Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the publisher nor the author assumes any liability for any injury and/or damage.

† Deceased.

Preface

Problem-based feline medicine was inspired by teaching students in the clinic, and from consulting to veterinarians in practice. It was apparent that the way veterinary medicine was traditionally taught often caused problems when the students were in the clinic. Many times they did very well in written examinations, but could not utilize the material taught to make a diagnosis in the clinic. Traditional disease-based text books, divided into sections based on aetiology, assumed the clinician knew whether the disease was viral or bacterial, fungal or metabolic. Clients usually do not say “my cat has feline leukaemia and what is the most appropriate treatment”. They say “my cat is losing weight and is not as active as normal”. The dilemma for students is, which page of a text-book do I turn to? Making a diagnosis is the most important part of being a veterinarian, because without a diagnosis, determining appropriate treatment is problematic.

My hope is that this book will support students and veterinarians in practice, and assist them in turning to the “right page” for the information they need to make a diagnosis. A challenge in writing a book like this, is the duplication of material, and differences between authors when writing about the same disease in different chapters. I think this contributes to the richness of information in the book, and reflects that life is not black and white, and there are different opinions based on different experiences.

One difficulty students had using the acronym DAMNPIT, was that in formulating a list of likely diseases causing the problem, they often omitted obvious diseases. When they first listed the organs or body systems that could cause the signs, and then used DAMNPIT, it increased their score rate. Sometimes the organ system is not evident when

the signs are not organ-specific, and to help them walk through the thought processes, they were first encouraged to answer the question “What mechanisms can be responsible for these signs?” Hence the first section in the summary table and introduction answers the questions: “What mechanism/s causes this problem?” (MECHANISM?), “Which organs or body systems cause this problem?” (WHERE?), “What diseases/s cause this problem?” (WHAT?)

The format for each chapter is the same. The chapter title is based on a presenting sign. A summary page lists the answers to “MECHANISM?”, “WHERE?”, and “WHAT?” This is followed by a quick reference guide to the diseases that should be considered as potential rule-outs. They are starred with 0-3 stars to indicate how important the disease is as a cause of the problem. Some diseases are common but rarely cause the sign (problem), and they did not get

a frequency star. Next is the introduction, which in more detail describes “MECHANISM?”, “WHERE?”, and “WHAT?”. This is followed by the diseases, roughly listed in order of likelihood of causing the sign. Therefore, diseases with 3 stars are listed before those with no stars, that are rare causes of the signs. Some suggested reading lists are included if the reader wants to delve further. Although Veterinary Information Network (VIN) is not referenced specifically for most chapters, the reader is encouraged to

utilize VIN to check new developments, particularly in diagnostic tests and treatment.

Strive for excellence and enjoy. Remember, making a diagnosis is one of the most important things you do as a veterinarian.

If you have suggestions for the next edition of the book, I would love to hear them (contact me by email: j.rand@uq.edu.au).

Jacquie

This book is dedicated to those who shaped my life:

*To my dad who taught me that “if a job is worth doing, it is worth doing well”, and that
“a job is not done until it is finished”.*

To my mum who has always been a cheerful supporter in all the twists and turns in my life.

To the students who inspired, taught and challenged me.

To my husband Tom, my rock, my safe and welcoming harbor, and my sanctuary in stormy seas.

*To my daughter Lisette, who reminded me when it was time to play, and the
importance of having a balanced life.*

Thank you all and bless you

Acknowledgments

There are many people I would like to thank who have helped turn my vision of a problem-based text into a reality. Firstly, the contributing authors, who helped make this text happen when it became apparent that it was expanding into too big a vision for one person to accomplish. Secondly, to Annette Litster who proof read many chapters, and joined as a contributing author late in the project, responding cheerfully to urgent requests to write and subedit the gastrointestinal tract section. Thirdly, to the many staff and students who helped with formatting the manuscript and editing, including Heidi Farrow, Joanne Chapel, Philippa Williams, Sarah Gestier and Desley Badrick.

I would like to acknowledge the invaluable resource of the Veterinary Information Network (VIN), which greatly assisted in my commitment to include the most recent material and practical

information. Although sometimes the information sourced from VIN is not referenced in the text, I would especially like to acknowledge the usefulness and great support that this database provides to veterinarians in practice and academia.

I would also like to acknowledge the veterinary class of '95 at the University of Queensland, who inspired me to embark on this project, and all the students, before and after, who reinforced the belief that this format would help veterinarians in practice.

In the early mornings, Merlin our Burmese cat provided me with company and inspiration while I worked on the manuscript, by sitting on the keyboard, on pages I was reading, or on my lap purring.

Lastly, but most importantly, this book would not have been possible without the support and love of my husband Tom and daughter Lisette.

1. How to make a problem-based diagnosis

Jacquie Rand

- Competence at making a diagnosis is the most important part of being a veterinarian. Therefore, it is the most important skill learnt in veterinary education. High-level surgery skills and in-depth knowledge of drugs may be useless if the wrong diagnosis is made.
- Making a diagnosis involves problem-solving. If clinical signs are treated without first making a diagnosis, it is likely that corticosteroids, antibiotics and euthanasia will be over-prescribed.

There are two ways to make a diagnosis. Firstly there is the “**expert method**”. This is the way many veterinarians make a diagnosis, and it involves pattern recognition.

The disadvantages of the “expert method” are that it requires a lot of experience to be accurate, and there is a greater chance of being wrong, especially for the less-experienced practitioner, because the same signs may occur for many diseases. For example, diarrhea may be caused by many diseases including intestinal parasites, food intolerance, intussusception, lymphoma and inflammatory bowel disease. The appropriate treatment varies depending on the diagnosis.

The second method of making a diagnosis is by using a **problem-based approach**. This leads to fewer mistakes and facilitates better veterinary practice.

KEY ELEMENTS FOR MAKING A PROBLEM-BASED DIAGNOSIS

To make a problem-based diagnosis, the signs exhibited are separated out into individual problems, and each problem is considered separately.

The individual steps in making a problem-based diagnosis are as follows.

1. Obtain detailed data from a complete history and physical examination.

Take an exact and detailed history. It is critical that questions are asked to cover a detailed history in all areas of the pet’s health, not just for the problem presented. To get the correct information it may be necessary to ask the same question in different ways.

Complete a thorough physical examination.

The history and physical examination are the most critical parts of making a diagnosis.

Diagnostic tests may not overcome deficiencies in the history and physical examination. For example, if hematology and biochemistry analyses were performed but a chest radiograph was not taken because increased frequency of coughing was missed in the history, or dyspnea was missed on the physical examination, a primary lung tumor may be missed despite performing many other tests to determine the cause of lethargy.

- Normal physical examination findings need to be appreciated before abnormal findings can be identified. Veterinary students are encouraged to take every opportunity to practice physical examinations so the range of normal is recognized.

2. List the problems identified based on the history and physical examination.

It is important to only **list the problem at the level that it is understood**. For example, if the cat has an abdominal mass, the problem is initially listed as an abdominal mass and not a neoplasm, because it may be caused by a number of other conditions including reactive lymphadenomegaly, feces, abscess, etc.

Characterize each problem listed based on duration, character and severity.

Characterize each problem by the 3 Cs:

- **Chronicity** (duration)
- **Character**
- **Concern** (severity/frequency/size).
 - For example, the problem “sneezing and nasal discharge” may be characterized as 2 months duration (chronicity), purulent (character), occurring approximately six times/day (i.e. moderate severity).

Select the problem/s to consider first. Choose those that are most likely to provide a diagnosis.

Choose problems for consideration first that are:

- **Severe or frequent problems.** Problems that are infrequent or mild may not lead to the main definitive diagnosis as quickly, or may be independent problems.
- **Represent the problem the owner was concerned about.**
- **Problems that are most specific for an organ or body system.** Avoid using non-specific problems such as lethargy or anorexia. These problems indicate severity of the problem, but are not organ-specific and can be caused by almost any disease in the body. They are not useful diagnostically because they require a wide range of diagnostic tests to be performed in an attempt to detect an organ-specific abnormality.

3. List the differential diagnoses (likely diseases) for each problem. To formulate a list of differentials, it helps to ask two questions, “WHERE?” and “WHAT?”.

To answer “**WHERE?**”, ask yourself which organs or body systems can cause the problem?

If possible, try to first categorize the answer to “**WHERE?**” into sub-headings. For example, for seizures, the problem could have extra-cranial or intra-cranial causes. Similarly, for vomiting, there could be extra-gastrointestinal or gastrointestinal causes; and for jaundice, the sub-headings pre-hepatic, hepatic, and post-hepatic are appropriate.

“**WHERE?**” for an abdominal mass includes liver, GIT, spleen, urinary tract, omentum, reproductive tract, etc. “**WHERE?**” for alopecia is skin; “**WHERE?**” for PU/PD is kidney, which is the end organ influencing water intake and urine output. It is usually better to simplify the answer in this way, rather than listing all the organs that can cause polyuria/polydipsia, although this can also be done, e.g. kidney, liver, brain, kidney, adrenal, bladder, etc.

To answer “**WHERE?**”, you may have to answer the question what is the “**MECHANISM?**” that results in this problem, and use your knowledge of pathophysiologic principles to answer “**WHERE?**”

- For example, abdominal effusion can be due to:
 - Decreased oncotic pressure as a consequence of hypoalbuminemia resulting from liver, GIT or kidney dysfunction.
 - Increased hydrostatic pressure resulting from cardiac disease or vascular obstruction.
 - Increased permeability of blood vessel walls.
 - Lymphatic obstruction involving abdominal lymphatics.

If the answer to “**WHERE?**” is more than one organ system, then **diagnostic tests are usually required to localize the problem**. For example, for an abdominal mass, results of diagnostic tests such as a serum biochemistry profile (showing increased liver enzymes), radiography (indicating hepatomegaly), and/or ultrasound (revealing a mass in area of liver), may be required to answer the question **WHERE?** (liver).

Once the organ systems involved have been identified, you can move on to answering the question “**WHAT?**”. That is, for each organ or body system identified as potentially being involved, what diseases are potential causes of the problem?

- To assist in listing the diseases that can cause the problem, it helps to use an acronym such as **DAMNPIT** to aid the memory.

- D** : * degenerative
- A** : * anomaly (congenital)
* accident (e.g. volvulus, intussusception)
- M** : * metabolic (e.g. electrolyte, hormonal)
* mechanical (e.g. foreign body, urolith)
- N** : * neoplastic
* nutritional

- P :** * physical (e.g. heat, cold, water, fire)
 * psychological
 * pharmacological (drug effect)
- I :** * infectious (viral, bacterial, mycoplasma, rickettsial, protozoal, fungal, parasitic)
 * immune
 * iatrogenic (caused by you)
 * idiopathic (unknown)
 * infarct
- T :** * trauma
 * toxic/adverse drug

For example, the answer to “WHAT?” diseases could cause polyuria/polydipsia in a 10-year-old male castrated domestic shorthair cat that has a history of losing weight for 2 months, a good appetite until the last couple of days, frequently urinating in the litter box, and drinking 1 liter/day include:

- D :** Chronic renal failure
- A :**
- M :** Diabetes mellitus
 Diabetes insipidus
 Hyperthyroidism
 Hyperadrenocorticism
 Hepatic failure
 Hypercalcemia
 Acromegaly
 Hypoadrenocorticism
 Hypercalcemia
- N :** Renal neoplasia
 Lymphoma and
 pseudohyperparathyroidism
 Polycythemia vera
- P :**
- I :** Infectious Pyelonephritis
 Cystic endometrial hyperplasia/
 pyometra
- Immune Glomerulonephritis/renal
 amyloidosis
- T :** Vitamin D toxicity
 Drugs such as
 corticosteroids

After listing the diseases, rank the diseases as likely, possible or unlikely based on cross-matching the patient’s data with the characteristics of the disease.

To rank diseases as likely, possible, or unlikely, **cross-match** the patient’s signalment (breed, age, gender), clinical signs, and physical examination findings **with the known characteristics of the disease including** typical signalment, signs and physical examination findings of the disease and frequency of disease (how common it is).

- For the differential diagnosis “diabetes mellitus”, consider whether the typical signalment, history and physical examination findings of this disease fit the patient’s findings. An example of the thought processes are the following: Diabetes mellitus is a **very likely** cause of the problem because it occurs in older cats, male cats are more often affected, and the patient has all the expected signs, including signs of chronic disease, polydipsia and polyuria, weight loss and a good appetite until recently. The high volume of water drunk by this cat can occur with diabetes mellitus.
- For the differential diagnosis, “chronic renal failure” an example of the thought processes is: Chronic renal failure is a **possible** cause of the problem because the expected signs include evidence of a chronic disease, with weight loss and recent inappetence. However, cats with renal failure that have marked polydipsia often have a more picky appetite once weight loss is apparent, and the volume of water drunk is usually less.
- For the differential diagnosis “hepatic failure”, an example of the thought processes is: Hepatic failure is an **unlikely** cause of this cat’s problem because although this cat has some of the clinical signs expected with hepatic failure, it does not have all of the typical signs. The signs of this patient that fit include: chronic disease with lethargy, inappetence and weight loss. Polydipsia can occasionally occur if there is liver failure. However, cats with hepatic failure sufficient to cause weight loss and affect renal concentrating mechanisms are usually inappetent and jaundiced. In addition, hepatic failure is a rare cause of polydipsia in cats.
- It helps to know **1–5 lines of information for each disease on your list of differential diagnoses. You should know more about the common diseases than uncommon diseases.** Learn the typical signalment, clinical signs, physical examination findings, and frequency of diseases that occur in your area.

4. Formulate a **diagnostic plan** to prove or disprove each possible disease. **Choose the initial diagnostic tests based on:**

- Prioritizing, ruling in or out the most likely diseases
- Choose tests initially that are least invasive, and to some extent easiest and/or cheapest to perform
- Choose the tests that have the best combination of specificity and sensitivity.

Remember that each negative or normal test result makes the list shorter.

For example, for the problem “liver mass” that was identified based on ultrasound, radiology and biochemistry profile, the following is an example of a diagnostic plan.

- Following ultrasound identification of the mass, fine-needle biopsy and cytological examination will be performed, with culture requested if no neoplastic cells are obvious. Although the sensitivity and specificity are not as high as with a wedge biopsy or laparotomy, it is balanced by the less-invasive nature, ease and cost. These diagnostic decisions need to be made in conjunction with the owner.
- If a definitive diagnosis is not possible from the results of the fine-needle biopsy, the next diagnostic tests that could be considered would be a needle biopsy suitable for histological examination, or laparotomy and wedge biopsy. The decision will require balanced consideration of many factors including input from the owner regarding cost, invasiveness, etc.

5. Formulate a rational treatment plan based on the diagnoses identified.

- Treatment may either be specific for a disease process, such as antibiotics and drainage of an abscess, or be non-specific, for example, IV fluids for dehydration. Initial treatment plans will often be formulated in parallel with diagnostic plans, because some problems such as dehydration or cyanosis need addressing early.
6. As diagnostic data are received and the response to initial therapy is observed, it is important to

update the problem list, differential diagnoses, diagnostic plan and treatment plan.

Summary of the steps in making a problem-based diagnosis

1. Obtain data from a detailed history and physical examination.
2. List the problems identified based on the history and physical examination.
3. List the differential diagnoses for the major and most organ-specific problems.
Use your answers to “WHERE?” and “WHAT?” to formulate a logical list of differential diagnoses. Cross-match the patient and disease characteristics to identify the most likely diseases.
4. Formulate a diagnostic plan to rule-in or rule-out the likely differential diagnoses.
5. Formulate a treatment plan.
6. Update points 2–5 as diagnostic data become available and the response to therapy is observed.

USING THE BOOK

This book is set out to facilitate making a problem-based diagnosis. At the start of each chapter there is a summary of the answers to the questions ‘Mechanism?’, ‘Where?’, and ‘What?’ for each problem. A quick reference summary lists the diseases that can be associated with that problem. Stars after each disease denote the importance of the disease as a cause of the problem.

PART 1

Cat with upper respiratory tract signs

2. The cat with acute sneezing or nasal discharge

Jacquie Rand

KEY SIGNS

- Serous, mucoid, purulent or bloody nasal discharge less than 2 weeks' duration.
- Acute sneezing or snuffling.

MECHANISM?

- Signs of acute sneezing or nasal discharge usually result from viral, chlamydophilial or mycoplasmal infection.

WHERE?

- Nose (nasal cavity, paranasal sinuses).

WHAT?

- Most cats (80%) with acute onset of sneezing or nasal discharge have calicivirus or herpesvirus.

QUICK REFERENCE SUMMARY

Diseases causing acute sneezing or nasal discharge

MECHANICAL

- Foreign body (p 15)

Acute onset of sneezing and rubbing face, progressing to chronic discharge, often unilateral, no systemic signs.

NEOPLASIA

- Bleeding ulcer on external nares (p 16)

Acute sneezing and bleeding may occur with a bleeding ulcer on the external nares, particularly the nasal septum. Usually caused by squamous cell carcinoma (SCC), but occurs occasionally with eosinophilic granuloma or associated with acute calicivirus infection. Signs are often episodic with squamous cell carcinoma.

- Intranasal tumors (p 17)

Occasionally present with acute sneezing, \pm nasal discharge and bleeding.

INFECTIOUS

Bacterial:

- *Bordetella bronchiseptica* (p 14)

Pyrexia, sneezing, nasal discharge, mandibular lymphadenopathy, coughing and dyspnea.

Viral:

- **Feline rhinotracheitis virus (herpesvirus-1)*** (p 7)**

Paroxysms of sneezing, severe serous to mucopurulent oculonasal discharge, usually bilateral severe conjunctivitis with tearing, photophobia and chemosis, \pm corneal lesions.

- **Feline calicivirus*** (p 11)**

Fever, mild upper respiratory tract signs, oral ulcers.

Chlamydophila, Mycoplasma:

- ***Chlamydophila felis (Chlamydophila felis)**(p 13)***

Mainly conjunctivitis, initially unilateral, later bilateral and often chronic.

- *Mycoplasma* (p 14)

Mainly conjunctivitis, usually without systemic illness; often occurs as secondary infection in viral upper respiratory tract disease.

Fungal:

- *Cryptococcus* (p 16)

Usually chronic signs, but occasionally acute onset of sneezing and nasal discharge.

Immune:

- Allergic (p 17)

Serous or mucoid ocular and/or nasal discharge, without systemic signs. Signs may be seasonal in occurrence.

INTRODUCTION

MECHANISM?

Signs of acute sneezing or nasal discharge indicate inflammation of the nasal cavity, which in cats is almost always the result of infection, usually viral or associated with chlamydophilia or mycoplasma.

WHERE?

Nose (nasal cavity, paranasal sinuses).

WHAT?

Most cats (80%) with acute onset of sneezing or nasal discharge have calicivirus or herpesvirus.

DISEASES CAUSING ACUTE SNEEZING OR NASAL DISCHARGE

FELINE RHINOTRACHEITIS VIRUS (FELINE HERPESVIRUS-1), “RHINO” OR “SNUFFLES”****

Classical signs

- Acute onset of sneezing, pyrexia, depression.
- Marked discharge from eyes and nose, initially serous but progressing to mucopurulent.
- Severe conjunctivitis with chemosis and photophobia.
- Corneal keratitis or ulcers in some cats.
- Generally less than 10–14 days duration.

For more details of ocular changes see page 1212 (The Cat With Ocular Discharge or Changed Conjunctival Appearance) and page 1237 (The Cat With Abnormalities Confined to the Cornea).

Pathogenesis

Herpesvirus causes an **acute infection of the upper respiratory tract**, conjunctiva and cornea.

Virus multiplication is **temperature restricted**, and most lesions occur on cooler mucosal-epithelial surfaces, e.g. nasopharynx, conjunctiva, turbinates.

Necrosis of epithelium occurs within 24–48 h of viral contact.

Signs occur **2 to 6 days after infection**.

Secondary bacterial infection of lesions usually occurs, producing purulent ocular-nasal discharges.

Osteolysis of the turbinate bones may occur.

Virus may cause **corneal necrosis** resulting in keratitis, ulceration, and occasionally corneal rupture and loss of the eye.

Concurrent infections with calicivirus, *Chlamydomphila*, *Mycoplasma* or *Bordetella bronchiseptica* are common, and may alter the clinical signs.

Clinical signs

Earliest sign is paroxysms of sneezing.

Severe conjunctivitis occurs, with tearing, photophobia and chemosis.

Severe ocular and nasal discharges occur which are initially serous, but progress rapidly to mucopurulent. Discharge is typically more marked than with calicivirus.

Later, discharge and crusting of nares and conjunctiva may produce nasal obstruction and sealing of the eyelids.

Anorexia, depression and pyrexia are common; dehydration may occur.

Tracheal and bronchial inflammation may result in coughing and dyspnea, and occasionally bacterial pneumonia occurs in kittens.

Very rarely, ulceration on the nose or tongue occurs, but this is much more frequent with calicivirus infection.

Corneal involvement resulting in keratitis may occur 1–2 weeks later. Keratitis is visible as corneal cloudiness (edema and inflammation), and punctate or branching ulcers, which may coalesce to large ulcers.

Corneal perforation and secondary bacterial infection may result in destruction of the eye; this occurs more often in young kittens (ophthalmia neonatorum).

Herpesvirus keratitis often occurs in the absence of signs of active upper respiratory tract infection.

Infection of the pregnant queen may lead to fetal absorption, abortion, or kittens either born infected or developing signs shortly after birth.

Signs in newborn kittens include continuous crying, nasal discharge, sneezing and dyspnea.

Signs are worse in:

- **Young kittens** once maternal antibody levels decrease.
- **Conditions of crowding**, e.g. animal shelters, breeding colonies and pet shops.
- **Stress factors** or other **intercurrent disease**, e.g. FIV, FeLV, renal failure.

Signs of rhinotracheitis usually resolve in 2 weeks, but purulent rhinitis and sinusitis may persist longer.

Superficial ulcerative dermatitis occasionally occurs on the face, trunk and footpads. The lesions are usually more severe on the face and occur on the nasal planum or haired skin. They consist of vesicles, ulcers and crusts, and may be pruritic. Upper respiratory tract signs may or may not be present, and signs appear to occur in situations of reactivation of latent infection.

Stomatitis may be associated with latent herpesvirus infection, and may or may not occur with dermatitis.

Diagnosis

A definitive diagnosis is usually not made, and a presumptive diagnosis is based on clinical signs.

The following diagnostic tests are offered by some laboratories: **fluorescent antibody** staining of **conjunctival** or **nasal mucosal scrapings or biopsy**, antibody titers (measured initially and after convalescence), virus isolation or polymerase chain reaction (PCR).

- These are **infrequently performed** for individual cats with signs of upper respiratory tract disease, because the result rarely changes the treatment.
- Obtaining a definitive diagnosis is more useful if a cattery problem persists despite vaccination.
- Diagnostic tests are indicated to confirm herpesvirus infection if corneal ulceration is poorly responsive to treatment, but false-negative results are common.

Histopathological examination of the skin lesions indicates ulcerative dermatitis with epithelial cell necrosis and eosinophilic inflammation. Epidermal cells may contain basophilic intranuclear inclusion bodies. PCR indicates the presence of herpesvirus in skin samples.

Differential diagnoses

Calicivirus usually has milder upper respiratory signs; oral ulcers are classical; **no** keratitis or corneal ulceration; occasionally viral pneumonia occurs.

Chlamydophila generally has milder signs, although young kittens can have severe conjunctivitis and ocular-nasal discharge; typically conjunctivitis lasts longer (weeks) with *Chlamydophila*.

Cryptococcosis or nasal tumors may occasionally present with an acute onset of sneezing; however, signs do not resolve, but become chronic and progressive.

Concurrent FeLV or FIV should be suspected in cats with very severe, prolonged signs, or in adult vaccinated cats with severe signs, and in cats with recurrent upper respiratory disease.

See page 1213 for more details of differential diagnoses in The Cat With Ocular Discharge or Changed Conjunctival Appearance.

Treatment

Minimize hospital contamination. Cats should be treated as outpatients, unless dehydrated or requiring oxygen.

Use **broad-spectrum antibiotics** if nasal discharge is mucopurulent, indicating secondary bacterial infection.

- Antibiotics also help prevent chronic rhinitis.
- Amoxicillin, cephalosporin, doxycycline or trimethoprim-sulfadiazine are indicated.
- Doxycycline is useful if concurrent infections of *Chlamydophila*, *Mycoplasma* or *Bordetella* are suspected.

Correct dehydration and maintain optimum hydration using subcutaneous or intravenous fluids.

- Dehydration is common, because cats will not eat or drink, and marked fluid loss may occur from the ocular-nasal discharge and salivation.

Improve airflow through the respiratory tract.

- **Clean crusted discharge** from the nose three times daily.
- Use a protective agent such as vaseline on the nose to prevent excoriation.
- Use a **vaporizer or nebulizer** to provide airway humidification, or have the owners put the cat in a steamy bathroom.

- Nasal decongestants (intranasal or oral) are generally not well tolerated by cats, but can be tried.
 - **Intranasal decongestants** (e.g. pediatric preparations of phenylephrine, neosynephrine or oxymethazoline, 1 drop in one nostril) may be useful, but do not use longer than a couple of days.
 - **Oral decongestants**, e.g. ephedrine or pseudoephedrine (e.g. Sudafed) can be tried, but are unpalatable to cats, and may induce severe salivation.

Treat eyes with topical therapy. For more treatment details see page 1214 (The Cat With Ocular Discharge or Changed Conjunctival Appearance) and page 1239 (The Cat With Abnormalities Confined to the Cornea).

- Clean discharges from eyes three times daily.
- **Antibiotic eye ointment (without steroids)**, e.g. tetracycline or tobramycin. Avoid use of bacitracin-neomycin-polymyxin ointment because of reports of acute death associated with its use.
- **Antiviral eye drops** or ointment should be used if **herpetic keratitis** is present; they may also help conjunctivitis.
 - **Idoxuridine** q 4–5 h (Dendrid, Herplex, IDU, Stoxil), **vidarabine** q 5 h (Vira-A), **trifluorothymidine** q 2–4 h for 3 weeks (Viroptic). Viroptic was the most effective of the viricidal agents in vitro, but it is expensive, and may be very irritating to the eye.

Acyclovir (100–200 mg/cat q 8–12 h, per os; Zovirax) may be useful in resistant ulcers. If using this drug monitor white and red cell counts for evidence of bone marrow suppression. The efficacy is controversial in FHV-1 infection because the enzyme involved in conversion to the active form has low activity in cats compared to humans, and the drug is 100 times less active.

L-lysine (500 mg/cat q 24 h, per os) is recommended, and may help to reduce signs and viral shedding. It competes with arginine which is essential for viral replication.

Interferon (30 IU α -interferon) orally and topically (30 u/ml in artificial tears q 6 h) daily until lesions have resolved and then taper.

Support nutrition

- **Appetite stimulants.** Use diazepam (Valium; 0.1–0.2 mg/kg, IV) and immediately place food in

front of cat, or oxazepam (Serax; 2–2.5 mg/cat, PO q 12 h) or cypioheptadiene (Periactin, 1–2 mg/cat PO q 12 h) just before feeding.

- Multivitamins (A, B and C) but especially **thiamine** and vitamin A.
- **Tempt to eat** with strong smelling foods, e.g. fried chicken or sardines. Warming food to body temperature increases palatability.
- Handfeed or force feed initially.
- **Tube feed via** a naso-oesophageal, esophageal or gastrostomy tube if the cat is still depressed and anorexic after 3 days.

Warmth enhances recovery because the virus is temperature sensitive (e.g. use incubator or heating pad).

Prognosis

Mortality is usually low, although may be higher (up to 30%) in young kittens.

Persistent or recurrent **chronic bacterial rhinitis and sinusitis** occurs in some cats as a result of nasal epithelium damage and osteolysis.

- Chronic rhinitis is evident as recurrent sneezing, and mucopurulent nasal discharge, which responds temporarily to antibiotics.

Scarring and **occlusion of the lacrimal ducts** may produce chronic wetting of the face from tears.

Rarely, chronic keratitis, poorly healing corneal ulcers, conjunctival adhesions (symblephron), and keratoconjunctivitis sicca occur.

Herpesvirus **ulcerative facial dermatitis or stomatitis** syndrome appears to occur in some cats in situations associated with reactivation of latent infection.

Carrier state is common (up to 80% of recovered cats), and may last years.

- Virus is shed **intermittently**, often following stress; shedding may or may not be associated with mild clinical signs.
- Glucocorticoid administration or environmental stress such as from overcrowding or relocation may predispose to reactivation of infection.

Transmission

Herpesvirus is highly contagious with rapid spread in catteries, veterinary hospitals and multicat households.

- Infection rates may reach 100% in unvaccinated cats and kittens.
- Young kittens (5–8 weeks of age) are most susceptible.
- Occasionally kittens are born with infection.

Most infections occur via direct close contact with infected cats.

- **Fomites** are also important in spread, especially unwashed hands, food, bowls and contaminated cages.
- **Airborne transmission** occurs over short distances (approximately 1.2 m (4 feet)). Virus is present in the droplets formed by sneezing.
- **Virus is shed in secretions** (ocular, nasal and oral) for 1–3 weeks after infection.

Spread in boarding catteries, shelters and veterinary hospitals is facilitated by **the high frequency of carrier cats** in the population that shed virus at times of stress or glucocorticoid treatment and may show no signs of infection.

Vertical transmission occasionally occurs from a carrier queen, resulting in kittens born with disease.

- More usually, carrier **queens shed virus 4–6 weeks after queening**, infecting kittens at the time maternal immunity is waning.

Feline herpesvirus is relatively **fragile**, and is stable for less than 24 h outside the host.

- The virus is **susceptible to most disinfectants**.

Prevention

Vaccination

Parenteral and intranasal vaccines are available in combination with feline calicivirus vaccine.

Combinations with feline parvovirus, chlamydia, rabies and/or feline leukemia vaccines are also available.

- **Parenteral** vaccines for subcutaneous administration are available as modified live or inactivated vaccines.
 - Administer twice with a 3–4-week interval between doses.
 - If the kitten is less than 8 weeks old at the first dose, give a third dose 3–4 weeks after the second dose.

- If a cattery problem occurs, vaccinate litters as early as 4 weeks of age, and repeat every 3–4 weeks until 14 weeks of age.

- **Intranasal** vaccine is a modified live vaccine, which produces rapid immunity (1–4 days). Some cats have transient mild sneezing and naso-ocular discharge after vaccination.
 - Vaccinate with a single dose. If less than 10 weeks of age at the first dose, give second dose 3–4 weeks later.
 - If a cattery problem occurs, divide the dose amongst the litter and give at 2 weeks of age, and follow with a parenteral vaccination every 4 weeks until 14 weeks of age.
- The **combination of intranasal and subcutaneous vaccination** reduced the incidence of upper respiratory tract disease (31% of cats developed signs) in a shelter compared with subcutaneous vaccination alone (51% of cats developed signs), and was cost-effective.

The frequency of **booster vaccinations is controversial**. Annual boosters are typically recommended, particularly because occurrence of upper respiratory tract signs is common in vaccinated cats, especially when exposed to stress. However, measurement of serum titers suggests that humoral immunity lasts for 48 months or more. Serological titers are not equivalent to protection from challenge, although the predictive value for resistance to challenge for a positive serum antibody titer was 70% for herpesvirus and 92% for calicivirus. Additional boosters are recommended before a heavy challenge, e.g. boarding in a cattery.

Live parenteral vaccine can produce signs of upper respiratory tract disease if aerosolized or spilt on the cat's hair, so take care with administration.

Maternal antibodies can block the effect of the vaccine.

- Antibody levels vary between kittens, and **may last 5–6 weeks with herpesvirus (7–8 weeks with calicivirus)**.

Vaccinating queens 1–4 weeks before partum increases colostrum-derived maternal immunity.

- **DO NOT USE WITH LIVE PANLEUKOPENIA VACCINE** in pregnant queens.

Localized viral infection can occur in vaccinated cats, and may produce mild ocular and nasal discharge, and viral shedding.

Disease control in the cattery or shelter

Vaccinate kittens early, and vaccinate all cats regularly to maintain immunity.

Isolate sick cats, and pregnant and nursing queens from the main cattery.

Vaccinate and **isolate** incoming cats for 3 weeks.

- Avoid introducing cats that are likely carriers, i.e. from catteries with known infection problems.

Carrier queens shed virus and infect nursing kittens, therefore, remove queens that repeatedly have infected litters, or wean kittens early.

Avoid overcrowding and other causes of stress.

Clean and disinfect cages daily and **bowels** with **sodium hypochlorite** (0.175%, i.e. 1:32 dilution of household bleach) added to detergent.

FELINE CALICIVIRUS (FCV)**

Classical signs

- Lethargy, anorexia, fever.
- Oral ulcers of less than 1 week duration.
- Mild upper respiratory tract signs (sneezing, discharges).

See other reference on page 1137 for details (The Fading Kitten and Neonate).

Pathogenesis

Calicivirus replicates in epithelial cells of the upper respiratory tract, conjunctiva, tongue and in pneumocytes of the lung alveoli.

Multiple antigenic subtypes occur with differing pathogenicity.

- Most isolates cause low mortality.
- Some very pathogenic isolates cause severe pneumonia and significant mortality.
- Other isolates cause “limping kitten syndrome”.
- FCV-Ari isolate produces high mortality.

Clinical signs

Clinical signs vary from mild to severe, depending on viral subtype and immune status of the cat.

- Signs are often milder than feline herpesvirus infection.

Early signs are often non-specific, and typical of a sick cat, i.e. **lethargy, anorexia and pyrexia**.

Nasal and ocular discharge is often only **mild and serous** or mucoid, or may be absent.

Sneezing is less prominent than in herpesvirus and is not paroxysmal.

Oral ulcers are characteristic and present in 70% of cats.

- Oral ulcers may occur either as small ulcers (2–5 mm in diameter) or as a large ulcer.
- Typically ulcers are located on the **anterior or lateral margin of the tongue**. Less frequently they occur at the angle of the jaws, on the hard palate, nasal philtrum or lips.
- Footpad ulcers occur occasionally, hence the name “paw and mouth disease”.

Salivation may be profuse in the first few days after ulcers form.

Conjunctiva are generally only **mildly hyperemic**, and are not chemotic, as occurs with herpesvirus or chlamydia.

Viral pneumonia occurs occasionally with certain strains, and may produce significant mortality. Death is often sudden and preceded by labored respiration.

Rarely, vomiting and diarrhea occur as a result of enteritis.

“**Limping kitten syndrome**” occurs occasionally with some strains of virus.

- Acute viral arthritis results in reluctance to move, and acute swelling and pain on palpation of the joints.

A **rare variant strain (FCV-Ari)** reported from California, USA, produces a **high fever, facial and paw edema** (50% of cats), ocular and nasal discharge, conjunctivitis and ulcerative stomatitis (50% of cats), **hemorrhage from the nose, GIT**, etc. (30–40% of cats), **icterus** (20% of cats) and **rapid death**. **Mortality is high** (30–50%).

- Swelling of the feet and face is a combination of edema and hemorrhage, which is thought to result from vasculitis. Hemostatic abnormalities have

been attributed to vasculitis and disseminated intravascular coagulation (DIC).

- Some cats also had pneumonia, pleural effusion, pancreatitis and abdominal effusion.

Diagnosis

Presumptive diagnosis of calicivirus infection is **based on clinical signs**

A definitive diagnosis is usually not made except where there is an ongoing cattery problem, and is based on demonstrating a **rising antibody titer, or on PCR or viral isolation**. These tests are available through some laboratories.

Identification of **FCV-Ari** is based on the clinical syndrome, pathology and **culture of virus from blood, nasal or ocular discharge, spleen or lungs**. Thrombocytopenia and prolonged PT and aPTT may be evident in some cats.

Differential diagnosis

Herpesvirus generally has more pronounced ocular-nasal discharge and paroxysms of sneezing. Corneal lesions in herpesvirus infection are usually diagnostic, and mouth ulcers rarely occur.

Mycoplasma often occurs as a secondary infection in viral upper respiratory tract disease, rather than a primary disease, and is not associated with mouth ulcers.

Chlamydia generally has mild upper respiratory tract signs, but no mouth ulcers; conjunctivitis often persists longer and is more severe than with calicivirus.

Caustic stomatitis generally does not cause fever. Ocular-nasal discharge is usually absent, or if present, is a mild, serous discharge.

Concurrent infection with herpesvirus, mycoplasma or *Bordetella* may confuse the clinical picture.

Acetaminophen (paracetamol) toxicity produces similar facial and paw swelling in an acutely ill cat as does FCV-Ari, but cats are not febrile.

Other acute infectious illnesses may appear similar to FCV-Ari, for example *Yersinia pestis* (feline plague), *Salmonella* spp. (song-bird fever), *Francisella*

tularensis (tularemia), all may be difficult to differentiate pre-mortem if the illness progresses rapidly to death.

Pancreatitis does not usually produce such a high fever as FCV-Ari.

Treatment

Treatment for calicivirus infection including the hemorrhagic form involves **supportive therapy** (see treatment of herpesvirus for details, page 8).

- Maintain good hydration.
- Humidify airways using a vaporizer or nebulizer.
- Use broad-spectrum antibiotics for secondary infections.
- Clean discharges from face.
- Provide oxygen if dyspneic.
- Analgesics (e.g. buprenorphine) may help make the cat more comfortable if there is severe ulceration.

No specific therapy is available, and no antiviral drug is effective.

Prognosis

Signs generally resolve within 5–7 days.

Rarely, mortality is high with strains causing severe viral pneumonia or vasculitis (FCV-Ari), and kittens may die suddenly.

Chronic gingivitis and stomatitis occurs in some carriers.

Persistent mild conjunctivitis or ulcerative keratitis may be a problem.

Transmission

Calicivirus is highly contagious, with nearly 100% morbidity in susceptible cats.

Infection spreads rapidly when multiple cats are housed together.

- Young unvaccinated kittens 2–6 months of age are most susceptible.

Incubation period is 2–4 days. First signs generally occur 3 days after exposure, but this varies with dose and virulence of virus.

Transmission is primarily **via direct contact with infected cats**.

- **Fomite** transmission occurs, e.g. food and water bowls, cages, human hands, shoes and clothing.
- Virus can survive several days, and in some situations up to 8–10 days, on contaminated objects.

Virus is shed in secretions from the mouth and nose of sick cats.

The carrier state is common, and may last years. Carrier cats provide a source of infection, and shed virus **continuously**, mainly from the tonsils.

Virus is resistant to lipotrophic disinfectants, and **sodium hypochlorite** (1:32 dilution of household bleach) is efficacious.

Prevention

Vaccines are available **combined with feline herpesvirus** vaccine (see herpesvirus (page 10) for administration details).

Vaccination decreases severity and duration of signs.

- Vaccination may **not afford 100% protection** if challenged by a subtype that is different from the vaccine strain.

Cattery control involves vaccination, isolation of incoming cats and good hygiene (see herpesvirus, page 11).

CHLAMYDOPHILA FELIS (CHLAMYDOPHILA FELIS PSITTACI)**

Classical signs

- Conjunctivitis, initially acute but progressing to chronic inflammation.
- Sneezing and nasal discharge is usually mild and often becomes chronic.

See other reference on page 1215 for details (The Cat With Ocular Discharge or Changed Conjunctival Appearance).

Pathogenesis

Chlamydiae cause approximately 20% of upper respiratory tract disease in cats, but is a frequent cause of conjunctivitis.

Infection may occur concurrently with herpes or calicivirus infection.

Clinical signs

Conjunctivitis is often initially unilateral, but progresses to bilateral involvement.

- Conjunctiva are **hyperemic**, which is usually mild but can be severe, and are occasionally edematous and chemotic.
- Ocular discharge is initially seromucous, but rapidly becomes mucopurulent.

Sneezing and nasal discharge result from ocular discharge draining through the nasolacrimal duct.

Pneumonia occasionally occurs in kittens.

Chlamydia may cause abortion and infertility, although this is controversial and poorly documented in cats.

Diagnosis

Visualization of inclusion bodies in epithelial cells obtained from conjunctival scraping (Diff-Quick stain) is diagnostic.

- Inclusion bodies are visible as groups or clusters of organisms in the cytoplasm (in the same plane as the nucleus).
- Inclusions are most often visible in the first 2 weeks of infection, and numbers decrease with chronicity.

Antibody-based detection in conjunctival scrapings using **ELISA or latex agglutination** is available. False positives occur with both tests if many bacteria are present.

- Use a dry swab, and roll well to get sufficient tissue for the test.

PCR is becoming more commonly available from diagnostic laboratories, and is the technique now used predominantly for studies involving chlamydia.

Differential diagnosis

Herpesvirus generally produces more severe ocular-nasal discharge and systemic signs. If ulcerative keratitis is present, it is usually diagnostic for herpesvirus.

Calicivirus typically causes oral ulcers, which are not present with chlamydia.

Mycoplasma may not be clinically distinguishable from chlamydia.

Treatment

Use **tetracycline ophthalmic** ointment. Continue for **10 days after clinical remission** (usually 2–4 weeks of treatment 3–4 times daily). Avoid use of bacitracin-neomycin-polymyxin ointment because of reports of acute death associated with its use.

Oral doxycycline therapy may also be required in **resistant cases**. It is excreted in tears, and is also effective as a sole agent. Treat for 21 days, although up to 6–8 weeks treatment may be required in refractory cases.

Oral azithromycin (Zithromax, Pfizer, 5 mg/kg q 24 h PO for 14 days) is an alternative treatment to tetracycline.

Some chronic cases may require long-term systemic therapy.

Prognosis

Chlamydophilosis frequently **progresses to chronic signs**, with conjunctival thickening and prominent conjunctival lymphoid follicles.

Untreated cats frequently relapse after apparent recovery.

Transmission

Transmission is by direct contact with an infected cat.

MYCOPLASMA

Classical signs

- Conjunctivitis with purulent ocular discharge; unilateral progressing to bilateral.

See main reference on page 1218 for details (The Cat With Ocular Discharge or Changed Conjunctival Appearance).

Pathogenesis

Causal agents are *Mycoplasma felis* and *M. gatae*.

Mycoplasma more often plays a secondary role to herpesvirus or calicivirus infections.

Clinical signs

Conjunctivitis is initially unilateral, progressing to bilateral involvement.

- Conjunctiva may be normal, hyperemic or edematous.
- In severe infections, conjunctiva may be covered in a gray pseudomembrane (diphtheritic membrane).

Nasal discharge is mild, and results from ocular discharge draining into the nose.

Diagnosis

Diagnosis is based on visualization of clusters of **coc-coid or coccobacillary organisms** in the periphery of epithelium cells from stained (e.g. Diff-Quik stain) conjunctival scrapings.

Isolation of the organism can be done in most laboratories from clean conjunctival swabs. Remove ocular discharges with sterile normal saline solution prior to taking the sample, to reduce contamination from secondary bacterial infections.

Differential diagnosis

Chlamydia has similar clinical signs, but is more common.

Treatment

Chloramphenicol or doxycycline ophthalmic ointment (6 mm (1/4 inch) strip q 6 h).

BORDETELLA

Classical signs

- Pyrexia.
- Sneezing and nasal discharge.
- Mandibular lymphadenopathy.
- Coughing.
- Dyspnea, cyanosis, pneumonia.

Pathogenesis

Bordetella bronchiseptica may act as a primary pathogen, or play a secondary role to herpesvirus or calicivirus infection.

Infection appears **widespread in the feline population**. *B. bronchiseptica* may be a normal commensal in the respiratory tract of cats, because it can be isolated from many healthy cats. It can be isolated from as many as 20% of cats in rescue catteries. The lowest rates of isolation are from one- and two-cat households.

Overgrowth of the organism may produce upper respiratory tract inflammation or pneumonia.

Severe cases with **bronchopneumonia** have occurred in situations of **overcrowding** and other stress factors.

The incidence in cats is reported to be higher in households where signs were present in dogs.

In most cats, **signs resolve after approximately 10 days**. Occasionally, coughing persists longer.

Clinical signs

Signs are most likely to occur in cats from **multi-cat environments, especially rescue or shelter catteries**, where calicivirus and herpesvirus are also a problem.

Typically there is an **acute onset of pyrexia, and sneezing and nasal discharge**.

Mandibular lymphadenopathy may be palpable.

Coughing may be spontaneous, or only evident on tracheal pressure. Generally, coughing is not as pronounced as in dogs.

Dyspnea, cyanosis, crackles and wheezes may be auscultated over lung fields in some cats. Death from **pneumonia** may occur, especially in young kittens less than 8 weeks old.

Diagnosis

Bacteria can be isolated from the nasal discharge, oropharyngeal secretions, tonsillar swabs, or a transtracheal wash.

- Samples should be transported in **special medium** (e.g. charcoal Amies transport medium), and need special media for culture.
- Although *B. bronchiseptica* is a normal commensal in many cats, in cats with disease from the organism, **large numbers of organisms** are often isolated.

Differential diagnosis

Herpesvirus and calicivirus can have similar signs, and mixed infections are common, making definitive diagnosis impossible based solely on signs.

Treatment

Use **appropriate antibiotics** based on susceptibility data and the ability to reach therapeutic concentrations in respiratory secretions such as oxytetracycline, doxycycline or enrofloxacin. Beware of sudden retinal degeneration if using enrofloxacin.

Montelukast (Singulair, 0.25–1 mg/kg SID) is a leukotriene receptor blocker. Although the cat has insufficient leukotriene receptors for cysteinyl leukotrienes to cause bronchoconstriction, anecdotal evidence suggests that montelukast may **reduce sneezing and nasal discharge** associated with *Bordetella*. This effect may be mediated through blockage of leukotriene-mediated attraction of inflammatory cells such as eosinophils and neutrophils, and their subsequent release of inflammatory cytokines and other chemicals.

Prevention

An **intranasal modified live vaccine** is available which does not prevent or eliminate infection with *Bordetella*, but usually prevents severe overgrowth and clinical signs. It is most useful in catteries or shelters with culture-proven outbreaks of disease. It is effective in 3–5 days.

The rate of adverse signs (e.g. sneezing) associated with *Bordetella* vaccination probably exceeds the frequency of disease caused by the organism in cats living in one- or two-cat households.

Improve cattery/shelter conditions to decrease overcrowding if the organism appears to be causing recurrent problems.

FOREIGN BODY

Classical signs

- **Acute onset of sneezing and face rubbing, progressing to chronic signs.**
- **Unilateral discharge.**
- **Gagging.**

See main reference on page 28 for details (The Cat With Chronic Nasal Disease).

Grass or seeds may occasionally enter the nose of cats. Other foreign bodies such as gun pellets are less common.

Clinical signs

Typically there is an **acute onset of sneezing and distress**, and rubbing at the face.

Signs may progress to chronic gagging, or sneezing and discharge.

A **unilateral** serosanguinous discharge is typically present.

Diagnosis

Visualize foreign body using an otoscope, fiberoptic scope, or with a dental mirror in the nasopharynx. Use a spray hook to retract the soft palate for better visualization.

Flushing the nose using a naso-esophageal feeding catheter may remove parts or all of the whole foreign body for diagnosis.

CRYPTOCOCCOSIS

Classical signs

- Chronic nasal discharge and sneezing, progressing in severity.
- Soft tissue swelling over the nasal bones (Roman nose), or polyp-like mass in nasal cavity.
- Facial distortion.

See main reference on page 25 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Occasionally, the initial signs of cryptococcosis are **acute in onset**.

Upper respiratory tract signs are most common, and include **sneezing, snuffling and chronic nasal discharge**.

Nasal discharge may be unilateral or bilateral, and serous, mucopurulent or hemorrhagic.

Distortion and swelling over the bridge of nose, or a **polyp-like mass** projecting from the nasal cavity are present in 70% of cats with the respiratory form.

Depression, anorexia or inappetence and **weight loss** are often present with nasal or CNS involvement.

Submandibular lymph nodes are often **enlarged**.

Diagnosis

Diagnosis is based on **cytological identification of the organism** in nasal discharge, exudate from skin lesions, lymph node aspirate, cerebrospinal fluid (CSF), or ocular aspirate. *Cryptococcus* appears as **yeast-like organisms** (5–15 µm) surrounded by a **wide, clear capsule**.

Serology to detect cryptococcal capsular antigen in blood, CSF, or urine is **sensitive and specific**.

Tissue biopsy of the granulomatous mass or skin lesion, and histological identification of the organism may be required if cytology is negative.

Fungal isolation with **culture** is rarely required for diagnosis, but is **useful for sensitivity testing**.

BLEEDING ULCER ON EXTERNAL NARES

Classical signs

- Bleeding ulcer on external nares.
- ± Sneezing.

See main reference on page 27 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Acute sneezing and/or discharge may occasionally occur associated with a bleeding ulcer on the external nares, particularly the nasal septum. It is usually associated with **squamous cell carcinoma (SCC)**, but occasionally with **eosinophilic granuloma** or with **acute calicivirus infection**.

Diagnosis

Cytological examination of an **impression smear**, or **biopsy and histological** examination of the lesion is usually diagnostic for squamous cell carcinoma of the external nares.

Eosinophilic granuloma requires biopsy for diagnosis.

Acute calicivirus infection is diagnosed based on clinical signs, and in some cases PCR.

INTRANASAL TUMORS

Classical signs

- Chronic nasal discharge and sneezing, progressing in severity.
- Facial distortion.

See main reference on page 23 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Acute sneezing and/or discharge may occasionally occur associated with an **intranasal tumor**. Suspect this disease when signs do not resolve over 2–3 weeks, and instead progress with worsening discharge, and often nasal distortion.

Intranasal tumors are associated with **chronic sneezing and snuffling**, which **progressively worsen** with time and a **purulent or bloody nasal discharge, which may temporarily respond to antibiotics**. The discharge may initially be unilateral and progress to bilateral involvement.

Snoring, snorting, inspiratory stridor, stertor or dyspnea may result from **nasal obstruction**.

Facial distortion, e.g. elevation of bridge of nose (Roman nose) or facial swelling may occur.

Diagnosis

Intranasal tumors usually require an **invasive approach** for diagnosis. Cytological examination of the discharge or atraumatic nasal flush usually reveals evidence of inflammation (neutrophils and bacteria) but no tumor.

- **Radiography** demonstrates increased opacity of the nasal cavity and often **destruction of the turbinates, nasal septum, lateral bone and loss of teeth** adjacent to the lesion. Radiographic changes are often unilateral or asymmetrical.
- A **traumatic flush using a stiff catheter** and syringe (e.g. cut-off dog urinary catheter) yields better results than an atraumatic flush.
- A **biopsy** is often required to obtain tissue for a histological diagnosis. Tissue may be obtained using biopsy **forceps** through the external nares or via a **rhinotomy**.

ALLERGIC RHINITIS

Classical signs

- Acute or chronic serous or mucoid nasal discharge, often seasonal.

Clinical signs

Allergic rhinitis appears to be a rare and poorly documented condition in cats.

It presents as serous or mucoid ocular and/or nasal discharge without systemic signs, and may be seasonal in occurrence.

It has been reported associated with allergy to **Japanese cedar** (*Cryptomeria japonica*).

Diagnosis

Diagnosis is based on **exclusion of all other causes** of nasal discharge, and biopsy results indicating rhinitis with no evidence of underlying pathogens. A mixed neutrophilic and eosinophilic rhinitis has been reported.

Most cases with similar signs are the result of viral upper respiratory disease, often with chronic bacterial rhinitis cases.

Treatment

A combination of antihistamine and steroid may work well in some cats. For example, trimeprazine tartrate (5 mg) and prednisolone (2 mg) in Temaril-P (1/4 to 1/2 tablet PO q 12–24 h).

3. The cat with signs of chronic nasal disease. (chronic > 3 weeks duration)

Jacquie Rand

KEY SIGNS

- Chronic mucoid, purulent and/or bloody nasal discharge.
- Chronic sneezing or snuffling.
- Stertorous respiration, snoring, dyspnea or mouth breathing.
- Facial distortion or nasopharyngeal distortion.
- Gagging.

MECHANISM?

- Signs of chronic disease result from chronic inflammation or obstruction of the nasal structures or its junction with the pharynx.

WHERE?

- External nares, nasal cavity, frontal sinuses and nasopharynx

WHAT?

- Most cats with signs of chronic nasal disease have secondary bacterial infection following herpes or calicivirus infection; less common causes are *Cryptococcus* and neoplasia.

QUICK REFERENCE SUMMARY

Diseases causing signs of chronic nasal disease

ANOMALY

- **Congenital anomaly of the nose or hard palate** (p 27)**

Breed-related obstruction of the external nares (e.g. Persian cats) causes chronic snuffling and stertorous respiration.

Cleft palate, and congenital anomalies of the nasal cavity cause signs in young kittens which depend on the type and severity of the anomaly, e.g. nasal discharge and inability to suckle associated with a cleft palate.

MECHANICAL

- Foreign body (p 28)

Acute onset of sneezing and rubbing face or gagging, followed by chronic unilateral nasal discharge and sneezing, or gagging. Often associated with a blade of grass, a grass seed or awn.

continued

continued

NEOPLASTIC

- **Neoplasia** (p 23)**

Chronic mucopurulent or hemorrhagic nasal discharge, often unilateral initially, but progressing to bilateral; sneezing, stertorous respiration \pm facial distortion.

- **Nasopharyngeal polyp (p 30)**

Chronic snuffling, stertorous respiration and dyspnea from nasal obstruction; retching or gagging with eating, \pm mucopurulent nasal discharge.

INFLAMMATION

- **Secondary rhinitis associated with dental disease* (p 27)**

Mild, chronic mucopurulent or hemorrhagic discharge and sneezing.

- **Nasopharyngeal stenosis (p 30)**

Chronic snuffling, partial nasal obstruction, retching or gagging with eating.

INFECTIOUS

Bacterial:

- **Secondary bacterial rhinitis*** (p 21)**

Occurs secondary to viral upper respiratory tract disease. Signs include chronic mucopurulent or hemorrhagic nasal discharge, sneezing, stertorous respiration, occasionally nasal distortion.

Fungal:

- ***Cryptococcus**** (p 25)**

Chronic mucopurulent or hemorrhagic nasal discharge, sneezing, stertorous respiration, distortion over bridge of nose (Roman nose), polyp-like mass in nasal opening.

- **Other fungi**

Aspergillus, *Penicillium*, *Sporothrix* or other fungi are very rare causes of chronic nasal disease.

***Chlamydomydia felis* and *Mycoplasma*:**

- ***Chlamydomydia felis* (*Chlamydomydia felis psittaci*) and *mycoplasma* (p 29)**

Chronic ocular and nasal discharge, chronic conjunctivitis and sneezing.

Immune:

- **Allergic rhinitis (p 31)**

Acute or chronic serous or mucoid nasal discharge, which is often seasonal.

Trauma:

- **Oronasal fistula or nasal fractures following trauma (p 29)**

Chronic snuffling, sneezing and nasal discharge associated with cleft palate, oronasal fistula or obstructed nasal cavity.

INTRODUCTION

MECHANISM?

Chronic nasal disease should be suspected when a cat has any of the **following signs for more than 3 weeks**.

- **Chronic sneezing** or snuffling.
- **Nasal discharge which may be mucoid, purulent or bloody.**
- **Signs of nasal obstruction**, such as stertorous respiration (snoring), stridor (high-pitched whistling indicating obstruction), dyspnea or mouth breathing.
- **Gagging.**
- **Facial distortion.**
- **Nasopharyngeal distortion** or bulging of the soft palate into the oral cavity.

The nasal mucosa responds to chronic disease by increased mucoid discharge.

- A **purulent discharge** occurs with infection or necrosis.
- **Blood** may be present if there is severe **inflammation or erosion**.
 - **Bleeding without other signs of nasal disease**, such as a purulent nasal discharge, may indicate a **systemic bleeding problem**, rather than nasal disease.

Facial distortion occurs with **neoplasia or chronic infection**.

- Fungal (usually *Cryptococcus*) more often causes nasal distortion than chronic bacterial infection.

Gagging occurs when there is **nasopharyngeal stimulation** from a mass lesion, a **foreign body**, or caudal nasal discharge.

Ciliated columnar epithelium lining of the nasal cavity **undergoes squamous metaplasia after herpesvirus infection**.

- This decreases mucociliary clearance and predisposes to secondary bacterial infection.

WHERE?

Signs of chronic nasal disease result from problems in any of the following sites:

- **External nares, nasal cavity, frontal sinuses and nasopharynx.**

Careful **history taking** and **physical examination** help localize the lesion.

Examination of the oropharynx under anesthesia and **radiography** aid localization and diagnosis.

WHAT?

The most common cause of chronic nasal disease is **secondary bacterial infection following herpes or calicivirus infection**

- Less common causes are *Cryptococcus* and neoplasia.
- **Foreign bodies are generally rare** causes of chronic nasal signs in cats.
 - **Grass in the nasopharynx** is more common, and causes **gagging**.

Diagnosis is based on history and physical examination findings, radiography, *Cryptococcus* titer, and cytological or histopathological examination of tissue samples.

DISEASES CAUSING SIGNS OF CHRONIC NASAL DISCHARGE

SECONDARY BACTERIAL RHINITIS***

Classical signs

- Chronic sneezing and snuffling following acute upper respiratory tract signs.
- Chronic mucopurulent nasal discharge.
- Stertorous respiration.
- Occasionally, nasal distortion.

Pathogenesis

Secondary bacterial infection of the nasal cavity and sinuses following feline herpesvirus or calicivirus infection is one of the most common causes of chronic sneezing and nasal discharge in cats.

Feline herpesvirus (feline rhinotracheitis virus) **predisposes to persistent or recurring** bacterial infection of the nose and sinuses.

Herpesvirus **causes structural changes in the nose and sinuses.**

These changes decrease mucociliary clearance from the nose, and cause nasal and sinus obstruction.

- Structural changes include necrosis of the nasal epithelium, **squamous metaplasia**, osteolysis of the turbinates, and mucosal gland hypertrophy.
- The result is decreased density of cilia and increased viscosity of mucus. This **decreases mucociliary clearance** from the nose and sinuses.
- Persistent **thickening of the lining tissues of the nasal cavity and sinuses** leads to nasal and sinus obstruction, predisposing to chronic sinusitis.
- The normal opening between the nasal cavity and frontal sinuses is small in cats, and is relatively easily obstructed.

Organisms most frequently isolated are those that comprise the normal flora of the nose (e.g. *Staphylococcus*, *Streptococcus*, *Pseudomonas*).

Cats with feline immunodeficiency virus (FIV) or feline leukemia virus (FeLV) may be more susceptible.

Clinical signs

Chronic sneezing, snuffling and mucopurulent nasal discharge is often present for months or years.

Stertorous respiration, (snoring) or stridor (whistling), may be audible from the nasal area.

Occasionally, nasal distortion is present when signs have been present for years.

Diagnosis

History of chronic snuffling following acute upper respiratory tract infection.

Radiographic findings

- Usually there is **loss of lucency in the nasal cavity** (fluid density) and often in the frontal sinuses.
- Radiographic changes are usually **bilaterally symmetrical**.
- **Osteolysis of the turbinates** and/or nasal septum may be evident.

Cytology or histology reveals many neutrophils with intra- and extracellular bacteria, and no evidence of *Cryptococcus neoformans* or neoplastic cells.

- **Beware of similar cytologic findings with neoplasia**, and sometimes cryptococcosis. Often neoplasia is

misdiagnosed as bacterial infection, because of the presence of neutrophils and bacteria.

- To exclude neoplasia, material must be collected via a **traumatic flush** using a stiff polypropylene catheter attached to a syringe, or via a **biopsy** using a pinch biopsy technique through the nares, or a core biopsy via a trephine, or surgical biopsy via rhinotomy.
- Cytological examination of the **nasal discharge or atraumatic nasal flush is inadequate to exclude neoplasia** as a cause of the secondary bacterial infection.
- Surgical **rhinotomy** and biopsy may be necessary to exclude neoplasia when the history and radiographic findings are equivocal.

Negative *Cryptococcus* titer.

Check FeLV and FIV status.

Differential diagnosis

Neoplasia produces similar signs, but duration of signs is usually less than 6 months, and cats are often older than 10 years of age. **Radiographic lesions are often unilateral or asymmetric**, whereas chronic rhinitis tends to be bilaterally symmetrical.

Cryptococcosis produces similar signs, although 70% of cats with nasal involvement have distortion over the bridge of the nose, or a polyp-like mass visible in the nasal cavity.

- **Only rarely do cats with chronic bacterial infection have nasal distortion**, and this is usually only after signs have been evident for years.
- Diagnosis of cryptococcosis is based on finding evidence of the organism on cytology, histology or serology.

Treatment

Treatment requires prolonged antibiotic therapy for 1–4 months. Many cats cannot be cured, and nasal discharge and sneezing persist, requiring repeated therapy when signs are exacerbated. Different combinations of therapy work better in individual cats.

- Use **broad-spectrum antibiotics**, or base choice on culture and sensitivity. Because of the large number of normal flora in the nasal cavity, culture, and therefore sensitivity results, are hard to interpret. The best antibiotics to use are broad spectrum with efficacy against anaerobes, and that penetrate bone and cartilage.

- Commonly used antibiotics include doxycycline, cephalexin, amoxicillin-clavulanic acid, clindamycin, enrofloxacin and azithromycin. Amoxicillin-clavulanic acid, metronidazole, clindamycin and azithromycin are good first choices.
- Doxycycline and metronidazole may be advantageous because they have an **immunomodulating effect** which may help **reduce inflammation**.
- Azithromycin is attractive because of the alternate day dosing, and in cattery and breeder situations the pharmacokinetics allow twice weekly dosing (q 72 h).
- One regime that is effective in many cats is **enrofloxacin** (Baytril; 2.5 mg/kg q 12 h for 30 days) together with **azithromycin** (Zithromax; 20 mg QD for 30–45 days).
 - Fluroquinolones, particularly enrofloxacin may be associated with **retinal degeneration and blindness**, especially at high doses, and many ophthalmologists avoid using these drugs.
- Cats with *Pseudomonas* cultured from the sinuses may respond to a long course of carbenicillin.
- If signs return rapidly after stopping antibiotics, long-term antibiotics administered once daily at half the total daily dose may help control signs in some cats. However, resistance to antibacterial action commonly occurs, and a better strategy is a longer course of antibiotics based on culture and sensitivity using dosages suitable for osteomyelitis, followed by a course of antibiotics when signs relapse.
- **Intranasally administered antibiotics** such as gentamicin ophthalmic drops sprayed into each nostril twice daily for 30 days may help, if the cat will tolerate them.
- **Acetylcysteine** (Mucomyst) helps to liquefy nasal secretions when used with nebulization, but may be expensive for long-term use.
- In some cats, **intermittent flushing of the nasal cavity** under anesthesia (with tracheal intubation) can be useful in controlling clinical signs.
- Occasionally, cats will tolerate local instillation of **saline drops** in the nasal cavity. This stimulates a sneeze response and encourages evacuation of mucus.
- Individual cats may show improvement with antihistamines especially second-generation **antihistamines** such as loratidine (Claritin; 2.5 mg/day) because of their anti-inflammatory effects as well as their ability to dry up excessive mucus.

- Leukotriene antagonists like **zafirlukast** (Accolade; 0.5–1.0 mg/kg PO q 12–24 h) or **montelukast** (Singulair, 0.25–1.0 mg/kg SID) help by reducing pain and inflammation, and may be effective in some cats.

If signs persist despite antibiotics, **surgical removal of chronically inflamed tissue** via a rhinotomy is sometimes successful.

- Surgery is generally **more successful for chronic sinusitis** with radiographic evidence of fluid in the sinuses, than for chronic rhinitis. Opening the foramen between the sinus and nasal passages facilitates drainage of the sinus.
- **Surgery involves turbinectomy and/or ablation of the frontal sinuses.** For frontal sinus ablation, the sinuses are curetted out, the periosteum removed, and the cavity filled with subcutaneous abdominal fat or methylmethacrylic.

Interferon alone or with ATZ (zidovudine) or PMEA (phosphonomethoxyethyl adenine) may help in FeLV- and FIV-infected cats to stimulate immunity and improve signs.

Prognosis

Most cats have a good quality of life, although signs often persist and must be controlled with antibiotics.

Prevention

Regular vaccination to prevent feline calicivirus and herpesvirus infection is recommended, because most chronic bacterial rhinitis occurs secondary to upper respiratory viral infection.

NEOPLASIA**

Classical signs

- Progressively worsening chronic sneezing and snuffling.
- Purulent or blood-tinged nasal discharge, which may temporarily respond to antibiotics.
- Epiphora, ± signs of retrobulbar pressure, e.g. exophthalmos.
- Nasal obstruction, and occasionally facial distortion.

Pathogenesis

Neoplasia may involve **primarily the external nares, the nasal cavity or the paranasal sinuses**.

- Neoplasia typically causes purulent nasal discharge, bleeding, sneezing and/or obstruction.

Neoplasia involving **primarily the external nares** is most commonly **squamous cell carcinoma**. Less frequently fibrosarcoma or fibroma are involved.

- **Squamous cell carcinoma** usually occurs in older cats with a non-pigmented nose, that live in a sunny climate and are outside during the day.

Neoplasia primarily involving **the nasal cavity or the frontal sinuses** is most commonly **adenocarcinoma and lymphoma**.

- Less common tumors are undifferentiated carcinoma or sarcoma, olfactory neuroblastoma, fibrosarcoma, chondrosarcoma, chondroma, osteosarcoma and squamous cell carcinoma.

Neoplasia usually occurs in **older cats** (> 8–10 years).

Most occur in the **caudal third of the nasal passage**.

Clinical signs

Squamous cell carcinoma involving the **external nares** may cause **sneezing** and a **bloody nasal discharge**.

- Lesions causing signs of nasal disease many consist of a bleeding ulcer on the nasal septum, or an **advanced erosive lesion on the external nares**.
 - Signs may be present for **months or years**.

Intranasal tumors are associated with the following signs:

- **Chronic sneezing and snuffling**, which **progressively worsen** with time.
- **Purulent or bloody nasal discharge**, which may **temporarily respond to antibiotics**.
 - The discharge may initially be unilateral and progress to bilateral involvement.
- **Snoring, snorting, inspiratory stridor, stertor or dyspnea from nasal obstruction**.
- Facial distortion, e.g. elevation of bridge of nose (Roman nose) or facial swelling.
- Epiphora (associated with obstruction of the lacrimal duct), or a bloody ocular discharge.
- Signs of **retrobulbar pressure** may be present, e.g. exophthalmos and ocular deviation.

- Occasionally, central nervous system signs occur, e.g. seizures, circling, ataxia, behavioral change.
 - Signs may be present for days, or in rare cases, for as long as 2 years. Usually, signs are present for less than 6 months prior to diagnosis.

Diagnosis

Cytological examination of an **impression smear**, or **biopsy and histological examination** of the lesion is usually diagnostic for squamous cell carcinoma of the **external nares**.

Intranasal tumors require a more **invasive approach**. Cytological examination of the discharge or atraumatic nasal flush usually reveals evidence of inflammation (neutrophils and bacteria) but no tumor.

- **Radiography** demonstrates increased opacity of the nasal cavity and often **destruction of the turbinates, nasal septum, lateral bone and loss of teeth** adjacent to the lesion. Radiographic changes are often unilateral or asymmetrical.
- A **traumatic flush using a stiff catheter** and syringe (e.g. cut-off dog urinary catheter) yields better results than an atraumatic flush.
- A **biopsy** is often required to obtain tissue for a histological diagnosis. Tissue may be obtained using biopsy **forceps** through the external nares or via a **rhinotomy**.

Differential diagnosis

Cryptococcosis can produce very similar signs to intranasal tumors. However, 70% of cats with cryptococcosis have either **distortion of the bridge of the nose** or a **polyp-like mass** visible projecting from the nasal cavity.

- Most have a positive *Cryptococcus* titer.
- Cats with cryptococcosis tend to be younger than cats with neoplasia.
- **Chronic bacterial infection** of the nasal cavity secondary to viral upper respiratory disease may produce similar signs. However, signs are typically present for longer, and only very rarely is there nasal distortion.

Treatment

Treatment of squamous cell carcinoma involving the external nares depends on the extent of local invasion.

- **Radiotherapy, cryotherapy, intralesional chemotherapy, or resection of the nasal planum** are indicated depending on the lesion.
- If ulcerated and erosive, radical resection of the nasal planum yields best results.

Lymphoma is best treated with radiotherapy and/or chemotherapy.

Other tumors of the nasal cavity have a guarded to poor prognosis. At the time of diagnosis, there is usually **extensive local invasion**, and the **recurrence rate after radiotherapy and/or surgery is high**.

Prognosis

Squamous cell carcinoma of the external nares can have a good prognosis if the lesion is small, or if radical resection of the nasal planum totally removes the tumor. Local recurrence may occur, but the tumor is slow to metastasize.

Lymphoma has a guarded prognosis, but may respond to chemotherapy or radiotherapy.

Other **intranasal tumors** have a **very poor prognosis**, especially if destruction of the turbinates is evident radiographically.

CRYPTOCOCCOSIS*–**

Classical signs

- Chronic nasal discharge and sneezing, progressing in severity.
- Soft-tissue swelling over the nasal bones (Roman nose), or polyp-like mass in nasal cavity.

Pathogenesis

Cryptococcus neoformans most commonly produces granulomatous lesions in the nasal cavity or paranasal sinuses.

Disease is caused by *Cryptococcus neoformans neoformans* or *Cryptococcus neoformans gattii*.

Cryptococcus neoformans neoformans is shed in pigeon feces; high concentrations of organisms are

found in soil contaminated by pigeon droppings, and in the debris of pigeon roosts.

Cryptococcus neoformans gattii is found in the **developing flower of Red River gums** and forest red gums; high concentrations of organisms are found in the bark and the accumulated debris surrounding the base of the tree.

- These trees have been widely exported around the world from Australia.

Organisms are **viable for at least 2 years**, if protected from direct sunlight and drying.

Nasal infection occurs via inhalation of airborne organisms or contamination of the wound with organisms.

- There are **no reports of transmission between animals or people**; infection is from the environment.
- Cell-mediated immunity may be compromised in infected animals; there are some reports of a higher incidence of FIV infection in cats with *Cryptococcus*.
- **Cats are more susceptible** than dogs or humans.
- Any age of cat can be infected, but the **average age is 5 years** (younger than cats with neoplasia).
- Following inhalation, the organism deposits in the **upper respiratory tract producing nasal granulomas**, or deposits in the alveoli producing pulmonary granulomas, which are usually subclinical.
- The organism **may disseminate through the cribriform plate** or via the blood to the central nervous system (CNS).
- If CNS signs develop, cats may or may not have concurrent signs of respiratory infection.

In cats with cryptococcosis, **50–80% have respiratory disease** involving mainly the nasal cavity, and **10–40% have cutaneous or subcutaneous lesions**. **Central nervous system (CNS) involvement and ocular disease** are less common.

Clinical signs

Upper respiratory tract signs are most common, and include **sneezing, snuffling and chronic nasal discharge**.

- Nasal discharge may be unilateral or bilateral, and serous, mucopurulent or hemorrhagic.

Distortion and swelling over the bridge of the nose, or a **polyp-like mass** projecting from the nasal cavity are present in 70% of cats with the respiratory form.

Depression, anorexia or inappetence and **weight loss** are often present with nasal or CNS involvement.

Submandibular lymph nodes are often **enlarged**.

Skin lesions consist of **papules or nodules** varying from 0.1–1 cm in diameter.

- Lesions may ulcerate and exude serous fluid, or remain as intact nodules.
- Skin lesions may be single or multiple, and occur alone, or with involvement of other organs.

Central nervous system signs result from inflammation of the brain and meninges or a mass lesion (granuloma).

- Signs reported are referable to the **cerebrum** (seizures, circling, ataxia, behavioral change, head pressing, blindness), or **brainstem** (head tilt, nystagmus, facial paralysis, paresis, ataxia, circling).
- Occasionally, signs are referable to the spinal cord.

Ocular signs include epiphora, dilated unresponsive pupils, blindness and anterior uveitis.

Occasionally, other organs are involved, e.g. bone, kidney.

Diagnosis

Diagnosis is based on **cytological identification of the organism** in nasal discharge, exudate from skin lesions, lymph node aspirate, cerebrospinal fluid (CSF) or ocular aspirate.

- Stain sample with **new methylene blue**, Indian ink or Diff-Quick.
- *Cryptococcus* appears as **yeast-like organisms** (5–15 µm) surrounded by a **wide, clear capsule**.
- Organism **buds from a narrow base**, in contrast to *Blastomyces* which has broad-based budding and thinner capsule.

Serology to detect cryptococcal capsular antigen in blood, CSF, or urine is **sensitive and specific**.

Tissue biopsy of the granulomatous mass or skin lesion, and histological identification of the organism may be required if cytology is negative.

Fungal isolation with **culture** is rarely required for diagnosis, but is **useful for sensitivity testing**.

Radiographs often reveal **turbinate lysis and opacity** of the nasal cavity (soft-tissue density). Sinus involvement is common.

Differential diagnosis

Neoplasia may have similar signs. The presence of a polyp-like mass in the nose, or swelling over the bridge of the nose suggest cryptococcosis rather than neoplasia. Cats with neoplasia are on average older than cats with cryptococcosis.

Chronic bacterial infection of the nasal cavity secondary to viral upper respiratory disease has similar signs. However, it is only rarely associated with nasal distortion.

Treatment

Best success occurs using a **multi-drug regime** comprising of **amphotericin** (fungicidal) plus **5-fluorocytosine** (flucytosine), combined with or followed by **fluconazole** or **itraconazole** (fungistatic).

- **Amphotericin B is very nephrotoxic**, so use diuresis to protect the kidneys. Liposomal or lipid-encapsulated amphotericin B are safer than regular amphotericin B but are expensive.
 - Amphotericin B can be given IV (see standard texts) or SC (0.5–0.8 mg/kg) in 400 ml of 0.45% saline containing 2.5% dextrose. Administer subcutaneously two or three times a week for 1–3 months, until a total cumulative dose of 12–26 mg/kg is reached. Monitor serum creatinine, urea (more sensitive, but influenced by many non-renal factors) and urine specific gravity and sediment for casts. If azotemia develops, discontinue amphotericin until it resolves and reduce dose (Malik et al. 1996).

Sensitivity to amphotericin toxicity varies considerably between cats, and some cats develop acute renal failure with relatively small doses. It is imperative that serum urea concentration and urine are checked prior to each dose. The client should be instructed to return immediately if the cat becomes lethargic, inappetent or is vomiting.

Combine with 5-fluorocytosine 50 mg/kg q 8 h PO.

Either during or after the course of amphotericin is completed, **use an imidazole/triazole** to mop up infection (fungistatic):

- **Ketaconazole is cheapest**, but has most side effects (anorexia, vomiting, hepatic disease) and is perhaps least potent (10 mg/kg PO q 12–24 h).
- **Itraconazole** may work better than ketaconazole, and has fewer side effects (5 mg/kg PO q 12–24 h).

- **Fluconazole** is better for CNS infection, but is expensive (2.5–10 mg/kg PO q 12 h).

Approximately **3 weeks of treatment are required before there is an improvement in clinical signs.**

A **decreasing serum *Cryptococcus* titer is predictive of recovery**, but depending on the laboratory, it may be expensive to get the actual titer measured.

Clinical signs return if treatment is stopped too early. Ideally, **treat until titer is negative, which may be longer than 1 year.** However, some healthy cats remain antibody positive. If the cat is clinically healthy and the titer drops 16–32-fold, it is unlikely to relapse.

Alternatively treat for 4 weeks after resolution of all signs, with a minimum treatment period of 8 weeks. Relapses are more common with these shorter treatment periods.

Prognosis

Prognosis is variable. A falling titer in response to therapy suggests optimistic prognosis for cure. Prognosis is guarded if there is CNS involvement.

CONGENITAL ANOMALY OF THE NOSE OR HARD PALATE**

Classical signs

- Chronic snuffling and stertorous respiration.
- Dyspnea or mouth breathing.
- Narrow external nares.

Pathogenesis

Congenital stenosis of the external nares is common in some breeds, e.g. **Persians, Himalayans.**

- The combined effects of stenosis of the external nares and reduced nasal air space cause respiratory obstruction.
- Partial obstruction results in **increased respiratory effort and stertorous respiration.**
- **With stress** (e.g. visit to veterinarian or cat show), stridor becomes more pronounced, and **cats may become severely dyspneic and mouth breath.**

Clinical signs

Typically, there is **chronic snuffling and stertorous respiration** from the nasal region. Signs may be evident most or all of the time if the stenosis is severe.

Dyspnea or mouth breathing occurs with stress.

Narrow external nares are visible on physical examination.

Diagnosis

The diagnosis is usually based on clinical signs (nasal stridor) and physical examination (stenotic nares).

Differential diagnosis

The features of stenotic nares (signs since the cat was a young adult, cranial nasal stertor and narrow external nares) make most other diseases unlikely.

Treatment

Treatment involves surgical removal of the wing of the nostril.

Prognosis

Prognosis is good with surgery, provided there is not concurrent marked narrowing of the nasal cavity.

SECONDARY RHINITIS ASSOCIATED WITH DENTAL DISEASE*

Classical signs

- Chronic sneezing.
- Chronic unilateral or bilateral mucopurulent nasal discharge, which may be bloody.
- Oronasal fistula.

Pathogenesis

An **oronasal fistula** may result in **low-grade chronic rhinitis**, because **food and fluids enter the nose** from the mouth.

An oronasal fistula usually results from **advanced periodontal disease** of the **canine teeth**, with or without loss of the tooth.

- Often, the tooth is still present, and a **deep periodontal pocket** extends into the nasal cavity or maxillary sinus.
- Occasionally, a **periapical abscess from a dental fracture or caries** results in rhinitis.
- Iatrogenic oronasal fistula may result from poor dental extraction technique.

Clinical signs

Chronic sneezing, and mucopurulent nasal discharge, which may be blood-tinged.

Presence of an **ornasal fistula** associated with tooth loss or advanced periodontal disease, or a tooth fracture suggesting a periapical abscess.

- Examination under deep sedation or general anesthesia is often required for diagnosis.

Diagnosis

Diagnosis is based on signs of chronic nasal disease and the presence of an oronasal fistula.

Rarely, a periapical abscess is the cause. This is visible on radiograph.

Differential diagnosis

Visualization of the oronasal fistula is diagnostic.

- Very rarely another disease process is also present, and is responsible for the signs of chronic nasal disease, e.g. oronasal fistula with concurrent neoplasia or chronic bacterial infection secondary to viral upper respiratory tract disease.
- **Radiograph the nose prior to surgery.** Evidence of turbinate lysis suggests tumor, cryptococcosis or chronic bacterial rhinitis secondary to herpesvirus.
- Failure to respond to surgery suggests another disease process.

Treatment

Seal oronasal fistula surgically using a mucoperiosteal pedicle flap.

Prognosis

Prognosis is excellent, if the fistula is successfully closed, but some fistulas may be difficult to close.

FOREIGN BODY

Classical signs

- **Acute onset of sneezing and rubbing face, progressing to chronic signs.**
- **Unilateral discharge.**
- **Gagging.**

Pathogenesis

Most foreign bodies are of **plant origin**, and are either **grass, grass seeds or awns**.

Shotgun or airgun pellets, wood or bone are less frequent.

Clinical signs

Signs depend on where the foreign body lodges. Foreign bodies lodging in the nasal cavity cause sneezing and nasal discharge. Blades of grass tend to lodge in the nasopharynx and produce gagging.

Typically, there is a sudden onset of:

- **Sneezing**, which initially is **marked and paroxysmal**, and then becomes chronic.
- **Rubbing or pawing** at the nose.
- **Unilateral nasal discharge**, which is initially **serous or blood-tinged**, but progresses to **mucopurulent** and may be bloody.
- **Gagging** occurs when the foreign body lodges in the nasopharynx, or discharge drains into the pharynx from a foreign body in the posterior nasal cavity.

Diagnosis

Diagnosis is **based on visualizing** the foreign body using:

- An **otoscope or rhinoscope** for foreign bodies in the anterior nasal cavity.
- A **dental mirror** (warmed and sprayed with defogging agent) for foreign bodies in the caudal nasal cavity and nasopharynx. Pull the soft palate rostrally to improve the view.
- A **nasal flush** may remove all or parts of the foreign body for diagnosis.
- **Rhinotomy**, when all else fails.

Radiographs are rarely diagnostic, except for gun pellets.

Differential diagnosis

Chronic bacterial rhinitis secondary to viral upper respiratory infection may produce **similar laboratory findings** with neutrophils and bacteria, and no neoplastic or fungal elements. However, the **discharge** is typically **bilateral**, whereas with a foreign body it is typically unilateral.

Neoplasia and cryptococcosis may have similar signs, and the discharge is initially often unilateral. Positive diagnosis can be difficult with neoplasia and foreign bodies, and may require a rhinotomy.

Treatment

Treatment involves **removing the foreign body** by flushing, or grasping with forceps via the nares, nasopharynx or rhinotomy.

Prognosis

The prognosis is excellent if the foreign body can be entirely removed.

ORONASAL FISTULA OR NASAL FRACTURES FOLLOWING TRAUMA

Classical signs

- Chronic snuffling, sneezing and nasal discharge.
- Cleft hard palate (lateral or midline).

Pathogenesis

Cats that have been **hit by a car**, or have **jumped out of a high-rise building** often have **splitting of the hard palate along the symphysis**.

Signs of chronic nasal discharge and sneezing result when food and water enter the nasal cavity.

Spontaneous healing of the cleft often occurs within 2–3 weeks.

If the hard palate is shattered into several pieces, **necrosis of a fragment** may occur, forming an **oronasal fistula**.

Clinical signs

Typically there is chronic snuffling, sneezing and nasal discharge in a cat that sustained facial injuries in a fall or car accident.

Examination reveals a **split hard palate** either **centrally along the palatine symphysis**, or **laterally adjacent to the teeth** along the maxillary symphysis.

Signs often resolve spontaneously with spontaneous healing of the cleft.

Diagnosis

Diagnosis is based on a history of trauma, signs of nasal disease and visual evidence of the cleft.

Differential diagnosis

Congenital cleft palate may look similar, but usually signs are present from a few weeks of age, rather than a recent onset following trauma.

Oronasal fistula associated with dental disease may produce similar signs; evidence of advanced periodontal disease and lack of history or evidence of facial trauma should allow differentiation.

Treatment

If spontaneous resolution does not occur in 2–3 weeks, surgical repair is necessary.

Prognosis

Good.

CHLAMYDOPHILA FELIS (CHLAMYDOPHILA FELIS PSITTACI) AND MYCOPLASMA

Classical signs

- Chronic ocular-nasal discharge.
- Chronic conjunctivitis.
- Chronic sneezing.

See main references on page 13 for details (The Cat With Acute Sneezing or Nasal Discharge) and Page 1215 (The Cat With Ocular Discharge or Changed Conjunctival Appearance).

Clinical signs

Chlamydophila and mycoplasma infection may result in **chronic mucopurulent ocular and nasal discharge**.

Typically there is **chronic conjunctivitis**. **Follicular hyperplasia of lymphoid tissue** in the conjunctiva and nictitating membrane is often visible as multiple, small white nodules.

Chronic sneezing may occur.

Diagnosis

A **presumptive diagnosis** is often made based on signs. A **definitive diagnosis** is based on identification of the organism.

- Examine a stained (e.g. Diff-Quick) preparation of a conjunctival scraping or smear obtained with a dry cotton bud. *Chlamydophila felis* infection is associated with **inclusion bodies** in epithelial cells but they are difficult to identify in chronic disease. Mycoplasma is seen as clusters of coccoid or coccobacillary organisms in the periphery of epithelium cells.

Antibody-based detection in conjunctival scrapings using ELISA or latex agglutination may be useful for *Chlamydophila felis*, but false positives occur with both tests if many bacteria are present.

Polymerase chain reaction (PCR) and **IFA techniques** for detection of the organisms are also available from some laboratories.

NASOPHARYNGEAL STENOSIS

Classical signs

- Stertorous respiration from nasal area, \pm dyspnea.
- No nasal discharge.

See main reference on page 38 for details (The Cat With Stridor).

Clinical signs

Chronic snuffling is typically present for 3 months to 2 years.

Stertorous respiration (snoring) or stridor (whistling noise) may be evident, and results from partial nasal obstruction. **Dyspnea** may occur, particularly when the cat is stressed.

Retching or gagging may occur on eating.

No or minimal nasal discharge is present.

Diagnosis

With the cat under general anesthesia, visualize the stenosis with a dental mirror. Pull the soft palate rostrally for an improved view.

- Stenosis is visible as a **pin-point opening in the nasopharynx**. The normal opening is approximately 5 mm in diameter.

Radiographs are generally normal.

NASOPHARYNGEAL POLYP

Classical signs

- Stertorous respiration from nasal area, or dyspnea.
- \pm Nasal discharge.

See main reference on page 37 for details (The Cat With Stridor).

Clinical signs

Stertorous respiration is audible from the nasal area. If the obstruction is severe, there may be dyspnea, and open mouth breathing may occur with stress.

There may be **no nasal discharge**, or a mucopurulent discharge may be evident.

Discharge from ear and **signs of otitis media** may also be present.

Diagnosis

With the cat under general anesthesia, **visualize the polyp directly or with a dental mirror**. Pull the soft palate rostrally for an improved view. The rostral soft palate may bulge down into the oral cavity with pressure from the polyp.

Radiography reveals a rounded density in the nasopharynx, just caudal to the hard palate.

ALLERGIC RHINITIS

Classical signs

- **Acute or chronic serous or mucoid nasal discharge, often seasonal.**

Clinical signs

Allergic rhinitis appears to be a rare and poorly documented condition in cats.

It presents as serous or mucoid ocular and/or nasal discharge, with no systemic signs and is typically seasonal in occurrence.

It has been reported associated with allergy to **Japanese cedar** (*Cryptomeria japonica*).

Diagnosis

Diagnosis is based on **exclusion of all other causes** of nasal discharge and biopsy results indicating rhinitis with no evidence of underlying pathogens. A mixed neutrophilic and eosinophilic rhinitis has been reported.

Most cases with similar signs are the result of viral upper respiratory disease often with chronic bacterial rhinitis cases.

Treatment

A combination of antihistamine and steroid may work well in some cats. For example, Temaril-P (1/4 to 1/2 tablet PO q 12–24 h).

4. The cat with stridor or stertor

Jacquie Rand and Robert Allen Mason

KEY SIGNS

- Stridor.
- Snuffling.
- Snoring.

MECHANISM?

- Stridor is a harsh, high-pitched respiratory sound and stertor is a snoring sound created by upper airway obstructive diseases, such as laryngeal obstruction. Airflow through a narrowed upper airway has increased resistance and becomes more turbulent.
- With dynamic obstructions, such as laryngeal paralysis and tracheal collapse, the airflow limitation occurs mainly during inspiration. Fixed obstructions, such as foreign objects and mass lesions, affect airflow during both inspiration and expiration.

WHERE?

- Stridor or stertor arise from luminal narrowing in the upper airways, generally involving the pharynx, soft palate, laryngeal structures and the upper trachea. Nasal stridor may also be encountered.

WHAT?

- Most cats with respiratory stridor have nasal disease. Persians and Himalayans frequently have respiratory stridor from stenotic nares. Chronic bacterial rhinitis following viral upper respiratory tract infection, neoplasia or *Cryptococcus* infections are the most common acquired causes of stridor.

NASAL STRIDOR

QUICK REFERENCE SUMMARY

Diseases causing stridor or stertor

ANOMALY

- **Stenosis of the external nares** (p 35)**

Breed-related obstruction of the external nares (e.g. Persian cats) causes chronic snuffling and stertorous respiration.

MECHANICAL

- Foreign body (grass, grass seed, awn) (p 40)

Acute onset of sneezing and rubbing face or gagging followed by chronic unilateral nasal discharge and sneezing. Occasionally stridor.

NEOPLASTIC

- **Neoplasia** (p 36)**

Chronic mucopurulent or hemorrhagic nasal discharge, often initially unilateral progressing to bilateral, sneezing, stertorous respiration ± facial distortion.

- Nasopharyngeal polyp (p 37)

Chronic snuffling, stertorous respiration and dyspnea from nasal obstruction, retching or gagging with eating ± mucopurulent nasal discharge.

INFLAMMATION

- Nasopharyngeal stenosis (p 38)

Chronic snuffling, partial nasal obstruction, retching or gagging with eating.

INFECTIOUS

Bacterial:

- **Secondary bacterial rhinitis*** (p 35)**

Typically there is a history of signs of chronic bacterial rhinitis occurring following acute viral upper respiratory tract disease. Signs include chronic mucopurulent or hemorrhagic nasal discharge, sneezing, stertorous respiration and occasionally nasal distortion.

Fungal:

- **Cryptococcosis and other fungi** (p 36)**

Cryptococcosis typically results in chronic mucopurulent or hemorrhagic nasal discharge, sneezing, stertorous respiration and distortion over bridge of nose (Roman nose), or a polyp-like mass in the nasal opening. Occasionally there are signs of a nasopharyngeal mass only. Other fungi such as *Aspergillus*, *Penicillium*, *Sporothrix* and some other fungi are very rare causes of chronic nasal disease.

Chlamydophila and *Mycoplasma* spp:

- *Chlamydophila* and *Mycoplasma* spp (p 38)

Chronic ocular and nasal discharge, and chronic conjunctivitis. Sneezing and occasionally stridor.

Trauma:

- Oronasal fistula or nasal fractures following trauma (p 39)

Chronic snuffling, sneezing, stridor or stertor and nasal discharge associated with cleft palate or obstructed nasal cavity.

continued

continued

STRIDOR FROM PHARYNGEAL, LARYNGEAL OR TRACHEAL AREA

Degenerative:

- Laryngeal paralysis (p 43)

Generally neurogenic paresis/paralysis of the abductor muscles of the arytenoid cartilages of the larynx. Often idiopathic, although traumatic causes are reported. Inspiratory dyspnea with stertor (snoring sounds) or stridor (whistling obstructive sounds) is the hallmark of laryngeal paralysis. Changes in voice and character of purring are often reported by owner.

- Tracheobronchial collapse (p 44)

Harsh, “honking” cough caused by degeneration of the cartilage support of the large airway walls. If upper cervical trachea is involved, stridor may be present. Rare in cats.

Anomaly:

- **Congenital anomalies of the upper respiratory tract* (p 39)**

Dyspnea usually indicates fixed obstruction (inspiratory and expiratory) because of the stenotic nature of most defects. Inspiratory dyspnea, stertor and stridor occur with the brachycephalic syndrome.

Mechanical:

- Airway foreign bodies (p 40)

Harsh, productive cough and acute dyspnea occur with foreign objects that have been inhaled, regurgitated or aspirated into the nasopharynx, trachea or bronchi. Stridor is noted when the foreign body is lodged in the larynx or trachea. Nasal foreign bodies create a form of stridor that has a more whistling character than laryngeal stridor. Sneezing and nasal discharge are common with nasal foreign bodies.

