusion	
Senna	Constipation	5 ml/cat (syrup) 1/2 tsp/cat w/food (granules)		24 24
Silver nitrate solution 0.5%	Burns	Saturate wet dressings		12-24
Silver sulfadiazine	Burns	Apply light coating		12 for several days, then 2
Sodium bicarbonate	Otitis externa	Dilute 1:1 with water	Pack cleaned ears	12
	Renal failure	10-15 mg/kg	P0	8
	Certain toxicoses	50 mg/kg (1 tsp is approx 2 g)	P0	8-12
	Acidosis	0.3 x wt (kg) x (target bicarb- patient bicarb)	IV, dose for acidosis	
		0.5-1.0 mEq/kg (8.5% soln=1 mEq/ml of NaHCO ₃)	IV, dose for acidosis	
	Hyperkalemic crisis	2-3 mEq	IV	over 30 min
	Urine alkalization	0.65-5.85 g	P0	maint. pH 7.0 up to 7.5
Sodium chloride	Hypoadrenocorticism	1-5 g/day	P0	
	Hyponatremia: acute renal failure	1-4 g/day	P0	divided every 8
	(0.9% soln)	40-50 ml/kg/day	IV, SC, IP