Neoplastic:

- Airway tumors (p 41)

Signs depend on the site of the tumor. Nasal tumors causing obstruction may produce stridor and open-mouth breathing. Pharyngeal tumors causing obstruction may result in dysphagia, stridor, stertor and voice changes. Tracheal tumors result in a fixed obstruction, and inspiratory and expiratory dyspnea, stridor and commonly a cough.

Inflammation:

- Laryngeal edema (p 42)

Usually occur secondary to an allergic reaction, following alphaxalone/alphadolone anesthesia or laryngeal trauma. Signs include inspiratory dyspnea and stertorous breathing or stridor.

- Laryngeal stenosis (p 42)

Common in cats after laryngeal trauma or surgery. Results in dyspnea and stridor on inspiration.

- Laryngeal eosinophilic granuloma (p 45)

Occurs weeks or months after signs of viral upper respiratory tract infection. Signs include stridor from the laryngeal region and swollen, edematous arytenoid cartilages of larynx.

INTRODUCTION

MECHANISM?

Airflow through a narrowed upper airway has increased resistance and becomes more turbulent. This resistance is a function of the diminished luminal diameter of the tube, **the resistance increasing to the fourth power of the radius.**

With **dynamic obstructions, dyspnea occurs during inspiration**, because the negative intraluminal airway pressure creates a vacuum, pulling the walls inwardly. Any weakened area of the airway wall will tend to move into the lumen, decrease the luminal diameter, and create an obstruction.

Fixed obstructions cause both inspiratory or expiratory stridor, although inspiratory noises are more prominent.

Stertor are snoring sounds. Stridor is a harsh, high-pitched whistling respiratory sound created by upper airway obstructive diseases, such as the inspiratory sound of acute laryngeal obstruction.

WHERE?

Stridor or stertor arise from luminal narrowing in the **upper airways**, generally involving the pharynx, soft palate, laryngeal structures and the upper trachea. Nasal stridor or stertor may also be encountered.

WHAT?

With dynamic obstructions, the airflow limitation occurs mainly during inspiration. Dynamic obstructions include **laryngeal paralysis, tracheal collapse and epiglottic entrapment.**

Fixed obstructions, such as **foreign objects and mass lesions**, affect airflow during both inspiration and expiration, although inspiratory noises are generally more prominent.

DISEASES CAUSING NASAL STRIDOR

SECONDARY BACTERIAL RHINITIS***

Classical signs

- Chronic sneezing and snuffling.
- Chronic mucopurulent nasal discharge.
- Stertorous respiration or stridor.
- Occasionally, nasal distortion.

See main reference on page 21 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Chronic secondary bacterial rhinitis occurs in some cats following viral upper respiratory tract disease.

Typically there is a history of chronic sneezing and snuffling following acute upper respiratory tract signs.

Chronic mucopurulent nasal discharge.

Stertorous respiration (snoring) or stridor (high pitched whistling respiration).

Occasionally, nasal distortion.

Diagnosis

Diagnosis is based on a history of chronic signs of long duration (>6 months), especially if the history includes acute upper respiratory tract signs preceding the chronic problem. Diagnosis is based on exclusion of neoplasia and cryptococcosis.

STENOSIS OF THE EXTERNAL NARES**

Classical signs

- Chronic snuffling and stertorous respiration or stridor.
- Dyspnea or mouth breathing.
- Narrow external nares.

Pathogenesis

Congenital stenosis of the external nares is common in some breeds, e.g. Persians, Himalayans.

The combined effects of stenosis of the external nares and reduced nasal air space cause respiratory obstruction.

Partial obstruction results in increased respiratory effort and stertorous respiration or stridor.

With stress (e.g. visit to veterinarian or cat show), stridor becomes more pronounced, and cats may become severely dyspneic and mouth breath.

Clinical signs

Chronic snuffling and stertorous respiration or stridor.

Dyspnea or mouth breathing.

Narrow external nares in a brachycephalic cat.

Diagnosis

Based on clinical signs and physical examination.

Treatment

Surgical removal of the wing of the nostril.

NEOPLASIA **

Classical signs

- Progressively worsening chronic sneezing and snuffling.
- Purulent or blood-tinged nasal discharge, which may temporarily respond to antibiotics.
- Nasal obstruction and epiphora.
- Occasionally facial distortion ± signs of retrobulbar pressure, e.g. exophthalmos.

See main reference on page 23 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Chronic sneezing and snuffling, which progressively worsen with time.

Purulent or bloody nasal discharge, which may temporarily respond to antibiotics.

The discharge may **initially be unilateral** and **progress to bilateral involvement**.

Snoring, snorting, inspiratory stridor, stertor or dyspnea from nasal obstruction are common.

Facial distortion, e.g. elevation of bridge of nose (Roman nose) or facial swelling may be evident.

Epiphora (associated with obstruction of the lacrimal duct), or a bloody ocular discharge may occur.

Signs of **retrobulbar pressure** may be present, e.g. exophthalmos and ocular deviation.

Occasionally, central nervous system signs, e.g. seizures, circling, ataxia, behavioral change occur.

Nasal signs may be present for days, or in rare cases, for as long as 2 years. Usually, signs are present for less than 6 months prior to diagnosis.

Diagnosis

Radiography demonstrates increased opacity of the nasal cavity and often destruction of the turbinates, nasal septum, lateral bone and loss of teeth adjacent to the lesion. Radiographic changes are often unilateral or asymmetrical.

Cytological examination of the discharge or atraumatic nasal flush usually reveals evidence of inflammation (neutrophils and bacteria) but no tumor.

A traumatic flush using a stiff catheter and syringe (e.g. cut-off dog urinary catheter) yields better results than an atraumatic flush.

A biopsy is often required to obtain tissue for a histological diagnosis. Tissue may be obtained using biopsy forceps through the external nares or via a rhinotomy.

CRYPTOCOCCOSIS AND OTHER FUNGI**

Classical signs

- Chronic nasal discharge, stridor and sneezing, progressing in severity.
- Soft tissue swelling over the nasal bones (Roman nose), or polyp-like mass in nasal cavity.

See main reference on page 25 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Sneezing, snuffling, stridor or stertor and chronic nasal discharge are most common with cryptococcosis.

Nasal discharge may be unilateral or bilateral, and serous, mucopurulent or hemorrhagic.

Distortion and swelling over the bridge of nose, or a polyp-like mass projecting from the nasal cavity are present in 70% of cats with the respiratory form of cryptococcosis.

Depression, anorexia or inappetence and weight loss are often present with nasal or CNS involvement.

Mandibular lymph nodes are often enlarged.

Vestibular disease has been reported associated with cryptococcal infection.

Aspergillus, *Penicillium*, *Sporothrix* and some other fungi are very rare causes of chronic nasal disease.

Diagnosis

Cytological identification of the organism in nasal discharge, exudate from skin lesions, lymph node aspirate, cerebrospinal fluid (CSF), or ocular aspirate is diagnostic. Note that very occasionally small numbers of organisms may be cultured from the nasal exudate of normal cats.

Serology to detect cryptococcal capsular antigen in blood, CSF, or urine is **sensitive and specific**.

Tissue biopsy of the granulomatous mass or skin lesion, and histological identification of the organism may be required if cytology is negative.

PCR (polymerase chain reaction) assays are now available to detect cryptococcal antigens in biopsy material.

Fungal isolation with **culture** is rarely required for diagnosis, but is **useful for sensitivity testing**.

Radiographs often reveal **turbinate lysis and opacity** of the nasal cavity (soft tissue density). Sinus involvement is common.

NASOPHARYNGEAL POLYP

Classical signs

- Nasal discharge and congestion.
- Inspiratory dyspnea and stridor.

Classical signs—Cont'd

- Chronic non-responsive otitis, head tilt and Horner's syndrome.

Clinical signs

Nasopharyngeal polyps are thought to **occur secondary to chronic upper respiratory tract inflammation** as they consist of inflammatory tissue covered by epithelium. They are thought to **arise from the Eustachian tube or bulla**.

They are a **relatively common cause of stridor and dyspnea**, and typically occur in young cats (average age 1½ years old), and most begin to exhibit signs before they are 1 year of age. Abyssinians may be pre-disposed.

Chronic mucopurulent nasal discharge and congestion is common, but may be absent.

Inspiratory noises, usually stridor, but sometimes stertor, along with dyspnea and open-mouth breathing have been reported.

Signs of ear disease, including chronic discharge, head tilt and possibly Horner's syndrome on the affected side, may be present.

Diagnosis

Radiographs or CT may show a soft tissue **mass lesion in the nasopharynx**

Rhinoscopy and otoscopy are valuable in visualizing the mass and obtaining biopsy material. The polyp may be visualized directly or with a dental mirror. The rostral soft palate may bulge down into the oral cavity with pressure from the polyp. Pull the soft palate rostrally for an improved view.

Differential diagnosis

Tracheitis from feline rhinotracheitis virus is generally associated with other upper respiratory signs.

Laryngeal paralysis or edema, tracheal foreign body, and tracheobronchial neoplasm can be differentiated endoscopically.

Nasopharyngeal stenosis may have similar signs, and caudal rhinoscopy is required to distinguish this from polyp formation.

Treatment

Surgical therapy to remove the polyp is required. Concurrent bulla osteotomy may be needed to remove the entire source of the polyp and prevent recurrence. Generally, removal is via the mouth. The soft palate is retracted and the base of the polyp grasped with forceps. Gentle traction should be applied until the polyp detaches. Alternatively, the stalk may be cut. Bleeding may be profuse, but more often is minimal.

NASOPHARYNGEAL STENOSIS

Classical signs

- Stertorous respiration from nasal area.
- Dyspnea.
- No or minimal nasal discharge.

Pathogenesis

Rare condition thought to arise secondary to chronic nasal inflammation or trauma.

A strong membrane forms across the nasopharynx. It may completely occlude the nasopharyngeal opening, or more often it reduces the opening to pin-point size.

Clinical signs

Chronic snuffling of 3 months to 2 years duration is reported.

Any age of cat from < 1 year to 10 years may be affected.

Stertorous respiration (snoring) or stridor (whistling noise) occurs from partial nasal obstruction.

Dyspnea, or open-mouth breathing may occur.

Retching or gagging may be evident on eating.

No or minimal nasal discharge.

Diagnosis

With the cat under general anesthesia, visualize the stenosis with a dental mirror. Pull the soft palate rostrally for an improved view.

Stenosis is visible as a pin-point opening in the nasopharynx (normal opening is approximately 5 mm).

Radiographs are generally normal.

Diagnosis

Diagnosis is based on the history, signs and visual evidence of the stenosis.

Treatment

Treatment involves surgical removal of the stenosis.

Prognosis

Prognosis is good with surgery

CHLAMYDOPHILIA AND MYCOPLASMA

Classical signs

- Chronic ocular-nasal discharge.
- Chronic conjunctivitis.
- Acute or chronic sneezing.
- Stertor and stridor

See main references on page 13 for details (The Cat With Acute Sneezing or Nasal Discharge) and pages 1215, 1218 (The Cat With Ocular Discharge or Changed Conjunctival Appearance).

Clinical signs

Chlamydomphila felis and *Mycoplasma* spp. infection may result in initial acute signs of upper respiratory tract infection progressing to chronic conjunctivitis, chronic mucopurulent ocular and nasal discharge.

Sneezing and occasionally stridor or stertor may occur.

Follicular hyperplasia of lymphoid tissue in the conjunctiva and nictitating membrane is often visible as **multiple, small white nodules** in *Chlamydomphila* infection.

Diagnosis

A **presumptive diagnosis** is often made based on signs. A **definitive diagnosis** is based on identification of the organism.

Examine a stained (e.g. Diff-Quick) preparation of a conjunctival scraping or smear obtained with a dry cotton bud. *Chlamydophila felis* infection is associated with **inclusion bodies** in epithelial cells but they are difficult to identify in chronic disease. Mycoplasma is seen as clusters of coccoid or coccobacillary organisms in the periphery of epithelium cells.

Antibody-based detection in conjunctival scrapings using ELISA or latex agglutination may be useful for *Chlamydophila felis*, but false positives occur with both tests if many bacteria are present.

Polymerase chain reaction (PCR) and IFA techniques for detection of the organisms are also available from some laboratories.

ORONASAL FISTULA OR NASAL FRACTURES FOLLOWING TRAUMA

Classical signs

- Chronic snuffling, sneezing, stridor or stertor and nasal discharge .
- Cleft hard palate (lateral or midline).

See main reference on page 29 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Typically there is chronic snuffling, sneezing, **stridor or stertor**, and nasal discharge in a cat that sustained facial injuries in a fall or car accident.

Examination may reveal a **split hard palate** either **centrally along the platine symphysis**, or **laterally adjacent to the teeth** along the maxillary symphysis.

Signs often resolve spontaneously with spontaneous healing of the cleft or nasal fracture.

Diagnosis

Diagnosis is based on a history of trauma, signs of nasal disease, visual evidence of the cleft and radiography.

FOREIGN BODY (GRASS, GRASS SEED, AWN)

Classical signs

- Acute onset of sneezing and rubbing face, progressing to chronic signs.
- Unilateral discharge.
- Gagging.

See main reference on page 28 for details (The Cat With Signs of Chronic Nasal Disease).

Grass or seeds may occasionally enter the nose of cats. Other foreign bodies such as gun pellets are less common.

Clinical signs

Typically there is an **acute onset of sneezing and distress**, and rubbing at the face.

Signs may progress to chronic gagging, or sneezing and discharge.

A **unilateral** serosanguineous discharge is typically present.

Diagnosis

Visualize foreign body using an otoscope, fiber-optic scope, or with a dental mirror in the nasopharynx. Use a spay hook to retract the soft palate for better visualization.

Flushing the nose using a naso-esophageal feeding catheter may remove parts or all of the whole foreign body for diagnosis.

THE CAT WITH PHARYNGEAL, LARYNGEAL OR TRACHEAL STRIDOR OR STERTOR

CONGENITAL ANOMALIES OF THE UPPER RESPIRATORY TRACT*

Classical signs

- Usually inspiratory and expiratory dyspnea.
- Inspiratory dyspnea with both stridor and stertor occurs with the brachycephalic syndrome.

Pathogenesis

Congenital anatomic anomalies characteristic of **brachycephalic breeds (Persians, Himalayans)**, are related to the flat face and short neck. Stenotic nares is the most commonly evident anomaly.

Brachycephalic syndrome includes stenotic nares, elongated soft palate, eversion of the lateral laryngeal ventricles, laryngeal collapse and hypoplastic trachea.

Clinical signs

Stenotic nares, hypoplastic trachea, etc., create a non-dynamic, fixed obstruction leading to inspiratory and expiratory dyspnea.

Dynamic obstructions occur with an elongated soft palate and create **inspiratory dyspnea with stertor**.

Stridor is present with laryngeal collapse or lateral ventricular eversion.

Collapse, exercise intolerance, dyspnea or dysphagia may also be reported.

Oronasal reflux, especially with fluids, occurs with a cleft palate.

Diagnosis

Diagnosis is based mostly on **clinical signs of stertor and stridor in a brachycephalic cat**. Nasal stenosis can be assessed visually. **Pharyngoscopy and laryngoscopy** are required to diagnose and stage the severity of **palatal and laryngeal involvement**.

Lateral cervical and thoracic radiographs are needed to assess tracheal hypoplasia.

Differential diagnosis

Upper airway foreign bodies and **masses** may mimic brachycephalic syndrome in a brachycephalic breed, although careful history-taking will usually differentiate them based on time of onset. Laryngeal edema may occur due to causes other than congenital malformation.

Treatment

If possible, **surgically correct** the defect, if the signs are severe. This includes wedge resection of the nares,

palatal resection, and resection of the everted lateral ventricles.

Prognosis

The prognosis is excellent for nasal, palatal and laryngeal defects with surgical intervention, if indicated. **Tracheal hypoplasia is currently not treatable**. **Prevention or treatment of obesity** is a major prognostic factor, as lean cats tolerate this much better than obese cats.

Prevention

Prevention is via selected breeding programs. Not using severely affected cats for breeding will help to reduce the prevalence.

AIRWAY FOREIGN BODIES

Classical signs

- Sneezing and stridor (nasal foreign bodies).
- Coughing and stridor (pharyngeal and tracheobronchial foreign bodies).

Clinical signs

Grass is one of the most common foreign bodies. The blade of grass becomes adherent to the roof of the pharynx and extends into the nasopharyngeal region.

Cuterebra larvae may bury in the **retropharyngeal tissue or in the pharyngeal soft palate**. A clue to diagnosis is evidence of a hole in the mucosa or a mass lesion.

Bone fragments and sewing needles may become embedded in the pharynx. **Cotton, string and fishing line** may get caught around the base of the tongue. **Grass seeds** may cause nasal foreign bodies.

Acute onset of sneezing and nasal discharge are common signs of nasal foreign bodies. The cat may be in sudden and severe distress attempting to dislodge the foreign body. Pawing at the face and mouth is commonly observed.

Signs of **fixed obstruction** occur with nasal and tracheobronchial foreign bodies because airflow is limited during inspiration and expiration due to constant partial obstruction of the airway. This may result in increased breathing sounds, and often stridor and dyspnea during inspiration and expiration.

Typically **nasal foreign bodies have sneezing, stridor and pawing or rubbing of the face**, while **pharyngeal and tracheobronchial foreign bodies present with coughing, stridor, gagging or retching**, pawing at the mouth, salivation and dyspnea. Typically the signs are frequent, marked and have a sudden onset.

Diagnosis

Some nasal and most tracheal foreign bodies may be seen radiographically.

Rhinoscopy and tracheobronchoscopy can be both diagnostic and therapeutic. Rigid tracheoscopy allows for larger retrieval instruments to be utilized than with flexible endoscopy.

Differential diagnosis

Nasopharyngeal polyps may cause similar signs of nasal obstruction and sneezing, but tend to have a more chronic course.

Tracheal or bronchial neoplasia may have similar signs, but again are more chronic in nature and can be distinguished bronchoscopically.

Treatment

Removal of the foreign body, either surgically or endoscopically, is often curative. Nasal foreign bodies may be endoscopically retrieved or hydropulsed, but occasionally require surgical rhinotomy.

AIRWAY TUMORS

Classical signs

- Nasal obstruction: stridor, open-mouth breathing.
- Pharyngeal obstruction: dysphagia, stridor, stertor and voice changes.
- Tracheal tumors: fixed obstruction, inspiratory and expiratory dyspnea and stridor. Cough is common.

See reference on page 23 for details (The Cat With Signs of Chronic Nasal Disease).

Pathogenesis

Nasal tumors are most commonly squamous cell carcinoma (SCC) of the nasal planum, solid nasal carcinomas and nasal lymphoma.

SCCs of the tonsil are common pharyngeal masses, along with **benign nasopharyngeal polyps**.

Tracheal tumors consist of lymphoma, SCC, leiomyosarcoma and osteochondral tumors from the tracheal rings. Adenocarcinomas have increased prevalence in the Siamese.

Lymphosarcoma and squamous cell carcinomas are the most frequent tumor types involving the larynx.

Clinical signs

Nasal obstruction produces stridor, open-mouth breathing, unilateral nasal discharge and coughing from post-nasal drip. Anosmia may lead to inappetence.

Pharyngeal masses produce dysphagia, stridor, stertorous dyspnea and voice changes. **Fetid halitosis** is also reported.

Tracheal tumors cause fixed obstruction, leading to **both** inspiratory and expiratory dyspnea with stridor, which is often louder on inspiration. A harsh, dry cough is common.

Diagnosis

Diagnosis is made via rhinoscopy, pharyngoscopy or tracheoscopy with biopsy. It is possible to image soft tissue masses radiographically, but endoscopy is still advised for biopsy. Other imaging modalities (CT and MRI) provide excellent images and aid in surgical and radiotherapy planning.

Differential diagnosis

Inhaled and penetrating foreign bodies may produce similar signs, but usually have a history of acute onset. Benign or parasitic **granulomas** of the airways may mimic neoplastic masses but can be differentiated on biopsy.

Treatment

Solid nasal tumors often respond well to external beam radiotherapy, with survival times of 20–27 months. Rhinotomy with turbinectomy has been reported to be successful.

Often, there is extensive local invasion by the neoplasm, and the recurrence rate after radiotherapy with or without surgery is high.

Nasal lymphoma responds well to standard chemotherapy for lymphoma, with remission times of 16 months reported. See page 676 for therapy.

Pharyngeal and tracheal masses and nasopharyngeal polyps (see page 37) are best addressed with surgical resection.

Laryngeal tumors are difficult to resect and generally carry a poor prognosis.

LARYNGEAL EDEMA

Classical signs

- Inspiratory dyspnea.
- Stertorous breathing, stridor.

Pathogenesis

Usually occurs **secondary to an allergic reaction** (type I hypersensitivity) from an **insect sting**, or following **vaccination**.

Acute laryngeal edema occurs in some cats associated with the intravenous anesthetic agent **alfaxalone/alphadolone (Saffan, Scherng-Plough)** which is available in Europe and other countries. The oil-based preparation causes histamine release.

Edema may be the result of **laryngeal trauma**, either blunt trauma to the throat, penetrating trauma (cat-bite wound), or from the **ingestion of sharp objects** or **caustic materials** (phenols, alkalis, acids) or **plants** (poinsettias, philodendrons, dieffenbachia).

Clinical signs

Inspiratory dyspnea, which may be associated with severe respiratory distress and cyanosis.

Stertor occurs, which is worsened with excitement or exercise.

Diagnosis

Acute onset of inspiratory dyspnea.

Laryngoscopic inspection under heavy sedation or light anesthesia with a rigid laryngoscope and blade reveals erythema and edema of the laryngeal mucosa.

Differential diagnosis

Laryngeal paralysis, laryngeal mass lesion or foreign bodies may have similar signs, but are differentiated on history and visualization of the larynx.

Treatment

Corticosteroids are indicated.

- Dexamethasone (0.1–0.25 mg/kg IV or IM), or prednisolone sodium succinate (10–30 mg/kg IV) are good parenteral choices.

Antihistamines may be useful, but histamine release has generally already occurred at the time of presentation.

Intubation or tracheostomy may be indicated in severe situations.

Prognosis

Generally good, but severe obstruction, if untreated, can be fatal. Laryngeal edema can also be a harbinger of systemic anaphylaxis.

Prevention

Avoidance of insect stings, access to poisonous plants and caustic agents such as dishwashing powder and cleaning agents.

Use of the new formulation of alfaxalone (Alsaxon-CD, Turox, Australia), which is water-based.

LARYNGEAL STENOSIS

Classical signs

- Dyspnea and stridor on inspiration.
- Common in cats after laryngeal trauma or surgery.

Pathogenesis

The cat appears to be more prone to fibrosis and stricture formation of the upper airway than is the dog. **Trauma** from external penetrating wounds, **aspirated foreign bodies**, or from **caustic chemical damage**, or **post-operative scarring** can lead to excessive scar formation and stricture.

The narrowed lumen creates the airway resistance and stridor. A **web of fibrosis** may **form across the larynx** and is especially dangerous.

Clinical signs

Laryngeal stenosis causes a dynamic airflow limitation, resulting in **inspiratory stridor and dyspnea**.

Stridor is worse with excitement or exercise.

Occasional stertor is evident.

Voice changes (absent or whisper-like meow), or harsh purring sounds may be reported.

Diagnosis

Diagnosis is based on clinical signs and history of prior laryngeal damage or surgery.

Laryngoscopic inspection under heavy sedation or light anesthesia with a rigid laryngoscope and blade reveals the stricture.

Low-dose ketamine (4–6 mg/kg IV), ketamine/diazepam (3–5 mg/kg/0.1–0.2 mg/kg IV) or propofol (4–6 mg/kg IV) allows visual inspection.

Differential diagnosis

Other causes of fixed upper respiratory tract obstruction are considerations, but can usually be differentiated visually or on biopsy. They include the following:

- **Oropharyngeal neoplasia** (SCC, oral melanoma, nasopharyngeal polyp).
- **Laryngeal or tracheal neoplasia** (intraluminal adenocarcinoma, extraluminal masses) or foreign bodies.

Treatment

Surgical intervention is generally required.

- Surgical resection of the stricture, if possible, is indicated. Laryngeal tie-back surgery (**arytenoid**

lateralization) may be required (see Laryngeal paralysis section).

In emergency respiratory distress, temporary tracheostomy may be required below the stricture, although this too can lead to future stricture formation.

Prognosis

Depends upon the nature and location of the stricture.

Prevention

At the time of laryngeal trauma or surgery, corticosteroids may help diminish scar formation.

LARYNGEAL PARALYSIS

Classical signs

- Inspiratory dyspnea and increased airway noise.
- Stertorous breathing (*snoring*).
- Stridor (high-pitched whistling = obstructive).
- Voice changes, absence of purring.

Pathogenesis

Exact pathomechanism is unclear in cats because of the small numbers reported.

It may be congenital, although most cases appear in **middle-aged to older cats**.

Peripheral neuropathies of recurrent laryngeal nerves can cause laryngeal paralysis. In dogs they have been associated with endocrinopathies (hypothyroidism – but this is rare in cats), myasthenia gravis, immune-mediated or paraneoplastic peripheral neuropathies, but this association has not been documented in cats.

Trauma, either to the recurrent laryngeal nerve (head, cervical or thoracic trauma) or to the structure of the larynx itself, can impair the laryngeal function. **Temporary or permanent damage** to the recurrent laryngeal nerve may occur following **cervical surgery, for example following thyroidectomy**.

Neoplasia, affecting either the innervation of the larynx (i.e., thyroid adenocarcinoma) or affecting the laryngeal structures directly (i.e., squamous cell carcinoma) can create laryngeal paralysis.

Parasitic involvement of the larynx and lead poisoning are very rare associations.

Percutaneous ultrasound-guided radiofrequency heat ablation and ethanol injections for treatment of hyperthyroidism in cats are both recent procedures, and laryngeal paralysis was a reported side effect of both.

Clinical signs

Inspiratory dyspnea, tachypnea.

Stridor, worse with excitement or exercise.

Occasional stertor.

Voice changes (absent or whisper-like meow), harsh purring sounds.

Dysphagia and weight loss.

Diagnosis

Diagnosis is based on clinical signs of laryngeal stridor and inspiratory dyspnea.

Laryngoscopic inspection under heavy sedation or light anesthesia with a rigid laryngoscope and blade reveals **absent or paradoxical motion** of the arytenoid cartilages. Normally they should abduct on inspiration. If they close on inspiration, it is paradoxical motion.

One retrospective study of 16 cases revealed 12 to be bilateral, and four to be unilateral.

Erythema and swelling of the arytenoid mucosa (“kissing lesions”) may be evident from the repetitive trauma at the contact surfaces.

Low-dose ketamine (4–6 mg/kg IV), ketamine/diazepam (3–5 mg/kg/0.1–0.2 mg/kg IV) or propofol (4–6 mg/kg IV) allows visual inspection without diminishing laryngeal function.

Differential diagnosis

Other causes of dynamic or fixed upper respiratory tract obstruction are distinguished on laryngoscopic inspection.

Dynamic causes of upper respiratory tract obstruction are:

- **Brachycephalic airway syndrome** (elongated soft palate, lateral ventricle eversion).
- **Cervical tracheal collapse.**
- Pyogranulomatous or lymphoplasmacytic **laryngitis.**

Other causes of fixed upper respiratory tract obstruction include:

- **Oropharyngeal neoplasia** (SCC, oral melanoma, nasopharyngeal polyp).
- **Tracheal neoplasia** (intraluminal adenocarcinoma, extraluminal masses).
- **Tracheal foreign bodies.**

Treatment

Correction of the underlying cause of the neuropathy is rarely possible.

Surgical intervention is generally required for bilateral disease.

- Laryngeal tie-back surgery (**arytenoid lateralization**) is recommended by most surgeons, although other techniques are described. Success is directly correlated with skill of the operator.

In emergency respiratory distress, temporary tracheostomy may be required.

Prognosis

Generally good to excellent long-term prognosis with successful surgery.

Prevention

None known.

TRACHEOBRONCHIAL COLLAPSE

Classical signs

- Harsh, honking cough.
- Stridor on inspiration if cervical segment involved.
- Very rare in cats.

Clinical signs

Tracheobronchial collapse is **very rare in cats** and generally occurs **secondary to trauma or to com-**

pression caused by an **extraluminal mass**. It has been reported associated with proximal tracheal obstructions from a tracheal granuloma or polyp.

The **cough is often harsh, non-productive and paroxysmal**, ending in a gagging episode which may appear to be productive.

Cervical trachea collapse produces inspiratory dyspnea, while intrathoracic tracheal or bronchial collapse will lead to mostly expiratory dyspnea. Stridor is occasionally reported.

Diagnosis

Radiographs may show attenuation of the tracheal or bronchial lumina. Fluoroscopy may be more sensitive for dynamic collapse.

Tracheobronchoscopy is valuable in both diagnosing and grading the severity of the collapse.

Differential diagnosis

Tracheitis from feline rhinotracheitis virus is generally associated with other upper respiratory signs.

Laryngeal paralysis or edema, tracheal foreign body and tracheobronchial neoplasm can be differentiated endoscopically.

Small airway disease (feline asthma/bronchitis complex) can worsen upper airway collapse, but generally diagnosis is based on the radiographic peribronchiolar pattern and airway inflammation on lung wash cytology.

Treatment

Medical treatment is indicated for a short and minimally attenuated collapsing segment, and consists primarily of antitussive therapy (**butorphanol** 1 mg/cat PO q 6–12 h as needed).

Surgical therapy may be indicated with severe collapse due to trauma. This generally requires referral to a specialist with experience in airway surgery. Extraluminal spiral ring prostheses made from a 3 ml syringe case were successful in reducing signs in two cats.

Weight loss and avoidance of neck collars can be very beneficial in affected cats.

LARYNGEAL EOSINOPHILIC GRANULOMA

Classical signs

- Stridor from laryngeal region.
- Swollen, edematous arytenoid cartilages of larynx.

Clinical signs

Syndrome often occurs **weeks or months** after signs of **viral upper respiratory tract infection**.

Stridor from laryngeal region is evident.

The larynx appears edematous and swollen.

With stress, cats become dyspneic and may mouth breathe.

Diagnosis

Visual appearance and biopsy are diagnostic. Biopsy reveals an eosinophilic granuloma.

Differential diagnosis

Invasive squamous cell carcinoma may have a similar appearance but can be differentiated on biopsy.

Other inflammatory infiltrations of the larynx, for example with lymphocyte, may appear similar, but are differentiated on biopsy.

Treatment

Oral steroids such as **prednisolone** 2 mg/kg bid PO for 10 days, then taper dose.

If oral medication cannot be given, methylprednisolone acetate (2–4 mg/kg 7 days for 2–6 treatments), can be used.

Occasionally, refractory cases need chlorambucil (0.1–0.2 mg/kg q 24 h initially PO, IM, then q 48 h).

PART 2

Cat with lower respiratory tract or cardiac signs

5. The dyspneic or tachypneic cat

Robert Allen Mason and Jacquie Rand

KEY SIGNS

Dyspnea

- Anxious, uncomfortable breathing.
- Increased respiratory effort.
- Respiratory distress.

Tachypnea

- Rapid breathing, not necessarily labored.

MECHANISM?

- Dyspnea can be caused by several mechanisms:
 - obstruction to airflow.
 - weakness of ventilatory muscles.
 - pleural space disease, inhibiting expansion of the lungs.
 - diminished oxygen-carrying capacity of the blood.

WHERE?

- Upper respiratory tract (nasal cavity, paranasal sinuses, pharynx, larynx, trachea).
- Lower respiratory tree (bronchial tree, small airways).
- Lung parenchyma, pleural space, chest wall and ventilatory muscles.

WHAT?

- Acute severe dyspnea in cats is often caused by an acute asthma attack, trauma or decompensating congestive heart failure.

QUICK REFERENCE SUMMARY

Diseases causing a dyspneic or tachypneic cat

DEGENERATIVE

- **Cardiomyopathy** (p 54)**

Dilated cardiomyopathy (DCM), hypertrophic (HCM), intermediate (ICM) or restrictive (RCM) often present as acute dyspnea. Abnormal heart sounds are often audible as murmurs, gallops and arrhythmias. Adventitious lung sounds, such as crackles may be audible with pulmonary edema. Occasionally, marked pleural effusion is present and heart and lung sounds are muffled ventrally. Coughing is an uncommon presenting sign in the cat.

- **Tracheobronchial collapse (p 69)**

Very rare in cats. Degeneration of the cartilage support of the large airway walls results in tracheobronchial collapse. Cervical collapse causes inspiratory dyspnea, while intrathoracic collapse causes expiratory dyspnea. Harsh honking cough and stridor may be evident.

- **Laryngeal paralysis (p 67)**

Idiopathic laryngeal paralysis is reported in cats. Iatrogenic paralysis may occur after cervical surgery or trauma. Inspiratory dyspnea, stridor and stertor are common signs.

ANOMALIES

- **Congenital heart defects (p 67)**

Atrioventricular valve dysplasia, septal defects, aortic and pulmonic stenosis (rare) and patent ductus arteriosus all lead to pressure and/or volume overload on the heart and potentially result in congestive heart failure. Dyspnea, open-mouth breathing, cyanosis, exaggerated chest excursions with minimal airflow all may occur. Abnormal heart sounds are common.

- **Congenital anomalies of the upper respiratory tract (p 68)**

Stenotic nares, elongated soft palate, hypoplastic trachea (i.e., brachycephalic syndrome) create variable upper airway resistance. Stertor and inspiratory dyspnea are common signs.

- **Acquired or congenital diaphragmatic defects* (p 57)**

Abdominal contents lie within the pleural or pericardial cavities, creating variable degrees of dyspnea. Signs include increased chest excursions with decreased airflow, muffled heart and lung sounds, and reluctance to lie in lateral recumbency. Palpation of the abdomen has an empty feel.

MECHANICAL

- **Grass awns, foreign bodies (p 65)**

Foreign bodies may be inhaled into the nasal cavity, upper respiratory tract or lower airways. The character of the dyspnea is dependent on location.

- **Pleural effusion** (p 54)**

Dyspnea characterized by excessive chest excursions with poor airflow, orthopnea, muffled heart and lung sounds. Signs of chronic illness may be present such as weight loss.

METABOLIC

- **Myopathy/neuropathy (p 61)**

Hypokalemia, myasthenia gravis, polyradiculoneuritis (rare in cats), botulism, polymyositis and other causes of weakness of the respiratory muscles cause poor ventilatory muscle excursions.

- **Anemia/hypoxemia* (p 57)**

Reduced oxygen-carrying capacity of the blood results from anemia (blood loss, hemolysis, myelodysplastic disease) or altered hemoglobin (methoxyhemoglobinemia from acetaminophen toxicity, carboxyhemoglobinemia from CO toxicity). Tachypnea, pallor, cyanosis or brick-red mucous membranes may be seen.

- **Pulmonary thromboembolism***

Secondary to hypercoagulable states, blood flow stasis, vascular injuries and heartworm disease. Creates significant ventilation/perfusion mismatch, with sudden onset of severe dyspnea and tachypnea. Cyanosis and collapse may occur. Lung parenchyma may appear normal radiographically.

- **Aortic thromboembolism* (p 58)**

Acute single-limb paresis or, with “saddle” thrombus, bilateral hindlimb paralysis. The affected limb is cold, painful and the foot pads are cyanotic. Signs of congestive heart failure may be severe, with marked worsening of dyspnea.

NEOPLASTIC

- **Pleural/mediastinal masses***

Signs relate to the space-occupying nature of the mass. Dyspnea with muffled heart and lung sounds or pleural effusion. Heart sounds are typically asymmetric because of displacement of the heart by the mass. Compression of the chest wall may reveal decreased compliance.

- **Airway tumors**

Nasal, laryngeal and cervical tracheal masses create stertor, stridor and inspiratory dyspnea. Thoracic tracheal and bronchial masses create expiratory dyspnea. Coughing may occur with tracheal masses.

- **Pulmonary neoplasia**

Dyspnea may be subtle. Systemic signs such as weight loss and possibly coughing may be evident. Inappetence, weight loss, fetid breath and reluctance to play may also be noted.

- **Cardiac tumors**

Extremely rare in cats. Space-occupying effect in chest or signs of congestive heart failure from obstruction of blood flow may produce dyspnea.

INFLAMMATORY

INFECTIOUS

- **Acute and chronic infectious upper respiratory tract disease****

Sneezing, acute or chronic oculonasal discharge, and sometimes conjunctivitis are present. Inspiratory dyspnea occurs if there is marked nasal obstruction. Nasal distortion may be present with cryptococcosis, neoplasia or rarely with secondary bacterial rhinitis.

Bacterial:

- **Pyothorax****

Dyspnea characterized by excessive chest excursions with poor airflow, orthopnea, muffled heart and lung sounds. Signs of chronic illness may be present such as weight loss. Signs of sepsis such as hypothermia and hypoglycemia are occasionally present. Often signs of chronic illness such as weight loss and inappetence were evident before presentation for dyspnea.

continued

continued

- **Pneumonia**

Uncommon in cats. Fever, fetid halitosis, crackles and wheezes heard over lung fields.

Parasitic:

- **Parasites**

Heartworm (*Dirafilaris immitis*), lung worm (*Aleurostrongylus abstrusus*, *Capillaria aerophila*), lung flukes (*Paragonimus kellicoti*), and migrating nematodes (*Toxocara cati*) are potential lung pathogens. Coughing may be seen. Inappetence, weight loss and poor hair coat may be evident. Vomiting is reported in feline heartworm disease along with dyspnea. Acute marked respiratory distress and sudden death may also occur with heartworm.

Immune:

- **Feline asthma/bronchitis complex)*****

Acute dyspnea occurs with *status asthmaticus*. Cats are air-starved, and present with frantic, open-mouth breathing, increased expiratory effort, and with possible wheezing and coughing.

- **Laryngeal edema (p 64)**

Laryngeal edema may follow a hypersensitivity reaction. Inspiratory dyspnea, stridor and stertor are common signs.

- **Acute systemic anaphylaxis (p 68)**

Clinical signs include acute dyspnea, collapse, pale mucus membranes and other signs of hypotensive shock. There may be a history of exposure to a foreign antigen, usually protein. Anaphylaxis may occur on the first exposure to the inciting antigen.

Idiopathic:

- **Pulmonary fibrosis (p 69)**

Pulmonary fibrosis causes both inspiratory and expiratory dyspnea. It is a very rare condition and may be associated with feline asthma/bronchitis complex. A syndrome consistent with usual interstitial pneumonia in human beings has been reported in cats.

- **Fibrosing pleuritis (p 70)**

Restrictive fibrosing pleuritis cause both inspiratory and expiratory dyspnea. It is a rare sequel of pyothorax and other chronic pleural effusions, especially chylothorax. Heart and lung sounds are muffled ventrally.

Trauma:

- **Upper airway/chest wall trauma*****

Character of the dyspnea corresponds to the area of injury. Marked inspiratory dyspnea, stridor and subcutaneous emphysema may be evident with laryngeal or trachea trauma. Chest wall trauma may result in dyspnea, cyanosis, abnormal or decreased lung sounds and evidence of shock.

INTRODUCTION

MECHANISM?

Dyspnea is the distressful feeling associated with difficult or labored breathing. In animals, the term dyspnea is often applied to labored breathing that appears to be uncomfortable.

Tachypnea is rapid breathing (not necessarily labored).

Hyperpnea is deep breathing.

Hyperventilation refers to increased air entering the pulmonary alveoli, brought about by prolonged, rapid and deep breathing.

Panting, however, refers to swift and shallow breathing, with a rapid respiratory frequency and a small tidal volume.

Respiratory causes of dyspnea include upper and lower airway obstruction.

Upper airway obstructions may be fixed or dynamic. Airflow through a narrowed upper airway has increased resistance and becomes more turbulent. This resistance is a function of the diminished luminal diameter of the tube, **the resistance increasing to the fourth power of the radius.**

- **Fixed obstructions** affect both **inspiration** and **expiration.**
- **With dynamic obstructions, dyspnea occurs during inspiration,** because the negative intraluminal airway pressure creates a vacuum, pulling the walls inwardly. Any weakened area of the airway wall will tend to move into the lumen, decrease the luminal diameter, and create an obstruction.

Lower airway obstructions may be **obstructive** or **restrictive.**

- **Obstructive** include intraluminal masses and foreign bodies, bronchoconstriction, extraluminal compression by masses or left atrial enlargement, and rarely tracheobronchial collapse.
- **Restrictive obstructions** include pleural space disease (pneumothorax, hydrothorax, pleural masses) and primary pulmonary disease (pulmonary fibrosis, pneumonia) that restrict expansion of the lung.

Non-respiratory causes of dyspnea are varied and include:

- Weakness of ventilatory, muscles or diseases which restrict thoracic expansion (myopathies, neuropathies, neuromuscular disease, obesity and organomegaly).
- Pulmonary vascular disease (pulmonary hypertension, pulmonary thromboembolism, shock).
- Diminished oxygen-carrying capacity (methemoglobinemia, anemia).
- Cardiac disease (congestive heart failure, cyanotic heart disease with right-to-left shunting).
- Miscellaneous (pain, fever, anxiety, hyperthermia).

WHERE?

Upper respiratory tract (nasal cavity, paranasal sinuses, pharynx, larynx, trachea). With upper respiratory tract obstructions, stertor and stridor may be evident. Stertor is a snoring sound. Stridor is a harsh, high-pitched whistling respiratory sound created by upper airway obstructive diseases. Stridor arises from luminal narrowing in the upper airways, generally involving the pharynx, soft palate, laryngeal structures and the upper trachea. Nasal stridor may also be encountered.

Lower respiratory tree (bronchial tree, small airways).

Lung parenchyma, pleural space, chest wall and ventilatory muscles. Pleural space disease often has dyspnea with excessive chest wall excursions accompanied by minimal nasal airflow.

Oxygen delivery system (blood vessels, RBCs, heart).

What?

Acute severe dyspnea in cats is often caused by an acute asthmatic attack, decompensating congestive heart failure or trauma.

The dyspneic cat is extremely fragile, and needs to be handled very gently and with minimal restraint. Cats with open-mouth breathing and cyanosis have very little respiratory reserve left, and the slightest additional stress may be lethal.

In most cases, we need to resist the temptation to make a definitive diagnosis until our patient is more stable. These cats are focusing on their next breath, and are

not in the least concerned with our welfare and well-being.

These cats often require much less restraint than a well cat. If there is the slightest resistance to restraint – **STOP RESTRAINING THEM** – and proceed with supportive care in as least a stressful manner as possible.

DISEASES CAUSING DYSPNEA OR TACHYPNEA

UPPER AIRWAY/CHEST WALL TRAUMA***

Classical signs

- Inspiratory dyspnea (in upper airway trauma).
- +/- Subcutaneous emphysema.
- +/- Paradoxical chest wall motion with flail chest.
- Evidence of superficial trauma.

Clinical signs

The character of the dyspnea corresponds to the area of injury and whether the upper or lower respiratory tract is involved.

Blunt (car injury, horse kick or fall) or penetrating (bite or firearm wound) trauma to the larynx or trachea, may cause inspiratory dyspnea.

Air leakage from a wound to the upper or lower respiratory tract may lead to **subcutaneous emphysema and pneumomediastinum**. Crepitus is evident on palpation with subcutaneous emphysema.

Dyspnea, cyanosis, abnormal or decreased lung sounds occur with severe pulmonary contusions, and signs of shock may be evident.

Paradoxical chest wall motion of a flail chest segment can occur, that is, inward motion during inspiration.

Traumatic hemothorax may produce increased chest wall motion with poor air movement.

Other signs of superficial trauma and shredded nails are usually evident with automobile trauma.

Pyrexia often occurs within 24 hours of cat-bite wounds.

Diagnosis

Diagnosis is based on the history and physical exam findings.

Radiographic assessment of the severity of lung trauma may be misleading in the early stages. Often there is a lag time of 12–18 hours from the time of blunt trauma of the chest wall to appearance of interstitial fluid densities in the lung. This is analogous to deep bruising on the skin and muscle after trauma – it takes time for the bruise to fully develop.

Complete focal lung consolidation with severe contusion may be evident radiographically after chest wall trauma.

Differential diagnosis

Upper airway neoplasia or foreign body in some situations may present similarity to trauma, but can be differentiated on diagnostic findings such as radiography or endoscopy.

Pleural space disease, pneumonia and pulmonary neoplasia can be differentiated based on history, physical exam and diagnostic findings.

Treatment

Treatment involves supportive care, wound cleaning and microbial therapy. Surgical repair of upper respiratory tract trauma may be required.

Flail chest is defined as a segment of the rib cage with proximal and distal fractures, resulting in an unstable segment of the chest wall.

- **Temporary stabilization** may be provided with techniques using Bachaus towel clamps, wooden tongue depressors, etc.
- Rapid definitive surgical correction of the flail chest is not as important as **stabilizing the patient** from the severe trauma, and treating the severe pulmonary contusion with oxygen supplementation, antibiotics, analgesics, bronchodilators, etc.

Tube thoracostomy and intermittent or continuous drainage of the pleural space is indicated when

significant pneumothorax requires that air be removed more than three times within 24 h.

Positive-pressure ventilation must be used with extreme caution due to the fragility of the traumatized lung and susceptibility to additional barotrauma.

FELINE ASTHMA/BRONCHITIS COMPLEX***

Classical signs

- Expiratory dyspnea with wheezing.
- Cough is a prominent sign.
- *Status asthmaticus* – severe acute respiratory distress.
- Cyanosis, open-mouth breathing.

See main reference on page 92 for details (The Coughing Cat).

Clinical signs

Signs can occur at any age, although average is 2–8 years.

Signs may be episodic (with asthma) or chronic (with bronchitis).

There may or may not be a history of coughing for weeks or months preceding an episode of mild to severe, life-threatening respiratory distress from bronchoconstriction. Cats may present severely air-starved, with cyanosis, open-mouth breathing and a significant expiratory push.

Diagnosis

Adventitial lung sounds such as wheezing and crackles are very common.

Thoracic radiographs may be normal or have the following changes:

- **Hyperlucency, hyperinflation**, and flattening of the diaphragm due to air trapping may be seen with asthma.
- Diffuse prominent peribronchiolar pattern is the hallmark of chronic bronchitis.
- Right heart enlargement may be present.

Lung wash for cytology and culture.

- Transtracheal wash may be performed in the awake cat.
- Bronchoscopy for bronchoalveolar lavage (BAL) or unguided catheter BAL are performed in the anesthetized cat and are preferred by most clinicians over a transtracheal wash.

Cytology reveals highly cellular samples with **intact non-degenerative neutrophils** as the primary cells.

- Eosinophils are not a reliable marker of inflammation in the cat due to the increased prevalence (up to 24%) in normal airways.

Pulmonary function testing for increased airway resistance includes spirometry, whole-body plethysmography, and tidal breathing flow–volume loops (TBFVL). These are rarely available outside of teaching institutions.

Differential diagnosis

Main differential for *status asthmaticus* is acute congestive heart failure of cardiomyopathy.

Other respiratory diseases, such as parasitic pneumonia, aspiration pneumonia, bronchopulmonary neoplasia and pleural space diseases may present with dyspnea.

Treatment

- The cornerstone of therapy for cats with *status asthmaticus* is to minimize handling until signs abate, and administer oxygen, bronchodilators and glucocorticoids.
- **Oxygen supplementation** is required during respiratory distress and an oxygen chamber or tent seems to be best tolerated by air-starved patients. Oxygen hoods made with an Elizabethan collar and cellophane, or oxygen delivery via a nasal canula have proven useful in some cats, but may stress other cats and exacerbate signs.
- **Minimal handling** and restraint of acutely dyspneic patients is essential.
- For severe signs (dyspnea, open mouth breathing +/- cyanosis) which are a life-threatening emergency, it is important not to stress the cat as this may precipitate death. Administer **oxygen** via oxygen cage or nasal canula, **methylprednisolone** sodium succinate (100 mg/cat IV) or **dexamethasone**

(2 mg/kg IV) and **terbutaline** (0.01 mg/kg IV) q30 minutes for up to 4 h until a response is observed.

- Once stabilized cats are discharged with **fluticasone (Flovent®)** 220 mcg q 12 h and **albuterol (Proventil, Ventolin)** q 6 h as needed
- See page 94 The Coughing Cat for details of acute and chronic therapy

CARDIOMYOPATHY**

Classical signs

- **Dyspnea** – mild to acute and severe with cyanosis.
- **Abnormal heart sounds** (murmurs, gallops, arrhythmias).
- **+/- Signs of pleural effusion or pulmonary edema.**

See main reference on page 128 for details (The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

Clinical signs

Dyspnea varies from **mild** and associated with reduced activity levels and reluctance to play, to **acute, fulminant air-starvation** with open-mouth breathing and cyanosis.

Abnormal heart sounds (murmurs, gallops, arrhythmias) may be present, or may be difficult to assess in the distressed patient.

Pleural effusion is occasionally present especially with DCM, and results in increased chest excursions with little airflow (can be detected by listening close to the muzzle during breathing) and muffled ventral sounds.

Pulmonary edema is more common especially with hypertrophic and restrictive/intermediate cardiomyopathies, and results in increased adventitial lung sounds such as crackles.

Diagnosis

Definitive diagnosis is based on ultrasonographic characterization of the type and severity of the cardiomyopathy present.

Differential diagnosis

Acute marked dyspnea is most often associated with status asthmaticus and is differentiated from cardiogenic dyspnea on signs, expiratory push, wheezing, prior history of coughing and radiographic findings.

Treatment

Oxygen therapy (O₂ chamber or tents).

Furosemide (1–2 mg/kg IV or IM).

Provide **sedation** if the cat is frantic (morphine 0.1 mg/kg IM prn, or butorphanol 0.2–0.4 mg/kg IM q 4–6 h as needed).

If there are signs of pleural effusion, **emergency thoracocentesis** in cats with severe respiratory distress may be life saving.

- A butterfly set on a 60 ml syringe is introduced at the 5th–7th intercostal space (ICS) on the right, just above the costochondral junction. Remove as much fluid as possible, or until breathing improves.

Definitive therapy is based on ultrasonographic characterization of the type and severity of the cardiomyopathy present. See page 130 for treatment details (The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

PLEURAL EFFUSION**

Classical signs

- **Muffled heart and/or lung sounds ventrally.**
- **Dyspnea characterized by excessive chest excursions with poor airflow.**
- **Orthopnea (positional dyspnea).**

See main reference on page 71 for details (The Cat With Hydrothorax).

Clinical signs

Marked chest wall excursions and minimal airflow.

Orthopnea (worsening dyspnea in lateral recumbency) and reluctance to lie in lateral recumbency.

Muffled heart and lung sounds ventrally, dull chest percussion.

Depending on the etiology of the effusion, signs of chronic illness may be present such as weight loss. Inappetence or anorexia and pyrexia may be present with pyothorax.

Diagnosis

With mild to moderate clinical signs, thoracic radiography may be diagnostic. Signs are evident when fluid exceeds 50 ml/kg.

With severely affected cats in respiratory distress, radiography should be delayed until after thoracocentesis.

- CATS WITH PLEURAL EFFUSIONS DIE IN RADIOLOGY!

Fluid analysis is essential to determine etiology.

Differential diagnosis

Hemothorax, transudation from increased hydrostatic pressure (cardiac disease) or decreased oncotic pressure (protein-losing enteropathies, nephropathies or hepatic disease), lymphatic obstruction (thoracic neoplasia), chylothorax and pyothorax are all forms of hydrothorax that need to be differentiated.

Treatment

Thoracocentesis is part of the universal therapy for all forms of pleural effusion.

Definitive therapy is based upon the underlying cause.

PYOTHORAX**

Classical signs

- Dyspnea related to pleural effusion.
- Signs of chronic disease (weight loss, inappetence).
- +/- Fever.
- Turbid, flocculent and other fetid-smelling pleural fluid.

See main reference on page 75 for details (The Cat With Hydrothorax).

Clinical signs

Pyothorax is more common in intact males and is likely associated with fight wounds.

Dull or muffled heart and lung sounds are audible ventrally.

Marked chest wall excursions with minimal airflow are evident, and dyspnea is worsened by lateral recumbency (orthopnea).

The cat typically has a sick, septic, thin, unkempt appearance and may be febrile.

Diagnosis

A thick, fetid, septic, suppurative exudate is obtained on thoracocentesis. Cytology and Gram stains reveal many degenerate neutrophils, some with intracellular bacteria. Culture and sensitivity should be performed, but may show no growth of organisms.

ACUTE AND CHRONIC INFECTIOUS UPPER RESPIRATORY TRACT DISEASE**

Classical signs

- Acute or chronic nasal discharge (bilateral, copious, mucopurulent).
- Open-mouth breathing.
- Coughing.
- Ocular discharge.
- +/- Nasal distortion.

See main reference on page 19 for details (The Cat With Signs of Chronic Nasal Disease) and page 5 (The Cat With Acute Sneezing or Nasal Discharge).

Clinical signs

Upper respiratory tract disease may cause inspiratory dyspnea as a result of nasal obstruction.

Signs may be acute and associated with calici or herpes virus infection or chronic associated with cryptococcosis, neoplasia or chronic secondary bacterial rhinitis following calici or herpes viral infection.

When dyspnea is present, **nasal discharge** is usually bilateral, often mucopurulent and copious.

Open-mouth breathing may occur especially with stress.

Coughing may be present if *Bordetella bronchiseptica* or herpes virus are involved.

Ocular discharge, conjunctivitis and chemosis occur with acute upper respiratory tract infection with calici or herpes virus and *Chlamydomphila felis*.

Stertorus respiration (snoring) may be evident.

Nasal distortion may occur with cryptococcosis, neoplasia or rarely with chronic secondary bacterial rhinitis.

Diagnosis

Signalment, clinical signs and history are often suggestive of the etiology. In acute upper respiratory tract infection, multiple cats in the home are often affected.

Radiographic findings:

- Usually there is loss of lucency in the nasal cavity resulting from fluid (fluid density). In chronic nasal diseases causing dyspnea, there is often osteolysis of the nasal turbinates. Lysis tends to be asymmetrical with neoplasia and is more often symmetrical with cryptococcosis and chronic bacterial rhinitis secondary to viral disease.

Culture or PCR is now available for calicivirus, herpesvirus and *Chlamydomphila felis*. Bacterial culture may be useful to identify bacteria in secondary bacterial rhinitis so the most appropriate antibacterial therapy can be selected, e.g. *Pasteurella* spp.

Cats with cryptococcosis frequently have nasal distortion over the bridge of the nose or a polyp-like mass visible in the nasal cavity. Diagnosis is based on cytology, histology or a positive serology titer.

Neoplasia is most reliably diagnosed on histology, although a cytological sample may be diagnostic.

PLEURAL/MEDIASTINAL MASSES*

Classical signs

- Muffled heart and lung sounds ventrally or asymmetrical sounds.
- Dyspnea characterized by excessive chest excursions with poor airflow.
- Orthopnea (positional dyspnea).

Clinical signs

Mediastinal masses are often thymomas, thymic lymphoma, or mediastinal lymphoma. Occasionally, ectopic thyroid adenocarcinoma may create a space-occupying mass of the mediastinum. Pleural masses include mesotheliomas, osteosarcoma or chondrosarcoma of the ribs or sternabrae.

Signs are related to the space-occupying nature of the mass, or to obstruction of lymphatic drainage, leading to pleural effusion.

Orthopnea (dyspnea worsened by lateral recumbency), tachypnea, minimal airflow with increased chest excursions, muffled heart and lung sounds, or **asymmetrical sounds if the heart is displaced laterally**.

Extraluminal compression of the trachea can cause dyspnea and cough.

Compression of the anterior chest wall may reveal decreased compliance.

Diagnosis

Thoracic radiography may reveal the mass lesion or the secondary pleural effusion.

Thoracic ultrasound can be extremely useful.

- Small mediastinal masses surrounded by aerated lung may not be visible from a paracostal approach, and may require a thoracic inlet window.
- Transesophageal ultrasonography is excellent for demonstrating mediastinal masses, but requires specialized equipment and general anesthesia.

Analysis of the thoracocentesis fluid may be diagnostic on the rare occasions that the neoplasm has exfoliated into the fluid. Pleural effusions associated with tumors are usually modified transudates, but may be transudates, exudates or chylous. Surgical or ultrasound-guided biopsy of the mass is usually required for a definitive diagnosis.

Mediastinal lymphoma occasionally has hypercalcemia as a paraneoplastic syndrome.

Differential diagnosis

Other causes of pleural effusion need to be differentiated. Chylothorax is more commonly idiopathic and

associated with lymphatic lymphangiectasia, although cardiac disease and trauma need to be excluded. History, signs (evidence of murmurs, gallops and arrhythmias), radiography and ultrasound help to differentiate these causes from thoracic neoplasia.

Treatment

Lymphoma of the thymus or mediastinal lymph nodes is best handled with standard chemotherapy protocols for lymphoma (see page 676).

Surgical excision is the treatment of choice for thymoma, and may be curative.

Mesothelioma is an infiltrative disease that cannot be readily resected, and there are few reports in the literature of effective chemotherapy. Local infusion of carboplatin may be helpful with or without intravenous doxorubicin. Prognosis is grave.

ANEMIA/HYPOXEMIA*

Classical signs

- Dyspnea, tachypnea and tachycardia.
- Pallor from anemia, cyanosis with methemoglobinemia.

Clinical signs

Signs may be acute or chronic in onset depending on the underlying disease process.

Pale mucous membranes, tachycardia and tachypnea occur with anemia.

Cyanosis occurs with methemoglobinemia.

Cherry red mucous membranes occur with carboxyhemoglobinemia from carbon monoxide (CO) toxicity.

Diagnosis

Diagnosis of anemia is based on finding a decreased hematocrit on CBC.

- PCV < 10% may be associated with dyspnea, especially if the cat is stressed.
- Evidence of blood loss or poor RBC production may be evident.

- Bone marrow biopsy may be indicated if there is evidence of anemia of longer than 4–6 days duration without a regenerative response.
- Measurement of carboxyhemoglobin concentration is required for diagnosis of CO toxicity. Routine STAT assays are available in human hospitals.

ACQUIRED OR CONGENITAL DIAPHRAGMATIC DEFECTS*

Classical signs

- May or may not have clinical signs.
- Muffled heart and/or lung sounds.
- Occasionally dyspnea, cyanosis.
- Vague gastrointestinal signs, gaunt abdomen on palpation.

Clinical signs

Diaphragmatic hernia may occur as a **congenital defect** allowing abdominal organs to move into the thoracic space or pericardium, or may follow **trauma, especially a motor-car accident or fall from a building**.

With congenital hernias, signs may be evident as a kitten or there may be no signs until later in life, depending on the severity of the hernia.

With acquired hernias, signs may or may not be evident immediately following trauma, and worsen or improve as adhesions form to limit movement of viscera. In some cats, signs are only present with activity or stress.

Typically there are muffled heart and lung sounds, and occasionally borborygmus is audible in the chest.

The **severity of dyspnea** is variable from mild, to acute and severe. Sudden worsening of signs may occur when more abdominal viscera move into the chest.

Tachypnea, orthopnea (worsened dyspnea in lateral recumbency) and cyanosis may occur depending on the volume of abdominal organs in the thorax.

On palpation, the abdomen has a gaunt or empty feel. **Other ventral midline defects** such as umbilical hernias, *pectus excavatum*, etc., may be present with congenital hernias.

Intermittent vomiting and inappetence are the most common gastrointestinal signs.

Diagnosis

Thoracic radiographs demonstrate bowel loops, or space-occupying soft tissue densities within the pleural or pericardial space. Globose cardiomegaly is evident with peritoneopericardial diaphragmatic hernia.

Other imaging modalities such as ultrasonography, positive contrast upper GI series, pneumoperitoneography or contrast injected into the abdomen (celiogram) may be useful for diagnosis.

Differential diagnosis

Pleural space disease (effusions, pneumothorax, mass lesions), pericardial effusion and cardiomyopathy may have similar signalment and signs to traumatic diaphragmatic hernia, but can usually be differentiated on radiography and ultrasonography.

Treatment

Treatment consists of **surgical repair** after stabilizing the patient. If dyspnea is the major clinical sign, stabilization may not be possible until the pericardial or pleural cavities are evacuated. Oxygen therapy is of little value in a patient with severe pleural occupation.

AORTIC THROMBOEMBOLISM*

Classical signs

- Acute single or bilateral limb paresis or paralysis, most often involving hindlimbs.
- Signs of congestive heart failure – cyanosis, respiratory distress, pleural effusion.
- Heart murmurs, arrhythmias and gallops.

See main reference on page 915 for details (The Weak and Ataxic Cat or Paralyzed Cat).

Clinical signs

Cardiomyopathy in cats is sometimes associated with thrombus formation in the left atrium. The thrombus may be dislodged, and most commonly obstructs the aorta at its trifurcation (saddle thrombus).

Typically, there is **acute onset of single limb paresis or paralysis**, which most often involves the **hindlimbs**. Signs may be bilateral with a “saddle thrombus” at the aortic trifurcation.

On physical examination the **limb is cool and pulseless, with cyanotic foot pads or nail beds**. The gastrocnemius muscle is firm and painful on palpation.

Signs of congestive heart failure including cyanosis, respiratory distress, or evidence of pleural effusion may be present. **Dyspnea and tachypnea** may be acutely exacerbated. Heart murmurs, arrhythmias and gallops are often evident.

Diagnosis

Diagnosis is based on the clinical signs and confirmed by evidence of lack of blood flow in the distal limb measured by a Doppler flow meter.

Thoracic radiography and ultrasonography demonstrate underlying heart disease, often with significant chamber enlargement, especially of the left atrium.

Contrast arteriography of the affected limb is the “gold standard”, but not frequently used in clinical cases.

PULMONARY THROMBOEMBOLISM*

Classical signs

- Sudden onset of severe dyspnea with normal lung parenchyma radiographically.
- Peracute dyspnea, orthopnea, tachypnea.
- Cyanosis, collapse.
- Cough, with or without hemoptysis.

Pathogenesis

Pulmonary thromboembolism involves **embolic showering** of the pulmonary arterial tree, causing obstruction of blood flow to that portion of the lung.

Thrombi may be produced locally (i.e., feline heartworm disease), or may embolize from distant locations. Thrombi may originate in the right atrium (**cardiomyopathy, advanced tricuspid valvular disease**), caudal vena cava, femoral veins, mesenteric venous system or jugular veins.

Hypercoagulable states such as **protein-losing nephropathies** (i.e., glomerulonephritis, renal amyloidosis, hypertension) or **enteropathies** (i.e., IBD, lymphangiectasia), stasis of blood flow, **exposure of vascular subendothelial tissue** (i.e., vasculitis, right atrial dilation, post-stenotic “jet lesions”, trauma and indwelling jugular catheters) all predispose to thrombus formation.

Pulmonary arterial obstruction causes ventilation/perfusion (V/Q) mismatch, resulting in **hypoxemia and dyspnea**.

- Increased pulmonary arterial pressure may induce cor pulmonale, or right-sided heart failure.

Feline heartworm disease frequently presents as severe peracute pulmonary inflammation, edema and pulmonary thromboembolism resulting in acute respiratory failure and death.

Clinical signs

Severity of signs is proportional to the degree of arterial obstruction.

Acute onset of severe dyspnea and tachypnea is typical. Cyanosis or collapse may also occur. Massive disease may result in sudden death.

Orthopnea (positional dyspnea), especially in lateral recumbency, and reluctance to lie in lateral recumbency, may be an early sign.

Coughing may be evident, and ranges from mild to severe, and may involve hemoptysis.

Signs of right-sided heart failure may occur, such as tachycardia, jugular venous distension and split second heart sounds.

Often presenting signs relating to the primary condition are also evident, i.e., weight loss and diarrhea with protein-losing enteropathy.

Diagnosis

Thoracic radiographs may be totally normal, and in the presence of severe dyspnea, increase the index of suspicion of pulmonary thromboembolism.

- Enlarged or truncated pulmonary arteries may be seen.

When lesions are evident radiographically, lung patterns range from focal areas of hyperlucency to alveolar infiltration, and mild to moderate pleural effusion.

Pulmonary arterial angiography is the “gold standard” for evaluation of pulmonary thromboembolism (PTE) in people. This requires catheterization of the right heart and injection of contrast material into the pulmonary arterial tree. Areas of obstruction or decreased blood flow may be detected.

Scintigraphic ventilation/perfusion studies utilize both aerosolized and injected radioisotopes to identify areas of V/Q mismatch. Special facilities and expertise are required, which are generally unavailable outside of teaching institutions.

Echocardiography may reveal right atrial enlargement with thrombus formation, pulmonary arterial dilation, right ventricular enlargement, pulmonary hypertension on Doppler studies of the tricuspid and pulmonic valves, or evidence of heartworm in the right heart or pulmonary arteries.

Tall P waves on ECG may indicate right atrial enlargement, and right axis shift supports right ventricular enlargement consistent with cor pulmonale.

Differential diagnosis

Severe dyspnea and cyanosis with normal thoracic radiographs may accompany upper airway obstruction or feline asthma.

Treatment

Oxygen therapy during the respiratory crisis is **important**, but limited in efficacy if the blood delivery to the lung is compromised.

The **primary disease condition**, if identified, should be addressed as a priority.

Thrombolytic therapy is controversial. The use of tissue plasminogen activator (TPA) has been advocated, but requires local delivery into the pulmonary arterial circulation. This requires cardiac catheterization under fluoroscopy. There are inherent risks involved with the procedure, and the risk of inducing a bleeding diathesis.

Anti-thrombotic therapy using heparin has been advocated to prevent further thrombin formation. Various protocols ranging from low (100 IU/kg SQ q 8

hours) to moderate doses (300 IU/kg SQ q 8 h) have been published, with no clear advantages of any one protocol.

Coumadin is a more potent anti-thrombotic agent in the cat. Having an oral liquid suspension compounded makes the titration of the dosage much more reliable in the cat. Doses of 0.1 mg/kg PO q 24 h are a recommended starting point. Monitoring the prothrombin time (PT) and the INR (international normalization ratio), with a treatment endpoint of an INR of 2.0–3.0, may help to prevent overdosage, although trials in cats are lacking.

Fluid therapy must be used judiciously, due to the predisposition of right-sided heart failure.

Prognosis

Prognosis is directly proportionate to the severity of the lesion, as well as to the underlying cause. Resolvable causes (i.e., trauma or catheter-induced) have a better long-term prognosis than do patients with irreversible causes (i.e., renal amyloidosis).

Prevention

Treat underlying risk factors early in the disease course, for example, protein-losing nephropathies and enteropathies.

Acetylsalicylic acid or heparin theoretically may help prevent further thrombus formation, although there are no studies demonstrating efficacy in cats.

AIRWAY TUMORS

Classical signs

- **Nasal obstruction produces stridor and open-mouth breathing.**
- **Pharyngeal obstruction results in dysphagia, stertor and voice changes.**
- **Tracheal tumors produce fixed obstruction with inspiratory and expiratory dyspnea, and often coughing.**

See main reference on pages 41 and 24 for details (The Cat With Stridor, and The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Nasal tumors are most commonly squamous cell carcinoma of the nasal planum, solid nasal carcinomas and nasal lymphoma.

Nasal obstruction produces stridor, stertor or open-mouth breathing, uni- or bilateral nasal discharge and coughing from post-nasal drip. Anosmia may lead to inappetence.

Squamous cell carcinomas of the tonsil are common pharyngeal masses, along with benign nasopharyngeal polyps.

Pharyngeal masses produce dysphagia, stertorous dyspnea and voice changes. Fetid halitosis is also reported.

Tracheal tumors consist of lymphoma, squamous cell carcinoma, leiomyosarcoma and osteochondral tumors from the tracheal rings. Adenocarcinomas have increased prevalence in Siamese cats.

Tracheal tumors cause fixed obstruction, leading to **both** inspiratory and expiratory dyspnea. A harsh, dry cough is common.

Diagnosis

Diagnosis is by rhinoscopy, pharyngoscopy or tracheoscopy with biopsy. It is possible to image soft tissue masses radiographically, but endoscopy is still advised for biopsy.

Differential diagnosis

Inhaled and penetrating foreign bodies, and benign or parasitic granulomas of the airways may mimic neoplastic masses. Foreign bodies result in acute onset of signs and often distress, compared to chronic signs in neoplasia and granulomas. Visualization and biopsy will differentiate these diseases.

Treatment

Solid nasal tumors respond well to external beam radiotherapy, with survival times of 20–27 months. Rhinotomy with turbinectomy has been reported to be successful.

- Often, there is extensive local invasion by the neoplasm, and the recurrence rate after radiotherapy and/or surgery is high.

Nasal lymphoma responds well to **standard chemotherapy** for lymphoma, with remission times of 16 months reported.

Pharyngeal and tracheal masses and nasopharyngeal polyps are best treated with surgical resection.

PARASITIC DISEASE

Classical signs

- Coughing.
- Reduced physical activity and reluctance to play.
- Mild to severe dyspnea.
- Weight loss, poor coat, inappetence.
- Sudden marked respiratory distress (feline heartworm).

See main reference on page 104 for details (The Coughing Cat).

Clinical signs

Heartworm (*Diraflaria immitis*), lungworm (*Aelurostrongylus abstrusus*, *Capillaria aerophila*), lung flukes (*Paragonimus kellicotti*), migrating nematodes (*Toxocara cati*) and toxoplasmosis all may cause respiratory signs.

Coughing may be present and is typically harsh, productive and paroxysmal.

Mild to marked dyspnea and reduced activity may be observed, depending on the severity of the lung disease.

Weight loss, poor coat and ill-thrift may be evident.

Vomiting is a common sign with feline heartworm disease. Sudden death or sudden extreme respiratory distress and generalized respiratory failure occur in approximately 30% of symptomatic cats with heartworm disease.

Diagnosis

Feline heartworm disease is suggested by a positive heartworm antibody test, radiographic changes of dilated and blunted pulmonary arteries and evidence of

heartworms on ultrasound. Occasionally peripheral basophilia is evident (see Feline heartworm page 104, The Coughing Cat).

Lungworm infection with *Capillaria aerophila* is diagnosed by finding eggs in the stools or lung wash, and with *Aelurostrongylus abstrusus*, by finding larvae in the lung wash or fecal Baermann.

Lung flukes (*Paragonimus kellicotti*) produce operculated eggs in the stool.

Toxoplasmosis rarely produces clinical disease in cats. Mixed fluffy interstitial and alveolar patterns are typically evident on radiographs. Tachyzoites may be recovered in the lung wash.

Differential diagnosis

Other forms of pneumonia, including bacterial, viral, fungal, inflammatory and neoplasia, need to be considered if no larvae or ova are found in the stool or lungwash.

Treatment

Feline heartworm disease therapy is usually symptomatic, as adulticide therapy is associated with a high mortality rate (see Feline heartworm disease, page 105, The Coughing Cat).

Lungworm – *Capillaria aerophila* and *Aelurostrongylus abstrusus* – **fenbendazole** (50 mg/kg PO q 24 h for 3 days) or **ivermectin** (400 µg/kg PO, SQ).

Lung flukes – *Paragonimus kellicotti*, fenbendazole (50 mg/kg PO q 24 h for 3 days), or **praziquantel** (25 mg/kg PO q 8 h for 2 days).

Toxoplasmosis – **clindamycin**, 12.5 mg/kg PO q 12 h, potentiated sulfa (trimethoprim or ormetoprim) or azithromycin.

MYOPATHY/NEUROPATHY

Classical signs

- Dyspnea characterized by weakened chest excursions.
- Weakened gait, ventroflexion of the head.
- Regurgitation may lead to aspiration pneumonia.

See main reference on page 941 for details (The Cat With Generalized Weakness).

Clinical signs

Dyspnea associated with myopathy or neuropathy is related to weakness of the intercostal and diaphragmatic muscle, causing diminished ventilation.

Signs related to the underlying disease will be evident, for example:

- **Hyperthyroid myopathy** is usually seen in older cats. Signs include ravenous appetite, restlessness, weight loss, poor haircoat, generalized muscle wasting and weakness.
- **Hypokalemic myopathy** occurs in older cats usually secondary to renal insufficiency, or in Burmese cats less than 1 year of age. Ventroflexion of the head, a stiff stilted gait, inability or reluctance to walk or jump are common signs. Sensitivity to palpation of the larger muscle groups may be evident.
- **Hypocalcemic myopathy** results in episodic generalized weakness, tetany or tremors. It occurs most commonly after thyroidectomy, but occasionally occurs with hypoparathyroidism, chronic renal failure, pancreatitis, eclampsia or phosphate-containing enemas.
- **Hyperadrenocorticism** results in poorly controlled diabetes mellitus, unkempt haircoat, pot-bellied appearance and generalized muscle weakness.
- **Myasthenia gravis** occurs typically in adult cats or Siamese < 1 year of age and presents as generalized muscle weakness and stiff stilted gait exacerbated with exercise. Severe dyspnea may be evident if aspiration pneumonia is present.
- **Polymyositis** produces generalized pain on palpation of muscle groups, and a stiff stilted gait.
- **Botulism toxicity** results in flaccid paralysis of skeletal or respiratory muscles.
- **Polyradiculoneuritis** produces an ascending flaccid paralysis of skeletal and respiratory muscles.
- **Tick paralysis** from *Demacantor* spp. and *Ixodes* spp. ticks, produces a rapidly progressive skeletal and respiratory paralysis.

Diagnosis

Serum electrolytes (i.e., potassium and calcium) should be measured to rule out hypokalemia and hypocalcemia.

Endocrine testing involves measurement of total T4 and free-T4 (hyperthyroidism), blood and urine glucose, fructosamine concentration (diabetes mellitus), or ACTH stimulation testing (hyperadrenocorticism) if clinical signs are consistent.

Acetylcholine receptor antibodies assay is used for myasthenia gravis.

Measurement of muscle enzymes (creatine phosphokinase activity) and muscle biopsy are necessary for diagnosis of myositis.

PNEUMONIA

Classical signs

- Cough.
- Inspiratory/expiratory dyspnea.
- Fever.
- Occasional nasal discharge.

Pathogenesis

Pneumonia may be primary or secondary and associated with bacterial, mycoplasmal, *Chlamydomphila felis*, fungal or viral agents.

Primary bacterial pathogens include *Bordetella bronchiseptica* and *Pasteurella multocida*, which are common flora of the oropharynx, and can colonize the lower respiratory tree.

Secondary bacterial infection is possible with many opportunist organisms including streptococci, *Bordetella bronchiseptica*, *Pseudomonas* spp., *Nocardia* spp. and *Actinomyces* spp.

Pneumonia may occur following lung damage from various sources, or associated with diseases that reduce immunocompetence such as:

- Aspiration as a result of esophageal dysmotility, or during recovery from general anesthesia, etc.
- Metabolic disease including uremic pneumonitis, hyperadrenocorticism and diabetes mellitus.
- Trauma (blunt, penetrating or surgical trauma).
- Immunosuppression from drugs, neoplasia, or retroviral infection.
- Pre-existing infection.

Mycoplasma pneumonia is rare, but may be a sequel of severe URT infection.

Chlamydiosis can result in pneumonitis in kittens.

Protozoal (toxoplasmosis) and parasitic (capillariasis, aelurostrongylosis, *Paragonimus kellicotti*) pneumonia may occur.

Primary fungal pneumonia is mainly restricted to *Cryptococcus neoformans*. Infection can occur as a sequel to fungal rhinosinusitis, or as primary pneumonia.

Viral interstitial pneumonia with feline calici virus has been reported.

Less common fungal pneumonias include blastomycosis, histoplasmosis, aspergillosis and candidiasis.

Clinical signs

A **deep productive cough** may be heard, although coughing is not as common as in dogs.

Fetid breath halitosis.

Fever is common, although a subnormal body temperature can occur if the cat is septic.

Inspiratory and expiratory dyspnea may be evident, often with open-mouth breathing.

Adventitial breath sounds, including crackles, wheezes, snaps and pops may be audible. Breath sounds may be absent over areas of lobar consolidation.

Lethargy and anorexia are typically present, and weight loss and ill thrift may be evident if the pneumonia is more chronic.

Infectious pneumonia is uncommon in cats. A recent study of 39 cats with infectious pneumonia showed that a substantial proportion had no clinical signs that were referable to the respiratory tract (36% of cats), they lacked clinical signs of systemic illness (41%), and had unremarkable findings on hematology (22%) and thoracic radiography (23%).

Diagnosis

Thoracic radiography findings include focal or generalized alveolar densities with air bronchograms, or focal areas of complete consolidation.

- A ventral distribution of lesions may signal aspiration as the cause of pneumonia.
- A miliary interstitial pattern is seen with blastomycosis.

- **Hilar lymphadenopathy** supports **fungal or mycobacterial** pneumonia, although infiltrative **lymphosarcoma** may mimic this.

Hematology may reveal neutrophilia with or without a left shift and toxic neutrophils (Doehle bodies, etc.).

- Low-grade non-responsive anemia and monocytosis may support chronicity.

Hypoxemia ($\text{PaO}_2 < 80$ mmHg on room air or $\text{SPO}_2 < 90\%$) may be present, with trends monitored by arterial blood gas or pulse oximetry.

- **Note:** the oxygen saturation curve **drops steeply** with SPO_2 values $< 90\%$.

Samples for cytology and culture can be obtained using percutaneous lung aspiration, transtracheal wash, unguided bronchioalveolar lavage or bronchoscopic lavage. Cultures for aerobic and anaerobic bacteria should be performed and a fungal culture is indicated if infection is possible within the geographical region. Results of cultures must be evaluated in light of other data including the concentration of bacteria, cytological findings, etc.

- Bacterial pneumonia is characterized by suppurative inflammation involving degenerative neutrophils with intracellular bacteria.
- Fungal and mycobacterial diseases have pyogranulomatous inflammation, with characteristic organisms seen on routine or special stains.

Cryptococcal titers may aid in the diagnosis.

Differential diagnosis

Chronic small airway disease (feline asthma/ bronchitis), pulmonary infiltrate with eosinophils (PIE) and lymphomatoid granulomatosis may share many similar historical, clinical and radiographic signs and need to be differentiated on clinical and histopathologic findings.

Pulmonary neoplasia, either primary (squamous cell carcinoma, bronchogenic carcinoma), or metastatic disease, is differentiated on histopathology.

Treatment

Bacterial pneumonia requires antimicrobial therapy.

- The parenteral route is used in debilitated or septic patients, and oral therapy in outpatients.
- Antibiotic selection is best based upon specific culture and sensitivity testing.

- Initial empirical choices can be based upon Gram stain of the cytology sample.
 - Gram negative rods – amikacin, fluoroquinolones, trimethoprim-sulfa, chloramphenicol.
 - Gram positive cocci – beta-lactams, trimethoprim-sulfa, chloramphenicol.
 - *Bordetella* – amikacin, tetracycline, chloramphenicol.
 - Anaerobes – beta-lactams, second-generation cephalosporins, clindamycin.

Fungal pneumonia requires antifungal therapy.

- **Itraconazole** at 5–10 mg/kg PO daily is the drug of choice, with 50–60% response rates quoted in cats.
- **Amphotericin B** (0.25 mg/kg IV q 2 days), alone or in combination with itraconazole.
- If CNS signs are present with cryptococcosis, **fluconazole** (2.5–5.0 mg/kg PO daily) is the drug of choice to cross the blood–brain barrier (see Cryptococcosis, page 27 in The Cat With Signs of Chronic Nasal Disease).

Viral pneumonia treatment is mostly supportive. There is no clear evidence to suggest antiviral therapy is of benefit. Low-dose oral **alpha interferon** (30 IU PO daily) may possibly be beneficial, although reports are anecdotal.

Supportive care is vital. Airway and systemic hydration are essential for mucociliary clearance.

- Intravenous crystalloids need to be used judiciously if there is increased vascular permeability in the lung.
- Nebulization with saline may be helpful.
- **Physical therapy**, such as positional changes, coupage of the chest wall (percussion with a cupped hand) and enforced mild exercise, all enhance the clearance of debris from the lung.
- **Oxygen enrichment** via nasal O₂ catheter, oxygen tent or cage may be essential in critical cases.
- Bronchodilator therapy remains controversial in the treatment of pneumonia.

Prognosis

Prognosis depends on the agent and the severity of the infection.

Bacterial pneumonia has a fair to good prognosis if there are no other debilitating factors, but prognosis

is worse in patients with pre-existing illness (neoplasia, multiple trauma, multiple organ failure), or patients on immunosuppressive therapy for immune-mediated disease or organ transplantation.

Prognosis for **cryptococcal pneumonia** is generally fair to good provided the cat is not debilitated on presentation, and therapy is continued sufficiently long enough for antibody titers to fall to zero.

Prevention

Avoid the source of infectious agents, such as bird droppings and other risk factors, for example, aspiration after anesthesia.

LARYNGEAL EDEMA

Classical signs

- Inspiratory dyspnea.
- Stertorous breathing.

See main reference page 42 (The Cat With Stridor).

Clinical signs

Inspiratory dyspnea which may be associated with severe respiratory distress.

Stertor occurs, which is worsened with excitement or exercise.

Diagnosis

Acute onset of inspiratory dyspnea.

Laryngoscopic inspection under heavy sedation or light anesthesia with a rigid laryngoscope and blade reveals erythema and edema of the laryngeal mucosa.

Differential diagnosis

Laryngeal paralysis, laryngeal mass lesion or foreign bodies.

GRASS AWNS, FOREIGN BODIES

Classical signs

- Sneezing (nasal foreign bodies), coughing (tracheobronchial foreign bodies).
- Inspiratory/expiratory dyspnea, depending on location.
- Nasal discharge.

Pathogenesis

Foreign bodies are usually **inhaled or regurgitated** and rarely penetrate through the skin. Barbed grass awns or seeds or blades of grass favor one-way migration (i.e., difficult to expel backwards).

Inhaled foreign bodies tend to lodge in the nasal cavity in cats.

- As cats rarely mouth-breathe, inhaled tracheal foreign bodies occur much less commonly than in dogs.

Penetrating foreign bodies can lodge in the nasal cavity, such as pellets or a tooth broken from an opponent during a cat fight.

Nasopharyngeal foreign bodies may lodge above the soft palate after vomiting. Food, hairballs and blades of grass are more common than grass seeds in this area.

Tracheobronchial foreign bodies are often the **result of aspiration** of regurgitated ingesta.

Clinical signs

Nasal foreign bodies create intense sneezing, pawing or rubbing the nose along the ground, and nasal discharge (often unilateral) with stridorous (*whistling*) nasal breathing.

Nasopharyngeal foreign bodies cause gagging, dysphagia and reverse sneezing. Coughing may occur secondary to post-nasal drip (aspiration of caudal nasal discharge). Stertorous breathing (*snoring*) may occur.

Tracheobronchial foreign bodies cause **coughing** and **signs of fixed obstruction** (i.e., both inspiratory and expiratory dyspnea).

- The coughing is often harsh and productive, and may be elicited with tracheal palpation.

Diagnosis

Nasal and nasopharyngeal foreign bodies often result in little change on radiographs other than a unilateral fluid density. Rhinoscopy is often both diagnostic and therapeutic, if the foreign body can be retrieved.

Tracheal foreign bodies may be seen radiographically. Rigid tracheoscopy allows for larger retrieval instruments to be utilized than with flexible endoscopy.

Bronchial foreign bodies may cause complete lobar atelectasis or abscessation radiographically. **Right caudal and accessory lobes** are most often affected with **inhalation foreign bodies**. **Right middle lobe** is affected commonly with **aspiration of vomitus**.

Differential diagnosis

Other nasal diseases, such as infectious (especially fungal), nasal cuterebriasis or neoplastic disease, tend to have a more insidious onset. Upper respiratory tract viral infection, especially calicivirus, causes acute paroxysms of sneezing, which in the early stages could appear similar to a nasal foreign body.

Nasopharyngeal polyps tend to have a more insidious onset.

Tracheal or bronchial neoplasia have a more insidious onset.

Treatment

Effective treatment involves removal of the foreign body and most can be removed endoscopically. Nasal foreign bodies may be endoscopically retrieved or hydropulsed. Occasionally, rhinotomy is required, especially for foreign bodies that have migrated into the frontal sinuses.

If a lung lobe is abscessed with a bronchial foreign body, lobectomy may be required.

Prognosis

Prognosis is excellent with removal of the foreign body.

Prevention

Appropriate hairball prophylaxis with combing and oral lubricant/laxatives reduces the likelihood of vomiting and aspiration of vomitus or the hairball.

Avoidance of grass fields during seed time.

PULMONARY NEOPLASIA

Classical signs

- Non-productive cough, with or without hemoptysis.
- Reduced activity.
- Tachypnea and dyspnea – subtle to marked, especially if pleural effusion is evident.
- Fetid halitosis.
- Mass lesion radiographically.
- Anorexia, weight loss, muscle wasting.

Pathogenesis

Pulmonary neoplasia may be **primary** or result from **secondary** metastases from distant neoplasms.

Primary tumors include **bronchogenic carcinoma**, **pulmonary adenocarcinoma** and **squamous cell carcinomas**.

Secondary metastatic tumors include a wide variety of carcinomas (i.e., mammary adenocarcinomas) and sarcomas (i.e., osteosarcoma), and local metastases from primary lung tumors.

Pleural malignancy may cause dyspnea, either by the space-occupying nature of the mass, or from secondary pleural effusion.

Clinical signs

Reduced activity with reluctance to play or run may be observed.

Inappetance or anorexia and weight loss are often present.

Fetid halitosis may be noticed on physical exam or by the owner.

A non-productive cough, with or without hemoptysis is sometimes present. Dyspnea (inspiratory and expiratory) and respiratory distress may be evident in the later stages, or if pleural effusion develops.

Pleural effusion results in muffled heart and lung sounds ventrally and worsening of dyspnea in lateral recumbency.

Very rarely, lameness occurs from peripheral appendicular bone lesions of hypertrophic osteopathy.

Diagnosis

Chest radiographs demonstrate a solid tissue mass(es) or nodular interstitial pattern.

- Sensitivity is limited to masses > 10 mm diameter, and multiple views are important to maximize diagnosis. Hilar lymphadenopathy may be present.

Other imaging modalities, such as CT or MRI are useful if available.

Biopsy of mass(es) is required for definitive diagnosis, as well as for distinguishing the origin of tumor.

- Biopsy options include percutaneous needle aspiration or core biopsy, bronchoscopy, or unguided bronchioalveolar lavage, or transbronchial lung biopsy.
- Ultrasound is often a poor tool to guide percutaneous biopsy needles, unless the entire lung lobe has become consolidated, as the sonic beam is reflected by any aerated lung tissue.
- Triangulating the landmarks based on two orthogonal radiographic views is extremely effective for percutaneous biopsy.
- Transbronchial cytology (TTW or BAL) is often disappointing, due to the interstitial nature of the lesion.
- Transbronchial lung biopsy is a promising technique for obtaining samples for histopathology, but is only available at some institutions.

Surgical biopsy may be performed via thoracotomy, generally during lobectomy.

- Local lymph nodes should be aspirated or biopsied for staging.

Thoracocentesis and cytology of pleural fluid is occasionally diagnostic if neoplastic cells have exfoliated.

Differential diagnosis

Infectious disease, especially fungal and parasitic granulomas, foreign body reactions, inflammatory granulomatous lesions, and lung lobe torsions may mimic neoplastic disease clinically and radiographically.

Treatment

Surgical resection is the treatment of choice for solitary primary neoplasms. Cure or long-term remission is possible with wide surgical margins. If non-resectable,

excision of nodules may palliate clinical signs temporarily.

Chemotherapy and radiation have been attempted in generalized pulmonary neoplasms, with disappointing results. Metastases from distant tumors carry a grave prognosis, although pulmonary lymphoma may attain remission with chemotherapy.

General supportive care and nutrition are important.

Prognosis

Fair to excellent with surgically resectable **primary pulmonary neoplasms** without metastasis.

Grave with metastatic disease or malignant pleural effusions.

CONGENITAL HEART DEFECTS

Classical signs

- Reluctance to play or run.
- Anxious, uncomfortable breathing.
- Dyspnea – if present varies from mild to severe.
- Abnormal heart sounds (murmurs, gallops, arrhythmias).
- Signs of pleural effusion – increased chest excursions with little airflow.

Clinical signs

Atrioventricular valve dysplasia, septal defects, aortic and pulmonic stenosis (rare) and patent ductus arteriosus all lead to pressure and/or volume overload on the heart, and potentially result in congestive heart failure.

Heart murmurs at various locations (left apex for mitral valve dysplasia, right apex for ventricular septal defect), and intensities (continuous murmur of patent ductus arteriosus) occur depending on the type of congenital heart defect.

The **cat may be reluctant to play or run**, and if present, **dyspnea** varies from mild to severe. Open-mouth breathing or cyanosis may occur with severe defects.

Signs of pleural effusion include increased chest excursions with little airflow.

Treatment

Corrective surgery for patent ductus arteriosus and pulmonic stenosis (rare in cats) is available in specialist centers.

Most other problems require medical management depending on the presenting signs (see page 140, The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

LARYNGEAL PARALYSIS

Classical signs

- Inspiratory dyspnea and increased airway noise.
- Stertorous breathing (*snoring*).
- Stridor (high-pitched *whistling* = *obstructive*).
- Voice changes, absence of purring.

See main reference page 43 (The Cat With Stridor).

Clinical signs

Inspiratory dyspnea.

Stridor which is worse with excitement or exercise.

Occasional stertorous breathing or snoring.

Voice changes such as an absent or whisper-like meow, or harsh purring sounds.

Diagnosis

Diagnosis is based on signs of laryngeal stridor, inspiratory dyspnea and visualization of the larynx.

Laryngoscopic inspection under heavy sedation or light anesthesia with a rigid laryngoscope and blade reveals absent or **paradoxical motion** of the arytenoid cartilages. Normally they should abduct on inspiration. If they close on inspiration, it is paradoxical motion.

Erythema and swelling (“kissing lesions”) of the arytenoid mucosa may be evident as a result of repetitive focal impact of the touching surfaces of the corniculate processes.

Low-dose ketamine (4–6 mg/kg IV), ketamine/diazepam (3–5 mg/kg/0.1–0.2 mg/kg IV) or propofol (4–6 mg/kg IV) allows visual inspection without diminishing laryngeal function.

Differential diagnosis

Other causes of dynamic or fixed upper respiratory tract obstruction are distinguished on laryngoscopic inspection (see Chapter 4, The Cat With Stridor).

Dynamic causes of upper respiratory tract obstruction are:

- Brachycephalic airway syndrome. This results in an elongated soft palate causing partial laryngeal obstruction and entrapment of the epiglottis, and lateral ventricle eversion causing ballooning of the mucosa of the lateral ventricles into the lumen.
- Cervical tracheal collapse.
- Pyogranulomatous or lymphoplasmacytic laryngitis results in a roughened, proliferative mucosa of the arytenoids and epiglottis.

Fixed causes of upper respiratory tract obstruction are:

- Oropharyngeal neoplasia (squamous cell carcinoma, oral melanoma, nasopharyngeal polyp).
- Tracheal neoplasia (intraluminal adenocarcinoma, extraluminal masses).
- Tracheal foreign bodies.

CONGENITAL ANOMALIES OF THE UPPER RESPIRATORY TRACT

Classical signs

- **Dyspnea, usually fixed obstruction (inspiratory and expiratory) due to stenotic nature of most defects.**
- **Inspiratory dyspnea and stertor occur with the brachycephalic syndrome.**

See main reference on page 39 for details (The Cat With Stridor).

Clinical signs

Stenotic nares, hypoplastic trachea, etc., potentially create a non-dynamic, fixed obstruction leading to inspiratory and expiratory dyspnea, although inspiratory dyspnea may be more prominent with stenotic nares and hypoplastic trachea, if there is a dynamic component to the obstruction.

Dynamic obstructions such as occur with elongated soft palate create **inspiratory dyspnea with stertor**.

Oronasal reflux, especially with fluids, occurs with cleft palate.

With stress, nasal obstruction may result in mouth breathing.

Treatment

Treatment involves surgical correction of the defect, if possible.

ACUTE SYSTEMIC ANAPHYLAXIS

Classical signs

- **Acute dyspnea**
- **Hypotensive shock**
- **Collapse**
- **Pale mucous membranes**

See main reference on page 566 for details (The Cat With Polycythemia).

Clinical Signs

- Pulmonary signs such as **severe acute dyspnea** predominate, because the lung is the “**shock organ**” in cats.
- Signs of **hypotensive shock**, such as pallor and collapse, accompany the pulmonary signs.
- **The onset of clinical signs occurs in seconds to minutes after exposure** to the inciting antigen.
- Occasionally, **cutaneous swelling** may be noted around the face and paws.

Diagnosis

- Diagnosis is made by a **combination of appropriate history and characteristic clinical signs**.
- **No laboratory tests are currently available to make a definitive diagnosis** of acute systemic anaphylaxis.

CARDIAC TUMORS

Classical signs

- **Dyspnea and trachypnea.**

Clinical signs

Cardiac tumors are extremely rare in cats.

Dyspnea may occur from obstruction of blood flow to or from the heart (i.e., aortic body chemodectomas), or because the tumor acts as a space-occupying mass compressing the mainstem airways at the hilus.

Malignant pleural or pericardial effusion may occur, creating dyspnea and weakness or lethargy.

Diagnosis

Diagnosis is based on finding a mass lesion on the heart base when imaged with radiography or ultrasonography.

TRACHEOBRONCHIAL COLLAPSE

Classical signs

- Harsh, honking cough.
- Stridor on inspiration if cervical segment involved.
- Very rare in cats.

See main reference on page 44 for details (The Cat With Stridor).

Clinical signs

Tracheobronchial collapse is **very rare in cats** and generally occurs **secondary to trauma or to compression** caused by an **extraluminal mass**. It has been reported associated with proximal tracheal obstructions from a tracheal granuloma or polyp.

The **cough is often harsh, non-productive and paroxysmal**, ending in a gagging episode which may appear to be productive.

Cervical trachea collapse produces inspiratory dyspnea, while intrathoracic tracheal or bronchial collapse will lead to mostly expiratory dyspnea. Stridor is occasionally reported.

Diagnosis

Radiographs may show attenuation of the tracheal or bronchial lumina. Fluoroscopy may be more sensitive for dynamic collapse.

Tracheobronchoscopy is valuable in both diagnosing and grading the severity of the collapse.

PULMONARY FIBROSIS

Classical signs

- Dyspnea.
- Rare in cats.

Clinical signs

Chronic progressive dyspnea associated with restrictive pulmonary disease and tachypnea.

Occasionally cats will cough, especially if a secondary bacterial infection occurs.

Very rare in cats, and may be associated with chronic small airway disease (feline asthma/bronchitis complex) or chemotherapy.

A recent paper cited an emerging syndrome of spontaneous feline idiopathic pulmonary fibrosis. In this study, chronic respiratory disease with pathology consistent with usual interstitial pneumonia (UIP) spontaneously developed in domestic short- and long-hair cats and Persians.

- Duration of respiratory signs ranged from years (6/22 cats) to acute death (3/22 cats). Cough (12/16), dyspnea (16/19) and increased respiratory rate (19/19 cats) were present. Crackles, wheezes, and harsh or loud lung sounds were auscultated in some cats.

Diagnosis

Marked interstitial pattern is visible on radiographs.

Bronchioalveolar fluid may contain a predominance of lymphocytes or non-lytic neutrophils, eosinophils and macrophages. Culture sample to rule out secondary bacterial infection.

Diffuse interstitial fibrosis is evident on histopathology of a lung biopsy.

Treatment

Bronchodilators orally such as sustained release theophylline (TheoDur or Slo-bid Gyrocaps 25 mg/kg q

24 h in the evening) or inhaled via a face mask (albuterol).

Steroids at anti-inflammatory doses are usually the cornerstone of therapy (prednisone 1 mg/kg q 12 h for 7 days then 1 mg/kg q 24 h, then reducing to the minimum effective dose over 2–4 months).

Antibiotics are indicated when signs worsen and do not respond to steroids. If there are many neutrophils in the BAL fluid, a preliminary course of antibiotics may be indicated before steroids are used, to see if there is any improvement in signs. Be careful about combined use of enrofloxacin and theophylline, as enrofloxacin has the potential to inhibit liver metabolism of theophylline and increase plasma concentrations.

FIBROSING PLEURITIS

Classical signs

- Dyspnea.
- Muffled heart and lung sounds ventrally.

Pathogenesis

Fibrosing pleuritis is a rare sequence of pyothorax and other chronic pleural effusions, especially chylothorax.

Chronic pleuritis results in restrictive fibrosis of the pleura, which prevents the lungs expanding.

Because of the restricted expansion of the lungs during inspiration, negative pressure is increased in the pleural space, resulting in rapid reaccumulation of fluid.

Clinical signs

Dyspnea occurs which is inspiratory and expiratory.

Muffled lung and heart sounds are audible ventrally as a result of the pleural effusion.

There is rapid return of hydrothorax, even after the pyothorax has been successfully treated.

Diagnosis

Radiography may reveal distorted poorly expanded rounded lung lobes.

Diagnosis is frequently only made at surgery.

Treatment

Stripping of the fibrotic pleura from the lungs followed by glucocorticoid therapy has been attempted, but is rarely successful.

Prognosis

Prognosis is generally poor.

6. The cat with hydrothorax

Robert Allen Mason

KEY SIGNS

- Dyspnea worsened in lateral recumbency.
- Dull heart and lung sounds ventrally.
- Fluid aspirated from chest (chyle, blood, transudate, modified transudate, exudates).

MECHANISM?

- Accumulation of fluid (blood, transudate, modified transudate, exudate, chylous) in the pleural cavity.
- There is a delicate balance of the normal fluid dynamics between the slight transudation across the parietal pleura and the slight absorption across the visceral pleura.
- Factors which facilitate pleural effusion include decreased oncotic or increased hydrostatic pressure within blood vessels, increased vessel wall permeability, and lymphatic obstruction.
- Excessive fluid in pleural cavity (chyle, blood, transudate, modified transudate, exudate).
- Pleural effusion encroaches on the space generally occupied by the lungs, and creates hydraulic pressure opposing expansion of the lungs.

WHERE?

- Pleural space is the cavity between the **visceral** and the **parietal pleura**. Generally, this space contains a few milliliters of fluid to act as a lubricant.

WHAT?

- Chylothorax – secondary to congestive heart failure, mediastinal neoplasia, lymphangiectasia, or trauma.
- Hemothorax – secondary to trauma, coagulopathy, or neoplasia.
Pyothorax – from penetrating chest wound, ruptured lung abscess, or systemic bacteremia.
- Transudation – secondary to hypoalbuminemia from hepatic failure, protein-losing enteropathy, or protein-losing nephropathy. May also occur from increased hydrostatic pressure from congestive heart failure or lymphaticovenous obstruction from a neoplastic or granulomatous disease of the chest.
- Modified transudates result either from causes of chronic transudates or occur early in diseases, which cause exudates such as vasculitis secondary to feline infectious peritonitis, uremia, neoplasia or pancreatitis.

QUICK REFERENCE SUMMARY

Diseases causing hydrothorax

DEGENERATIVE

- **Congestive heart failure (cardiomyopathy)* (p 83)**

Pleural effusion may result from right-sided or biventricular failure, most commonly associated with cardiomyopathies. Cardiac tamponade from pericardial effusion may cause pleural effusion. Abnormal heart sounds (gallops, murmurs, arrhythmias) are commonly noted. Cardiomegaly, pulmonary venous congestion and pulmonary edema may be seen radiographically. Effusion fluid is commonly a modified transudate or chylous effusion. Rarely, heartworm disease has been associated with pleural effusion of a clear transudate.

ANOMALY

- **Chylothorax** (p 77)**

Milky white, lipid-rich lymphatic fluid accumulates in the pleural space secondary to thoracic duct hypertension. Idiopathic chylothorax is the most common form. Less commonly chylothorax is associated with cardiomyopathy, or mediastinal neoplasia. Affected cats are often chronically ill for several months prior to the onset of dyspneic signs of pleural space disease.

MECHANICAL

- **Pleural/mediastinal masses (p 84)**

Malignancies like thymoma or thymic lymphoma may cause obstruction of the lymphatic drainage of the pleural cavity, leading to hydrothorax and dyspnea. Mass lesions may be observed radiographically, especially after thoracocentesis. Dyspnea rarely may not improve significantly after drainage. Transudate or exudate found on fluid analysis.

- **Hemothorax (p 87)**

Trauma or bleeding diatheses from congenital coagulopathies (hemophilia, Chediak–Higashi) or acquired coagulopathies (rodenticide toxicity) may create hemothorax. Fluid is pink to frankly red in color, but often defibrinated and does not clot. Evidence of blunt or penetrating chest trauma is common. There may be other signs of coagulopathy (scleral hemorrhages, hematoma formation, epistaxis, etc.).

METABOLIC

- **Hypoproteinemia (p 88)**

Protein-losing enteropathy, protein-losing nephropathy, and hepatic failure are common causes of low serum protein, specifically hypoalbuminemia, which may result in decreased oncotic pressure and transudation. This fluid is clear to lightly straw-colored. Signs include dyspnea, weight loss, especially loss of muscle mass +/- icterus.

NEOPLASTIC

- **Airway / Pulmonary neoplasia (p 87)**

Tracheal adenocarcinomas (i.e., Siamese), primary pulmonary masses (pulmonary adenocarcinoma) or secondary metastatic disease from distant neoplasms may create effusions. Fluid is often modified transudate and is often grossly opaque. It is more common in middle-aged to older cats.

INFECTIOUS

- **Pneumonia (p 84)**

Moist, productive cough, fever, halitosis may be seen. Parapneumonic pleural effusions are commonly sterile inflammatory exudates, often grossly serous or hemorrhagic rather than purulent. They often resolve with treatment of the lung disease.

- **Feline infectious peritonitis (FIP)* (p 81)**

Vasculitis caused by the immune response to feline coronavirus causes exudation of a protein-rich fibrinous fluid into various body cavities including the pleura. Systemic illness is common.

- **Pyothorax*** (p 75)**

There is an accumulation of grossly obvious purulent exudate in the pleural cavity. Turbid, flocculent, often fetid-smelling fluid with cells that are primarily degenerative neutrophils. Dyspnea, signs of chronic disease (weight loss, ill-thrift), and fever are common signs.

INTRODUCTION

MECHANISM?

Pleural space is the cavity between the **visceral pleura** (covering the lungs and the pericardium) and the **parietal pleura** (covering the internal thoracic wall, diaphragm and mediastinum).

Generally, this space contains a few milliliters of fluid to act as a lubricant for motion of the lungs and the heart. This fluid is very close to the composition of serum.

Visceral and parietal pleurae have distinctly separate vascular supplies and lymphatics. The parietal pleural lymphatics have **stomata** – gaps that exist to remove particulate matter from the pleural space. Absorption through these stomata may be facilitated by motion of the chest wall during breathing. Obstruction of the stomata may decrease absorption of exudative effusions.

Normal fluid dynamics of the pleura balance between opposing **hydrostatic** and **oncotic pressures** across the pleurae. There is a delicate balance between the slight transudation across the parietal pleura and the slight absorption across the visceral pleura, that maintains a steady ratio of production to drainage of fluid through the pleural space.

Disease conditions that disrupt this balance can lead to pleural effusion by changing;

- oncotic pressure.
- systemic or pulmonary vascular pressure.
- lymphatic hydrostatic pressure, compliance or permeability.
- vascular permeability.

Hydrothorax is the accumulation of fluid in the pleural cavity, which may consist of blood, transudate, modified transudate, exudate or chylous fluid

Various fluid types that may accumulate include:

- **Hemorrhage** consists of frank blood, and may be caused by neoplasia, coagulation defects or trauma. The hematocrit of the fluid is often much lower than the peripheral blood, and it rarely clots after removal.
- **Transudates** are low protein (< 15 g/L), low cellularity ($< 1.0 \times 10^9$ /L) fluids that leak out of the vascular space secondary to lymphatic or venous occlusion from congestive heart failure, mediastinal mass obstruction or infiltration of the pleura.
- **Modified transudates or exudates** are more cellular ($1.0\text{--}7.0 \times 10^9$ /L and $5.0\text{--}20 \times 10^9$ /L, respectively), and higher protein (25–50 g/L and 30–80 g/L, respectively) fluids.
 - **Modified transudates** are associated either with **diseases that cause chronic transudates**, or occur **early in diseases that produce exudates**. Over time, chronic transudates produce pleural irritation that results in increased cell numbers and slightly increased protein in the fluid, which is then classified as a modified transudate. Modified transudates also occur early in diseases

that produce exudates from leaking blood vessels such as neoplasia, and vasculitis associated with feline infectious peritonitis, uremia, pancreatitis or neoplasia.

- **Pyothorax** is pus in the chest cavity from bacterial infection. Protein is high (30–70 g/L) and nucleated cell counts are high ($5\text{--}300 \times 10^9/\text{L}$).
- **Chylothorax** is a lipid-rich tissue fluid from obstruction or trauma to the thoracic duct. Protein content ranges from 25–60 g/L and cell counts from $1.0\text{--}20 \times 10^9/\text{L}$.

The fluid from these various forms of pleural effusion encroaches on the space generally occupied by the lungs, and creates hydraulic pressure that opposes the expansion of the lungs. Fluid volumes greater than 50 ml/kg result in dyspnea.

WHERE?

Hydrothorax is the result of conditions that affect the pleural space, especially conditions affecting the blood vessels or lymphatics of the pleura.

Blood vessel problems that contribute to hydrothorax include:

- Increased hydrostatic pressure from congestive heart disease or vascular obstruction.
- Decreased oncotic pressure from hypoalbuminemia secondary to liver disease, kidney or gastrointestinal protein loss.
- Increased vascular permeability from inflammation (vasculitis).
- Vascular rupture and hemorrhage (trauma, neoplasia).

Lymphatic diseases that contribute to hydrothorax include:

- Obstruction from congestive heart disease, lymphangiectasia or neoplasia.
- Rupture from trauma.

WHAT?

The following conditions are most commonly associated with the different forms of hydrothorax in cats:

- **Hemothorax** usually results from trauma or coagulopathy.
- **Transudation** results from either **increased hydrostatic pressure** (mediastinal mass, lymphatic infiltration or obstruction, and cardiac disease) or from

decreased oncotic pressure as a result of hypoalbuminemia (protein-losing enteropathy, protein-losing nephropathy or hepatic failure).

- **Chylothorax** is usually idiopathic and associated with lymphangiectasia, or may occur in association with congestive heart failure, mediastinal neoplasia or thoracic duct rupture.
- **Pyothorax** is most often associated with mixed bacterial infections presumed from a penetrating wound or foreign body.
- **Thoracic exudates** are most commonly associated with feline infectious peritonitis, but may also occur with neoplasia, pancreatitis and uremia.
- **The most common forms of hydrothorax** in the cat are pyothorax, neoplastic effusions, transudation from cardiac disease and chylothorax.

DIAGNOSIS

For cats with **mild to moderate clinical signs**, thoracic radiography may be diagnostic. Pleural fissure lines, separation of the lung borders from the thoracic wall, loss of cardiac detail, blunting of the costophrenic angles (lateral and VD views), widening of the mediastinum (DV view) can all indicate the presence of fluid in the pleural space.

With **severely affected cats** in respiratory distress, **radiography should be delayed** until after thoracocentesis (**cats with pleural effusions die in radiology!**).

An algorithm for the approach to the dyspneic cat follows;

- **A** – Airway – establish a patent airway.
- **B** – Breathing – be certain the patient is ventilating.
- **C** – Centesis – if the dyspnea has not resolved with steps A and B, then evaluating for the presence of pleural space disease via thoracocentesis is not only diagnostic, but therapeutic for both hydrothorax and pneumothorax. A negative tap would suggest the presence of a mass lesion or primary parenchymal disease such as *status asthmaticus*.

Thoracocentesis

- In the acute, emergency setting, a butterfly set may be rapidly introduced to alleviate life-threatening accumulations.
- In chronic or more stable cases, a polypropylene or Silastic IV catheter on an IV extension set with a three-way stopcock attached to a 20–60 ml syringe

works very well. Local anesthetic blockade may or may not be required, depending on the level of respiratory distress.

● **Technique**

- Have the patient sitting, standing or in sternal recumbency.
- Clip and aseptically prepare the 4th–7th intercostal space – above and below the costochondral junction.
- Infiltrate around the 7th intercostals space just above the costochondral junction with local anesthetic field block (optional if peracute and in severe distress), using 2% lidocaine or 2% mepivacaine. Block the skin, muscles and parietal pleura, as this is the most painful area.
- **Use 25 gauge needles and INJECT SLOWLY!**
- Place the catheter at the 7th intercostal space just above the costochondral junction. With a syringe on the catheter, aspirate using minimal negative pressure.
- Direct the catheter ventrally for fluid removal. If drainage is inadequate use a butterfly needle and aspirate the intercostal junction from the 4th–6th intercostals or place a chest drain.

● **Fluid analysis** should be performed to determine the etiology of the hydrothorax.

- Cytologic, clinicopathologic, and bacteriologic analysis will help determine the etiology. Common assessments include **physical parameters** such as color, transparency, specific gravity (SG), total protein (TP), and total nucleated cell counts (TNCC) and some **biochemical parameters** such as triglyceride, cholesterol, glucose and certain enzyme levels, such as lactate dehydrogenase (LDH).
- Hemothorax is characterized by frank blood. Erythrophagocytosis which is usually defibrinated may be evident cytologically, and generally has a hematocrit lower than peripheral blood.
- Transudates are clear and colorless with a specific gravity (SG) ≤ 1.013 , total protein (TP) < 2.5 g/L and low cellularity (total nucleated cell count [TNCC] $< 1.5 \times 10^9$ /L).
- Modified transudates are typically straw-colored to pink-white. Total protein is between 2.5 and 4.0 g/L, and TNCC between 1.0 and 7.0×10^9 /L. Modified transudates result from transudates modified from chronicity, prolonged increased

hydrostatic pressure (i.e., heart failure), or occur in acute inflammatory disease prior to exudation.

- Exudates vary from white to red, turbid to opaque, are high protein (> 3.0 g/L), and highly cellular (TNCC $> 7.0 \times 10^9$ /L. They are associated with inflammatory or neoplastic disease.

- **Thoracic radiography** should be performed after thoracocentesis to help to assess the success of pleural drainage and to facilitate imaging of mediastinal masses, pulmonary lesions or cardiac changes that may have contributed to the effusion. These changes may have been previously masked by the presence of the effusion.

Other imaging may be required depending on the character of the effusion (i.e., cardiac ultrasound if transudate, lymphangiography if chylous effusion, etc.).

DISEASES CAUSING HYDROTHORAX

PYOTHORAX***

Classical signs

- Dyspnea with exaggerated chest excursions/poor airflow.
- Muffled heart and/or lung sounds ventrally.
- Orthopnea (positional dyspnea – reluctance to lay in lateral recumbency).
- Signs of chronic disease (weight loss, ill-thrift), and fever are common.
- Grossly purulent exudate in the pleural cavity.
- History of fight wounds several weeks previous to presentation.

Pathogenesis

Septic bacterial infection of the pleural cavity results in purulent exudation.

Multiple routes of infection, include:

- Hematogenous with systemic sepsis spread via vasculature or lymphatics.
- **Extension from an adjacent infected structure**, including parapneumonic spread from lung infection or abscess, or from esophageal rupture, or mediastinitis.

- **Penetrating wound** as a result of a fight, a foreign body or thoracic surgery.

Fibrinous exudation and cellular infiltration occurring in response to bacterial infection results in obstruction of the parietal pleural stomata, which further reduces drainage of the exudation.

Clinical signs of systemic illness result from the chronic sepsis. Eventually respiratory signs become evident as fluid reaches critical volume (estimated in cats to be 50 ml/kg).

Clinical signs

Pyothorax is more common in **intact males**, and there is a **history of fight wounds** several weeks prior to presentation.

Heart and lung sounds are dull ventrally. Breathing sounds are harsh dorsally in standing or sternal recumbency. Chest wall percussion may be dull ventrally.

Dyspnea is characterized by marked chest wall excursions with minimal airflow. Orthopnea, or positional dyspnea is common. Dyspnea is worsened in lateral recumbency and cats often are **reluctant to lie in lateral recumbency**.

Signs of chronic disease are often evident. The cat may appear sick, septic, thin and unkempt.

Fever or, in the latter stages, hypothermia may be present.

There may be caudal displacement of the liver due to pleural fluid pressure on the diaphragm.

Diagnosis

Typically there is a vague history of being unwell for weeks, with inappetance, weight loss and recent onset of dyspnea.

Thoracic radiographs show significant pleural effusion with pleural fissure lines and loss of the cardiac silhouette. Effusions are usually bilateral, although not always.

Thoracocentesis may be both diagnostic and therapeutic in pleural space disease.

- Thoracocentesis should be **performed in all acutely dyspneic animals**, especially trauma patients, **prior to radiography**. These patients are extremely fragile, and even the minimal restraint involved in radiography may be excessive, and they may die during the procedure!
- A negative tap for air or fluid suggests solid pleural space disease (mass or herniated viscus), primary pulmonary (i.e., contusion in the trauma patient) or cardiac disease. If the tap is positive, remember that small animals may accommodate up to 50 ml/kg free fluid in the chest prior to becoming dyspneic.
- Be certain to remove as much fluid as possible, do not stop after you have a diagnostic sample.

Cytology

Cytology and Gram stain are important in identification of the pathogen, as culture is often negative.

Pyothorax is characterized by a thick, fetid, septic suppurative exudate. Cytology reveals a high protein fluid (TP > 30 g/L), highly cellular (TNCC > 7.0×10^9 /L) with mostly degenerative neutrophils, often with intracellular bacteria. Macrophages and reactive mesothelial cells are common.

- Bacterial infection is characterized by suppurative inflammation involving degenerative neutrophils with intracellular bacteria.
- Fungal and mycobacterial diseases have pyogranulomatous inflammation, with characteristic organisms seen on routine or special stains.

Bacteriology

Bacterial culture for aerobic and anaerobic bacteria is important, but negative cultures are not surprising, as many bacteria have been killed or had their growth inhibited by the lysozymes present in the exudate. Gram staining is an excellent way to document the initial categories of bacteria present, as well as following the response to therapy.

Hematology

Blood smear may reveal neutrophilia with or without a left shift and toxic neutrophils (Doehle bodies, etc.).

A low-grade non-responsive anemia and monocytosis may support chronicity.

Differential diagnosis

All causes of pleural effusion show similar signs of dyspnea and dull chest sounds. Most other causes, however, do not show the same severe systemic signs, other than some forms of pleural or pulmonary neoplasia.

Treatment

Thoracostomy (T) tube placement and chest drainage is the cornerstone of therapy.

- Tubes may be placed surgically or via a trocar. Placement along the ventral thoracic floor helps maximize complete drainage.
- **Continuous underwater sealed suction** with 20 cmH₂O of vacuum appears to be superior to intermittent drainage, but requires 24-hour direct supervision. Disposable, self-contained collection units are easily adaptable to cats. These are commercially available one-piece plastic chambers that adapt to a suction line on one end, and to the thoracostomy tube on the other. The effusion is collected and volume measured in the calibrated chamber.
- Occasionally bilateral T-tubes are required for complete drainage. Average duration of tube use is 3–5 days with continuous suction. Intermittent suction generally requires longer duration of therapy. Tubes are usually removed once less than 2 ml/kg of fluid is drained.
- Controversy exists as to the benefit of pleural lavage. There has been no convincing evidence showing any advantage to lavage, and the risk of contamination is high.

Systemic support with **IV fluid hydration** and antibiotic therapy is very important. Most patients are hypovolemic on presentation, and the initial fluid losses via the T-tube can be tremendous. Fluid requirements must include **volume replacement, maintenance, and ongoing losses** through the T-tube. Keeping the patient well-hydrated helps to promote the “dialysis membrane” effect of the pleura, effectively “washing” the pleural space and draining the excess fluid through the T-tube. Serum potassium and phosphorus levels should be monitored and supplemented, when indicated.

Antibiotics

Antibiotic selection is best based upon specific culture and sensitivity testing. Initial empirical choices can be based on the Gram stain of the cytology sample.

- **Gram-positive rods** – fluoroquinolones, chloramphenicol, clindamycin.
- **Gram-positive cocci** – beta-lactams, chloramphenicol.
- **Note:** aminoglycosides require oxygen-rich environments to be effective, and trimethoprim-sulfa drugs may be inactivated in purulent debris. For these reasons, these medications are not indicated in pyothoraces.

Beta lactams such as **ampicillin** at 20–40 mg/kg IV initially q 4 hours for 48 hours, then PO q 6–8 hours are sufficient for the majority of community-acquired infections.

Clindamycin is effective against *Bacteriodes fragilis*, found in approximately 15% of cases, and is dosed at 25 mg/cat PO q 12 hours.

Recommendation for length of antibiotic therapy varies from 4 to 12 weeks.

Prognosis

Prompt, aggressive and complete drainage of the abscess cavity in the pleural space is essential for successful therapy. The use of T-tube(s) with continuous suction has increased the treatment success rate of this disease tremendously.

Prognosis also varies with the presence or absence of underlying risk factors, such as pre-existing immunosuppressive disease with retroviral infection or systemic neoplasia.

With aggressive therapy, lack of significant risk factors, and long-term therapy with appropriate antibiotics, prognosis is very good to excellent.

Prevention

Neuter intact males. Prevent roaming and fighting.

CHYLOTHORAX**

Classical signs

- Muffled heart and/or lung sounds ventrally.
- Exaggerated chest excursions with poor airflow.
- Orthopnea (positional dyspnea with reluctance to lie in lateral recumbency).

Pathogenesis

Chyle is the lymphatic fluid being transported from the abdominal organs to the prehepatic circulation. It contains lipid-rich products such as chylomicrons, and grossly it is pink to milky white. Protein content may vary, and measurement may be interfered with by the presence of the lipids. Cells are primarily small lymphocytes, and the count (TNCC) is $< 10 \times 10^9/L$.

The **thoracic duct** is the cranial continuation of the **cysterna chyli**, the major lymphatic structure draining the abdominal organs. The **thoracic duct passes through the diaphragm at the aortic hilus** and proceeds cranially in the mediastinum dorsal to the thoracic aorta and ventral to the azygous vein. It terminates cranially at the lymphaticovenous junction **at the thoracic inlet, either into left jugular, subclavian, or brachiocephalic veins**. Here the lymphatic fluid from the entire body, except the right side of the face, the right pectoral limb, and the right thoracic wall, which drain into the right lymphatic duct, re-enters the venous circulation.

The rate of lymph flow through the thoracic duct in cats has been estimated **at 2 ml/kg/hour**, increasing up to 10-fold after a high-fat meal. Rapid accumulation of several hundreds of milliliters of fluid can occur with obstruction of or leakage from lymphatic drainage.

Chylous effusion in cats is most often idiopathic. The most commonly known causes are associated with increased lymphatic hypertension from congestive heart failure or obstructive neoplasia (see sections under Cardiomyopathy or Mediastinal masses in this chapter).

Increased systemic venous pressure associated with dilated cardiomyopathy and rarely heartworm diseases may result in lymphatic hypertension and, occasionally chylothorax.

Mediastinal neoplasia, especially lymphosarcoma and thymoma are most common neoplasias associated with chylothorax.

Occasionally thrombus formation associated with an indwelling jugular catheter results in chylothorax.

Idiopathic chylous **effusions** are associated with thoracic duct disease.

- Thoracic duct lymphangiectasia, demonstrated via contrast lymphangiography, is the most common finding in primary chylothorax in cats. There is

controversy whether this finding represents a cause and effect of lymphatic hypertension.

- Thoracic trauma is a less common cause of thoracic duct rupture, although this has been documented.
- Chronic chylothorax is irritating to the pleura and may cause fibrosing pleuritis and pericarditis.
- New evidence suggests this secondary fibrosing pericarditis may lead to increased right-sided pressures and decreased lymphaticovenous drainage, resulting in diminished drainage of the thorax, and persistence of the chylothorax.

Clinical signs

Chylothorax generally occurs in **middle-aged cats**, possibly more common in purebreds.

Vague signs of depression and lethargy, often for greater than 1 month, are common.

Tachypnea, dyspnea and the ventilation pattern typical for pleural space disease are present. This involves increased chest wall excursion, often with the head and neck extended, but very little airflow present. Dyspnea may be reported as acute in onset. Dyspnea is often worsened in lateral recumbency and cats are reluctant to lie in lateral recumbency.

Heart sounds are muffled but become more apparent after the chest tap and are generally normal.

Abnormal heart sounds such as murmurs, gallops or arrhythmias may be present if the chylous effusion is associated with congestive heart disease, but are generally absent in idiopathic chylous effusion.

Coughing may be present from pleural irritation.

Diagnosis

Clinically there are signs of pleural effusion and muffled heart sounds.

Thoracocentesis should be performed prior to radiography in the severely dyspneic patients, both as an emergency treatment and a diagnostic procedure.

- The typical effusion is grossly chylous with milky-white to pink fluid. Cell count is usually $< 1 \times 10^9/L$ and is largely lymphocytes, unless the effusion is chronic in which case large numbers of neutrophils and macrophages may be present.

- Cholesterol and triglyceride levels of the serum and the effusion may be measured and compared to definitively diagnose true chylous effusion, but these findings rarely change the prognosis or the management. True chylothorax has higher triglyceride and lower cholesterol levels than serum.
- So-called pseudo-chylous effusions have the same gross appearance but with higher cholesterol and lower triglyceride concentrations than serum. Pseudo-chylous effusion has been discussed in the veterinary literature for years, but there is little evidence that this exists as a clinical entity in cats.

Thoracic radiography should be performed after thoracocentesis.

- If cardiac or pulmonary vessel abnormalities are evident radiographically, this indicates the pleural effusion may be secondary to congestive heart failure.
- Chronic chylothorax may result in fibrosing pleuritis evidenced by rounded or collapsed lung lobes on radiography.
- Contrast lymphangiography may be performed if no underlying cardiac disease or neoplasia is detected.
 - A mesenteric lymphatic vessel is cannulated via celiotomy, and iodinated contrast media are injected. Thoracic duct lymphangiectasia is the most common finding with primary chylothorax in cats. Radiographically, dilated, tortuous lymphatics are found in the cranial mediastinum of affected cats. This procedure adds significant time under anesthesia, and may be technically difficult to perform without intraoperative radiography or fluoroscopy capabilities. There is current debate whether this finding of lymphangiectasia is the cause or an effect of thoracic lymphatic hypertension.

Echocardiography is the definitive modality for ruling out cardiomyopathy, pericardial effusion, or other causes of congestive heart failure.

If the cat is only mildly dyspneic, ultrasound should be performed before the pleural fluid is drained as the fluid aids in the detection of a mediastinal mass. Severely dyspneic cats should have some fluid drained first, as the stress of ultrasound can be fatal.

Differential diagnosis

Other forms of pleural effusion may have similar clinical signs but the appearance of the fluid is different.

Chylous effusions may occur as part of **congestive heart failure**. If cardiac abnormalities are detected, then a complete cardiac diagnostic evaluation should be performed (see Cardiomyopathy section in this chapter).

Treatment

Emergency thoracocentesis should be performed immediately in cats with severe respiratory distress.

- A 23 G butterfly infusion set on a 60 ml syringe is introduced at the 5th–7th intercostal space (ICS) on the right, just above the costochondral junction. Remove as much fluid as possible, or until breathing improves. This can usually be performed without sedation or local anesthetic block with the cat standing or in sternal recumbancy. Drainage at multiple locations below the costochondral junction between the 4th and 6th intercostal space is sometimes more effective.
- Placement of a chest drain is recommended for all patients except those that are very debilitated.
- Fluid should be aspirated 1–2 times/day and the tube removed once less than 1–2 ml/kg daily is obtained.
- Intermittent thoracocentesis may be required until definitive therapy has been effective.

Definitive therapy if congestive heart failure is diagnosed is based upon ultrasonographic characterization of the type and severity of the cardiomyopathy present (see page 128 The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

Removal of the jugular catheter and drainage of the chyle usually results in resolution of the chylothorax in those cases associated with an indwelling jugular catheter.

For idiopathic primary chylothorax, both medical and surgical management have been advocated.

Medical management

- **This is based around decreasing the lymphatic flow through the thoracic duct. Restricting dietary fats** is the cornerstone of medical management. Parenteral intravenous feeding is used in humans, but is not a practical long-term solution in cats. Low-fat-reducing diets, commercial or home-made, help reduce chyle flow, but must be formulated to meet the nutritional needs of the patient. MCT oil (medium chain triglycerides) is a way to

supply calories from fats that are absorbed directly into the portal circulation and bypass the thoracic duct lymphatics. Whether this truly decreases thoracic duct flow has come under question in the dog, and information is still lacking in cats. MCT oil is generally reserved for extremely cachectic cats. It tastes terrible, and may worsen inappetence.

- **Nutriceutical “fat binders” such as Chitin/Chitosan** may be beneficial to decrease the fat-induced chlye flow.
- **Rutin**, another oral nutriceutical therapy, has shown mixed results in idiopathic chylothorax.
- Rutin is a bioflavonoid and a derivative of vitamin C. It stimulates macrophage uptake of protein and processing of inflammatory cells, thus improving the absorption of the remaining fluid. Dose is 50 mg/kg tin, which can be mixed up with food.
- Octreotide (Sandostatin, Novartis) a synthetic somatostatin is being trialled in cats as a SQ injection tid, but its efficacy is currently unknown.
- Medical management together with intermittent thoracocentesis may be used during the treatment for the underlying disease (cardiac therapy, cancer treatments, etc.).

Surgical management.

- Surgery should only be considered for patients who do not respond to medical management within 6–10 days. Success following surgery is disappointingly low. Surgery is best performed by a specialist with experience in thoracic duct ligation.
 - **Ligation of the thoracic duct** is the definitive therapy for idiopathic chylothorax. Surgical approaches and techniques are described in standard surgical texts. Some surgeons prefer to give cream orally prior to surgery so that the thoracic duct is filled with white chyle at the time of surgery, for easier identification. Others prefer to perform a mesenteric lymphatic dye study similar to what is described for lymphangiography, but using new methylene blue dye rather than radiographic contrast material. This dye is visible at the time of surgery to ease identification.
 - A postoperative contrast lymphangiogram may be performed through the same mesenteric lymphatic catheter to assess the success of the ligation. A thoracostomy tube is placed postoperatively

and removed once the fluid production through the tube falls below 1 ml/kg daily.

- There is current debate whether this procedure is useful in idiopathic lymphangiectasia, or whether the lymphatic hypertension continues despite ligation.
- **Pleuroperitoneal drainage**, either with passive drains with diaphragmatic mesh implants, or active sump drains between the pleural and peritoneal cavities have been described, but there is a lack of data on the outcomes of these procedures in cats. Blockage of the drain is a problem.
- Some surgeons report success with pericardectomy, as a means to decrease the underlying lymphatic hypertension. Recent studies combining pericardectomy with thoracic duct ligation have resulted in 80% success in a group of ten cats with chylothorax.

Prognosis

The success of medical management has been documented at 20% or less. The author’s clinical experience has been somewhat below that figure. Traumatic injuries to the thoracic duct may have a slightly better response rate to medical management. Successful treatment of the underlying disease process usually results in resolution of the chylothorax for taurine-responsive dilated cardiomyopathy and neoplasia. The poor success rate in idiopathic chylothorax likely relates to persistence of the underlying pathophysiology.

Prognosis for success of surgical ligation varies from 25–53%, and likely varies directly with the skill and experience of the surgeon. Continued effusion occurred in 30% of cats after thoracic duct ligation in one study. Proponents of the primary lymphatic hypertension theory feel that surgical ligation does not change the underlying pathophysiology. New data regarding the success rate of pericardectomy are very promising, with one report of an 80% remission rate in ten cats.

Chyle is a very irritating fluid to the pleura. Chylofibrosis and restrictive pleuritis may follow as a complication even after successful surgical ligation. If the fibrosis is severe, the lungs may fail to expand even after thoracocentesis. Pleural stripping has been described, but is not commonly performed in cats, so the success rate is unknown.

Prevention

Taurine supplementation of commercial cat foods in North America has dramatically decreased the incidence of dilated cardiomyopathy in cats. Other causes of cardiomyopathies remain unclear at this time.

FELINE INFECTIOUS PERITONITIS (FIP)*

Classical signs

- Muffled heart and/or lung sounds ventrally.
- Exaggerated chest excursions with poor airflow.
- Orthopnea (positional dyspnea with reluctance to lie in lateral recumbency).
- Anorexia, weight loss, depression, dehydration and fever are common early signs.

See main reference on page 372, for details (The Pyrexia Cat).

Pathogenesis

Feline infectious peritonitis (FIP) is caused by a strain of feline coronavirus called feline infectious peritonitis virus (FIPV).

- **This virus specifically infects the mononuclear phagocytic cells** of the spleen, liver and lymph nodes. Replication of the virus occurs primarily in these cells and creates a systemic viremic state within 1 week of experimental exposure.
- **Virus and virus-infected circulating monocytes deposit** in the endothelial lining of venules. Immune complex interaction to the viral antigen creates an intense vasculitis with complement-mediated damage to the vessel walls.
- The “holes” created in the vessels result in the **exudation of the fibrin-rich characteristic “FIP fluid”**.

Three forms of FIP exist. The **effusive or “wet” form** is of most significance in creating pleural effusion. It is the damage caused by the humoral immune system, rather than viral cytotoxicity per se, that is the major pathogenic mechanism in the formation of the effusion.

The large body cavities such as the chest and abdomen are most prone to fluid accumulation.

Clinical signs

No real age, sex or breed predisposition. **Kittens 6–12 months old** and **purebred queens up to 5 years** of age are over-represented. Another peak is reported in aged cats. Cats from **multi-cat environments** are at greatest risk.

Anorexia, weight loss, depression, fever or hypothermia (terminally), and dehydration may all occur, but none are specific to FIP.

The effusive form is more rapid and fulminant than the non-effusive form.

Progressive accumulation of ascites and pleural effusion in an inappetent, lethargic and pyrexia cat is characteristic of effusive FIP. **Dyspnea occurs in about 1/3 of cats** and results from the pleural restriction of the pleural effusion as well as the compromised diaphragmatic excursions secondary to the ascites.

Typically the wet form progresses to **death within 5–7 weeks** of onset of clinical signs. This progression may be shortened to a few days in young kittens.

Diagnosis

Clinical signs of pleural and abdominal effusion with normal heart sounds in an inappetent, lethargic and often pyrexia cat are highly suggestive of FIP.

Serology

- **Up to 10–40% of healthy cats have positive coronavirus titers.** A positive titer means exposure to a feline coronavirus, but not necessarily FIPV.
- High titers in the presence of typical signs of FIP in a cat from a one- or two-cat household may suggest FIP, however, methodology is not standard between labs. Some healthy cats, especially pure-bred or from multi-cat households, have very high titers.
- **PCR (polymerase chain reaction)** may be more accurate at detecting viral antigens. One study, however, showed 8/9 cats suspected with FIP (87.5%) were positive, but 51/84 cats (61%) were positive in non-suspects.
- **A 7B FIP ELISA** test is available which detects antibody to the 7B protein, which is specific to some coronavirus strains causing FIP. Specificity and sensitivity data have not been published. Anecdotal evidence suggests this is not sensitive for FIP.

Thoracocentesis or abdominocentesis and examination of the fluid are very valuable.

The high protein (50–120 g/L) and fibrin content of the fluid makes it thick, viscous and straw-colored. Cell count is moderate ($10 \times 10^9/L$), and consists predominantly of non-degenerative neutrophils.

Electrophoretic separation of the proteins within the fluid may be helpful.

- Fluid with gamma globulins $> 32\%$ has a high positive predictive value for FIP.
- Fluids with protein comprised of $> 48\%$ albumin had a very high negative predictive value for ruling out FIP.
- **Histopathology** of liver, kidney or other abdominal tissue with inflammation is diagnostic.

Differential diagnosis

There are few other differential diagnoses for hydrothorax with a clear or straw-colored, highly proteinaceous fluid. Other forms of pleural effusion with an exudative fluid are usually turbid, such as pyothorax.

- **Pyothorax** may have systemic clinical signs and effusion fluid that resembles FIP. FIP fluid has high protein content (50–120 g/L) with low to moderate cellularity ($10 \times 10^9/L$), and predominantly non-degenerative neutrophils, while pyothorax fluid has moderately high protein levels (30–70 g/L), and extremely high nucleated cell counts ($5\text{--}300 \times 10^9/L$), which are mostly degenerative septic neutrophils. Electrophoresis and bacterial culture of the fluid may help separate these entities. FIP fluid has high gamma globulin and is sterile, where pyothorax fluid has a balanced albumin/globulin ratio, and is a septic exudate, based on Gram stain or culture results.

Pericardial effusion may present with ascites and pleural effusion.

Treatment

Emergency thoracocentesis should be performed in cats with severe respiratory distress (see section on Pleural effusions, this chapter).

Medical management

- **Management strategies for FIP** take advantage of the different immunopathogenic mechanisms of the

effusive (humoral, beta cell mediated) and granulomatous (cell-mediated, T-cell response) forms of the disease, but generally have a very poor outcome in almost all cases. For a more thorough discussion, see page 458, The Cat With Abdominal Distention or Abdominal Fluid.

- For effusive FIP, several strategies have been advocated, including:
 - **Corticosteroids:** prednisone 2–4 mg/kg/day PO.
 - **Cytotoxic drugs:** cyclophosphamide 2.2 mg/kg/day PO 4 days each week, or 50 mg/m² PO q 48 hours, or melphalan 2 mg/m² PO q 48 h, or chlorambucil 1.5 mg/m² PO q 24 hours.
 - **Antiviral drugs:** ribavirin 5 mg/kg IV q 24 h. Ribavirin is very toxic to cats, mainly myelosuppressive. It has not been shown to substantially improve the longevity, although a slight increase in survival time (10 days) with fewer clinical signs has been documented. Ribavirin can be combined with interferon therapy. Low-dose oral human interferon-alpha (Roferon) 30 IU/day PO has been advocated.
 - **NB: in high risk, systemically ill cats, omitting the cytotoxic and antiviral agents is recommended.**

Ancillary treatment consists of using the serotonin antagonist **cyproheptadine** (1–2 mg PO q 12 hours) for appetite stimulation. Antibiotics have been used, especially with neutropenia and fever, but with no data to support efficacy. Amphotericin B has been shown to have in vitro antiviral effects against FIP, but its nephrotoxicity limits its use in cats.

Prognosis

Long-term prognosis for effusive FIP is extremely poor. Average survival from onset of clinical signs is 5–7 weeks, although some stronger “healthier” individuals may have a more insidious disease course, and may survive for 6–8 months.

Prevention

Management strategies

- One study showed kittens raised in catteries with all other cats or isolated from other cats except queens had 30–50% positive titers for FIPV, and 1–2% death rate from clinical FIP. However, kittens raised in a cattery, that were weaned and

separated from queens at 4–6 weeks of age had 0% positive titer, 0% died of FIP.

- The recommendation from this study was to **wean early and separate kittens from the queen** before the maternal antibodies are lost.

Vaccination

- A **heat-sensitive modified-live intranasal vaccine** was tested for efficacy. In this study, of 550 cats arriving at shelter, half were vaccinated and 2/254 developed clinical FIP, where 8/246 unvaccinated controls developed FIP. However, an experimental study using a different challenge strain to the vaccine strain found no protection and antibody-dependent enhancement occurred resulting in accelerated disease.

CONGESTIVE HEART FAILURE (CARDIOMYOPATHY)

Classical signs

- Muffled heart and/or lung sounds ventrally.
- Exaggerated chest excursions/poor airflow.
- Orthopnea (positional dyspnea – reluctance to lay in lateral recumbency).
- Dyspnea ranging from mild to acute and severe with cyanosis.
- Abnormal heart sounds (murmurs, gallops, arrhythmias).

See main reference on page 128 for details (The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

Pathogenesis

Mechanism of pleural effusion in cats with congestive heart failure is currently unknown, but there are two leading theories:

- **Left-sided failure** results in pulmonary venous and capillary hypertension, which leads to reflex pulmonary vasoconstriction. The resultant pulmonary hypertension leads to **right-sided heart failure** and pleural effusion. Evidence against this theory is that other signs attributed to right heart failure (right heart enlargement, hepatic venous distention, etc.) are rarely found in cats with congestive heart failure and pleural effusion.
- The **visceral pleural veins in cats drain into the pulmonary veins** (as seen in humans), and pul-

monary venous hypertension leads to pleural effusion. This is suspected, but not proved, in cats.

Pleural fluid tends to be a **modified transudate or chylous** in nature with congestive heart failure.

Cardiomyopathies such as hypertrophic, dilated or intermediate forms are most often associated with pleural effusions. Dilated cardiomyopathy is more often associated with pleural effusion than the other forms of cardiomyopathy, but it is now a rare disease following taurine supplementation of commercial pet food.

Rarely heartworm disease has been associated with pleural effusion.

Clinical signs

Dyspnea varies from **mild and associated with reduced activity levels and reluctance to play**, to acute, fulminant air-starvation with open-mouth breathing and cyanosis.

Abnormal heart sounds (murmurs, gallops, arrhythmias) may be present, or may be difficult to assess in the distressed patient.

Signs of pleural effusion include increased **chest excursions with little airflow** (can be detected by listening close to muzzle during breathing).

The cat may present with signs of aorto-iliac thromboembolism, such as paresis of one or more limb, nail bed cyanosis, cool anesthetic limb, firm cramping of the gastrocnemius muscle, vocalization and tachypnea or dyspnea.

Orthopnea (worsened dyspnea in lateral recumbency) or reluctance of the patient to lay in lateral recumbency may be reported.

Muffled heart and lung sounds are audible ventrally, with harsh breathing sounds dorsally in the standing or sternal recumbency positions. Dull percussion of the chest wall is evident ventrally.

The liver may be displaced caudally due to fluid pressure exerted on the diaphragm.

Diagnosis

Typically there are **clinical signs of pleural effusion** together with abnormal heart sounds.

Thoracocentesis is indicated in the dyspneic patient with clinical signs of effusion.

- Thoracocentesis should be performed in all acutely dyspneic animals, **prior to radiography**. These patients are extremely fragile, and even the minimal restraint involved in radiography may be excessive, and they may die during the procedure.
- A **transudate, modified transudate, or chylous effusion** are the most common fluid types in heart disease.
- **Heart sounds are often more apparent** after the chest tap, and murmurs, gallops or dysrhythmias may be heard. Be certain to remove as much fluid as possible, do not stop after you have a diagnostic sample.
- A negative tap for fluid suggests pulmonary edema rather than effusion from cardiac disease.

Thoracic radiography

- This is best performed in the acutely dyspneic patient **after** thoracocentesis and stabilization.
- Findings may include enlarged cardiac outline, pulmonary venous distention, and patchy alveolar infiltrates indicating pulmonary edema.

Echocardiography

- This is the definitive modality for diagnosis of cardiomyopathy, as well as the primary tool for categorization of the type and severity of disease. Various forms of cardiomyopathy include hypertrophic (HCM), dilated (DCM), restrictive (RCM) and intermediate (ICM). Therapeutic strategies and prognosis rely heavily on the echocardiographic information. Thoracocentesis should be performed prior to echocardiography in the severely dyspneic patient, otherwise death may occur during the procedure.
- **Electrocardiography** is important if an arrhythmia is detected during physical exam or ultrasound exam.

Differential diagnosis

Other forms of pleural effusion are not associated with abnormal heart sounds (murmurs, gallops, arrhythmias).

Pericardial effusion may create pleural effusion, an enlarged heart shadow on radiographs and possibly an abnormal ECG pattern. *Electrical alternans* on ECG tends to signal pericardial effusion, especially if the pleural effusion has been drained. Ultrasound is defini-

tive in distinguishing cardiomyopathy from pericardial effusion.

Treatment

Emergency thoracocentesis can be **life saving** in cats with severe respiratory distress.

- A 23 G butterfly set on a 60 ml syringe is introduced at the 5th–7th intercostal space (ICS) on the right, just above the costochondral junction. Remove as much fluid as possible, or until breathing improves. Thoracocentesis can usually be performed without sedation or local anesthetic block

Oxygen therapy should be administered using an O₂ chamber, masks or tents.

Furosemide (1–2 mg/kg IV or IM) should be administered without stressing the patient.

Use sedation if the cat is frantic (morphine 0.1 mg/kg IM prn, or butorphanol 0.2–0.4 mg/kg IM q 4–6 h as needed).

Nitroglycerin 2% cream – 1/8 to 1/4 inch applied to the skin of the medial pinna q 4–6 hours for 24 hours.

Take a “hands off” approach until stable, as the **slightest stress can cause lethal decompensation** in these fragile cases.

Definitive therapy is based upon ultrasonographic characterization of the type and severity of the cardiomyopathy present, but this is not performed until the patient is stable.

Prognosis

The prognosis is related to the clinical and echocardiographic severity. Severe left atrial enlargement predisposes to aorto-iliac thromboembolism, which worsens the prognosis.

Prevention

Taurine supplementation of commercial cat foods in North America has dramatically decreased the incidence of dilated cardiomyopathy in cats. Causes for the other cardiomyopathies remain unclear at this time.

PLEURAL/MEDIASTINAL MASSES

Classical signs

- Muffled heart and lung sounds ventrally.
- Dyspnea characterized by excessive chest excursions with poor airflow.
- Orthopnea (positional dyspnea with reluctance to lie in lateral recumbency).

See main reference on page 56 for details (The Dyspneic or Tachypneic Cat).

Clinical signs

Mediastinal masses are often **thymomas**, **thymic lymphoma** or **mediastinal lymphoma**. Occasionally, ectopic thyroid adenocarcinoma may create a space-occupying mass of the mediastinum. **Pleural masses** include mesotheliomas, osteosarcoma or chondrosarcoma of the ribs or sternabrae.

Signs are related to the space-occupying nature of the mass, or to obstruction of lymphatic drainage and secondary pleural effusion.

Signs include increased **dyspnea in lateral recumbency** (i.e., orthopnea), tachypnea, minimal airflow with increased chest excursions, **muffled heart and lung sounds** or **asymmetrical sounds if the heart is displaced laterally**.

Extraluminal compression of the trachea can cause dyspnea and cough.

Compression of the anterior thorax may reveal decreased compliance.

Diagnosis

Thoracic radiography may reveal the mass lesion or the secondary pleural effusion.

- Separation of the “cupolae” (anterior tips of the cranial lobes) on ventrodorsal projection, representing widening of the anterior mediastinum, may be a sensitive indicator of a subtle mass lesion.

Thoracic ultrasound can be extremely useful.

- Small mediastinal masses surrounded by aerated lung may not be visible from a paracostal approach, and may require a **thoracic inlet window**.

- **Transesophageal ultrasonography** is excellent for demonstrating mediastinal masses, but requires specialized equipment and general anesthesia.
- Surgical or ultrasound-guided biopsy of the mass may be required for a definitive diagnosis.

Thoracocentesis and analysis of the fluid may be diagnostic if the neoplasm has exfoliated into the fluid. This is, however, a rare occurrence. Typically the fluid is a modified transudate, although occasionally it is an exudate.

Mediastinal lymphoma may have **hypercalcemia** as a paraneoplastic syndrome, but this is **rare** in the cat.

Tissue biopsy and histopathology are required for definitive diagnosis.

Differential diagnosis

Other causes of pleural effusion that typically cause a modified transudate are cardiac disease and other airway neoplasias. Radiography and ultrasound can usually differentiate these.

Treatment

Lymphoma of the thymus or mediastinal lymph nodes is best handled with standard chemotherapy protocols for lymphoma (see page 676).

Surgical excision is the treatment of choice for **thymoma**, and may be curative.

Mesothelioma is an infiltrative disease that cannot be readily resected, and there are few reports in the literature of effective chemotherapy. Local infusion of carboplatin may be helpful with or without the addition of doxorubicin intravenously. Prognosis is grave.

PNEUMONIA

Classical signs

- Moist, productive cough, with adventitial lung sounds.
- Fever.
- Fetid halitosis.
- **Parapneumonic pleural effusion** can create dyspnea and decreased ventilation, possibly with exaggerated chest excursions/poor airflow.

continued

Classical signs—Cont'd

- Muffled heart and/or lung sounds ventrally.
- Orthopnea (positional dyspnea with reluctance to lie in lateral recumbency).

See main reference on page 62 for details (The Dyspneic or Tachypneic Cat).

Clinical signs

Infectious pneumonia is rare in cats.

A **deep productive cough** may be present, which generally is infrequent unless the pneumonia is secondary to bronchitis (see page 104, The Coughing Cat).

Inspiratory and expiratory dyspnea, often with open-mouth breathing is present when pneumonia is severe and associated with a parapneumonia pleural effusion.

Adventitial breath sounds, including crackles, wheezes, snaps and pops are audible.

Heart sounds may be muffled and lung sounds poorly audible ventrally, although the effusion volume is usually small.

Systemic signs include lethargy, anorexia, weight loss, fever and ill thrift.

Halitosis may be noted.

Deep chest excursion and diminished oral airflow occurs when parapneumonic pleural effusion is present.

Geographical location and other signs might suggest the etiology of the pneumonia, including bacterial, fungal, viral and *Chlamydophila felis* pneumonitis.

Diagnosis

Thoracic radiography reveals alveolar densities (focal or generalized) and possible areas of complete consolidation. There is subtle radiographic evidence (e.g. pleural fissure lines) of a **small-volume pleural effusion**.

- Hilar lymphadenopathy supports fungal or mycobacterial pneumonia.

On hematology neutrophilia is common, with or without a left shift or signs of toxicity.

- Low-grade, non-responsive anemia and monocytosis may support chronicity.

- **On thoracocentesis** there is a **small volume of effusion** which is commonly a **sterile inflammatory exudate**, and is often grossly serous or hemorrhagic rather than purulent.

Cytology and culture samples from percutaneous lung aspiration, transtracheal wash or bronchoscopic lavage may be diagnostic. Fungal, aerobic and anaerobic bacterial cultures are generally submitted.

Cryptococcal titers may aid in the diagnosis.

Differential diagnosis

Other causes of pleural effusion, such as pyothorax, congestive heart failure, chylothorax, FIP and mediastinal masses may mimic the parapneumonic effusion of some pneumonias. Typically, pneumonic patients are more severely dyspneic than would be attributed to the subtle effusion, because of the associated compromise of the lung parenchyma in pneumonia, which is not usually found in other causes of effusion.

Each of the infectious pneumonias can have overlapping features.

Treatment

Bacterial pneumonia

- Appropriate antimicrobial therapy is the mainstay of therapy. The parenteral route is used if the patient is debilitated or septic. The oral route can be used with outpatients. Antibiotic selection is best based upon specific culture and sensitivity testing.
- Pending culture results, some therapeutic decisions may be based upon Gram stain results.
 - **Gram-positive cocci** – ampicillin, amoxicillin, amoxicillin-clavulanic acid, trimethoprim-sulfa, cephalosporins.
 - **Gram-negative rods** – chloramphenicol, trimethoprim-sulfa, fluoroquinolones.
 - **Bordetella** – tetracycline, doxycycline, chloramphenicol, fluoroquinolones.
 - **Suspected anaerobes** – clindamycin, amoxicillin-clavulanic acid, metronidazole.

Fungal pneumonia

- Systemic **itraconazole** given at 5–10 mg/kg PO daily is the drug of choice. If there are CNS signs with cryptococcosis, use **fluconazole** (2.5–5.0 mg/kg PO daily) as it crosses the blood–brain barrier.

Viral pneumonia mostly involves supportive treatment.

Supportive care includes airway and systemic hydration, which are essential for mucociliary clearance. Intravenous crystalloids should be used judiciously. Nebulization with saline may be helpful. Physical therapy including coupage, positional drainage, position changes, etc., and oxygen enrichment are indicated. **Bronchodilator therapy** with beta agonists such as terbutaline (0.625–1.25 mg PO q 12 hours) or methylxanthines such as sustained-release theophylline (*Theo-Dur* 25 mg/kg PO q 24 hours) may be helpful.

Thoracocentesis is rarely required for treatment, as the parapneumonic pleural effusion generally resolves with appropriate therapy for the pneumonia.

AIRWAY/PULMONARY NEOPLASIA

Classical signs

- Muffled heart and/or lung sounds ventrally.
- Exaggerated chest excursions with poor airflow.
- Orthopnea (positional dyspnea with reluctance to lie in lateral recumbency).
- Non-productive cough, with or without hemoptysis.
- Mass lesion seen radiographically.
- Anorexia, weight loss, muscle wasting.

See main reference on page 66 for details (The Dyspneic or Tachypneic Cat).

Clinical signs

Tracheal adenocarcinomas (i.e., Siamese), primary pulmonary masses (pulmonary adenocarcinoma) or secondary metastatic disease from distant neoplasms may create effusions. It is more common in middle-aged to older cats.

A non-productive cough may be present, with or without hemoptysis. Dyspnea (inspiratory and expiratory) and reluctance to lie in lateral recumbency, or respiratory distress is present if pleural effusion is of large volume.

Very rarely, lameness occurs from peripheral appendicular bone lesions of hypertrophic osteopathy.

Systemic signs such as anorexia and weight loss (cancer cachexia) are often present.

Dull chest sounds and dyspnea result from pleural effusion.

Diagnosis

Diagnosis is usually made by radiography followed by biopsy via endoscopy, thorocolony or is ultrasound-guided.

Pleural effusion fluid is often a modified transudate and is often grossly opaque.

Differential diagnosis

Other causes of pleural effusion such as congestive heart failure and mediastinal masses may produce a similar type of effusion but are differentiated on radiography, ultrasound and biopsy.

Treatment

Surgical resection via partial or total lobectomy is the treatment of choice for solitary primary neoplasms. Cure or long-term remission is possible with wide surgical margins. If non-resectable, excision of nodules may palliate clinical signs temporarily.

Chemotherapy and radiation have been attempted in generalized pulmonary neoplasms, with disappointing results. Metastases from distant tumors carry a grave prognosis, although pulmonary lymphoma may attain remission with chemotherapy.

HEMOTHORAX

Classical signs

- Muffled heart and lung sounds ventrally.
- Dyspnea characterized by excessive chest excursions with poor airflow.
- Orthopnea.
- Pallor, possibly other sites of bleeding (epistaxis, hyphema, etc.).

See main reference on page 493 for details (The Bleeding Cat).

Clinical signs

Hemorrhagic effusions generally result from either **trauma or coagulopathy**. History and physical exam findings are vital in the separation of these causes.

Signs related to pleural effusion and anemia include dyspnea, orthopnea (positional dyspnea), tachypnea, minimal airflow with increased chest excursions and muffled heart and lung sounds ventrally.

Weakness, hemic heart murmur, watery thready femoral pulse, pale mucous membranes all support possible blood loss.

Trauma may have **signs of external trauma** such as skin abrasions, rib fractures, penetrating thoracic wounds, etc., present.

Coagulopathies may involve other bleeding sites such as abdominal effusion (hemoabdomen), epistaxis, hyphema and hematoma formation. Common coagulopathies include rodenticide toxicity, factor VIII deficiency (hemophilia A), and factor XII deficiency (although this rarely causes clinical bleeding).

Diagnosis

Thoracic radiography reveals signs of pleural effusion, indistinguishable from other causes. Alveolar densities may be also present, indicating intrapulmonary hemorrhage.

Thoracocentesis

- Analysis of the fluid reveals obvious bloody fluid, often with a packed cell volume (PCV) lower than peripheral blood, except in cases of severe peracute frank hemorrhage where the PCV is similar to peripheral blood. The blood is generally defibrinated with no platelets observed cytologically, but, in acute bleeding situations, frank clotting blood with platelets may be present.

Coagulation testing.

- Coagulation tests help rule in and categorize types of coagulation disorders.
- In-clinic tests include activated clotting time (ACT, generally normal considered to be less than 65 seconds in the cat) to test the intrinsic cascade, blood smear for platelet numbers (should be 11–25 per high-power field), and buccal mucosal bleeding time (BMBT, normal considered to be 1–3 minutes) for platelet function (i.e., Von Willebrand's disease).

- Send-out lab tests include prothrombin time (PT – extrinsic system), partial tissue thromboplastin time (PTT – intrinsic system), and PIVKA test for rodenticide toxicity. Factor analysis for deficiencies of factors II, VII and X may be requested.
- Common coagulopathies include rodenticide exposure and genetic bleeding diatheses.

Differential diagnosis

Differential diagnoses include any cause of pleural effusion with bleeding into the pleural fluid, such as bleeding neoplasms, some chylothoraces (the fluid is less bloody and more “tomato soup-like”), as well as iatrogenic bleeding from previous thoracocenteses.

Treatment

Thoracostomy tube placement is generally contraindicated, especially in coagulopathies as it may trigger further bleeding.

Gentle handling and supportive care are indicated in trauma patients, as well as tending to other injuries.

Whole blood transfusion may be lifesaving in severe thrombocytopenia or coagulopathy. Depending on the breed (i.e., Persians) and the geographic location, cats with type B blood may be common. Cross-matching must be performed to avoid catastrophic transfusion reactions.

Results of coagulation tests may help with therapeutic decisions.

- **Vitamin K1** may be used for rodenticide toxicity.
- **Fresh frozen plasma transfusions** may be used for coagulation factor deficiency, etc.

HYPOPROTEINEMIA

Classical signs

- Muffled heart and lung sounds ventrally.
- Dyspnea characterized by excessive chest excursions with poor airflow.
- Orthopnea (positional dyspnea).
- Muscle wasting, weight loss, ascites, limb edema.

See main reference on pages 358 and 760 for details (The Thin, Inappetent Cat and The Cat With Signs of Chronic Small Bowel Diarrhea).

Clinical signs

Protein-losing enteropathy, protein-losing nephropathy and hepatic failure are common causes of low serum protein, specifically hypoalbuminemia, which may result in decreased oncotic pressure and transudation.

Signs are related to pleural effusion, ascites and muscle loss.

Orthopnea, tachypnea, minimal airflow with increased chest excursions, muffled heart and lung sounds may be present if the pleural effusion volume is > 50 ml/kg.

Weight loss with prominent muscle wasting is common. Distention of the abdomen from weakness of abdominal muscles, as well as presence of ascites may be present. Hair coat is typically poor quality.

Appetite may be ravenous in protein-losing enteropathy, and diarrhea and weight loss are evident.

Rarely, signs of hepatic encephalopathy including ptyalism, dementia, somnolence and pica occur with liver failure.

Icterus may be present.

Diagnosis

Thoracic radiography demonstrates signs of pleural effusion, indistinguishable from other causes.

- Thoracocentesis reveals a clear and colorless fluid, which is a pure transudate with a specific gravity (SG) < 1.013, low total protein (TP) < 2.5 g/L, and low cellularity (TNCC < 1.5×10^9 /L).

Hypoalbuminemia (< 15 g/L) is a persistent finding.

- Protein-losing enteropathy (PLE) has panhypoproteinemia as the hallmark (hypoalbuminemia, globulin < 20 g/L) (see page 760, *The Cat With Signs of Chronic Small Bowel Diarrhea*).
- Protein-losing nephropathy (PLN) is characterized by proteinuria, urine protein:creatinine ratio > 2, hypoalbuminemia, possible hypertension and hypercholesterolemia (nephrotic syndrome) (see page 358, *The Thin, Inappetent Cat*).
- Hepatic failure may be characterized by low urea, hypoalbuminemia, low to elevated cholesterol, possible hypoglycemia, normal to low liver enzyme levels, elevated serum bilirubin levels may be present (see page 421, *The Yellow Cat or Cat With Elevated Liver Enzymes*).

Differential diagnosis

Once hypoalbuminemia has been established and the pleural effusion has been characterized as a pure transudate, a general biochemistry panel will help to distinguish the major causes of hypoproteinemia.

Treatment

Thoracostomy tube placement is generally not indicated.

Treatment for the underlying disorders will be covered in the chapters for those conditions. If serum albumin can be increased above 15–20 g/L with treatment of the underlying disease, the hydrothorax and ascites will resolve providing there is not underlying hypertension or vasculitis.

7. The coughing cat

Robert Allen Mason and Jacquie Rand

KEY SIGNS

- Cough ranging from soft to harsh or honking.
- Gagging, which may appear as vomiting or regurgitation.

MECHANISM?

- Coughing is a reflex that produces **rapid expulsion of air** in response to mechanical or chemical irritation of the pharynx, larynx, trachea, bronchi and small airways, to free the airway of foreign material.

WHERE?

- Coughing occurs in response to irritation of the upper respiratory tract (nasal cavity, pharynx, larynx, trachea), lower respiratory tract (bronchial tree, small airways), lung parenchyma or the pleural space.

WHAT?

- **Coughing is usually a sign of small airway disease in cats.** Unlike dogs, coughing is rarely associated with congestive heart failure (CHF).

QUICK REFERENCE SUMMARY

Diseases causing a coughing cat

DEGENERATIVE

- Cardiomyopathy (Dilated cardiomyopathy (DCM), hypertrophic (HCM), intermediate (ICM) or restrictive (RCM)) (p 107)

Although dyspnea is common with congestive heart failure and pulmonary edema, coughing is an uncommon presenting sign in the cat.

- Tracheobronchial collapse (p 102)

Harsh “honking” cough caused by degeneration of the cartilage support of the large airway walls. Rare in cats.

MECHANICAL

- Grass awns/foreign bodies (p 98)

Sudden onset of a harsh, productive cough and acute dyspnea from foreign objects that have been inhaled, regurgitated or aspirated into the nasopharynx, trachea or bronchi.

- Inhalation of noxious agents (p 99)

Inhalation of gas, smoke, fumes, dust particles or hair can stimulate an aggressive cough reaction.

NEOPLASTIC

- Airway/pulmonary neoplasia (p 97)

Tracheal masses and primary or metastatic pulmonary masses in middle-aged to older cats may cause coughing ranging from soft to harsh and productive. Weight loss and ill-thrift are also seen.

- Pleural/mediastinal masses (p 107)

These masses cause pleural effusion or extraluminal compression of the trachea resulting in dyspnea, orthopnea, tachypnea and rarely cough. Heart and lung sounds are muffled from pleural effusion.

INFECTIOUS

Bacterial:

- Pneumonia (p 103)

Lethargy, inappetence, tachypnea, fever and halitosis are typical signs. Moist, productive cough and dyspnea may be present. Causes may include bacterial, fungal, viral, protozoal (toxoplasmosis) and chlamydia *Chlamydia felis* pneumonitis.

- **Bordetella*** (p 98)

Acute onset of pyrexia, sneezing and nasal discharge. Coughing may be spontaneous or only evident on tracheal pressure. Signs resolve in 1–2 weeks.

Parasitic:

- Parasitic pneumonia (p 106)

A variable degree of coughing occurs. Peripheral eosinophilia or parasitic larva/ova may be present in the stool or lungwash. Lungworm (*Aelurostrongylus abstrusus*, *Capillaria aerophilia*), lung flukes (*Paragonimus kellicoti*) and migrating nematodes (*Toxacara cati*) are potential causes.

- **Heartworm disease*** (p 104)

Coughing, dyspnea and vomiting may occur together. Acute respiratory failure and death may occur from acute pulmonary inflammation and edema. Generally limited to cats from heartworm endemic areas.

Immune:

- **Feline asthma/bronchitis complex***** (p 92)

An inhalant allergic response leads to bronchitis and bronchospasm. Coughing is the most common clinical sign, along with expiratory dyspnea and wheezing.

- **Pulmonary infiltrates with eosinophils (PIE)/Eosinophilic bronchopneumopathy*** (p 96)

Coughing varies from mild to severe. Crackles or wheezes, or areas of diminished lung sounds are heard on auscultation. Cats may have peripheral eosinophilia on CBC. Thoracic radiographs often show an interstitial pattern, although patchy alveolar or nodular densities may occur.

- Laryngitis (p 101)

Laryngeal edema from allergic reactions and idiopathic laryngeal paralysis have been reported in the cat. They may lead to aspiration of food, water or saliva and create significant harsh coughing. Stridor, dysphonia and inspiratory dyspnea are reported.

INTRODUCTION

MECHANISM?

Coughing is a reflex rapid expulsion of air in response to mechanical or chemical irritation of the pharynx, larynx, trachea, bronchi and small airways, to free the airway of foreign material.

Afferent impulses from epithelial receptors reach the cough center in the medulla via the vagus nerve. A complex series of events transpires from this point, namely:

- Air is inspired to 2–3 times the tidal volume.
- There is closure of the epiglottis and vocal folds.
- Contraction of the diaphragm, intercostal and external abdominal muscles occurs against the closed glottis, which increases intrapleural pressure (Valsalva maneuver) and decreases the luminal diameter of the small airways.
- Sudden opening of the glottis occurs with rapid expulsion of air from the small airway at speeds of 75–100 miles per hour.
- Explosive release carries the offending particulate matter clear of the lower airways.

In **acute conditions** (aspiration, inhalation of noxious fumes, etc.) this cough reflex is a **protective mechanism**. In the **chronic state**, however, it **becomes a debilitating problem**. Chronic airway irritation decreases the threshold of the cough receptor, which brings about more coughing and more mucosal damage and irritation.

WHERE?

Cough receptors are found along the entire airway, but are **especially dense at the larynx and the carina**. All receptors are innervated by the parasympathetic system.

In cats, receptors have been found as far distally as the alveoli.

WHAT?

The most common cause of acute coughing in the cat is foreign body aspiration, often associated with hairballs trapped in the oropharynx.

Aspiration of food or fluid can be more serious, creating aspiration pneumonia.

Chronic coughing in cats is often caused by feline asthma/bronchitis complex.

Unlike dogs, coughing is rarely associated with congestive heart failure (CHF).

DISEASES CAUSING COUGHING

FELINE ASTHMA/BRONCHITIS COMPLEX***

Classical signs

- Cough is a prominent sign.
- Expiratory dyspnea with wheezing.
- *Status asthmaticus* –severe acute respiratory distress.
- Cyanosis, open-mouth breathing, wheezing.

Pathogenesis

Exposure of the respiratory epithelium to an inhaled antigen results in multiple inflammatory responses that create airway obstruction, namely:

- Edema.
- Cellular infiltration into airway walls.
- Epithelial hypertrophy or metaplasia with erosion or ulceration.
- Excessive mucus production.
- Decreased mucus clearance.
- Inflammatory exudation within the lumen.
- Hyperreactivity of the airway smooth muscle causing bronchoconstriction fibrosis.
- Emphysema.

Coughing results from enhanced airway sensitivity.

Wheezing is generated by air forced through narrowed airways, caused by mucosal thickening (epithelial hypertrophy, infiltration and edema) and bronchoconstriction.

Crackles result from excessive airway mucus.

The systemic inflammatory reaction, increased work of breathing and airflow limitation all create **systemic lethargy**.

There are **multiple inflammatory mediators** involved in the airways of cats:

● Serotonin

- Serotonin is released from feline mast cell granules during exposure to an allergen.
- Serotonin antagonists are useful in decreasing associated signs.
- Mast cell stabilizing agents may play a role in decreasing the severity and frequency of attacks.

● Histamine

- It has been demonstrated that histamine does not play a role in feline asthma.
- Stimulation of the H3 receptors in the feline airway causes relaxation of the airway smooth muscle, the exact opposite effect seen in humans.
- This work might suggest that antihistamines are contraindicated in feline asthma.

● Leukotrienes

- Cats have far fewer leukotriene (LT) receptors in the airways than do people, but enough are present to make a significant contribution to the inflammatory cascade.
- Leukotrienes are released from eosinophils, and via the lipoxygenase cascade, are converted to various forms of leukotrienes, all with variable inflammatory effects.
- Because cats have poor glutathione pathways, the inflammatory leukotrienes LTC₄ and LTD₄ are not produced in significant amounts, but the pathway is directed toward LTB₄ production.
- LTB₄ is a known chemotactic agent for eosinophils.
- Recent evidence questions the role of leukotriene in asthmatic cats.
- Mast cells have recently been incriminated in having a more profound role in asthmatic pathogenesis in humans than previously thought. Research is on-going in cats.

Clinical signs

Signs can occur at any age, although the **average is 2–8 years**.

Typically there is a **history of coughing for weeks or months**. The cough may be mild to severe and intermittent or continuous. It may be productive and stimulated with *coupage of the chest wall*.

Dyspnea may range from mild, to severe life-threatening respiratory distress from bronchoconstriction.

Signs may be episodic (with asthma) or chronic (with bronchitis).

There may be a **history of exposure to the offending allergen**, including dusty litter, perfumes, carpet cleaners, smoke from fireplaces, cigarette smoke and insulation materials.

Cats may present severely air-starved, with **cyanosis**, **open-mouth breathing**, and a significant abdominal expiratory push.

Diagnosis

Many cats with asthma may have eosinophilia on hematology.

On auscultation, typical lung sounds are wheezes and crackles, which may be worse on expiration.

- Severely affected cats may have diminished air sounds from emphysema.

Thoracic radiographs may be normal or abnormal.

- Asthma is characterized by hyperlucency, hyperinflation and flattening of the diaphragm from air trapping.
- Chronic bronchitis typically has a diffuse, prominent peribronchiolar pattern, with or without patchy alveolar infiltrates (especially the right middle lobe from atelectasis). Right heart enlargement may be present.
- A **lung wash for cytology and culture** can be obtained via transtracheal wash in the awake cat, or using a catheter or bronchoscope to lavage the bronchi and alveoli in the anesthetized cat, which is the method preferred by most clinicians. Culture for mycoplasma should be requested, because mycoplasmal infection may cause chronic coughing.
- **Cytological examination** typically reveals highly cellular samples with intact non-degenerative neutrophils as the primary cells. Eosinophils are not a reliable marker because of the increased prevalence (up to 24%) in the airways of normal cats. Neutrophilic or mixed inflammatory cellular patterns are common.
- There is on-going research looking for other biochemical markers of asthma leukotriene levels, IgA, IgG and IgE titers, etc., but none is yet clinically available as a test.

- Pulmonary function testing includes spirometry, whole-body plethysmography and tidal breathing flow–volume loops (TBFVL). Increased airway resistance with aerosol challenge, and decreased resistance with bronchodilator therapy are diagnostic of asthma. This testing is rarely available outside of teaching or research institutions.
- Asthma is differentiated from bronchitis on the basis of a positive response to an inhaled bronchodilator with asthma.

Differential diagnosis

Main differential for *status asthmaticus* is **acute congestive heart failure**, usually due to cardiomyopathy, although cats with heart failure rarely cough.

Other respiratory diseases, such as upper airway obstruction (laryngeal paralysis), pulmonary disease (pneumonia, neoplasia), and pleural space disease may also cause chronic coughing.

Treatment

Status asthmaticus – **oxygen** supplementation is required during respiratory distress. An O₂ chamber or tent is best tolerated by air-starved patients. Use injectible **terbutaline** (0.01 mg/kg SQ), and **dexamethasone** (0.25–0.5 mg/kg IV or IM), and in severe cases, **epinephrine** (0.5 ml 1:10 000) SQ as a bronchodilator. Minimal handling and restraint of acutely dyspneic patients is essential.

Asthma

- As this is a bronchoconstrictive disorder, it responds more briskly to bronchodilators.
- Bronchodilators seem to have a synergistic effect when used with steroids, or when two classes of bronchodilator are combined.

Bronchitis

- As this is an inflammatory disease, anti-inflammatories, and perhaps leukotriene inhibitors and mast cell stabilizing agents are more indicated for long-term therapy.

Bronchodilators

Bronchodilators are an important part of therapy for asthmatic cats, and can be administered orally, parentally or by inhalation.

- **Terbutaline** 0.01 mg/kg SQ will usually result in bronchodilation within 10–15 mins; for longer term therapy it can be administered orally (0.1 mg/kg PO q 12 h (1/4 – 1/2 × 2.5 mg tablet) or inhaled (*Brethine*). In a crisis, it can be given IV (0.01 mg/kg IV q 30 min for up to 4 h) until a response is observed, or by inhalation.
- **Inhalant bronchodilators (beta₂-adrenergic agonists such as terbutaline (*Brethine*), albuterol [also known as salbutamol] (*Proventil*, *Ventolin*))** may be used in a crisis situation (q 30 min repeated for 2–4 h) with an effect seen in 5–10 min. This route is more effective than IM, SC, or oral administration. They are administered using a spacer chamber attached to the metered dose inhaler at one end and a face mask at the other end. *Aerokat*® (www.aerokat.com) mask and spacer chamber is made specifically for cats, or ones made for infants such as the *Pocket Chamber*® combined with the smallest *Panda Mask*® (Ferraris Medical Inc) can be used to deliver drug inhalant therapy. Empty toilet paper rolls or paper coffee cups have also been used successfully as spacing chambers in cats. Two “puffs” or metered doses of the bronchodilator is used to fill the spacer chamber, and the mask is gently placed over the cat’s mouth and nose while the cat breathes 10–15 times (approx 30–45 secs). There are several anecdotal reports of success, leading to weaning off systemic drug dosages or decreasing severity and frequency of attacks. Albuterol is reported to be rapid acting, and may be used in an emergency situation, or for chronic therapy q 12 h as needed (prn). **Salmeterol** [Serevent] has a slower onset and a 12 hour duration, and can be used for chronic therapy. Adverse effects of beta₂-adrenergic agonists are musculoskeletal twitchiness, excitability, insomnia, and anorexia, but are very rare in cats, suggesting these drugs have a high safety margin in cats.
- **Sustained release theophylline** 25 mg/kg PO q 24 h or 10 mg/kg PO q 12 h. Consistent pharmacokinetics have only been demonstrated with a few products (*Theo-Dur*® (Key Pharmaceuticals), *Slo-Bid Gyrocaps*® (Rhone-Poulenc Rorer Labs), and *Theocap ER*® and *Theochron ER*® (Inwood Laboratories or Forest Laboratories), and the first two are unavailable in the US. *Theochron ER*® tablets can only be broken along the scored line into half, and *Theocap ER*® capsules can be opened

and divided into smaller doses by a compounding pharmacy. Beta₂-adrenergic agonists are more effective than the xanthine derivatives (theophylline) in producing bronchodilation.

Glucocorticoids

- **Prednisone** 1 mg/kg PO q 12 h for 5 days, then 1 mg/kg PO q 24 h and slowly weaned to a minimum effective dosage over 2 to 4 months. For seasonal allergy, prednisone may be weaned entirely until the following year. Alternatively, the cat may require chronic low dose therapy, 2.5–5.0 mg PO q 48 h. Some cats respond poorly to oral prednisone, and may respond better to **dexamethasone** 0.25 mg/kg PO q 12 h for 5 days, then wean slowly or switch to oral prednisone. Other cats require parenteral dosing with 20 mg **methylprednisolone acetate** IM q 3–6 weeks. However, this potentially has greater side effects, including inducing diabetes mellitus, than alternate day prednisone therapy. In a crisis, methylprednisolone sodium succinate (100 mg/cat IV) or dexamethasone (0.5–2 mg/kg IV or IM) can be given.
- **Inhaled steroids** such as fluticasone (**Flovent**®) are beneficial in cats that tolerate face mask inhalers. Topical therapy has less systemic side effects, which may be important in diabetic cats and cats predisposed to diabetes. In general, inhaled steroids are preferred because of their reduced side-effects, but they are more expensive. Fluticasone may take 5–10 days to work, so oral steroids should be administered concurrently for 5–10 days, depending on the severity of signs.

Oxygen supplementation is required during respiratory distress and an oxygen chamber or tent seems to be best tolerated by air-starved patients. Oxygen hoods made with an Elizabethan collar and cellophane have proven very useful in cats.

Minimal handling and restraint of acutely dyspneic patients is essential.

Serotonin antagonists

- **Cyproheptadine** (Periactin®) – 2–4 mg/cat PO q 12–24 h. This drug blocks serotonin, the major inflammatory mediator from feline mast cells in airway disease.

Leukotriene receptor blockers

- **Zafirlukast** (Accolade®) 0.5–1.0 mg/kg PO q 12–24 h. This drug is not useful in acute attacks, but

can be used to stabilize long-term patients. Use may allow for a decrease of steroid dosages (beneficial in diabetic patients). It may decrease eosinophil chemotaxis. This drug should be considered in cases of severe eosinophilic inflammation, or cases refractory to standard therapy. Liver damage has been infrequently reported in cats.

- **Montelukast** (Singulair®, 0.25–1.0 mg/kg SID) is a leukotriene blocker that has been used in cats for maintenance therapy but by itself is rarely effective. Although the cat has insufficient leukotriene receptors for cysteinyl leukotrienes to cause bronchoconstriction, anecdotal evidence suggests that montelukast may reduce bronchial inflammation and coughing. This effect may be mediated through blockage of leukotriene-mediated attraction of inflammatory cells such as eosinophils and neutrophils and their subsequent release of inflammatory cytokines and other chemicals. Montelukast may allow for the dose of steroids to be reduced or for cyproheptadine to replace the steroids.

Other agents

- **Mast cell stabilizers**
 - **Cromolyn** is an inhalant that stabilizes mast cell degranulation. It may be helpful for long-term control, and to diminish maintenance doses of steroids. Use 1 metered dose (800 mcg) q 12–24 h.
 - **Amitriptyline** is a systemic mast cell stabilizer. There is no information on its use in cats for airway disease, but it has been used for urine marking and psychogenic dermatoses at 1.1–2.2 mg/kg PO q 12 h.
- **Antitussives**
 - Debate exists whether the cough of bronchitis should be suppressed, as it is a protective mechanism of the airway.
 - **Butorphanol** (**Torbutrol**) can be dosed at 0.05–0.6 mg/kg PO q 6–12 h, prn to control cough. “Pulse antitussive therapy” may be helpful. This involves treating for 2–3 days to break the cycle of the harmful effects of the cough, then stopping for 2–3 days to allow improved airway clearance. Administration must be judged on a case-by-case basis.

Therapeutic protocol recommended by Dr Phil Padrid:

- For mild signs (cough only): fluticasone 110 mcg q 12 h and albuterol prn
- For moderate signs (cough and tires easily, and sleep disruption for client): prednisolone 1 mg/kg PO q 12 h for 5 days, and on an ongoing basis, fluticasone (**Flovent®**) 220 mcg q 12 h and albuterol prn;
- For marked signs (cough and dyspnea at rest with diminished quality of life): prednisolone 1 mg/kg PO q 12 h for 5 days, q 24 h for 5 days, q 48 h for 5 days, and on an ongoing basis, fluticasone 220 mcg q 12 h and albuterol prn;
- For severe signs (dyspnea, open mouth breathing +/- cyanosis) which are a life-threatening emergency, it is important not stress the cat as this may precipitate death. Administer oxygen via oxygen cage or nasal canula, methylprednisolone sodium succinate (100 mg/cat IV) or dexamethasone (2 mg/kg IV) and terbutaline (0.01 mg/kg IV) q 30 minutes for up to 4 h until a response is observed. Once stabilized, cats can be discharged with fluticasone 220 mcg q 12 h and albuterol q 6 h as needed.

Prognosis

Patients in *status asthmaticus* are extremely fragile, and may decompensate and die without rapid therapy administered with minimal handling.

Chronic cases, or once *status asthmaticus* resolves, have a fair to good prognosis with prolonged therapy.

Cure is rare, but with long-term therapy, management is frequently quite successful.

Prevention

Identification and removal of the offending antigen is highly desirable, but often difficult.

Clean the furnace or air-conditioning air ducts, shampoo carpets (avoiding perfumed cleansers), remove scented candles or potpourri, avoid using hair spray or aerosol cleaners near the patient, switch to **dust-free and unscented cat litter**, and quit smoking.

High-quality home air-filtration systems have been shown to help human asthmatics, and it is logical that cats would also benefit. HEPA filters (class III and above) decrease inhaled particles significantly.

Recently, there appears to be epidemiologic evidence of decreased risk of asthma in male cats neutered before 5.5 months of age.

PULMONARY INFILTRATES WITH EOSINOPHILS (PIE) (EOSINOPHILIC BRONCHOPNEUMOPATHY)*

Classical signs

- Coughing – mild to severe.
- Crackles, wheezes or diminished lung sounds.
- Possible peripheral eosinophilia on CBC.

Pathogenesis

Interstitial or alveolar infiltration of pulmonary parenchyma with **eosinophils**. The infiltrate may form space-occupying eosinophilic granulomas measuring up to 20 cm diameter. Varies from mild, self-limiting disease, to severe and life-threatening.

Antigenic source, such as migrating parasites (*Toxocara* spp.) or heartworms may be found. Eosinophil-derived cytokines (leukotrienes, major basic protein, etc.) can damage the offending parasite or the host tissue, depending on the circumstances or severity.

In most cases, the inciting allergen is not identified.

Clinical signs

Mild to severe coughing for weeks to months prior to presentation is common.

Signs of systemic illness such as weight loss, anorexia and depression, may be present.

Adventitial lung sounds such as crackles or wheezes, or areas of diminished lung sounds may be present on thoracic auscultation.

Coughing may be elicited on tracheal palpation or coupage of the chest.

Diagnosis

Peripheral eosinophilia is present on CBC in 50–75% of patients.

Thoracic radiography

- **Interstitial or alveolar patterns** with air bronchograms, ranging from mild to severe.
- Nodular interstitial densities may mimic neoplastic masses. Dilated and truncated pulmonary arteries indicate potential heartworm disease or pulmonary hypertension. Hilar lymphadenopathy may be present.

Cytology

- Method of sample acquisition is dependent upon the predominant radiographic pattern.
- **Peribronchiolar or alveolar infiltrates** may produce excellent samples via **airway wash** (transtracheal or bronchoscopic lavage).
- **Interstitial densities** exfoliate poorly into the airways, and are better sampled via **percutaneous lung aspirates**.
- Cytology reveals a heavy infiltration of non-neoplastic eosinophils. Samples should be evaluated for the presence of antigens (parasites, fungal agents). Some neoplasms may be chemotactic to eosinophils.

Allied testing includes heartworm antigen or antibody testing, fecal floatation and Baermann exams for parasite ova and larvae, fungal culture (*Cryptococcus* spp.) from lung fluid, and fungal serology.

Differential diagnosis

Pulmonary neoplasia may mimic the nodular infiltrates radiographically. Cytology or lung biopsy is required for differentiation.

Congestive heart failure may also have alveolar infiltrates, but usually other clinical signs (tachyarrhythmias, murmurs, gallop rhythms) or radiographic signs of heart disease such as cardiomegaly, pulmonary venous congestion, pleural effusion are present.

Treatment

Treatment of the underlying disease is preferable, where possible (i.e., parasiticide therapy with fenbendazole for lungworm, praziquantel for lung flukes, etc.). Changing to a dust free cat litter and eliminating passive smoke from the environment may help.

Glucocorticoids – prednisone 1–2 mg/kg PO q 12 h for 5–7 days. Repeat thoracic radiographs, and if there is

improvement noted, slowly taper the dosage over several months. Serial radiographs are useful for long-term monitoring. Many cases require long-term therapy for months to years, at the minimum effective dosage.

Cytotoxic drugs – if large mass lesions are present (eosinophilic granulomatosis), more aggressive immunosuppression may be required. **Cyclophosphamide** (50 mg/m² PO q 48 h) has been used in conjunction with prednisone. **Azathioprine should be avoided in cats due to toxicity.**

Prognosis

Eosinophilic inflammation can be very damaging to the host tissues.

If identification and elimination of the offending allergen is possible, the prognosis is excellent. If no allergen can be identified, the prognosis for cure is poor, but good to excellent control may be achieved with long-term therapy.

Eosinophilic granulomatosis carries a **poor long-term prognosis**, although remission of weeks to months is possible.

Prevention

Parasite prevention programs.

- Heartworm prophylaxis in endemic areas.
- Routine anthelmintic treatments with pyrantel pamoate or fenbendazole for nematodes such as *Toxocara cati* and *Aelurostrongylus* spp.
- Limit exposure to intermediate hosts (i.e., crayfish for *Paragonimus kellicotti*).

Limit exposure to inhalant allergens. Clean the furnace or air-conditioning air ducts, steam-clean carpets (avoiding perfumed cleansers), remove scented candles or potpourri, avoid using hair spray or aerosol cleaners near the patient, switch to dust-free and unscented cat litter (clumping litters may be especially dusty), and reduce exposure to cigarette smoke (quit or smoke outside), high-efficiency in-home air filtration systems may reduce antigenic load.

Avoid exposure to cats with respiratory tract infections, as PIE patients may be more prone to serious respiratory infections, especially if receiving immunosuppressive therapy.

BORDETELLA*

Classical signs

- Pyrexia.
- Sneezing and nasal discharge.
- Mandibular lymphadenopathy.
- Coughing.
- Dyspnea, cyanosis, pneumonia.

See main reference on page 14 for details (The Cat With Acute Sneezing or Nasal Discharge).

Clinical signs

Signs are most likely to occur in **cats from multi-cat environments, especially rescue or shelter catteries** where calicivirus and herpesvirus are also a problem.

Typically there is an acute onset of pyrexia, sneezing and nasal discharge.

Mandibular lymphadenopathy may be palpable.

Coughing may be spontaneous, or only evident on tracheal pressure; generally, coughing is not as pronounced as in dogs.

Dyspnea, cyanosis, crackles and wheezes may be auscultated over lung fields in some cats. Death from pneumonia may occur, especially in young kittens less than 8 weeks old.

Treatment

Oxytetracycline, doxycycline or enrofloxacin.

Montelukast (Singulaire, 0.25–1 mg/kg SID) is a leukotriene receptor blocker. Although the cat has insufficient leukotriene receptors for cysteinyl leukotrienes to cause bronchoconstriction, anecdotal evidence suggests that montelukast may reduce sneezing and nasal discharge associated with *Bordetella*. This effect may be mediated through blockage of leukotriene-mediated attraction of inflammatory cells such as eosinophils and neutrophils and their subsequent release of inflammatory cytokines and other chemicals.

GRASS AWNS/FOREIGN BODIES

Classical signs

- Sneezing with nasal foreign bodies, and coughing with pharyngeal and tracheobronchial foreign bodies.
- Inspiratory/expiratory dyspnea, depending on location.

Pathogenesis

Foreign bodies may be inhaled directly into the rostral nasal cavity or tracheobronchial tree, or may be regurgitated into the caudal nasopharynx. Common solid foreign bodies include grass, seeds, hairballs, twigs and occasionally stones, while particulate foreign bodies include coal dust (UK) and metal dust from road grime (Australia).

Occasionally, penetrating foreign bodies, such as projectiles (pellets) or a broken tooth from an opponent during a cat fight, can lodge in the nasal cavity or airway.

Tracheobronchial foreign bodies may be caused by aspiration of vomited or regurgitated ingesta.

Clinical signs

Acute onset of sneezing and nasal discharge are common signs of nasal foreign bodies, although coughing may be the predominant sign with post-nasal drainage into the pharynx. These cats may be in sudden and severe distress attempting to dislodge the foreign body. Pawing at the face and mouth is commonly observed.

Coughing and signs of **fixed obstruction** – meaning there is airflow limitation during both inspiratory and expiratory due to constant partial obstruction of the airway – may be seen with tracheobronchial foreign bodies. The coughing is often harsh, and may be elicited with tracheal palpation.

Diagnosis

Tracheal foreign bodies may be seen radiographically. Tracheobronchoscopy can be both diagnostic and therapeutic. Rigid tracheoscopy allows for larger retrieval

instruments to be utilized than with a flexible endoscopy.

Bronchial foreign bodies may cause complete lobar atelectasis or abscessation radiographically. The right caudal and accessory lobes are most often affected with inhalation foreign bodies. The right middle lobe is affected commonly with aspiration of vomitus.

Differential diagnosis

Nasopharyngeal polyps may cause similar signs of nasal obstruction and sneezing, but tend to have a more chronic course.

Tracheal or bronchial neoplasia may have similar signs, but again are more chronic in nature and can be distinguished bronchoscopically.

Treatment

Removal of the foreign body, either surgically or endoscopically, is often curative. Nasal foreign bodies may be endoscopically retrieved or hydropulsed, but occasionally require surgical rhinotomy.

Bronchial foreign bodies, especially with lung lobe abscesses, require lung lobectomy.

Prognosis

Excellent with removal of the foreign body.

Prevention

Hairball prophylaxis.

Avoidance of grass fields during seed time.

INHALATION OF NOXIOUS AGENTS

Classical signs

- Acute onset of severe coughing.
- Evidence of inhalation of gas, smoke, fumes, dust particles or hair.

Pathogenesis

Poor ventilation, engine exhaust, smoke from fires or cigarettes, all can stimulate an aggressive cough reaction.

Fires may cause thermal damage to the upper airway. Burning plastics release toxic fumes causing direct chemical damage to lungs.

Carbon monoxide exposure results in carboxyhemoglobin formation, lowering the oxygen-carrying capacity of hemoglobin, and worsening the hypoxemia.

Airways irritated by underlying disease such as bronchitis, may be hyperresponsive to cigarette smoke or household fumes.

Clinical signs

Patients rescued from fires smell of smoke, have burned hair or vibrissae, may be coughing, and are often expectorating soot-tinged sputum.

Cherry-red mucus membranes indicate carboxyhemoglobinemia, and cyanosis indicates hypoxemia.

Stridor and inspiratory dyspnea suggest **laryngeal edema**.

Crackles indicate increased airway fluid.

Wheezes indicate diminished airway diameter via bronchoconstriction, congestion, mucus accumulation, and airway edema.

Diagnosis

Presumptive diagnosis is based upon evidence of recent exposure to noxious agent and acute onset of coughing.

Thoracic radiography.

- May vary from peribronchiolar to patchy interstitial lung pattern, with possible lobar consolidation.
- Infiltrates are generalized, although the caudodorsal fields may be more affected.
- These changes may lag several hours behind clinical signs.

Pulse oximetry may indirectly assess oxygenation through SPO_2 (hemoglobin saturation).

Blood gases.

- **Arterial oxygen (PaO_2)** represents dissolved oxygen content not bound to hemoglobin.
- $\text{PaO}_2 < 60$ mmHg indicates severe hypoxemia, often associated with cyanosis.

- PaO₂ may be misleading in CO toxicity due to extreme carboxyhemoglobinemia and very low O₂-carrying capacity.
- A profound mixed acidosis may be present.

Measuring **carboxyhemoglobin** levels are needed to diagnose carbon monoxide toxicity. Routine STAT assays are available in human hospitals.

Treatment

Emergency treatment focuses on assessing three critical areas – **ABC – airway, breathing, circulation**.

A – airway

- If the upper airway is burned or edematous, establishing a patent airway may require laryngeal suctioning, tracheal intubation, or transtracheal catheterization, or tracheostomy.

B – breathing

- **Oxygen is the single most important drug to use.** Carbon monoxide is displaced from the carboxyhemoglobin complex 8–10 times faster on 100% O₂ than on room air. Continue 100% O₂ until carboxyhemoglobin < 10% on follow-up samples.
- Bronchodilators – **terbutaline** (0.01 mg/kg SQ) can be repeated every 4 hours.

C – circulation

- **Crystalloid** administration supports the blood pressure and cardiovascular status, promotes diuresis of absorbed toxins, but must be used judiciously and monitored carefully for iatrogenic pulmonary edema. **Colloids** (fresh frozen plasma, synthetic starch products, synthetic blood substitutes) may be beneficial.

The prophylactic use of **antibiotics** is controversial. Antibiotics reduce the normal flora, and may predispose to a more serious nosocomial infection. If infection is suspected, antibiotic selection should be based on culture results of lung wash fluid.

Prognosis

The prognosis is directly related to the extent of the injuries, both to the airways and non-respiratory damage (i.e., skin burns, other organ damage, etc.). Signs may progressively worsen over the initial 24–48 hours.

Prevention

Ensure proper ventilation for heaters and wood stoves, avoid exposure to aerosol chemicals, and reduce exposure to cigarette smoke (quit smoking or smoke outdoors).

AIRWAY/PULMONARY NEOPLASIA

Classical signs

- Dyspnea, other inspiratory and expiratory
- Coughing, ranging from harsh and dry to soft and productive.

Pathogenesis

Upper respiratory tract masses may produce a cough from post-nasal drip.

Pulmonary or airway masses cause coughing by stimulation of cough receptors within the airway lumina, or from extraluminal compression and distortion of the airway.

Upper airway neoplasms include:

- Nasopharyngeal polyps, oropharyngeal squamous cell carcinoma, tracheal adenocarcinoma (Siamese), nasal adenocarcinoma.

Pulmonary neoplasms include:

- Primary pulmonary neoplasia.
 - Bronchogenic carcinoma, pulmonary adenocarcinoma, and squamous cell carcinomas.
- Secondary metastases from distant neoplasms, including a variety of carcinomas (i.e., mammary adenocarcinomas) and sarcomas (i.e., osteosarcoma), as well as local metastases from primary lung tumors.

Pleural malignancy may cause coughing.

Clinical signs

Tracheal tumors create **fixed obstruction**, leading to inspiratory and expiratory dyspnea, and a harsh, dry cough. Hemoptysis may be present.

Bronchial tumors may be associated with a softer, productive cough, fetid halitosis and hemoptysis.

Very rarely, lameness from hypertrophic osteopathy occurs.

Diagnosis

Radiographs.

- **Cervical radiographs** may show soft tissue masses of the throat and trachea.
- **Thoracic radiographs** showing solid tissue masses or nodular interstitial pattern are highly supportive of neoplasia. Multiple orthogonal views (left and right lateral projections, as well as both dorsoventral and ventrodorsal views) are important to assess potential mass lesions. Hilar lymphadenopathy may be present.

Other imaging modalities, such as CT or MRI may be employed.

Histological examination of the mass(es) is required for definitive diagnosis, as well as for distinguishing the origin of the tumor. Biopsy options include percutaneous fine-needle (20–22 gauge) aspiration, percutaneous core biopsy with 14–18 gauge *TruCut*®-style needle, bronchoscopy for cytology via BAL or bronchial brushings, or transbronchial lung biopsy.

- Ultrasound is a poor tool to guide percutaneous biopsy needles, unless the entire lung lobe has become consolidated, as the sonic beam is reflected by any aerated lung tissue. Triangulating the landmarks based on two right-angled radiographic views is extremely effective. However, pulmonary tumors in cats often have a thin rim of neoplastic tissue surrounding a large necrotic mass, which makes it very difficult to get diagnostic tissue using needle biopsy techniques.
- **Transbronchial cytology** (TTW or BAL) is often disappointing, because of the interstitial nature of the lesion, as neoplastic diseases rarely cross into the airway lumen. Transbronchial lung biopsy is a promising technique.
- **Surgical biopsy** during open thoracotomy is an option, generally during lobectomy. Local lymph nodes should be biopsied for staging of the tumor. There is evidence that any mass in the lung large enough to biopsy requires thoracotomy and surgical excision, because even benign inflammatory diseases (i.e., eosinophilic granulomatosis) respond poorly to medical management, and that eventually, thoracotomy is required.

Thoracocentesis and cytology of pleural fluid may be diagnostic.

Differential diagnosis

Inhaled and penetrating foreign bodies, benign or parasitic granulomas of the airways, and lung lobe torsions, abscesses and pulmonary infiltrates with eosinophils (PIE) may mimic neoplastic masses. Biopsy is often required to differentiate.

Treatment

Tracheal (adenocarcinoma) and some bronchial tumors (bronchogenic carcinoma) may be surgically resectable.

Surgical resection is the treatment of choice for solitary pulmonary neoplasms. Cure or long-term remission is possible with wide surgical margins, generally meaning complete lung lobectomy. If non-resectable, excision of nodules may palliate clinical signs.

Chemotherapy and radiation have been disappointing in generalized pulmonary neoplasms. Metastases from distant tumors carry a grave prognosis, although pulmonary lymphoma may attain remission with chemotherapy.

General supportive care and nutrition are important.

Prognosis

Prognosis is fair to excellent with surgically resectable primary pulmonary neoplasms that have not metastasized at the time of surgery.

Prognosis is grave with metastatic disease or malignant pleural effusions.

Prevention

None known.

LARYNGITIS

Classical signs

- Dysphonia (voice changes) and stridor.
- Harsh gagging cough.
- Inspiratory dyspnea.

Pathogenesis

Laryngeal edema may occur secondary to laryngeal trauma (bite wounds, endotracheal intubation, near-

strangulation from neck collars), excessive vocalization (senility, sexual behavior), or other laryngeal disease (laryngeal paralysis).

Laryngeal trauma may directly inflame the larynx, or may cause nerve damage, secondary laryngeal paralysis and subsequent mucosal edema from abnormal arytenoid cartilage motion.

Aspiration of lavage solutions from dental prophylaxis or endodontics may be caustic to the laryngeal mucosa, creating significant edema.

Laryngeal edema may occur as part of a **type I hypersensitivity** reaction to insect stings or vaccination.

Inflammatory diseases like eosinophilic laryngeal granuloma can cause edema (see *The Cat With Stridor*, page 45).

Coughing may occur from irritation of the laryngeal cough receptors, or from aspiration of food, water or saliva due to laryngeal paresis.

Clinical signs

The cough is usually non-productive, but is typically harsh and may stimulate a gag reflex and expectoration of pharyngeal contents.

Inspiratory dyspnea and stridor, which is worse with excitement or exercise, may be evident.

Dysphonia or voice change, often a whisper-like or hoarse sound, is frequently observed in cats.

Diagnosis

Laryngoscopy requires deep sedation or anesthesia and a rigid laryngoscope and blade, and often reveals erythema and edema of the laryngeal mucosa.

Samples of abnormal tissue may be taken for cytology and histology. Culture of the larynx is of questionable value.

If biopsies are taken, this may worsen edema. Post-operative steroids may decrease iatrogenic edema. Occasionally, temporary tracheostomy may be required after biopsy.

Differential diagnosis

Laryngeal mass lesion or foreign bodies are differentiated visually and by biopsy. Other causes of upper air-

way obstruction such as tracheal collapse, are differentiated with laryngotracheobronchoscopy.

Treatment

Anti-inflammatories, especially glucocorticoids, are used to diminish the local inflammation.

- **Dexamethasone** (0.1–0.25 mg/kg IV or IM), or prednisone (0.5–1.0 mg/kg PO q 12–24 h).
- Little is known about the application of **NSAIDs** in laryngeal edema.

Antibiotics are only indicated if there is evidence of bacterial infection.

Antitussives may be indicated when the cough has become protracted and debilitating, and lower respiratory disease has been ruled out.

- **Butorphanol** (0.2 mg/kg SQ q 6 h or 1 mg/cat PO q 6–8 hours prn) may be effective.

Prognosis

Fair to excellent.

Prevention

Use of break-away neck collars on outdoor cats may significantly decrease strangulation injury to the larynx and the laryngeal nerves.

Avoidance of insect stings is helpful.

Neutering tom cats helps to prevent both fighting and mating behaviors such as excessive vocalization.

TRACHEOBRONCHIAL COLLAPSE

Classical signs

- Harsh, honking cough.
- Dynamic airflow limitation on inspiration if cervical segment, and expiratory if intrathoracic segment involved.
- Very rare in cats.

Clinical signs

The cough is often harsh, non-productive and paroxysmal, ending in a gagging episode which may appear to be productive.

Cervical trachea collapse produces inspiratory dyspnea, while intrathoracic tracheal or bronchial collapse will lead to mostly expiratory dyspnea.

Generally occurs **secondary to trauma** or to compression caused by an **extraluminal mass**.

Diagnosis

Radiographs may show attenuation of the tracheal or bronchial lumina. Fluoroscopy may be more sensitive for dynamic collapse.

Tracheobronchoscopy is valuable in both diagnosing and grading the severity of the collapse.

Differential diagnosis

Tracheitis from feline rhinotracheitis virus is generally associated with other upper respiratory tract signs.

Laryngeal paralysis or edema, tracheal foreign body and tracheobronchial neoplasm can be differentiated endoscopically.

Small airway disease (feline asthma/bronchitis complex) can worsen upper airway collapse, but generally diagnosis is based on radiographic peribronchiolar pattern and airway inflammation on lung wash cytology.

Treatment

Medical treatment is indicated if the collapsing segment is short and minimally attenuated, and consists primarily of antitussive therapy (**butorphanol** 1 mg/cat PO q 6–12 h prn).

Surgical therapy may be indicated with severe collapse due to trauma. This generally requires referral to a specialist with experience in airway surgery.

Weight loss and avoidance of neck collars can be very beneficial in affected cats.

PNEUMONIA

Classical signs

- Moist, productive cough.
- Fever or hypothermia may be present.
- Fetid halitosis.
- Adventitial lung sounds are common.

See main reference on page 64 for details (The Dyspneic or Tachypneic Cat).

Clinical signs

Deep productive cough, may be soft and ineffective.

Inspiratory and expiratory dyspnea, often with open-mouth breathing.

Adventitial breath sounds, including crackles, wheezes, snaps and pops.

History of signs consistent with bacterial, fungal, viral, mycoplasmal and *Chlamydomphila felis* pneumonitis.

Constitutional signs include lethargy, anorexia, weight loss, fever and ill thrift.

Diagnosis

Thoracic radiography shows alveolar densities (focal or generalized) and possible areas of complete consolidation. Hilar lymphadenopathy supports fungal or mycobacterial pneumonia.

Hematology often shows neutrophilia with or without a left shift or signs of toxicity. Low-grade, non-responsive anemia and monocytosis may support chronicity.

Cytology and culture of lung samples may be obtained via percutaneous lung aspiration, transtracheal wash, or bronchoscopic lavage. Fungal, aerobic and anaerobic bacterial cultures are generally submitted.

Serology may aid in the diagnosis of cryptococcal pneumonia.

Differential diagnosis

Chronic small airway disease (feline asthma/bronchitis), PIE and lymphomatoid granulomatosis, and pulmonary neoplasia, either primary or metastatic disease, may mimic pneumonia.

Small airway disease tends to have peribronchiolar infiltrates compared to the alveolar pattern of pneumonia. Also, although asthmatic cats may be severely dyspneic, systemic signs of fever, or neutrophilic leukocytosis are rare.

PIE, granulomas or neoplasms tend to have a nodular or interstitial density on radiographs, but biopsy results are required to distinguish these diseases.

Each of the infectious pneumonias can have overlapping features.

Treatment

Bacterial pneumonia – antimicrobial therapy, parenteral if debilitated or septic, and oral if cat is an outpatient. Antibiotic selection best based upon specific culture and sensitivity testing.

Fungal pneumonia – systemic **itraconazole** at 5–10 mg/kg PO daily is the drug of choice. If there are CNS signs with cryptococcosis, **fluconazole** (2.5–5.0 mg/kg PO daily) crosses the blood–brain barrier.

Viral pneumonia – mostly supportive.

Supportive care is essential. Adequate airway and systemic hydration are essential for mucociliary clearance. Intravenous crystalloids are important for systemic hydration, but should be used judiciously to avoid over-hydration. Nebulization with saline may be helpful. Physical therapy, oxygen enrichment and bronchodilator therapy may be helpful.

Prognosis

Prognosis depends on the etiological agent and the severity of the infection.

Bacterial pneumonia has a fair to good prognosis, but the prognosis is worse in patients with pre-existing illnesses or patients on immunosuppressive therapy.

The prognosis for **aspiration pneumonia** depends on the degree of tissue damage.

Cryptococcal pneumonia generally has a fair to good prognosis, although it is poor if CNS signs are present.

Prevention

Avoid the source of infectious agents (i.e., aspergillus from bird droppings) and risk factors (i.e., aspiration).

FELINE HEARTWORM DISEASE

Classical signs

- Cough.
- Acute-onset dyspnea.
- Vomiting together with respiratory signs.

Pathogenesis

***Dirofilara immitis* larvae (L3) infect the cat** following a bite from an infected mosquito.

Larvae molt and migrate to the pulmonary arteries, **arriving as immature heartworms (L5) approximately 100 days** or more after **initial infection**.

Cats typically have **fewer adult worms than dogs**. Less than six adults is usual and often only one or two worms are present. Adult worms live shorter lifespans in cats compared to dogs, typically 18 months to 3 years.

The **prevalence** of heartworm infection in cats is **approximately 5–10% of the infection rate in dogs** in the same location, although the ratio may be higher in some areas. A recent report from Florida showed 5% of necropsied cats were positive for the parasite, and 17% of tested cats were seropositive. In a similar study in Georgia, *D. immitis* were found in four of 184 cats (2.1%).

Indoor cats are as likely to be infected as outdoor cats.

In some studies, male cats had a higher incidence of infection and had a higher worm burden.

Cats infected with heartworm may be **asymptomatic, have chronic coughing, acute respiratory distress or die suddenly**.

Clinical signs are most likely to occur at the time of arrival of the immature heartworms in the lungs or with death of adult worms.

Initial arrival of the immature worms results in a marked inflammatory response, and signs similar to the feline asthma/bronchitis complex may occur. With maturation to the adult worm, signs may improve or resolve.

Death of adult heartworms may produce acute severe pulmonary inflammation with edema, and an acute respiratory distress syndrome characterized by generalized respiratory failure.

Clinical signs

Harsh and productive coughing is the most common sign.

Dyspnea may be **acute and life threatening**. Acute dyspnea is associated with pulmonary thromboem-

bolism, or **acute pulmonary inflammation and edema** associated with worm death. Acute respiratory distress syndrome (ARDS) and generalized respiratory failure are not uncommon.

Acute death is reported in approximately 30–45% of cats presenting with clinical signs of heartworm disease.

Vomiting is often reported and when it occurs together with respiratory signs, it is suggestive of chronic feline heartworm disease.

A gallop rhythm is sometimes audible.

Neurological signs such as blindness and vestibular signs may be associated with aberrant migration of **L4 larvae** to the brain.

A report describes two cases of **cutaneous nodular lesions** associated with *D. immitis* adult parasites in domestic short-haired cats living in an endemic area in northern Italy.

Diagnosis

Mild non-regenerative anemia, peripheral basophilia, eosinophilia and hyperglobulinemia are sometimes evident.

Heartworm testing.

- **Antigen tests** (ELISA test) are **highly specific, but only moderately sensitive**. False negatives occur with low numbers (< 5) worms, and as most cats have only one or two worms, the test is positive in less than 50% of infected cats.
- **Antibody tests** are more sensitive, but less specific for active infection than antigen testing, as they may remain positive for 18 months after infection has resolved.
- A higher sensitivity and specificity is obtained if both the antigen and antibody tests are performed and the results considered together.
- **Microfilarial tests are unreliable** in the cat because the concentration of microfilaria is very low and microfilariaemia is transient, lasting only 1–2 months.

Thoracic radiographs may show **dilated and blunted pulmonary arteries**, which are most prominent in the caudal pulmonary arteries, particularly the right side. The dilation may not be evident beyond the cardiac shadow.

- **Lung changes vary** from **patchy pulmonary infiltrates** to **severe alveolar densities** suggestive of lung lobe atelectasis or consolidating pneumonia. Occasionally pleural effusion is present.

Cardiac ultrasound may show hollow linear densities (worms) in the **right chambers** and **pulmonary artery**, as well as pulmonary arterial dilation.

- Cardiac ultrasound has similar sensitivity to antigen tests. False negatives occur because worms may reside in the extremities of the pulmonary arteries where they cannot be detected with the ultrasound. Occasionally, false-positive results may occur from linear densities detected where the main pulmonary artery branches.

Differential diagnosis

Other causes of chronic coughing or acute respiratory distress should be considered as differentials.

- **Lungworm and lung flukes** are diagnosed with fecal Baermann exams.
- **Feline asthma** is not associated with vomiting, and basophilia is uncommon.
- **Cardiomyopathy** is diagnosed with echocardiography.
- **Hydrothorax** is diagnosed radiographically and classified based on examination of the fluid.
- **Other forms of pneumonia**, (bacterial, viral, fungal, inflammatory), and **neoplastic disease** may appear similar, and are differentiated by lack of evidence of feline heartworm on serology, radiology and ultrasound. Radiography, serology and cytological or histological examination of tissue may provide a definitive diagnosis.

Treatment

Asymptomatic cats do not require treatment and spontaneous resolution of infection may occur as worms live only about 1.5–2 years in cats.

Symptomatic cats.

- Stabilize with oxygen therapy, **prednisone** (1–2 mg/kg PO q 12–24 h for 10–14 days, then slowly wean down), **bronchodilator therapy** (Theophylline, **TheoDur®** 25 mg/kg PO q 24 h) and if needed **antiemetics**.

- **Adulticide therapy is not recommended** as there is a **high risk (25–30%) of mortality**, mostly from pulmonary thromboembolism within the first 5 days. The death rate following treatment is at least as high as the death rate in untreated cats.
- **Manual removal of worms by a specialist** is associated with a lower mortality rate than killing the worms with parasiticides. This technique is only recommended in symptomatic cats with worms visible in the right heart and main pulmonary arteries on ultrasound. Shock-like signs and death may occur if the worms are damaged during extraction.

Prevention

The currently available drugs licensed for **prevention of heartworm** in cats are **ivermectin** (24 µg/kg once monthly) and **selamectin** (*Revolution*®, Pfizer Animal Health, 6 mg/kg once every 30 days). **Milbemycine oxime** (*Interceptor*®, Novartis Animal Health, 500 µg/kg once monthly) is effective but not licensed for use in cats.

Imidacloprid and **moxidectin** (*Feline Advantage Heart*®, Bayer Health Care) topical solution as monthly treatment for prevention of heartworm infection in cats.

As indoor cats are as likely to be infected as outdoor cats, restricting the cat to indoors is not effective prevention.

PARASITIC PNEUMONIA

Classical signs

- Variable cough.
- +/- Eosinophilia.
- +/- Larva/ova in stool.

Clinical signs

Etiological agents include heartworm disease, lungworm (*Capillaria aerophila* or *Aelurostrongylus abstrusus*), lung flukes (*Paragonimus kellicotti*), migrating nematodes and toxoplasmosis.

Coughing may be present, and is typically harsh and productive.

Dyspnea and exercise intolerance, evidenced as lethargy, physical inactivity, reluctance to play or weakness, may occur.

Weight loss, poor coat and ill-thrift may be evident.

Vomiting sometimes occurs with feline heartworm disease.

Diagnosis

Feline heartworm disease – peripheral basophilia, positive heartworm antibody testing, dilated and blunted pulmonary arteries and patchy pulmonary infiltrates on radiographs, and evidence of heartworms on ultrasound (see page 105 for details).

Lungworm infection with *Capillaria aerophila* is diagnosed by finding eggs in the stools or lung wash, and with *Aelurostrongylus abstrusus* by finding larvae in the lung wash or fecal Baermann.

Lung flukes (*Paragonimus kellicotti*) produce operculated eggs in the stool.

Toxoplasmosis rarely produces clinical disease in cats. Mixed fluffy interstitial and alveolar patterns are typically evident on radiographs. Tachyzoites may occasionally be recovered on lung wash.

Differential diagnosis

Other forms of pneumonia, namely bacterial, viral, fungal, inflammatory and neoplasia need to be considered if no larvae or ova are found in the stool or lung wash.

Treatment

Feline heartworm disease, see page 105 for main reference.

Lungworm – *Capillaria aerophila* and *Aelurostrongylus abstrusus* – **fenbendazole** (50 mg/kg PO q 24 h for 3 days) or **ivermectin** (400 µg/kg PO, SQ).

Lung flukes – *Paragonimus kellicotti*, **fenbendazole** (50 mg/kg PO q 24 h for 3 days), or **praziquantel** (25 mg/kg PO q 8 h for 2 days).

Toxoplasmosis – **clindamycin** (12.5 mg/kg PO q 12 h), potentiated sulfa (trimethoprim or ormetoprim), or azithromycin (7–15 mg/kg PO q 12 h).

Migrating nematodes – *Toxocara* spp., **pyrantel pamoate** (20 mg/kg PO, repeat 7–10 days).

CARDIOMYOPATHY (DILATED CARDIOMYOPATHY (DCM), HYPERTROPHIC (HCM), INTERMEDIATE (ICM) OR RESTRICTIVE (RCM))

Classical signs

- Dyspnea.
- Gallop rhythm, murmur or arrhythmia.
- Coughing is an uncommon presenting sign in the cat.

See main reference on page 54 for details (The Dyspneic or Tachypneic Cat).

Clinical signs

Coughing is very uncommon in cats, even in advanced congestive failure.

Dyspnea is common with CHF and pulmonary edema, and signs vary from mild exercise intolerance (lethargy, weakness, reluctance to move or play) to severe, open-mouth breathing with cyanosis.

Abnormal heart sounds (murmurs, gallops, arrhythmias) are often present.

Treatment

Oxygen therapy (O₂ chamber or tents work well), **furosemide** (1–2 mg/kg IV or IM), sedation if frantic (**morphine** 0.1 mg/kg IM prn, or **butorphanol** 0.2–0.4 mg/kg IM q 4–6 h prn), and emergency thoracocentesis if hydrothorax is present. See page 84 for treatment details.

PLEURAL/MEDIASTINAL MASSES

Classical signs

- Dyspnea, orthopnea, tachypnea or rarely, coughing.
- Muffled heart and lung sounds from pleural effusion.

See main reference on page 85 for details (The Cat With Hydrothorax).

Clinical signs

Mediastinal lymphoma, **thymomas**, and **mesothelioma** cause pleural effusion or extraluminal compression to the trachea.

Extraluminal compression of the trachea can cause **dyspnea and coughing**.

Other signs that may be present include orthopnea (recumbent dyspnea), tachypnea, minimal airflow with increased chest excursions, or muffled heart and lung sounds from a mass or effusion.

Treatment

Lymphoma is best handled with standard chemotherapy protocols. See page 676 for details.

Surgical excision is the treatment of choice for **thymoma**, and may be curative.

Mesothelioma is an infiltrative disease that cannot be readily resected. Although there are few reports in the literature of effective chemotherapy, local infusion of **carboplatin** may be helpful. Prognosis is grave with or without doxorubicin intravenously.

8. The cyanotic cat

Grainne Muire McCarthy

KEY SIGNS

Bluish discoloration of the skin and/or mucous membranes.

MECHANISM?

- Cyanosis is **bluish discoloration of the skin and/or mucous membranes** due to **reduced oxygen saturation of hemoglobin** in the blood causing hypoxia. Hypoxia producing cyanosis results either from **central** (cardiac or respiratory) or **peripheral causes**.

WHERE?

- Central hypoxia results from **cardiac or respiratory disease**, including disease of the upper or lower respiratory tract, pleural cavity, thoracic wall or diaphragm.
- Peripheral hypoxia may be generalized and associated with generalized vasoconstriction, or is localized and the result of **arterial or venous obstruction**.
- Occasionally abnormal hemoglobin with decreased oxygen carrying capacity is the cause of the cyanosis.

WHAT?

- The **commonest causes of cyanosis** are central causes and include bronchial and pulmonary disease, pleural effusions, cardiac disease, mediastinal neoplasia, diaphragmatic hernia and poisoning with acetaminophen.
Peripheral cyanosis is usually the result of arterial thromboembolism.

QUICK REFERENCE SUMMARY

Diseases causing a cyanotic cat

CENTRAL HYPOXIA

WHERE? – CARDIAC HYPOXIA

ANOMALY

- Congenital heart anomaly (p 113)
Tetralogy of Fallot, reversed shunting (R–L), patent ductus arteriosus, tricuspid valve atresia, Eisenmenger's syndrome, endocardial cushion defect, and transposition of the great arteries can all cause cyanosis. Cats with congenital cyanotic heart conditions are usually stunted and cyanotic, and frequently present with a history of lethargy and syncope. Abnormal heart sounds may be audible.

continued

NEOPLASTIC

- Heart base tumors (p 113)
Muffled heart and lung sounds, pleural effusion and ascites.

INFECTIOUS (PARASITIC)

- **Dirofilariasis** (p 112)**
Most cats are asymptomatic, others may have non-specific signs of cough, lethargy, anorexia. Sudden death may occur.

IDIOPATHIC

- **Cardiomyopathy*** (p 112)**
Dyspnea and tachypnea and cats with arterial thromboembolism may present with posterior paresis.

WHERE? – RESPIRATORY HYPOXIA

ANOMALY

- Diaphragmatic hernia (p 115)
Usually occurs following trauma, but may be congenital. Clinical signs of dyspnea and tachypnea may be present early in life or may not occur for years. Vomiting, regurgitation or inappetence may also occur.

MECHANICAL

- Airway obstruction (p 117)
Acute onset of inspiratory dyspnea and cough occur with foreign bodies lodged in airways. Coughing and wheezing occur when the obstruction is due to bronchoconstriction.
- **Pleural effusion/pneumothorax*** (p 114)**
Multiple causes of pleural effusion, both cardiac and non-cardiac, result in dyspnea and tachypnea. Inappetence, weight loss and pyrexia may occur depending on the cause.
- Pulmonary thromboembolism associated with heartworm disease (p 116)
Sudden onset of coughing, dyspnea, pulmonary crackles on auscultation and occasionally hemoptysis. Vomiting may also occur.

NEOPLASTIC

- **Cranial mediastinal lymphosarcoma** (p 115)**
Dyspnea, tachypnea, regurgitation and reduced compressibility of the cranial thorax may be evident. Inappetence and weight loss may also occur.

INFLAMMATION (INFECTIOUS)

- Bacterial/viral/fungal/parasitic/protozoal/mycoplasmal
Pneumonia; depression, fever, tachypnea, cough and dyspnea. The cat may also show signs of upper respiratory tract disease.

INFECTIOUS (IMMUNE)

- **Feline bronchopulmonary disease/feline bronchitis complex/feline asthma** (p 114)**
Typically, there is wheezing and coughing which may progress to severe dyspnea, open-mouthed breathing and cyanosis.

TRAUMA

- **Diaphragmatic hernia* (p 115)**

Dyspnea and tachypnea may occur acutely or months or years following blunt trauma. Vomiting, regurgitation, inappetence and weight loss may also occur.

- **Central nervous system damage to the respiratory center (p 118)**

Persistent or episodic weakness, Cheyne–Stokes respiration and cyanosis.

TOXIC

- **Drug overdosage (p 117)**

Excessive administration of barbiturates, narcotics, opiates, tranquilizers or anesthetic agents may lead to decreased respiratory effort, loss of consciousness and cyanosis. During anesthesia, reduced bleeding at surgical sites and indicators of a deep plane of anesthesia are present.

PERIPHERAL HYPOXIA WHERE? – GENERALIZED MECHANICAL

- **Vasoconstriction* (p 118)**

Peripheral hypoxia occurs due to vasoconstriction as a consequence of hypovolemic, cardiogenic or septic shock or due to hypothermia. Clinical signs, physical findings and history point to one of these causes. There may be evidence of shock, trauma, dehydration, pyrexia, blood loss or reduced urinary output. Signs of cardiac failure include dyspnea, cardiac murmur, gallop rhythm, slow capillary refill time, pale/cyanotic mucous membranes and pulse deficits. Frequent or severe vomiting, diarrhea or diuresis may indicate fluid loss.

LOCALIZED MECHANICAL

- **Arterial thromboembolism** (p 120)**

Ninety percent lodge at the distal aortic bifurcation causing bilateral hindlimb pain and paresis, weak or absent femoral pulses, cold, cyanotic footpads and lack of spontaneous movement of the muscles of the hindlimbs. Other areas embolized less commonly are the thoracic aorta, renal, mesenteric, coronary, cerebral and branchial arteries which cause acute, severe and variable clinical signs.

- **Venous obstruction (p 121)**

Clinical signs relate to the area drained by the obstructed vein, mainly edema and vasodilatation distal to the site of obstruction. Cranial vena caval obstruction results in edema of the neck, ventral head, cranial thorax and forelimbs.

ABNORMAL HEMOGLOBIN WITH DECREASED OXYGEN-CARRYING CAPACITY WHERE? – HEMOGLOBIN IN RED BLOOD CELLS WHAT?

TOXICITY

- **Paracetamol/acetaminophen toxicity (p 121)**

Acute onset and rapid progression of salivation, vomiting and depression. Cyanosis develops within 4–12 hours of ingestion. Subcutaneous edema of the face may be evident, which may be accompanied by lacrimation and puritis. Hematuria, hemolysis and Heinz bodies occur associated with methemoglobin formation.

INTRODUCTION

MECHANISM?

Cyanosis is **bluish discoloration of the skin and/or mucous membranes** due to reduced oxygen saturation of hemoglobin in the blood causing hypoxia. Cyanosis most commonly results from **decreased oxygen saturation of normal hemoglobin**. Only rarely it results from abnormal hemoglobin with decreased oxygen-carrying capacity. Hypoxia producing cyanosis results either from **central (cardiac or respiratory) or peripheral causes**.

WHERE?

Hypoxia (i.e. decreased oxygen saturation of normal hemoglobin).

Central hypoxia results from congenital **cardiac** anomalies such as tetralogy of Fallot and pulmonary arterial hypertension secondary to a large PDA, VSD, ASD or truncus arteriosus, **respiratory** diseases including tracheal and laryngeal neoplasia (rare), pleural effusions, pulmonary edema, pneumonia, thoracic wall lesions and rupture of the diaphragm.

Peripheral hypoxia is either **generalized** as a result of generalized vasoconstriction due to hypothermia, heart failure or shock or **localized** as a result of **arterial or venous obstruction**. Acute arterial obstruction may result from thromboembolism or thrombosis occurring with cardiomyopathy, bacterial endocarditis, hypercoagulable conditions and cold agglutinin disease. Venous obstruction occurs as a result of thrombophlebitis and restrictive devices such as a rubber band around the limb.

Abnormal hemoglobin with decreased oxygen-carrying capacity.

WHAT?

In the cat, the commonest causes of cyanosis include bronchial and pulmonary disease, pleural effusions, cardiac disease, mediastinal neoplasia, diaphragmatic hernias and poisoning with acetaminophen. Peripheral cyanosis is usually the result of arterial thromboembolism.

CARDIAC HYPOXIA

CARDIOMYOPATHY***

Classical signs

- Dyspnea and tachypnea.
- Lethargy.
- Anorexia/vomiting.
- Posterior paresis.
- Abnormal heart sounds.

See main reference on page 128 for details (The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

Clinical signs

Dyspnea and tachypnea, or in severe cases open-mouthed breathing, occur because of pleural effusion and/or pulmonary edema.

Lethargy, anorexia and occasional vomiting may be present.

Occasionally, acute onset of posterior paresis occurs with painful hardening of the quadriceps and gastrocnemius groups of muscles, cyanosis of the nail beds and cold extremities associated with aortic thromboembolism.

Diagnosis

Thoracic radiography may show cardiac enlargement, pleural effusion and pulmonary edema.

Echocardiography may show left ventricular hypertrophy and left atrial enlargement in hypertrophic cardiomyopathy or left atrial and ventricular dilation with reduced contractility in dilated cardiomyopathy.

DIROFILARIASIS**

Classical signs

- Most cats are asymptomatic.
- Cough, lethargy, anorexia, vomiting, dyspnea and syncope.
- Acute dyspnea and sudden death.

See main reference on page 104 for details (The Coughing Cat).

Clinical signs

Many cats are **asymptomatic**.

Sudden death occurs in 30–40% of cats with clinical signs from dirofilaria.

Most cats are presented with non-specific signs such as lethargy, anorexia, vomiting, coughing, dyspnea and syncope.

Acute dyspnea may result from acute thromboembolism.

Right-sided heart failure is rare.

Diagnosis

Thoracic radiography may show prominent blunted or tortuous caudal lobar arteries and right heart enlargement.

Laboratory tests reveal eosinophilia and a non-regenerative anemia in 33% of cases. **Adult antigen tests** detect only about 25% of infected cats because of low worm numbers. **Tests for circulating antibody** to heartworm are more sensitive, but there are problems with false positives and negatives. Antibodies may persist for up to 18 months after worms have died, so a positive test does not necessarily indicate current infection.

Echocardiography may reveal worms in the pulmonary artery, right heart or vena cava.

Non-selective angiography may show linear filling defects associated with the presence of worms.

CONGENITAL HEART ANOMALY

Classical signs

- Stunting.
- Cyanosis.
- Signs of congestive heart failure.
- Abnormal heart sounds.

See main reference on page 140 for details (The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

Pathogenesis

Congenital cardiac anomalies causing cyanosis result from **defects in the partitions of the heart or**

great vessels and an obstruction to pulmonary blood flow.

This leads to **right-to-left shunting** and results in mixing of unsaturated and saturated blood which is then ejected into the systemic circulation.

Tetralogy of Fallot, reversed shunting (R–L), patent ductus arteriosus, tricuspid valve atresia, Eisenmenger's syndrome, endocardial cushion defect and transposition of the great arteries can all cause cyanosis.

Clinical signs

Cyanosis in a young cat or kitten frequently is suggestive of a congenital heart anomaly.

They may present with lethargy, exercise intolerance, syncope and tachypnea.

Signs of **congestive heart failure** or **abnormal heart sounds** may be present.

Diagnosis

Dorsoventral thoracic radiographs may show **enlargement of the right atrium** at the 8–11 o'clock position, right ventricular enlargement at the 5–9 o'clock position or post-stenotic dilation of the pulmonary artery at the 1–2 o'clock position.

Lateral thoracic radiographs may show rounding of the cranial border of the heart with **increased sternal contact** and elevation of the trachea in the cranial thorax. On both views the **pulmonary vessels may be underperfused**.

Echocardiography is useful for visualizing the abnormal cardiac and vascular shunts. Doppler studies will help to identify the presence and direction of shunts.

Hematological examination may indicate a **polycythemia with a PCV often in excess of 75%.**

HEART BASE TUMORS

Classical signs

- Muffled heart sounds.
- Right heart failure.
- Pale mucous membranes.
- Weak arterial pulses.

See main reference on page 137 for details.

Clinical signs

Heart base tumors **are rare in cats**.

Heart sounds are often muffled **associated with a pericardial/pleural effusion**.

Weakness, dyspnea and tachypnea are often present.

Ascites is commonly present due to cardiac tamponade.

Edema of the head, neck and forelegs occurs if the tumor presses on the cranial vena cava.

Weight loss may be present.

Diagnosis

Thoracic radiography may show a rounded cardiac silhouette and pleural effusion.

Pericardiocentesis, cytological analysis and contrast pericardiography may help diagnose a heart base tumor.

Echocardiography may enable visualization of the tumor and enable ultrasound-guided fine-needle aspirate biopsy of the tumor for histologic analysis.

RESPIRATORY HYPOXIA

PLEURAL EFFUSION/PNEUMOTHORAX***

Classical signs

- Dyspnea.
- Tachypnea.

See main reference on page 54 for details (The Dyspneic or Tachypneic Cat).

Clinical signs

Progressively worsening dyspnea frequently occurs with thoracic fluid accumulation.

Acute dyspnea may occur with **traumatic pneumothorax** and **tension pneumothorax**.

Muffled lung sounds occur due to the presence of thoracic fluid.

Lung sounds may be inaudible with a pneumothorax.

If due to a cranial mediastinal mass it may result in a non-compressible cranial thorax.

Diagnosis

Thoracic radiograph may show the presence of fluid, air or a mediastinal or other space-occupying mass.

Thoracocentesis may yield fluid which can be classified as transudate, exudate, chylous or hemorrhagic effusion.

Thoracocentesis may yield air indicative of a pneumothorax.

FELINE BRONCHOPULMONARY DISEASE/FELINE BRONCHITIS COMPLEX/FELINE ASTHMA**

Classical signs

- Cough.
- Wheeze.
- Severe dyspnea, open-mouthed breathing and cyanosis.

See main reference on page 92 for details (The Coughing Cat).

Clinical signs

Coughing of variable severity is frequently seen as a result of bronchoconstriction.

Dyspnea and tachypnea will appear if there is severe bronchoconstriction or marked cellular infiltration into the lung parenchyma.

Dyspnea may be inspiratory or there may be **end-expiratory grunting** due to difficulty in expelling air from the cat's hyperinflated lungs.

Acute exacerbations may cause severe dyspnea, orthopnea, open-mouth breathing and cyanosis, which may be life-threatening.

Diagnosis

The **clinical findings** are very supportive of a diagnosis as there are few other clearly recognized causes of **coughing and dyspnea** in the cat.

Wheezing and crackling with moist gurgling sounds can be heard on auscultation.

Thoracic radiographs may show a bronchial or a mixed bronchial/interstitial or alveolar pulmonary pattern throughout the entire lung field.

In the **acute phase** there may be **hyperinflation** of the lungs and **flattening of the diaphragm**. Occasionally collapse of the right middle lung lobe may be seen.

Bronchoalveolar lavage fluid usually shows an inflammatory response which is usually eosinophilic but may be neutrophilic in nature.

Differential diagnosis

Lungworm and lung fluke infestation are diagnosed with fecal Baermann exams.

Heartworm disease is often associated with vomiting, and sometimes basophilia. On radiographs, **dilated and blunted pulmonary arteries**, which are most prominent in the caudal pulmonary arteries, particularly the right side, may be seen. **Lung changes vary** from **patchy pulmonary infiltrates** to **severe alveolar densities**, and sometimes are difficult to differentiate from those of feline bronchopulmonary disease/ asthma.

Treatment

Acute respiratory distress requires a **rapid-acting corticosteroid** such as methylprednisolone sodium succinate given intravenously at a dose of 30–50 mg/kg, oxygen and **terbutaline** at a dose of 0.01 mg/kg IM or SQ q 4 h.

Long-term management involves eliminating potential allergens and intermittent anti-inflammatory and bronchodilator therapy.

CRANIAL MEDIASTINAL LYMPHOSARCOMA**

Classical signs

- Dyspnea.
- Tachypnea.
- Regurgitation.
- Pleural effusion.
- Non-compressible cranial thorax.

See main reference on page 56 for details (The Dyspneic or Tachypneic Cat) and page 676 for details of treatment.

Clinical signs

Dyspnea and tachypnea are often associated with a pleural effusion.

Regurgitation may occur due to compression of the esophagus by the mass.

Cyanosis may result from compression of the mediastinal vessels.

Reduced compressibility of the cranial mediastinal thorax may be evident because of a space-occupying mass.

Diagnosis

Thoracic radiography shows a space-occupying lesion causing widening of the cranial mediastinum. A pleural effusion is frequently present.

Cytologic evaluation of pleural fluid is useful as it often contains **lymphoblastic cells**.

Fine-needle aspiration of the mass under ultrasound guidance will yield a sample for histopathologic examination.

Test cat for FeLV as approximately 60% of cats with mediastinal lymphosarcoma are FeLV-positive in USA. This may be lower in countries where FeLV is rare.

Test for FIV as this virus is also associated with increased rates of lymphosarcoma.

DIAPHRAGMATIC HERNIA (CONGENITAL ANOMALY OR TRAUMATIC)*

Classical signs

- Dyspnea.
- Tachypnea.

See main reference on page 58 for details (The Dyspneic or Tachypneic Cat).

Clinical signs

Acute tachypnea/dyspnea may develop **after a blunt traumatic event**. There may be signs of shock and other injuries related to an event such as a road traffic accident.

Acute exacerbations of chronic diaphragmatic hernia may occur following the development of a **pleural effusion or dilation of a herniated stomach**.

In **chronic cases**, signs may be restricted to **exercise intolerance**, or **signs of gastrointestinal upset** may occur, weeks or months after the trauma.

Entrapment of viscera following traumatic diaphragmatic hernia may lead to **pleural effusion**. Even partial herniation of liver may result in significant effusion.

Congenital peritoneo-pericardial hernias also occur causing similar clinical signs.

Diagnosis

Clinical findings of **muffled lung sounds**, **displacement of cardiac apex**, **gut sounds audible in thorax** and **reduced volume of abdominal contents** are suggestive.

Thoracic radiography may show loss of diaphragmatic line, abdominal contents in the thorax or pleural effusion.

Thoracic ultrasound can identify the presence of abnormal contents in the thorax and loss of continuity of the diaphragmatic line.

PULMONARY THROMBOEMBOLISM ASSOCIATED WITH HEARTWORM DISEASE

Classical signs

- Severe dyspnea.
- Tachypnea.
- Cyanosis.

See main reference on page 104 for details (The Coughing Cat).

Clinical signs

Acute dyspnea is associated with **pulmonary thromboembolism** or **acute pulmonary inflammation and edema** associated with worm death. **Acute respiratory distress syndrome** (ARDS) and generalized respiratory failure is not uncommon.

Cats usually have an **acute onset of severe dyspnea, tachypnea and cyanosis**, and may mouth breathe.

Dyspnea may be **worsened in lateral recumbency** (orthopnea) and the cat is reluctant to lie in this position.

There may be splitting of the second heart sound, resulting in a **gallop rhythm**, due to acute pulmonary arterial hypertension.

Diagnosis

Thoracic radiographs may show evidence of **parenchymal lung disease**, **right-sided cardiomegaly**, or **enlargement of the caudal lobar arteries** or may be normal.

Ultrasound examination may reveal heartworm as **hollow linear densities** in the main pulmonary artery or right atrium, as well as pulmonary arterial dilation.

Definitive diagnosis of the thromboembolism requires angiography or **pulmonary scintigraphy**.

Blood chemistries may indicate the presence of a hypercoagulable condition.

Heartworm tests may be positive.

PNEUMONIA

Classical signs

- Fever.
- Tachypnea.
- Cough.
- Dyspnea.
- Inappetance.

See main reference on page 62 for details (The Dyspneic or Tachypneic Cat).

Clinical signs

Cats are usually **inappetent, dull, febrile and lethargic** and may have a productive cough or fetid halitosis with bacterial pneumonia.

Tachypnea and dyspnea may be evident, and **open-mouth breathing** may occur with stress.

Aspiration pneumonia after oral dosing with liquid paraffin or mineral oil, or associated with megaesophagus may also result in **coughing**.

Viral pneumonia with feline calicivirus causes a non-productive cough.

Diagnosis

Crackles and wheezes may be heard on **pulmonary auscultation** especially in the **ventral lung fields**.

Thoracic radiographs show a **patchy interstitial or alveolar pattern, and possibly lung lobe consolidation in the cranioventral lung fields**. There may be evidence of **megaesophagus** present.

Tracheal and bronchoalveolar lavage cytology may reveal a neutrophilic inflammatory response with many degenerate neutrophils. Alternately, the presence of eosinophils may indicate an allergic, parasitic or neoplastic etiology.

Microbial culture of cytospun lavage fluid deposit may reveal a primary pathogen (bacterial, fungal, parasitic or myoplasma).

Bronchoscopy may show inflammatory exudate in the airways.

Routine hematologic examination may reveal a left shift in bacterial pneumonia.

Check FeLV and FIV status in cats with chronic pneumonia as they may be immunosuppressed.

AIRWAY OBSTRUCTION

Classical signs

- Inspiratory dyspnea.
- Cough.
- Stridor.
- Cyanosis.

See main reference on page 65 for detail. (The Dyspneic or Tachypneic Cat (Foreign bodies)) and page 92 (The Coughing Cat (Feline asthma/bronchitis complex)).

Clinical signs

Acute-onset inspiratory dyspnea and stridor occur shortly after inhalation of a foreign body. **Tracheal foreign bodies** are more common in cats than dogs.

Coughing is likely with bronchial foreign bodies and the right middle lobe most likely to be involved.

Tracheobronchial compression caused by **space-occupying** lesions (most often lymphoma or thymoma) usually lead to coughing and dyspnea.

Airway obstruction caused by **bronchoconstriction** associated with feline asthma or bronchitis complex leads to severe dyspnea, wheezing and coughing.

Diagnosis

Thoracic radiography may reveal foreign bodies, tumors or other structures compressing or obstructing the airways.

Bronchoscopy may reveal structures compressing the airway or a foreign body or other material in the airways.

DRUG OVERDOSAGE

Classical signs

- Decreased respiratory effort.
- Absence of voluntary respiration.
- Loss of consciousness.
- Cyanosis.
- Reduced bleeding from surgical site.

Clinical signs

Respiratory depression or even failure can result from **excessive administration of barbiturates, narcotics, opiates, tranquilizers or anesthetic agents**.

This leads to **loss of consciousness and cyanosis** due to hypoxemia.

If it occurs during a surgical procedure, there may be **reduced bleeding** from the surgical site and the color of the **blood darkens**. **Loss of blink reflex** indicates a deep plane of anesthesia and is associated with increased respiratory depression.

Diagnosis

Diagnosis is based on **clinical signs** together with **anesthetic records** indicating drug overdose, or a **history of access** to sedative, narcotic or anesthetic drugs.

CENTRAL NERVOUS SYSTEM DAMAGE TO THE RESPIRATORY CENTER

Classical signs

- Persistent or episodic weakness.
- Cheyne–Stokes respiration.
- Cyanosis.

Clinical signs

Central respiratory depression as a result of CNS infection, increased intracranial pressure or head injury leads to slow, gasping respirations (Cheyne–Stokes respiration).

The cat may be unconscious and cyanotic.

Other evidence of trauma, or neurologic deficits may be present.

Diagnosis

Neurological examination demonstrates neurologic deficits consistent with a medullary lesion together with a typical respiratory pattern.

PERIPHERAL HYPOXIA – GENERALIZED

VASOCONSTRICTION*

Classical signs

- Generalized cyanosis.
- Signs of hypovolemic, cardiogenic, or septic shock or hypothermia.

Pathogenesis

Peripheral hypoxia occurs due to vasoconstriction as a consequence of **hypovolemic, cardiogenic or septic shock or due to hypothermia**. This leads to inadequate capillary perfusion and oxygen delivery to peripheral tissues becomes impaired, which may lead to generalized peripheral cyanosis.

Hypovolemia occurs when blood volume is diminished by **whole blood loss or by extracellular fluid losses**. Compensatory mechanisms include splenic and venous constriction to translocate blood from the venous capacitance vessels to the central arterial circulation; arteriolar constriction to maintain diastolic blood pressure and increasing heart rate to increase cardiac output. When severe, hypovolemic shock ensues resulting in generalized peripheral hypoxia.

Cardiogenic shock occurs with any condition that **interferes with forward outflow from the heart** to such an extent that adequate tissue perfusion is not achieved. Examples include acute or chronic heart failure, cardiomyopathy, intracardiac thrombosis, pericardial tamponade, heartworm disease and severe arrhythmias.

When an animal's blood has become **infected by bacteria, viruses, rickettsia, fungi or protozoa it is considered septic**. Some of these organisms produce **toxins** which are directly **vasoactive** or release vasoactive substances. When the infection is affecting the animal to the extent that tissue perfusion is compromised, **septic shock** has ensued.

Hypothermia results when heat loss exceeds heat production. Decreasing body temperature decreases the partial pressure of oxygen, increases solubility and shifts the oxygen–hemoglobin dissociation curve to the left. These changes impede oxygen unloading at the tissue level. Thermoregulatory vasoconstriction further decreases oxygen delivery.

Clinical signs

Generalized cyanosis together with **signs of severe hypovolemia, severe cardiac disease, hypothermia or sepsis**, which suggest vasoconstriction is leading to inadequate capillary perfusion and impaired oxygen delivery to peripheral tissues.

Signs of cardiac failure include dyspnoea, cardiac murmur, gallop rhythm, slow capillary refill time, pale/cyanotic mucous membranes and pulse deficits.

Evidence of shock, trauma, pyrexia, blood loss or reduced urinary output may indicate cause of peripheral vasoconstriction.

History of frequent or **severe vomiting, diarrhea or diuresis** are suggestive of marked fluid loss leading to **hypovolemia**.

Fluid accumulations in the thoracic or abdominal cavities or in intracellular spaces suggest cardiac disease, sepsis, bleeding or severe hypoalbuminemia is the cause of the vasoconstriction and cyanosis.

Acute weakness, bradycardia and cyanosis, with or without a history of polyuria/polydipsia or GIT signs, in a young to middle-aged dog is suggestive of **hypo-adrenocorticism** (Addison's disease).

Diagnosis

Diagnosis is based on clinical signs and physical findings which suggest that hypovolemia, severe cardiac disease, sepsis or hypothermia are causing marked vasoconstriction and generalized peripheral cyanosis.

Cardiovascular examination, including echocardiography are important in assessing cardiac function.

Complete blood profile may indicate sepsis or hypovolemia.

Thoracic and abdominal radiographs may show cardiomegaly, fluid accumulations, evidence of hypovolemia, evidence of trauma or masses such as abscesses.

Treatment

For cardiogenic shock, treatment is directed at restoring organ perfusion to provide adequate tissue oxygenation, i.e. supporting arterial blood pressure, forward cardiac output and vascular volume. Diuresis, vasodilation, calcium channel- or beta-blocking drugs, anti-arrhythmics, oxygen and thoracocentesis may be required in hypertrophic cardiomyopathy. Continuous monitoring of cardiac, pulmonary and renal status is essential. Supportive

therapy includes cage rest where necessary, weight reduction, avoidance of pregnancy and general reduction in cardiac workload. See page 130 (The Cat With Abnormal Heart Sounds and/or an Enlarged Heart) for treatment.

For shock, treatment depends on the cause. For hypovolemia administer intravenous fluids, and if indicated, a blood transfusion and control any continuing blood loss. For septic shock, fluid therapy and intravenous broad-spectrum antibiotic therapy is indicated. For anaphylactic shock, in addition to fluid therapy, epinephrine is of proven efficacy. Careful monitoring of acid-base balance, urine output, heart rate, pulse quality, capillary refill time, mucous membrane color and mental state are important. The reader is advised to consult a specialist source for an in-depth review of shock therapy.

Rewarming is required for hypothermia. When the **body temperature is less than 32 degrees Centigrade (90 degrees Fahrenheit)** **active central rewarming is required.** This includes the use of **warmed (to 35 degrees Centigrade/95 degrees Fahrenheit) IV fluids, flushing stomach, rectum and open body cavity with warmed isotonic fluids**, and providing warmed, humidified air. If body temperature is between **32 and 36 degrees Centigrade (90 and 96 degrees Fahrenheit)** **active surface rewarming** can be carried out using hot water bottles, heat pads, radiant heaters and hair dryers. At body temperatures above 36 degrees Centigrade (96 degrees Fahrenheit) passive rewarming by covering the cat with blankets is sufficient.

Prognosis

With **hypovolemia** recovery rates can be high, providing adequate correction of fluid deficits can be achieved.

Cardiogenic shock is usually associated with advanced heart disease and so recovery rates are less.

Mortality rates in **septic shock** are high.

The systemic consequences of mild to moderate **hypothermia** are minimal but those of severe prolonged hypothermia are serious and fraught with many complications including cardiac arrhythmias, electrolyte disturbances, coagulopathies, blood glucose upset and cold diuresis.

PERIPHERAL HYPOXIA – LOCALIZED

ARTERIAL THROMBOEMBOLISM**

Classical signs

- Acute onset of posterior paresis/paralysis.
- Cyanosis of footpads and cold extremities.
- Marked pain and swollen, turgid hind limb muscles.
- Weak or absent femoral pulses.

See main reference on page 915 for details (The Weak and Ataxic or Paralyzed Cat).

Pathogenesis

Arterial thromboembolism is a relatively common and serious **sequela to feline cardiomyopathy**. **Thrombi form in the left atrium** due to a combination of factors including sluggish blood flow, endothelial damage and increased blood coagulability. The blood flow through the atria of cats with cardiomyopathy is normal to slow. Slow blood flow enables red cells and other blood factors to clump together and platelet aggregability in cats with cardiomyopathy is reported to be increased.

Once a thrombus is formed it may remain in the atrium and cause no symptoms. It may become an **embolus and travel to the distal aorta** and extend down the external iliac arteries forming a “**saddle thromboembolus**” obstructing blood flow to the hindlimbs. Ninety percent of cats with arterial thromboembolism are thus affected.

It is thought that the embolus releases **serotonin and thromboxane A₂**, which are powerful **vasoconstrictors**. This results in very poor collateral blood flow beyond the embolus, leading to tissue hypoxia and muscular ischemia.

Other emboli may obstruct the **femoral, brachial, renal, mesenteric, coronary or cerebral** arteries causing a wide variety of clinical signs.

Clinical signs

Many cats are in heart failure and therefore are **tachypneic and dyspneic**, and may have a heart murmur or a gallop rhythm.

Typically there is an **acute onset of posterior paresis/paralysis**.

Weakness or absence of one or both **femoral pulses** is evident.

There is **early severe pain in hindlimb muscles** which are **swollen and turgid**. The pain subsides as sensory nervous input is lost over several hours.

Pallor and cyanosis of footpads and **coldness of extremities** are evident.

Later over days to weeks, depending of the degree of arterial obstruction, neurological deficits begin to resolve.

Other organs may be affected depending on deposition of emboli.

Diagnosis

Diagnosis is based primarily on **clinical findings**.

Lack of blood flow to hindlimbs can be confirmed using a **Doppler arterial blood pressure** monitor.

Echocardiography is valuable to identify cardiomyopathy.

Biochemical profiles may help to identify other organ involvement.

Differential diagnosis

Other causes of posterior paresis/paralysis such as road traffic accidents and trauma should be considered.

Treatment

Treatment is mostly palliative, such as cage rest and consider the administration of drugs such as aspirin, heparin or arteriolar dilators. **Heparin** is given to prevent new thrombus formation at an initial dose of 220 U/kg IV followed by a maintenance dose of 70–200 U/kg SC every 6 hours. The dose should be tailored to increase the activated thromboplastin time to at least 1.5 times baseline.

Surgical intervention to remove the embolus and balloon embolectomy may lead to reperfusion syndrome

and most cats will be in heart failure, so are poor anesthetic risks.

Thrombolytic therapy using **tissue plasminogen activator** reduces time to reperfusion and ambulation, however 50% of treated cats died during clinical trials.

Pain treatment in the early stages of the disease using oxymorphone (0.05–0.15 mg/kg IM or IV every 6 hours) and butorphanol (0.02–0.4 mg/kg every 4 hours IM or SC) is essential.

Acetylpromazine (0.05–0.1 mg/kg IV) may be useful as an anxiolytic.

Treatment of the heart failure must also be undertaken.

VENOUS OBSTRUCTION

Classical signs

- Localized cyanosis and edema referable to site of obstruction.
- Edema of neck, ventral head, cranial thorax and forelimbs (vena cava obstruction).

Pathogenesis

Localized peripheral hypoxia resulting from venous obstruction is usually the result of thrombosis, phlebitis or venous obstruction from external compression.

- **Thrombosis** is typically caused by blunt trauma and perforating injury, such as venepuncture or prolonged venous catheterization.
- **Phlebitis** may result from tissue inflammation extending to the veins, or originate from a venous intimal lesion.
- Venous obstruction may be caused by **compression** by **abscesses, hematomas, tumors or enlarged lymph nodes**.

Clinical signs

Clinical signs **depend on the anatomic location** and the extent of the obstructive process, the collateral vessel reserve and the capacity of the draining lymphatics.

Large lesions may result in **edema and cyanosis** in the area, which is usually short-lived because of large collateral circulation.

If all veins draining an area are obstructed, edema, cyanosis and **necrosis** may occur.

Cranial vena caval obstruction results in edema of the neck, ventral head, cranial thorax and forelimbs.

Diagnosis

Diagnosis is based on historical and clinical findings.

Treatment

Thrombosis is usually self-limiting once catheters are removed. Broad-spectrum antibiotic cover may be necessary for septic lesions.

Surgical management is by drainage of abscesses and hematomas, and debulking of tumors where indicated.

Treat the underlying cause of **lymphadenopathy** using antibiotics, chemotherapy or surgical excision where appropriate.

Prognosis

Prognosis depends on the primary disease process.

ABNORMAL HEMOGLOBIN WITH DECREASED OXYGEN-CARRYING CAPACITY

ACETAMINOPHEN (USA)/PARACETAMOL (EUROPE, AUSTRALIA) TOXICITY

Classical signs

- Salivation, vomiting and depression and cyanosis.
- Subcutaneous edema of face and extremities.
- Lacrimation and facial pruritis.
- Hematuria and hemolysis.

Pathogenesis

Feline hemoglobin is particularly **susceptible to oxidative damage**, and therefore to the formation of **methe-moglobin** and **Heinz bodies** in erythrocytes.

Most species biotransform acetaminophen by hepatic conjugation with glucuronic acid and excrete it in the urine.

However, **cats have limited ability to conjugate drugs as glucuronides** and so they **excrete** the majority of acetaminophen as a **sulfate conjugate**.

This pathway is saturated at relatively low drug concentrations leading to early oxidative toxicity in the cat.

Hepatocellular injury associated with acute acetaminophen toxicity in other species is not seen in cats because cats develop oxidative toxicity at much lower doses than those required for hepatotoxicity in other species.

Accumulation of oxidative metabolites produces methemoglobin, which reduces oxygenation of blood.

Methemoglobinemia leads to the **denaturing of hemoglobin and Heinz bodies** are formed from the **precipitation of this denatured haemoglobin** within the red blood cells.

Heinz bodies lead to **increased osmotic fragility** of red blood cells causing **hemolysis and anaemia**.

The **feline toxic dose of acetaminophen is 50–100 mg/kg**, and the average size of a regular tablet is 325 mg (USA) or 250 mg (Europe).

Clinical signs

Salivation, vomiting and depression progress rapidly and **cyanosis** develops **within 4–12 hours** of ingestion.

Hematuria and hemolysis appear when blood levels of **methemoglobin reach 20%**.

Subcutaneous edema of face and extremities may happen and be accompanied by **lacrimation and pruritis**.

Death may occur.

Jaundice is seen 2–7 days post-exposure if the cat survives.

Diagnosis

Diagnosis is based on the history of exposure and clinical signs.

Finding the pills in stomach contents is confirmatory.

Frequent laboratory findings include; **methemoglobinemia, depletion of erythrocyte-reduced glutathione, Heinz bodies and a decreased packed cell volume**.

Elevated hepatic enzyme levels and total and direct bilirubin levels are evidence of hepatic necrosis.

Differential diagnosis

Other causes of methemoglobinemia include, **benzocaine** (used as a laryngeal local anesthetic spray to facilitate intubation), **DL methionine** (used as a urinary acidifier), **phenacetin** (used as an analgesic in humans) and **phenazopyridine** (used as a urinary analgesic drug).

Methylene blue, a drug previously used to treat cats with methemoglobinemia may actually cause Heinz body formation and hemolytic anemia.

Familial methemoglobin reductase deficiency has been reported in a family of domestic shorthair cats and is thought to have an autosomal recessive form of inheritance.

Treatment

Induce emesis and administer **activated charcoal** if the cat is treated **within the first 4 hours post-ingestion**.

N-acetylcysteine will provide the cysteine moiety required for the increased **synthesis of glutathione** and may increase the concentration of **free serum sulfate**. A dose of 140 mg/kg IV should be followed by 70 mg/kg IV every 6 hours for a total of seven treatments.

Ascorbic acid provides a reserve system for the **non-enzymatic reduction of methemoglobin back to hemoglobin** and can be given at a dose of 30 mg/kg IV four times a day.

Blood transfusion may provide a lifesaving fraction of **functional hemoglobin** until the methemoglobin can be reduced.

Cimetidine, which works differently to acetylcysteine and ascorbic acid in the metabolism of acetaminophen, has been used in an attempt to **reduce hepatotoxicity**. The suggested dose rate is 15 mg/kg IV every 8 hours or 100 mg/kg orally every 8 hours.

Prognosis

The time between ingestion and initiation of therapy is of primary importance and the dosage of acetamin-

ophen ingested is the other important consideration. The sooner the animal is treated the better the outcome. **Most cats treated within the first 24 hours will survive.**

PART 3

Cat with signs of heart disease

9. The cat with abnormal heart sounds and/or an enlarged heart

Luis A H Braz-Ruivo and Kathy A Arrington

KEY SIGNS

- Heart murmur.
- Gallop rhythm.
- Muffled, displaced or absent heart sounds.

MECHANISM?

- Murmurs are abnormal heart sounds caused by turbulent blood flow due to valvular stenosis or insufficiency.
- Innocent or functional murmurs may be present in the absence of morphologic heart disease.
- Gallop rhythms are caused by extra heart sounds and are due to abnormalities in myocardial relaxation.
- Displaced, absent, or muffled heart sounds are caused by intrathoracic masses, effusions or structural changes.
- Cardiac enlargement is the result of alterations of blood flow causing volume overload, myocardial hypertrophy or due to primary myopathic processes.

WHERE?

- Heart.
- Mediastinum.

- Diaphragm.
- Thoracic skeleton.

WHAT?

- Most cats with heart murmurs **are not symptomatic** for heart disease.
- The most common form of acquired heart disease in cats is **hypertrophic cardiomyopathy**.
- Some cats with cardiac enlargement have normal physical exam findings.

QUICK REFERENCE SUMMARY

Diseases causing abnormal heart sounds and/or an enlarged heart

DEGENERATIVE

- Valvular endocardiosis (p 155)

A murmur localized to the left sternal apex is heard. It is a rare disease of old cats. Some cats may present with congestive heart failure.

ANOMALY

- **Ventricular septal defect* (p 140)**

A congenital systolic murmur is heard which is loudest over the right sternal border. Most cats are asymptomatic.

- Patent ductus arteriosus (p 142)

A congenital continuous murmur loudest over the left cranial thorax is heard. A palpable thrill is usually present. It is more common in Siamese and Persian cats.

- Tetralogy of Fallot (p 149)

A systolic murmur is heard over the left cranial thorax (pulmonic area). A split second heart sound may also be found. Cyanosis is usually present.

- Atrial septal defect (p 144)

A breed predilection in Persian cats is reported. A systolic murmur over the left cranial thorax is heard.

- Mitral valve dysplasia/stenosis (p 145)

This is the most commonly encountered congenital valvular malformation and is associated with a systolic and/or diastolic murmur over the left cardiac apex.

- Aortic stenosis (p 146)

Aortic stenosis is associated with a systolic murmur over the left aortic area. There is an increased incidence in Siamese cats.

- Pulmonic stenosis (p 148)

Pulmonic stenosis is associated with a systolic murmur over the pulmonic area and is usually seen with other defects.

- Tricuspid dysplasia

Tricuspid dysplasia is associated with a low-frequency systolic murmur over the right thorax.

continued

continued

- **Peritoneal-pericardial diaphragmatic hernia (p 153)**

A murmur may or may not be heard. The cardiac silhouette is extremely enlarged on thoracic radiographs. Many cats are asymptomatic, but some cats present for gastrointestinal signs or respiratory distress.

METABOLIC

- **Hypertensive heart disease*** (p 133)**

A systolic murmur, tachycardia and/or gallop rhythm may be heard. Hypertension in cats is most commonly secondary to chronic renal failure or hyperthyroidism. Essential or idiopathic hypertension is less common.

- **Hyperthyroid heart disease*** (p 131)**

A systolic murmur, tachycardia and/or gallop rhythm may be heard. Hyperthyroid heart disease is associated with other clinical signs of hyperthyroidism including weight loss, restlessness, palpable thyroid nodule, low frequency of gastrointestinal signs and is seen in older cats.

- **High cardiac output state* (p 138)**

A murmur, gallop rhythm or tachycardia may be heard on auscultation. It can be caused by anemia secondary to other disease states or hyperthyroidism. The heart size may be variable depending on the disease or the chronicity of the anemia.

NEOPLASTIC

- **Neoplasia** (p 137)**

Displaced or muffled heart sounds can be caused by neoplasia from a mass or effusion. Lymphoma is the most common neoplasia seen in cats and occasionally infiltrates the myocardium.

INFECTIOUS

- **Infectious**

Infectious diseases can rarely cause secondary cardiomyopathies in cats. Most cats die unexpectedly and/or are systemically ill. Etiologies suspected are viral (feline infectious peritonitis), secondary bacterial or parasitic (toxoplasmosis). Bacterial (pyothorax, myocarditis, pericarditis) and viral (myocarditis, pericarditis) infections can cause displaced or muffled heart sounds and/or arrhythmias (p 157).

- **Heartworm disease* (p 139)**

Dirofilaria immitis (heartworm disease) in cats is less common than in dogs. Cardiac signs are variable and may include signs of right heart failure, gallop rhythm or murmurs. Coughing, vomiting or sudden death may also occur. Heartworm disease in cats is more common in male cats, outdoor cats, and occurrence depends on geographical location.

IDIOPATHIC

- **Hypertrophic cardiomyopathy*** (p 128)**

A systolic murmur varying in location, arrhythmia and/or gallop rhythm may be heard. It is the most common form of heart disease in cats and occurs usually in male and middle-aged cats. It can also be seen in young (less than 1 year of age) cats and older cats. It may be genetically transmitted in some pure-breed cats. The heart may or may not be enlarged on radiographs.

- **Restrictive and unclassified cardiomyopathies** (p 135)**

A systolic heart murmur, gallop rhythm and/or arrhythmia may be heard. Abnormal heart sounds are not always heard on auscultation. The heart is usually enlarged.

- **Dilated cardiomyopathy (p 151)**

A systolic murmur, gallop rhythm and/or arrhythmia may be heard. The heart shows generalized enlargement. Dilated cardiomyopathy can occur in cats eating taurine-deficient diets.

- **Chylous effusion* (p 139)**

Displaced or muffled heart sounds may be heard. Etiologies are trauma, infection, cardiomyopathy, neoplasia and idiopathic. In most cases, the cause is idiopathic.

TRAUMATIC

- **Diaphragmatic hernia (p 154)**

Displaced and/or muffled heart sounds may be heard. Dyspnea may or may not occur.

INTRODUCTION

MECHANISM?

Abnormal heart sounds are defined as follows:

Systolic murmurs are **common** and are caused by turbulent blood flow secondary to a valvular stenosis or insufficiency. **Systolic murmurs** are the most common and account for >95% of murmurs.

Diastolic and continuous murmurs are rare.

Continuous murmurs occur during diastole and systole and most commonly occur from a patent ductus arteriosus.

In thin cats, murmurs may be caused by mechanical compression of the chest during auscultation.

Gallop rhythms are extra heart **sounds** due to abnormalities in relaxation. The gallop rhythm is classified as either S₄ or S₃ but it is difficult to distinguish between these in cats.

Arrhythmias are disturbances in **rate** and **rhythm** and are noted by an irregular rhythm.

Tachycardia is defined as a heart rate greater than **220 bpm**.

Loud heart sounds are usually normal in thin cats and during tachycardia.

Displaced heart sounds and **muffled** heart sounds are most commonly caused by masses within the thorax

(neoplasia) and/or effusions (cardiomyopathy, neoplasia or infection) or rarely structural changes (hernias or pericardial effusion).

Cardiac enlargement most commonly results from cardiomyopathy secondary to hypertrophy.

WHERE?

Abnormal heart sounds and/or cardiac enlargement result from problems in any of the following sites:

Heart, mediastinum, diaphragm, thoracic skeleton, lungs.

WHAT?

The most **common** cause of cardiac disease is **hypertrophic cardiomyopathy**. It is usually **acquired** and **idiopathic**.

Congenital heart disease is **rare** and a **murmur** is **usually** heard at a young age.

The most **common** congenital defect in cats is ventral septal defect followed by mitral valve dysplasia.

Most cats with **heart murmurs** are **asymptomatic**.

Abnormal heart sounds in **asymptomatic** cats **always** warrants a **cardiovascular** work-up.

Cats with **abnormal heart sounds** may or may not have cardiac enlargement.

Lack of **cardiac enlargement** on radiographs in cats with **abnormal heart sounds** does not exclude heart disease.

Diagnosis is based on history, physical examination, radiography, electrocardiography and echocardiography.

Normal echocardiographic values for the **interventricular septum and left ventricular posterior wall** in diastole are up to 5 mm in thickness. The dimension between 5–6 mm represents questionable hypertrophy.

Normal echocardiographic values of the **left atrium** are up to 13 mm or a left atrium to aorta ratio less than 1.5.

Normal **left ventricular dimension** in diastole is up to 17 mm. Increased dimensions are consistent with left ventricular eccentric hypertrophy (dilation).

Fractional shortening (percent change between the left ventricular diastolic and systolic dimensions) ranges from 35–55%.

The above values can be obtained from the two-dimensional image or the M mode.

Cardiomegaly on radiographs is an indicator of heart disease although a **normal-size heart does not rule out heart disease**. Cardiac enlargement on radiographs can be determined by conventional methods or the vertebral heart scale.

The vertebral heart scale (VHS) compares cardiac dimensions to the length of the thoracic vertebrae, which is an indicator of body size.

The VHS method is as follows: The long axis and short axis dimensions of the heart are transposed onto the vertebral column and recorded as the corresponding number of vertebrae as measured caudally from the cranial edge of T4. These values are added to obtain the vertebral heart size (VHS).

The depth of the thorax is measured from the dorso-caudal border of the seventh sternebra to the closest edge of the vertebral column.

Normal cats' VHS are: mean VHS in lateral radiographs, 7.5 v (upper limit 8.0 v), mean cardiac short axis in lateral radiographs, 3.2 v (upper limit 3.5; mean cardiac short axis in VD or DV radiographs, 3.4 v (upper limit 4 v); The cardiac long axis in the lateral view approximates the length of three sternebrae, measured from S2 to S4.

Conventional methods of evaluating heart size in cats are on the lateral view with the normal heart width approximately 2–2.5 intercostal spaces. On the ven-

trodsorsal view or dorsoventral view, the maximum width of the normal heart occupies up to 50% of the width of the chest cavity at the same level.

DISEASES CAUSING ABNORMAL HEART SOUNDS AND/OR AN ENLARGED HEART

HYPERTROPHIC CARDIOMYOPATHY***

Classical signs

- Heart murmur (in some cases it may not be present).
- Gallop rhythm.
- Arrhythmia.
- Dyspnea.
- Collapse.
- Lameness, paralysis or paresis from systemic thromboembolism.

Pathogenesis

Hypertrophic cardiomyopathy is defined as the presence of left ventricular hypertrophy in the absence of systemic disease causing secondary hypertrophy. Hypertrophy may be generalized or focal.

Focal hypertrophy **may be recognized in the** interventricular septum, **left ventricular free wall** or papillary muscles.

Any combination of hypertrophic changes is possible.

Hypertrophic cardiomyopathy (HCM) is recognized to be **genetically determined** in selected families of cats: Persian, Maine Coon, American Shorthair and possibly in Ragdolls. Transmission is suspected to be **autosomal dominant**.

The cause for hypertrophy is probably related to **genetic alteration** of the β -myosin heavy chain.

An association with increased levels of **growth hormone** concentration has also been found.

Echocardiographically there are two distinct varieties, a **non-obstructive** form and an **obstructive** form.

The **non-obstructive** form results primarily in **diastolic dysfunction** due to delayed or decreased **myocardial relaxation**.

The **obstructive form** is caused by **anterior motion of the mitral valve** during systole, which obstructs the left ventricular outflow tract. This results in **decreased cardiac output** at faster heart rates, in addition to abnormal diastolic function.

The outflow obstruction may contribute to the presence of ventricular concentric hypertrophy.

Histologically there is myocardial fiber disarray and diffuse myocardial fibrosis. HCM is usually limited to the left ventricle but in some cases, concurrent right ventricular hypertrophy is present.

The development of **left ventricular hypertrophy** is associated with altered intracellular calcium regulatory mechanisms. This results in the development of **relaxation abnormalities** during diastole.

The **chronic diastolic** dysfunction ultimately results in **left atrial dilatation**, elevation of **left atrial pressures** and finally **congestive heart failure**.

Clinical signs

Hypertrophic cardiomyopathy most commonly occurs in **middle-aged male cats**.

A **heart murmur** is usually present, but in some cases may not be present. When present, the murmur is systolic and varies in location and intensity.

A **gallop rhythm** is commonly heard. It is identified when more than two heart sounds are present on auscultation. The extra sound is classified as S_3 or S_4 .

The fast heart rate in cats makes it often impossible to distinguish between a S_3 and S_4 sound.

Arrhythmias are occasionally heard as premature heart beats with pulse deficits. Ventricular arrhythmias are most common.

Dyspnea is seen in symptomatic cases together with an increased respiratory rate (greater than 30 breaths/min) at rest or with open-mouth breathing in extreme cases.

Collapse may result from impaired cardiac output associated with either ventricular tachycardia or the obstructive form of hypertrophic cardiomyopathy.

Sudden onset of lameness, paralysis or paresis may occur and is usually the result of systemic thromboembolism.

Most cats with aortic saddle thrombosis present for acute onset of hindlimb paralysis, hypothermia, pain, absent femoral pulses, cool extremities and cyanosis of the nail bed. In some cases a history of episodic lameness is given.

Diagnosis

Clinically, cats with hypertrophic cardiomyopathy present with a history of a heart murmur, arrhythmia, collapse or respiratory distress. Radiographic and electrocardiographic findings may support the diagnosis, but echocardiography is required for a definitive diagnosis.

Radiographic findings

The cardiac image varies from normal to obvious left ventricular and atrial enlargement.

Enlargement of the pulmonary veins may be seen, representing venous congestion.

Areas of focal alveolar densities representing pulmonary edema may be found. In some cases, pleural effusion may be present.

Electrocardiographic findings

Tachycardia (HR > 220 bpm), **left anterior fascicular block** (evidenced as left axis deviation with a mean electrical axis (MEA) from 0 to –60 degrees, a QRS in lead I and aVL with a QR pattern, and large S waves in leads II, III, aVF), **tall R waves on lead II** (>0.9 mV), and notched QRS in any lead may be seen.

Ventricular arrhythmias are more common than supraventricular arrhythmias.

Atrial fibrillation is rare but if present is always associated with extreme dilatation of the left and/or right atria.

Echocardiographic findings

Left ventricular hypertrophy (diastolic dimension of the interventricular septum and/or LV posterior wall greater than 6 mm), which may be global or focal (see Pathogenesis), and left atrial enlargement (dimension greater than 13 mm) can be seen.

- Elongated mitral valve leaflets with systolic anterior motion (anterior displacement into the left ventricular outflow of the anterior mitral valve leaflet) causing secondary left ventricular outflow obstruction.

tion as determined by Doppler study (velocity of blood flow >2.0 m/s) is seen in the obstructive form.

Differential diagnosis

Congenital heart disease

- A murmur is usually present from birth. Most congenital murmurs do not change in loudness with alterations of the heart rate. Congenital murmurs are usually relatively loud.

Dilated cardiomyopathy.

- Murmurs are usually very soft, and in many cases may not be present. A gallop rhythm is usually present.

Restrictive cardiomyopathy.

- It is difficult to differentiate from hypertrophic cardiomyopathy on auscultation; many cases have a gallop rhythm.

Intra-thoracic masses.

- A murmur may not be present unless there is compression of the heart by the mass or concurrent unrelated heart disease. Most commonly, dyspnea and lethargy are seen.

Feline asthma or chronic bronchitis.

- Unless cardiac disease is also present, most cats do not have a murmur. Cough and increased respiratory rate are common. Symptoms in the cat with feline asthma may be episodic and seasonal.

Chylous effusion.

- A murmur may not be present. In most cases, cardiac disease is not present. The most common clinical signs are dyspnea, increased respiratory rate and lethargy.

Neurological disease causing collapse or hindlimb paralysis

Cardiac signs are usually absent, however a full cardiac work-up may be warranted to rule out the presence of silent heart disease. Neurological disease usually is not associated with alterations of peripheral systemic perfusion.

Treatment

The treatment recommended depends on the severity of signs and the presence of left ventricular outflow tract (LVOT) obstruction.

Treatment of the asymptomatic cat.

- **Hypertrophic non-obstructive cardiomyopathy (HCM)** – Wall dimensions larger than 6 mm and normal Doppler LV outflow study ($LVOT_{max}$ less than 1.8 m/s).
 - **Normal** left atrial size – no therapy.
 - **Increased** left atrial size (>13 mm or $LA/Ao > 1.5$).
 - **Beta-blocker**
Atenolol 12.5 mg/cat PO q 12–24 h.
- OR
- **Calcium channel blockers:**
Diltiazem 7.5–15 mg PO q 8 h OR
Diltiazem slow release – 60 mg PO daily.
- **Hypertrophic obstructive cardiomyopathy (HOCM)** with presence of systolic anterior motion of the mitral valve and LV outflow obstruction ($LVOT_{max} < 3.5$ m/s).
 - **Normal** left atrial size – no therapy.
 - **Increased** left atrial size – beta-blocker as above.
- **Hypertrophic obstructive cardiomyopathy** (presence of systolic anterior motion of the mitral valve and LV outflow obstruction - $LVOT_{max} > 3.5$ m/s).
 - **Normal or increased** left atrial size – beta-blocker as above.

Treatment of the symptomatic cat with congestive heart failure (**acute management**).

Criteria to start therapy:

- Respiratory distress (open-mouth breathing or very abnormal respiratory pattern).
- Pulmonary congestion (moderate to severe) on radiographs and/or pleural effusion.
- Hypothermia.
 - Oxygen.
 - Diuretics
 - Furosemide 1–2 mg/kg IV or IM q 6–12 h until respiration rate and pattern are normalized.
 - Furosemide constant rate infusion (if normal renal values at presentation) 0.5–1 mg/kg/hr until congestion is resolved but not for longer than 24 hours.
 - Nitroglycerin ointment (2%) 1/4 of an inch (6 mm) q 8 h until resolution of the congestion.
 - Angiotensin-converting enzyme inhibitor.
 - Enalapril 0.25–0.5 mg/kg q 24 h OR
 - Benazepril 0.25–0.5 mg/kg q 24 h.
 - Thoracocentesis if there is evidence of moderate to severe pleural effusion on radiographs.

- Aspirate from the right thorax to avoid puncturing the enlarged auricles.
- Hypertrophic non-obstructive cardiomyopathy – use calcium channel blocker OR beta-blockers as above.
- Hypertrophic obstructive cardiomyopathy – use beta-blockers as above.

Symptomatic cat with congestive heart failure (chronic management).

Criteria to start therapy:

- Maintenance therapy after initial therapy to control signs of acute onset of congestive heart failure.
- Any patient found to have early evidence of congestive heart failure (usually on radiographs) but without symptoms, that will require acute intervention if untreated.

Hypertrophic non-obstructive cardiomyopathy – use calcium channel blocker or beta-blocker as above.

Hypertrophic obstructive cardiomyopathy – use beta-blocker as above.

Diuretics:

- Furosemide 1–2 mg/kg IV or IM q 6–12 h until respiration rate and pattern are normalized.
- Furosemide constant rate infusion (if normal renal values at presentation) 0.5–1 mg/kg/hr and congestion is resolved but not for longer than 24 hours.
- **Hydrochlorothiazide** 1–2 mg/kg PO q 12 h **OR/AND**
- **Spironolactone** 2–4 mg/kg PO q 12 h.

Angiotensin-converting enzyme inhibitor:

- **Enalapril** 0.25–0.5 mg/kg q 24 h **OR**
- **Benazepril** 0.25–0.5 mg/kg q 24 h.

Diuretics should be used cautiously in cats. Overzealous therapy for 1–2 days may rapidly result in severe fluid and electrolyte imbalances and **metabolic alkalosis**.

Judicious concurrent administration of **low-sodium solutions** (NaCl concentration $\leq 0.45\%$) with potassium supplementation may be required in some cases that are clinically dehydrated after diuretic therapy.

The volume of fluid administered varies with the degree of dehydration present, but in severe cases rates up to twice maintenance can be infused. While infusing fluids in a cardiac patient, special attention to respiratory function is recommended.

Potassium supplementation should be based on serum levels. Patients with normal potassium (3.5–5.5 mmol/L

[Meq/L]) should receive solutions with 20 mmol/L [Meq/L] added.

In cases of hypokalemia refer to standard guidelines of therapy. Do not exceed rates of potassium 0.5 mmol/L (Meq)/kg/h.

Chronic diuretic administration is **not required in some cases**. **Multiple diuretic therapy** can be used for refractory cases but monitor renal function and hydration carefully.

Renal function and electrolytes should be monitored in all cats on diuretics and angiotensin-converting enzyme inhibitor therapy.

Some cats develop **anorexia or poor appetite** while taking Diltiazem slow-release preparations.

Prognosis

Hypertrophic cardiomyopathy and hypertrophic obstructive cardiomyopathy ultimately result in congestive heart failure and/or aortic saddle thromboembolism. Sudden death occurs in some cases, usually in younger cats less than 3 years old.

Median survival time for cats without congestive heart failure is 732 days (over 33% alive after 5 years).

Median survival for cats with congestive heart failure is 92 days.

Median survival time for cats with thromboembolism is 61 days.

Heart rate less than 200 beats per minute at initial presentation is associated with longer survival (1830 days vs 152 days).

HYPERTHYROID HEART DISEASE***

Classical signs

- Weight loss.
- Polyphagia.
- Heart murmur.
- Tachycardia.

See main reference page 304 (The Cat With Weight Loss and a Good Appetite).

Clinical signs

Cats are usually older than 8 years of age (mean age is 13 years old) with no breed or sex predilection.

Typically there is progressive **weight loss** with a good appetite.

A heart murmur **is heard in some cases, and a gallop rhythm may be noticed.**

Tachycardia **is persistent even at rest. Many cats have heart rates above 240 bpm.**

Arrhythmias are present in more advanced cases.

A hyperkinetic peripheral pulse, **usually the femoral pulse, is very easy to palpate.**

Loud heart sounds and a strong precordial impulse are **typically present, which is the result of increased sympathetic tone and decreased fat deposits over the chest.**

Increased respiratory rate or panting is particularly seen in cats in a crisis (thyroid storm). This may be mistaken for respiratory distress when it is only hyperventilation.

Respiratory distress may occur secondary to heart failure when pulmonary edema and/or pleural effusion are present.

Cats are often difficult to handle and owners report a change in behavior (irritability and restlessness).

Polyuria, polydipsia and vomiting are seen in approximately 50% of the cases.

Palpable thyroid nodules are common.

Diagnosis

An **increased serum total thyroxine (T_4)** is usually diagnostic. The upper range of normal is 51 nmol/L (4.0 µg/dl).

A single random serum T_4 level is usually diagnostic.

If a random serum T_4 level does not confirm the disease in a highly suspected case, repeat serum T_4 or free T_4 in 1–2 weeks or perform a T_3 suppression test.

Radiographic findings

Heart size varies from normal to severe dilation of all chambers.

Pleural effusion and/or pulmonary edema may be present in severe cases.

Electrocardiographic findings

Sinus tachycardia (Heart rate > 220 bpm) is common. Increased R wave amplitude (>0.9 mV), supraventricular premature beats and ventricular arrhythmias are commonly found.

Echocardiographic findings

Heart chambers may be of normal size but in many cases, **some degree of ventricular concentric hypertrophy is present.** Interventricular septum and LV free wall measurements in diastole are greater than 6 mm.

The “typical” hyperthyroid heart shows mild to moderate increase in wall thickness (see above), upper range of normal ventricular chamber size (LV diastolic dimension 16–17 mm) and increased contractility (fractional shortening higher than 55%) reflecting hyperdynamic cardiac function.

Variable degrees of left atrial dilation are present.

In some cases (usually advanced cases), a dilated form of cardiomyopathy may be seen. It is difficult to differentiate from restrictive or dilated cardiomyopathy.

Systemic blood pressure

Hypertension is commonly found. Systolic arterial blood pressure, measured by Doppler technique, consistently **above 180 mmHg is diagnostic.**

Treatment

Antithyroid drugs (Methimazole, Carbimazole), **radioactive iodine** and **thyroidectomy** are treatment choices for hyperthyroidism (for further details refer to page 305).

Tachycardia and **hypertension** should be treated with beta-blocking drugs. This class of drugs controls the cardiovascular effects of hyperthyroidism and improves clinical signs.

Beta-blockers do not decrease serum thyroid hormones. Beta-blockade therapy is discontinued upon normalization of serum thyroid hormones and resolution of cardiovascular signs.

- **Propranolol** 0.5–1.0 mg/kg PO q 8 h **OR**
- **Atenolol** 12.5 mg/cat PO q 12 h.

If **congestive heart failure is present** refer to the section on hypertrophic cardiomyopathy for therapeutic options (page 128).

HYPERTENSIVE HEART DISEASE***

Classical signs

- Heart murmur.
- Gallop rhythm.
- Tachycardia.
- Blindness due to retinal hemorrhage or detachment.
- Hyphema.

Pathogenesis

Hypertension is defined as systemic arterial pressure higher than 180/100 mmHg (systolic/ diastolic).

Hypertension is most commonly **secondary** to an underlying etiology.

- The two most common causes in cats are **hyperthyroidism** and **chronic renal failure** (CRF).
- The **mechanism for development of hypertension in hyperthyroidism** is the increased number and sensitivity of **adrenergic receptors** coupled with an **increase in cardiac output**.
- The **mechanism for development of hypertension in CRF** is renal hypertension with retention of salt and activation of the renin-angiotensin aldosterone system.
- The **hypertension of hyperthyroidism is reversible** upon control of the thyroid state while the hypertension secondary to CRF requires continued therapy and monitoring.
- **There is no correlation between the degree of renal disease and the severity of hypertension.**
- **Essential hypertension** is an exclusion diagnosis when diagnostic tests failed to identify a **specific cause**.

Chronic untreated hypertension has several long-term adverse effects.

The increase in systemic vascular resistance results in increased afterload and **development of left ventricular hypertrophy**.

Chronic elevation of arterial pressure results in dysregulation of endothelial homeostasis leading to hypertensive vasculopathy.

- The vascular beds **most sensitive to chronic hypertension** are the ocular, renal, cerebrovascular and cardiac vessels.

Clinical signs

Signs directly related to the systemic hypertension **are not common**.

Ocular changes (retinal hemorrhages, hyphema, arterial tortuosity and retinal detachments) are the **most common** clinical signs seen in hypertensive cats.

- Most cats initially present for **blindness** secondary to retinal detachment and hemorrhages.
- Retinal examinations should be done in all cats diagnosed with systemic hypertension.
- Retinal examination is a good way to evaluate the organ damage resulting from systemic hypertension.

Weight loss, polyuria and polydipsia seen in hypertensive cats are secondary to the underlying disease (CRF or hyperthyroidism) and are not directly referable to the hypertension.

Seizures and syncope are **rare** neurological abnormalities seen in hypertensive cats.

- They are the results of cerebrovascular accidents from the hypertension.

Diagnosis

Retinal vascular changes with evidence of retinal hemorrhage and detached retinas **are commonly seen in hypertensive cats** on ocular examination.

- Indirect and direct ophthalmoscopy should be done on all hypertensive cats.
- Cats are **often presented blind** with **dilated non-responsive pupils**. Aged cats with a sudden onset of blindness should be evaluated for hypertension.
- Common findings are retinal hemorrhages, hyphema, retinal edema and partial or complete retinal detachments.

Elevated systemic arterial pressure (higher than 180 mmHg systolic pressure) is seen.

Hyperthyroidism or chronic renal disease are common underlying etiologies.

- Hyperthyroidism is diagnosed with an increased total thyroxine greater than 51 mmol/L (4 µg/dl) and

consistent clinical signs (weight loss, ravenous appetite, palpable thyroid nodules, polyuria, polydipsia).

- Chronic renal disease is diagnosed with an increased urea of greater than 11.6 mmol/L (32.5 mg/dl), increased creatinine greater than 163 μ mol/L (1.84 mg/dl) with a decreased urine specific gravity less than 1.035.

Radiographic findings

Heart size varies from normal to marked generalized cardiomegaly.

Enlarged aortic arch is seen in chronic cases.

Undulation of the caudal aorta is suggestive of hypertension.

Electrocardiographic findings

Tachycardia with a heart rate greater than 220 bpm is usually present with hyperthyroidism.

Electrocardiogram is usually normal but evidence of left ventricular hypertrophy (R wave > 9 mm on lead II) may be seen.

Echocardiographic findings

Mild to moderate **left ventricular hypertrophy** may be seen. Left atrial size is usually normal.

Transmitral inflow velocity Doppler profile may show evidence of impaired relaxation (small E and tall A wave).

Enlarged aortic arch equal or greater than 11 mm is seen in chronic cases.

For findings in hyperthyroidism see page 132 (Hyperthyroid heart disease).

Differential diagnosis

Cats with either hypertension or cardiomyopathy commonly have murmurs.

- However, cats with hypertension **most commonly** present with **ocular signs**.
- **Most** hypertensive cats have polyuria, polydipsia or weight loss consistent with chronic renal disease or hyperthyroidism.

- **Cats with cardiomyopathy** usually do not have weight loss but may show dyspnea secondary to congestive heart failure.

Cats with **coagulopathy, optic neuritis, systemic infectious disease and neoplasia** may have similar ocular signs (retinal hemorrhages, hyphema and detached retinas) as hypertensive cats.

Documentation of hypertension is needed to **help differentiate** these diseases from hypertensive cats. Cerebrovascular accidents in cats with hypertension are **rare**.

Cats with cerebrovascular accidents are **usually secondary** to an underlying neurological disease.

Treatment

Beta-blockers – refer to page 306 on hyperthyroidism.

Amlodipine is the **drug of choice if the etiology is CRF or unknown**. The dose is 0.625 mg (cat < 5 kg) to 1.25 mg (cat \geq 5 kg) orally once a day for hypertension caused by diseases other than hyperthyroidism.

ACE inhibitors (Enalapril or Benazepril) can be used as adjuvant therapy.

- ACE inhibitors can be used carefully in cases with concurrent chronic renal failure. Close follow-up of renal function is mandatory.
- If serum creatinine is higher than 265 μ mol/L (3.0 mg/dl) at baseline, ACE inhibitors should not be used.
- Start at 0.25–0.5 mg/kg once a day for Benazepril OR Enalapril.
- Obtain baseline renal values and recheck at 5 and 10 days after starting medications.

In refractory cases, multiple drug therapy may be required (amlodipine, beta-blockers, diuretics, ACE inhibitors).

Low-salt diets may be used in refractory cases.

The **goal of therapy** is to decrease systolic blood pressure to **140–160 mmHg**.

- Drugs should be titrated to effect.

Prognosis

Hypertension caused by **hyperthyroidism** is **usually reversible** with normalization of the serum thyroid levels.

Hypertension caused by **other diseases** requires **long-term life-long management**.

RESTRICTIVE AND UNCLASSIFIED CARDIOMYOPATHIES**

Classical signs

- Heart murmur (in some cases may not be present).
- Gallop rhythm.
- Arrhythmia.
- Dyspnea.
- Hypothermia.
- Collapse.
- Lameness, paralysis or paresis from systemic thromboembolism.

Pathogenesis

Endocardial, subendocardial and myocardial fibrosis are the primary **pathologic characteristics** of **restrictive** cardiomyopathy. Myocardial fibrosis is also present in **intermediate/unclassified** cardiomyopathy. Geometrically the left ventricle may be normal or misshapen.

Histopathologically, **myocardial infarction** is reported to be a **feature of intermediate/ unclassified** cardiomyopathy, but it can also be seen in cases with restrictive cardiomyopathy.

Adhesions of papillary muscle and chordae tendinae may interfere with normal ventricular blood flow during systole, causing mid-ventricular obstruction. Mononuclear infiltration of the myocardium suggests an **inflammatory** process, resulting in endomyocarditis.

Left atrial (echocardiographic dimension > 13 mm), **biatrial** and right **ventricular** enlargement (maximal internal diameter > 7 mm) are often found. **Intracardiac thrombi** are frequently observed. **Infiltrative myocardial** disease may be present.

Hemodynamically this disease is **characterized by pure diastolic dysfunction** due to abnormally low compliance of the ventricular chambers. **Systolic function** is usually preserved or just slightly decreased.

Abnormal chamber compliance results in inadequate ventricular filling. The non-compliant ventricle rapidly reaches end-diastolic filling pressure typically during the first half of the diastolic phase.

Chronic **diastolic** dysfunction leads to the progressive development of **increased left atrial** size and secondary increase in left **atrial pressures** resulting in **pulmonary venous** congestion, **pulmonary edema** and in advanced cases **pulmonary artery hypertension**.

Chronic **pulmonary artery hypertension** will result in **right-sided** congestive heart failure.

Classification of these forms of cardiomyopathies is poorly defined.

Clinically it is difficult to distinguish between restrictive and unclassified forms of cardiomyopathy.

Clinical signs

There is no age or sex predilection.

Burmese cats seem to have a higher incidence of restrictive cardiomyopathy.

Heart murmur is often present but in some cases may not be present. When present, a systolic murmur varies in location and intensity with variations in heart rate.

Gallop rhythm is commonly heard. It is identified when more than two heart sounds are present on auscultation.

Arrhythmias are frequently heard as premature heart beats with pulse deficits. Ventricular arrhythmias are most common.

Dyspnea is seen in symptomatic cats with an increased respiratory rate (greater than 30 breaths/min) at rest or with open-mouth breathing in extreme cases.

In symptomatic cats, hypothermia is common.

Collapse may result from impaired cardiac output (ventricular tachycardia).

Lameness, paralysis or paresis is usually the result of systemic thromboembolism. Aortic saddle thrombosis resulting in hindlimb paralysis may be seen. In some cases, embolism may only cause lameness.

Most cats with aortic saddle thrombosis present for acute onset of hindlimb paralysis, pain, absent femoral

pulses, cool extremities and cyanosis of the nail bed. In some cases a history of episodic lameness is given.

Diagnosis

Usually a history of **heart murmur, arrhythmia, collapse or respiratory distress** is present. Some cats may not have an audible murmur but a gallop rhythm is commonly heard.

Diagnosis is based on supportive radiographic, electrocardiographic and especially echocardiographic findings.

Radiographic findings

Severe **left atrial** or **biatrial** enlargement.

Enlarged pulmonary veins can be seen.

Pulmonary edema with or without **pleural effusion** may be present.

Electrocardiographic findings

Ventricular arrhythmias are more **common** than with other types of feline myocardial disease.

Atrial fibrillation is more common than with HCM; and if present is usually associated with **extreme dilatation of the left** and/or right atria.

Tachycardia (heart rate above 220), ventricular conduction disturbances (notched QRS), tall R waves on lead II (>0.9 mV) may be seen.

Echocardiographic findings

Severe left atrial or biatrial enlargement is commonly found. Left atrial to aortic ratio is usually >2.0.

Left ventricular size may be normal to mildly dilated (LV end-diastolic dimension up to or above 16 mm).

Systolic function is normal or mildly decreased (normal FS is between 35–55%)

Right ventricular dilatation may be seen (RV end-diastolic dimension > 7 mm)

Hyperechoic endocardium and/or myocardium are frequently observed.

Focal areas of myocardial hypertrophy bordering areas of **myocardial thinning** are seen which probably represent myocardial **infarction**.

The **mitral inflow profile** is recorded at the tips of the mitral valve from the four-chamber left parasternal view. It commonly shows increased early inflow veloc-

ity (E wave > 1.1 m/s) and normal or decreased atrial flow component.

Thrombi (homogeneous mass) in the left atrium and/or ventricle may be found.

Differential diagnoses

Congenital heart disease.

- A murmur is usually present from birth. Most congenital murmurs do not change in loudness with alterations of the heart rate. Congenital murmurs are usually relatively loud.

Dilated cardiomyopathy.

- Murmurs are usually very soft, and in many cases may not be present. A gallop rhythm is usually present.

Hypertrophic cardiomyopathy.

- It is difficult to differentiate on auscultation from restrictive or intermediate/unclassified cardiomyopathy. A gallop rhythm may be more common in restrictive or intermediate/unclassified cardiomyopathies.

Intrathoracic masses.

- A murmur may not be present unless there is compression of the heart by the mass or concurrent unrelated heart disease. Most commonly, dyspnea and lethargy are seen.

Feline asthma or chronic bronchitis.

- Unless cardiac disease is also present, most cats do not have a murmur. Cough and increased respiratory rate are common. Symptoms may be seasonal.

Chylous effusion.

- A murmur may not be present. In most cases, cardiac disease is not present. The most common clinical sign is dyspnea, increased respiratory rate and lethargy.

Neurological disease causing collapse or hindlimb paralysis.

- Cardiac signs are usually absent, however a full cardiac work-up may be warranted to rule out the presence of silent heart disease. Neurological disease usually is not associated with alterations of peripheral systemic perfusion.

Treatment

Asymptomatic cat.

- Angiotensin-converting enzyme inhibitors

- **Enalapril** 0.5 mg/kg PO q 24 h **OR**
- **Benazepril** 0.5 mg/kg PO q 24 h.

Symptomatic cat with congestive heart failure (acute management). Criteria to start therapy:

- Respiratory distress (open-mouth breathing or very abnormal respiratory pattern).
- Pulmonary congestion (moderate to severe) on radiographs and/or pleural effusion.
- Hypothermia.
- **Oxygen.**
- Diuretics.*
 - **Furosemide** 1–2 mg/kg IV or IM q 8–12 h until respiratory rate and pattern are normalized.
 - Furosemide constant rate infusion (if normal renal values at presentation) 0.5–1 mg/kg/hr until congestion is resolved but not for longer than 24 hours.
- Venodilator.
 - **Nitroglycerin** ointment (2%) 1/4 of an inch (6 mm) q 8 h.
- **Thoracocentesis (right thorax** to avoid puncturing of the enlarged auricles) if there is evidence of moderate to severe pleural effusion on radiographs.
- Angiotensin-converting enzyme inhibitor.
 - **Enalapril** 0.25–0.5 mg/kg PO q 24 h **OR**
 - **Benazepril** 0.25–0.5 mg/kg PO q 24 h.

Symptomatic cat with congestive heart failure (chronic management). Criteria to start therapy:

- Maintenance therapy after initial therapy to control signs of acute congestive heart failure.
- Any patient found to have early evidence of congestive heart failure (usually on radiographs) but without symptoms, that will require acute intervention if untreated.
- Diuretics*
 - **Furosemide** 0.5–1.0 mg/kg PO q 12–24 h **OR**
 - **Hydrochlorothiazide** 1–2 mg/kg PO q 12 h **OR/AND**
 - **Spironolactone** 2–4 mg/kg PO q 12 h.
- Angiotensin-converting enzyme inhibitor
 - **Enalapril** 0.25–0.5 mg/kg PO q 24 h **OR**
 - **Benazepril** 0.25–0.5 mg/kg PO q 24 h.
- Arrhythmia control
 - **Sotalol** 15–30 mg/cat PO q 8 h **OR**
 - **Propranolol** 0.5–1.0 mg/kg PO q 8 h **OR**
 - **Atenolol** 12.5 mg/cat PO q 12–24 h **OR**
 - **Diltiazem** 15 mg/cat PO q 8 h.
- Associated intracardiac thrombus or systemic thromboembolism.

- Anti-thrombotic therapy:

- **Heparin** and **Warfarin** therapy are controversial and should be utilized under the guidance of an experienced clinician.
- **Low-molecular-weight heparins** have been recently suggested. This class of heparins does not require continued monitoring of coagulation parameters.
- **Enoxaparin** (Lovenox®) 1 mg/kg SQ q 24 h.
- **Aspirin** 80 mg PO q 48–72 h is recommended by some clinicians but its efficacy has not been established. A lower dose (5 mg/cat PO q 24 h) has also been recommended, because of concerns of that prostacyclin production is inhibited at the higher dose.

Thrombolytic therapy is contraindicated if an intracardiac thrombus is present, and controversial in aortic saddle thrombus (see page 916, The Weak and Ataxic or Paralyzed Cat).

Prognosis

Almost **all cats** after development of congestive heart failure **have a poor prognosis**.

It is unknown if early therapy **of asymptomatic cats results in delay of onset of clinical signs**.

NEOPLASIA**

Classical signs

- Anorexia.
- Weight loss.

Clinical signs

Cats commonly present with anorexia and secondary weight loss.

A cranial mediastinal mass may cause a **non-compliant chest wall during compressive palpation**.

The presence of intrathoracic or pericardial masses may cause **effusions** which will result in **muffled heart sounds** or displaced lung and/or heart sounds.

If a mass compresses the heart, a new murmur can result.

Some cats with pericardial effusion secondary to neoplasia present for the evaluation of **ascites**.

Diagnosis

Radiographic findings

Soft tissue density seen within the cranial mediastinum.

Elevated trachea.

Pleural effusion.

Electrocardiographic findings

Normal.

Echocardiographic findings

Normal cardiac function unless concurrent heart disease is present.

A cardiac mass may be seen (rare).

Ultrasound of the cranial mediastinum may reveal a mass.

Pleural effusion may be seen.

HIGH CARDIAC OUTPUT HEART DISEASE*

Classical signs

- Heart murmur.
- Gallop rhythm.
- Tachycardia.

Pathogenesis

High cardiac output heart disease in cats is secondary to hyperthyroidism or chronic anemia.

High cardiac output heart disease is uncommon.

Etiologies of chronic anemia are infectious (feline leukemia virus, feline immunodeficiency virus), neoplastic (lymphoma, thymoma), and metabolic diseases (chronic renal failure). Refer to page 526, (The Anemic Cat) for a more detailed description of anemia.

In chronic anemia, increased cardiac output results from decreased blood viscosity and systemic arteriolar tone augmenting stroke volume.

Anemia causes high cardiac output, which increases cardiac work and results in congestive heart failure when a co-existing cardiac disease or a hyperkinetic state is present.

In chronic anemia, the heart rate may be normal or only mildly increased.

For hyperthyroid heart disease refer to page 131.

Clinical signs

A systolic blowing murmur louder at the heart base is usually present.

A gallop rhythm may be present.

Sinus tachycardia is usually present, with heart rates above 220 bpm.

Displaced and/or muffled heart sounds are heard secondary to intrathoracic masses displacing the heart. In some cases, this finding may be due to the presence of pleural effusion.

Other systemic signs:

- Pale mucus membranes, prolonged capillary refill time, petechiae, anorexia, ravenous appetite, weight loss and palpable thyroid glands bilaterally.

Diagnosis

Anemia is present if the hematocrit is less than 0.24 L/L (PCV = 24%).

Secondary cardiac changes are not usually present unless a chronic anemia with a hematocrit less than 0.15 L/L (PCV ≤ 15%) is present.

Hyperthyroidism is considered present if total thyroxine is increased and there are consistent clinical signs. Refer to page 304 (The Cat With Weight Loss and a Good Appetite).

Radiographic findings

Heart size ranges from normal to severe enlargement.

Pulmonary edema may be present in rare cases.

Electrocardiographic findings

Tachycardia (>220 bpm) and increased R wave amplitude in lead II (>0.9 mV).

Echocardiographic findings

In **anemia**, a normal to moderate increase in left ventricular dimension (LVIDd > 18 mm) with hyperkinetic (FS > 55%) cardiac function is found. Left atrial size is usually normal to mildly increased.

In rare cases, findings similar to dilated cardiomyopathy are present.

Refer to page 132 for echocardiographic findings in hyperthyroidism.

Differential diagnosis

Cardiomyopathy.

Hyperthyroidism.

Treatment

Treatment should be directed towards the underlying disease.

Refer to page 305 (The Cat With Weight Loss and a Good Appetite) for hyperthyroidism and page 526 (The Anemic Cat) for anemia.

If congestive heart failure is present, with concurrent myocardial failure refer to section on dilated cardiomyopathy, page 151.

If congestive heart failure is present without myocardial failure refer to section on hypertrophic cardiomyopathy, page 128.

Prognosis

Varies depending on disease process.

CHYLOUS EFFUSION*

Classical signs

- Dyspnea/tachypnea.
- Anorexia.
- Lethargy.

See main reference page 77 (The Cat With Hydrothorax).

Clinical signs

Chylous effusion in cats is often of **unknown cause**. The **most common causes are right heart failure** from cardiomyopathy or heartworm or mediastinal neoplasia associated with lymphoma or thymoma. Chylothorax may occur secondary to a thrombus associated with an indwelling **jugular catheter**.

Dyspnea and tachypnea are common presenting clinical signs. Commonly an abdominal respiratory component is seen.

The presence of chest fluid results in muffled heart sounds and absent lung sounds in the ventral thorax.

Cats develop **poor appetite** when a large amount of fluid is present (> ~150 ml).

Cats with symptoms may show **open-mouth breathing and/or cyanosis** after mild to moderate exercise.

Diagnosis

Thoracocentesis findings

Aspiration of the chest fluid commonly yields a milky white fluid (can be slightly pink). This fluid may feel greasy.

Determination of fluid triglyceride level with a paired serum triglyceride sample (obtained at the same time) always reveals a **higher triglyceride level** in the chest fluid.

Cytological evaluation usually reveals a homogeneous population of **mature lymphocytes** and **neutrophils**.

Bacterial culture is negative.

Radiographic findings

Marked pleural effusion.

Elevated trachea.

Obscured cardiac silhouette.

Collapsed lung lobes.

Electrocardiographic findings

Normal.

Abnormalities may be seen if there is concurrent heart disease.

Echocardiographic findings

Many cats have a normal echocardiogram.

In some cases, chylous effusion may be secondary to severe heart disease of any etiology.

HEARTWORM DISEASE*

Classical signs

- Respiratory distress.
- Coughing.
- Vomiting.
- Sudden death.

Clinical signs

Many cats are asymptomatic.

Sudden death is seen in some cases.

Vomiting, lethargy, anorexia and syncope are seen in symptomatic cases.

Respiratory signs such as **cough or dyspnea** are common.

Respiratory signs may be quite **similar to feline chronic bronchitis or asthma**.

Some cats can present for evaluation of pneumothorax/chylothorax.

Occasionally aberrant larval migration results in neurological signs such as seizures, collapse, blindness and vestibular signs.

See main reference page 104 (The Coughing Cat).

Diagnosis

Radiographic findings

Enlarged and tortuous caudal pulmonary arteries are visible on both projections of the chest, but especially the DV/VD views.

Diffuse pulmonary infiltrates characterized by a mixed interstitial and peribronchial pattern.

Electrocardiographic findings

The ECG is generally not useful in diagnosis of feline heartworm disease.

Sinus tachycardia (HR > 220 bpm)

Right heart enlargement in advanced cases. The MEA is usually beyond +180 degrees clockwise.

Echocardiographic findings

Main pulmonary artery may be normal or enlarged.

Linear parallel densities may present in the main pulmonary artery or the main branches.

Dilatation of the right ventricle is seen in advanced cases; RV internal dimension in diastole > 6 mm.

Echocardiography has high specificity for the diagnosis of feline heartworm disease, but sensitivity is highly dependent on the experience of the ultrasonographer.

Cardiac catheterization findings

Non-selective angiography may show:

- Linear filling defects within the pulmonary arterial tree.
- Dilated and tortuous pulmonary arteries.
- Dilated right ventricle.

Blood examination and serologic findings

Microfilaremia is rare in cats and transient (possibly about 1 month). If present, the number of microfilaria is small.

Serologic testing should include both an **antibody and antigen test**.

A positive antibody test is consistent with exposure with or without current infestation. It is a useful screening test and cats with a positive test should be followed up with antigen test.

A **positive antigen test** may be consistent with current infestation. The sensitivity of the current antigen tests is considerably less than the antibody test.

Combining results from serum Ab and Ag tests achieves higher sensitivities than using serum Ab and Ag test results alone.

Negative serologic findings do not absolutely rule out heartworm infestation. If clinical signs are compatible, repeat Ab and Ag testing by a different method, **evaluate chest radiographs and consider echocardiographic examination**.

Treatment

Adulticide treatment is not usually recommended in cats because of severe side effects. Infestation is small (1–2 worms) and their lifespan is short (average 2 years).

Surgical removal of the worms through a jugular approach can be attempted in severe cases.

Medical treatment is mainly symptomatic.

VENTRICULAR SEPTAL DEFECT*

Classical signs

- **Systolic murmur** loudest over the right sternal border.

Pathogenesis

The shunting of blood depends on the size of the defect and the relative resistance of the systemic and pulmonary circulations.

- **Normally, shunting occurs from the left to the right**, unless right heart pressures rise above systemic pressures causing reversal of shunting of blood flow.

In most cases, the defect is present in the **perimembranous area of the interventricular septum**, immediately below the aortic valve annulus.

- The right ventricular location of the defect is commonly situated below the septal leaflet of the tricuspid valve, but can also be located in other areas of the perimembranous septum.
- Primary muscular defects of the septum are rare.

With small defects, the amount of blood being shunted is small and unlikely to create volume overload of the pulmonary circulation and the left heart.

- However, with large defects different degrees of volume overload can be expected, depending on the shunt fraction.
- In some cases chronic volume overload may lead to the development of **left-sided congestive heart failure**.
- In rare instances, chronic volume overload of the pulmonary circulation may result in increased pulmonary vascular resistance with significant elevation of right ventricular systolic pressures that may result in **reversal of the direction of shunting (Eisenmenger's syndrome)**.
- Large defects can result in abnormal morphology of the aortic valve annulus leading to aortic valve prolapse and variable degrees of aortic insufficiency.

Clinical signs

No sex or breed predilection is reported and it is seen usually in cats less than 1 year old.

Systolic murmur is heard over the right sternal border (**the louder the murmur the smaller the VSD**).

In many cases, a **thrill** is felt over the right sternal border.

Most cases are **asymptomatic**.

Tachypnea and/or dyspnea may be a clinical complaint.

The **femoral pulses** are normal.

Bounding pulses occur in cases with significant aortic insufficiency (usually with large VSDs).

Diagnosis

Congenital systolic ejection murmur is heard over the right sternal border in a young cat.

VSD is the most **common cause** of a congenital murmur in the cat.

Radiographic findings

Pulmonary over-circulation demonstrated by a prominent and enlarged vasculature of the lungs.

Left atrium and ventricular dilation with variable degrees of right ventricular enlargement can be seen.

Echocardiographic findings

Most defects are not visualized except for large ones.

Demonstration of shunting and direction of blood flow across the interventricular septum is possible using Doppler technique.

Left atrial and ventricular dilation may be present.

High-velocity flow across the pulmonic valve may be found (relative stenosis due to high volume if large shunting fraction is present). Usually maximal blood flow velocity obtained with continuous flow Doppler is higher than 1.8 m/s.

In severe cases, right ventricular dilation is observed.

If shunting from right to left, an injection of saline from a peripheral systemic vein will demonstrate “bubbles” traveling from the right ventricle to the left ventricle and/or aorta.

In large defects, aortic insufficiency is commonly found.

Cardiac catheterization

Left ventricular injection with angiographic contrast shows shunting of blood from the left ventricle to right ventricle.

If direction of shunting is right to left, a right ventricular injection of contrast shows shunting to the left ventricle.

Increase in oxygen saturation equal to or above 5% from the right atrium to the right ventricle is diagnostic for a left to right ventricular septal defect.

Differential diagnosis

Cardiomyopathy is uncommon in young cats. **Cardiomyopathy murmurs are usually not as loud.** Cardiomyopathy murmurs may sound different with serial auscultations.

In pulmonic or aortic stenosis, the murmur is usually **louder on the left cranial thorax** and its character is harsher than a VSD murmur.

In tricuspid valve dysplasia, the murmur is usually lower frequency and a thrill is uncommon.

In tetralogy of Fallot, peripheral cyanosis may be present; the murmur is similar to the murmur of pulmonic stenosis.

Treatment

Treatment is not required in most cases.

Pulmonary arterial banding should be considered in cases where severe volume overload of the left heart is evident.

If signs of congestive heart failure are present refer to hypertrophic cardiomyopathy section for treatment detail (page 130).

Prognosis

The prognosis is good in most cases, unless congestive heart failure is present at the time of presentation.

Most cats have a normal lifespan.

PATENT DUCTUS ARTERIOSUS

Classical signs

- Continuous murmur is heard loudest over the left cranial thorax.
- Palpable thrill, which may be present bilaterally.
- Bounding arterial pulses.
- Strong precordial impulse.
- Signs of left-sided heart failure may be present (respiratory distress, tachypnea, crackles).

Pathogenesis

The ductus arteriosus should normally close within the first 72 hours of life. **Failure of the ductus arteriosus** to close will maintain a **patent ductus** and allow for shunting between the aorta and pulmonary artery and is called a patent ductus arteriosus (PDA).

The **most common** direction of shunting is **left to right** (aorta to pulmonary artery).

The amount of blood being shunted is **proportional to the size of the ductus.**

Volume overload of the pulmonary circulation and the left heart may be present and ultimately lead to the development of congestive heart failure.

Chronic overload of the left atrium and ventricle results in progressive dilatation of these chambers, and increased left ventricular filling pressures.

Ventricular dilatation causes changes in geometry of the left ventricle and results in functional mitral regurgitation.

Typically, systolic **arterial pressures are increased** due to the increased stroke volume and **diastolic pressures are lower** than normal explaining the bounding pulse.

In some cases, it is believed that **chronic volume overload of the pulmonary circulation** results in vascular changes, which **increase pulmonary vascular resistance.**

If **pulmonary vascular resistance is elevated** above systemic vascular resistance, the direction of **shunting of blood is right to left** (pulmonary artery to aorta) resulting in **lower arterial oxygen content** and an **increase in red blood cell numbers (polycythemia).**

Systemic hypoxemia results in signs of dyspnea, panting and decreased energy, which may be followed by collapse.

Right to left shunting is uncommon.

Clinical signs

No breed or sex predilection is seen. Cats at presentation are usually less than 1 year of age.

No symptoms are present in 1/3 of the cases at initial presentation.

Cats are usually presented for **abnormal respiration** (29%), **lethargy** (24%) and **stunted growth** (14%).

A **continuous murmur** is located over the heart base in 71% of the cases. The other 29% have systolic murmurs only.

Bounding arterial pulses are commonly found.

A strong precordial impulse is commonly found and results from the cardiomegaly.

Arrhythmias can be found in severe cases.

Faint diastolic murmur or no murmur is present in right to left PDAs.

Polycythemia with PCV exceeding 65% may be found in right to left PDA.

Concurrent cardiac defects are found in 29% of the cases.

Diagnosis

Left to right shunt:

- Congenital **continuous murmur** is heard with bounding arterial pulses.

Radiographic findings

Left atrial and ventricular enlargement can be seen.

Large pulmonary vessels suggesting over-circulation can be seen.

Enlarged main pulmonary artery and aortic arch can be seen.

Pulmonary edema may be present in complicated cases.

Electrocardiography

Left ventricular hypertrophy (R wave in lead II > 0.9 mV) is common.

Left atrial enlargement (P wave > 40 ms) can be seen.

Tachycardia can be seen.

Arrhythmias are uncommon.

Echocardiographic findings

Left heart enlargement (LVIDd > 18 mm), hyperkinetic left ventricular function (FS > 55%), enlarged main pulmonary artery (MPA > 10 mm) and aortic arch are seen.

Doppler shows **persistent flow of blood within the main pulmonary artery** through all phases of the cardiac cycle.

Mitral regurgitation may be present.

A small amount of aortic insufficiency may be seen.

Diagnosis

Right to left shunt.

- These cases are rare.
- There is a history of a loud murmur that resolved or is only diastolic now.
- A loud second heart sound, which may be split, may be heard.
- Lethargy, dyspnea and/or collapse are common.

Radiographic findings

Generalized cardiomegaly with a large main pulmonary artery is seen.

Pulmonary over-circulation is not seen with a right to left shunt.

Electrocardiographic findings

Right heart enlargement pattern (right axis deviation) is seen.

Echocardiographic findings

Right ventricular hypertrophy is seen (RVIDd > 6 mm and RVFWd > 3 mm).

Left heart enlargement (LVIDd > 18mm) may also be present.

Doppler flow across PDA from right to left or bi-directional flow can be seen.

Differential diagnosis

Aorticopulmonary window can only be differentiated by echocardiographic study; continuous blood flow with shunting between the aorta and MPA is seen at the level of the aortic root.

Truncus arteriosus can be differentiated by echocardiography; a common large outlet for the left and right ventricles is seen.

Pulmonary arteriovenous fistula will produce similar hemodynamic abnormalities as a left to right PDA but the flow within the main pulmonary artery is normal.

Treatment

Surgery is curative for left to right PDA. The success rate of surgery is 85% when performed by an experienced surgeon.

- Surgery should be accomplished as soon as the patient is a good anesthetic risk.
- If heart failure is present, a period of stabilization prior to surgery is required.
- See treatment for HCM (page 130) for therapy of heart failure.
- **Surgery is contraindicated** in right to left shunts. Treatment is mainly palliative.
- If clinical signs of lethargy, tachypnea and/or collapse are present and if the **packed cell volume is above 60–65%** periodic phlebotomy is indicated. Phlebotomy decreases blood viscosity and improves peripheral perfusion. The presence of clinical signs alone is an indication for phlebotomy.
- If there are signs of right-side heart failure, diuretics will be necessary.
- Rest is recommended.

Prognosis

Left to right PDA.

- Prognosis is good for long-term survival after surgical correction.
- Even in animals presented in heart failure, successful correction of the PDA results in resolution of signs. A normal life expectancy is seen in most of these cases.
- Right to left PDA.
 - **Prognosis is poor for long-term survival**, however many cats can still live for several years with minimal symptoms.

ATRIAL SEPTAL DEFECT

Classical signs

- **Soft systolic murmur** is heard over the left heart base and may radiate to the apex.
- **Dyspnea.**
- **Collapse.**

Pathogenesis

Left to right shunting occurs through the atrial septal defect.

In the absence of significant **mitral regurgitation**, the **shunt fraction** is small and animals may not have any symptoms. With increased amounts of mitral regurgita-

tion, the shunt fraction increases and if significant, **volume overload** of the right and left heart is present.

Mitral regurgitation may occur secondary to left heart volume overload or congenital abnormalities of the formation of the valve.

Kittens with severe disease develop left-sided **congestive heart failure** by 6 weeks of age.

Clinical signs

Signs depend on the degree of **shunt fraction**.

Most cats are **asymptomatic**.

At the left heart base, a soft **systolic ejection murmur** is heard. It is often also heard on the right side of the chest.

Signs of **increased respiratory rate, dyspnea or collapse** may be seen while playing.

Stunted growth is seen in severe cases.

Some cases present with **ascites**, suggesting right-side heart failure.

Diagnosis

Congenital murmur is found over the left heart base. The murmur is systolic and usually soft.

Radiographic findings

Pulmonary over-circulation demonstrated by a prominent and enlarged vasculature of the lungs.

Areas of focal alveolar densities representing **pulmonary edema** may be found.

Generalized cardiomegaly.

Electrocardiographic findings

Sinus tachycardia (HR > 220 bpm) if heart failure is present

Evidence of left ventricular hypertrophy with a tall R wave in lead II (> 0.9 mV)

In cases where the defect may interrupt or deviate the His bundle, notching and prolongation of the QRS may be seen.

Echocardiographic findings

Echocardiographic evidence of an atrial septal defect is seen as **echo drop out** at the regions of the interatrial septum.

It is important to note that due to the thickness of the septum in a normal heart, many times there is the illusion of an echo drop out. Multiple views must be obtained to reach a diagnosis.

Doppler confirmation of left-to-right shunting is documented across the atrial septal defect.

Doppler study may show variable degrees of mitral regurgitation.

Relative pulmonic stenosis (blood flow velocity > 2.0 m/s) secondary to increased volume of blood may be seen with significant shunt fractions.

In severe cases, biatrial and bi-ventricular enlargement can be seen.

Cardiac catheterization

A catheter can be passed across the interatrial septum into the left atria and ventricle.

An increase greater than 5% in oxygen saturation at the level of the right atrium when compared with blood from the caudal vena cava is indicative of an atrial septal defect with left-to-right shunting.

Angiographic contrast study from the left atria will show shunting of blood into the right heart with opacification of the right atria and ventricle.

Differential diagnosis

Cardiomyopathy is uncommon in young cats. Cardiomyopathy murmurs are usually not as loud. Cardiomyopathy murmurs may sound different with serial auscultations.

Ventricular septal defects usually have a louder murmur on the right sternal border and the character is harsher.

Mitral valve dysplasia occurs with a murmur louder at the apex, in some cases a diastolic murmur may be present if there is significant mitral stenosis.

Pulmonic or aortic stenosis present with louder and harsher murmurs than atrial septal defects.

Treatment

Many cases are asymptomatic and there is no need for therapy.

Definitive therapy requires surgical repair, which is very difficult to accomplish in veterinary medicine.

If the patient is in congestive heart failure, refer to hypertrophic cardiomyopathy section (page 130) for treatment details.

Prognosis

Prognosis is good in most cases, but it depends on the degree of shunt fraction, which is dependent on the degree of mitral regurgitation present.

Many cats have a normal lifespan.

MITRAL VALVE DYSPLASIA/STENOSIS

Classical signs

- Systolic and/or diastolic murmur is heard over the left apex.
- Dyspnea.
- Thromboembolic disease

Pathogenesis

Congenital mitral valve malformation will result in poor coaptation of its leaflets and secondary regurgitation.

In some cases, the mitral valve is thick and misshapen with restricted motility during diastole, causing impaired blood flow from the left atrium to the left ventricle.

In some cases, more than two leaflets may be present. Most commonly, the anterior leaflet may be subdivided and it is called a cleft mitral valve.

Clinical signs

A heart murmur is heard loudest over the left heart apex and is present from a young age.

Dyspnea or respiratory distress occur if congestive heart failure is present.

Signs of **increased respiratory rate, dyspnea or collapse** may be seen while playing.

Lameness, paralysis or paresis may result from systemic thromboembolism.

Atrial arrhythmias may be present if there is severe left atrial enlargement. Atrial premature contractions, paroxysmal atrial tachycardia or atrial fibrillation can be seen.

Diagnosis

Radiographic findings

Marked left atrium enlargement is seen, as demonstrated by elevation of the carina and bulging of the caudal atrial wall on the lateral view. A valentine-shaped heart may be seen on the V/D view.

Pulmonary venous congestion defined by a larger pulmonary vein than the accompanying artery, with or without **pulmonary edema** may be present.

Left ventricular enlargement is seen with the cardiac silhouette larger than two intercostal spaces on the lateral view, secondary to severe mitral valve regurgitation.

Electrocardiographic findings

Left ventricular hypertrophy demonstrated by a **tall R wave in lead II** (> 0.9 mV).

Sinus tachycardia (HR > 220 bpm) if heart failure is present.

Some cases may have **atrial premature contractions** or paroxysmal atrial tachycardia. If **atrial fibrillation** is present, there is invariably severe left atrial enlargement.

Echocardiographic findings

A thick and misshapen mitral valve is seen which may have poor motility during diastole.

Systolic anterior motion of the mitral valve may be seen (anterior displacement into the left ventricular outflow of the anterior mitral valve leaflet causing outflow obstruction).

Variable degrees of mitral regurgitation are found on Doppler study.

Determination of the mitral valve inflow velocity profile is essential to determine the presence and degree of mitral stenosis.

- The early diastolic wave (E wave) of mitral inflow shows delayed deceleration of blood flow in mid-diastole, and there is fusion with the atrial diastolic wave (A wave). This results in an M-shaped mitral inflow profile or in severe cases a rectangular shape.

Secondary **left atrial enlargement** occurs with the left atrial to aortic ratio usually > 2.0 . Left atrial enlargement is either secondary to restriction of filling of the left ventricle by a stenotic valve or because of severe regurgitation.

In cases with **severe mitral regurgitation**, secondary **left ventricular enlargement** (LV end-diastolic dimension > 17 mm) is usually seen.

Severe mitral regurgitation and stenosis do not necessarily have to co-exist in the same patient.

Differential diagnosis

Cardiomyopathy is uncommon in young cats. Cardiomyopathy murmurs are usually not as loud. Cardiomyopathy murmurs may sound different with serial auscultations.

Pulmonic or aortic stenosis is present with louder and harsher murmurs than mitral valve dysplasia/ stenosis.

Atrial septal defects usually have soft murmur present at the left heart base.

Differential diagnosis solely based on physical exam may be difficult.

Treatment

Many cases are asymptomatic and there is no need for therapy.

If the patient is in congestive heart failure, refer to the hypertrophic cardiomyopathy section (page 130) for treatment details.

Prognosis

Prognosis is good in most cases. Cats with marked mitral regurgitation may only develop symptoms of congestive heart failure between 5–10 years of age.

Patients with severe regurgitation may present in congestive heart failure within the first year of life.

Prognosis is worse with the presence of co-existent thromboembolic disease.

AORTIC STENOSIS

Classical signs

- Systolic murmur is heard over the left heart base or over the cranial aspect of the sternum.

Pathogenesis

With congenital valvular malformation of the aortic valve, there is **thickening of the valve leaflets and**

poor motility during systole, resulting in fixed obstruction of outflow of blood. In some cases, supra- or subvalvular stenosis may be found.

Secondary left ventricular hypertrophy may develop. The degree of hypertrophy is directly dependent on the severity of the stenosis. Valvular gradients above 100 mmHg are classified as severe.

Clinical signs

A systolic murmur is heard over the left heart base or over the cranial aspect of the sternum.

Most cats are asymptomatic. Most common symptoms in severe cases are exercise intolerance and syncope.

If severe, in the first 1–2 years of life, cats may die suddenly or develop congestive heart failure.

Diagnosis

Radiographic findings

There is widening of the cranial mediastinum as a result of **post-stenotic dilation of the aortic arch**. This is evident on both views (dorsoventral view and lateral view).

Left ventricular enlargement with elongation of the left heart occurs secondary to hypertrophy.

If congestive heart failure is present, pulmonary venous distention (pulmonary vein larger than accompanying pulmonary artery) and evidence of pulmonary edema may be seen (focal areas of marked interstitial or alveolar densities).

Electrocardiographic findings

The electrocardiogram may be normal or have evidence of left ventricular hypertrophy with a tall R wave in lead II (> 0.9 mV).

Left axis deviation and/or left fascicular anterior block may be present.

Ventricular arrhythmias may be present, but are not common.

Echocardiographic findings

Left ventricular hypertrophy is seen (diastolic dimension of the interventricular septum and/or LV posterior wall greater than 6 mm).

If valvular stenosis is present, the valve appears thick and has restricted opening.

A subvalvular or supra- or subvalvular fibrous ridge may be identified.

In some cases, left atrial enlargement may be present.

Doppler study of the left ventricular outflow reveals **increased velocity of blood flow** (> 2.0 m/s).

Cardiac catheterization findings

Cardiac catheterization is not routinely done, since the introduction of echocardiography.

Injection of contrast in the left ventricle will show:

- Left ventricular hypertrophy.
- Narrow left ventricular outflow.
- Filling defect at the aortic valve level (due to a thickened valve).
- Post-stenotic dilatation of the aortic arch.
- Subvalvular or supra- or subvalvular filling defects may be seen.

Differential diagnosis

Hypertrophic obstructive cardiomyopathy (HOCM) differs from aortic stenosis in the location and pathophysiology of the stenosis. With HOCM the stenosis is dynamic (changes with heart rate) while in aortic stenosis the obstruction to blood flow is fixed.

Treatment

In mild and moderate cases (Doppler-derived pressure gradient less than 100 mmHg and asymptomatic), there is no benefit from medical therapy.

In cases complicated with ventricular arrhythmias and/or left ventricular concentric hypertrophy, beta-blockers may reduce the likelihood of sudden death and/or collapse. Refer to section in hypertrophic cardiomyopathy (page 130).

If congestive heart failure is present, refer to hypertrophic cardiomyopathy section (page 130).

Caution with the use of angiotensin-converting enzyme inhibitors, which may increase the pressure gradient across the stenosis.

No surgical therapy is currently being offered for treatment of this disease.

Prognosis

Prognosis is dependent on severity of the stenosis and the presence of congestive heart failure with or without collapse.

Some cats may have a normal lifespan.

Severely affected cats die within the first 1–2 years of life.

Cats with aortic stenosis are at an increased risk of developing bacterial valvular endocarditis.

PULMONIC STENOSIS

Classical signs

- **Systolic murmur is heard over the left heart base over the pulmonic area.**

Pathogenesis

With congenital valvular malformation of the pulmonic valve, there is **thickening of the valve leaflets and poor motility during systole**, resulting in fixed obstruction of outflow of blood. In some cases, supra- or subvalvular stenosis may be found.

The increased resistance to blood flow across the pulmonary valve stenosis results in elevation of right ventricular systolic pressure. Secondary right ventricular hypertrophy and dilation may develop, along with arrhythmias.

Dilation and hypertrophy of the right ventricle may result in secondary tricuspid insufficiency.

Signs of right-sided congestive heart failure may develop.

Pulmonic stenosis is often seen with other cardiac defects such as tetralogy of Fallot, septal defects and tricuspid dysplasia.

It is a rare congenital defect in cats.

Clinical signs

Many cats are asymptomatic and present for evaluation of a heart murmur.

The age of presentation varies from the **first few months of life until middle age**.

Cats with symptoms may show dyspnea or open-mouth breathing after mild to moderate exercise.

The murmur is best heard at the **left heart base**. It is an ejection systolic murmur, which varies in intensity during systole because of the crescendo and decrescendo character.

Characterization of the ejection murmur may be difficult in a cat because of the fast heart rate.

Diagnosis

Radiographic findings

Normal cardiac size or right ventricular enlargement is found.

Dilated main pulmonary artery (post-stenotic dilatation) is seen as a bulge in the left cranio-lateral part of the cardiac silhouette in the ventro-dorsal view or dorso-ventral view.

Under-perfused pulmonary circulation is seen as hypovascular lung fields characterized by hyperinflated lungs and a decreased peripheral pulmonary vasculature.

Electrocardiographic findings

Tachycardia is frequently seen with a heart rate greater than 220 bpm.

Right axis deviation is seen between -60 and -180 degrees in the frontal plane.

Deep S waves are seen on leads II, aVF and III.

Echocardiographic findings

Pulmonary valve stenosis is present. Pulmonary artery hypoplasia and a dysplastic pulmonic valve may be evident.

Doppler study across the pulmonary valve will determine the degree of stenosis. Velocities of blood flow obtained by continuous wave Doppler above 2.0 m/s are diagnostic of stenosis.

Cardiac catheterization findings

Selective angiography of the right ventricle will show:

- Right ventricular hypertrophy.
- Pulmonary valve stenosis and post-stenotic dilatation of the main pulmonary artery.

Differential diagnosis

Tetralogy of Fallot.

- The murmur of pulmonic stenosis may be similar to the murmur heard in tetralogy of Fallot.
- Cyanosis or brick-red mucus membranes are not seen with pulmonic stenosis.

Cardiomyopathies.

- The murmur is usually not as loud and may vary in intensity.

Treatment

Use **furosemide** if congestive heart failure is present and treat arrhythmias (see page 160 The Cat With Tachycardia, Bradycardia or an Irregular Rhythm).

Surgical options are available but rarely performed.

- Blalock–Taussig shunt can be recommended (artificial shunt from the left subclavian artery to the pulmonary artery). This increases blood flow through the pulmonary circulation.
- Other modified techniques have been described. Consult with an experienced surgeon.

Catheter balloon valvuloplasty can be very successful in reducing the gradient across the stenotic valve. The catheter is positioned through the valve and the balloon inflated to dilate the stenosis.

Prognosis

Most cats reach middle age and some even have a normal lifespan.

Long-term prognosis depends on the severity of obstruction to blood flow.

TETRALOGY OF FALLOT

Classical signs

- Systolic murmur over the cranial ventral thorax.
- Cyanosis or brick-red mucus membranes may be present.
- Signs of increased respiratory rate (with open-mouth breathing), dyspnea or collapse may be seen while playing.
- Many cats are asymptomatic on presentation.

Pathogenesis

Tetralogy of Fallot implies four separate anatomic abnormalities:

- Large ventricular septal defect (VSD).
- Pulmonic valvular stenosis.
- Overriding aorta (dextroposition of the aorta) results from the cranial displacement of the aorta relative to the interventricular septum. This leads to the abnormal alignment of the aorta and the left ventricular outflow tract. A portion of the aorta is positioned over the right ventricular outflow tract.
- Right ventricular hypertrophy.

These abnormalities have a common morphogenetic cause and **result from anterior deviation of the interventricular septum** during development.

It is a rare congenital disease in the cat and is inherited as a **simple autosomal recessive** trait.

The increased resistance to blood flow across the pulmonary valve stenosis results in elevation of right ventricular systolic pressures above left ventricular systolic pressures. These hemodynamic alterations cause the shunting of blood through the large ventricular septal defect.

The cranial displacement of the aortic root allows for direct ejection of blood from the right ventricle into the aorta.

The degree of shunting is relative to the amount of pulmonary stenosis and dextroposition of the aorta. In some patients, minimal shunting occurs at rest, and symptoms are only present during exercise.

Chronic hypoxia results in polycythemia (PCV > 65%).

Clinical signs

Many cats are asymptomatic at rest and present for evaluation of a heart murmur.

The age of presentation varies from the **first few months of life until middle age**.

Cats with symptoms may show open-mouth breathing and/or cyanosis after mild to moderate exercise. In some cats, syncope is seen.

The **mucus membranes may be pink or cyanotic** depending on the degree of the polycythemia and shunting.

The murmur is usually due to the pulmonic stenosis and best heard at the **left heart base**. It is an ejection systolic murmur, which varies in intensity during systole because of the crescendo and decrescendo character.

Characterization of the ejection murmur may be difficult in a cat because of the fast heart rate.

Diagnosis

Radiographic findings

Normal cardiac size or right ventricular enlargement is found.

Dilated main pulmonary artery (post-stenotic dilatation) is seen as a bulge in the left cranio-lateral part of the cardiac silhouette in the ventro-dorsal view or dorso-ventral view.

Under-perfused pulmonary circulation is seen as hypovascular lung fields characterized by hyperinflated lungs and a decreased peripheral pulmonary vasculature.

Electrocardiographic findings

Tachycardia is frequently seen with a heart rate greater than 220 bpm.

Right axis deviation is seen between -60 and -180 degrees in the frontal plane.

Deep S waves are seen on leads II, aVF and III.

Echocardiographic findings

A large **perimembranous ventral septal defect** is seen below an overriding aorta.

Pulmonary valve stenosis is present. Most cases have pulmonary artery hypoplasia and a dysplastic pulmonic valve.

Doppler study of the flow across the VSD will determine the direction of shunting of blood. Most frequently, there is right to left shunting.

Doppler study across the pulmonary valve will determine the degree of stenosis. Velocities of blood flow obtained by continuous wave Doppler above 2.0 m/s are diagnostic of stenosis. Usually the degree of stenosis is severe ($V_{max} > 5.0$ m/s).

Saline contrast studies may be helpful in identifying the direction of shunting.

Cardiac catheterization findings

Selective angiography of the right ventricle will show:

- Right ventricular hypertrophy.
- Large VSD.
- Pulmonary valve stenosis and post-stenotic dilatation of the main pulmonary artery.
- Overriding aorta.

Cardiac catheterization demonstrates equalization of right ventricular and left ventricular pressures.

Pulmonary artery pressures are normal.

Differential diagnosis

Pulmonary stenosis.

- Cyanosis or brick-red mucus membranes are not seen with pulmonic stenosis.
- The murmur of pulmonic stenosis may be similar to the murmur heard in tetralogy of Fallot.

Right to left PDA.

- In many cases, no murmur is heard although cyanosis and exercise intolerance are usually present.
- Cyanosis of the right-to-left PDA is usually peripheral and localized to the caudal portion of the body.

Cardiomyopathies.

- Cyanosis is only present in cases of severe pulmonary edema.
- The murmur is usually not as loud and may vary in intensity.

Treatment

Medical therapy consists of periodic phlebotomy to control clinical signs.

- Blood of volume removed = $[BW \text{ (kg)} \times 0.08] \times 1000 \text{ ml/kg} \times \frac{\text{Actual Hct.} - \text{Desired Hct.}}{\text{Actual Hct.}}$
- Repeat PCV in 2 hours. The goal is to decrease PCV to ~60%. CAUTION—removing too much red cell mass may render the patient symptomatic at rest.

Avoid heavy playing and keep confined within the household.

Use **beta-blockers** if the **heart rate** is greater than 200 bpm at rest.

- Propranolol – 0.5–1 mg/kg q 8 h **OR**
- Atenolol 6.25–12.5 mg/cat q 12 h.

Surgical options are available but rarely performed.

- Blalock–Taussig shunt can be recommended (artificial shunt from the left subclavian artery to the pulmonary artery). This increases blood flow through the pulmonary circulation.
- Other modified techniques have been described. Consult with an experienced surgeon.

Prognosis

Most cats can reach middle age and some even have a normal lifespan.

Long-term prognosis depends on the severity of blood flow.

DILATED CARDIOMYOPATHY

Classical signs

- Heart murmur (in some cases may not be present).
- Gallop rhythm.
- Arrhythmia.
- Dyspnea.
- Hypothermia.
- Collapse.
- Lameness, paralysis or paresis from systemic thromboembolism.

Pathogenesis

This disease **in most cats is due to a deficiency in taurine concentration**. Taurine supplementation in commercially available diets has reduced significantly its incidence.

Any cat fed a non-commercial diet should have taurine supplementation. Cats fed home-made vegetarian diets are at high risk of taurine deficiency. However, not all cats experimentally fed a taurine-deficient diet have developed dilated cardiomyopathy.

Dilated cardiomyopathy (DCM) is not always the result of taurine deficiency. Currently most of the cases are idiopathic.

Retinal degeneration changes consistent with taurine deficiency are present in 33% of cats.

Other potential causes for DCM include a late expression of chronic myocarditis, genetic abnormalities, and in some cats, the cause is unknown.

In cats fed commercially available feline diets, DCM is a **rare form of cardiomyopathy**.

All cardiac chambers are dilated. Atrophy of papillary muscles is present.

Myocardial sections on post-mortem show patchy white areas. Microscopically there is myocyte atrophy with interstitial fibrosis.

The hemodynamic hallmark is severe systolic dysfunction.

Clinical signs

There is no age or sex predilection.

Usually cats with dilated cardiomyopathy have a history of being fed a non-commercial diet, or dog food.

A heart murmur is often present, but in some cases may not be. When present, a systolic murmur varies in location and intensity with variations in heart rate.

Gallop rhythm is commonly heard. It is identified when more than two heart sounds are present on auscultation.

Arrhythmias can be heard as premature heart beats with pulse deficits.

Dyspnea is seen in symptomatic cats with an increased respiratory rate (greater than 30 breaths/ min) at rest or with open-mouth breathing in extreme cases. Pleural effusion may be present and result in muffled heart sounds.

In symptomatic cats, hypothermia is common.

Collapse may result from impaired cardiac output (ventricular tachycardia)

Lameness, paralysis or paresis are usually the result of systemic thromboembolism.

Most cats with aortic saddle thrombosis present for acute onset of hindlimb paralysis, pain, absent femoral pulses, cool extremities and cyanosis of the nail bed. In some cases a history of episodic lameness is given.

Ascites is found in a small minority of cases.

Diagnosis

Radiographic findings

Severe generalized cardiomegaly and enlarged pulmonary veins are seen. Pulmonary edema with or without

pleural effusion may be present. Pleural effusion is more common in dilated cardiomyopathy than in other forms of cardiomyopathy. The fluid may be a transudate, modified transudate or chylous.

Electrocardiographic findings

Ventricular arrhythmias are present in about 50% of cases.

Tachycardia, ventricular conduction disturbances (notched QRS), or tall R waves on lead II (> 0.9 mV) are **commonly** found.

Atrial fibrillation is more common than in HCM and is usually associated with **extreme dilatation** of the left and/or right atria.

Echocardiographic findings

The echocardiographic findings reveal **severe biventricular dilatation with severe biatrial enlargement**. The left atrial to aortic ratio is usually > 2.0 .

Left ventricular systolic function is markedly diminished (fractional shortening is less than 20–25% in most cases). Normal FS is between 35–55%.

Left ventricular internal dimensions in diastole is usually larger than 20 mm. Intracardiac thrombi may be found. Normal LV end-diastolic dimension is up to 17 mm.

In **taurine-deficient cats**, improvement in chamber size and contractility is seen 6–8 weeks after starting supplementation.

Laboratory findings

Plasma **taurine levels** (heparinized sample) are less than 30 nmol/ml in most cats. Plasma levels of 40–60 nmol/ml may be consistent with taurine deficiency.

Cats with congestive heart failure may show **azotemia** due to decreased renal perfusion.

Treatment

Treatment of the asymptomatic cat:

- Angiotensin-converting enzyme inhibitors
 - **Enalapril** 0.25–0.5 mg/kg PO q 24 h **OR**
 - **Benazepril** 0.25–0.5 mg/kg PO q 24 h.
- Nutraceuticals
 - **Taurine** PO 250–500 mg q 12 h.

Treatment of the symptomatic cat with congestive heart failure (acute management).

Criteria to start therapy:

- Respiratory distress (open-mouth breathing or very abnormal respiratory pattern).
- Pulmonary congestion (moderate to severe) on radiographs and/or pleural effusion.
- Hypothermia.
- Oxygen.
- Diuretics.
 - **Furosemide** 1–2 mg/kg IV or IM q 8–12 h until respiratory rate and pattern are normalized.
 - Furosemide constant rate infusion (if normal renal values at presentation) 0.5–1 mg/kg/hr until congestion is resolved but not for longer than 24 hours.
- Venodilator.
 - **Nitroglycerin** ointment (2%) 1/4 of an inch (6 mm) q 8 h.
- Inotropic support.
 - **Dobutamine** continuous rate infusion, IV 1–3 μ g/kg/min (watch for vomiting or seizures). **OR**
 - **Pimobendan** 0.25 mg/kg PO q 12 h (only if able to pill without causing distress)
- **Thoracocentesis (right thorax** to avoid puncturing of the enlarged auricles) if there is evidence of moderate to severe pleural effusion on radiographs.
- **Angiotensin-converting enzyme inhibitor** (see above).
- **Taurine** supplement (see above).
- **Thermoregulatory support** (heating blanket).
 - Fluid therapy should be done cautiously until stable cardiac function is established.

Symptomatic cat with congestive heart failure (**chronic management**).

Criteria to start therapy:

- Maintenance therapy after initial treatment for acute congestive heart failure.
- Any patient found to have early evidence of congestive heart failure (usually on radiographs) but without symptoms, that will require acute intervention if untreated.
 - Diuretics
 - **Furosemide** 0.5–1.0 mg/kg PO q 12–24 h **OR**
 - **Hydrochlorothiazide** 1–2 mg/kg PO q 12 h **OR/AND**
 - **Spironolactone** 2–4 mg/kg PO q 12 h.
- Angiotensin-converting enzyme inhibitor (see above)
- Taurine supplement (see above)

Inotropic Support

- Digoxin 0.016 mg/cat PO q 24–48 h (monitor for anorexia and gastrointestinal signs). **OR**
 - For monitoring, obtain a serum sample 8 hours after giving digoxin dose. Do not store the serum in plastic tubes, since digoxin binds to plastic. Therapeutic serum concentrations range from 1.3–3.2 nmol/L (1.0–2.5 ng/ml). The authors prefer not to exceed levels higher than 1.9 nmol/L (1.5 ng/ml). The side effects usually are GI signs and anorexia.
- **Pimobendan** 0.25 mg/kg PO q 12 h.
- Arrhythmia control.
 - Improvement is usually seen with supportive treatment.
 - Caution should be exercised if beta-blockers or calcium channel blockers are used, due to the negative inotropic effects of these drugs.
 - For ventricular or supraventricular arrhythmias:
 - **Procainamide SR** 10–20 mg/kg PO q 8 h.
 - Associated intracardiac thrombus or systemic thromboembolism.
- Anti-thrombotic therapy:
 - **Heparin** and **Warfarin** therapy are controversial and should be utilized under the guidance of an experienced clinician.
 - **Low-molecular-weight heparins** have been recently suggested. This class of heparins does not require continued monitoring of coagulation parameters.
 - **Enoxaparin** (Lovenox®) 1 mg/kg SQ q 24 h.
 - **Aspirin** 80 mg PO q 48–72 h is recommended by some clinicians but its efficacy has not been established. A lower dose (5 mg/cat PO q 24 h) has also been recommended, because of concerns that prostacyclin production is inhibited at the higher dose.

Thrombolytic therapy is contraindicated if an intracardiac thrombus is present, and controversial in aortic saddle thrombus.

Prognosis

Prognosis is good if the etiology is taurine deficiency.

Most cases currently seen are not due to taurine deficiency and the prognosis is poor.

Prevention

Cats should be maintained on a diet designed for the feline patient, which has adequate amounts of taurine.

PERITONEAL-PERICARDIAL DIAPHRAGMATIC HERNIA (PPDH)

Classical signs

- Vomiting.
- Diarrhea.
- Weight loss.
- Dyspnea.

Pathogenesis

Persistent communication occurs between the **pericardial and peritoneal cavities** because of abnormal fusion of the septum transversum with the pleuroperitoneal folds during development.

The hernia is of variable size.

The most likely organs to be herniated are the **liver and gallbladder, small intestine, spleen, stomach**.

Clinical signs

Signs are mostly related to the gastrointestinal system and include vomiting, diarrhea and weight loss.

Most cases are asymptomatic and it is an incidental finding. An increased incidence in Persian cats is suspected.

Physical exam is often normal. In some cases, the heart sounds may be muffled.

In symptomatic patients, respiratory signs can be present, particularly under stressful conditions.

Diagnosis

Radiographic findings

Extreme enlargement of the “cardiac” silhouette.

Dorsal displacement of the trachea.

Silhouetting of the caudal border of the heart with the diaphragm.

Heterogeneous densities of the “cardiac” silhouette due to varied contents of the pericardial cavity.

Abdominal radiographs may show an absent or smaller than normal liver.

Electrocardiographic findings

Some patients have a normal ECG.

The expected QRS complexes in a cat with a severely enlarged heart diagnosed by radiography are not present in patients with peritoneopericardial diaphragmatic hernia.

The mean electrical axis may be shifted (depending on the abnormal deviation of the heart by the viscera).

Echocardiographic findings

The cardiac exam is commonly normal.

In cases where primary cardiac disease is present, it is difficult to obtain a true evaluation of the heart due to compression by nearby organs.

Abnormal blood flow patterns may be caused by compression forces of the viscera against the heart.

The liver and other organs can be visualized in direct contact with the heart.

Cardiac catheterization findings

Non-selective angiography demonstrates that the pericardial sac is filled with other organs.

Differential diagnosis

Pericardial effusion is usually associated with clinical signs of cardiac or infectious disease. Radiographically the cardiac silhouette lacks heterogeneous densities.

Dilated cardiomyopathy is usually associated with signs indicative of heart disease. Radiographically the heart never develops the degree of enlargement seen with PPDH.

In a diaphragmatic hernia the heart, size is normal and displaced. There is loss of distinct diaphragmatic borders. A history of trauma is common.

Treatment

If the patient is asymptomatic and the diagnosis is incidental, then surgery is not necessary.

Surgical correction should be reserved for cases with symptoms attributed to this condition.

- Post-operative care may be complicated in some cases. Consult with an experienced surgeon.

Prognosis

Asymptomatic patients have a good prognosis in general.

Surgically corrected patients have an excellent prognosis.

DIAPHRAGMATIC HERNIA

Classical signs

- **Dyspnea/tachypnea.**

See main reference page 57 (The Dyspneic or Tachypneic Cat).

Clinical signs

Trauma associated with a **motor vehicle accident** or a **fall from several stories** is the most common cause, although it can occasionally occur as a **congenital problem**.

Tachypnea and **dyspnea** are often evident, and may begin at the time of trauma or a few hours later. In some cats, the respiratory signs improve after a few days and are most evident only after physical activity.

Typically there is a **vague history of gastrointestinal signs** including vomiting, inappetance and weight loss, usually beginning some time after a motor vehicle accident or fall.

Physical examination may be normal. Often the **heart sounds are muffled** on one or both sides of the chest. There may be an impression of an “empty” **abdomen** on abdominal palpation because of organ displacement.

Diagnosis

Radiographic findings

Abdominal viscera are identified within the thorax. Stomach and small intestine can be easily identified as gas-filled or fluid-filled structures.

Displacement of abdominal and thoracic structures is found due to shifting of the organs through the diaphragmatic surface.

Partial or complete **loss of the thoracic–diaphragmatic surface** outline is seen.

In some cases, pleural effusion is detected.

Electrocardiographic findings

Mean electrical axis may be shifted due to the altered position of the heart in the chest.

A typical mean electrical axis shift cannot be expected, due to the variable position of the heart in each individual case.

Echocardiographic findings

A normal echocardiogram is found, unless concurrent heart disease is present.

The abdominal viscera may displace the heart making it difficult to obtain standard imaging planes.

Abdominal organs are visualized **within the chest cavity**.

VALVULAR ENDOCARDIOSIS

Classical signs

- Systolic murmur.
- Gallop.
- Dyspnea or tachypnea if symptomatic.

Pathogenesis

This is a **rare disorder** in cats.

Degeneration of the collagen matrix of the valve occurs resulting in laxity of the chord apparatus and prolapse of the valve.

There is **thickening of the valve leaflets**.

Clinical signs

Systolic murmur located over the apex of the heart.

Gallop rhythm may be present.

Tachypnea or dyspnea may be present in cases with concurrent congestive heart failure.

Diagnosis

Radiographic findings

Marked left atrial enlargement.

Left ventricular enlargement.

Dorsal displacement of the trachea.

Pulmonary edema.

Dilatation of the pulmonary veins relative to the pulmonary arteries.

Pleural effusion may be present (rare).

Electrocardiographic findings

Sinus tachycardia if heart failure is present.

Left ventricular enlargement (R wave > 0.9 mV on lead II).

Left anterior fascicular block (LAFB) may signify left ventricular enlargement. In LAFB the QRS duration is normal, there is marked left axis deviation (between –60 and –90 degrees), small Q wave and tall R wave in leads I and aVL, deep S waves in lead II, III and aVF.

Arrhythmias are uncommon.

Echocardiographic findings

Thick and prolapsing mitral valve.

Marked mitral regurgitation.

- Marked left atrial enlargement
- Variable degrees of left ventricular enlargement occur depending on the degree of valvular insufficiency.
- **Hyperkinetic left ventricle** (contraction is exuberant, stronger than normal) with a fractional shortening often greater than 55%.

Differential diagnosis

Any type of cardiomyopathy.

- Cardiomyopathy cases have in general **normal valvular morphology**.
- In cardiomyopathy patients, the degree of valvular insufficiency is usually less than with endocardiosis.

Treatment

If not in congestive heart failure:

- Treatment is not required and probably will not change the outcome.
- If severe left atrial enlargement is present (left atrial to aortic ratio >2), consider beta-blocker therapy (refer to HCM section for doses, page 130).

If in congestive heart failure (respiratory distress with open-mouth breathing or very abnormal respiratory pattern, pulmonary congestion on radiographs with or without pleural effusion and hypothermia) refer to section on HCM for therapy (page 130).

Prognosis

The prognosis is variable and depends on the severity of the mitral regurgitation and degree of cardiac enlargement present.

If congestive heart failure is present, life expectancy is around 1–2 years.

10. The cat with tachycardia, bradycardia or an irregular rhythm

Luis A H Braz-Ruivo, Kathy A Arrington and Fiona Campbell

KEY SIGNS

- Tachycardia.
- Bradycardia.
- Irregular heart sounds or pulse.

MECHANISM?

- Arrhythmias are caused by two basic abnormalities: disorders of impulse formation and disorders of impulse conduction.
- Alterations of impulse formation are usually the result of diseased myocardial cells.
- Alterations of electrical impulse conduction occur secondary to primary diseases of the conduction system.

WHERE?

- Arrhythmias can occur wherever there is excitable cardiac tissue in the heart.

WHAT?

- Most cats with a cardiac arrhythmia are asymptomatic.
- The most common arrhythmia is ventricular premature contractions (VPCs).

QUICK REFERENCE SUMMARY

Diseases causing tachycardia, bradycardia or an irregular rhythm

TACHYARRHYTHMIAS

ANOMALY

- Ventricular pre-excitation

This is a rare cardiac arrhythmia resulting from the presence of a congenital bundle of muscle across the atrioventricular annulus – allowing bypass of the electrical impulse to the ventricles.

It can occur at any age; in many cases, it is an incidental finding. The most common symptom is syncope or lethargy during the periods of supraventricular tachycardia.

continued

continued

METABOLIC

- **Tachyarrhythmias (sinus tachycardia, supraventricular/atrial tachycardia, ventricular premature beats and ventricular tachycardia)*** (p 160)**

Tachyarrhythmias can result from hyperthyroidism, acidosis and uremia or be drug-induced.

Cats tolerate tachycardia better than other species. Syncope, lethargy and weakness are the most common signs in addition to the sign of the underlying disease.

- **Ventricular arrhythmias (ventricular premature beats, ventricular tachycardia)*** (p 164)**

Ventricular arrhythmias may result from hyperthyroidism, acidosis, uremia or be drug-induced. In addition to the signs related to the underlying disease, cats may present with lethargy, weakness, anorexia and syncope.

- **Atrial arrhythmias (supraventricular/atrial tachycardia, atrial fibrillation) (p 161)**

Atrial arrhythmias may be seen in hyperthyroidism. In addition to the signs related to the underlying disease, cats may present with lethargy, weakness and syncope.

NEOPLASTIC

- **Ventricular arrhythmias (ventricular premature beats, ventricular tachycardia) (p 164)**

Ventricular arrhythmias may be seen in primary or metastatic cardiac disease. Most patients do not show clinical signs from the arrhythmia. Most of the clinical signs are related to the underlying disease.

INFECTIOUS

- **Ventricular arrhythmias (ventricular premature beats, ventricular tachycardia) (p 164)**

Ventricular arrhythmias may be seen with bacterial infections (endocarditis, myocarditis) and viral infections (myopericarditis). Fever, lethargy, anorexia and a new heart murmur are the most common clinical signs.

IDIOPATHIC

- **Ventricular arrhythmias (ventricular premature beats, ventricular tachycardia)*** (p 164)**

Ventricular arrhythmias are most commonly seen in cases of feline cardiomyopathies. The majority of the cases do not have symptoms related to the arrhythmia. Periods of ventricular tachycardia (rates above 300 bpm) may cause lethargy or syncope.

- **Atrial fibrillation* (p 162)**

Atrial fibrillation can be seen in end-stage cardiomyopathies when severe left atrial enlargement is present. Clinical signs include worsening of heart failure, weakness or syncope. Signs related to systemic thromboembolism (paresis/paralysis of hindlimbs) may be present.

- **Supraventricular arrhythmias (supraventricular/atrial tachycardia, atrial fibrillation)** (p 161)**

Atrial tachycardias, atrial premature beats and other forms of supraventricular tachycardias can occur in cats with cardiomyopathies. The majority of the cases do not have symptoms related to the arrhythmia. Periods of supraventricular tachycardia (rates above 300 bpm) may cause lethargy or syncope.

TRAUMATIC

- Ventricular arrhythmias (ventricular premature beats, ventricular tachycardia) (p 164)
Ventricular arrhythmias can be seen in cases following severe trauma to the chest. These are usually secondary to traumatic myocarditis. The majority of the cases do not have symptoms related to the arrhythmia. Periods of tachycardia (rates above 300 bpm) may cause lethargy or syncope

BRADYARRHYTHMIAS

DEGENERATIVE

- Atrioventricular block (p 169)
Several degrees of atrioventricular block are due to His bundle degeneration, vacuolization and fibrosis.
Bradyarrhythmias cause clinical signs of lethargy, weakness and syncope. Depending on the degree of the bradyarrhythmia, many cats may not show clinical signs and usually are an incidental finding.

METABOLIC

- Sinus bradycardia (p 168)
Sinus bradycardia can result from hyperkalemia, hypokalemia, hypoglycemia, acidosis and hypothermia or be drug-induced. In addition to the signs related to the underlying disease, cats may present with lethargy, weakness, anorexia and syncope. Heart rate is <120 beats/min.
- Atrial standstill (p 168)
Atrial standstill can result from hyperkalemia primarily associated with urethral obstruction or from long-standing cardiac disease, most commonly dilated cardiomyopathy. In addition to the signs related to the underlying disease, cats may present with lethargy, weakness, anorexia and syncope.

TOXIC

- **AV block**** (p 169)
AV block can be drug-induced with digitalis, beta-blockers and calcium-channel blockers. In addition to the signs related to the underlying disease, cats may present with lethargy, weakness, anorexia and syncope.

INTRODUCTION

MECHANISMS?

The normal electrical impulse is generated in the **SA node** and spreads through the atria via the Bachmann bundles, continues down through the **AV node**, **His bundle**, **bundle branches** and **Purkinje fibers** and finally reaches the **ventricles**.

Arrhythmias are caused by two basic abnormalities, disorders of **impulse formation** and disorders of **impulse conduction**.

Alterations of **electrical impulse formation** occur secondary to **instability of the resting membrane potential** and are usually the result of **diseased myocardial cells**.

- If the electrical impulse forms **earlier** than expected, a **premature beat** is generated. If the electrical impulse forms **later** than expected, a **pause** in the cardiac rhythm is seen.

Alterations of **electrical impulse conduction** occur secondary to **primary diseases of the conduction system**. These either result in **block of conduction** of the electrical wave, or alterations that facilitate the **perpetuation of the electrical wave** in a circuit (re-entry).

Abnormal conduction of the electrical impulse can be either **blocked**, choose an **alternative pattern of conduction** (aberrantly conducted) or **re-enter** previously excited tissue (re-entry).

An arrhythmia should always be suspected whenever an **irregularity in cardiac rhythm** or **arterial pulse** is detected.

WHERE?

Arrhythmias can occur wherever there is **excitable** cardiac tissue in the heart.

Arrhythmias that originate in the **atria, interatrial septum, or above the AV node** are termed **supraventricular**.

Arrhythmias that originate in the ventricles or anywhere below the bifurcation of the His bundle are termed ventricular.

WHAT?

The most common arrhythmia is ventricular premature contractions (VPCs).

Cats with cardiac arrhythmias are generally suspected of having myocardial disease, even if radiographic and echocardiographic findings are within normal limits.

Cardiomyopathies are the most common form of cardiac disease associated with arrhythmias.

The diagnosis of atrial fibrillation in a cat is almost invariably associated with the presence of severe left atrial enlargement.

Most cats with a cardiac arrhythmia are asymptomatic.

Ventricular arrhythmias in young cats with severe left ventricular hypertrophy may be associated with a high risk of sudden death.

TREATMENT

Most cats do not require specific therapy with anti-arrhythmics unless they are symptomatic.

Class I anti-arrhythmics block the sodium channels and result in decreased excitability of the diseased cells. The most common examples are procainamide and lidocaine (high risk of toxicity).

Class II anti-arrhythmics are beta-blockers. This group antagonizes the action of catecholamines and is most useful when increased sympathetic tone is present. Most common examples include propranolol (non-selective) and atenolol (beta-1 selective). They are contraindicated for cats with symptomatic respiratory disease.

Class III anti-arrhythmics block the potassium channels. This group hyperpolarizes the cells making it more difficult to reach threshold, and they prolong the refractory period. The most common used drug is sotalol. Sotalol, besides class III properties, also has class II properties.

Class IV anti-arrhythmics block the calcium channels. These drugs inhibit transmembrane calcium transport and the most pronounced effects are at the sinoatrial and atrioventricular nodes. The most common example is diltiazem.

DISEASES CAUSING TACHYCARDIA OR AN IRREGULAR RHYTHM

SINUS TACHYCARDIA***

Classical signs

- Heart rate greater than 220 beats per minute.
- Strong precordial impulse.
- Loud S1 heart sound.

Pathogenesis

This **arrhythmia** originates from the **sinoatrial node**, the normal pacemaker of the heart.

It results from **increased sympathetic tone**. The **causes of increased sympathetic tone** include stress, fever, pain, metabolic disease (hyperthyroidism), hypovolemia, thromboembolic disease, shock and anemia.

Clinical signs

In the majority of patients, clinical signs are related to the underlying disease.

Clinical signs related to a fast heart rate (> 280 bpm) include restlessness, tachypnea, open-mouth breathing, poor pulse quality and delayed capillary refill time.

Diagnosis

The diagnosis is based on physical examination and an electrocardiogram (Figure 10.1).

The **heart rate** is above **220 bpm**.

The **cardiac rhythm** is regular.

There is a **P wave for every QRS complex** with a constant P-R interval.

The morphology of the **P wave** is **normal**.

The **QRS complex morphology** is **normal**.

The **changes in the heart rate** occur **gradually** (i.e. gradual acceleration or deceleration of the heart rate).

Differential diagnosis

Supraventricular tachycardias including atrial tachycardia, AV nodal re-entrant tachycardia, atrial flutter with 2:1 conduction need to be differentiated from sinus tachycardia. Supraventricular tachycardia may look identical to sinus tachycardia on the ECG. Excessive heart rate (greater than 250 bpm) is more likely to be supraventricular tachycardia. Supraventricular tachycardia may have abnormal P wave morphology or lack P waves compared to sinus tachycardia where P waves are normal.

Treatment

Before initiating treatment, **determine the underlying etiology**, and treat appropriately.

If associated with **low systemic blood pressure** and the **cause is not** hypovolemia, shock or blood loss, and systolic myocardial function is preserved, consider **heart rate control** with:

- Propranolol at 0.5–1 mg/kg PO q 8–12 hours.
- Atenolol at 6.25–12.5 mg/cat PO q 12 hours.
- Sotalol at 10–20 mg/cat PO q 12 hours.
- Diltiazem at 7.5–15 mg/cat PO q 8 hours.

Prognosis

The **prognosis** depends on the underlying **etiology**.

Most cases have a favorable outcome.

SUPRAVENTRICULAR/ATRIAL TACHYCARDIA**

Classical signs

- Fast and regular heart rate above 220 bpm.
- Strong precordial impulse.
- Loud S1 heart sound.
- Weakness/collapse.

Pathogenesis

The arrhythmia originates from anywhere above and including the atrioventricular node.

Supraventricular/atrial tachycardias most commonly result from primary myocardial disease.

These arrhythmias are most commonly seen in association with hypertrophic or restrictive cardiomyopathies.

Clinical signs

In the majority of patients, clinical **signs are related to** the underlying disease such as **cardiomyopathy** rather

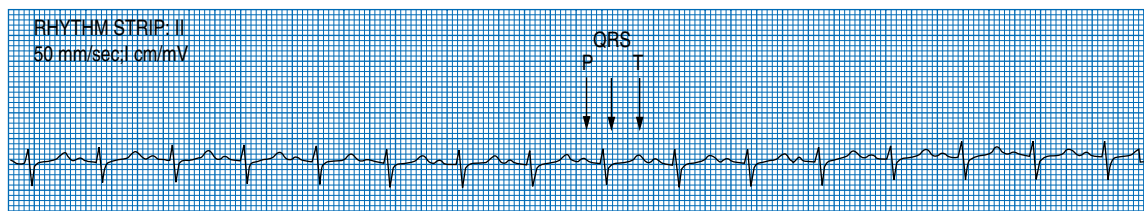

Figure 10.1. Sinus tachycardia at 225 bpm.

than the tachycardia, and include a heart murmur, dyspnea, weakness, collapse and lameness, paralysis or paresis from systemic thromboembolism.

Clinical signs related to a fast heart rate (> 280 bpm) include restlessness, tachypnea, open-mouth breathing, poor pulse quality and delayed capillary refill time.

Diagnosis

The diagnosis is based on physical examination and an electrocardiogram.

The **heart rate** is above **220 bpm**.

The **cardiac rhythm** is **regular**.

The **QRS complex** morphology is **normal**.

There is a P wave for every QRS complex, but the **P wave morphology may or may not be different** from normal sinus beats.

P waves may be “buried” in the S–T segment.

The **arrhythmia** may be **sustained** or **occur in paroxysms**.

The **changes** in the **heart rate** are **abrupt**. The **arrhythmia may terminate spontaneously** with a sudden decrease in heart rate.

The **QRS complex** may be slightly **aberrant** in the beginning of the paroxysm of tachycardia.

The QRS complex may alter its configuration (electrical alternans) in the first few seconds of the run of tachycardia.

Differential diagnosis

Sinus tachycardia may look identical to supraventricular tachycardia sinus on the ECG. Excessive heart rate (greater than 250 bpm) is more likely to be supraventricular tachycardia. Supraventricular tachycardia may have abnormal P wave morphology or lack P waves compared to sinus tachycardia where P waves are normal.

Motion or electrical artifact can usually be resolved by improved ECG recording technique: repositioning the electrodes, moistening the skin with alcohol, positioning the cat on a non-metal table isolated from other electrical devices.

Treatment

If the patient is **symptomatic** (hypotension, cardiogenic shock, collapse) for the arrhythmia, then treatment is required. The following drugs can be used in succession and are written in order of preference if the previous drug is not effective.

- **Diltiazem** at 0.1–0.3 mg/kg IV slow bolus over 3–5 minutes. The dose can be repeated in 5–10 minutes if sustained SVT. After IV bolus an intravenous constant rate infusion can be started at 5–20 µg/kg/min. Diltiazem is compatible with any type of IV fluids.
- **Esmolol** at 250–500 µg/kg IV bolus given slowly over 1 minute. The bolus can be followed with a constant rate infusion at 50–200 µg/kg/min. Esmolol is compatible with 5% dextrose.
- **Propranolol** at 20 µg/kg IV slow bolus over 5 minutes. Propranolol can be given up to a total dose of 100 µg/kg in repeated boluses.

If the patient is **not symptomatic** for the arrhythmia:

- Atenolol at 6.25–12.5 mg/cat PO every 12 hours.
- Diltiazem at 7.5–15 mg/cat PO every 8 hours.
- Propranolol at 2.5–5 mg/cat PO every 8–12 hours.
- Sotalol at 10–20 mg/cat PO every 12 hours.

Prognosis

The **prognosis** depends on the underlying **etiology**.

In general, the presence of this arrhythmia suggests advanced underlying cardiac disease.

In cases where the etiology is due to the existence of a by-pass tract, the cat may have a good prognosis, provided there is good control of the tachycardia.

ATRIAL FIBRILLATION*

Classical signs

- Fast and irregularly irregular variable heart rate.
- Strong precordial impulse.
- Loud and variable S1 heart sound.
- Weakness/collapse (rare).

Pathogenesis

This arrhythmia results from rapid disorganized atrial activity “bombarding” the AV node.

The heart rate may be normal or increased.

Its presence is usually associated with severe left atrial enlargement.

Clinical signs

In the majority of patients, clinical signs are related to the underlying cardiac disease.

Clinical signs related to a fast heart rate (> 280 bpm) include restlessness, tachypnea, open-mouth breathing, poor pulse quality and delayed capillary refill time.

The onset of atrial fibrillation may be marked by decompensation of the heart disease with pulmonary congestion.

Diagnosis

The heart rate may be normal or increased (Figure 10.2).

There are no visible P waves in any lead.

Small fluctuations on the baseline (f waves) may be seen and are not related to the QRS complex.

The ventricular rate is irregularly irregular, and the QRS complex has a normal configuration.

Differential diagnosis

Atrial flutter with variable conduction: With atrial fibrillation the baseline may have some deflections

which appear similar to P waves, but these can be distinguished from true P waves because they do not occur in every lead. With atrial flutter, P waves can be identified in all leads with a regular P–P interval.

Frequent paroxysmal supraventricular tachycardia: Usually paroxysmal supraventricular tachycardia is sustained for several beats. These beats have a regular R–R interval compared to atrial fibrillation where the R–R interval is always irregular.

Treatment

The goal is to obtain a **heart rate** below **180 beats per minute** in the exam room. The **heart rate** should be **determined by ECG rhythm strip**. Several recheck visits, usually weekly, may be needed for adjustment of medication to reach the target heart rate.

For cats with underlying dilated cardiomyopathy:

- Digoxin at 1/4 of 0.125 mg tablet/cat PO every 24–48 hours. Cats should be monitored carefully for signs of toxicity, and medication stopped if anorexia or vomiting develop.

For cats with preserved myocardial systolic function:

- Atenolol at 12.5 mg/cat PO every 12 hours.
- Diltiazem at 7.5–15 mg/cat PO every 8 hours.
- Propranolol at 2.5–5 mg/cat PO every 8–12 hours.
- Sotalol at 10–20 mg/cat PO every 12 hours.

Prognosis

In general, this arrhythmia is associated with **end-stage cardiac disease** and with **severe left atrial enlargement**. It may predispose to the development of thromboembolic disease.

The **prognosis** for long-term survival is **poor**.

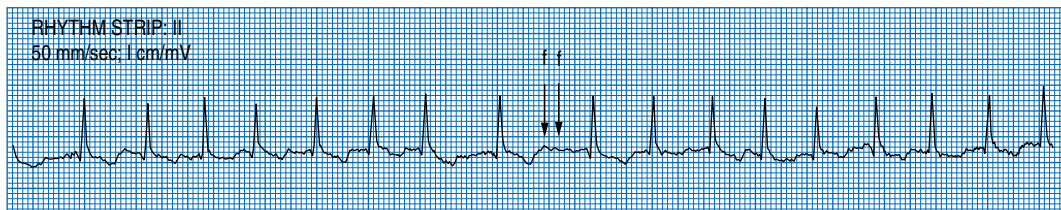

Figure 10.2. Atrial fibrillation. Note fibrillatory “f” waves.

VENTRICULAR TACHYCARDIA***

Classical signs

- Fast and regular heart rate above 220 beats per minute.
- Strong precordial impulse.
- Loud S1 heart sound.
- Weakness/collapse (rare).

Pathogenesis

The arrhythmia originates from the ventricles.

Ventricular tachycardias most commonly result from primary cardiac disease.

Most often, it is the result of myocardial fibrosis associated with a cardiomyopathy.

Sustained ventricular tachycardia may be caused by myocardial infarction.

Other causes of ventricular tachycardia include metabolic acidosis and drug-induced (digitalis).

Clinical signs

In the majority of patients, clinical signs are related to the underlying disease.

Some patients do not show clinical signs from the tachycardia.

Clinical signs related to a fast heart rate (> 280 bpm) include restlessness, tachypnea, open-mouth breathing, poor pulse quality and delayed capillary refill time.

Diagnosis

The heart rate is above 220 bpm (Figure 10.3).

There is no association between P waves and the QRS complex (P waves may be seen anywhere in the cardiac cycle).

The QRS morphology is aberrant.

This arrhythmia is usually regular, but some degree of variability of the cardiac rhythm may be present.

This arrhythmia may be sustained or occur in paroxysms.

Changes in heart rate are abrupt.

Differential diagnosis

Supraventricular tachycardia (supraventricular tachycardia with aberrant ventricular conduction, or atrial flutter without variable conduction but with aberrant ventricular conduction) may appear similar to ventricular tachycardia on the ECG. Supraventricular tachycardia may have P waves preceding the QRS complex.

Motion or electrical artifact can usually be resolved by improved ECG recording technique: repositioning the electrodes, moistening the skin with alcohol, positioning the cat on a non-metal table isolated from other electrical devices.

Treatment

If the patient is **symptomatic** (hypotension, cardiogenic shock, collapse), or sustained **heart rate** greater than **220 bpm**, then immediate therapy is recommended.

Correct any metabolic, electrolyte or acid–base abnormalities.

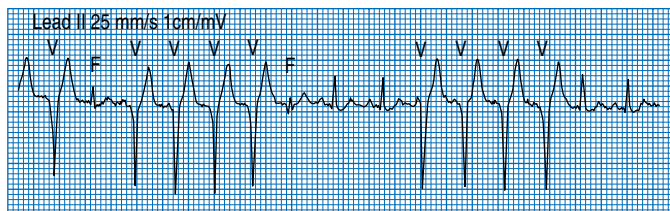

Figure 10.3. Ventricular tachycardia. “V” marks VPCs. Fusion beats are marked “F”.

- The authors use **procainamide** at 5–10 mg/kg slow IV bolus. This bolus can be repeated once if necessary.
- **Esmolol** at 250–500 µg/kg IV bolus given slowly over 1 minute. The bolus can be followed with a constant rate infusion at 50–200 µg/kg/min. Esmolol is compatible with 5% dextrose.
- **Propranolol** at 20 µg/kg slow IV bolus. Repeat boluses can be given up to a total maximum dose of 100 µg/kg.

DO NOT USE LIDOCAINE IN CATS. Severe neurotoxicity can occur.

If patient is **not symptomatic** for the arrhythmia:

- Atenolol 6.25–12.5 mg/cat PO every 12 hours.
- Propranolol at 2.5–5 mg/kg PO every 8 hours.
- Sotalol 10–20 mg/cat PO every 12 hours.
- Procainamide 10–20 mg/kg PO every 8–12 hours.

Prognosis

Most cats with sustained ventricular tachycardia have severe myocardial damage and are at high risk of sudden death.

The prognosis is fair.

PREMATURE BEATS

The following are definitions of electrocardiographic findings necessary to understand the distinguishing features between supraventricular and ventricular premature beats:

- A **fusion beat** occurs when the ventricles are **activated by two different wave** fronts, resulting in **abnormal/aberrant appearance** of the QRS complex.
- An **interpolated beat** is when a ventricular beat occurs between **two normal beats** without **disturbing** the cardiac rhythm.
- The **re-setting** or **non-resetting** of the **sinoatrial node** refers to the **influence** of the **premature beat** on the **basic sinus rhythm**.
- If the rhythm is **disturbed** by the **premature beat** then the rhythm is **reset**. **Resetting** of the basic rhythm is also referred to as **non-compensatory pause**.

SUPRAVENTRICULAR PREMATURE BEATS (SVPBS)***

Classical signs

- Pulse deficits.
- Interruptions of rhythm regularity.

Pathogenesis

Premature beats result from two mechanisms, alterations in impulse formation and alterations in impulse conduction.

Alterations of impulse formation depend on the intrinsic automaticity of diseased cardiac cells.

- Diseased myocardial cells outside the specialized conduction system can acquire automaticity because of changes in the resting membrane potential.

Alterations of impulse conduction result from re-entry and by-pass tracts.

- **Re-entry**, is a self-sustaining electrical circuit that **repeatedly depolarizes** surrounding tissue.
- **By-pass tracts** alter the normal pathway of conduction by providing an **alternative pathway around** the AV node.

Clinical signs

Most patients show no evidence of clinical signs.

In some cases panting, restlessness and anxiety may be seen.

Diagnosis

The heart rate is normal and the cardiac rhythm is irregular because of the premature beats (Figure 10.4).

The ectopic P wave is premature, the configuration may be different from normal sinus beats.

The **morphology** of the **QRS complex** is **similar** to a normal sinus beat.

The **QRS complex** is usually **narrow**, but in **very premature beats** it may be **wider (longer duration)** than **normal**.

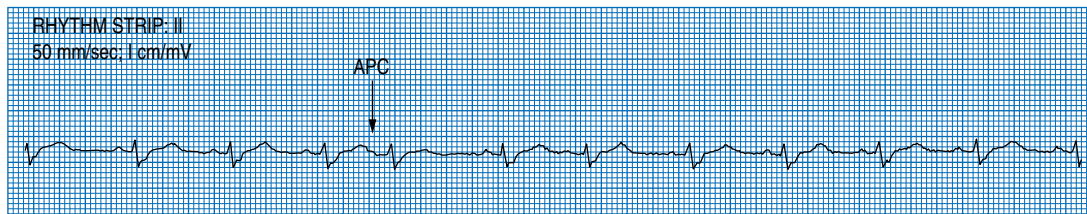

Figure 10.4. Atrial premature contraction (APC).

There is **association** between **P waves** and the **QRS complex**.

Supraventricular premature beats cause **re-setting** of the **sinoatrial node**.

Supraventricular tachycardia is always **regular**.

Differential diagnosis

Marked respiratory sinus arrhythmia is rare in cats but may mimic the presence of premature beats. **Sinus arrhythmia is rare** in cats and only occurs at slow heart rates. Increasing the heart rate above 180 bpm by excitement or atropine (0.04 mg/kg parenterally) will abolish sinus arrhythmia.

Motion or electrical artifact may mimic premature beats. Premature beats can be distinguished from motion artifact because they occur simultaneously in all leads.

Ventricular premature beats without a wide QRS complex may be erroneously classified as supraventricular premature beats. Supraventricular premature beats will usually reset the sinus rate.

Treatment

Isolated premature beats do not require therapy unless they present with other more severe arrhythmias.

If there is suggestion of hemodynamic compromise therapy may be considered:

- Atenolol at 6.25–12.5 mg/cat PO every 12 hours.
- Diltiazem at 7.5–15 mg/cat PO every 8 hours.
- Propranolol at 0.5–1 mg/kg PO every 8–12 hours.
- Sotalol at 10–20 mg/cat PO every 12 hours.

Prognosis

The prognosis depends on the underlying cardiac disease, but in general, this class of arrhythmias is

not likely to severely compromise the patient's outcome.

If the arrhythmia is frequent and is a result of **severe left atrial enlargement**, these beats may reflect atrial electrical instability and **precede the development of atrial fibrillation**.

VENTRICULAR PREMATURE BEATS (VPBS)***

Classical signs

- Pulse deficits.
- Interruptions of rhythm regularity.

Pathogenesis

Premature beats result from two mechanisms, alterations in impulse formation and alterations in impulse conduction.

Alterations of impulse formation depend on the intrinsic automaticity of diseased cardiac cells.

- Diseased myocardial cells outside the specialized conduction system can acquire automaticity because of changes in the resting membrane potential.

Alterations of impulse conduction result from re-entry and by-pass tracts.

- **Re-entry**, is a self-sustaining electrical circuit that **repeatedly depolarizes** surrounding tissue.
- **By-pass tracts** alter the normal pathway of conduction by providing an **alternative pathway around the AV node**.

Clinical signs

Most patients show no evidence of clinical signs.

In some cases with frequent VPBs panting, restlessness and anxiety may be seen.

Diagnosis

The heart rate is normal and the cardiac rhythm is irregular because of the premature beats (Figure 10.5).

The **morphology** of the QRS complex is **abnormal/aberrant** when compared with the normal sinus beat.

The **QRS complex** is **wider** than normal and has a **bizarre appearance**.

VPBs may occur as a **fusion beat**.

VPBs may occur as an **interpolated beat**.

There is **no association** between the P waves and the QRS complex.

VPBs do **not re-set** the sinoatrial node.

Differential diagnosis

Marked respiratory sinus arrhythmia is rare in cats but may mimic the presence of premature beats. **Sinus arrhythmia is rare** in cats and only occurs at slow heart rates. Increasing the heart rate above 180 bpm by excitement or atropine (0.04 mg/kg parenterally) will abolish sinus arrhythmia.

Motion or electrical artifact may mimic premature beats. Premature beats can be distinguished from motion artifact because they occur simultaneously in all leads.

Supraventricular premature beats with aberrant ventricular conduction may be erroneously classi-

fied as ventricular premature beats. Supraventricular premature beats will usually reset the sinus rate.

Treatment

Isolated premature beats do not require therapy unless present with other more severe arrhythmias.

If there is a large number of ventricular premature beats where the **premature QRS falls within the preceding T wave** (R on T phenomenon), therapy should be considered.

If there is suggestion of hemodynamic compromise therapy may be considered:

- Atenolol at 6.25–12.5 mg/cat PO every 12 hours.
- Propranolol at 0.5–1 mg/kg PO every 8–12 hours.
- Procainamide at 10–20 mg/kg PO every 8–12 hours.
- Sotalol at 10–20 mg/cat PO every 12 hours.

Prognosis

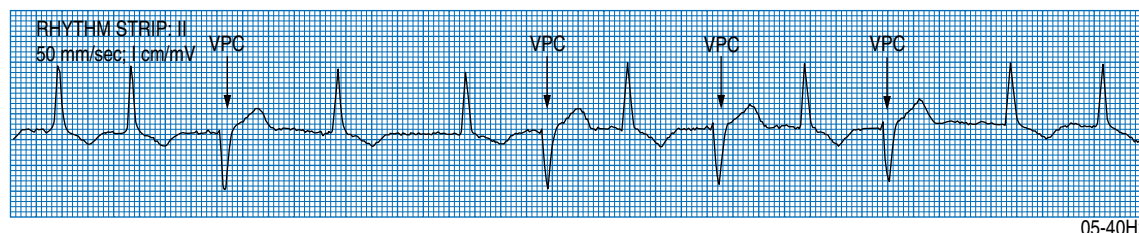

The prognosis depends on the underlying disease.

In most cases isolated premature beats are not life threatening.

When R on T phenomenon is present, patients may be predisposed to the development of ventricular tachycardia and/or sudden death.

If VPBs are due to **primary heart disease**, this likely reflects an advanced stage and may be associated with a **less-favorable prognosis**.

If due to causes **other than primary heart disease**, the **prognosis** is dependent on the **underlying disease**.

05-40Hz

Figure 10.5. Ventricular premature contractions.

DISEASES CAUSING BRADYCARDIA

SINUS BRADYCARDIA*

Classical signs

- Heart rate less than 120 beats per minute.
- Pulse is regular.
- Weakness.
- Collapse.

Pathogenesis

This arrhythmia originates from the sino-atrial node, the normal pacemaker of the heart. It is usually indicative of **severe underlying cardiac disease** or secondary to **extracardiac** disease.

Extracardiac causes most commonly associated with this arrhythmia are:

- Respiratory disease.
- Intracranial disease.
- Electrolyte disturbances (hyper or hypokalemia).
- Metabolic disturbances (acidosis, hypoglycemia).
- Hypothermia and hypoxia.
- Overdose of beta-blockers or calcium channel blockers, anesthetic agent or digitalis.

Clinical signs

If the heart rate is less than 100 beats per minute, weakness, collapse and lethargy may be seen.

In the majority of patients, clinical signs are related to the underlying disease.

Diagnosis

The heart rate is lower than 120 bpm.

There is a P wave for every QRS complex.

The QRS complex morphology is normal.

The atropine response test is normal (give 0.04 mg/kg IV while recording rhythm strip, if no response in 2 minutes repeat dose).

Differential diagnosis

Sinus bradycardia may be diagnosed as a junctional escape rhythm in cases where P waves are isoelectric.

Recording several leads, especially chest leads, will facilitate identification of P waves.

Treatment

Treat the underlying disease.

The response to atropine administration should be determined to assess normal sinus node function.

Prognosis

The prognosis depends on the underlying disease.

ATRIAL STANDSTILL*

Classical signs

- Weakness.
- Collapse.
- Lethargy.

Pathogenesis

The arrhythmia can result from atrial cardiomyopathy.

The arrhythmia can occur in **long-standing cardiac disease**, more commonly seen in the **dilated form**.

The arrhythmia can result from **hyperkalemia**, primarily because of feline urethral obstruction syndrome.

A serum potassium greater than 8.5 mEq/L (mmol/L) results in disappearance of P waves and results in atrial standstill.

Clinical signs

Signs may be related to the underlying disease.

Weakness, lethargy and collapse are most commonly seen.

Diagnosis

The heart rate is slower than 120 bpm (Figure 10.6).

There are no P waves in any lead.

The ventricular rhythm is regular.

The QRS complex morphology may be normal or increased in duration and bizarre in morphology.

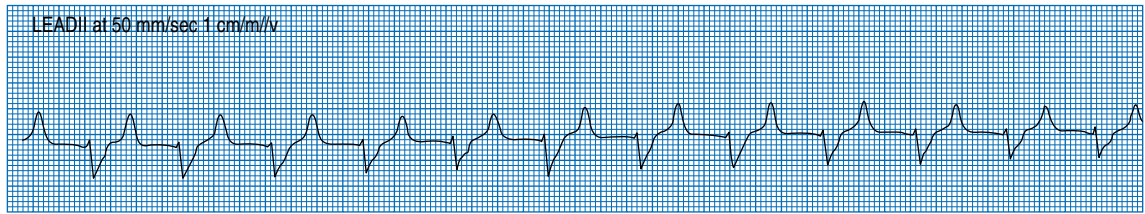

Figure 10.6. Atrial standstill with right bundle branch block. Note lack of P waves.

P waves should not be present in any lead.

In hyperkalemia T waves are tall and peaked.

Differential diagnosis

Sinus bradycardia with isoelectric P waves can mimic atrial standstill.

Recording several leads, especially chest leads, will facilitate identification of P waves.

Treatment

Treat the underlying disease. If patient is **symptomatic** for the slow heart rate, a pacemaker is indicated.

Pacemaker lead should be implanted on the epicardium.

Prognosis

Normal atrial activity will not be restored unless the cause is **hyperkalemia**.

After a successful pacemaker implantation, the prognosis is fair because the underlying atrial myopathy is likely to progress to congestive heart failure or thromboembolic disease.

SECOND DEGREE ATRIO-VENTRICULAR BLOCK**

Classical signs

- Weakness.
- Lethargy.
- Collapse.

Pathogenesis

The arrhythmia results from intermittent block of the atrial electrical wave through the AV node. There are two different types:

Mobitz type I

- This type of second-degree AV block is usually the result of **enhanced parasympathetic tone** and is **not associated** with **conduction system disease**.
- The **block** is usually **located above the His bundle bifurcation**.
- It is found in some patients with cardiomyopathy and in some cases may be drug induced (digitalis, beta-blockers, calcium channel blockers).

Mobitz type II

- This type of second-degree AV block is the result of **primary conduction system disease**, either due to degeneration of the His bundle, infiltrative cardiac disease or cardiomyopathy.
- The site of **block** is **located at or below the His bundle**.

Clinical signs

Mobitz type I

- This type of AV block is usually not associated with clinical signs.

Mobitz type II

- Most cases are asymptomatic, when symptoms are present the most common are:
 - Weakness.
 - Lethargy.
 - Collapse.

Diagnosis

Second degree AV block Mobitz type I (Figure 10.7).

- The basic rhythm is a **sinus** rhythm.

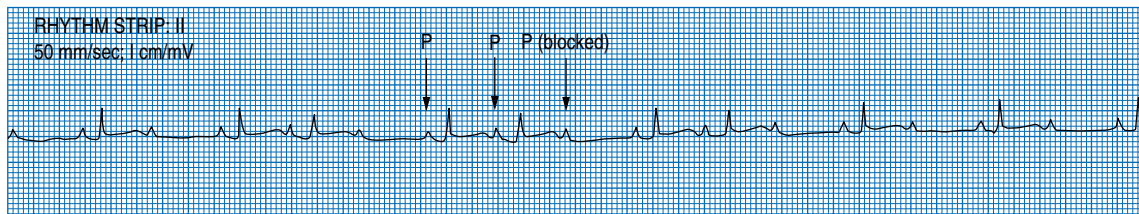

Figure 10.7. Second-degree AV block Mobitz type 1. Note progressive lengthening of the P–R interval.

- The **heart rate** may be **normal** or **lower** than normal.
- There is **progressive prolongation** of the **P–R interval**.
- The P–R interval prolongation is seen at progressively decreasing increments.
- There is progressive shortening of the R–R interval.
- One or more of the P waves are blocked.
- The P–R interval of the beat immediately after a blocked P wave is shorter than the beat immediately before the blocked beat.

Second-degree AV block Mobitz type II.

- The basic rhythm is a **sinus** rhythm.
- The **P–R interval** and the **R–R interval** are **constant**.
- There is unexpected failure of a P wave to conduct to the ventricle.
- The **ventricular rate** is **slower** than the **atrial rate**.
- The **degree of block**, i.e. the relative number of P waves and QRS complex is **variable**.
- The **QRS complex** morphology may be **abnormal**.

Differential diagnosis

When the atrial and ventricular rates are multiples of each other and variable in rate, **third-degree AV block** may mimic second-degree AV block Mobitz type II. Usually the QRS complexes are wide and bizarre with third-degree AV block, but look normal with second-degree AV block.

Artifact mimicking a blocked P wave. Premature beats can be distinguished from motion artifact because they occur simultaneously in all leads.

Treatment

Second-degree AV block Mobitz type I:

- Usually **does not** require **therapy**.

- The response to atropine should be determined. With normal AV nodal function, blocked P waves should disappear and the rhythm becomes regular.

Second-degree AV block Mobitz type II:

- The **treatment** depends on the **severity** of the **block**.
- If the ventricular rate is adequate and the patient does not have symptoms that are explained by the cardiac rhythm, then treat the underlying disease.
- If the patient is **symptomatic** for the bradyarrhythmia:
 - Medical therapy can be tried:
 - Theophylline 20 mg/kg PO every 24 h.
 - Propantheline bromide 7.5 mg/cat PO every 8–12 h.
 - Terbutaline 0.625 mg/cat PO every 8–12 h.
 - Responses to medical therapy are variable and usually temporary, and a **pacemaker** is usually indicated.

Prognosis

Second-degree AV block Mobitz type I:

- The prognosis is good.

Second degree AV block Mobitz type II:

- If the patient is **asymptomatic** and there is no progression of the severity of the AV block, then the prognosis is **favorable**.
- This **form** of AV block may **progress** to **third-degree AV block**.
- Restoration of normal AV conduction is not expected.

THIRD-DEGREE AV BLOCK

Classical signs

- Weakness.
- Lethargy.
- Collapse.

Pathogenesis

This arrhythmia results from **complete block** of the atrial electrical wave through the AV node.

The site of **block** is **at or below the bundle of His**.

The most common etiologies are:

- Cardiomyopathy.
- Degeneration, fibrosis or infiltration of the conduction system.

Clinical signs

In some cases, no clinical signs are present.

If there are clinical signs these are due to a combination of the underlying disease and the degree of bradycardia.

Usually the heart rate is below 100 beats per minute and the signs are:

- Weakness.
- Lethargy.
- Collapse.

Diagnosis

In third-degree AV block there is **complete dissociation** between the **atrial rhythm** and the **ventricular rhythm** (Figure 10.8).

The **P–P interval** and **R–R interval** are usually **constant**.

The atrial rate is higher than the ventricular rate.

The **P wave** configuration is **normal**.

The QRS complex morphology is normal if the escape focus responsible for ventricular activation is located above the bifurcation of the His bundle.

The **QRS complex** morphology is more **commonly abnormal** and is wide and bizarre.

Differential diagnosis

Advanced second-degree AV block may mimic intermittent third-degree AV block.

Treatment

Many cats are **asymptomatic** with this arrhythmia; therefore treatment is not indicated for these patients.

If **symptoms** of collapse or weakness are present medical therapy can be tried:

- Theophylline 20 mg/kg PO every 24 h.
- Propantheline bromide 7.5 mg/cat PO every 8–12 h.
- Terbutaline 0.625 mg/cat PO every 8–12 h.

Responses to medical therapy are variable and usually temporary and a **pacemaker** is indicated.

Prognosis

The prognosis is poor for restoration of normal AV conduction.

Successful pacemaker implant is associated with a good prognosis if severe morphologic cardiac disease is not present.

- **Epicardial leads are recommended.** The authors do not recommend the use of transvenous pacemaker leads in cats. Transvenous pacemaker leads are commonly associated with post-operative complications, resulting in severe pleural effusion due to thrombosis of the cranial vena cava.

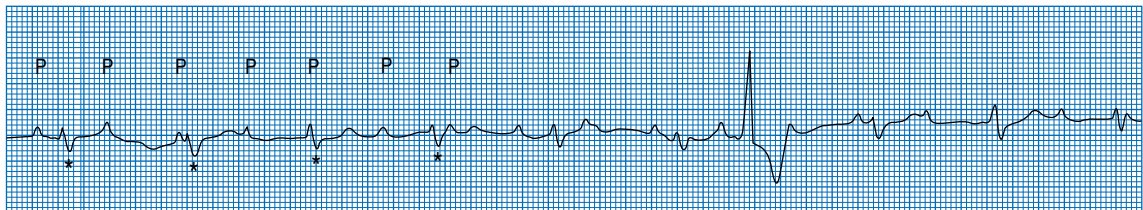

Figure 10.8. Third-degree AV block. Note the lack of relationship between P waves and QRS complexes marked with asterisk.

PART 4

Cat with urinary tract signs

11. The cat straining to urinate

Lucio John Filippich

KEY SIGNS

- Straining to urinate.
- Excessive time spent in the litter box.
- Urination in inappropriate places.

MECHANISM?

- Straining in cats during micturition is due to **increased urethral outflow resistance and/or lower urinary tract inflammation or pain**.
- Hematuria associated with difficult or painful urination indicates lower urinary tract bleeding.
- Cats straining to urinate may also **spend excessive time in the litter box** or have **inappropriate urination** which needs to be differentiated from constipation, and behavioral causes of inappropriate urination.

WHERE?

- Lower urinary tract (urinary bladder, urethra and prostate gland).

WHAT?

- Although several lower urinary tract diseases can cause cats to strain, most are idiopathic, followed by urolithiasis and bacterial cystitis/urethritis.

QUICK REFERENCE SUMMARY

Diseases causing straining to urinate

MECHANICAL

- **Hypercontractile bladder*** (p 190)

Occurs when detrusor muscle contractions are triggered at low volumes and pressure, resulting in urinary bladder storage dysfunction. It may be due to reduced bladder capacity, excessive sensory input or neurologic disorders. Clinical signs include incontinence and pollakiuria associated with a relatively empty urinary bladder.

- **Urethral stricture** (p 191)

Dysuria associated with urine dribbling and an over-distended urinary bladder.

METABOLIC

- **Urolithiasis**** (p 184)

Mainly seen in middle-aged cats showing persistent or recurring cystitis and hematuria. The formation of small uroliths can lead to urethral obstruction, especially in male cats. Most frequent uroliths are calcium oxalate and struvite.

NEOPLASTIC

- **Neoplasia*** (p 191)

Tumors of the lower urinary tract are rare, often malignant and mainly seen in cats over 8 years of age. Dysuria and intermittent or persistent hematuria may occur depending on the type and location of the neoplasm.

INFLAMMATORY

- **Infectious cystitis/urethritis*** (p 187)

Infectious agents, usually bacterial, may cause inflammation of the urinary tract. Most bacterial infections are secondary to other causes of lower urinary tract disease or the use of indwelling urinary catheters. Clinical signs include dysuria, pollakiuria with or without hematuria. The urinary bladder is usually empty.

IDIOPATHIC

- **Obstructed lower urinary tract disease (LUTD)**** (p 179)

Urethral plugs are formed causing mechanical urethral obstruction that can lead to bladder distention, post-renal renal failure and death. Occurs mainly in male cats under 5 years of age. Acute onset of dysuria, pollakiuria and stranguria. Abdominal palpation reveals a non-expressible, firm, often painful, over-distended urinary bladder. Signs of uremia include depression, vomiting, dehydration, hypothermia, bradycardia and general muscle weakness.

- **Non-obstructed lower urinary tract disease (LUTD)/feline idiopathic cystitis***** (p 176)

Hemorrhagic cystitis of unknown etiology mainly seen in cats 2–6 years of age. History of recurring bouts of dysuria, pollakiuria and hematuria. Abdominal palpation reveals a small contracted, painful urinary bladder. The urine usually contains frank blood and the duration of the hematuria varies.

TRAUMA

- **Urethral trauma*** (p 189)

May result from pelvic fractures, surgery and catheterization especially when associated with urethral obstruction. Urethral rupture may result in subcutaneous accumulation of urine in the perineal region leading to swelling, discoloration and necrosis of the skin.

TOXIC

- Cyclophosphamide toxicity (p 191)

The use of cyclophosphamide as a therapeutic agent can lead to hematuria and dysuria.

INTRODUCTION

MECHANISM?

Straining in cats during micturition is due to increased urethral outflow resistance and/or lower urinary tract inflammation or pain.

Straining cat exhibits clinical signs such as **dysuria** (difficult or painful urination), **stranguria** (slow and painful urination with a narrow or dribbling urine stream), **pollakiuria** (abnormally frequent urination) with or without hematuria.

Hematuria associated with dysuria indicates lower urinary tract bleeding.

Owners may complain of **inappropriate urination** or **excessive time spent in the litter box**, so these need to be differentiated from behavioral causes of inappropriate urination and constipation.

Urinary bladder **innervation is primarily autonomic. The storage phase is controlled by sympathetic innervation.**

- During the **filling phase**, **sympathetic autonomic activity (hypogastric nerve)** dominates and causes the body of the **bladder to relax (β -adrenergic stimulation)** and the **internal sphincter to contract (α -adrenergic stimulation)**.
- There is also an α -receptor-mediated inhibition of parasympathetic ganglion transmission.

Pudendal nerves (somatic innervation) stimulate contraction of the external urethral sphincter (and anal sphincter).

Bladder emptying is under parasympathetic control.

Stretch receptors in the detrusor muscle are gradually stretched during bladder fill. **Afferent pelvic nerve fibers (parasympathetic) detect changes in the amount of stretch** during filling and when the threshold of bladder capacity is reached, they **discharge impulses to the sacral spinal cord**.

- These impulses are relayed through the spinoreticular pathways to the **pons** (pontine mesencephalic reticular activating system) in the brain stem where a detrusor response is integrated.
- Efferent motor impulses descend the spinal cord via the reticulospinal pathway to the sacral parasympathetic nucleus, and then on to the **detrusor muscle via the pelvic nerve**.

Each muscle fiber in the detrusor muscle does not receive direct innervation; rather **“pacemaker” fibers** scattered through the detrusor are depolarized with subsequent **spread** of excitation to adjoining muscle fibers through **“tight junctions”**. Tight junctions are areas of fusion of the outer components of the cell membrane.

The resulting wave of excitation causes **contraction of the detrusor, which pulls the neck of the bladder open like a funnel and squeezes out the urine**.

Simultaneously with detrusor muscle contraction, **inhibitory interneurons** are activated in the sacral spinal cord, which synapse on **pudendal motor neurons**. The **pudendal neurons are inhibited, resulting in relaxation of the external urethral sphincter**.

Once the bladder is empty, pelvic nerve activity ceases and the hypogastric and pudendal nerves are no longer inhibited. Detrusor muscle relaxation and urethral sphincters contraction returns and the filling phase begins again.

A **thin mucus layer of glycosaminoglycans (GAGs)** which help **prevent transepithelial movement of urinary substances** covers the urinary bladder mucosa. Defects in surface GAGs may allow urinary substances (protons, potassium ions or hyperosmolar fluid) to penetrate the bladder mucosa initiating sensory nerve stimulation, mast cell activation and/or induce an immune-mediated or neurogenic inflammatory response.

Excitation of sensory afferent neurons (c-fibers) and release of neuropeptides and/or **activation of mast cells** in proximity to neuropeptide-containing sensory neurons may **lead to inflammation, pain and tissue injury**.

Mast cell activation results in secretion of biologically active substances (histamine) that may be responsible for the inflammation, pain and smooth muscle contraction seen in bladder disease.

WHERE?

Lower urinary tract (urinary bladder, urethra and prostate gland).

WHAT?

Incidence is about 0.5–0.8% of hospital admissions. Although several lower urinary tract diseases can cause cats to strain, **most are idiopathic**, followed by **urolithiasis and bacterial cystitis/urethritis**.

DISEASES CAUSING SIGNS OF STRAINING

NON-OBSTRUCTED IDIOPATHIC LUTD (IDIOPATHIC CYSTITIS, INTERSTITIAL CYSTITIS)***

Classical signs

- Frequently seen trying to urinate (pollakiuria).
- Spends more time in litter box.
- Strains with little or no urine passed (stranguria/dysuria).
- Blood tinged urine ± blood clots (hematuria).
- Cat may cry out during urination.
- Cat may urinate in inappropriate places.

Pathogenesis

Non-obstructed idiopathic LUTD, also known as **idiopathic or interstitial cystitis**, commonly **presents as hemorrhagic cystitis**. It is the most common cause of signs of lower urinary tract disease in cats, and accounts for 60–70% of cases.

The syndrome is **self-limiting, but recurring**.

Although the etiology is unknown, uropathogens, and inflammation triggered by neurogenic mechanisms or urinary constituents have been postulated.

Stress may play a precipitating role in some cases.

Cats were significantly more likely to be **male, overweight and pedigree**. Several **stress factors** were found to be involved including **living with another cat with which there was conflict**.

Signs and pathophysiology appear analogous to **interstitial cystitis in human beings**.

Feline idiopathic or interstitial cystitis has been associated with local abnormalities in the bladder, and abnormalities in the endocrine system, the central nervous system, and the efferent and afferent neurons.

Bladder abnormalities include decreased urine glucosaminoglycan (GAG) excretion, submucosal petechial hemorrhage (glomerulations) visible when the bladder is distended with water at low or high pressure, increased mast cells in the bladder wall, and increased bladder permeability.

Increased concentrations of the neurotransmitter P and its receptor are present in the bladder wall which may increase the inflammatory response.

Increased sympathetic outflow from the brain is present, and this may result in increased inflammatory response in the bladder and increased permeability.

- Stress and pain increase the sympathetic outflow from the brain, and stress appears to precipitate signs in susceptible cats.

Cats with interstitial cystitis have **reduced cortisol concentrations after stimulation with ACTH**, and have smaller adrenal glands with smaller zona fasciculata and reticularis than healthy cats. These findings suggest cats with interstitial cystitis have primary adrenal insufficiency. Reduced adrenal cortical reserve may result in increased sympathetic nervous system

output. Replacement therapy is not effective and not indicated.

Cats with interstitial cystitis are more likely to have **gastrointestinal signs and behavior abnormalities**, suggesting **multiple organ abnormalities**. Recent data suggest interstitial cystitis represents a neuroendocrine disorder rather than a primary bladder disorder.

Clinical signs

More common in female cats in some countries, for example Australia, although equal sex distribution is reported in other countries (USA).

Mainly occurs in **cats 2–6 years of age**.

Typical history is of **recurring bouts of hematuria lasting a few hours to several days** associated with frequent urination and straining. The cat urinating in inappropriate places is also often reported.

Abdominal palpation reveals a **small contracted urinary bladder**, which is often painful on palpation.

The **urine usually contains frank blood** and the duration of the hematuria may vary from a few hours to many days. Blood clots may be seen occasionally in the voided urine.

Diagnosis

Diagnosis of non-obstructed idiopathic LUTD or idiopathic cystitis **is one of exclusion**. It is based on the presence of signs of lower urinary tract disease, and exclusion of other causes of signs using urine culture, and imaging techniques such as plain radiographs, contrast radiography and ultrasonography.

History and physical examination can exclude urethral obstruction. External abdominal palpation reveals a small, often firm, urinary bladder that may go into spasm on palpation. In contrast, with urethral obstruction, the bladder is large on palpation.

Urinalysis.

- A voided sample is sufficient to confirm hematuria but a **cystocentesis sample is required for urinalysis and culture**. If the bladder is empty at presentation, the cat will need to be admitted and bladder fill monitored (see page 188, Infectious Cystitis).

- Urinalysis is more suggestive of a bleeding disorder (**hematuria; >5 RBC/hpf, <5 WBC/hpf**) than an inflammatory disease (pyuria > 5 WBC/hpf).
 - Erythrocytes in urine may be at various stages of degeneration, suggesting chronic bleeding.
 - **Pyuria (>5 WBC/hpf) is not a feature of this disease.**
- Urine is bacteriologically sterile.
- Crystalluria is usually absent, and when present, the crystals (struvite) are of normal size and number.

Radiography or ultrasonography.

- Survey abdominal radiographs are usually normal.
- Contrast radiographs may reveal **bladder wall thickening and mucosal irregularities**.
- **Ultrasonographic finding may be normal** or reveal hyperechoic material presumed to be crystalline in nature, blood clots and **mural irregularities or thickenings**.
- Imaging can be used to exclude urolithiasis and neoplasia.

Cystoscopic examination may show increased mucosal vascularity, superficial urothelial desquamation and **submucosal hemorrhage**.

Bladder wall biopsy via cystoscopy is increasingly being used in practice and may show epithelial hyperplasia, mucosal necrosis, muscular degeneration, edema, fibrosis, and perivascular accumulation of lymphocytes and hemorrhage.

Differential diagnosis

Cystitis/urethritis typically occurs in middle-aged or older cats and is characterized by pyuria and bacteriuria.

Urolithiasis occurs in middle-aged or older cats, and imaging reveals a urolith.

Hypercontractile bladder is usually not associated with hematuria, despite signs of straining and pollakiuria.

Neoplasia occurs in older cats and ultrasound or contrast radiography reveals a mass.

Behavioral causes of inappropriate urination are generally **not associated with hematuria, dysuria and stranguria**.

TREATMENT

Goals of therapy are to relieve the discomfort and pain associated with cystitis and to reduce the frequency of recurrence.

Signs are self-limiting despite therapy. Remission usually occurs within 7 days.

Several treatments, such as antimicrobials, glucocorticoids, progestagens (megestrol acetate), intravesicular administration of DMSO (10–20 ml of 10% solution instilled in bladder for 10 minutes under general anesthesia), anticholinergic agents, diuretics (furosemide), elimination diets, pentosan polysulfate and the surgical placement of a copper ring in to the bladder have been advocated, but their efficacy is questionable.

Antispasmodic drugs can provide symptomatic relief from straining. Flavoxate (50 mg BID), propantheline bromide (7.5 mg/cat sid PO), or phenoxybenzamine (2.5–10 mg PO q 8–12 h).

Pain relief via opiates (including a fentanyl patch, butorphanol elixir) are indicated for cats that are frequently straining to urinate.

Anti-inflammatory drugs such as piroxicam (0.3 mg/kg PO sid) may decrease straining and pollakiuria.

Megestrol acetate 5 mg sid PO for 5 days has been reported by one author (Norsworthy) to be the most effective drug for relieving dysuria.

Hydrodistension of the urinary bladder (80 cm of water for 10–15 minutes) may give relief of signs in some cats and prevent recurrence.

Cosequin (pentosan polysulfate (Elmiron) 8 mg/kg PO q 12 h) is a **glycosaminoglycan (GAG)** which is used in humans with interstitial cystitis to promote urothelial GAG formation. It can be mixed in the food and given indefinitely to reduce recurrence. However, GAG replacers have not been proven to be more effective than placebo in cats with interstitial cystitis.

Feed exclusively a specially formulated non-calcinogenic **diet that is used to minimize struvite crystal formation and maintain a low urine pH (<6.5) and specific gravity (<1.030)**. Such diets have been shown to be effective. However, struvite crystalluria does not appear to be a significant factor in non-obstructed

LUTD, and the benefit of these diets may be from the reduction in urine SG.

Canned food has been shown to reduce the incidence of feline lower urinary tract disease compared to dry food, probably because of the lower urine SG produced. **Constancy of diet may help as dietary change can precipitate signs.**

Aim for a **low urine specific gravity (eg. 1.020)**, by adding water or a meat-flavored liquid to the food. Urine should look like water and have no odor. If feeding dry food, add 1 cup of water to 1 cup of dry food and allow it to soak for at least 5 minutes.

Amitriptyline (2.5–5 mg/cat orally at night) may be useful in some cats to reduce signs of irritative voiding but not hematuria. It is a tricyclic antidepressant which prevents mast cell degranulation and has anti-inflammatory, analgesic, anticholinergic and alpha adrenergic blocking effects. A significant reduction in the frequency of recurrence may occur with prolonged use, without improvement in urinalysis or cystoscopy findings. Adverse reactions reported in cats include sedation, weight gain, unkempt haircoat, urine retention, thrombocytopenia and neutropenia.

Reduction of stress and environmental change may help to prevent recurrence. In susceptible cats, episodes can be triggered by environmental change (e.g. changes in food, house, animals or people in the house).

- Use of the synthetic **feline facial pheromone** (Feliway, Ceva Animal Health), which reduces anxiety in cats may be beneficial in some situations. In cats with interstitial cystitis, there was a trend to show fewer days with clinical signs of cystitis in cats where the environment was treated with the pheromone.

Ensure that there are sufficient litter boxes and they are cleaned frequently.

If signs do not resolve within 7 days, the cat should be re-evaluated for other diseases causing these signs.

Prognosis

Prognosis for recurrence is guarded because the etiology is unknown and treatment is largely supportive in nature.

Recurrence of signs within 6–12 months occurs in a high percentage of cats.

OBSTRUCTED IDIOPATHIC LUTD**

Classical signs

- Straining with little or no urine passed (stranguria/dysuria).
- Frequently seen trying to urinate (pollakiuria).
- Cat may cry out during urination.

Pathogenesis

Historically, diets or components of diets, such as magnesium and phosphate, have been implicated in the pathogenesis of some forms of idiopathic LUTD in cats.

Although the etiology is unknown, **urethral plugs** are formed causing mechanical urethral obstruction that can lead to bladder distention, post-renal renal failure and death.

- It occurs **mainly in male cats** possibly because their **urethra is longer, narrower** and less distensible.
- The **urethral plugs are composed of colloidal matrix** into which are embedded crystals, usually struvite crystals (magnesium ammonium phosphate).
 - The ratio of matrix to crystalline material varies with **some urethral plugs (about 5%) lacking crystalline material** and are known as non-crystalline matrix plugs.
 - Other **crystals that occur less commonly** include ammonium acid urate, and **calcium phosphate** and calcium oxalate.
 - Some urethral plugs may also contain erythrocytes.
 - The exact chemical composition and **origin of the matrix are unknown** although **Tamm-Horsfall protein of renal origin has been implicated**.
- The factors(s) involved in the formation of urethral plugs are unknown and may be different for the different plugs.
- Since minerals other than struvite may be found in some urethral plugs, suggesting matrix per se may play an important primary role in the formation of some plugs.

- Acid–base status of the urine is important in crystal formation, with alkaline urine favoring struvite formation and acid urine favoring oxalate formation.
- The role of viruses is controversial.

Occasionally urethral obstruction is from a urolith, rather than a plug. Calcium oxalate urate and cystine uroliths are more common causes of urethral obstruction than struvite uroliths. The mechanism for urolith formation is different from plug formation, and is covered on page 184 in Urolithiasis.

Urethral obstruction **can result in post-renal renal failure** (obstructive nephropathy).

- The severity of the renal failure depends on the degree and duration of the obstruction.
- **Post-renal renal failure can be biochemically detected by 24 hours after complete obstruction**, and by **48 hours** clinical and metabolic changes can become **life threatening**.
- Post-renal renal failure is invariably reversible with appropriate treatment.

Bladder over-distention may result in ischemia, edema, hemorrhage and **loss of epithelium**. The **urethra, proximal to the obstruction, will have similar injuries** with desquamation of epithelium, edema and infiltration of neutrophils around blood vessels, lamina propria and muscle layers.

Post-obstructive diuresis may occur following relief of the obstruction and last for several days.

- The diuresis is possibly due to the clearance of accumulated metabolites and a temporary loss of concentrating ability by the renal tubules.
- Dehydration and possibly hypokalemia can occur during this polyuric phase.

Clinical signs

Almost always seen in **male cats under 5 years of age**.

History of **excessive licking around the perineal area and the penis** is often seen extruded from the prepuce.

Acute onset of dysuria.

The cat may cry out during urination.

Close inspection of the penis may show a **whitish, chalky material blocking the urethral orifice** and the tip of the penis traumatized due to excessive licking.

Abdominal palpation reveals a **non-expressible, firm, often painful, over-distended bladder**. Cats **obstructed for over 48 hours may show little or no signs of pain** on abdominal palpation and in such cases, the **bladder may rupture** if handled other than with extreme care and gentleness.

Cats with partial obstruction may be able to maintain a small bladder size and not develop renal failure. Such cats show stranguria (painful urination with a narrower urine stream).

Signs of uremia indicate complete obstruction for at least 48 hours.

- **Depression, anorexia**, vomiting, dehydration and **hypothermia**.
- **Hyperkalemia can cause bradycardia**, ventricular arrhythmia and general muscle weakness.
- Metabolic acidosis may exacerbate the effects of hyperkalemia on the myocardium.
- Shock.

Diagnosis

History and physical examination.

- **Acute onset of dysuria in a male cat.**
- A **distended, firm** and often painful urinary **bladder** on abdominal palpation.
- Whitish, chalky material seen blocking the urethral orifice or around the prepucal/perineal area.

Urinalysis.

- Varying degrees of **hematuria** depending on the duration of the obstruction.
- Pyuria is variable.
- **Crystalluria is often seen** and on many occasions large crystals are found in the urine. The significance of these large crystals is unclear.
- Urinary pH and specific gravity values, at presentation, are variable, but pH is usually acidic and **specific gravity generally approaches 1.020 with prolonged obstruction**.
- Glucosuria is variable.

Radiography. Urethral plugs are often not visible on plain radiographs.

Electrocardiography.

- Hyperkalemia (>6.0 mmol (mEq)/L). ECG changes are often evident when $K > 7$ mmol(mEq)/L.
 - Bradycardia.
 - Absence of a P wave.

- Widened QRS interval.
- Spiked T wave.

Blood tests.

- Changes in blood values (urea, creatinine, potassium, phosphorus, pH) depend on the severity of the renal failure.
- Serum values are usually normal in cats with lower urinary tract disease unless there is outflow obstruction or rupture.
 - **Post-renal azotemia (increased urea, creatinine), hyperphosphatemia, hyperkalemia** become evident by **24 hours**. Hypocalcemia is variable. Mild hyperglycemia may be present.
- The absence of clinical signs of hyperkalemia (bradycardia) does not eliminate the possibility of severe hyperkalemia.

Differential diagnosis

Urolithiasis occurs more often in middle-aged or older cats.

Functional urethral obstruction is often associated with other neurologic signs (see The incontinent cat).

Urethral trauma usually has a history and hindquarter lesions which are suggestive.

Stricture is usually preceded by a history of catheterization or trauma.

Neoplasia.

TREATMENT

Depends on the severity of the clinical signs at presentation.

If the cat is not showing clinical signs of renal failure or has not been obstructed for more than **24–36 hours, relieving the urethral obstruction** and giving a **balanced electrolyte solution**, subcutaneously or intravenously at 70 ml/kg is usually sufficient.

If the cat is showing **signs of renal failure**, or has been **obstructed for more than 36–48 hours, correcting the fluid and electrolyte imbalance takes priority over restoring urethral patency**.

- Cats in post-renal renal failure must first be stabilized before diagnostic tests, other than blood and urine sampling, are undertaken.

- Consider **cystocentesis** for **temporary relief of bladder distention**.
- Give **dextrose saline solution IV** (0.9% NaCl with 5% dextrose – add 100 ml of 50% dextrose per liter of fluids) to rehydrate the patient over 4–6 hours and reduce hyperkalemia, metabolic acidosis and azotemia.
- Cats in renal failure are frequently **hypothermic** and **should be warmed** to normal body temperature.

Remove the obstruction.

- **Immobilization.**
- **Sedation during catheterization will help minimize further urethral trauma and urethral or bladder rupture.**
- Urethral trauma from catheterization can lead to inflammation with edema of the periurethral tissue and subsequent functional urethral obstruction.
- Inappropriate force or the cat struggling during catheterization may result in urethral or bladder rupture.
- The degree of sedation required will depend on the cat's clinical condition and temperament.
- An opiate (pethidine (meperidine)) 1 mg/kg SC; butorphanol (0.05–0.4 mg/kg IV, SC; buprenorphine 0.005–0.01 mg/kg IV, SC) and acepromazine (0.02–0.05 mg/kg IV, SC) or an opiate and diazepam (0.25 mg/kg SC, IV) can be used.
- Premedicate with atropine sulfate (0.03 mg/kg) subcutaneously or intravenously combined in the same syringe as the opiate. **Intravenous ultra short-acting barbiturates** (sodium thiamylal or thiopentone (thiopental)), propofol, alfaxalone and **inhalant anesthetics** (isoflurane) can be used. Depressed cats can be masked down with isoflurane and oxygen. Beware of intubating the cat before it has reached a suitable plane of anesthesia, as intubation may cause reflex bradycardia or cardiac arrest. Spray the larynx with lignocaine (lidocaine) prior to attempting intubation.
- Succinylcholine is contra-indicated as it increases serum potassium levels.
- Catheterization of the bladder in cats with severe renal failure may be possible by using physical restraint only.
- **Catheterization.**
 - The method employed and the instrumentation used to remove the obstruction must ensure that no further urethral or bladder trauma occurs.
 - Exteriorize the penis from the prepuce and extend it caudally so as to straighten the natural curvature of the cat's penis. Clean with warm water.
 - As aseptically as possible, fill a **3.5 French, open-ended urinary catheter (olive tip urethral catheters, Jorgensen Laboratories) with lubricating gel (xylocaine jelly at room temperature)** and gently pass the catheter into the urethra, until it comes in contact with the obstructing material, which is **usually at the level of the bulbo-urethral gland** where the urethra narrows and becomes the penile portion.
 - **Instill 0.25 ml of lubricating gel** through the catheter into the urethra and remove the catheter. **After 3 minutes**, the jelly usually has lubricated and broken up the obstructing mass, allowing it to be spontaneously extruded like toothpaste by the high urethral pressure cranial to the obstruction. **If the material re-obstructs, repeat the procedure several times using 0.15 ml of gel**, until urine appears. This technique ensures that all the obstructing material in the urethra has been removed and little if any has been pushed into the bladder. If spontaneous resolution of the obstruction does not occur, **apply gentle pressure to the bladder**. Great care should be exercised when applying pressure to the urinary bladder, as it can lead to bladder rupture.
 - Retropulsion with a saline flush is commonly used in practice, but is more likely to lead to re-obstruction, because obstructing material is pushed into the bladder.
 - If **local anesthetic agents** are combined in the lubricating gel to anesthetize the urethral mucosa, they **should be used sparingly to avoid local and systemic toxic effects** that are more likely to occur in the presence of damaged urothelium.
 - **Recatheterize with a long, soft, flexible Teflon urinary catheter (3.5–4 French)**, secured in place with sutures, to empty the bladder completely.
 - Once the bladder has been catheterized, urine is allowed to drip freely. **Avoid removing urine by negative pressure (syringe) or by applying external pressure** on the urinary bladder as this can unnecessarily traumatize the bladder mucosa.
 - **If the urine is visibly clear: Instill 5–10 ml of sodium acetate/acetic acid buffer solution**

(**Wallpoles buffer solution**) into the **bladder** to **dissolve any struvite crystals**. If the catheterization was achieved with minimal trauma, an indwelling catheter is not required.

- **If hematuria is present: Wallpoles buffer solution should not be used.**
- **Instill 100 mg of ampicillin in 20 ml of normal saline** into the bladder. Give parenteral antimicrobials that are not nephrotoxic, such as amoxicillin/clavulanate, enrofloxacin. Leave the urinary catheter in situ for as shorter a time as possible. Indwelling catheters can induce further damage to the urothelium by disrupting its glycosaminoglycan coating and thus promote microbial adherence and urinary tract infection. **Remove the indwelling catheter once hematuria is no longer visible.**
- **An indwelling catheter is required if:**
 - Obstructing material was expelled into the urinary bladder.
 - Severe urethral trauma occurred associated with removal of the plug. Significant trauma occurs if excessive force or repeated catheterization attempts are necessary to unblock the urethra.
 - A large amount of potentially obstructing debris is present in the bladder, which may be determined during bladder emptying, by palpation of the empty bladder, or by radiography/ultrasonography.
 - Urine stream after relief of the obstruction is narrower than normal.
 - The urinary bladder does not contract normally after emptying, indicating atony.
 - Re-obstruction occurs, especially within 24 hours.
 - Measurement of urine flow rate is required during intensive care of critically ill cats.
 - In these situations, the advantages of maintaining urethral patency and decompression of a chronically distended, devitalized bladder outweighs the disadvantages of ascending bacterial infection and ongoing damage to the urethral mucosa.
 - Silicone elastomer catheters (Wysong urethral catheter) are preferred as they are soft, pliable, less irritant to the urethral mucosa and curl up inside the bladder without kinking as the bladder empties, thus avoiding bladder wall irritation.

- A closed urine drainage system is often impractical in the cat. However, it should be used if indwelling catheters are to be left in for more than 3–4 days. A closed drainage system involves connecting the urinary catheter, via extension tubing, to a sterile, empty fluid bag below the cat.
- Indwelling catheters should be used for as short a time as possible to minimize catheter-induced iatrogenic disease.
- Beginning the cat on phenoxybenzamine (2.5–10 mg PO q 8–2 h) may help to reduce re-obstruction or dysinergia once the catheter is removed.
- An Elizabethan collar and/or hobbles on the hind legs using self adhesive tape or elastoplast may be necessary to prevent the cat interfering with the urinary catheter.
- Most cats will not interfere with a properly placed or correctly selected indwelling urinary catheter. Interference usually indicates poor catheter placement or catheter-induced irritation.
- The use of antimicrobial therapy to prevent secondary urinary tract infection is controversial.
- To avoid developing resistant organisms, it is recommended that a broad-spectrum antimicrobial, such as amoxicillin be used only once infection occurs.
- Evidence that an infection is occurring includes the appearance of hematuria or increasing hematuria, bacteriuria and pyuria.
- Removal of the catheter at the first signs of urinary infection may obviate the need for antimicrobial therapy.
- Follow-up urine culture and susceptibility tests are essential to determine treatment success.
- Once the catheter is removed, the cat should be kept in hospital for a further 24 hours to ensure that it can urinate freely.
- **If the obstruction cannot be relieved:**
 - **General anesthesia** in an unanesthetized patient **may help to relieve urethral spasm**, and the intraluminal pressure present in the urinary bladder and urethra may facilitate the removal of the obstructing material.
 - The **use of acid buffer solutions** to dissolve the obstructing material **is ineffective** and time wasting, especially if the cat is in post-renal renal failure.

- **Decompress the bladder by cystocentesis** using a 23 G × 32 mm (1.25 in) needle attached to an extension tube, a 2-way valve and 50 ml syringe. Removal of approximately 30 ml of urine from the bladder **may trigger spontaneous micturition**. The bladder should not be manually palpated for the next 24 hours.
- Consider **cystotomy with placement of an indwelling catheter** (Foley catheter, 8 French; Stamey suprapubic catheter, 10 French) in the urinary bladder, and percutaneous prepubic urinary drainage or a perineal urethrostomy.
- **Perineal urethrostomy is only recommended as a last resort** because it does not prevent reoccurrence of non-obstructed disease and it can predispose to ascending urinary tract infection, urine scald dermatitis and urethral stricture.
- **Perineal urethrostomy is recommended if frequent urethral obstruction occurs despite adequate medical management or urethral lesions** exist that cause recurrent or persistent obstruction.

Prednisolone (2.5 mg/cat orally every 12 hours for 3–5 days) may reduce urethral inflammation but may predispose to urinary tract infection.

Functional urethral obstruction due to urethral irritation and inflammation resulting in urethral spasm can occur following mechanical obstruction. This is difficult to differentiate from mechanical urethral obstruction, however, failure to encounter obstructing material or a grating sensation during recatheterization, suggests function urethral obstruction.

Phenoxylbenzamine (5 mg/cat orally daily for 3–5 days) may help reduce urethral outflow resistance.

Bladder atony may occur due to overdistention and can be corrected (see The Incontinent Cat).

Postobstructive diuresis.

- Following relief of the obstruction, a **marked diuresis may occur and last for 2–10 days**.
- Intravenous fluid therapy is required to maintain hydration and electrolyte balance. Initially a **dextrose saline solution** is used to hydrate the patient over **4–6 hours**, followed by a **balanced electrolyte solution (lactated Ringers solution)** to maintain hydration and correct electrolyte imbalance.

- Hypokalemia may occur with prolonged diuresis or the use of potassium-free fluids. **Potassium supplementation** can be given in intravenous fluids (0.5 mmol/kg/h) or orally (2–6 mmol/cat/day) until the cat starts eating.
- The gluconate form of potassium is preferred orally.
- Once the cat voluntarily eats and drinks, the fluid rate is decreased over 24 hours while hydration status is monitored.

Prevention.

- Feed exclusively a specially formulated non-calcinogenic diet to minimize struvite crystal formation and maintain a low urine pH (<6.5) and low specific gravity (<1.030, ideally 1.020). Meat- or fish-flavored liquid or water can be added to increase water intake.
 - Canned food produces a lower urine specific gravity than dry food, and decreases the frequency of recurrence in cats. If feeding dry food, add 1 cup of water per 1 cup of diet and allow to soak at least 5 minutes before feeding.

Prognosis

The prognosis depends on the duration of the obstruction, on the ease of obtaining and maintaining urethral patency, and correction of renal failure.

Prognosis is grave if:

- The duration of the **obstruction is more than 60 hours**.
- The **packed cell volume of centrifuged bloody urine is greater than 2%**.
- **Urinary specific gravity is below 1.020**.

The **recurrence rate is 35–50%**, mainly within 6 months after hospitalization. Recurrence appears to be **higher in cats under 4 years of age**.

Studies on the efficacy of specially formulated diets in naturally occurring idiopathic LUTD are limited but the results are encouraging. Such diets have been formulated to reduce magnesium and phosphate intake and promote a dilute, acid urine. However, the pH of these diets may predispose to oxalate uroliths in susceptible cats.

The **prognosis following urethrostomy is good** in that recurrence of urethral obstruction is unlikely, but **recurring episodes of non-obstructed cystitis** may

occur. Post-surgically, urethral strictures and/or incontinence have been reported, but are uncommon following uncomplicated surgery. Urethrostomy may **predispose to ascending urinary tract infection.**

UROLITHIASIS**

Classical signs

- Blood-tinged urine (hematuria).
- Frequently seen trying to urinate (pollakiuria).
- Spends more time in litter box.
- Straining to urinate (dysuria).
- Cat may urinate in inappropriate places.

Pathogenesis

Urolithiasis in cats is uncommon and represents less than 5% of cats presented with hematuria and dysuria.

Urolithiasis is the formation of stones called uroliths (calculi) in the urinary tract.

Uroliths are made up of **crystalloid with very little organic matrix**, and although a particular chemical type usually predominates, the chemical composition of the urolith can be mixed.

- The main chemical composition of uroliths reported in cats, include **magnesium ammonium phosphate (struvite; 42%), calcium oxalate (46%)**, purine (uric acid and urates; 6%), calcium phosphate (<1%) and cystine (<1%).
- Each chemical type should be considered a separate disease process.
- The incidence of struvite uroliths appears to be decreasing while calcium oxalate uroliths are increasing. This is thought to be due to the increased use of acidifying diets in cats.

Urolithiasis is not a single disease entity, but rather the end result of one or more physiological and/or pathological processors, interrelated with some **predisposing factor(s), such as urine pH and concentration, excessive excretion of endogenous crystalloid-forming substances** (uric acid, amino acid cystine), **excessive mineral intake and genetic factors.**

Unlike the dog, struvite uroliths in cats are **usually not associated with urinary tract infection.**

Hypercalcemia (primary hyperparathyroidism, pseudohyperparathyroidism, idiopathic, hypercalcemia and vitamin D intoxication) results in hypercalciuria, which has been **associated with calcium oxalate urolith formation.** However, most cats with calcium oxalate uroliths have normal serum mineral levels.

Congenital portovascular anomalies and renal tubular reabsorptive defects have been associated with purine (urate) uroliths. Urate uroliths consist of either ammonium biurate (which occur with porto/vascular anomalies), uric acid or sodium acid urates (occur with tubular defects). Predisposed cats fed a high purine diet (e.g. liver) and producing concentrated, acidic urine are at a greater risk of producing purine uroliths.

Cystinuria due to **proximal renal tubular dysfunction** can **predispose to cystine urolith formation.**

Uroliths, especially those in the bladder, **can cause lower urinary tract disease.**

The formation of **small uroliths** can lead to **urethral obstruction**, especially in male cats.

Clinical signs

Mainly seen in **middle-aged adult cats.**

There appears to be no sex or breed predisposition.

Most cystoliths are asymptomatic.

Persistent or recurring cystitis may occur and present as increased frequency of urination, straining to urinate or increased time spent in the litter box or urinating in inappropriate places.

Hematuria varies from microscopic hematuria (>5 RBC/hpf) to gross hematuria.

Urethral obstruction may occur occasionally, more commonly with calcium oxalate, urate or cystine uroliths than with struvite uroliths.

Diagnosis

Physical examination. Cystic uroliths are usually difficult to palpate (<10%) because most are flattened disc-shape and few in number.

Urinalysis.

- Most uroliths and crystals in a urine sample are calcium oxalate or struvite, although heavy crystal-

luria with amorphous urates and phosphates is occasionally seen.

- **Urine sediment containing struvite crystals** (three- to six-sided colorless **prisms**) **suggests that the urolith is struvite** in composition.
- **Urine sediment containing calcium oxalate dihydrate** (colorless **envelopes** with dipyramidal or octahedral form) or monohydrate crystals (small spindles or dumbbells) suggests that the urolith is calcium oxalate in composition.
- **Ammonium biurate crystals** (yellow-brown spherulites; thorn apples) are common in cats with portosystemic vascular anomalies, however urate uroliths are uncommon. Rarely urate uroliths also occur due to tubular disease (cat has no signs of liver disease and normal pre- and post-prandial bile acids). Urate crystals associated with tubular disease appear different from biurates, and are composed of uric acid or sodium acid urate.
- However, **crystal type in urine and urolith composition can be different**.
- Uroliths found in alkaline urine are likely to be struvite or calcium phosphate (amorphous or long thin prisms).
- **Urinary tract infections are usually absent (<2%).**
- Hypercalciuria may occur with calcium containing uroliths.

Radiography.

- Plain abdominal radiographs may detect radiodense uroliths in the kidneys, bladder or urethra.
 - **Radiodense uroliths contain calcium salts**, such as calcium oxalate.
 - Struvite uroliths may contain calcium and become slightly radiodense.
- **Double-contrast cystography** can be used to detect radiolucent uroliths. The technique involves instilling, via a urinary catheter, 1–2 ml of water-soluble iodinated contrast material (positive contrast) into the urinary bladder, followed by a slow infusion of carbon dioxide or nitrous oxide gas (negative contrast), sufficient to distend the bladder (approximately 30 ml). Fatal air embolism can occur in cats with hematuria when air is used.
- **Retrograde contrast urethrography.** The technique involves infusing, as a bolus, 5 ml of positive contrast material through an open-ended urinary **catheter positioned in the distal ure-**

thra. To minimize back leakage, digital pressure around the catheter and urethra can be applied or balloon-tipped catheters (4 or 5 French) can be used to occlude the urethra. Radiographs are taken **during the infusion of the last portion of the bolus dose.**

Ultrasonography.

- Abdominal ultrasonography can be used to **identify radiodense and radiolucent cystic uroliths**, as well as soft tissue masses.

Blood tests (biochemistry).

- Elevated serum urea and creatinine levels suggest renal involvement.
- Elevated liver enzymes and/or low urea levels suggest liver dysfunction. Typically cats with ammonium biurate uroliths associated with portosystemic shunts have reduced serum urea levels, increased serum uric acid and bile acid levels and hyperammonemia.
- Hypercalcemia may suggest a calcium-containing urolith.

Urolith analysis.

- **Urolith analysis** provides valuable information that can be used in therapy to prevent the recurrence of urolithiasis.
- Crystallographic, X-ray diffraction and infrared spectroscopy techniques are preferable to qualitative chemical analysis (Oxford Stone Analysis Kit). A proper **quantitative analysis gives all the mineral components of the urolith by percentage and by location (surface, middle and center).** **Prevention therapy is based on the mineral composition of the center of the urolith** as precipitation of the central mineral initiates urolith formation.

Differential diagnosis

Infectious cystitis/urethritis is differentiated on the presence of bacteriuria and a positive culture.

Idiopathic LUTD tends to occur in young adult cats.

Treatment

Uroliths can be removed by medical dissolution or surgical resection. The type and location of the urolith, the severity of the clinical signs, the anesthetic risk, concurrent diseases, the sex and age of the cat, and the

owner's wishes will all influence which procedure is most appropriate.

- **Surgical removal.**

- Cystotomy is performed via a ventral midline abdominal approach. An avascular area near the apex of the bladder is selected, stay sutures (3-0 silk) placed on either side of the intended incision line and the bladder is emptied by cystocentesis. A 2-cm incision is made into the bladder wall and the uroliths removed. Before closure of the bladder, a urinary catheter attached to a saline-filled syringe is used to flush out any uroliths in the bladder neck and urethra.

- **Medical dissolution.**

- **Only nephroliths and cystoliths can be medically dissolved. Medical dissolution of uroliths in the ureters or urethra should not be attempted.**
- **Calcium oxalate uroliths can not be medically dissolved.**
- **Struvite uroliths can be medically dissolved.**
- Mineral composition of the urolith should be determined before dissolution therapy is attempted. However, this is often not possible, and crystals in the urine sediment are used as a guide.
- Dissolution diets are designed to produce an acidic, low-mineral, dilute urine environment in which cystic struvite uroliths dissolve over a period of 4–8 weeks. Nephroliths usually take longer to dissolve.
- **The dissolution diet should be fed for at least 2–4 weeks after uroliths are no longer visible radiographically or on ultrasound.**
- **Failure to dissolve the uroliths** may be due to poor owner compliance, the presence of urinary tract infection or the mineral composition of the urolith is not struvite.

Prevention

Long-term prevention strategies to prevent or minimize reoccurrence should be based on mineral composition of the urolith.

If infection is present, this must be treated and the urine (culture, urinalysis especially pH) monitored long term to ensure that the infection has been eliminated. **Urine**

pH should stay below 6.5 long term. Cats passing alkaline urine should be recultured.

Struvite urolithiasis.

- An acidifying, low-magnesium, low-phosphorus and low-calcium diet is recommended.
- Alternatively, urine acidifiers (ammonium chloride or DL methionine) to effect (approximately 1000 mg/cat/day) can be given orally at mealtime to ameliorate the postprandial alkaline tide. Acute toxicity with high doses cat occur, especially in kittens.
- Chronic metabolic acidemia due to long-term acidification can have adverse effects.

Calcium oxalate urolithiasis.

- A non-acidifying regular diet is recommended.
- Diets used to prevent struvite urolithiasis should not be used.
- If the diet does not maintain the **urine pH above 7.5, potassium citrate** (50–75 mg/kg orally 12 hourly) therapy may be used. Monitor total CO₂ to ensure alkalosis does not occur. Keep TCO₂ about 20 mmol(mEq)/L.
- **Vitamin B6** (2 mg/kg orally every 24–48 hours) may be useful.
- The cause of hypercalcemia, if present, should be determined and treated.
- **Thiazide diuretics** (chlorthiazide, 10 mg/kg orally 12 hourly) with potassium supplementation have been used in normocalcemic dogs with oxalate uroliths.

Urate urolithiasis.

- Avoid acidifying diets and diets high in purine precursors (e.g. liver).

Cystine urolithiasis.

- Acidifying diets should not be fed.

Prognosis

Recurrence rates of 19% and 37% have been reported.

Prognosis is guarded because in some cases recurrences occur despite the implementation of adequate preventative measures.

Unless preventative measures are implemented, urolithiasis will reoccur.

INFECTIOUS CYSTITIS/URETHRITIS*

Classical signs

- Frequently seen trying to urinate (pollakiuria).
- Straining with little urine passed (dysuria).
- Blood-tinged urine (hematuria).
- Cat may urinate in inappropriate places.

Pathogenesis

Inflammation of the feline urinary tract is rarely caused by an infectious agent.

About **5–10%** of cats with **lower urinary tract disease** have **urinary tract infections**, which may be primary or secondary.

The prevalence of urinary tract infections **increases with age**, being uncommon in young adult cats to middle age of either sex.

- Urinary tract infection accounts for **less than 2%** of cases of lower urinary tract disease in **cats from 1–10 years of age**.
- Of **cats older than 10 years of age** with signs of lower urinary tract disease, **46%** had a positive urine culture and a further **17%** had a positive culture associated with **urolithiasis**. Two thirds of cats with a positive culture not associated with urolithiasis had **chronic renal failure**.
- Of **cats with chronic renal failure**, **30%** had one or more positive urine cultures over a period of 4–8 months which were all *E. coli*.

Most bacterial infections in cats are **secondary** to other causes of lower urinary tract disease, perineal urethrostomy, the use of indwelling urinary catheters or chronic renal failure.

Predisposing causes of urinary tract infection include:

- **Anatomical abnormalities** (ectopic ureter, patent urachus, perineal urethrostomy).
- **Urethral incompetence** (usually associated with perineal urethrostomy).
- Loss of mechanical washout of the bladder and urethra due to bladder atony, **urolithiasis**, painful hindquarters and debility.

- Damage to the bladder mucosal defense barrier due to **trauma** (catheterization, surgery, uroliths) or **neoplasia**.
- **Changes in urine composition** (alkaline pH, glucosuria).
- **Chronic renal failure**.

Infectious agents include:

- **Bacterial** cystitis/urethritis (cystourethritis).
 - Rare in cats and **most are aerobic infections**.
 - Common organisms cultured include *Escherichia coli*, *Staphylococcus intermedius*, *Streptococcus* spp., *Proteus*, *Pasteurella*, *Klebsiella*, *Pseudomonas* and *Enterobacter*. Occasionally *Mycoplasma* and *Ureaplasma* are reported and these organisms do not grow on routine culture media.
 - **Mycoplasma cultures should be considered if pyuria is present but no aerobic bacterial growth occurs**.
 - Recurrent ascending urinary tract infections occur in **immunosuppressed** cats (FeLV, FIV, diabetes mellitus), and are common in cats with urethral incompetence, which occurs most frequently following **perineal urethrostomy**.
- **Viral**
 - A **herpesvirus** has been isolated from cats with sterile lower urinary tract inflammation but its significance is unclear.
- **Fungal**
 - Infections are **rare** and due to *Candida albicans* or *Aspergillus fumigatus*.
 - Mainly reported in cats on long-term antibiotic therapy with impaired host defenses (perineal urethrostomy and urine stasis).
- **Parasitic**
 - Rarely reported but include *Capillaria feliscati* and *Encephalitozoon cuniculi*.
 - *Capillaria feliscati* has been reported in Australia and USA. It is a trichurid nematode that usually attaches superficially to the bladder mucosa and so most cats are asymptomatic. However, on rare occasions it may produce recurrent bouts of hematuria and dysuria.

Clinical signs

Dysuria, pollakiuria with or without hematuria.

Cats with **chronic renal failure may or may not have clinical signs, and pyuria and bacteriuria** may not be obvious on examination of the urinary sediment.

Cats with urinary tract infection are rarely systemically affected.

- **Clinical signs of fever**, lethargy, dehydration, anorexia, vomiting, polydipsia, polyuria, weight loss, anaemia are consistent with **renal involvement and indicate ascending pyelonephritis**.

Capillaria infestation is usually reported in cats over 8 months of age and produces minimal clinical signs, but recurring bouts of hematuria and dysuria have been observed.

Encephalitozoon infestation may lead to renal failure.

Diagnosis

Urinalysis.

- **If the urinary bladder is empty**, cats can be given **normal saline (70 ml/kg)** subcutaneously, and bladder fill monitored. Alternatively, **furosemide (1 mg/kg) intravenously** can be used. Animals with acute lower urinary tract infection are usually pollakiuric, so several attempts to collect urine may be necessary throughout the day.
- **Hematuria** (>5 RBC/hpf), **pyuria** (>5 WBC/hpf) and **proteinuria** (>3.5 g (35mg)/kg/day) or increased protein/creatinine ratio >1.0 (N.B protein and creatinine values must be converted to mg/dl and $\mu\text{mol/L}$, respectively to calculate the ratio) **indicate inflammation of the urinary tract**. If bacteria are also seen or cultured, then the inflammatory process is due to or complicated by bacteria. If bacteria are not seen under light microscopy, it does not mean that an infection is not present as they, **especially cocci, are not always readily visualized**.
- **White blood cell casts or granular casts indicate renal tubular involvement** as in pyelonephritis. White blood cell casts appear as **tubular structures** composed of white cells and Tamm–Horsfall mucoprotein. These may degenerate and form granular casts, which are indistinguishable from degenerated renal tubular epithelial casts.
- Blastospores (yeast) or hyphae (*Aspergillus* spp.) in urine indicate fungal infection.
- *Capillaria* ova (bipolar) or *Encephalitozoon* spores can be seen in the urine. Heavy infestations of *C. feliscati* may be associated with proteinuria.

Bacteriology.

- Quantitative bacterial cultures $\geq 10^3/\text{ml}$ of urine obtained by cystocentesis indicate urinary tract infection.
- **Aerobic cultures** and antimicrobial susceptibility testing are **indicated in cats with pyuria (>5 WBC/hpf) or elevated urine pH (>6.5) whether or not bacteriuria is seen**.
- Fungal cultures are indicated if blastospores (yeast) or hyphae are seen in the urine.

Blood tests.

- Leucocytosis and elevated serum urea and creatinine levels indicate renal involvement in lower urinary tract disease.

Radiology.

- Plain and contrast radiography may help to identify some predisposing causes of urinary tract infections, as well as, determine the chronicity of the infection (thickened bladder wall, bladder fill capacity).

Differential diagnosis

Non-obstructed idiopathic LUTD. Some cats diagnosed as having bacterial cystitis/urethritis often represent with a recurrence of lower urinary tract disease with sterile urine during or after appropriate antimicrobial therapy. These cats have non-obstructed idiopathic LUTD with secondary bacterial infection and can only be identified by reoccurrence of signs associated with sterile urine.

Treatment

The principal objectives in the treatment of urinary tract infection are to eliminate the infectious agent, correct the predisposing cause, if possible, and prevent the recurrence of infection.

Eliminate the infectious agent.

- **For bacterial infections.**
 - Antimicrobial drugs, selected on the bases of bacterial sensitivity, should be used at appropriate doses for **14 days for acute urinary tract infection and for 28 days for chronic or recurrent urinary tract infection**.
 - Antimicrobial drugs often effective include **sulfa-trimethoprim, enrofloxacin and amoxicillin with clavulanic acid**.

- Nephrotoxic antimicrobials (aminoglycosides) should be avoided and when used, they should not be given for more than 7–10 days without carefully monitoring renal function, especially urinalysis for evidence of casts.
- **Response to therapy should be based on urinalysis and bacterial culture, rather than on clinical response to treatment**, as most cats will show a marked clinical improvement, despite unsuccessful eradication of the urinary tract infection.
- **Repeat urinalysis without culture should be done 7 days** after commencement of therapy to ensure that bacteriuria is no longer present.
- A urine sample for urinalysis should be examined on the **last day of antimicrobial therapy** for evidence of **pyuria** (>5 WBC/hpf). **Urinalysis and bacterial culture should be repeated 7 days after antimicrobial therapy has ceased and again at monthly intervals** until two consecutive urine samples are negative.
- Treatment for urinary tract infections associated with indwelling catheters may be delayed, if signs are absent, until the urinary catheter is removed, to avoid developing antimicrobial resistance.
- **For viral infections.**
 - Use lysine (250 mg/cat orally every 12 hours) or interferon alpha (30 U/cat orally daily).
- **For fungal infections.**
 - Ketoconazole and itraconazole have been suggested but their efficacy in the cat with urinary tract infection has not been determined.
- **For parasitic infestations.**
 - For Capillaria use fenbendazole (25 mg/kg orally every 12 hours for 3–10 days). Alternatively, methyridine 200 mg/kg orally once has been used.
 - No known effective treatment has been reported for Encephalitozoon in cats, but albendazole and the antibiotic fumagillin have been shown to have efficacy in humans and mice.

Correct predisposing cause, if possible.

- Anatomical abnormalities, such as ectopic ureter(s) should be surgically corrected.
- Urethral incompetence and loss of mechanical washout should be corrected, if possible.
- The continued use of indwelling catheters associated with secondary urinary tract infections should be reassessed.

Prevent the recurrence of infection.

● **Bacterial.**

- If urinary tract infection recurs, determine if it is due to a relapse or reinfection. **Reoccurrence of infection with the same organism** (relapse) usually indicates that the original treatment did not eliminate the infection. Recurrence of infection with a different organism (reinfection) suggests that the original treatment was effective but predisposing factors have allowed a new infection to occur.
- **Urinary acidifiers** can be used for long-term therapy to provide a less-favorable environment (pH < 6.5) in the urinary tract.
- **Encourage the patient to urinate more frequently** by providing clean litter trays or ready access to outdoors, thus utilizing mechanical washout.
- If urinary tract infection persists because predisposing causes cannot be corrected, **ampicillin, amoxicillin, sulfa-trimethoprim and methenamine can be used for long-term therapy**. Give half the daily dose late in the evening.

Prognosis

Prognosis depends on the causative agent, the use of appropriate drug therapy and the identification and correction of predisposing causes.

URETHRAL TRAUMA*

Classical signs

- History of trauma, especially following motor vehicle accidents, falling from high places and after forceful or excessive urethral catheterization.
- Dysuria.
- Perineal swelling.

Pathogenesis

Urethral trauma may result from **motor vehicle accidents** or abdominal trauma, especially those that result in pelvic fractures, perineal surgery via scalpel blade or **excessive handling of the urethra, and catheterization**, especially when associated with urethral obstruction.

Urethral rupture may result in **subcutaneous accumulation of urine in the perineal region** leading to swelling, discoloration and necrosis of the skin.

Clinical signs

Dysuria.

Stranguria.

Perineal swelling.

Red discoloration of the perineal skin.

Abdominal pain.

Signs of post-renal renal failure.

Diagnosis

History of trauma or catheterization.

Clinical signs of swelling, discoloration or necrosis in the perineal region.

Positive-contrast urethrography will demonstrate extravasation of contrast into the periurethral soft tissue. If the rupture is at the proximal end of the urethra, contrast agent may enter the abdomen.

HYPERCONTRACTILE BLADDER*

Classical signs

- Small urinary bladder.
- Dribbling urine.
- Pollakiuria.

Pathogenesis

Hypercontractility of the urinary bladder occurs when **detrusor muscle contractions are triggered at low volumes and pressure**, resulting in dysfunction of urinary bladder storage.

It may be due to reduced bladder capacity (**hypoplastic bladder, neoplasia**), excessive sensory input (**inflammation**) or neurologic disorders (**upper motor neuron lesions**).

Bladder hypercontractility (idiopathic detrusor instability), not associated with any known cause, has been reported in one cat with FeLV that responded to anticholinergic therapy.

Clinical signs

Small amounts of urine are frequently voided while the urinary bladder is still small.

Dribbling urine (incontinence) associated with a small bladder.

Pollakiuria.

Palpation of the bladder often initiates the act of urination.

*Diagnosis

Diagnosis is based on **clinical signs**, especially that the cat frequently urinates or **dribbles urine when the bladder is quite small**.

Urodynamic procedures, such as cystometrography, demonstrate reduced threshold volumes and pressure, which indicate reduced bladder compliance or detrusor hypercontractility.

Urinalysis may reveal pyuria or neoplasia.

Radiography may help to determine the underlining cause, for example neoplasia and cystitis (thickened bladder wall).

FeLV test.

Differential diagnosis

Infectious cystitis/urethritis – hematuria, pyuria and bacteriuria are usually present.

Non-obstructed LUTD – hematuria is usually present.

Treatment

Management of storage dysfunction of the urinary bladder may include elimination of urinary tract inflammation, correction of neurologic disorders or pharmacologic manipulation to reduce detrusor muscle excitability.

- Always treat urinary tract infections first before attempting pharmacologic manipulation.
- **Parasympathetic inhibitors (anticholinergic agents)**, such as **propantheline** (5–7.5 mg /cat orally every 72 hours or more frequently as required) and **oxybutynin** (0.5–1.25 mg/cat orally every 8–12 hours) may be used.

- **Tricyclic antidepressants, such as imipramine** (2.5–5 mg/cat orally every 12 hours) may improve urinary bladder compliance.

Clip the hair and clean around the perineal/abdominal area to minimize urine scolding.

NEOPLASIA*

Classical signs

- Hematuria.
- Distended bladder.
- Dysuria.

Pathogenesis

Tumors of the urinary bladder are rare and those of the ureters and urethra even rarer.

Most are **malignant epithelial tumors** such as **transitional cell carcinomas, squamous cell carcinomas and adenocarcinomas**.

Benign tumors occur very infrequently.

Clinical signs

Usually occurs in cats **over 8 years of age**.

Dysuria and intermittent or persistent hematuria may occur depending on the type and location of the neoplasm.

Soft tissue mass may be palpable in the bladder neck.

Secondary infection may occur.

History of unresponsiveness to treatment for cystitis.

Diagnosis

Urinalysis.

- Hematuria (RBC > 5 phf).
- Pyuria and bacteriuria occur due to secondary urinary tract infection.
- Sediment may show abnormal transitional cells.

Blood tests (hematology and biochemistry).

- Normal unless urinary tract obstruction has occurred.

- One cat with transitional cell carcinoma also had hypereosinophilia.

Abdominal palpation of a soft tissue mass in the bladder neck.

Ultrasonography or contrast radiography shows a soft tissue, space-occupying mass. Generally, a water-soluble iodinated contrast agent (5–10 ml/kg or enough to moderately distend the bladder) is used.

Biopsy via exploratory laparotomy or cystoscopy provides a definitive diagnosis.

Treatment

Surgical resection is rarely feasible due to the high percentage of tumors that are malignant, the frequently late presentation and location of the tumor.

URETHRAL STRICTURE

Classical signs

- Dribbling urine.
- Distended bladder.
- Dysuria.
- Stranguria.

See main reference on page 199 for details (The Incontinent Cat).

Clinical signs

Incontinence associated with a distended bladder (overflow incontinence) and dysuria.

Diagnosis

Radiography. Retrograde urethrography.

Urodynamic procedures. Urethral pressure profilometry may be used to identify focal urethral obstructions.

CYCLOPHOSPHAMIDE TOXICITY

Classical signs

- Hematuria.

Clinical signs

Hemorrhagic cystitis may occur during **cyclophosphamide therapy** (< 5% of cases) in cats due to the action of acrolein on the mucosa resulting in mucosal edema, necrosis and ulceration.

Diagnosis

History of access to toxic material.

Urinalysis reveals a **sterile hematuria** (RBC >5 hpf).

12. The incontinent cat

Lucio John Filippich

KEY SIGNS

- Urinary incontinence.
- Urine soiling around the perineal area.
- Perineal dermatitis.

MECHANISM?

- The incontinent cat has lost voluntary control over urination and intermittently or continuously dribbles urine. Maintenance of urinary continence in the cat depends on normal lower urinary tract anatomy and function and an intact nervous system. Urinary incontinence results from abnormalities of either the filling or emptying processes.
- During the filling phase (sympathetic stimulation), the body of the bladder acts as a reservoir with flaccid walls that generate little pressure, while the outlet of the bladder is a high-resistance duct preventing the passage of urine.
- During the emptying phase (parasympathetic stimulation), the roles are reversed and the body of the bladder becomes a pump that expels urine under high pressure while the outlet of the bladder reflexly opens and becomes a low-resistance duct.
- The two phases are functionally independent and depend on the cerebral cortex for co-ordination and voluntary control.

WHERE?

- Lower urinary tract (lower ureter, urinary bladder, urethra).

WHAT?

- Urinary incontinence in cats is uncommon. In juvenile cats, it is more likely due to a congenital abnormality (ectopic ureter); in the adult cat it is more likely neurologic in origin. Secondary urinary tract infections are common.

QUICK REFERENCE SUMMARY

Diseases causing an incontinent cat

ANOMALY

- **Ectopic ureter(s)* (p 198)**

A congenital or acquired anomaly where one or both ureters fail to terminate normally into the urinary bladder. Mainly seen in young cats showing continuous or intermittent dribbling of urine with wetness and dermatitis around the perineal area. The urinary bladder, if palpable, is not distended.

- **Patent urachus (p 201)**

Kittens show urine leakage from the umbilicus because the urachus between the urinary bladder and the umbilicus remains functionally patent after birth.

- **Spinal dysraphism (p 201)**

Young cats, especially Manx cats. Overflow incontinence occurs because of malformation of the sacral spinal cord segments and disruption of nerve pathways responsible for micturition. Commonly seen with other hindquarter abnormalities.

- **Colorocystic fistula (p 202)**

The fistula between the urinary bladder and colon predisposes to urinary incontinence and urinary tract infection.

- **Ectopic uterine horns (p 202)**

Ectopic uterine horns terminate in the urinary bladder and result in persistent urinary incontinence and cystitis.

- **Exstrophy (p 203)**

Urine dribbling from defects in the ventral abdominal wall, urinary bladder and external genitalia.

MECHANICAL

- **Hypocontractile bladder (detrusor atony)*** (p 195)**

Results from detrusor dysfunction or occurs secondary to increased urethral outflow resistance. Overflow incontinence occurs and the bladder may or may not be easily expressed. Often associated with hindquarter abnormalities.

- **Urethral incompetence* (p 200)**

Intermittent leakage occurs without a distended bladder, often while the cat is sleeping or relaxed. Results from trauma, dysraphism, urethral hypoplasia and possibly feline leukemia virus infection and desexing. More common in aged cats.

- **Urethral stricture* (p 199)**

May present as overflow incontinence and dysuria in a young cat (congenital), but more common secondary to trauma, inflammation or iatrogenic following traumatic catheterization of a blocked cat.

IDIOPATHIC

- **Dysautonomia (p 203)**

Overflow incontinence is associated with gastrointestinal and ocular signs due to an autonomic polyganglionopathy. Sudden onset of anorexia and depression occurs together with dilated unresponsive pupils, bradycardia, dry mucous membranes and GIT signs.

INTRODUCTION

MECHANISM?

The incontinent cat **intermittently or continuously dribbles urine** because it has **lost voluntary control over urination**.

Cats that urinate at inappropriate times or in inappropriate places need to be differentiated from incontinent cats through history taking and clinical examination.

Maintenance of urinary continence in the cat **depends on normal lower urinary tract anatomy** and an **intact sympathetic, parasympathetic and somatic nervous system**.

- Anatomical abnormalities can bypass (ectopic ureter) or negate (urethral hypoplasia) neuromuscular control mechanisms.

Continence during the filling stage is maintained via the following mechanisms: **sympathetic stimulation (hypogastric nerve) during the filling phase** causes the body of the bladder (detrusor muscle) to relax (β -receptors) and the bladder neck and urethral smooth muscles to contract (α -receptors).

- Additional urethral resistance is supplied by the **urethral striated muscle**, which reflexively contracts and is under voluntary control (pudendal nerve).

The emptying phase occurs as follows: **Parasympathetic stretch receptors in the detrusor muscle** detect bladder fill, and when the threshold of bladder capacity is reached, they discharge impulses via the sacral spinal cord to the pons in the brain stem, where a detrusor response is integrated.

Efferent motor impulses descend the spinal cord to the detrusor muscle via the **pelvic nerve causing detrusor muscle contraction**.

- Simultaneously, **inhibitory interneurons** are activated in the sacral spinal cord, which **synapse on pudendal motor neurons**, resulting in a **relaxation of the external urethral sphincter**.

Once the bladder is empty, parasympathetic activity ceases and the sympathetic and pudendal nerves are no longer inhibited.

Detrusor muscle relaxation and urethral sphincter contraction returns and the filling phase begins again.

Incontinence, pollakiuria or nocturia associated with an empty bladder reflect storage disorders (reduced bladder capacity, hyperactivity of the detrusor muscle, urethral incompetence).

In contrast, **urine retention with overflow, or incomplete voiding and a distended bladder indicate emptying disorders** (detrusor atony, urethral obstruction).

Following spontaneous bladder emptying there should be less than 0.5 ml of urine remaining in a normal cat.

WHERE?

Lower urinary tract (lower ureter, urinary bladder, urethra).

WHAT?

Urinary incontinence in cats is uncommon. In **juvenile cats**, it is more likely due to a congenital abnormality (**ectopic ureter**): in the **adult cat** it is more likely neurologic in origin. Secondary urinary tract infections are common.

DISEASES CAUSING SIGNS OF URINARY INCONTINENCE

HYPOCONTRACTILE BLADDER*** (DETRUSOR ATONIC/HYPOTONIC BLADDER)

Classical signs

- Dribbling urine.
- Distended urinary bladder.
- \pm Hindquarter ataxia or paresis.
- \pm Tail paralysis.

Pathogenesis

Hypocontractile bladder can occur due to detrusor dysfunction or secondary to prolonged bladder distention.

Detrusor dysfunction.

- **Lesions cranial to the sacral spinal cord** may disrupt sensory and motor pathways to the urinary bladder. This results in an upper motor neuron bladder:

- Detrusor function is lost resulting in a flaccid bladder.
- Urethral sphincter tone is maintained.
- Loss of inhibition may lead to increased pudendal nerve activity and thus, increased urethral outflow resistance.
- Over time, intrinsic spinal reflexes may re-establish detrusor activity but voiding is usually involuntary and incomplete.
- **Lesions involving the sacral spinal cord segments**, cauda equina (sacrum) or peripheral nerves supplying the bladder and urethra result in a lower motor neuron bladder.
 - Loss of most sensory and all motor input to the detrusor muscle.
 - Loss of urethral sphincter tone.
 - The urinary bladder is areflexic and easily expressed.
 - Overflow incontinence occurs when the bladder is distended or when intravesicular pressures exceed urethral pressure.

Prolonged bladder distention.

- Prolonged bladder distention leads to loss of tight muscular junctions in the bladder wall resulting in detrusor atony. Prolonged bladder distention results from reduced bladder emptying which may be from a number of causes:
 - Mechanical (urethroliths, urethral plugs, strictures, bladder neck or urethral masses, inflammation).
 - Functional (neurologic injury, urethral muscle spasm). When bladder fill pressures exceed urethral resistance, overflow of urine occurs.
 - Associated with hindquarter disorders (pain) or forced recumbency.

Neurologic injury, resulting in **urethral hyperactivity/dyssynergia**, has been rarely documented in cats. It can occur with **sacral spinal cord and cauda equina injuries**, resulting in the urethral musculature failing to relax during detrusor contraction, thus maintaining a high outflow resistance.

Urethral muscle spasm may occur following **urethral or pelvic surgery** or secondary to **urethral inflammatory disease**.

Functional urethral obstruction and detrusor atony are **common sequels** to **mechanical urethral obstruction**.

Feline dysautonomia may result in urinary incontinence. There is an inability to contract the bladder and the bladder is easy to express manually. Urinary incontinence is one of the less common signs. Typically there is a sudden onset of depression and anorexia over 24–48 h, and a variety of signs reflecting autonomic dysfunction, such as pupillary dilation with loss of PLR, dry eyes and nose, regurgitation, prolapsed 3rd eyelids, bradycardia and constipation or fecal incontinence.

Clinical signs

A hypocontractile bladder presents as urinary incontinence associated with a **distended urinary bladder** and **inability to completely void urine**.

The cat may or may not voluntarily attempt to urinate.

The **bladder may or may not be easily expressed** manually.

With **suprasacral (cranial to sacrum) spinal cord lesions**, the **bladder is initially distended, firm** and **difficult to express**.

- Over time there is emergence of the sacral reflex, and some bladder contractile function may return, resulting in frequent, uninhibited, incomplete voiding of small volumes of urine.
- If outflow resistance is high at this time, detrusor-urethral dyssynergia occurs resulting in dysuria (difficult or painful urination) and interrupted urination.
- Other clinical signs associated with suprasacral spinal cord lesions may include proprioceptive deficits, paraparesis or tetraparesis and hyperreflexia.

With **sacral spinal cord and peripheral nerve lesions**, the urinary bladder is usually distended but flaccid, and outflow resistance is generally low, so the **urinary bladder is easily expressed**.

- The cat may attempt to urinate, but fail to produce an adequate stream of urine.
- Clinical signs may also include hindlimb paresis or paralysis, reduced anal tone and perineal reflexes, fecal incontinence and tail paralysis.

Incontinence associated with **increased urethral outflow resistance** is initially characterized by bladder distention and difficulty in manually expressing urine, a large residual urine volume following voiding, dysuria and an attenuated urine stream (paradoxical incontinence).

If the cat initiates voiding but the urine stream is rapidly interrupted, consider detrusor–urethral dyssynergia.

Fecal incontinence and/or constipation may also be present.

Diagnosis

History may help to characterize the problem, differentiate it from inappropriate urination and identify the possible cause (trauma, prolonged recumbency).

Physical examination.

- Abdominal palpation reveals a distended bladder.
- If detrusor dysfunction is neurological in origin, other signs of neurological disease such as hindquarter paralysis are commonly seen.

Neurologic examination.

- Neurologic deficits in the limbs suggest a neurologic cause for the incontinence.
- Loss of anal tone, perineal sensation and tail function indicate a sacral spinal cord lesion.
- Ophthalmological signs (mydriasis) may suggest the incontinence is associated with dysautonomia.

Observe micturition.

- This should always be done.
- Assess the urine stream passed.
- Note change in bladder size and residual urine volume after voiding.

Detrusor dysfunction is suspected on the basis of the history, physical examination, and the exclusion of a mechanical obstruction to urine outflow.

Catheterize the urinary bladder to determine patency.

- If an obstruction is detected, survey and contrast radiographs are often necessary to further characterize the obstruction. If the obstruction is due to a urethrolith, survey abdominal radiographs are necessary to determine if other uroliths are present in the urinary tract (kidney, ureter and bladder).
- If an obstruction is not detected, retrograde urethrogram and contrast cystography may be needed to exclude soft tissue masses in the bladder and urethra.

If mechanical obstruction is ruled out, subjectively evaluate urethral resistance by palpating the urinary bladder and applying constant, firm digital pressure on the urinary bladder. The degree of pressure applied should not cause undue discomfort or pain to the cat.

- If detrusor activity is initiated and the cat begins to urinate, observe if the urine stream is abruptly interrupted and voiding is incomplete (functional urethral obstruction).
- If detrusor activity is not initiated and the bladder is easily expressed, bladder atony is present.

Ultrasonography is often useful in bladder diseases (neoplasia, urolithiasis) but does not visualize most of the urethra.

Urodynamic procedures.

- These are not readily available in veterinary practice.
- Cystometry, urethral pressure profilometry, uroflowmetry and electromyography can provide useful objective information about detrusor and urethral function.
- Cystometrography showing large filling volumes, and lack of sustained contractile peaks indicate detrusor atony.
- Urethral pressure profilometry can identify urethral incompetence and urethral hypertonicity.

Urinalysis is useful in detecting the presence of inflammation and infection.

Blood tests including serum urea, creatinine and electrolyte concentrations can be done to detect renal failure.

Biopsy a soft tissue mass, if detected.

Treatment

Immediately correct any life-threatening conditions, such as postrenal renal failure, and fluid and electrolyte imbalance.

Correct the primary cause, if possible.

Always treat urinary tract infections first before attempting pharmacologic manipulation.

For bladder atony.

- To facilitate smooth muscle recovery, the **residual urine volume** needs to be **kept small** by frequent manual expression, intermittent catheterization or temporary indwelling urinary catheter placement.
- Use pharmacologic manipulation, such as **parasympathomimetics (bethanechol chloride, a cholinergic agonist, 1.25–2.5 mg/cat orally every 8–12 hours)** to increase detrusor contractility and an **alpha-adrenergic antagonist (phenoxybenzamine, 0.25 mg/kg**

orally every 12 hours) to minimize urethral resistance, if necessary. Parasympathomimetic drugs are most likely to be effective when some neurologic innervation is still present. Drug doses may be increased incrementally, if needed, every 4–5 days, but patients should be carefully monitored for potential side effects (lacrimation, salivation, abdominal cramps, vomiting, diarrhea).

For increased **urethral resistance or detrusor–urethral dyssynergia**.

- The direct-acting skeletal muscle relaxant, **dantrolene sodium** (0.5–2 mg/kg orally 12 hourly or 1 mg/kg IV) may be effective in reducing striated-muscle resistance.
- The alpha-adrenergic antagonist (phenoxybenzamine) may be effective in reducing smooth-muscle resistance.
- Benzodiazepines such as diazepam (valium 2–5 mg PO tid) may reduce striated-muscle resistance.

Laboratory investigation, including plasma urea, creatinine and electrolyte concentrations and urinalysis, should be done to determine the degree of post-renal azotemia and to identify if hematuria, pyuria and/or infection are present.

Prognosis

Prognosis in neurologic cases is guarded and generally depends on the chronicity and severity of the neurologic lesion, response to medical therapy and the ease of manually maintaining an empty urinary bladder.

ECTOPIC URETER(S)*

Classical signs

- Young cat.
- Continuous dribbling of urine.
- Wetness around the perineal area.
- Perineal dermatitis.

Pathogenesis

A **congenital anomaly** where **one or both ureters fail to terminate normally in the trigone of the urinary bladder**. Ectopic ureter occurs because the origin or

migration of the metanephric ducts (which become the ureters) was abnormal.

Ectopic ureters **usually terminate in the urethra and less frequently in the vagina**.

Approximately **50% are unilateral**.

Because of the close relationship of the mesonephros and the metanephros and development of other urogenital organs, other anomalies such as cystic (bladder) hypoplasia, renal hypoplasia, hydronephrosis and megaureter may also occur.

Acquired ureteral ectopia may occur due to a vagino-ureteral fistula developing as a sequel to cesarian and ovario-hysterectomy.

Clinical signs

Congenital ureteral ectopia has been infrequently reported in cats and there appears to be no breed or sex predisposition.

Usually reported in **cats less than 18 months of age**.

Signs depend on the site of termination of the ectopic ureter(s) and the presence of other congenital or acquired abnormalities.

Continuous or intermittent dribbling of urine is typical.

Cats with bilateral ectopic ureters may or **may not urinate normally**, depending on how much urine refluxes back into the bladder.

Incontinent cats with unilateral ureteral ectopia urinate normally.

Urine scalding may result in vaginal discharge, phimosis (contraction of the prepuce orifice), and perivulvar or periprepuce dermatitis.

Soiled hair may discolor.

The **urinary bladder** on abdominal palpation is **not distended** (in contrast to urine retention with overflow).

Abdominal palpation may reveal an abnormal kidney(s).

Secondary **bacterial urinary tract infections are common** and may result in intermittent bouts of hematuria, cystitis and/or ascending pyelonephritis. With bilateral ectopia, renal failure may occur.

Diagnosis

A **history of urinary incontinence since birth or when acquired as a kitten** indicates congenital ureteral ectopia. Onset of signs following recent abdominal surgery at any age would suggest acquired ureteral ectopia.

Clinical signs which are suggestive are:

- Urinary incontinence without urinary bladder distention.
- Incontinence despite normal urination (unilateral ectopic ureter).

Radiographic techniques such as excretory urography/pneumocystography and retrograde urethrography or vaginourethrography provide information on the site of ureteral termination, renal size and ureteral shape.

- One or both ureters fail to terminate normally in the urinary bladder.
- Other anomalies, such as cystic and renal hypoplasia, hydronephrosis and megaureter may be seen.

Vaginoscopy may reveal the ectopic ureteral orifice if the ureter enters the vagina.

Ultrasonography may help to demonstrate the abnormal termination of the urethra or vagina.

Biochemistry

- Serum urea and creatinine estimations can be used to evaluate renal function.
- Urea and creatinine are more likely to be elevated with bilateral ureteral ectopia, especially if chronic.
- Elevations indicate both kidneys are diseased from ascending pyelonephritis or an associated congenital renal anomaly.

Urinalysis and bacterial culture can identify the presence of secondary infection.

Differential diagnosis

Urinary retention with overflow (overflow incontinence) is differentiated from ectopic ureter by finding a distended bladder on palpation.

Treatment

Vesico-ureteral transplantation is the treatment of choice when the kidney function is normal and the ureter is not markedly abnormal.

Ureteronephrectomy may be considered when the affected kidney is diseased and the contralateral kidney is normal.

Renal infarction by ligation of the renal blood vessel may be considered in azotemic cats with unilateral ureteral ectopia.

Continued incontinence after surgery may be due to concomitant urethral incompetence or reduced bladder capacity due to disuse. If the latter, bladder capacity usually improves with time.

Secondary bacterial infections are not uncommon and antimicrobials based on culture and sensitivity tests should be administered.

Prognosis

Following surgical correction, prognosis is generally good with immediate cessation of urinary incontinence.

Cats with ectopic ureters that terminate in the vagina are more likely to be continent after surgery.

Reimplantation of dilated ureters into the bladder may result in increased vesicoureteral reflux that can predispose to ascending pyelonephritis.

URETHRAL STRICTURE*

Classical signs

- Dribbling urine.
- Distended bladder.
- Dysuria.

Pathogenesis

Congenital urethral strictures are occasionally seen in young cats.

Acquired strictures are more common and occur secondary to trauma, inflammation or iatrogenic causes following catheterization or surgery.

Clinical signs

Typical signs are incontinence associated with a distended bladder (overflow incontinence) and dysuria (difficulty urinating) with a narrow urine stream.

Diagnosis

Diagnosis is via **radiography** using retrograde urethrography.

Following catheterization of the urethra using an open-ended cat catheter, contrast is injected (1–2 ml) while the radiographs are taken. Avoid over-distending the urinary bladder.

Urodynamic procedures such as urethral pressure profilometry may be used to identify focal urethral obstructions.

Treatment

Treatment depends on location and size of the stricture.

Extrapelvic strictures may be managed by urethrostomy, whereas, intrapelvic strictures may require urethral resection and anastomosis.

URETHRAL INCOMPETENCE*

Classical signs

- Small urinary bladder.
- Intermittent dribbling of urine.

Pathogenesis

Incontinence occurs because of reduced urethral outflow resistance during urine storage. This results from lost or **reduced urethral smooth or striated muscle tone**.

Reported causes of urethral incompetence include:

- **Pelvic and pudendal nerve damage** following trauma (**cystotomy**, **perineal urethrostomy**) and rarely neoplasia (acquired urethral incompetence).
- **Dysraphism** in Manx cats.
- **Urethral hypoplasia** has been reported in young female cats (congenital urethral incompetence).
- A relationship between incontinence and **feline leukemia virus** (FeLV) infection is suspected.
- **Reproductive hormone-responsive incontinence** has been reported in two female cats following ovariectomy and suspected in three neutered males.

Clinical signs

Normal or small urinary bladder.

Intermittent leakage of small volumes of urine, often while the cat is sleeping or relaxed.

If congenital in origin, other anomalies, such as vaginal aplasia and cystic hypoplasia are commonly present.

Many **FeLV-positive cats with urinary incontinence** may also have **anisocoria**, reproductive disorders, weight loss, vomiting and pyalism suggesting a **multifocal autonomic dysfunction**. In cats with FeLV-associated incontinence, digital palpation of the urinary bladder often elicits a urine flow.

In cats with urethral incompetence due to neoplasia, abdominal palpation may reveal a mass at the bladder neck. Others signs, such as dysuria and hematuria are often present.

Secondary urinary tract infections are common.

Diagnosis

Diagnosis is based on history and clinical signs of leakage of small amounts of urine, often when sleeping, and a normal or small bladder.

Ophthalmological signs (anisocoria) may suggest the incontinence is associated with FeLV infection.

A positive FeLV test.

Retrograde contrast vaginourethrography in female cats with urethral hypoplasia shows marked urethral shortening and other anomalies, such as vaginal aplasia and cystic hypoplasia.

Cystography or retrograde urethrography may reveal a mass at the bladder neck. Biopsy is necessary for a definitive diagnosis.

Urodynamic procedures, including urethral pressure profilometry can be used to identify urethral incompetence.

Differential diagnosis

Hypercontractile bladder (urge incontinence) is characterized by frequent conscious urination and a small bladder.

Treatment

Bladder neck reconstructive surgery may be considered in cats with urethral hypoplasia.

Alpha-adrenergic agonists, such as **phenylpropanolamine** (1.5–2.2 mg/kg PO 8–12 h) and **ephedrine** (2–4 mg/cat PO 8–12 h) may be used to alleviate the incontinence. Once the incontinence is controlled, the dosage can be reduced and/or the frequency lengthened.

High doses of oral estrogen therapy were reportedly effective in two cats that developed urinary incontinence following ovariectomy. However, at such doses nymphomania and toxic bone marrow effects may occur.

Testosterone propionate (5–10 mg intramuscularly), given to three neutered male cats suspected of reproductive hormone-responsive incontinence, gave **variable success**.

Prognosis

Response to drug therapy in severely affected animals is often poor.

PATENT URACHUS

Classical signs

- Immature cat.
- Dribbling urine from the umbilicus.
- Omphalitis.
- Ventral dermatitis.

Pathogenesis

Patent (persistent) urachus occurs when the entire urachus between the urinary bladder and the umbilicus remains functionally patent after birth.

Clinical signs

Kittens show **urine leakage from the umbilicus**.

A patent urachus is often associated with omphalitis (inflammation of the umbilicus), **ventral dermatitis** and signs of urinary tract infection.

Diagnosis

Physical examination reveals urine leakage from the umbilical region.

Differential diagnosis

Exstrophy of the bladder. The bladder wall and abdominal wall are not fully formed and are joined, with leakage of urine to the exterior.

Treatment

Surgical correction and antimicrobial therapy for secondary infection.

Prognosis

Good.

SPINAL DYSRAPHISM

Classical signs

- Young cat.
- Dribbling urine.
- Distended urinary bladder.
- ± Hindquarter abnormalities.

Pathogenesis

Incomplete closure of the neural tube during early prenatal development leads to **malformation of the sacral spinal cord segments** and disruption of nerve pathways responsible for micturition, resulting in **loss of detrusor responsiveness and urethral sphincter control**.

Sacrocaudal dysgenesis in Manx cats is due to a semi-lethal, autosomal dominant gene.

Clinical signs

Signs occur in young cats (< 6 months of age).

Severity of the clinical signs vary and may include abnormalities of urination, defecation and hindlimb gait.

Typically there is urinary incontinence (dribbling urine) with a distended urinary bladder that is easily expressed.

Perivulvar or periprepucial dermatitis.

Secondary urinary tract infections are common.

Other signs commonly seen include **fecal incontinence**, constipation, **locomotor disturbances** of the **hindlimbs** (plantigrade stance, hopping gait) and abnormal hindquarter conformation.

Diagnosis

Diagnosis is based on age, breed and clinical signs.

Survey radiographs may confirm vertebral abnormalities of the caudal spine.

Contrast myelography may demonstrate the presence of meningoceles.

Urodynamic procedures.

- Cystometrography may show large filling volumes and lack of a sustained contractile peak, consistent with detrusor atony.
- Urethral pressure profilometry can identify urethral incompetence.

Differential diagnosis

Most other congenital abnormalities do not produce the classical combination of dribbling urine from the penis/vulva and distended easily expressible bladder in a young cat.

Treatment

Treatment depends on the severity of the clinical signs.

Therapy should be directed at minimizing or overcoming overflow incontinence by **manual bladder compression** (provided there is not excessive urethral sphincter tone) and appropriate **treatment of urinary tract infections**.

Prognosis

Poor in severe cases.

COLO-UROCYSTIC FISTULA

Classical signs

- Dribbling urine in young cat.

Clinical signs

Colorocystic fistula has been reported in a male domestic shorthaired kitten.

This anomaly may result from incomplete division of the cloaca during embryogenesis.

Signs were of persistent urine dribbling and cystitis in a young cat.

Diagnosis

The abnormality predisposes to **urinary incontinence and urinary tract infection**.

Diagnosis can be established by contrast urography.

Treatment

Treatment is surgical correction of the fistula while preserving the colonic and urinary bladder function.

ECTOPIC UTERINE HORNS

Classical signs

- Urinary incontinence.

Clinical signs

Ectopic uterine horns terminating into the urinary bladder have been reported in a young female domestic shorthaired cat showing signs of persistent urinary incontinence and cystitis.

Diagnosis

Diagnosis based on contrast cystography.

EXSTROPHY

Classical signs

- Urine dribbles from abdominal defect.

Clinical signs

Very rare disorder in cats characterized by ventral mid-line defects in the ventral abdominal wall, urinary bladder, intestines and external genitalia.

Easily differentiated from other causes of incontinence as urine dribbles from the abdominal defect.

Diagnosis

Diagnosis is based on clinical signs. Exstrophy should be differentiated from patent urachus.

FELINE DYSAUTONOMIA

Classical signs

- Dribbling urine.
- Distended bladder.
- Gastrointestinal and ocular signs.

Pathogenesis

Feline dysautonomia is an autonomic polyganglionopathy (Key–Gaskell syndrome).

Autonomic ganglia (sympathetic and parasympathetic) are affected resulting in detrusor atony and urethral sphincter incompetence.

Overflow incontinence occurs as a result.

Clinical signs

Mainly seen in young cats.

Affected cats may voluntarily pass a small amount of urine with difficulty.

Typically there is a large flaccid urinary bladder (detrusor atony), which is easily manually expressed.

Other clinical signs usually predominate, such as an acute onset over 24–48 h of depression and anorexia, gastrointestinal signs (dysphagia, regurgitation, vomiting, tenesmus, diarrhea, constipation), mydriasis, prolapsed third eyelids, dry mucous membranes and bradycardia.

Diagnosis

Diagnosis is based on clinical examination findings of a flaccid bladder associated with acute onset of depression and gastrointestinal and ocular signs.

Radiographic signs are of megesophagus and a distended urinary bladder.

Ophthalmological examination reveals reduced tear production, dilated poorly responsive pupils in a visual cat, and prolapsed third eyelids.

Urodynamic procedures include the following:

- Cystometry and urethral pressure profilometry may be used to objectively evaluate detrusor and urethral function.
- Cystometrograms can be used to show large filling volumes, and lack of a sustained contractile peak indicates detrusor atony.
- Urethral pressure profilometry can be used to identify urethral incompetence.

Treatment

Bethanecol is effective in inducing urination in some cases, although it should not be used in cats with slow resting heart rates, as profound bradycardia and cardiac arrhythmia may occur.

13. The cat with discolored urine

Joseph William Bartges

KEY SIGNS

- Red, pink, orange, brown, black, white, blue or colorless urine.

MECHANISM?

- Urine color other than yellow including red, orange, white, blue, brown and black is abnormal. Red, brown or orange urine suggests blood, hemoglobin, myoglobin or bilirubin. Cloudy or white urine suggests pus, lipid or crystals. Pale yellow or colorless urine is associated with dilute urine and increased urine volume. Blue or green urine is uncommon, and is usually associated with excretion of drugs or toxins.

WHERE?

- Urogenital tract – urine is formed in the kidney and is usually yellow. Pigments that are filtered by the glomerulus may alter urine color. Blood cells may alter urine color if added to urine after formation.

WHAT?

- Red, pink, orange, brown or black urine***

QUICK REFERENCE SUMMARY

Diseases causing discolored urine

MECHANICAL

- **Urolithiasis causing hematuria*** (p 209)**

*Occurs in 15–30% of cats with lower urinary tract disease; *struvite most common in young cats; *calcium oxalate is most common in middle-aged or older cats; *nephroliths are often composed of calcium oxalate.

NEOPLASIA

- **Neoplasia causing hematuria* (p 210)**

*urinary tract neoplasia is rare in cats; *renal neoplasia is often associated with renomegaly; *hematuria may be the only clinical sign.

continued

continued

METABOLIC

- **Coagulopathy or thrombocytopenia causing hematuria (p 212)**

*coagulopathy and thrombocytopenia are rare in cats; *evidence of bleeding at other sites is often-present, although hematuria may be the only clinical sign; *coagulation testing should be performed in cats with undiagnosed hematuria.

- **Bilirubinuria** (p 211)**

*bilirubinuria is always abnormal in cats; *it may result from prehepatic, hepatic, or post-hepatic causes; *most common causes are hepatic disease.

- **Hemoglobinuria (p 212)**

*associated with hemolysis; *hemolytic anemia is uncommon in cats; *myoglobinuria; *results from muscle breakdown; *may occur secondary to polymyopathy, but uncommon.

INFECTIOUS

- **Urinary tract infection causing hematuria** (p 209)**

*bacterial UTI occurs in 1–2% of cats < 10 years of age, but may occur in >45% of cats > 10 years; * *E. coli* is the most common organism isolated from cats with bacterial UTI; *urine should be collected by cystocentesis to adequately assess bacterial UTI.

IDIOPATHIC

- **Idiopathic lower urinary tract disease causing hematuria*** (p 208)**

*Most common cause of lower urinary tract disease in cats less than 10 years. Clinical signs include hematuria, stranguria, pollakiuria, and inappropriate urination; *urethral obstruction may occur in male cats.

TRAUMA

- **Trauma causing hematuria* (p 210)**

*Trauma to any part of the urinary tract may result in hematuria; *evaluate for other signs of trauma; *if hematuria is secondary to trauma, assess integrity of urinary tract.

- **Cloudy white or white urine** (p 206)**

- **Crystalluria*** (p 213)**

*Commonly associated with urolithiasis, matrix-crystalline urethral plug formation in males; *struvite and calcium oxalate most common; *struvite and urate more common in kittens; *may or may not be pathologic.

- **Pyuria** (p 214)**

*Signifies inflammation, which is often but not always associated with bacterial UTI; *may result from lower or upper urinary tract diseases.

- **Lipiduria (p 214)**

*May be normal; * may be an indication of lipid metabolism disorders.

- **Pale yellow or colorless urine*** (p 207)**

- **Dilute urine*** (p 215)**

*Occurs with polyuric states; *most common causes of PU/PD are renal failure, diabetes mellitus, and hyperthyroidism; *other clinical signs may be present and relate to an underlying disorder.

- **Blue or green urine (p 207)**

*Drug discoloration; *occurs with some drugs or dyes especially methylene blue.

INTRODUCTION

MECHANISM?

Urine that is anything other than yellow is abnormal.

- **Normal urine** is typically transparent and yellow or amber on visual inspection.
- Two pigments, **urochrome** and **urobilin**, impart the yellow color.
- The intensity of the yellow color is in part related to the **volume of urine** collected and concentration of urine produced.
- Significant disease may exist when urine is normal in color.

Abnormal urine color is caused by the presence of several endogenous or exogenous pigments, and indicates a problem.

- **Pink, red, brown, orange or black urine** suggests the presence of **blood, hemoglobin, myoglobin or bilirubin**.
- **Cloudy or white urine** suggests the presence of **pus, lipid or crystals**.
- **Pale yellow or colorless urine** is associated with **decreased urine concentration** and **increased urine volume**.
- **Blue or green urine** is uncommon, and is usually associated with excretion of **drugs or toxins**.

Owners may observe discolored urine in the litter box or in areas of inappropriate urination.

Examination of urine sediment (for red blood cells) and plasma or serum color will aid diagnosis.

Whole blood, hemoglobin and myoglobin **all give a positive reaction on the blood test pad** on dipsticks.

- These can be distinguished as follows:

- **Blood (hematuria)** is present when centrifuged or settled urine is clear with a red sediment at the bottom of the tube, or there are > 10–20 red cells/HPF on microscopic examination of sediment.
- **Hemoglobin** is present if the urine remains pink after centrifugation or on settling, few red cells (< 10 RBC/HPF) are evident on microscopic examination of the sediment, and there is clinical and hematologic evidence of hemolytic anemia. Plasma has a reddish discoloration.
- **Myoglobin** is present if the urine remains pink after centrifugation or on settling, few red cells are evident on microscopic examination of the sediment, and there is clinical and biochemical evidence of muscle damage. Plasma is clear.

Clinical signs associated with discolored urine will aid in diagnosis.

- **Hematuria** (red or pink urine) indicates urinary tract disease (upper or lower) or bleeding disorders.
 - Signs that suggest the cause is **lower urinary tract disease** are stranguria, pollakiuria and dysuria (urine may be pink, red, brown, orange or cloudy in color).
 - Signs that suggest hematuria is from **upper urinary tract** disease include polyuria and polydipsia (urine is usually pale yellow or colorless, however, cloudy or red urine may occur).
 - A **bleeding disorder** is indicated by evidence of bleeding from other sites.
 - **Hemoglobin** in urine suggests **intravascular hemolysis**. Marked hemoglobinuria may occur in kittens with neonatal isoerythrolysis. Hemoglobinuria rarely occurs with *Hemobartonella* infection and immune-mediated anemia, which present mainly as extravascular hemolysis.

- Signs that suggest intravascular hemolysis and hemoglobinuria include acute illness, fever, pale mucous membranes, +/- jaundice, +/- splenomegaly, or acute lethargy and death in 1–3-day-old kittens.
- Hemoglobinuria and bilirubinuria may be both present with intravascular hemolysis.
- **Myoglobinuria** (red or brown urine) suggests acute muscle damage. In cats this is most often associated with ischemic myopathy secondary to an aortic thrombosis, muscle injury from trauma or ischemia (e.g. entrapment in window), or snake bite (especially Australian tiger snake).
 - Muscle damage with leakage of myoglobin is suggested by signs of muscle pain, biochemical evidence of muscle damage (increased creatine kinase) and other historical and clinical signs of trauma, thrombosis or snakebite.
- **Bilirubinuria** (dark yellow urine) suggests marked erythrocyte breakdown (hemolytic anemia), hepatic disease or bile duct obstruction.
 - Bilirubinuria is most often associated with hepatic disease including cholangiohepatitis complex, hepatic lipidosis, neoplasia and feline infectious peritonitis.
 - Occasionally it occurs when *Hemobartonella*-associated hemolysis is severe enough to cause jaundice.
 - Clinical signs are varied depending on the cause of bilirubinuria. Serum and plasma are also jaundiced.
- Cats with hematuria from upper urinary tract disease or hemoglobinuria, myoglobinuria or bilirubinuria may be systemically ill.
- Mucus membranes may be pale or yellow if urine discoloration is associated with hyperbilirubinemia or hemolytic anemia.
- Some cats with abnormal urine may have no other clinical signs.

WHERE?

Discolored urine is produced in the urinary tract. It may result from urinary tract disease (most common), a systemic bleeding disorder, or from excretion of pigments from the plasma.

Careful history and physical examination may help to determine if the discoloration is clinically significant.

WHAT?

Hematuria is the **most common** cause of discolored urine. This is most often associated with idiopathic lower urinary tract disease and less frequently with urolithiasis.

DISEASES CAUSING DISCOLORED URINE

RED, PINK, ORANGE, BROWN OR BLACK URINE

Red, pink, orange, brown or black urine suggests the presence of hematuria (frank blood), hemoglobin, myoglobin or bilirubin. Red or pink urine is most commonly associated with hematuria.

Cats with discolored urine may or may not have signs of lower urinary tract disease (stranguria, pollakiuria, dysuria, urination in inappropriate places).

Systemic illness may or may not be present.

Mucous membranes may be pale or yellow if associated with hyperbilirubinemia or anemia.

Diagnosis is aided by examination of urine sediment for red and white blood cells, and plasma or serum color.

IDIOPATHIC LOWER URINARY TRACT DISEASE CAUSING HEMATURIA*** (IDIOPATHIC FELINE LOWER URINARY TRACT DISEASE, IDIOPATHIC CYSTITIS-URETHRITIS COMPLEX, FELINE UROLOGIC SYNDROME, INTERSTITIAL CYSTITIS)

Classical signs

- Stranguria, pollakiuria, inappropriate urination and hematuria are present.
- Occurs most commonly in cats less than 10 years of age.

See main reference on page 176 for details on idiopathic lower urinary tract disease.

Clinical signs

Clinical signs are similar to other causes of lower urinary tract disease: **hematuria, pollakiuria, stranguria and urination in inappropriate places.**

Most commonly occurs in cats less than 10 years of age; **average age is 2–4 years.**

Occurs with even frequency in male and female cats.

May be associated with urethral plug formation and obstruction in male cats.

Diagnosis

Must be differentiated from other causes of lower urinary tract disease such as urolithiasis and bacterial urinary tract infection.

In cats less than 10 years of age, it occurs in 55–70% of cases of lower urinary tract disease; in cats greater than 10 years of age, it occurs in 5–10% of cases of lower urinary tract disease.

Diagnosis is made by excluding other causes of lower urinary tract disease.

Urinalysis reveals hematuria (>5 RBC/hpf) without a urinary tract infection; white blood cells are usually present at < 5–10/hpf and urine culture is negative.

Crystals may or may not be present on urine sediment examination.

Radiographs and ultrasonography of the lower urinary tract are usually normal; however, bladder wall thickening or intraluminal blood clots may be present.

Cystoscopy often reveals small mucosal hemorrhages called glomerulations, without identifying other diseases processes.

UROLITHIASIS CAUSING HEMATURIA***

Classical signs

- Stranguria, pollakiuria, inappropriate urination and/or urethral obstruction.
- Renal pain, hematuria, or uremia if uroliths present in upper urinary tract.

See main reference on page 184 for details on urolithiasis.

Clinical signs

If uroliths are located in the **lower urinary tract, stranguria, pollakiuria, inappropriate urination, hematuria** and/or urethral obstruction may occur.

If uroliths are located in the **upper urinary tract, renal pain, hematuria** or **uremia** (if bilateral) may be present.

Uremia is present with urethral obstruction or bilateral ureteral obstruction.

Clinical signs may also be absent with uroliths.

Diagnosis

Microscopic examination of urine sediment reveals RBCs.

Crystalluria may or may not be present. If present, they may aid in estimating mineral composition (see page 213 for description of crystal appearance).

Most common mineral composition includes struvite (magnesium ammonium phosphate hexahydrate) and calcium oxalate; urate (purine), cystine, calcium phosphate, and drug metabolites have also been observed to occur.

Struvite and calcium oxalate uroliths are usually radiodense; urate and cystine are usually radiolucent and require contrast radiography or ultrasonography to identify.

URINARY TRACT INFECTION CAUSING HEMATURIA**

Classical signs

- Hematuria, stranguria, pollakiuria, and/or inappropriate urination (urinary bladder infection).
- Urinary tract infection may occur secondary to another disease, and other clinical signs may be present.
- Asymptomatic or associated with fever, renal pain, or uremia (upper urinary tract infection).

See main reference on page 187 for details on urinary tract infections.

Clinical signs

Bacterial urinary tract occurs in approximately **1–2% of cats less than 10 years of age** that have lower urinary tract disease, **40–50% of cats greater than 10 years of age** that have lower urinary tract disease, and in approximately **20% of cats with renal failure**.

Bacterial urinary tract infection is more common than other infectious agents and usually involves the lower urinary tract.

Less common infectious agents causing hematuria include feline infectious peritonitis (FIP).

Urinary bladder is most common site of urinary tract infection. Clinical signs include **hematuria, stranguria, pollakiuria and/or inappropriate urination**; however, some cats may be asymptomatic.

If the upper urinary tract is involved, fever, renal pain and/or uremic signs may be present.

Bacterial urinary tract infection may occur secondary to diseases that alter normal host defense mechanisms such as renal failure, diabetes mellitus, urolithiasis or neoplasia; therefore, additional clinical signs may relate to the underlying disease.

Diagnosis

Urinalysis may reveal **pyuria (> 5 WBC/hpf), bacteriuria, hematuria (> 5 RBC/hpf), and/or proteinuria**; however, a bacterial urinary tract infection may be present with an inactive urinary sediment on microscopic examination, especially in cats with concurrent disease(s).

An aerobic culture and sensitivity should be performed on a urine sample collected by cystocentesis.

- This allows identification of the organism as well as selection of the appropriate antimicrobial for treatment.
- Nitrite and leukocyte test pads present on some dipsticks are not reliable and should not be used.
- **Urine may be stained with Wright's stain or Gram stain to aid in identification** of bacteria and to assist in selecting an appropriate antibiotic until culture results are returned.

TRAUMA CAUSING HEMATURIA*

Classical signs

- Hematuria.
- History of trauma may be present.
- Evidence for other trauma-induced injury (such as broken bones, diaphragmatic hernia, dyspnea, etc.).

Clinical signs

Evidence for trauma such as broken bones, dyspnea, pneumothorax, shredded nails, lacerations, etc., are often present.

History of traumatic episode, such as being hit by a car or attacked by a dog is often present.

Shock may be present.

Hematuria is present if the urinary tract is injured due to trauma (hemorrhage may be from upper urinary tract, lower urinary tract or both).

Diagnosis

Hematuria (numerous RBCs) is found on urinalysis.

- **Hemorrhage may be from the lower urinary tract, the upper urinary tract or both.**
- It is important to determine if the urinary tract is intact. This may require an excretory urogram to evaluate the upper urinary tract and/or contrast urethrocytography to evaluate the lower urinary tract.
 - Unexplained azotemia or uroabdomen (abdominal fluid with composition of urine, i.e. creatinine concentration > plasma) is an indication for contrast radiography and possibly surgical intervention.

Evidence for other organ systems being traumatized aids diagnosis.

NEOPLASIA CAUSING HEMATURIA*

Classical signs

- Hematuria, pollakiuria, stranguria and/or inappropriate urination may be present.

Classical signs—Cont'd

- Hematuria may be only clinical sign if upper urinary tract involved.

See main reference on page 191 for details on bladder/urethral neoplasia and page 250 for details on renal neoplasia.

Clinical signs

If the neoplasm involves the lower urinary tract, clinical signs may include **hematuria, stranguria, pollakuria and/or inappropriate urination.**

If the neoplasm involves the **upper urinary tract, hematuria** may be present; renomegaly may be palpated.

Diagnosis

Most common lower urinary tract neoplasms include **transitional cell carcinoma and lymphoma.**

- Neoplastic cells may be present on microscopic examination of urine sediment.
- A bladder or urethral mass may be detected by ultrasonography, contrast urethrocystography, urethrocystoscopy or cystotomy.
- Definitive diagnosis is made by fine-needle aspiration, biopsy or excision of mass.

Most common upper urinary tract neoplasms include **lymphoma and carcinoma.**

- **Renomegaly is usually present; lymphoma often involves both kidneys.**
- Neoplastic cells may be present on microscopic examination of urine sediment.
- Survey abdominal radiography may reveal renomegaly.
- Renal ultrasonography may reveal a discreet renal mass or **diffuse hyperechogenicity if lymphoma** is involved.
- Definitive diagnosis is made by fine-needle aspiration, biopsy or nephrectomy.

BILIRUBINURIA****Classical signs**

- Urine is dark yellow.
- Mucous membranes and skin are icteric.

See main reference on page 421 (The Yellow Cat or Cat With Elevated Liver Enzymes) for details on the icteric cat.

Clinical signs

Urine is dark yellow or brown from presence of bilirubin.

Cat may be weak and icteric.

Mucous membranes are pale if associated with hemolytic anemia.

Abdominal palpation may reveal hepatomegaly, hepatic masses or the liver may not be palpable.

Bilirubinuria may be associated with vomiting, anorexia, diarrhea and/or neurologic signs (seizure, hypersalivation, tremors).

Diagnosis

Bilirubinuria is diagnosed by a color change on the bilirubin pad on a urine dipstick.

- Bilirubinuria is always abnormal in a cat.
- **The bilirubin test pad may change color if the urine is heavily pigmented as with hematuria.**

Bilirubinuria may occur because of prehepatic, hepatic or posthepatic causes of excess bilirubin in the plasma.

- Bilirubinemia and bilirubinuria occur when the hepatic capacity to process bilirubin is overwhelmed by marked hemolysis. Hemolysis is associated with anemia that is usually regenerative, and most commonly caused by **Hemobartonellosis** or **immune-mediated** mechanisms.
- Bilirubinuria also occurs when the capacity of the liver to process bilirubin is reduced, causing bilirubinemia. There are many causes for **hepatic-related icterus**, but **hepatic lipidosis, cholangio-**

hepatitis complex, feline infectious peritonitis and lymphosarcoma are most common.

- ALT, GGT and/or alkaline phosphatase activities are abnormal.
- Liver function tests, such as provocative serum bile acid concentrations or blood ammonia concentrations, are abnormal.
- Abdominal radiography and ultrasonography may reveal focal or diffuse hepatomegaly with abnormal echotexture.
- Liver biopsy or fine-needle aspiration is necessary to confirm the underlying disease.

Bile duct obstruction (posthepatic cause of bilirubinemia and bilirubinuria) is associated with cholestatic icterus, and is most commonly associated with pancreatitis, pancreatic or duodenal neoplasia, or sludge bile syndrome.

- **Alkaline phosphatase activity is usually extremely elevated relative to other liver enzyme activities.**
- Enlarged bile duct may be observed by abdominal ultrasonography.

COAGULOPATHY OR THROMBOCYTOPENIA CAUSING HEMATURIA

Classical signs

- Hematuria may occur.
- Other evidence of hemorrhage is usually present.

See main reference on page 487 (The Bleeding Cat) for details on coagulopathies.

Clinical signs

Hematuria may be the only clinical sign, but hemorrhage may occur from other orifices or in body cavities; **petechiations may be present.**

There may be a history of exposure to an anticoagulant toxin.

Pale mucous membranes.

Diagnosis

Anemia due to blood loss is present.

- **Marked thrombocytopenia** is present if it is the cause of the bleeding disorder or if associated with **DIC**.
- Coagulation tests are prolonged if associated with rodenticide poisoning or clotting factor deficiency.

Hematuria is present; however, white blood cell counts are usually < 5–10/hpf.

HEMOGLOBINURIA

Classical signs

- Urine is red or pink.
- Mucous membranes may be pale if associated with anemia.

See main reference on page 532 for details (The Anemic Cat) on hemolytic anemia.

Clinical signs

Hemoglobinuria indicates severe intravascular hemolysis has occurred.

Urine is usually red or pink due to excretion of hemoglobin, which has exceeded the saturation limit of the carrier plasma protein (haptoglobin).

Pale mucous membranes may be present and the cat may be weak or may collapse due to anemia.

- Tachypnea and tachycardia may be present.

Other signs suggestive of intravascular hemolysis and hemoglobinuria include acute illness, fever, pale mucous membranes, +/- jaundice, +/- splenomegaly or acute lethargy.

Marked hemoglobinuria is **most common in kittens with neonatal isoerythrolysis**. Kittens are normal at birth but develop acute lethargy or death in the first 1–3 days of life. In adult cats, hemoglobinuria is very **rarely associated** with *Mycoplasma haemofelis* or immune-mediated anemia.

Diagnosis

Although **urine is red or pink, RBCs are not observed on microscopic examination** of urine sediment.

Hemoglobinuria may be differentiated from myoglobinuria by examination of **plasma or serum; plasma**

or serum is pink with hemoglobinuria but clear with myoglobinuria.

Anemia may be present.

- Plasma and serum are pink.
- May be Coombs positive if associated with immune-mediated hemolytic anemia.

MYOGLOBINURIA

Classical signs

- Urine is red or brown.
- Muscle weakness or pain present.

See main reference on page 950 (The Cat With Generalized Weakness) for details on snake bite, and page 915 (The Weak and Ataxic or Paralyzed Cat) for details on aortic thrombosis.

Clinical signs

Myoglobinuria is most **commonly associated with aortic thrombosis or snake bite**. Rarely, toxoplasmosis results in myoglobinuria or bilirubinuria in young cats.

Urine is red, brown, or black.

Muscle weakness or pain is present.

Vomiting, anorexia, or other polysystemic signs may be present.

Arrhythmia or heart murmur may be present if an aortic saddle thrombus is present secondary to underlying cardiomyopathy.

Diagnosis

Urine is red, brown or black.

No RBCs observed on microscopic examination of urine sediment.

Plasma and serum are normal in color.

Hyperkalemia and metabolic acidosis is often present if due to muscle injury.

There is evidence for other organ dysfunction if myoglobinuria is associated with toxoplasmosis, including dyspnea, anemia, vomiting, diarrhea, neurological signs or jaundice.

Evidence of cardiac disease is usually present with aortic-saddle thrombus.

Snake bite may be complicated by a coagulopathy and hemolysis, resulting in hemoglobinuria, hematuria, as well as myoglobinuria.

CLOUDY WHITE OR WHITE URINE

Cloudy or white urine suggests the presence of pus, lipid, or crystals.

Diagnosis is aided by microscopic examination of urine sediment for pyuria, crystalluria or lipiduria.

Consideration of the clinical signs aids diagnosis. Signs of lower urinary tract disease or systemic illness may or may not be present.

CRYSTALLURIA***

Classical signs

- White or cloudy urine.
- May or may not be associated with urolithiasis.

See main reference on page 184 (The Cat Straining to Urinate) for details on urolithiasis.

Clinical signs

Crystalluria may result in white or cloudy urine if the crystalluria is marked or the urine is concentrated.

Crystalluria may occur with or without urolithiasis, and uroliths may be present without crystalluria.

- Uroliths in the lower urinary tract may be associated with hematuria, stranguria, inappropriate urination, pollakiuria or urethral obstruction.
- Uroliths in the upper urinary tract may be associated with hematuria or renal pain.
- Uroliths may not be associated with clinical signs.

Diagnosis

Crystals are identified on microscopic examination of urine sediment.

- **Struvite** crystals are typically “coffin-lid”-shaped or amorphous, and occur in a neutral to alkaline pH.

- **Calcium oxalate** crystals are typically “**dumb-bell**”-shaped (**monohydrate**) or are “**square-shaped** with an ‘**X**’ in the center” (**dihydrate**), and occur in an acidic pH.
- **Urate crystals** are typically **yellow or brown** and **amorphous**, and occur in an acidic pH.
- **Cystine crystals** are **six-sided**, and occur in an acidic pH.
- Other crystals include other minerals (calcium phosphate), normal metabolites (leucine, bilirubin, tyrosine) or drugs (iodinated contrast media, sulfa-containing antibiotics).

Crystals may be present as artifact.

- Crystals may form due to a change in pH or temperature after collection; **struvite crystals commonly form in healthy cats if the urine is allowed to cool to room temperature** or colder (as with refrigeration).
- Crystals may also occur if the urine sample is allowed to evaporate.
- For accurate interpretation, a complete urinalysis including microscopic examination of sediment should be done on a **freshly collected sample in order to avoid artifact**.

PYURIA**

Classical signs

- Cloudy white or white urine.
- Stranguria, pollakiuria if inflammation involves lower urinary tract.
- Fever, vomiting, renal pain if inflammation involves upper urinary tract.

See main reference on page 187 (The Cat Straining to Urinate) for details on bacterial cystitis and page 225 (The Cat With Inappropriate Urination) for pyelonephritis.

Clinical signs

Pyuria is indicative of inflammation.

- This is usually associated with an infectious process.
 - **Bacterial infection is most common.**
 - Funguria is rare and is usually associated with a decrease in the host defense mechanisms such as diabetes mellitus, urolithiasis, chronic antibiotic administration, feline leukemia virus or feline

immunodeficiency virus infection, or neoplasia (see page 228, The Cat With Inappropriate Urination).

- Occasionally pyuria occurs without an infection.

Inflammation of the lower urinary tract is usually associated with **stranguria, dysuria, pollakiuria and/or inappropriate urination**; however, clinical signs may be absent.

Inflammation of the kidneys/ureters may be associated with **systemic illness** (fever, vomiting, renal pain and/or anorexia).

Diagnosis

Urine is white or cloudy.

Microscopic examination of urine sediment reveals increased numbers of WBC (typically > 50–100/hpf).

- Normal urine contains < 3–5 WBC/hpf.
- The significance of cell counts should be considered in association with the urine specific gravity.

Nitrite and leukocyte test pads present on some urine dipsticks are **not reliable** and should not be used.

LIPIDURIA

Classical signs

- White urine.
- Not usually associated with a systemic disease although may be associated with lipid metabolism abnormalities.

See main reference on page 425 (The Yellow Cat or Cat With Elevated Liver Enzymes) for details on hepatic lipidosis and page 569 (The Cat With Hyperlipidemia).

Clinical signs

Lipiduria may result in white urine.

Lipiduria is **not usually associated with clinical signs**; it appears to be normal in some cats particularly those that are **obese** and consuming **normal or increased amounts of dietary fat**.

It may be present with lipid metabolism disorders such as idiopathic hyperlipidemia, inherited hyperchylomicronemia and idiopathic feline hepatic lipidosis.

Diagnosis

Lipid droplets identified on **microscopic sediment examination**.

Lipid droplets may be stained using Sudan IV.

PALE YELLOW OR COLORLESS URINE

DILUTE URINE***

Classical signs

- Polyuria and polydipsia are usually present.
- Most common causes of polyuria in cats are renal failure, diabetes mellitus and hyperthyroidism.

See main reference on page 231 for details (The Cat With Polyuria and Polydipsia).

Clinical signs

Pale yellow or colorless urine implies increased urine volume; therefore, **polyuria and polydipsia** are usually present.

Polysystemic signs such as **vomiting, weight loss** and anorexia may be present with some diseases (renal failure and diabetes mellitus) and increased appetite may occur with hyperthyroidism and diabetes mellitus.

Diagnosis

Urine is pale yellow or colorless.

Urine specific gravity is isosthenuric (1.008–1.014) or hyposthenuric (< 1.008).

Pale yellow or colorless urine may be normal with consumption of a large quantity of water, consumption of a low-protein diet or administration of fluids or agents that induce diuresis.

Pale yellow or colorless urine should be considered abnormal if present with azotemia or dehydration.

BLUE OR GREEN URINE

DRUG DISCOLORATION

Classical signs

- Blue or green urine.
- History of administration of drugs especially methylene blue.

Clinical signs

A number of drugs and dyes cause blue or green urine but few are used in cats.

Blue or green urine occurs in cats following methylene blue use. In humans amitriptyline and riboflavin have been reported to cause blue or green urine.

Diagnosis

Careful questioning of the owner will usually identify the drug causing the urine discoloration.

14. The cat with inappropriate urination

Joseph William Bartges

KEY SIGNS

- Urination in inappropriate places.

MECHANISM?

- Urination occurs outside the litter box in inappropriate places. Urine may or not be of normal consistency and composition. Inappropriate urination occurs as a result of lower urinary tract diseases (urgency, irritation), polyuric states (inability to retain large volume of urine), incontinence (uncontrolled urination), or behavioral problems. In addition to inappropriate urination, clinical signs are variable depending on the underlying disease, if present.

WHERE?

- Urogenital tract.

WHAT?

- Most cats with inappropriate urination have an underlying disease process. Many lower urinary tract diseases are associated with inappropriate urination. Inappropriate urination may also be associated with polyuric states or behavioral problems.

QUICK REFERENCE SUMMARY

Diseases causing inappropriate urination

DEGENERATIVE

- Hormonally responsive incontinence (p 227)
Incontinence is uncommon in cats; cats unconsciously urinate especially when sleeping.

ANOMALY

- Congenital anatomic diseases of the bladder or urethra (p 226)
Congenital bladder and urethral diseases are uncommon; usually stranguria, pollakiuria or complete inability to urinate is observed in addition to inappropriate urination.

continued

continued

- **Incontinence (p 227)**

Incontinence resulting from congenital disease is uncommon. Affected cats may continuously pass small drops of urine.

METABOLIC

- **Polyuric states (p 224)**

Any disease associated with increased urine volume may result in cats urinating inappropriately if they are not able to adequately retain urine and use the litter box. Examples include chronic renal failure, diuretic therapy, diabetes mellitus and hyperthyroidism.

- **Urolithiasis** (p 222)**

Signs of lower urinary tract disease including pollakiuria, stranguria and hematuria are usually present, although uroliths may be present without clinical signs; may cause urethral obstruction.

NEOPLASTIC

- **Neoplasm involving urethra and/or urinary bladder (p 225)**

Pollakiuria, stranguria and hematuria usually present; may be associated with recurrent bacterial urinary tract infections or urethral obstruction.

- **Meningioma (p 227)**

May be associated with proprioceptive deficits, alteration of spinal reflexes and alteration of mentation: however, only clinical sign may be urinary incontinence.

PSYCHOLOGICAL

- **Behavioral*** (p 219)**

Inappropriate urination without clinical, biochemical or radiological evidence for an underlying disease involving the urinary bladder or urethra; may be associated with other behavioral problems or develop as a consequence of lower urinary tract disease.

INFECTIOUS

- **Bacterial urinary tract infection** (p 225)**

Pollakiuria, dysuria and hematuria are usually present; bacterial urinary tract infections are uncommon in cats and usually occur secondarily to another disease.

- **Fungal urinary tract infection (p 228)**

Cat may be asymptomatic or show pollakiuria, stranguria, hematuria and inappropriate urination; often occurs secondary to an underlying disease or immunosuppressive process.

- **Viral urinary tract infection (p 226)**

May result in secondary bacterial or fungal urinary tract infection (FeLV, FIV), or hypothesized to be one of the causes of idiopathic lower urinary tract disease.

IDIOPATHIC

- **Non-obstructive idiopathic lower urinary tract disease**** (idiopathic cystitis, feline urologic syndrome, interstitial cystitis, idiopathic FLUTD)*** (p 222)**

Cats show pollakiuria, hematuria, stranguria and inappropriate urination without an identifiable cause.

IATROGENIC

- **Catheterization of the urinary bladder or urethra* (p 224)**

History of catheterization for relief of urethral obstruction, bladder disease or for diagnostics.

TRAUMATIC

- **Trauma to urethra and/or urinary bladder*** (p 223)**

History of trauma or physical examination findings of trauma (fractures, skin abrasions, uroabdomen, etc.). Cats may be able to urinate even when the urinary bladder is compromised.

INTRODUCTION

MECHANISM?

Inappropriate urination is **defined as cats urinating in inappropriate places** (typically outside of a litter box) or at inappropriate times.

Lower urinary tract disease is the most common cause of inappropriate urination, and signs such as pollakiuria, stranguria and/or hematuria, are usually present.

Inappropriate urination **may also occur with incontinence, polyuric states** and an inability to retain urine appropriately, or as a **behavioral problem**.

- Inappropriate urination may be a behavioral problem that is learned while the cat is suffering from another lower urinary tract disease, such as idiopathic lower urinary tract disease or urolithiasis.
- Cats are inherently fastidious creatures and do not normally soil where they live.
- Male cats may urinate outside of the litter box to mark their territory.
- **Female cats usually do not mark territory;** however, they may do so if they are, or become, the **dominant cat** in the household.

WHERE?

Brain, bladder and urethral sphincter (mucosa, muscle, nerves).

- If pollakiuria, stranguria and hematuria are present, it localizes the disease to the lower urinary tract.

WHAT?

Most commonly, inappropriate urination occurs with lower urinary tract disease.

- In young cats, **idiopathic lower urinary tract disease is the most common cause** of lower urinary tract disease occurring in 50–70% of cases.
 - **Urolithiasis** is the second most common cause occurring in 15–25% of cases.
 - Bacterial urinary tract infection, trauma, neoplasia and incontinence are uncommon in young cats.
- In cats older than 10 years, **bacterial urinary tract infection** is the most common cause of lower urinary tract disease, occurring in 35–50% of cases.
 - Urolithiasis occurs in 10–15% of cases.
 - Idiopathic disease, trauma, neoplasia and incontinence are uncommon causes.

Inappropriate urination, however, may occur without signs of lower urinary tract disease.

- It may occur with **incontinence**.
- It may occur with **polyuric states**.
- It may be **behavioral**.

Diagnosis is based on historical information, physical examination findings and results of laboratory and radiological evaluation.

DISEASES CAUSING INAPPROPRIATE URINATION

BEHAVIORAL***

Classical signs

- Behavioral elimination problems are the most common behavior complaints of owners.
- Cats may urinate outside of the box.
- Behavioral urination problems may include inappropriate urination or urine marking.
- Underlying medical problems may result in a behavioral component causing inappropriate urination.

Pathogenesis

House-soiling problems are the most common behavior complaints made by cat owners.

Urine house-soiling problems include inappropriate urination and urine marking.

- Inappropriate urination involves elimination of urine outside the litter box at locations unacceptable to the owner.
 - **Inappropriate urination usually occurs on horizontal surfaces** outside the litter box.
 - Any age, breed or gender cat may be affected.
 - Location of inappropriate urination is variable.
 - **Inappropriate urination often results from a problem with the litter box** including, unwillingness by the cat to use certain types of litter, infrequent cleaning, change in litter consistency or amount and a deterrent to using the litter box because of other cats in the household.
- **Urine marking involves the use of urine in the act of olfactory communication, which may occur independent of the act of urination.**
 - Urine spraying occurs **more frequently in males than in females**, and in **intact animals** compared with neutered animals.
 - Urine marking may act as a means for cats to communicate their presence so that other cats will avoid using the same space at the same time.
 - Urine marking may be indicative of a high level of arousal, **often associated with the presence of other cats inside or outside of the house.**
 - Urine marking **often involves surfaces other than horizontal ones (such as drapes, walls and furniture)**; however, it may involve horizontal surfaces similar to inappropriate urination.
 - Urine marking is not usually associated with a medical condition.

Clinical signs

Inappropriate urination occurs when the cat urinates a normal amount of urine assuming a normal posture consciously outside of the litter box; inappropriate fecal elimination may also occur. Urinalysis may or may not be normal.

Urine marking involves passing small amounts of urine on surfaces other than horizontal to mark a territory that a cat inhabits or is passing through; urinalysis is normal.

Diagnosis

Underlying medical problems must be ruled-out for a diagnosis of a behavioral problem, although behavioral urination problems may occur in conjunction with or following an underlying medical condition.

A behavioral history should be performed once medical problems have been eliminated.

- The owner should be asked to keep a daily record of the number of eliminations in each litter box and the number of eliminations outside the litter box with the location noted.
- Information should also be obtained concerning the care of the litter box by the owner.
- It is beneficial to ask the owner to make a map of the interior of the home, with sites of elimination and litter boxes marked so patterns can be visually identified.
- If multiple cats are in the household or **if it is uncertain as to where a cat may be urinating** inappropriately, **fluorescein dye** (0.3 ml SQ, 0.5 ml PO, or six fluorescein strips in gel capsules given PO) may be administered; any urine that is found outside the litter box during the next 24 hours can be checked for fluorescence using a Wood's light.

Urine marking is typically characterized by a cat passing small amounts of urine in different places ("spraying").

- Owners may or may not observe this behavior.
- In a multi-cat household, more than one cat may exhibit this behavior.
- Although isolation of cats in a household may identify the individual, urine marking may cease when separated from housemates.
- Fluorescein dye as described before may also be used to identify offenders.

Differential diagnosis

Inappropriate urination may or not occur secondary to a medical disorder.

- Diseases associated with **polyuria**, such as **renal failure** and **diabetes mellitus**, may result in inappropriate urination, because the **cat finds the litter excessively wet.**
- Causes of **lower urinary tract disease**, such as **urolithiasis or idiopathic disease** (non-obstructive FLUTD or interstitial cystitis), result in inappropriate urination.

- **Incontinence** associated with a congenital or acquired anatomical problem may be interpreted as inappropriate urination.

Urine marking must be differentiated from inappropriate elimination.

- This can usually be accomplished on the basis of historical information and a good behavior history.
- **Underlying medical problems rarely result in urine marking.**

Treatment

The goal of treatment of inappropriate urination is to **enhance the appeal and accessibility of the litter box and to decrease the availability and appeal of alternate sites.**

- The litter box should contain a litter that is preferred by the cat and kept clean.
- A litter box may be used in the **area where inappropriate urination has occurred.**
 - Once the cat begins to use this litterbox, it may be moved slowly to a site more acceptable to the owner.
 - Deterrents such as an unacceptable substrate, e.g. plastic covers or odor may be used at the inappropriate site.
- **Positive reinforcement** when the cat uses the appropriate litter box is better than negative reinforcement when the cat inappropriately eliminates.
- Pharmacologic therapy is not usually necessary; **environmental therapy is much more effective** with behavioral inappropriate urination.
- Owners' compliance can be a problem, and owners should maintain records of the cat's elimination patterns; owners also need positive reinforcement.

Treatment of urine marking can be accomplished by environmental, behavior, surgical and pharmacological methods.

- Environmental treatment involves deterring the cat from urine marking.
 - Restrict the cat from areas where spraying occurs.
 - Block the indoor cat's view of outdoor cats.
 - Reduce the number of cats outside or inside the house.

- Make the location where the cat marks aversive to the problem cat.
- An **odor deterrent** such as citrus spray may be effective.
- **Spray synthesized facial pheromone** (the F3 fraction) **at the site(s).**
- Behavior modification consists of positive interactions with the cat in **scheduled play or grooming times.**
 - **Avoid punishment** because it may increase the cat's fear and anxiety.
- Pharmacologic treatment of urine marking attempts to attenuate the cat's arousal and/or anxiety in response to social or environmental situations.
 - **Benzodiazepines** have been used for their anxiolytic property.
 - They may not only decrease anxiety and fear, but they produce mild sedation.
 - Dosage of diazepam is 1–4 mg/cat q 12–24 h PO.
 - Side effects include sedation, muscle relaxation, increased appetite and paradoxical excitation; hepatic necrosis has been reported to occur rarely in cats.
 - Other **benzodiazepines** have not been thoroughly evaluated in cats.
 - Alprazolam may be given at 0.125–0.25 mg PO q 12 h or 0.05–0.1 mg/kg PO q 8 h.
 - Dosage for clonazepam is 0.016 mg/kg PO q 6–24 h.
 - Clorazepate dosage is 0.55–2.2 mg/kg PO q 12–24 h.
 - Flurazepam has been used primarily as an appetite stimulant at 0.2–0.4 mg/kg PO as needed.
 - Triazolam may also be tried at 0.03 mg PO q 12 h.
 - **Azaperones have serotonergic and dopaminergic mechanisms.**
 - **Buspirone** has been shown to be efficacious for the treatment of urine marking.
 - Dosage is 5–7.5 mg PO q 12 h, or 2–10 mg PO q 12–24 h, or 0.5–1 mg/kg PO q 12–24 h.
 - The drug has no potential for abuse and does not cause sedation.
 - It may take 1–3 weeks to show an effect.
 - Side effects include idiosyncratic changes in social behavior and mild gastrointestinal side effects.

- **Tricyclic antidepressants are used commonly to treat behavioral disorders.**
- Amitriptyline is used most commonly although clomipramine has been used.
- Dosage for **amitriptyline** is 2.5–10 mg PO q 24 h or 0.5–1 mg/kg PO q 24 h, and for **clomipramine**, it is 1–5 mg PO q 12–24 h.
- Side effects include sedation and possible anticholinergic effects.
- **Selective serotonin reuptake inhibitors** act selectively on the serotonin neurotransmitter system.
- Fluoxetine and paroxetine have been used to treat urine marking.
- Dosage for **fluoxetine** is 0.5 mg/kg PO q 12 h or 1–2.5 mg PO q 24 h, and for **paroxetine**, 0.5 mg/kg PO q 24 h or 1.25–2.5 mg PO q 24 h.
- Fluoxetine may take 3–4 weeks before an effect is observed; paroxetine has a shorter half-life and is quicker acting.
- Side effects include vomiting, diarrhea, nausea, inappetence, sleep disturbances and irritability.
- Historically, progestational compounds have been used to treat urine marking; however, because severe side effects such as diabetes mellitus may occur, other pharmacotherapy should be used.
- **Surgical treatment** can affect the incidence of urine marking.
 - **Castrate intact males.**
 - Olfactory transaction has been used rarely and is reserved for cats that are refractory to all other forms of therapy.

Prognosis

Prognosis for behavioral inappropriate urination is good; however, owner compliance is necessary.

Prognosis for urine marking is good; however, cats that are refractory to treatment often become unacceptable as indoor pets and are put outdoors or are euthanized.

Prevention

Inappropriate urination may be prevented by treating underlying medical problems and by appropriate care of the litter box.

Urine marking may be prevented by **castrating cats when kittens**, by **minimizing stress in the environment**, and by **early treatment of the problem**.

NON-OBSTRUCTIVE IDIOPATHIC LOWER URINARY TRACT DISEASE*** (IDIOPATHIC CYSTITIS, FELINE UROLOGIC SYNDROME, INTERSTITIAL CYSTITIS, IDIOPATHIC FLUTD)

Classical signs

- Inappropriate urination, hematuria, stranguria and pollakiuria.
- Signs are usually transient lasting between 3 and 7 days.

See main reference on page 176 for details (The Cat Straining to Urinate) on idiopathic lower urinary tract disease.

Clinical signs

Inappropriate urination, pollakiuria, stranguria and hematuria commonly occur.

Idiopathic disease is more common **in cats younger than 10 years of age**.

Clinical signs typically last between 3 and 7 days.

Diagnosis

The diagnosis of idiopathic lower urinary tract disease is based on clinical signs and exclusion of other causes of lower urinary tract disease.

- **Urinalysis reveals hematuria** (> 5 RBC/hbf).
- **Pyuria and bacteruria are not present** (i.e. < 5 WBC/hbf).
- Abdominal radiography and ultrasonography, and contrast urethrocystography are normal or only show mild thickening of the bladder wall.

Complete blood cell counts and serum biochemical analysis are normal, and FeLV and FIV are negative.

UROLITHIASIS**

Classical signs

- Inappropriate urination is usually associated with stranguria and hematuria.

See main reference on page 184 for details on urolithiasis.

Clinical signs

Inappropriate urination due to urolithiasis is usually associated with **stranguria, pollakiuria and hematuria**.

Most uroliths occur in **middle-aged to older cats**.

Urethral obstruction may also occur, therefore, post-renal uremia may also be present (vomiting, anorexia, oral ulceration).

If **urate uroliths** develop in association with a portal vascular anomaly, tremors, seizures, salivation, depression and stunted growth may also be observed. **Signs are usually present before 2 years of age.**

Diagnosis

Diagnosis is based on radiography and/or ultrasonography of the urinary tract.

- Because uroliths composed of **struvite and calcium oxalate** account for more than 85% of urocalculi, they are often **observed on survey radiography**. Contrast cystography will help identify radiolucent uroliths.
 - Uroliths composed of **cystine, urate and xanthine are not usually radiodense**.
 - Uroliths composed of drug metabolites are not usually radiodense.
- **Ultrasonography** may reveal presence of urocystoliths, but not urethroliths.

Urinalysis may reveal abnormalities.

- **Crystalluria** may or may not be present.
- **Hematuria** is often present, but not always.
- Bacterial urinary tract infection may occur, but is usually secondary to presence of uroliths.

Serum biochemical analysis is usually normal.

- **Approximately 35% of cats with calcium oxalate uroliths are hypercalcemic.**
- Urate uroliths associated with hepatic disease may also be associated with increases in liver enzyme activity, increased blood ammonia concentration, and increased bile acid concentrations (pre- or post-prandial).

TRAUMA TO URETHRA AND/OR URINARY BLADDER**

Classical signs

- Inappropriate urination, hematuria, pollakiuria and stranguria.
- Other signs of trauma, such as fractures and skin abrasions, may be present.

See main reference on page 189 for details on trauma to the lower urinary tract.

Clinical signs

Inappropriate urination, hematuria, pollakiuria and stranguria may be present because of trauma to the urinary bladder or urethra.

Other signs of trauma, such as fractures and skin abrasions, may be present.

Trauma to the caudal abdomen may result in rupture or **perforation of the urinary bladder**.

- Post-renal uremia may be present.
- **Only a small quantity or no urine at all may be passed despite attempts at urination.**
- **Abdominal effusion** may be present due to urine leakage from the damaged bladder.

Diagnosis

Microscopic examination of urine reveals an inflammatory reaction.

Serum biochemical analysis may reveal azotemia.

Contrast cystography is necessary to determine the integrity of the urinary bladder.

- Ultrasonography may reveal abdominal effusion.
- Survey abdominal radiography may have decreased contrast due to abdominal effusion.
- Abdominocentesis may reveal urine.

Other laboratory parameters may be abnormal depending on the extent of the trauma.

POLYURIC STATES**

Classical signs

- Polyuria, polydipsia and inappropriate urination.
- \pm Systemic signs such as anorexia or polyphagia, vomiting, weight loss, poor hair coat quality and/or diarrhea.

See main references on page 235 for details (The Cat With Polyuria and Polydipsia) on chronic renal failure, page 236 for details on diabetes mellitus, and page 304 for details (The Cat With Weight Loss and a Good Appetite) on hyperthyroidism.

Clinical signs

Polyuria and polydipsia may result in the cat being unable to adequately retain urine resulting in inappropriate urination.

History of drinking and urinating a greater volume than normal (polyuria and polydipsia).

Inappropriate urination may occur because of the inability to retain larger quantity of urine.

Other clinical signs are variable depending on the underlying disease process.

- The most common causes of polyuria and polydipsia in cats are **renal failure, diabetes mellitus and hyperthyroidism**.
 - Renal failure may be associated with inappetence, anorexia, vomiting, poor body condition and oral ulcers.
 - Diabetes mellitus may be associated with weight loss despite a good appetite; vomiting and anorexia may occur if associated with ketoacidosis.
 - Hyperthyroidism may be associated with weight loss despite polyphagia, poor body condition and intermittent vomiting.
- Other causes of polyuria and polydipsia may occur, but are less common.

Diagnosis

Polyuria is confirmed by a **low urine specific gravity** (<1.030).

Polydipsia may be difficult to confirm in cats because measurement of fluid intake may be difficult.

- Cats normally are not observed to drink very much, particularly if consuming canned diets. Cats eating a mix of canned and dry food drink < 20 ml/kg/24 h.
- Owners may notice cats drinking out of water sources, such as sinks and bowls, when the cat has not done so previously. **Water intake of > 100 ml/kg/24 h is abnormal**, even if cats are eating dry food.

Serum biochemical analysis and serum thyroxine concentrations should be performed, in addition to a complete urinalysis, in all cats that may have polyuria and polydipsia to aid in localizing the problem further.

CATHETERIZATION OF THE URINARY BLADDER OR URETHRA*

Classical signs

- Inappropriate urination, stranguria, pollakiuria and hematuria.

See main references on page 187 for details on bacterial urinary tract infection and page 181 for details on urinary catheterization.

Clinical signs

The **urethra or urinary bladder mucosa** may be **traumatized during catheterization** performed to clear an obstruction from the urethra or for diagnostic procedures; therefore, there is a history of urinary catheterization.

Indwelling urinary catheters may predispose to bacterial urinary tract infection.

Inappropriate urination, stranguria, pollakiuria and hematuria may occur following catheterization of the urinary tract if mucosal damage occurs, or if a secondary bacterial infection occurs. Occasionally a urethral or urinary bladder diverticulum is formed by traumatic catheterization, predisposing to recurrent bacterial infection.

Diagnosis

The diagnosis is made based on clinical signs and a history of urethral catheterization.

A urinalysis and urine culture should be performed to rule-in or rule-out an iatrogenic bacterial urinary tract infection.

If a polypropylene catheter is placed too far into the urinary bladder, perforation may occur.

- Post-renal azotemia may be found on serum biochemical analysis.
- **Abdominal effusion, if present, will have a composition similar to urine.**
- Contrast cystography is necessary to confirm the perforation although abdominal ultrasonography or survey abdominal radiography will demonstrate abdominal effusion if present.

BACTERIAL URINARY TRACT INFECTION*

Classical signs

- **Inappropriate urination occurs together with pollakiuria, stranguria and hematuria.**

See main reference on page 187 for details (The Cat Straining to Urinate) on bacterial urinary tract infection.

Clinical signs

Bacterial urinary tract infections often occur as a **consequence of an underlying disease of the urinary bladder, polyuric states or immunosuppressive states**; therefore, other clinical signs may be present.

- Any disease that disrupts the cat's normal defenses may result in a bacterial urinary tract infection.
- Systemic illness may be seen if the underlying disease process is a systemic disease such as diabetes mellitus, chronic renal failure, FeLV or FIV infection.

Urination in inappropriate places usually occurs together with signs of **pollakiuria, stranguria and hematuria**.

- Clinical signs of other lower urinary tract diseases are similar to those observed with bacterial urinary tract infections.

Diagnosis

Diagnosis is made by examination of urine.

- **Pyuria** (> 5 WBC/hpf) and bacteruria are often observed on microscopic examination of urine, but a bacterial urinary tract infection may be present with an inactive urinary sediment on microscopic examination, especially in older cats with concurrent disease(s).

- **Alkaluria** (pH > 7) may occur with **urease-producing bacteria**, such as *Staphylococcus spp.* and *Mycoplasma spp.*
- Urine culture is necessary to identify the species of bacteria and its antibiotic sensitivity pattern.
 - Urine should be collected by cystocentesis.
 - Nitrite and leukocyte esterase test pads on urine dipsticks are not reliable indicators of bacterial urinary tract infection, and should not be used.

Abdominal radiography or ultrasonography, or contrast studies of the urinary tract may be necessary to detect anatomic defects, and uroliths or neoplasms, that predispose the cat to a bacterial urinary tract infection.

Systemic diseases resulting in dilute urine, such as renal failure or diabetes mellitus, or in immunosuppression, such as FeLV, FIV or diabetes mellitus, may result in a bacterial urinary tract infection.

Drugs resulting in a diuresis, such as furosemide, or in immunosuppression, such as corticosteroids, may **predispose to bacterial urinary tract infection**.

Urethral catheterization may result in iatrogenic bacterial urinary tract infection, particularly if antibiotics are administered concurrently.

NEOPLASM INVOLVING URINARY BLADDER OR URETHRA

Classical signs

- **Inappropriate urination may occur with pollakiuria, stranguria and hematuria.**
- **Typically occurs in cats older than 10 years.**

See main reference on page 191 for details on neoplasia.

Clinical signs

Although uncommon, lower urinary tract neoplasia typically occurs in **cats older than 10 years**.

Inappropriate urination associated with neoplasia may occur with other signs of lower urinary tract disease such as **stranguria, pollakiuria and hematuria**.

Urethral obstruction may occur if neoplasm occurs at the trigone region, urethra or prepuce.

If urinary outflow obstruction occurs, signs of **post-renal uremia** may occur (**vomiting, anorexia, depression**).

Diagnosis

Some urinary bladder neoplasms may be palpated on abdominal palpation; urethral neoplasm may be palpated on rectal examination.

Transitional cell carcinoma of the urinary bladder is the most common lower urinary tract neoplasm; other types of neoplasia that may occur include **squamous cell carcinoma, lymphoma, fibrosarcoma, and leiomyoma or leiomyosarcoma.**

Ultrasonography and/or contrast urethrocytography may be necessary to identify the neoplasm.

Diagnosis may require biopsy or fine-needle aspiration of the mass.

- Occasionally, neoplastic cells may be found on microscopic examination of urine sediment.
- Fine-needle aspiration may be accomplished by palpation or by ultrasound guidance.
- Cystoscopy may also be used to identify and aspirate or biopsy a mass.
- It may be necessary to obtain a biopsy using surgery.

VIRAL URINARY TRACT INFECTION

Classical signs

- Lower urinary tract signs including inappropriate urination, pollakiuria, stranguria and hematuria.

See main references on page 187 for details (The Cat Straining to Urinate) on hemorrhagic cystitis and page 225 for details on bacterial urinary tract infection.

Clinical signs

FelV or FIV infections may result in bacterial urinary tract infections.

A cell-associated herpesvirus and a urotropic calicivirus have been hypothesized to be a cause of **idiopathic lower urinary tract disease** in cats resulting in hemorrhagic cystitis (non-obstructive feline lower urinary tract disease, interstitial cystitis).

Inappropriate urination may occur with other clinical signs of lower urinary tract disease including **hematuria, stranguria and pollakiuria.**

FelV and FIV may be associated with other clinical signs including **gingival disease**, infections of other organs, liver disease or renal disease.

Clinical signs of lower urinary tract disease, if idiopathic in nature (interstitial cystitis), usually resolve in 5–7 days, although a protracted course of clinical signs may occur.

Diagnosis

Hematuria may be observed with or without bacteruria and pyuria.

FelV and FIV testing should be performed on cats with lower urinary tract disease or **recurrent bacterial urinary tract infections.**

Viral particles have been observed by electron microscopy in some matrix-crystalline plugs retrieved from male cats with urethral obstruction.

CONGENITAL ANATOMIC DEFECTS OF BLADDER OR URETHRA

Classical signs

- Inappropriate urination usually occurs with other clinical signs such as pollakiuria, stranguria and possibly hematuria.
- Usually evident as a young kitten.

See main references on page 201 for details (The Incontinent Cat) on patent urachus and page 198 for details on ectopic ureters.

Clinical signs

Inappropriate urination is first observed at an early age. It may not be noticed until the kitten is older and litter box training is undertaken.

Pollakiuria, stranguria and/or hematuria may also be present.

Defects of the bladder or urethra may be associated with other congenital anomalies, especially of the vagina.

Diagnosis

Diagnosis is made by historical information concerning age of cat, physical examination of the urinary tract,

and radiology including contrast studies and ultrasonography of the lower urinary tract.

Many congenital anomalies are possible, but congenital anomalies are uncommon in cats.

- Patent urachus and ectopic ureters are the most common congenital anomalies.
- Other anomalies include, but are not limited to:
 - Bladder agenesis.
 - Bladder duplication.
 - Vaginal defects such as septal defects.
 - Urethral dysgenesis.
 - Urethral strictures.
 - Bladder and urethral diverticulae.

MENINGIOMA

Classical signs

- Inappropriate urination.
- Neurological deficits (altered mentation, abnormal proprioception or spinal reflexes).

See main reference on page 914 for details on meningioma.

Clinical signs

Meningiomas may be associated with urinary incontinence and inappropriate urination.

Inappropriate urination is usually due to incontinence related to a **spinal cord meningioma** but may be associated with cerebral meningioma.

Other neurologic deficits, such as proprioceptive deficits or abnormal spinal reflexes, may or may not be present.

Typically occurs in **old cats > 10 years**.

Diagnosis

Diagnosis is difficult.

- Meningiomas involving spinal cord may require myelography for diagnosis.
- Meningiomas that occur intracranially require computerized tomography or magnetic resonance imaging for diagnosis.

Laboratory evaluation is normal.

INCONTINENCE (INCLUDING HORMONALLY RESPONSIVE INCONTINENCE)

Classical signs

- Unconscious urination usually occurs when asleep.
- Cats with congenital disease may continuously pass small drops of urine whether awake or asleep.

See main reference on page 193 for details (The Incontinent Cat) on incontinence.

Clinical signs

Incontinence may be due to an underlying congenital or acquired anatomic problem.

Incontinence is urination that is uncontrolled or unconsciously done.

- Unconscious urination usually occurs when asleep.
- Cats with **congenital disease** may **continuously pass small drops of urine** whether awake or asleep.

Pollakiuria, dysuria and stranguria may also occur if a secondary bacterial urinary tract infection occurs.

Urinalysis is usually normal unless a secondary bacterial urinary tract infection is present.

Diagnosis

Diagnosis is usually made on the basis of historical and physical examination findings.

Incontinence must be **differentiated from consciously controlled inappropriate urination** as might be observed with bacterial urinary tract infection, urolithiasis, bladder or urethral neoplasia or other causes of lower urinary tract disease.

- **With lower urinary tract disease, cats appear to have urgency or discomfort when urinating.**
 - Hematuria and/or pyuria with or without crystaluria is usually present.
 - Laboratory and radiological evaluation may be abnormal.

- With incontinence, these signs are not present, instead cats urinate without being aware that they are doing so.
 - Urinalysis is typically normal.

FUNGAL URINARY TRACT INFECTION

Classical signs

- Usually asymptomatic.
- Pollakiuria, stranguria, hematuria and inappropriate urination may occur.
- Systemic clinical signs may be present.

Pathogenesis

Fungal urinary tract infections are **often associated with impaired systemic or local host defenses such as glucosuria, indwelling urinary catheters, urethrostomy and urolithiasis.**

Cats with immunosuppressive diseases such as **FeLV and FIV** infection are also at risk for development of fungal urinary tract infections.

Candida and *Torulopsis* are normal saprophytic inhabitants of the gastrointestinal tract and are the most common fungi observed to occur in urine.

Clinical signs

Fungi are not normally found in urine of healthy animals.

- Cats with funguria **may be asymptomatic.**
- However, clinical signs of systemic disease may be present.

Symptomatic fungal urinary tract infections are associated with **pollakiuria, hematuria, stranguria and inappropriate urination** if the infection occurs in the **lower urinary tract**, or **fever, inappetence, vomiting and septicemia** if it occurs in the **upper urinary tract.**

Rarely, bezoars (fungal balls) may form.

- **Bezoars are clusters of intertwined fungal hyphae** which may aggregate.
- Bezoars may be present in patients with symptomatic or asymptomatic fungal urinary tract infections.
- They are **sources of persistent funguria.**
- Large bezoars may result in urethral obstruction.

Diagnosis

Diagnosis of funguria is based on results of urinalysis and urine cultures.

- Microscopic examination of urine sediment reveals budding yeasts or elongated hyphae, and inflammation.
- Urine culture is necessary to definitively diagnose fungal urinary tract infections.
 - The **absolute number of fungal organisms does not correlate with infection**; however, fungi are not normal inhabitants of the urinary bladder.
 - A cystocentesis sample should be evaluated.
 - Use of **fungal culture media facilitates isolation and identification of the organism.**

Other diagnostic tests should be directed at identifying abnormalities in local or systemic host defenses.

- Serum biochemical analysis may reveal azotemia consistent with **renal failure**, or **hyperglycemia** consistent with diabetes mellitus.
- **FeLV and FIV** testing should be performed.
- Abdominal radiography, including contrast studies, and ultrasonography are necessary to determine if an abnormality of the lower urinary tract is present such as **urolithiasis or neoplasia.**

Differential diagnosis

Any disease of the lower urinary tract may present with similar signs.

Most common diseases with similar signs are non-obstructive idiopathic lower urinary tract disease and urolithiasis. **Differentiation is based on finding yeast or hyphae in the urine.** Urolithiasis may occasionally be concurrent with fungal infection.

Treatment

Some patients have asymptomatic funguria.

- No treatment may be necessary as some spontaneously clear the fungi if predisposing factors can be resolved.
- **Urinary catheters should be removed** or used intermittently.
- If possible, antibacterial and immunosuppressive medication should be discontinued.
- **Alkalinization of urine may aid in clearing of the fungal urinary tract infection.**

- *Candida* species survive poorly at alkaline pH.
- Alkalinization therapy has not been very successful.
- **Potassium citrate** may be administered at 50–75 mg/kg PO q 12 h.
- **Sodium bicarbonate** may also be used at 12 mg/kg PO q 8 h.

More aggressive treatment is warranted in patients that have symptomatic fungal urinary tract infections.

- An attempt should be made to **correct predisposing risk factors**.
- Antifungal drugs should also be used.
 - Flucytosine has a narrow range of antifungal activity, limited primarily to yeast-like fungi such as *Candida*, *Torulopsis* and *Cryptococcus*.
 - **Flucytosine** is deaminated to 5-fluorouracil in fungal cells which **interrupts intracellular protein synthesis** resulting in death of the cell.
 - Flucytosine is excreted largely unchanged in urine which makes it a good first-line treatment.
 - Dosage is 200 mg/kg/day PO divided into three or four sub-doses.
 - Resistance may occur.
 - Flucytosine should be **continued 2–3 weeks beyond clinical resolution** of fungal urinary tract infection.
- **Amphotericin-B** is also effective in the treatment of fungal urinary tract infection and can be used with **flucytosine** or an **imidazole**.
 - Occurrence of **nephrotoxicity** is a major disadvantage to its use.
 - Amphotericin-B disrupts fungal cell membranes making it effective.
 - Resistance is uncommon.
 - Dosage is 0.1–0.25 mg/kg IV (administered in 30 ml of 5% dextrose in water over 15 min) q 48 h for up to 6 weeks. It may be also given **subcutaneously** (see page 26, The Cat With Signs of Chronic Nasal Disease).
 - Amphotericin B may also be administered by **irrigation into the urinary bladder**.
 - A concentration of 200 mg of amphotericin-B per liter of sterile water is recommended.
 - This solution is infused at 5–10 ml/kg into the urinary bladder lumen **daily for 5–15 days**.
- **Imidazole derivatives** may be used as treatment for funguria.
 - Ketoconazole and itraconazole are not very effective because they have limited urinary excretion.
 - Fluconazole may be a viable alternative.
 - This imidazole is smaller, more water soluble, and less protein bound than other commonly used imidazoles.
 - Active **fluconazole is excreted primarily in urine**.
 - Use a dosage of 50–100 mg/cat PO with food.
- **Intravesicular clotrimazole**
 - Instillation of 1% clotrimazole intravesicularly has been successful in treating fungal cystitis.
 - Instillation can be accomplished by anesthesia or sedation and urinary catheterization or by cystocentesis.
 - Three to four treatments may be necessary.

Prognosis

Prognosis for asymptomatic funguria in cats is unknown.

- Funguria may spontaneously resolve.
- Funguria may also progress to symptomatic infection or to bezoar formation.
- Some animals may have persistent asymptomatic funguria without discernible harm.

Symptomatic funguria carries a variable prognosis.

- **If systemic fungal infection is present, prognosis is guarded.**
- If fungi are limited to the lower urinary tract, the prognosis is fair; however, **complete clearance of the fungal urinary tract infection may be difficult.**

Bezoar formation may require surgical removal if it causes urethral obstruction or persistent or recurrent funguria, and it cannot be disrupted by medical means.

Prevention

Because fungal urinary tract infection usually occurs as a result of a problem with local or systemic host defenses, identification and correction of risk factors may prevent it from occurring.

Urine from cats with indwelling urinary catheters should be examined periodically, particularly if the animal is receiving antibiotics or immunosuppressive therapy.

15. The cat with polyuria and polydipsia

Jacquie Rand

KEY SIGNS

- Drinking more than normal.
- Increased frequency of urination and increased volume and/or nocturia.
- Urinating outside litter box.

MECHANISM?

- Polyuria and polydipsia usually occur in cats because of an inability to concentrate urine.

WHERE?

- Kidney (the kidney controls urine production, but it is influenced by many other organs).

WHAT?

- Most cats with polyuria and polydipsia (PU/PD) have renal failure, diabetes mellitus or hyperthyroidism.

QUICK REFERENCE SUMMARY

Diseases causing polyuria and polydipsia

DEGENERATIVE

- **Chronic renal failure*** (p 235)**

Inappetence or anorexia, weight loss, PU/PD, vomiting, increased or decreased renal size.

METABOLIC

- **Diabetes mellitus*** (p 236)**

Usually older than 6 years of age, PU/PD of 1–12 weeks duration, weight loss, polyphagia or inappetence, may have been previously obese.

- **Hyperthyroidism*** (p 242)**

Older than 7 years of age, weight loss, polyphagia or inappetence, palpable cervical mass, vomiting, tachycardia, restlessness.

- **Diabetes insipidus* (p 243)**

Central form is rare, nephrogenic form is common, and associated with renal failure, hyperthyroidism, pyometra, etc. Urine specific gravity often <1.007.

continued

continued

- **Hyperadrenocorticism (p 251)**

Very rare; poorly controlled diabetes mellitus which may be insulin resistant, poor hair coat, weight loss despite higher than normal doses of insulin, thin fragile skin that bruises easily.

- **Acromegaly (growth hormone-producing tumor, hypersomatotrophism) (p 254)**

Very rare. Often associated with poorly controlled diabetes mellitus, which is usually insulin resistant, often requiring very high doses of insulin. Typically there is a large blocky cat with weight gain, enlarged tongue, widely spaced teeth, cardiomegaly and thickened soft palate.

- **Hypoadrenocorticism (p 252)**

Very, rare; lethargy, depression, anorexia, and weight loss are most frequent. Less frequent signs include vomiting, polyuria and polydipsia.

- **Hyperparathyroidism P (p 256)**

A rare cause of hypercalcemia in cats. Usually results from a solitary adenoma, but can be from solitary or bilateral adenocarcinoma or hyperplasia. Older cats (mean age 13 years) and Siamese are overrepresented. Clinical signs are of hypercalcemia and more than half of the cats have a palpable parathyroid mass.

- **Primary hyperaldosteronism (p 256)**

Rare cause of polyuria and polydipsia. Typically occurs in older cats (10–20 years) and is associated with an adrenal mass. Signs are of intractable hypokalemia and hypertension, and include muscle weakness, cervical ventroflexion, inappetence, weight loss, blindness and polyuria and polydipsia.

- **Primary sex hormone-secreting adrenal tumor (p 258)**

Very rare cause of polyuria, polydipsia. Progesterone-producing tumors result in signs indistinguishable from hyperadrenocorticism. Typically there is thin fragile skin that bruises easily, patchy symmetrical alopecia, secondary skin infections such as demodicosis and polyuria, polydipsia from poorly controlled diabetes mellitus.

- **Pheochromocytoma (p 257)**

Very rare cause of polyuria, polydipsia. Typically occurs in older cats (> 8 years of age) and associated with an adrenal mass. Signs are vague and include polyuria and polydipsia. Systemic hypertension is characteristic, and presents as sudden blindness from retinal hemorrhage or retinal detachment, or dyspnea from heart failure. Diabetic cats may be insulin resistant.

- **Polycythemia**

Dark pink or purple mucosae, bleeding, PU/PD, neurological signs including abnormal behavior and seizures.

- **Hypokalemia* (p 244)**

Lethargy, inappetence, weakness, ventroflexion of neck, stiff/stilted gait, impaired renal function. PU/PD are not prominent signs unless associated with chronic renal failure or hyperthyroidism.

NEOPLASTIC

- **Neoplasia (renal neoplasia or lymphoma) (p 250)**

PU/PD results from either renal neoplasia causing chronic renal failure, or lymphoma causing hypercalcemia (very rare in cats).

- Hypercalcemia (p 245)

Associated with renal failure, lymphoma or squamous cell carcinoma, primary hyperparathyroidism, cholecalciferol rodenticide, infectious disease, diabetes mellitus, hyperthyroidism, liver disease or idiopathic. Vomiting, weight loss, inappetence and in some cats, signs associated with calcium oxalate urolithiasis (dysuria and inappropriate urination) may be present. In some cats, signs are those of the primary disease process, e.g. renal failure or lymphoma.

PSYCHOLOGICAL

- Psychological polydipsia

This syndrome is not yet reported in cats.

INFLAMMATION INFECTIOUS (BACTERIAL)

- Pyelonephritis

Chronic form causes chronic renal failure with weight loss, inappetence. The acute phase may be associated with fever, lethargy and pain on palpation of the kidneys. Bacteriuria, pyuria, casts (especially WBC casts) may be present during the active infection, and occasionally leukocytosis occurs.

- Cystic endometrial hyperplasia/pyometra complex (p 259)

Causes nephrogenic diabetes insipidus and PU/PD; vaginal discharge, inappetence, and weight loss.

INFECTIOUS (IMMUNE)

- Chronic renal failure (glomerulonephritis or amyloidosis) (p 235)

Causes chronic renal failure and associated signs of PU/PD, weight loss, inappetence, lethargy, and in the later stages, vomiting.

TREATMENT

- Drug induced* (p 244)

Drugs such as diuretics, phenobarbitol, amphotericin, gentamicin, thyroxine, corticosteroids, and megestrol acetate may be associated with PU/PD through a number of mechanisms.

INTRODUCTION

MECHANISM?

Polyuria and polydipsia in cats usually occurs because of a primary inability to concentrate urine. This is referred to as **primary polyuria and leads to compensatory polydipsia**. Although not reported in cats, the kidney may also be overloaded with water from primary polydipsia, termed psychogenic polydipsia. **Mechanisms for primary polyuria are as follows:**

- **The solute load in the renal tubule is higher than the capacity to reabsorb it, resulting in osmotic diuresis.** This is characterized by isotonic urine with a SG 1.007–1.030. This occurs in the following circumstances:
 - Glomerular filtration of an **absorbable solute in excess of the renal tubular ability to reabsorb it**, e.g. glucose in diabetes mellitus. This may also occur when the glomerular filtration rate (GFR) is reduced, as the increased solute load on the remaining functioning nephrons may overwhelm their absorptive capacity.

- **Glomerular disease** resulting in **leakage of albumin and other poorly absorbable solutes** into the renal tubule.
- **Impaired tubular reabsorption** of glomerular filtrate solutes such as urea, creatinine, and phosphorus as occurs in renal failure and Fanconi syndrome.
- **Diuretics which act as a non-absorbable solute**, e.g. Mannitol.
- The **medullary osmotic gradient is compromised**, which decreases the concentrating ability of the kidney, producing urine with a SG of 1.007–1.030. Causes include:
 - **Interference with the NaCl pump in the loop of Henle.** This leads to a decrease in reabsorption of ions, which is followed by a decrease in medullary hyperosmolality. These effects result in the reduced movement of water out of the lumen of the distal tubules and collecting ducts and hence an increased excretion of water and solutes. Diuretics such as furosemide act via this mechanism.
 - **Rapid fluid flow through the tubules or rapid blood flow through the vasa recta** washes out the high concentration of solutes within the medulla interstitium, referred to as medullary washout. This impairs the countercurrent system, which normally generates a hyperosmotic environment in the renal medulla interstitium to promote the movement of water out of the lumen of distal tubules and collecting ducts. Medullary washout can occur secondary to marked polyuria, for example from diabetes insipidus, or following diuretic use.
 - **Disruption to urea recycling through the body** decreases the urea concentration in the medullary interstitium and hence decreases medullary osmolality. Disruption to urea cycling can be the result of decreased tubular response to antidiuretic hormone (ADH) leading to the reduced permeability of collection ducts to urea, or from decreased plasma urea concentration (cirrhosis, protein depletion). Urine specific gravity is 1.007–1.030.
- **Collecting ducts become impermeable to water.** This is characterized by urine with a SG 1.001–1.006, and is due to either:
 - **Deficiency of ADH** (central diabetes insipidus).

- **Renal insensitivity to ADH** (nephrogenic diabetes insipidus). Renal cells may not respond to adequate concentrations of ADH because of insufficiency of functioning nephrons, competitive inhibition for ADH receptors, or bacterial endotoxins. Altered cellular concentrations of Ca^{++} , Mg^{+} , prostaglandin E, and corticosteroids interfere with ADH receptor binding and render renal cells unresponsive to ADH (e.g. hyperadrenocorticism, hypercalcaemia). Endotoxins such as *E. coli* render nephrons insensitive to ADH (e.g. in pyometra–endometritis complex).

Polyuria should be differentiated from pollakiuria, which is increased frequency of urination of small quantities of urine, and is typically associated with bladder disease, especially cystitis. Inappropriate urination associated with behavioral disorders should also be differentiated from polyuria.

WHERE?

Primary polyuria is most common, and occurs when the ability to concentrate urine is decreased. Polydipsia is compensatory for polyuria.

Polyuria commonly results from structural and functional renal pathology, such as:

- Loss of functioning nephrons.
- Increased solute loading per nephron.
- Disruption of the medullary countercurrent system.
- Decreased renal responsiveness to ADH.

Polyuria may also be influenced by many **other organs and non-renal etiologies**.

Primary polydipsia (psychogenic polydipsia) has not been reported in the cat.

WHAT?

Renal disease (acute and chronic renal failure), **diabetes mellitus**, **hyperthyroidism** and **nephrogenic diabetes insipidus** are the most common causes of polyuria and polydipsia.

Hyperadrenocorticism, hypoadrenocorticism, acromegaly and central diabetes insipidus are uncommon causes.

Psychogenic polydipsia has not been reported.

DISEASES CAUSING POLYURIA AND POLYDIPSIA

CHRONIC RENAL FAILURE***

Classical signs

- Inappetence, anorexia, weight loss.
- Lethargy.
- Vomiting.
- Polyuria, polydipsia.
- Small \pm irregular kidneys, occasionally enlarged kidneys.

See main reference on page 333 for details (The Thin, Inappetent Cat).

Clinical signs

Inappetence or anorexia is the most common sign and occurs in 80% of cats.

Weight loss is frequent, together with poor body condition.

Lethargy or depression are common signs.

Polyuria and polydipsia are reported by owners in 40% of cats. Nocturia or urination in inappropriate places may also be observed and must be differentiated from other causes including behavioral.

Weakness occurs in nearly 50% of cats and is often associated with hypokalemia. Cats may appear reluctant to jump or unsteady with jumping, and be less active.

Constipation is common and results from dehydration.

Vomiting is less common, and if present, is usually intermittent and often low grade.

Diarrhea is rare, but very occasionally is hemorrhagic from uremic enterocolitis.

Halitosis, ulcers on the oral mucosa or tongue, brownish discoloration of dorsal surface of tongue, or sloughing of anterior of tongue may occur in advanced disease.

Pale mucous membranes from anemia may be evident.

Dehydration is commonly present because of inadequate water intake to balance the excessive fluid loss in urine.

Ocular signs related to hypertension are common, e.g. scleral or conjunctival injection, hyphema or retinal hemorrhage, retinal edema, retinal vessel tortuosity, retinal detachment.

Terminally, seizures, stupor or coma may occur.

Small and/or irregular kidneys may be palpable but occasionally kidneys are enlarged (associated with amyloid deposition, neoplasia or cystic kidneys).

Diagnosis

Increased blood urea (BUN) and creatinine (azotemia) concentrations together with a urine specific gravity of 1.007–1.030 (usually 1.007–1.015) is considered presumptive evidence of renal failure.

Other findings that may or may not be present are the following:

Hyperphosphatemia

- Serum phosphorus concentration increases when glomerular filtration rate (GFR) is below approximately 20% of normal, and **tends to parallel BUN concentration**.

Hypokalemia (< 3.5 mmol/l) occurs in 20% of cats.

- Clinical signs of **inappetence** and **generalized muscle weakness** (such as wobbliness, inability to jump, stiff, stilted gait and **ventroflexion of the neck**) may occur when potassium < 3 mmol (mEq)/L.
- Respiratory muscle failure and death may occur at < 2 mmol (mEq)/L.

Hyper- and hypocalcemia are infrequent abnormalities, and result from derangements of calcium metabolism associated with renal secondary hyperparathyroidism.

- Most cats have normal or low calcium; 10–20% have mild to moderate hypercalcemia (≤ 3.1 mmol/L, 12.5 mg/dl).

Acidosis is common (approximately 80% of cats), and is evident as decreased bicarbonate and increased anion gap.

Normochromic, normocytic, non-regenerative anemia is common when chronic renal failure is advanced.

- It occurs mainly from erythropoietin deficiency, but other factors contribute, such as decreased red cell lifespan.

Proteinuria is typically mild to moderate (1.5–2 times increase in protein excretion occurs).

Radiographs of kidneys may show small irregular kidneys; size may be normal or increased in some cats especially if renal failure is due to amyloid, neoplasia or polycystic kidneys.

Ultrasound examination frequently shows small hyperechoic kidneys.

Differential diagnoses

Pre-renal azotemia. This occurs secondary to dehydration or circulatory collapse; azotemia results from reduced renal blood flow; **typically urine specific gravity is ≥ 1.035** , in contrast to renal failure where SG is < 1.035 .

Pre-renal azotemia together with concomitant primary disease that affects renal concentrating ability can mimic renal failure, e.g. a dehydrated cat with central or nephrogenic diabetes insipidus may have azotemia with a urine specific gravity < 1.035 .

Treatment

See main reference on page 336 for details.

Correct dehydration, reduce uremia, and improve quality of life.

DIABETES MELLITUS***

Classical signs

- Older than 6 years of age, most > 8 years of age.
- Moderate to marked PU/PD, usually of 2–8 weeks duration.
- Weight loss, but may be normal weight, obese or underweight.
- Polyphagia or inappetence.

Pathogenesis

Most diabetic cats appear to have **type 2 diabetes mellitus**, previously called adult-onset diabetes or non-insulin-dependent diabetes.

- Type 2 diabetes is characterized by decreased insulin secretion, insulin resistance and amyloid deposition in the pancreatic islets.

Risk factors include old age, male gender, obesity, physical inactivity, confinement indoors, Burmese breed (in Australia, New Zealand and UK), and repeated or long-acting steroid or megestrol acetate administration.

At diagnosis, **endogenous insulin secretion is usually very low.**

- This is probably because of the combined effects of:
 - Impaired insulin secretion associated with the beta cell defect causing type 2 diabetes.
 - Amyloid deposition in the islets which replaces beta cells.
 - Suppression of insulin secretion by glucose toxicity.

Glucose toxicity is defined as suppression of insulin secretion by persistently (> 24 h duration) high blood glucose.

- Suppression of insulin secretion by glucose toxicity is **initially functional and reversible**, later it results in structural changes in beta cells. **With time (weeks) changes become irreversible**, and beta cells are lost.

Some cats (5–20%) have other specific types of diabetes. Their diabetes results from another disease process causing decreased insulin secretion or impaired insulin action (insulin resistance).

- **Pancreatic neoplasia** is a significant cause of diabetes in cats referred to specialists, accounting for as many as 18% of cases recorded at referral institutions in USA.
- **Pancreatitis** is commonly associated with feline diabetes (50% of diabetic cats have pancreatitis lesions at necropsy).
 - In most cats, pancreatitis is not severe enough to cause diabetes alone, but probably contributes to loss of beta cells.
- **Hyperadrenocorticism** and **growth hormone-producing tumors (acromegaly)** are rare causes of other specific types of diabetes associated with insulin resistance.

Clinical signs

Earliest signs are **polyuria and polydipsia**; nocturia and urinary incontinence may occur.

Weight loss occurs and is accompanied by increased appetite.

- At the time of diagnosis, some cats are **underweight**, some **normal weight** and others are **obese**.

At diagnosis, some cats have **decreased appetite** and are depressed, others are **polyphagic**.

Lethargy or depression may be present. Other cats are alert at presentation.

Muscle wasting and weakness are often present and may be evidenced as reluctance or inability to jump.

Dehydration is common in cats that are lethargic and inappetent.

Vomiting occurs in one third of cats, but is usually infrequent.

Hepatomegaly from hepatic lipidosis, and occasionally jaundice may be present.

Rear limb weakness or plantigrade posture (hocks touching the ground) occur occasionally secondary to diabetic neuropathy.

Acetone odor on breath may be evident on average 5 days before ketonuria is detected.

Poor unkempt scurfy hair coat.

Diagnosis

In most cats, **blood glucose greater than 20 mmol/l (360 mg/dl) is diagnostic** of diabetes.

If **blood glucose is 12–20 mmol/l (216–360 mg/dl)**, the **presence of typical clinical signs** (polyuria, polydipsia, polyphagia with weight loss), significant **glycosuria**, and **increased plasma fructosamine** or **betahydroxybutyrate** or **ketonuria** must be used to differentiate diabetes from stress-induced hyperglycemia.

- Plasma **fructosamine** > 406 $\mu\text{mol/L}$ is indicative of diabetes mellitus. However, some diabetic cats have a normal fructosamine concentration, and occasionally, non-diabetic sick cats have mildly increased fructosamine concentrations.
- Persistent hyperglycemia over 24 h is highly suggestive of diabetes, but may also occur with illness.

If persistent hyperglycemia is present in a sick cat, begin treatment with insulin, even if it is not clear if the hyperglycemia is illness-associated. Illness-associated stress hyperglycemia rarely results in blood glucose concentrations higher than 19 mmol/L (342 mg/dl).

- **Plasma betahydroxybutyrate** > 1 mmol/L (10 mg/dl) is indicative of diabetes mellitus. However, some diabetic cats have normal plasma betahydroxybutyrate.
 - A urine dipstick may be used in serum or heparinized plasma to detect ketonemia. A positive test indicates ketonemia. It detects mainly oxaloacetate rather than the predominant ketone in cats, β -hydroxybutyrate.

Differential diagnoses

Stress hyperglycemia from struggling or illness. Beware of misdiagnosis in cats with stress hyperglycemia from illness or struggling, which also have concomitant disease that produces similar signs to diabetes mellitus, e.g. renal failure or hyperthyroidism.

- In stress hyperglycemia associated with struggling, blood glucose concentration is generally < 12 mmol/L (216 mg/dl) within 4 h if the cat is hospitalized and further struggling does not occur.
- Stress hyperglycemia associated with illness may persist for several days and exceed 20 mmol/L (360 mg/dl). If in doubt, treat these cats with insulin and closely monitor blood glucose.

Hyperthyroidism may produce similar signs, i.e. old cat with weight loss, polyphagia and polyuria/polydipsia. Generally the polydipsia in hyperthyroidism is less pronounced. Glucose may be elevated but less than 20 mmol/L (360 mg/dl), from stress and insulin resistance. Elevated thyroxine concentration is diagnostic.

Treatment

General principles

For initial management, most cats have **better glycemic control using insulin** rather than oral hypoglycemic agents.

- **Insulin is more potent in decreasing blood glucose**; this enables beta cells to overcome the effects of glucose toxicity.

Approximately **5–30% of cats have good glycemic control using oral hypoglycemic drugs** which stimulate insulin secretion. The sulfonylurea, glipizide, is the most widely used oral hypoglycemic drug for cats.

Oral hypoglycaemic drugs are most useful as sole treatment when:

- Beta cells are not markedly suppressed by glucose toxicity (e.g. blood glucose is < 16 mmol/L (< 290 mg/dl)) or
- The owner refuses to give insulin injections.

Lente and NPH (Isophane) insulin must be given twice daily in all cats; most cats (up to 90%) require ultralente twice daily.

- In general, **lente and NPH insulin** have too **short a duration of action** to achieve excellent glycemic control in cats, although clinical control is often good, and signs of diabetes resolve in the majority of cats.
- For approximately 4 hours twice a day there is minimal exogenous insulin action when using these insulins. This means that most diabetic cats have episodes of hyperglycemia > 16 mmol/L (> 288 mg/dl) twice daily, which exacerbates glucose toxicity, and makes diabetic remission less likely than when using longer-acting insulins.

Long-acting insulins such as glargine, detemir and PZI in most cats provide better glycemic control and higher remission rates than lente, NPH and ultralente, and best results are obtained when they are administered twice daily.

Because of the small doses used in cats, 40 U/ml insulin is preferable to 100 U/ml insulin. However, expected duration of action is more important than concentration. Using 0.3 ml insulin syringes is advantageous when using 100 U/ml insulin. Syringes with $\frac{1}{4}$ u gradations are available.

Beef or pork insulins have a longer duration of action than human insulin. Most insulins for veterinary use are pork or beef/pork mixes. Human-use insulin is either identical to amino acid sequence in human insulin, or has substitutions to alter duration of action.

Eating does not need to be coordinated with insulin administration, because the postprandial increase in blood glucose is very prolonged (18+ h) in cats. Evidence suggests that a high-protein, low-carbohydrate diet (6–12% of calories from carbohydrate) is best for dia-

betic cats, because it lowers blood glucose and insulin requirement, and may increase the diabetic remission rate.

Underweight and normal bodyweight cats need a high-quality, calorie-dense feline diet that is palatable.

Obese cats should have their weight reduced by 1–2%/week (see page 454 The Cat With Abdominal Distention or Abdominal Fluid for treatment details). Use a high-protein, low-carbohydrate diet.

Transient diabetes.

- **Approximately 20–90% of diabetic cats will undergo remission** of their diabetes in 1–4 months, if good glycemic control is achieved.
- Remission is more **common in diabetic cats recently treated with insulin-antagonistic drugs**, such as megestrol acetate or long-acting steroids.
- Excellent glycemic control facilitates diabetic remission, by enabling beta cells to recover from glucose toxicity. Excellent glycemic control is aided by use of **long-acting insulin, especially glargine** administered twice daily, and a low-carbohydrate diet.
- **Remission rates increase with increasing duration of action of insulin**, and highest rates are obtained using glargine. PZI produces higher remission rates than lente insulin, when both are administered twice daily.

Hypoglycemia kills cats.

- Teach owners to recognize signs (**dazed drunken look, dilated pupils, wobbliness, weakness, head or body tremors, twitching, seizures or coma**). Signs may occur with little warning in cats that have apparently excellent clinical control of their diabetes.
- The owner should immediately start treatment with honey, or a glucose syrup designed for human diabetic patients, given per os. If the cat is seizing, rub honey or syrup into the gums, or give per rectum using the lubricated insulin syringe, if the needle can be removed.
 - Cats with **severe signs require intravenous glucose or glucagon**.
 - Give 50% dextrose at 0.5–1.0 ml/kg IV.
 - If intravenous access is not possible, 50% dextrose (0.5–1.0 ml/kg) or corn syrup (0.25–0.5 ml/kg) administered per os, or rubbed on the gums may be effective, but glucagon 0.25–1.0 mg IM is superior. Glucagon must be followed

by intravenous dextrose once seizures have stopped to maintain blood glucose.

- **Re-evaluate the cat;** usually the insulin dose needs to be decreased by 50–70%. Some cats will no longer require insulin, because their diabetes is in remission.
- It is important to **check if the cat is being inadvertently overdosed.** This can occur when different syringes have been dispensed with a different volume per gradation than was previously used. For example, for many brands of syringes, the **graduations on a 1 ml 100 U/ml syringe represent 2 U, whereas on a 0.5 ml syringe represent 1 U.** If owners are switched to 1 ml syringes, the dose may be inadvertently doubled, if the same number of graduations is used to dose the insulin. Similarly, a switch from syringes designed for U100 insulin to those for U40 insulin may result in an inadvertent 2.5 times increase in dose.

Treatment of “healthy” diabetic cats.

- If the cat is not very depressed or dehydrated, start **lente, ultralente, PZI or insulin glargine subcutaneously.**
 - Use an initial dose of 0.25 U/kg **ideal body weight q 12 h**, if blood glucose is between 12–19 mmol/L (220–350 mg/dl).
 - Use an initial dose of **0.5 U/kg ideal body weight q 12 h**, if blood glucose is 20 mmol/L (360 mg/dl) or more.

Glycemic control should be monitored using clinical parameters (water intake, urine glucose concentration, body weight), and at each major recheck, measurement of glucose concentration every 2 h (lente, ultralente) or 4 h (PZI, glargine). Water drunk, urine glucose and blood glucose concentrations are the most useful parameters for adjusting insulin dose.

- Water drunk of ≤ 20 ml/kg/24 h on canned food or ≤ 60 ml/kg/24 h on dry food indicates exemplary glycemic control.
- Water drunk is a better indicator of mean blood glucose and level of clinical control than is fructosamine concentration.
- **Water drunk** should be measured at home on at least two consecutive days prior to measurement of blood glucose concentration. Ideally, an owner should keep a daily diary of water drunk.

Monitoring urine glucose is very useful. This can be accomplished using poorly absorbent litter material such as silicon beads or shredded paper, which allows collection of urine for testing with a dipstick, or a litter box glucose detector system such as Glucotest (Purina) which is added to the box filler, and reacts to urine with color changes to indicate the level of glucosuria. Some owners are able to train the cat to tolerate a dipstick applied to the urine stream during urination. Alternatively, some of the urine-soaked litter can be mixed with water and tested with a dipstick after straining through a cloth.

- Weekly urine **glucose monitoring** is helpful for **detecting diabetic remission**, especially in cats treated with lente, NPH or ultralente insulin. Cats with negative urine glucose should be evaluated for remission.
- With the long duration of action of glargine, there should be minimal periods when blood glucose is > 14 mmol/L (240 mg/dl), and hence stable cats should almost always be 0 or 1+ for urine glucose. A value 2+ or greater likely indicates that an increase in dose is required.
- Because cats treated with lente, NPH or ultralente insulin usually have hyperglycemia within 6–8 h after insulin administration, which persists until the next dose, it is not recommended to use urine glucose measurements to increase the dose of these insulins.

Monitoring **fructosamine or glycated hemoglobin** concentration can be a useful indicator of glycemic control in cats susceptible to stress hyperglycemia, if the owner is unable to measure water intake. Fructosamine concentrations > 500 – 550 $\mu\text{mol/L}$ (normal < 400 $\mu\text{mol/L}$) or glycated hemoglobin > 3 – 4% (normal $< 2.6\%$) are consistent with poor glycemic control.

Adjusting insulin dose.

- In general, increase the dose by $\frac{1}{2}$ – 1 U/cat q 12 h every **1–4 weeks** to achieve a nadir glucose concentration of **7–9 mmol/L (126–162 mg/dl)**. Once clinical signs have resolved, and the blood glucose is relatively controlled, a nadir of 5–6 mmol/L can be achieved. Rebound hyperglycemia is a common consequence of aiming for a low nadir too early in the stabilization process, especially if using lente, ultralente or NPH insulin.

If using **lente, NPH or ultralente insulin**, adjust dose based on nadir (lowest) glucose concentration and clinical signs. Do not use pre-insulin blood glucose concentration to increase the dose, only to decrease the dose. There is little appreciable insulin action after 8–12 h, so for most cats on these insulins, the pre-insulin glucose concentration cannot be decreased by increasing insulin dose. In general, aim for a glucose nadir of 7–9 mmol/L (126–162 mg/dl) in the first 1–2 months. Later a nadir of 5–6 mmol/L (90–108 mg/dl) can be achieved in cats that are well controlled.

If using **glargine or PZI**, adjust the dose based on nadir (lowest) glucose and pre-insulin glucose concentration (concentration immediately before next insulin injection).

The following criteria can be used for adjusting insulin dose.

- **Indications for increasing dose of insulin** (recommendations assume insulin is being given twice daily):
 - If pre-insulin glucose concentration is > 12 mmol/L (216 mg/dl), then increase dose by 0.5–1 U/cat/injection provided nadir glucose is also high (**glargine and PZI only**)
AND / OR
 - If nadir glucose concentration is > 10 mmol/L (180 mg/dl) then increase dose by 0.5–1 U/cat/injection. For well controlled cats after several weeks of therapy, an upper cut-point of > 7 mmol/L (126 mg/dl) can be used.
 - If water intake is > 40 ml/kg on wet food or > 100 ml/kg on dry food and glargine or PZI are being used, then increase dose by 0.5–1 U/cat/injection. Dose may need to be increased or decreased if water intake is excessive when using lente insulin.
- **Indications for maintaining the same dose:**
 - If pre-insulin glucose concentration is \geq 10–12 mmol/L (\geq 240–360 mg/dl)
AND/OR
 - If nadir glucose concentration is 5–9 mmol/L (90–162 mg/dl). For well controlled cats aim for a nadir of 4–7 mmol/L (72–126 mg/dl).
- **Indications for decreasing the dose of insulin:**
 - If pre-insulin glucose concentration is \leq 10 mmol/L (\leq 180 mg/dl) decrease dose 0.5 U/cat/injection.

- If cat has been treated with insulin for more than 2 weeks, and total dose is 1 U/cat q 12 h or less, and pre-insulin glucose is \leq 10 mmol/L (\leq 180 mg/dl), withhold insulin and check subsequent blood glucose concentrations to determine if the cat is in diabetic remission.
- If nadir glucose concentration < 3 mmol/L (< 54 mg/dl) decrease dose by 1 U/cat/injection.
- If clinical signs of hypoglycemia develop, then reduce dose by 50%.
- **Insulin dose may be maintained, increased or decreased depending on the water intake, urine glucose, clinical signs and length of time the cat has been treated with insulin.**
 - If pre-insulin glucose concentration 11–14 mmol/L (198–252 mg/dl) or
 - If nadir 3–4 mmol/L (54–72 mg/dl) clinical parameters are essential for adjustment of insulin dose.

Most cats are well controlled on:

- 0.2–0.9 U/kg q 12 h of lente insulin (median dose of porcine lente was 0.5 U/kg q 12 h); only 10–15% require 1 U/kg or more. Most cats are controlled on 2–3 U/cat q 12 h.
- 0.3–1.2 U/kg q 12 h of PZI (average dose of PZI is 0.9 U/kg q 12 h); only about 10% of cats require more than 2 U/kg q 12 h. Most cats are controlled on 4–5 U/cat q 12 h.
- 0.25–0.5 U/kg q 12 h of glargine (average dose is < 0.5 U/kg q 12 h). Most cats are controlled on 1–2 U/cat q 12 h, only a few cats require doses of 4–6 U/cat q 12 h, and the requirement for these high doses may resolve within weeks.
- Using glargine, cats with exemplary control have nadir glucose concentrations of 4–7 mmol/L (72–126 mg/dl) and peak glucose concentrations of \geq 11 mmol/L (200 mg/dl).

Diabetic remission usually occurs in the first 4 months of therapy, and occurs most often in the first month of treatment in cats on glargine. Impending remission is suggested by a negative urine glucose measurement, and a pre-insulin blood glucose concentration of < 12 mmol/L (216 mg/dl). Decrease insulin dose gradually to 0.5–1 U q 12 h or even q 24 h. If urine glucose is still negative and pre-insulin blood glucose is still low on a minimal dose of insulin, stop insulin and monitor blood glucose for 12–24 h. If it remains low, send the cat home on a low-carbohydrate diet and re-evaluate in 1 week. The owner should

closely monitor water intake and urine glucose, and if either increase, the cat should be reassessed immediately and reinstituted if blood glucose ≥ 10 mmol/L (180 mg/dL).

Treatment of “sick” diabetic cats

Fluids are as important as insulin in dehydrated diabetic cats.

- Balanced electrolyte solutions or 0.9% sodium chloride is the best initial fluid depending on the initial potassium concentration, with 0.9% sodium chloride preferred in hyperkalemic cats.
- Once initial fluid and electrolyte deficits are corrected, use 0.45% NaCl with 30–40 mEq (mmol)/L of KCl added.

Serum potassium rapidly falls with treatment and potassium supplementation should be immediately instituted in fluids and orally, if potassium concentration is initially normal. Cats with hyperkalemia at presentation usually require potassium within 12–24 h.

- Supplement potassium in intravenous fluids at 20–80 mmol/L (or mEq/L); do not exceed 0.5 mmol/kg/h.
- Supplement potassium orally using potassium gluconate 2–3 mmol (or mEq), q 8–24 h.

Serum phosphorus falls rapidly with treatment. Hypophosphatemia causes hemolysis, muscle weakness and neurological signs. To supplement phosphate and potassium in intravenous fluids, give potassium as 50% potassium dihydrophosphate and 50% potassium chloride.

Bicarbonate is rarely required, because acidosis improves rapidly with fluids and insulin therapy. If bicarbonate is < 10 mmol/L (10 mEq/L), it can be added to the intravenous fluids using the formula: $\text{Body weight} \times 0.4 \times [12 - \text{patient's bicarbonate}]$.

Cats which have **normal hydration** or are only **mildly dehydrated** and not in shock can be started immediately on insulin given **subcutaneously** (0.25 U/kg if glucose is < 20 mmol/L (360 mg/dl); 0.5 U/kg ideal body weight if glucose is ≥ 20 mmol/L).

Subcutaneous insulin is poorly absorbed in significantly dehydrated cats. These cats need intramuscular or intravenous insulin.

For intramuscular dosing of insulin:

- **Dilute regular insulin** with saline or manufacturer's diluent to increase accuracy of dosing. Give 0.2 U/kg intramuscular initially, then continue with **hourly injections** at 0.1 U/kg.
- **Adjust the dose up or down** to achieve a decrease in glucose of 3–6 mmol/L (54–110 mg/dl) per hour.
- Once blood glucose is **16 mmol/L (288 mg/dl)**, give 0.1–0.4 U/kg **every 4–6 h** to achieve a blood glucose of 11–14 mmol/L (200–252 mg/dl) in the first 24 h.

For intravenous dosing of insulin:

- Use an infusion pump and add 25 IU of regular insulin to a 500 ml bag of 0.9% saline, to produce an insulin concentration of 0.05 IU/ml.
- Infuse the insulin/saline mix using a pump into the maintenance fluid line via a Y piece, at an initial rate of 1 ml/kg/h (0.05 IU/kg/h). Be sure to flush both sets of tubing before beginning the infusion, as insulin adheres to plastic.
- When blood glucose reaches 180 mg/dl (10 mmol/L), decrease the insulin infusion to 0.5 ml/kg/h. At the same time replace the maintenance fluids with 0.45% NaCl supplemented to contain 2.5% dextrose and 30 mmol/L KCl.

With either intramuscular or intravenous therapy, aim for a glucose drop of 54–72 mg/dl/h (3–4 mmol/L/h) and do not exceed a decrease of 108 mg/dl/h (6 mmol/L/h). In the first 24 h, aim for a glucose concentration of 11–14 mmol/L (200–252 mg/dl). Long-term adaptations to chronic hyperglycemia have occurred, and glucose should not be normalized for 24–48 hours.

If glucose falls below 8 mmol/L (144 mg/dl) in the first 24 h, add 50% dextrose to intravenous fluids to make a 5% solution.

Continue regular insulin until dehydration is corrected, and then swap to subcutaneous glargine, PZI, lente, or ultralente insulin administered q 24 h.

Prognosis

Prognosis is relatively good. Reported median survival time is 17 months, considering the average age at diagnosis is 10–13 years.

Prevention

Obesity, physical inactivity and repeated **long-acting steroid or megestrol acetate** administration are preventable risk factors for type 2 diabetes.

Individuals predisposed to type 2 diabetes by low insulin sensitivity (as evidenced by increased fasting glucose concentrations) or reduced beta cell function (evidenced as impaired glucose tolerance) should not become obese, and may benefit from a high-protein, low-carbohydrate diet.

HYPERTHYROIDISM***

Classical signs

- Weight loss.
- Hyperactive, restless, aggressive.
- Polyphagia.
- Tachycardia.
- Polyuria/polydipsia.

See main reference on page 304 for details (The Cat With Weight Loss and a Good Appetite).

Clinical signs

Polyuria/polydipsia is present in approximately 50% of hyperthyroid cats, and may be the major presenting complaint.

- Renal blood flow and glomerular filtration rate are increased in hyperthyroidism, leading to an increased water and solute load on the renal tubule. This may exceed the tubular reabsorptive capacity and cause medullary washout. In hyperthyroid humans, impaired concentrating ability is present.
- Because of the advanced age in many hyperthyroid cats, concurrent renal failure is also common.

Typically, a disease of old cats, as the average age is 12–13 years. It is very rare in cats < 8 years of age.

Weight loss is present in nearly all cats.

Two major presenting forms occur; either **restless, hyperactive, and polyphagic** (approximately 80% of cats), or **depressed and anorexic** (10–30% of cats).

Signs suggest **cardiac, GIT or renal disease**.

Typical signs of hyperthyroidism:

- Weight loss (95–98% of cats).
- Polyphagia (65–75%), decreased appetite (19–28%).
- Hyperactive, restless, aggressive (68–81%), lethargy (15–25%).
- Tachycardia (57–65%), heart murmur (10–54%).
- Polyuria/polydipsia (45–55%).
- Vomiting (33–50%), diarrhea (30–45%).
- Panting (13–28%).
- Muscle weakness/tremors (15–20%).

An enlarged thyroid gland or glands are palpable in more than 80% of cats.

- These are located anywhere from the larynx to the thoracic inlet.
- Most are 0.5–1 cm in size, although occasionally they are up to 3 cm.

Diagnosis

Increased **plasma total thyroxine (T_4) concentration (> 64 nmol/L (5 µg/dl))** is considered **diagnostic of hyperthyroidism**.

2–10% of hyperthyroid cats have a total T_4 concentration between 26–64 nmol/L (2–5 µg/dl), and require additional testing for diagnosis.

In mild (early) hyperthyroidism, total T_4 may be within the normal range.

Severe concurrent illness will also suppress total T_4 concentration.

If clinical signs suggest hyperthyroidism or a mass is palpable in the neck, **but** total T_4 is normal, either:

- Repeat total thyroxine measurement in 1–3 weeks, or
- Measure free T_4 (best option, but must use assay validated for cats), or
- Perform a T_3 (triiodothyronine) suppression test (hyperthyroid cats have little or no suppression), or
- Perform a TRH stimulation test (hyperthyroid cats have **no** increase in total T_4 after TRH).

Urine specific gravity ranges from **1.006–1.060** in hyperthyroid cats.

Approximately one third of hyperthyroid cats have **mild to moderate azotemia**. Many of these cats have underlying renal failure, but others have pre-renal azotemia associated with thyrotoxic cardiac failure.

Increased protein catabolism may also contribute to the azotemia.

See main reference on page 346 for details (The Thin, Inappetant Cat).

Differential diagnosis

Renal failure and diabetes mellitus both cause weight loss with PU/PD in aged cats. The PU/PD is more pronounced in diabetes and occurs with glycosuria. In renal failure, appetite is usually reduced rather than increased as in hyperthyroidism. The apathetic form of hyperthyroidism may be difficult to distinguish clinically from renal failure but measurement of urea, creatinine and thyroxine usually distinguishes these diseases.

Treatment

There are three treatment options: chronic administration of antithyroid drugs, surgical thyroidectomy, radioactive iodine. See main reference on page 347 for details (The Thin Inappetant Cat).

DIABETES INSIPIDUS*

Classical signs

- Any age cat.
- Mild to marked polyuria and polydipsia, often present for weeks to months.
- Nocturia or urinary incontinence may occur.
- Urine specific gravity is typically < 1.007, but in some dehydrated cats may be 1.007–1.020.

Pathogenesis

Diabetes insipidus (DI) occurs in two forms, central and nephrogenic.

Central diabetes insipidus is very rare in cats, and occurs when vasopressin (antidiuretic hormone, ADH) secretion from the hypothalamic-pituitary system is inadequate.

- Central DI is most commonly idiopathic (i.e. no cause identified on necropsy).

- The most frequent known causes are head trauma, neoplasia, hypothalamic-pituitary malformations (e.g. cystic structures), or following surgery to the hypothalamic-pituitary area.
- Rarely, central diabetes insipidus occurs in kittens, suggesting a congenital form.

Nephrogenic diabetes insipidus occurs when the renal tubules are unresponsive to vasopressin.

Unresponsiveness to vasopressin may result from problems either at the receptor or with postreceptor mechanisms, including inadequate hypertonicity of the renal medulla.

- Primary (familial) nephrogenic DI has not been reported in cats.
- **Secondary (acquired) nephrogenic DI is common.**
 - It occurs with **renal failure, hyperthyroidism, pyelonephritis, pyometra, hypercalcemia, hypokalemia and drugs.**

Clinical signs

Polyuria and polydipsia occur ranging from mild to severe, depending on cause, and is often present for weeks to months.

Nocturia or urinary incontinence may result because of the large volume of urine produced.

Weight loss may occur as a result of the underlying disease, or when the water intake is huge.

Neurologic signs may occur if DI is associated with a hypothalamic-pituitary neoplasia, e.g. stupor, disorientation, ataxia, seizures, circling.

Diagnosis

Urine specific gravity is usually < 1.007, and often 1.001 or 1.002 in classical DI.

- **Urine specific gravity may be 1.007–1.020 if the cat is very dehydrated, or has partial DI.**
- Partial DI frequently occurs with acquired nephrogenic DI such as renal failure, hypercalcemia, hypokalemia, pyometra and pyelonephritis.
- **Urine, hematologic and serum biochemistry analyses must be performed to exclude causes of acquired nephrogenic DI. Renal failure, hyperthyroidism, pyelonephritis, pyometra, hypercalcemia,**

hyperadrenocorticosteroidism, hypokalemia and drugs causing PU/PD (see page 244) must be ruled out.

Trial synthetic vasopressin (DDAVP) therapy to determine if PU/PD resolves. Pretreatment water intake is measured for 2–3 days, and then again following DDAVP therapy. A greater than 50% reduction of water intake suggests central or partial nephrogenic DI, but is rarely indicated.

A modified water deprivation test can be performed if the cat is not dehydrated, azotemic and laboratory tests do not indicate nephrogenic DI.

- **Ignoring these contraindications may kill the cat,** or make renal failure worse. The cat must be carefully monitored.
- **Rarely is a water deprivation test required in feline medicine,** because central diabetes insipidus is very rare and psychogenic polydipsia has not been reported.
- The main use of a water deprivation test is to determine if the kidney can concentrate urine when water is unavailable (indicating psychogenic polydipsia), and whether vasopressin therapy can increase urine concentration (central or partial nephrogenic DI) after medullary washout has resolved with water deprivation.
- Only consider performing a water deprivation test if there is massive polyuria and polydipsia, urine SG is < 1.008, and nephrogenic diabetes insipidus has been ruled out.
- Details of the test and interpretation are found in many standard textbooks.

Differential diagnosis

It is important to differentiate central DI from secondary nephrogenic DI, which is much more common. Test for **renal failure, hyperthyroidism, hyperadrenocorticosteroidism, pyelonephritis, pyometra, hypercalcemia and hypokalemia.**

Treatment

Ensure water is freely available at all times.

If nephrogenic DI, **manage the underlying disease,** e.g. renal failure, hyperthyroidism. Thiazide diuretics may be useful for reducing water consumption if the underlying disease is not treatable.

If central DI, administer **synthetic vasopressin** (desmopressin, DDAVP, SC, intranasal or conjunctival). Thiazide diuretics are less expensive, but less effective than desmopressin.

Prognosis

Prognosis depends on cause. The best prognoses occur with reversible nephrogenic DI (e.g. hyperthyroidism) and non-neoplastic central DI.

DRUG INDUCED*

Classical signs

- PU/PD following initiation of drug therapy.

Clinical signs

Common drugs causing polyuria and polydipsia include: diuretics, anticonvulsants (e.g. phenobarbital), thyroxine, salt supplementation, sodium bicarbonate, amphotericin B (from renal toxicity and hypokalemia), corticosteroids and megestrol acetate.

Polyuria and polydipsia occur following initiation of drug therapy.

Other clinical signs relate to the underlying disease process.

Diagnosis

Diagnosis is rarely a problem. If polyuria and polydipsia occur with **phenobarbital or thyroxine,** check dose is not excessive by **measuring trough serum concentration.**

Although cats are more resistant to the side effects of corticosteroids, polyuria and polydipsia does occur, but is usually less dramatic than in dogs.

HYPOKALEMIA*

Classical signs

- **Acute onset of muscle weakness, neck ventroflexion, a stiff, stilted gait, and muscle pain.**

Classical signs—Cont'd

- Decreased activity and inappetence for weeks to months.
- Dyspnea in severe cases.
- Signs relating to the underlying disease, e.g. polyuria and polydipsia in chronic renal failure.
- Occurs in older cats and Burmese kittens.

See main reference on page 893 for details (The Cat With Neck Ventroflexion).

Clinical signs

Acute onset of weakness. However, decreased activity and inappetence are often present for weeks to months prior to presentation.

Ventral neck flexion, stiff, stilted gait, and a reluctance to walk or jump are typical.

Larger muscle groups may appear sensitive or palpation.

Dyspnea occurs when the potassium is very low (2.0–2.5 mmol/L), because of weakness of the respiratory muscles. It may occur after **fluid administration** because volume dilution and increased urinary potassium loss induced by diuresis may lead to further worsening of the hypokalemia.

Polyuria, polydipsia may result from hypokalemia or be the result of the underlying disease causing hypokalemia, such as renal failure or hyperthyroidism.

Diagnosis

Decreased serum potassium concentrations (usually < 3.5 mmol/L) in association with clinical signs are required for diagnosis. The severity of signs varies between cats when potassium is 2.5–3.5 mmol/L. Below 2.5 mmol/L and especially below **2.0 mmol/L, signs are life threatening**, with death occurring from **respiratory muscle failure**.

Serum creatine kinase (CK) may be elevated reflecting the myopathy associated with hypokalemia.

HYPERCALCEMIA (HYPERCALCEMIA ASSOCIATED WITH MALIGNANCY, CHOLECALCIFEROL TOXICITY, CHRONIC RENAL FAILURE, HYPERPARATHYROIDISM AND IDIOPATHIC)

Classical signs

- Anorexia and lethargy.
- Vomiting.
- Weight loss.
- Dysuria, inappropriate urination, pollakiuria, stranguria.
- Respiratory signs.
- Lymphadenopathy.
- Palpable cervical mass.

Pathogenesis

Calcium is important for formation of **bones and teeth**, and is essential for **blood coagulation**. It is important for **muscle function**, including cardiac muscle, as well as **nervous system function** where it stabilizes nerve cell membranes. As a cation, it is important for **cell membrane permeability**.

Calcium is regulated in the body via:

- Gastrointestinal absorption.
- Renal excretion.
- Binding to plasma proteins.
- Tissue deposition, especially into bone.

Parathyroid hormone (PTH) and calcitriol (active form of vitamin D) **maintain calcium homeostasis**. Serum calcium concentration regulates parathyroid hormone secretion and their serum concentrations have an inverse linear relationship.

- **PTH is produced in the parathyroid gland** and acts to increase serum calcium. It stimulates bone resorption by increasing osteoclastic activity, which mobilizes calcium into the bloodstream. PTH promotes renal reabsorption of calcium and excretion of phosphorus.
- **Cholecalciferol (vitamin D)** is a fat-soluble vitamin that is metabolized by the liver and kidney to produce calcitriol (1,25 [OH]₂ vitamin D), which acts to increase serum calcium. Calcitriol enhances

intestinal calcium uptake and calcium resorption from bone.

- **Calcitonin** acts to decrease high calcium concentrations, but does not appear to be important in small day-to-day corrections of calcium concentration, which is the role of PTH and calcitriol. Calcitonin decreases osteoclast activity and formation of new osteoclasts.

Hypercalcemia occurs when there is some derangement of the interaction between parathyroid hormone, vitamin D and organs such as the gut, bone, kidneys and parathyroid glands.

Malignancy (lymphoma and squamous cell carcinoma), **renal failure and primary hyperparathyroidism** are the **most common causes** of hypercalcemia in cats. In many cats, the cause of the hypercalcemia is not identified, and is termed idiopathic hypercalcemia.

Hypercalcemia of malignancy is the most common cause of hypercalcemia in cats. It results from secretion of locally acting or humorally acting osteoclast-activating substances.

- In cats, **lymphoma and squamous cell carcinoma are most often associated with hypercalcemia** but multiple myeloma and adenocarcinoma have also been reported.
- In some tumors, for example lymphoma, there is autonomous secretion of a humorally acting PTH-related protein, which activates osteoclasts, increases intestinal absorption and increases renal tubular reabsorption of calcium and excretion of phosphorus. Endogenous PTH secretion is suppressed.
- Some neoplastic cells invade bone or bone marrow and secrete products that act locally to activate osteoclasts, such as prostaglandins, osteoclast-activating factor, calcitriol, interleukin-1, and PTH-related protein or PTH.

Chronic renal failure is the second most common cause of hypercalcemia in cats. A number of mechanisms associated with chronic renal failure lead initially to reduced extracellular calcium. In a few cats, compensatory mechanisms eventually result in hypercalcemia.

- Extracellular calcium concentration is decreased in renal failure because reduced renal mass and hyperphosphatemia reduce formation of calcitriol (active vitamin D), leading to reduced calcium absorption

from the GIT. Phosphate retention also reduces extracellular calcium.

- Chronic stimulation of the parathyroid glands to maintain serum calcium concentrations in renal failure leads to hyperplasia (renal secondary hyperparathyroidism). **In some cats, autonomous function** develops because some hyperplastic cell lines are very deficient in calcitriol receptors. **Calcitriol regulates synthesis of calcium receptors**, so these cells are also poorly sensitive to calcium concentrations, and **produce large amounts of PTH**. Uremia also reduces formation of calcium receptors in parathyroid gland cells, leading to inappropriate PTH secretion.

The diuretic phase of acute renal failure may also be associated with hypercalcemia via other mechanisms.

Primary hyperparathyroidism is a less common cause of hypercalcemia, and is the result of an autonomous adenoma producing excess PTH. It is usually a **solitary functional adenoma**, although bilateral cystadenomas and solitary or bilateral adenocarcinomas have been reported.

Vitamin D toxicosis may be acute and associated with **cholecalciferol (vitamin D) rodenticides**, or chronic due to **excess supplementation or plant ingestion**. In some countries, cholecalciferol rodenticides have been withdrawn from the market because of their potential for irreversible nephrotoxicity in children.

- **Acute toxicity occurs at 5 g of bait/kg body weight** and hypercalcemia occurs within 24 h of ingestion.
- At lower doses of vitamin D, the maximal effect on calcium and phosphorus may not be evident for 1–2 weeks after ingestion.
- Cats requiring supplementation with vitamin D and calcium following thyroidectomy are at risk of vitamin D toxicity and nephrocalcinosis, if calcium and phosphorus is not monitored carefully.
- **Some plants contain active metabolites of vitamin D** such as the houseplant *Cestrum diurnum* (day-blooming jasmine). *Solanum malacoxylon* and *Trisetum flavescens* also contain vitamin D metabolites.

Fungal and bacterial granulomatous disease is a rare cause of hypercalcemia. The inflammatory process may or may not directly involve the bone. The mechanism may involve local osteolysis or secretion of factors from inflammatory cells such as prostaglandins

and osteoclast-activating factors, which lead to bone resorption.

Hypoadrenocorticism is a very rare cause of hypercalcemia in cats (<2% of hypercalcemic cats). It is likely multifactorial, and in dogs is related to the severity of hyperkalemia. Mechanisms include hyperproteinemia from dehydration and increased renal resorption of calcium.

Other rare associations with hypercalcemia include **hyperthyroidism, diabetes mellitus, liver disease** (hepatic lipidosis, biliary fibrosis), and **bone marrow diseases** (myelodysplasia, myelofibrosis).

Idiopathic hypercalcemia is common in cats, and has been postulated to be associated with acidifying diets, which increase bone turnover of calcium, but hypercalcemia was not corrected by partial parathyroidectomy or a non-acidifying diet. Many features are similar to familial benign hypercalcemia reported in humans which is associated with a mutation in the calcium-sensing receptor.

Chronic over-supplementation with calcium in the diet increases the intestinal absorption of calcium. It also stimulates bone resorption and results in hypercalcemia and dystrophic calcification. Because the ability to excrete the increased filtered load of calcium is impaired in cats with renal failure, older cats are more sensitive to excess supplementation. Dietary over-supplementation is rarely seen because of the widespread use of balanced commercial diets.

Sequelae to hypercalcemia include:

- **Chronic renal failure.** High levels of **calcium are toxic to the renal tubular cells**, mineralize renal tissue and interfere with ADH action causing renal failure and polyuria/polydipsia. Hypercalcemia can also lead to **calcium oxalate urolithiasis** of the kidney, ureter, bladder or urethra and result in signs of lower urinary tract disease (LUTD).
- **Reduced excitability of smooth muscle** results in altered gastrointestinal function. Chronic vomiting is a common sign of hypercalcemia.
- **Depressed skeletal muscle contractility** and weakness, and altered cardiac contractility and arrhythmias occur with high calcium concentrations.

Clinical signs

Signs associated with hypercalcemia are compounded by signs of the underlying cause of hypercalcemia, such as malignancy, toxicity from cholecalciferol-containing rodenticides and renal failure.

In general there is no breed or gender predisposition, although **Siamese appear predisposed to primary hyperparathyroidism**.

- Cats with hypercalcemia have a **wide range of ages** (1–19 years) reflecting the multitude of causes, but mean age is 9 years old.
- Renal, gastrointestinal or neuromuscular signs occur, and in part may reflect the underlying cause.

Lethargy, anorexia and/or weight loss are typical of hypercalcemia, regardless of the cause.

Polyuria and polydipsia occur in up to **25% of cats** with hypercalcemia, and may be associated with inappropriate urination.

Signs of **lower urinary tract disease**, including dysuria and pollakiuria, occur in approximately 20% of cats. In a high proportion of cats, this is **associated with calcium oxalate urolithiasis** of the urinary bladder. Renal, ureteral, urethral or urolithiasis may also occur.

Vomiting occurs in 20–30% of cats with hypercalcemia, including cats with idiopathic hypercalcemia.

Constipation or diarrhea are infrequently reported.

Neuromuscular weakness evidenced as a **reluctance to jump, or unsteadiness with jumping** is less common.

Shaking, tremors, seizures, stupor and coma have the potential to occur with extremely high calcium concentrations, and are reported in dogs with cholecalciferol toxicity. Cats tend to ingest less toxin and these signs have not been reported.

Cardiac arrhythmias may occur if serum calcium is more than 4.5 mmol/L (18 mg/dL). Prolongation of PR interval and shortening of QT interval may be evident on ECG.

Acute cholecalciferol toxicity is associated with **lethargy, anorexia and polyuria/polydipsia within 24 h of ingestion**. Vomiting may occur, but the hematemesis and bloody stool seen in dogs have not been reported.

Toxicity is less frequently reported and signs are less severe in cats than dogs.

Lower levels of cholecalciferol toxicity result in PU/PD, inappetence and lethargy and low-grade vomiting, and clinically may be indistinguishable from acute or chronic renal failure.

Physical examination findings are dependent on the cause of hypercalcemia. Lymphadenopathy, abdominal organomegaly or dyspnea may be evident in cats with lymphosarcoma. Cats with squamous cell carcinoma-associated hypercalcemia most often have tumors of the head and neck. In contrast to dogs, a palpable cervical mass is present in about 40% of cats with primary hyperparathyroidism.

Diagnosis

Serum calcium concentration greater than 3 mmol/L (12 mg/dl).

- The serum calcium concentration does not fluctuate with age in cats as it does in dogs, where a healthy puppy can have higher calcium and phosphorus levels.

A **non-lipemic fasted blood sample** is required for measurement of serum calcium, phosphorus, urea nitrogen and creatinine concentrations to differentiate between several of the causes of hypercalcemia.

Hypercalcemia of malignancy is a relatively common cause of hypercalcemia in cats and is most often secondary to lymphoma and squamous cell carcinoma, but may be from multiple myeloma or adenocarcinoma. Serum phosphorus concentration is below the midpoint of the reference range, unless renal failure is present. Diagnosis of neoplasia-associated hypercalcemia is based on documenting increased PTH-related protein (PTH-rP) and suppressed PTH concentration in serum, or finding the primary tumor and demonstrating resolution of hypercalcemia with successful tumor therapy.

Primary hyperparathyroidism is rare in cats. It is associated with anorexia and lethargy, an inappropriately high PTH concentration relative to the hypercalcemia. Serum phosphorus is below the midpoint of the reference range unless renal failure is present, and in some cats, a palpable cervical mass is evident.

Cholecalciferol poisoning is associated with acute depression and anorexia, marked hypercalcemia and

hyperphosphatemia, and a history of recent exposure to rodenticide. Polyuria/polydipsia, vomiting and pain on palpation of the kidneys may also be present. PTH and PTH-rP concentrations would be expected to be low if the cat is not dehydrated, but have not been reported. Later there may be evidence of mineralization of abdominal and other soft tissues. Toxicity needs to be distinguished from other causes of hypercalcemia and hyperphosphatemia (renal failure and hypoadrenocorticism) on the basis of history, signs and ionized calcium (often normal or decreased in renal failure).

Chronic renal failure (renal secondary hyperparathyroidism) is associated with normal to elevated PTH concentrations and low to undetectable PTH-rP assay, hyperphosphatemia, but ionized serum calcium is usually normal or decreased. In contrast, ionized serum calcium is increased with other causes of hypercalcemia.

Idiopathic hypercalcemia is increasingly being identified in cats (mean age 5 years). Typically cats are hypercalcemic with normal or slightly low serum phosphorus concentration, and have normal serum concentrations of PTH, calcitriol and 25-hydroxycholecalciferol. Gross and histologic morphology of the parathyroid glands is normal. Subtotal parathyroidectomy does not resolve the hypercalcemia.

Differential diagnosis

Clinical signs of hypercalcemia (anorexia, lethargy, vomiting, weight loss) are **typical of many diseases**, and serum biochemistry analysis is necessary to detect hypercalcemia.

If PU/PD is present in addition to anorexia, vomiting and weight loss, **chronic renal failure would be the most likely differential diagnosis** based on clinical signs. Most cats with chronic renal failure are not hypercalcemic and of those that are, ionized calcium is usually normal or low.

Chronic renal failure with secondary hypercalcemia is usually **differentiated from other causes of hypercalcemia causing secondary renal failure** by the presence of anemia, small kidney size on palpation or ultrasound, and normal or low ionized calcium in chronic renal failure. Cats with chronic renal failure

and secondary hypercalcemia also tend to have lower calcium concentrations, higher phosphorus concentrations, lower urine specific gravity and higher levels of azotemia than cats with renal failure induced by hypercalcemia.

Treatment

Severe hypercalcemia is a medical emergency as cardiac arrhythmias may occur if serum calcium is more than 4.5 mmol/L (18 mg/dl).

Hypercalcemia with concurrent hyperphosphatemia is associated with **metastatic calcification** and **nephrotoxicity** when the calcium (mg/dl) \times phosphorus (mg/dl) product is > 60 – 80 .

- Hypervitaminosis D and hypercalcemia of renal failure are both associated with a high Ca \times P product and require early treatment to minimize further nephrotoxicity.

Fluids containing 0.9% NaCl should be used for volume expansion to dilute plasma calcium and to induce sodium diuresis, which causes calcium loss in urine. Avoid calcium-containing fluids.

Diuretics (furosemide) promote renal sodium diuresis and hence renal calcium loss.

- Thiazide diuretics are contraindicated as they can cause calcium retention.

Corticosteroids promote renal calcium loss, and decrease bone resorption and intestinal absorption of calcium, but should only be used once the diagnosis of lymphoma is excluded, as they can conceal the diagnosis.

Vitamin D toxicosis requires intensive therapy to reduce calcium levels and may require therapy to control seizures and arrhythmias.

- **Reduce GIT absorption** using an emetic and activated charcoal with a saline or osmotic cathartic. Do not use emetics in convulsing patients.
 - Xylazine (Rompun) can be used as an emetic in cats (1.1 mg/kg IM or SC).
 - Charcoal 1–4 g/kg combined with saline (5 ml per 1 g of charcoal) as a suspension in water should be administered orally or by gastric tube if ingestion occurred within 3–4 h.
- Reduce hypercalcemia using the **diuretic furosemide** (2–5 mg/kg PO q 8 h).

- **Prednisone** at 2 mg/kg PO q 12 h also increases renal loss of calcium.
- If available, **salmon calcitonin** should be administered until serum calcium levels normalize. Begin with 4–6 IU/kg SC q 2–3 h, and increase the dose up to 10 IU/kg if the lower doses are not effective.
 - Monitor serum calcium, hydration status and renal function via urine output.
 - Complications include soft tissue mineralization, renal failure, seizures and arrhythmias.

Cats with primary hyperparathyroidism are best treated with **surgical removal** of the parathyroid adenoma and **short-term vitamin D** and **calcium therapy** over 2–3 months to prevent post-operative hypocalcemia.

Cats with renal failure causing hypercalcemia, should be started on a low phosphorus diet. If phosphorus is not decreased into the middle of the normal range, add a phosphate binder.

- **Once phosphorus is < 1.9 mmol/L;** (normal range, 0.7–1.8 mmol/L) or < 6 mg/dl (normal range, 2.2–5.6 mg/dl), **begin low-dose calcitriol therapy** (2.5 ng/kg PO q 24 h) to decrease progression of renal failure.
- **Calcitriol decreases PTH concentrations** by inducing formation of the calcium receptor on the parathyroid gland cells membrane. In renal failure, calcium sensing is impaired because of the effect of uremia on formation of calcium receptors. This results in inappropriate PTH secretion. By increasing calcium sensing, PTH secretion is decreased, resulting in decreased serum calcium concentration.
- **PTH is a uremic toxin.** It contributes to **CNS depression** and **EEG abnormalities, appetite suppression and anemia associated with uremia.** It also **promotes progression of chronic renal failure.** Low-dose calcitriol has been shown to slow the progression of renal failure and decrease signs of chronic renal failure.
- At **phosphorus concentrations ≥ 1.9 mmol/L;** (normal range, 0.7–1.8 mmol/L) or 6 mg/dl (normal ≤ 5.6 mg/dl), **calcitriol loses its effectiveness** to suppress PTH secretion. Using higher doses of calcitriol in the face of hyperphosphatemia risks worsening progression of the renal failure, due to mineralization of renal tissue. It is essential to

monitor calcium and phosphate regularly when using calcitriol therapy.

- See Chronic renal failure in The Thin Inappetent Cat (page 336) for details of treatment of chronic renal failure.

In cats with idiopathic hypercalcemia, dietary modification may be partially or fully effective in a minority of cats. Dietary modification is worth trying initially, as the only other reported therapy to be effective is **long-term corticosteroids**.

- Dietary modifications reported to have variable success include use of a **high-fiber diet** (Hills w/d) to reduce availability of calcium for intestinal absorption, or use of a **less-acidifying diet** (Hills k/d) to reduce bone turnover.
- **Prednisone** (2–3 mg/kg PO q 24 h) has been reported to be partially or fully effective in normalizing both total and ionized serum calcium in the small number of cats reported, however therapy was required long term (> 12 months).

Prognosis

If hypercalcemia is unresponsive after aggressive treatment, the prognosis is poor.

In contrast to dogs, cats are reported to have a good prognosis following ingestion of cholecalciferol-containing rodenticide, if appropriate fluid and diuretic therapy are instituted.

Prevention

Do not use calcium-containing intestinal phosphate binders.

Be aware of the **risk of hypercalcemia** and soft tissue calcification when using **calcium supplementation** and **calcitriol therapy** in hypocalcemia.

Avoid inappropriately high doses of calcitriol or other vitamin D preparations, and **monitor calcium and phosphate concentrations** carefully when using these products. Moderately increased ionized calcium does not contraindicate use of calcitriol in chronic renal failure, as low doses of calcitriol (2.5 ng/kg q 24 h) do not significantly increase intestinal calcium absorption. Increased serum phosphate concentration is a contraindication for calcitriol use.

Restrict access to cholecalciferol-based rodenticides.

Avoid diets or dietary supplements that are unusually high in vitamin D, such as liver or cod-liver oil.

NEOPLASIA (RENAL NEOPLASIA OR LYMPHOMA)

Classical signs

- Inappetence, weight loss and lethargy.
- Enlarged kidney/s or abdominal mass on palpation.
- ± Vomiting.
- ± Polyuria, polydipsia.
- ± Dysuria, inappropriate urination, pollakiuria, stranguria.
- ± Respiratory signs.
- ± Lymphadenopathy.
- ± Palpable cervical or abdominal mass.

Clinical signs

Neoplasia is a cause of polyuria in cats.

Lethargy, anorexia and/or weight loss are typical, regardless of the cause.

Renal, gastrointestinal, respiratory or neuromuscular signs may occur, and in part reflect the underlying cause.

Hypercalcemia associated with lymphoma is rare in cats but does occur (see page 245, **Hypercalcemia**). Hypercalcemic cats may have **polyuria and polydipsia** which may be associated with inappropriate urination, and/or have signs of **lower urinary tract disease**, including dysuria and pollakiuria, which is commonly **associated with calcium oxalate urolithiasis**.

Vomiting may occur associated with the underlying neoplasm, hypercalcemia or uremia.

Other signs include unilateral or bilateral renal enlargement on palpation, or an abdominal, cervical or thoracic mass.

Diagnosis

Serum creatinine and urea concentrations may be increased if the neoplasia is associated with renal failure.

Urine specific gravity is usually dilute.

Identification of a mass on palpation or imaging. Biopsy and histology is required for a definitive diagnosis.

HYPERADRENOCORTICISM

Classical signs

- Diabetes mellitus.
- Polyuria and polydipsia.
- Weight loss.
- Fragile skin and poor hair coat.

See main reference on page 324 for details (The Cat With Weight Loss and a Good Appetite).

Pathogenesis

Hyperadrenocorticism is a rare disease in cats.

Usually occurs in **middle-aged to older** cats (average age 10–11 years).

Pituitary-dependent form is most common (approximately 75–80% of cases); a functional adrenocortical tumor is less frequent (20–25%).

Clinical iatrogenic hyperadrenocorticism is less pronounced in cats as they are more resistant to the effects of excess exogenous glucocorticoids than dogs. PU/PD may occur with exogenous steroids, but is less dramatic than in dogs.

Chronic insulin resistance from excess endogenous steroid may result in **diabetes mellitus**.

Clinical signs

Polyuria, polydipsia is typical, which may be marked (>120 ml/kg/24 h) if concurrent diabetes is present.

Weight loss occurs as a result of poorly controlled diabetes.

Lethargy is common.

Many of the common signs are attributable to poorly controlled diabetes mellitus (although not all cats with hyperadrenocorticism have diabetes). The diabetes tends to be insulin resistant. Normal doses of insulin often produce a minimal decrease in glucose concentra-

tion and doses greater than 1.5 U/kg q 12 h are often required. **Poor glycemic control** is often still present despite higher than normal doses of insulin.

Thin, fragile skin that bruises easily is a common sign. Some cats have extremely fragile skin, and normal grooming, or lifting the skin for injection or restraint results in severe skin tears.

Poor unkempt hair coat, patchy alopecia, or skin infections including demodicosis may be evident.

Potbelly, which may be reported by the owner as weight gain or abdominal enlargement.

Muscle wasting.

Hepatomegaly.

Other concomitant infections may occur, e.g. bacterial cystitis, pyothorax.

Diagnosis

Diagnosis is based on consistent clinical signs and an abnormal dexamethasone suppression test, i.e. failure of cortisol to suppress below 41 nmol/L (1.5 µg/dl) at both 4 and 8 h after IV dexamethasone.

- Because up to 20% of normal cats do not suppress using 0.01 mg/kg dexamethasone, a higher dose is recommended in cats, i.e. 0.1 mg/kg.
- It is important not to stress the cat when doing this test.
- Cats with pituitary-dependent hyperadrenocorticism may fail to suppress, or exhibit suppression at 3–4 hours followed by “escape” of suppression at 8 hours. The latter pattern is diagnostic for pituitary-dependent disease, and makes further testing unnecessary.

A normal **urine cortisol:creatinine ratio** is useful for **excluding hyperadrenocorticism**, but lacks specificity for diagnosis.

The **corticotropin (ACTH) stimulation test** is best used to differentiate endogenous from iatrogenic hyperadrenocorticism, rather than as a diagnostic test for hyperadrenocorticism, because 15–30% of cats with hyperadrenocorticism have a normal response.

The **combined dexamethasone suppression/ACTH stimulation test** has been used successfully to diagnose hyperadrenocorticism in cats. The combined test

does not appear to be more advantageous than the ACTH stimulation and dexamethasone suppression tests evaluated separately.

Differentiation of pituitary-dependent from adrenal tumors is based on **abdominal ultrasound** (one enlarged adrenal if adrenal tumor) and **ACTH concentration**. Normal to increased ACTH concentrations support a diagnosis of pituitary-dependent disease. Low concentrations support adrenal disease. This test must only be used after hyperadrenocorticism is confirmed, because normal cats often have low ACTH concentrations.

Differential diagnosis

Other causes of poorly controlled diabetes need to be considered, e.g. excessive insulin dose, too short a duration of action of insulin, hyperthyroidism and acromegaly.

Some cats appear to have poorly controlled diabetes based on persistently high blood glucose concentrations measured in hospital, but have good control of clinical signs (e.g. stable weight and water intake < 60 ml/kg). These cats have **stress hyperglycemia** associated with visits to the veterinarian. In contrast, **cats with undiagnosed hyperadrenocorticism and diabetes usually have persisting clinical signs of diabetes**, despite insulin therapy.

Treatment

Medical therapy produces inconsistent results, but is useful in improving the presurgical condition of the cat.

- Drugs which have produced improvement in some cats are **ketoconazole** (15 mg/kg q 12 h) and **metirapone** (65 mg/kg q 12 h).
- **Trilostane** and L-deprenyl have been used in dogs successfully, but there is comparatively little information available on their use in cats. Trilostane ameliorates clinical signs of hyper adrenocorticism in cats based on the studies published.

Surgical **adrenalectomy (unilateral for adrenal tumor and bilateral for pituitary-dependent hyperadrenocorticism)** provides the best response.

- Begin glucocorticoids, fluids and antibiotics just before surgery.
- Fatal post-operative complications are relatively common.

Transsphenoid hypophysectomy may be available in some referral centers.

Prognosis

Prognosis is guarded to grave. Cats that have adrenocortical tumors surgically removed have the longest survival.

HYPOADRENOCORTICISM

Classical signs

- Very rare disease.
- Lethargy, depression, anorexia and weight loss.
- Dehydration, hypothermia, \pm weakness or collapse.
- \pm Bradycardia.
- \pm Vomiting.
- \pm Polyuria and polydipsia.
- \pm Waxing and waning illness, that responds to fluids or glucocorticoids.

Pathogenesis

Hypoadrenocorticism results from a **deficiency of glucocorticoids and/or mineralocorticoids** produced by the adrenal gland.

It can be **classified as either primary or secondary adrenocortical insufficiency**.

- **Primary adrenocortical failure** occurs rarely in cats as a naturally occurring disease, and is presumed to **result from immune-mediated destruction of the adrenal cortices**.
- **Secondary adrenocortical failure** involves only a **deficiency of glucocorticoid secretion** as a result of reduced secretion of pituitary ACTH.
- Spontaneously occurring secondary hypoadrenocorticism has not been reported in cats.
- Iatrogenic secondary hypoadrenocorticism can be demonstrated with an ACTH stimulation test after withdrawal of potent glucocorticoids or progestins, especially after long-term use. However, clinical signs are rarely seen.

Glucocorticoid (cortisol) deficiency impairs the body's response to stressful situations.

Mineralocorticoid (aldosterone) deficiency directly affects renal function and the body's ionic and water homeostasis.

- Loss of aldosterone secretion results in impaired renal conservation of sodium and chloride and excretion of potassium, leading to **hyponatremia, hypochloremia and hyperkalemia**.
- The loss of sodium and chloride **reduces the extracellular fluid volume**, resulting in hypovolemia, hypotension, reduced cardiac output and decreased renal perfusion.
- Hyperkalemia has deleterious effects on myocardial electrical activity.

For clinical signs to develop there must be a loss of at least 85–90% of the adrenal cortices.

Disease progression varies in severity depending on the degree of stress and the adrenocortical reserve.

An Addisonian crisis is the **most severe presentation** of hypoadrenocorticism. This is the result of severe hyponatremia and hyperkalemia, which are the precursors for hypovolemia, prerenal azotemia and cardiac arrhythmias.

Clinical signs

Very rare disease in cats.

Most common in **young to middle age** 1–9 years (average, 6 years old).

In general, **signs are similar to those in dogs**. It often presents with only vague clinical signs of lethargy, anorexia and weight loss. Vomiting and diarrhea are less common signs in cats, as are changes in the electrocardiogram associated with hyperkalemia.

Signs may be present for only **a few days or up to 4 months** prior to diagnosis.

Lethargy or depression are frequent signs.

Anorexia and weight loss are also common.

On physical examination, most cats (>50%) are **dehydrated, hypothermic or depressed**.

Weakness, weak femoral pulses, and slow capillary refill are common although, unlike dogs, collapse and bradycardia are rare.

Vomiting may be reported.

Polyuria and polydipsia are reported in **30% of cats**.

Partial adrenal deficiency is characterized by episodic, non-specific gastrointestinal signs and lethargy or depression, which occur particularly at times of stressful events (travel, boarding, surgery).

A waxing and waning course of illness is typical.

A history of previous response to steroids or fluids is common.

Diagnosis

Diagnosis is based on clinical signs plus a sodium:potassium ratio of < 24:1.

Definitive tests are an ACTH stimulation test combined with measurement of ACTH concentration.

- Synthetic ACTH (Cortrosyn, Organon) administered at 0.125 mg/cat IM with blood samples collected at 0, 30 and 60 minutes or IV with samples collected at 0, 60 and 90 minutes or ACTH gel (2.2 mg/kg) IM with samples at 0, 60 and 120 minutes.
- Cortisol concentration pre- and post-ACTH < 55 nmol/L (2 µg/dl) is diagnostic.
- Elevated ACTH concentration differentiates spontaneous primary hypoadrenocorticism from iatrogenic steroid administration, because the cause of the spontaneous disease is lack of cortisol response to ACTH.

Hyponatremia occurs in cats, and is usually accompanied by hypochloremia.

Hyperkalemia occurs in 90% of cats, but is less marked (< 7.6 mmol/L or mEq/L) than in dogs.

Azotemia, hyperphosphatemia and dehydration occur in nearly all cats.

Urine specific gravity < 1.030 was present in 70% of cats.

Differential diagnosis

Renal failure is much more common, and also typically presents with azotemia and urine specific gravity of < 1.030, and can have similar signs. The ACTH stimulation test is normal in renal failure and the cats tend to be older.

Chronic glucocorticoid or megestrol acetate administration may result in a similar ACTH stimulation test result. The cortisol increase is suppressed in the ACTH stimulation test. However, ACTH concentration is also suppressed, and electrolytes are normal.

An Addisonian crisis needs to be differentiated from other critical conditions such as **diabetic ketoacidosis, necrotizing pancreatitis and septic shock**.

Mild hypoadrenocorticism displays signs that are relatively non-specific, and are often seen in other gastrointestinal and renal diseases.

Treatment

An acute Addisonian crisis is a medical emergency.

Immediate correction of hypotension, hypovolemia, electrolyte imbalances and metabolic acidosis via fluid administration is essential. Use isotonic fluids (0.9% NaCl) at 40 ml/kg/h IV initially for the first 1–4 hours. Once dehydration is corrected, reduce the fluid rate to 60–90 ml/kg/day, using the higher fluid rate if the cat is not eating.

- Potassium supplementation in fluids is contraindicated, but if the only fluids available immediately have potassium, use them.

Provide an immediate source of **glucocorticoids**.

- Prednisolone sodium succinate (4–20 mg/kg, IV) or dexamethasone (0.1–2.0 mg/kg, IV or IM).
- Mineralocorticoids should be replaced using oral fludrocortisone acetate (0.05–0.1 mg/cat PO q 12 h) or DOCP (deoxycorticosterone pivalate, 2.2 mg/kg, IM q 25 days). In Australia, the long-acting form in oil for intramuscular injection is an acetate product (DOCA).
- If the cat is in shock, higher doses of glucocorticoids may be warranted.

Despite appropriate therapy, lethargy, anorexia and weakness may persist for 3–5 days, unlike the rapid response in dogs.

In the long term, **glucocorticoid and mineralocorticoid replacement** is required lifelong. Use either **fludrocortisone acetate** (0.05–0.1 mg/cat PO q 12 h) or **DOCA** (2.2 mg/kg, IM q 25 days) for mineralocorticoid replacement long term. Some cats require additional glucocorticoid replacement long term or at times of stress, which can be provided using prednisolone/pred-

nisone (0.25–1 mg/cat PO q 12 h) or methylprednisolone (10 mg IM q 1 month).

Stressful events may warrant an increase in medication dose.

Prognosis

Prognosis is good with appropriate treatment, provided the hyperkalemia and electrolyte imbalance is corrected in time. Cats with adrenal insufficiency will have a normal life expectancy provided they are treated appropriately.

Prevention

Secondary adrenocorticism caused by rapid withdrawal of chronic corticosteroid therapy can be prevented via staged withdrawal of steroids and progestins, which allows adrenal gland function to recover from chronic suppression.

ACROMEGALY (HYPERMOMATOTROPISM; GROWTH HORMONE-PRODUCING TUMOR)

Classical signs

- Poorly controlled, insulin-resistant diabetes mellitus requiring high doses of insulin.
- Polyuria, polydipsia, polyphagia.
- Weight gain despite poorly controlled diabetes.
- Large, blocky or coarse body and head.
- Enlarged tongue, widely spaced teeth, thickened soft palate.
- Cardiomegaly.

See main reference on page 322 for details (The Cat With Weight Loss and a Good Appetite).

Pathogenesis

Very rare disease.

Caused by a functional adenoma of the pars distalis which produces excess growth hormone.

Excess growth hormone results in soft tissue and bone overgrowth from the chronic hypertrophic actions of

the hormone. These anabolic actions are mediated by insulin-like growth factor-1, a growth factor synthesized in the liver and also locally in the growth plate of bones. The effects of excess growth hormone are chronic and insidious.

Acute catabolic actions of growth hormones result in fat breakdown (lipolysis) and glycolysis. Hyperglycemia results from increased gluconeogenesis in the liver and decreased glucose uptake into tissues as a result of insulin resistance. Long term, the marked insulin resistance results in diabetes mellitus.

Insulin resistance may be extreme with insulin doses between 20–130 U/day required to control blood glucose.

Clinical signs

Cats are typically middle aged to elderly, with a predominance of males.

All cats reported have diabetes mellitus, and in most cats, their diabetes is poorly controlled and insulin-resistant. Normal doses of insulin produce no or minimal decrease in glucose concentration, and in many cats, very large doses of insulin are required to produce an acceptable glucose-lowering effect.

Polyphagia, polyuria and polydipsia are associated with poorly controlled diabetes.

Typically, there is **weight gain despite poorly controlled diabetes**, although sometimes weight loss is present.

A **large, blocky or coarse body** is typical, and cats often have coarse facial features. General coarsening of body type is evident when the cat is compared to pictures taken several years before.

Acromegalic cats often have **thickened enlarged tongues**, sometimes widely spaced teeth and a thickened soft palate. Displacement of lower canine teeth forward (prognathia inferior) may occur.

Cardiomegaly is often evident on radiographs and occasionally congestive heart failure occurs resulting in dyspnea.

Degenerative arthritis may occur resulting in stiffness on rising and walking. Periosteal reaction is evident around the joints on radiographs.

Renal failure occurs in some cats.

Diagnosis

Diagnosis is based on clinical signs and **increased plasma concentrations of insulin-like growth factor-1** (> 1200 U/L).

Growth hormone concentrations can be measured with an assay developed for dogs, available at some research laboratories. Demonstration of persistently elevated GH concentrations, which do not increase with stimulation from GHRH or clonidine, support the diagnosis, but is not readily available to most practitioners.

A pituitary mass on CT or MRI scan supports the diagnosis, and is useful for monitoring response to irradiation therapy.

Differential diagnosis

Other causes of poorly controlled insulin-resistant diabetes need to be distinguished from acromegaly. When insulin resistance is extreme and insulin dose exceeds 20–30 U/cat/injection without causing hypoglycemia, the likely cause is acromegaly. Most other causes of insulin resistance produce less extreme insulin resistance and very high doses of insulin produce severe hypoglycemia.

Hyperadrenocorticism causes poorly controlled insulin-resistant diabetes. Typically, insulin doses required to control hyperglycemia are much lower than for acromegaly. In contrast to acromegaly, cats with hyperadrenocorticism have weight loss. Other signs suggestive of hyperadrenocorticism are a poor hair coat and fragile skin, which may tear with restraint for blood sampling or insulin injection. Many have a potbelly (may also be present in acromegaly) and hepatomegaly.

Other causes of apparent insulin resistance such as **excessive insulin dose resulting in rebound hyperglycaemia or use of an insulin of insufficient duration of action** result in poorly controlled diabetes, but clinical signs of acromegaly are absent.

Treatment

Cobalt radiation has been used successfully, and may result in resolution of the diabetes in some cats.

Pituitary ablation using cryosurgery may be effective (refer to current literature).

The long-acting somatostatin analog, octreotide has the potential to lower GH concentrations, but its use has not been reported in cats.

Prognosis

Without specific treatment for the GH excess, the **long-term prognosis is poor**; most eventually die with congestive heart failure, renal failure or neurologic signs from the expanding pituitary tumor within 1–2 years. Short-term prognosis is reasonable, provided sufficient doses of insulin are administered to control hyperglycemia and resolve the clinical signs of diabetes mellitus.

HYPERPARATHYROIDISM

Classical signs

- Anorexia and lethargy.
- Vomiting.
- Weight loss.
- Dysuria, inappropriate urination, pollakiuria, stranguria.
- Weakness, tremors.
- Palpable cervical mass.

See main reference on page 245 for details of hypercalcemia (The Cat With Polyuria and Polydipsia).

Clinical signs

Primary hyperparathyroidism is an uncommon cause of hypercalcemia, and is usually the result of an autonomous adenoma producing excess PTH. It is usually a **solitary functional adenoma**, although bilateral cystadenomas and solitary or bilateral adenocarcinomas have been reported.

Affected cats are typically old (average age 13 years) and Siamese cats are over-represented.

Clinical signs are of **hypercalcemia** and include **anorexia and lethargy** (50% of cats), **gastrointestinal signs** including vomiting, diarrhea or constipation (27%), polyuria and/or polydipsia (24%), lower uri-

nary tract signs including dysuria, inappropriate urination, pollakiuria and stranguria (23%), and weakness and/or muscle tremors (14%).

A **palpable parathyroid mass** is present in more than half the cats.

Diagnosis

A presumptive diagnosis is based on finding **hypercalcemia** and demonstrating a **parathyroid mass** on palpation or cervical ultrasound.

PTH concentrations are **inappropriately high** for the calcium concentration, and are in the normal range or increased.

A definitive diagnosis is by surgical removal of the parathyroid mass and normalization of serum calcium concentrations. Vitamin D and calcium are usually administered following surgical removal to prevent life-threatening hypocalcemia (see page 248, Hypercalcemia).

PRIMARY HYPERALDOSTERONISM

Classical signs

- Weakness, cervical ventroflexion.
- Inappetence and weight loss.
- Polyuria, polydipsia.
- Blindness.

Pathogenesis

Primary hyperaldosteronism is a very rare cause of polyuria and polydipsia, and results from an aldosterone-secreting adrenal tumor.

Aldosterone stimulates reabsorption of sodium in the distal tubule and collecting ducts. To maintain electrical and osmotic neutrality, chloride, bicarbonate and water are reabsorbed, and potassium and hydrogen ions are excreted. Hyperaldosteronism results in hypokalemia, metabolic alkalosis, and systemic hypertension from the sodium and water reabsorption.

Clinical signs

Affected cats are typically old, ranging from **10–20 years**.

Clinical signs are mainly of **hypokalemia** including muscle weakness, ventroflexion of the neck, inappetence and weight loss, or of **hypertension** and include blindness from hypertensive retinopathy. Other signs include ataxia, abdominal enlargement and polyuria and/or polydipsia with two of the five reported feline cases also having **diabetes mellitus**.

Diagnosis

Serum creatinine kinase activity is increased reflecting hypokalemic myopathy.

Urine specific gravity is usually dilute.

A presumptive diagnosis is based on finding **persistent hypokalemia** despite supplementing with high doses of potassium, and **intractable hypertension** in an elderly cat. The finding of an adrenal mass and increased aldosterone concentrations help confirm the diagnosis.

Differential diagnosis

Pheochromocytoma may also cause hypertension in an elderly cat and be associated with an adrenal mass.

Other causes of hypertension in elderly cats including **hyperthyroidism** and **renal disease** need to be ruled out.

Treatment

Clinical signs can be improved or resolved with **potassium supplementation** and **antihypertensive therapy**.

- Use **potassium gluconate** solution, tablets or powder (4–10 mmol (mEq)/cat PO q 24 h in divided doses. See treatment of hypokalemia in The Cat With Generalized Weakness (page 946) and The Cat With Neck Ventroflexion (page 895).
- Use **amlodipine** (0.625 mg or 1/4 of a 2.5 mg tablet, PO q 24 h) for hypertension. Some cats with severe hypertension may require doses as high as 1.25 mg PO q 12 h. Titrate dosage carefully, based upon blood pressure determinations.
- Trilostane has been used in humans with hyperaldosteronism, but its use has not been reported in cats.

Long-term resolution involves **surgical removal** of the adrenal mass.

PHEOCHROMOCYTOMA

Classical signs

- Polyuria, polydipsia.
- Signs of systemic hypertension (blindness, dyspnea from heart failure).

Pathogenesis

Pheochromocytoma is a rare tumor, that develops from the medullary region of the adrenal gland, or occasionally as an extra-adrenal mass.

Functional tumors may produce **adrenaline (epinephrine)**, **noradrenaline (norepinephrine)** and occasionally other hormones such as dopamine.

Signs result from either **elevated catecholamine concentrations** or from a **mass effect** of the tumor, metastasis or local invasion.

Excessive catecholamine concentrations may produce **severe hypertension** and associated signs such as retinal hemorrhage and detachment.

Polyuria and polydipsia may result directly from the excessive catecholamine concentrations, hypertensive renal damage or from insulin resistance. In diabetic cats with unexplained insulin resistance, pheochromocytoma is a rare potential cause.

Clinical signs

Affected cats are typically old, ranging from **10–20 years**.

Clinical signs are vague and diagnosis pre-mortem is rare. Signs include polyuria and/or polydipsia. In diabetic cats, pheochromocytoma may result in poor glycemic control associated with insulin resistance.

Sudden blindness with evidence of retinal hemorrhage and detachment has been reported as well as congestive heart failure.

Differential diagnosis

Primary hyperaldosteronism may also cause hypertension in an elderly cat and be associated with an adrenal mass. Typically there is hypokalemia, which is

difficult to control, and increased aldosterone concentrations.

Other causes of hypertension in elderly cats including **hyperthyroidism** and **renal disease** need to be ruled out.

Hyperadrenocorticism may be associated with an adrenal mass and polyuria, polydipsia, but can be ruled out based on clinical signs and a low dose dexamethasone test.

Diagnosis

An index of suspicion is required to make a presumptive diagnosis. **Systemic hypertension** together with an **adrenal mass**, in the absence of signs of hyperadrenocorticism or hypokalemia are suggestive of pheochromocytoma.

The mass can be imaged with ultrasound, MRI or CT. Biopsy may establish a definitive diagnosis.

A definitive diagnosis based on demonstration of increased plasma or 24 h urinary catecholamine excretion is rarely performed.

Treatment

Clinical signs can be improved using **alpha (phenoxybenzamine)** blockers, and if needed beta blockers (e.g. atenolol).

Long-term resolution involves **surgical removal** of the adrenal mass, but perioperative care is critical, and includes use of preoperative alpha blockers for 1–2 weeks prior to surgery. Surgery is best performed where a specialist anesthetic service is available.

PRIMARY SEX HORMONE-SECRETING ADRENAL TUMOR

Classical signs

- Fragile skin and poor hair coat.
- Polyuria and polydipsia.
- Poorly controlled diabetes mellitus.

Pathogenesis

Rarely, adrenal tumors secrete sex hormones. The most common is a **progesterone-secreting** tumor, and

one cat was reported to have an estradiol- and testosterone-secreting tumor.

The few cats reported were **middle-aged to older** cats (aged 7–14 years).

In humans and dogs, progesterone binds to cortisol-binding proteins displacing cortisol and resulting in increased concentrations of free cortisol. Progesterone is also a potent insulin antagonist.

Cats with progesterone-secreting tumors have clinical signs indistinguishable from hyperadrenocorticism, including concurrent diabetes mellitus.

Clinical signs

In cats with a progesterone-secreting tumor, skin and hair coat changes are the most common signs. **Thin, fragile skin that bruised easily, an unkempt greasy hair coat**, non-pruritic symmetrical alopecia, and skin infections including demodicosis were the most common signs reported.

Polyuria, polydipsia is typical, and in the majority of cats was attributable to **poorly controlled diabetes mellitus**.

Weight loss occurs as a result of poorly controlled diabetes.

One cat with an **estradiol- and testosterone-secreting tumor**, developed behavioral changes including aggression, had vulval hyperplasia, urine with a strong “tom-cat” smell and an unkempt hair-coat.

Diagnosis

Diagnosis of a progesterone-secreting tumor is based on consistent clinical signs, an abnormal dexamethasone suppression test (0.1 mg/kg), i.e. basal cortisol concentrations are low-normal, but there is failure of cortisol to suppress below 41 nmol/L (1.5 µg/dl) at both 4 and 8 h after IV dexamethasone, increased basal progesterone concentrations and evidence of an adrenal mass on ultrasound. Alternatively, as with dogs, basal cortisol may be low-normal and suppress normally following dexamethasone.

- Cortisol concentrations were below the reference range after ACTH stimulation, but that occurs in 50% of cats with hyperadrenocorticism.

The cat with an **estradiol- and testosterone-secreting tumor**, had **bilaterally enlarged adrenal glands**, and basal estradiol and testosterone concentrations were markedly elevated.

A skin biopsy shows changes consistent with an endocrinopathy.

Differential diagnosis

Hyperadrenocorticism is the most likely differential diagnosis and may appear identical clinically and on hormonal testing to a progesterone-secreting tumor, except for the absence of markedly increased basal progesterone concentrations.

Other causes of poorly controlled diabetes need to be considered, e.g. excessive insulin dose, too short a duration of action of insulin, hyperthyroidism and acromegaly.

Other causes of a poor hair coat need to be considered.

Treatment

Aminoglutethimide (AGT; approximately 6 mg/kg q 12 h PO) was used successfully for 1–2 months in some cats to control signs prior to surgery.

- Aminoglutethimide inhibits the enzyme, which converts cholesterol to prenenolone during synthesis of adrenocortical steroids.
- Mammary gland enlargement following treatment has been reported in a male cat.

Trilostane resulted in a temporary improvement in the cat with the **estradiol- and testosterone-secreting tumor**.

Surgical removal of the **adrenal tumor** is the treatment of choice once signs have been controlled medically. Surgery resulted in long-term survival and resolution of clinical signs including diabetes mellitus.

Prognosis

Prognosis is good for cats that respond to medical therapy and undergo successful surgical removal of the adrenal mass.

CYSTIC ENDOMETRIAL HYPERPLASIA/PYOMETRA COMPLEX

Classical signs

- Low-grade inappetence and lethargy.
- Vaginal discharge or distended uterus palpable.
- \pm Fever.
- \pm Polyuria, polydipsia.

See main reference on page 269 for details of acute pyometra/metritis (The Cat With Depression, Anorexia or Dehydration).

Clinical signs

Chronic cystic endometrial hyperplasia/pyometra complex presents with **vaginal discharge**, and cats may have **polyuria** and **polydipsia** as a presenting sign. **Pyrexia is rare**.

Stump pyometra is **rarely** a cause of polyuria, polydipsia; it more often presents as vaginal discharge.

Chronic cystic endometrial hyperplasia/pyometra complex occurs in **intact cats of any age, regardless of whether they have previously had kittens**.

Copious vaginal discharge (watery or thick) is most common.

Low-grade inappetence may be present for weeks or months.

Weight loss, lethargy, unkempt appearance and mild dehydration may be evident.

Depression, listlessness, \pm mild dehydration. Cats are usually not pyrexia.

Polyuria, polydipsia occurs in some cats.

Diagnosis

Clinical signs that are highly suggestive of cystic endometrial hyperplasia/pyometra complex are vaginal discharge and listlessness in an intact cat, plus a **distended uterus on radiograph**. Radiographically,

cystic endometrial hyperplasia/pyometra can only be distinguished from a pregnant uterus after approximately 42 days, when calcification of the fetal skeleton is visible.

Ultrasonography readily distinguishes between pregnancy and pyometra 21 days after last breeding date.

Increased white cell count and/or left shift are found in some cats.

PART 5

Cat with acute illness

16. The cat with acute depression, anorexia or dehydration

Anthony Abrams-Ogg

KEY SIGNS

- Acute lethargy, depression or listlessness.
- Acute inappetence or anorexia.
- Dry mucous membranes, skin tenting.

MECHANISM?

- Depression, anorexia and dehydration are non-specific signs that frequently occur together and accompany most diseases.
- Depression may result from a primary neurologic disorder or be secondary to diseases of other organs.
- Reduced eating behavior may be due to **primary anorexia**, **secondary anorexia** due to an underlying disorder, **pseudoanorexia** and **physiologic anorexia**.
- Dehydration occurs when drinking cannot compensate for water losses.

WHERE?

- Disorders of **any organ system** may cause acute depression, anorexia or dehydration.

WHAT?

- The most common causes of acute depression, anorexia and dehydration without other more specific signs are **pancreatitis**, **hepatopathies** and **poisoning**.

QUICK REFERENCE SUMMARY

Diseases causing acute depression, anorexia or dehydration

METABOLIC

- **Acute anemia** (p 270)**

Acute anemia of any cause will result in depression, anorexia and dehydration. Pale mucous membranes are typical, with or without splenomegaly or icterus. Polypnea may be evident, and fever may be present if due to *Mycoplasma haemofelis* (*Haemobartonella felis*).

- **Acute renal failure* (p 278)**

This is usually due to renal ischemia or nephrotoxins, and results in progressive depression and anorexia, vomiting, and polyuria, oliguria or anuria. Acute exacerbation of chronic renal failure may also occur.

- **Urethral obstruction*** (p 267)**

Progressive depression and anorexia occur. Dysuria may not be witnessed and non-specific signs predominate due to acute uremia. A turgid bladder is evident on palpation.

- **Hepatic encephalopathy (p 297)**

In young cats this is usually due to a porto-systemic shunt. In mature cats this is usually due to hepatic lipidosis. Intermittent disorientation and ptyalism are the most common signs.

- **Diabetic ketoacidosis* (p 292)**

Insulin deficiency and dehydration lead to hyperglycemia and ketoacidosis. This may occur acutely without a history of weight loss and polyuria/polydipsia. Depression and anorexia are the main signs and a history of infrequent vomiting may be present.

- **Acute hypoglycemia (p 296)**

This is usually due to insulin overdose. Lethargy, disorientation, trembling, ataxia and dilated pupils are often present. Signs may progress to coma or seizures if not treated.

- **Acute hypokalemia** (p 271)**

Hypokalemia has numerous causes including chronic renal failure, post-obstructive diuresis, intravenous fluid therapy with potassium-poor fluids, furosemide therapy, vomiting, hyperaldosteronism (rare) and the treatment of diabetic ketoacidosis. Anorexia may contribute to hypokalemia, which in turn may exacerbate anorexia and depression.

- **Hypophosphatemia* (p 295)**

Severe hypophosphatemia may complicate the treatment of diabetic ketoacidosis and enteral alimentation of an anorexic cat, causing increased depression and anorexia and hemolysis.

- **Hypoparathyroidism* (p 295)**

Hypoparathyroidism is usually caused by parathyroidectomy during thyroidectomy. Idiopathic hypoparathyroidism is uncommon. Hypocalcemia results in anorexia and depression that may progress to muscle fasciculations and seizures.

- **Hypernatremia (p 298)**

Hypernatremia should be considered in a critically ill cat with progressive depression not attributable to other causes.

- **Acute heart failure* (p 292)**

Non-specific signs of lethargy and inappetence may occur prior to dyspnea. An arrhythmia, murmur and/or a weak pulse may be evident. Abnormal lung sounds consistent with edema or pleural fluid may be auscultated.

NEOPLASTIC

- **Neoplasia* (p 293)**

Many tumors may cause acute signs, and non-specific signs of lethargy and inappetence often appear prior to specific signs.

- **Central nervous system neoplasia (p 297)**

The tumor may acutely affect alertness or appetite. Other neurologic signs may or may not be present.

NUTRITIONAL

- **Unpalatable food* (p 294)**

Primary anorexia may occur due to a change in the diet. History of a diet change, together with normal physical examination findings are suggestive.

- **Alternate food source* (p 294)**

Physiologic anorexia may occur after consumption of an unknown source of food.

PHYSICAL

- **Separation or situation anxiety** (p 270)**

Change in environment and routine may cause primary anorexia and depression. Withdrawal or hiding may occur.

- **Environmental stress* (p 294)**

Temperature extremes may cause primary anorexia and inactivity.

INFLAMMATION

- **Fever*** (p 267)**

Acute fever and its underlying disorder may cause acute depression, anorexia and dehydration. Localizing signs may or may not be present.

- **Pancreatitis* (p 272)**

Non-specific signs of depression and/or anorexia dominate the clinical picture. Unlike the dog, vomiting and abdominal pain are not consistent findings.

- **Gastrointestinal foreign body and inflammation*** (p 268)**

Non-specific signs often predominate and vomiting and diarrhea may or may not be witnessed. Occasionally, a linear foreign body is evident wrapped around the base of the tongue.

- **Esophageal foreign body and inflammation (p 299)**

Regurgitation and gagging may not be witnessed, and non-specific signs may predominate.

- **Acute intranasal, oral or pharyngeal inflammation ** (p 269)**

Sneezing, nasal discharge and stertor may not be witnessed initially and non-specific signs predominate including depression, anorexia and pyrexia. Careful examination may reveal a mild serous ocular

continued

continued

discharge or tongue ulceration. Acute oral and oropharyngeal inflammation will cause pseudoanorexia. The associated pain and underlying condition may cause non-specific signs. Salivation and halitosis may be evident.

- **Central nervous system inflammation (p 297)**

Acute meningitis or encephalitis may initially be characterized by non-specific signs. Careful neurological examination may reveal cranial nerve or proprioceptive deficits.

INFECTIOUS

Viral:

- **Panleukopenia** (p 272)**

Non-specific signs of extreme lethargy and anorexia usually appear prior to the onset of vomiting. Diarrhea may occur 1–2 days after vomiting begins. Fever may or may not be present.

- **Feline leukemia virus infection (p 299)**

Occasionally the only signs of infection are acute depression, anorexia and dehydration.

Bacterial:

- **Bacterial sepsis** (p 269)**

Depression, anorexia and fever are typical of bacterial infection, although fever may not be present, especially in severe sepsis, and hypothermia may herald impending septic shock. Evidence of an internal site of infection may or may not be present on physical examination.

Parasitic:

- **Toxoplasmosis* (p 293)**

Lethargy, anorexia and fever are early signs. Dyspnea is present in the majority of cats, and is associated with increased respiratory sounds over the chest. Neurological signs, icterus, uveitis or evidence of other specific organ involvement may or may not be apparent.

Idiopathic:

- **Primary anosmia (p 299)**

Reduced sense of smell may cause anorexia. Primary anosmia may be idiopathic or neurologic.

Toxic:

- **Acute poisoning and envenomation* (p 283)**

Poisoning with ingested substances or animal venoms commonly causes acute non-specific signs, although more specific signs are often present as well. Depending on the toxin, these signs include salivation, vomiting, diarrhea, polypnea, arrhythmias, pale mucous membranes, hypothermia, tremors (which may cause hyperthermia), excitability and other behavioral changes, seizures and profound generalized weakness.

- **Ethylene glycol poisoning* (p 287)**

Acute depression in acute ethylene glycol toxicosis is due to direct central nervous system effects. Depression is due later to acute renal failure. Other signs include ataxia, vomiting, tremors, polyuria, painful and swollen kidneys and seizures.

- **Lily poisoning* (p 290)**

Acute depression occurs following ingestion. Later depression is due to acute renal failure. Other signs include vomiting, polyuria, oliguria or anuria and painful and swollen kidneys.

- **Snake bite envenomation* (p 291)**

Acute weakness caused by snake venom neurotoxins may present as acute depression. Other signs depend on the specific snake toxins, which include procoagulants, hemolysins, nephrotoxins, myotoxins and local cytotoxins.

- **Drug therapy*** (p 268)**

Many drugs can cause anorexia.

Traumatic

- **Trauma*** (p 266)**

Trauma may cause primary and secondary depression, anorexia and dehydration. External signs of trauma may be subtle or obvious. Shorn nails are often evident. A fractured jaw and tongue lacerations or puncture wounds cause pseudoanorexia and impede drinking.

- **Pain*** (p 268)**

Pain may contribute to the depression and anorexia seen in many of the disorders listed in all categories above. Other signs of pain include vocalization (spontaneous and evoked by palpation), defensive aggression evoked by palpation, lameness, hunched posture (abdominal pain) and reluctance to move.

INTRODUCTION

MECHANISM?

Depression, anorexia and dehydration are non-specific signs that frequently occur together and accompany most diseases.

- The severity of the signs varies with the primary disease and the temperament of the animal.
- Signs may be stable or progressive.
- Various non-specific (e.g. acute phase response) and specific (e.g. uremia) mechanisms may be involved, depending on the primary disease.

Depression refers to dullness, lethargy and withdrawal from contact (hiding). The animal is less responsive, but not to the extent that it would be considered stuporous or comatose. Depression may result from a primary neurologic disorder or be secondary to diseases of other organs. Weakness, behavioral factors (e.g. anxiety), and depression of the reticular activating system may contribute to depression due to non-neurologic disorders.

- Depressed and critically sick cats may still purr, and the presence of purring should not be interpreted as an indication of mild illness.

Anorexia refers to a reduced appetite. Anorexia may be complete or partial. (“Inappetence” is commonly used to refer to partial anorexia. In this chapter “anorexia” will be used to refer to a reduced appetite regardless of severity.)

- **Primary anorexia** is due to anosmia, behavioral factors or neurologic disorders.
 - The smell of food is important to appetite stimulation, especially in cats.
 - Behavioral (psychologic) factors causing anorexia include fear, change in routine and unpalatable food.
 - Central neurologic disorders may impair the appetite center in the hypothalamus.
- **Secondary anorexia** occurs when a primary disease process affects the cytokine, endocrine and neurologic control of appetite.
 - Most disorders may result in secondary anorexia by various mechanisms.
 - This is the most common cause of anorexia in cats.

- Anorexia may also be due to **pseudoanorexia** and **physiologic anorexia**.
 - In pseudoanorexia the animal has a normal appetite but is reluctant to eat because of oral pain. (If there is a non-painful disorder of prehension, the presenting complaint will be dysphagia not anorexia.)
 - In physiologic anorexia the animal is satiated after eating. This may mimic true anorexia if the animal has an unknown source of food.

Dehydration refers to a reduction in body water other than that present in the transcellular compartment (third space, i.e. the gastrointestinal tract, pleural cavity and peritoneal cavity). It occurs when the animal does not drink and absorb sufficient quantities of water to replace physiologic or pathologic losses. Thirst may be reduced by analogous mechanisms that reduce appetite.

WHERE?

Disorders of **any organ system** may cause acute depression, anorexia or dehydration. The focus of this chapter is diseases where the owner complaint is typically that the cat is suddenly quiet and/or refusing to eat or drink. Specific signs are often not reported and are not obvious on physical examination. Meticulous and repetitive history-taking and physical examinations may be needed to detect subtle signs and development of new signs as the disease progresses. Laboratory assessment and imaging are often required to establish a diagnosis. Acute pyrexia and acute anemia as causes of depression, anorexia and dehydration are discussed in The Pyrexia Cat (page 364) and The Anemic Cat (page 526). The reader should also refer to The Cat With Stupor or Coma (page 821), The Cat With Seizures, Circling and/or Changed Behavior (page 795), and The Cat With Generalized Weakness (page 941). In the absence of a specific diagnosis, treatment should be supportive.

WHAT?

The focus of this chapter is **diseases of acute onset**, as opposed to acute exacerbation of chronic diseases. In most cases the cat will be in **good body condition**.

The most common causes of acute depression, anorexia and dehydration without other more specific signs are **pancreatitis, hepatopathies and poisoning**.

DISEASES CAUSING ACUTE DEPRESSION, ANOREXIA OR DEHYDRATION

TRAUMA***

Classical signs

- Shorn nails, dirty haircoat, dyspnea, pale mucous membranes, weak pulses, lameness or inability to walk.
- Fractured mandible, broken canine teeth, scleral hemorrhages, neurologic signs (head trauma).

Clinical signs

Cats with generalized trauma may be **depressed and anorexic** for a number of reasons including shock, hypovolemia, dyspnea, pain from soft tissue contusions and fractures, herniations and concussion.

Pseudoanorexia may occur from fractures of the jaw and teeth and lacerations to the tongue.

Diagnosis

External signs of trauma are not always obvious. Although shorn nails are usually evident, this sign may be absent. For example, nails may not be shorn on ice following motor vehicle trauma in the winter. Subtle signs of trauma include dried blood around the external nares, blood against the tympanic membranes, bite wounds or lacerations to the ventral surface of the tongue, and pain on palpation of the pelvis of a cat with normal ambulation.

Differential diagnosis

Other causes of acute depression.

Treatment

Intravenous fluids and transfusions to treat hypovolemia.

Surgical and conservative management of injuries.

Injuries to the oral cavity may necessitate placement of an esophagostomy or gastrostomy tube for nutritional support.

FEVER***

Classical signs

- Depression, anorexia.
- Elevated body temperature.

See main reference on page 364 for details (The Pyrexia Cat).

Clinical signs

Febrile cats may be presented for acute depression and anorexia.

Other clinical signs will depend upon cause of fever.

Diagnosis

Fever must be **distinguished from hyperthermia** as a result of environmental stress, activity or anxiety.

To identify the cause of the fever see The Pyrexia Cat (page 364).

Differential diagnosis

Other causes of acute depression and anorexia with superimposed hyperthermia mimicking a febrile condition must be differentiated.

Treatment

Treatment of the underlying cause is of primary importance.

If antipyretic agents are not contraindicated, reducing the fever will usually improve the well-being and appetite of the cat. Dipyrone is the superior agent, but has been discontinued in some countries. Ketoprofen and meloxicam may be used at standard doses.

Hyperthermia is treated by placing the cat in a cool environment.

URETHRAL OBSTRUCTION***

Classical signs

- Straining to urinate (owner reports “constipation”).
- Progressive depression and anorexia.

See main reference on page 179 for details (The Cat Straining to Urinate).

Clinical signs

Straining to urinate, vocalizing, growling when handled, difficulty walking, vomiting.

Progressive depression and anorexia.

Pain on abdominal palpation and a turgid bladder are evident.

Whitish, chalky material may be seen blocking the urethral orifice or around the prepuce/perineal area and the cat may be excessively licking the area.

Progressive weakness and bradycardia may occur.

Diagnosis

Palpation of a turgid bladder is diagnostic. Rarely, spontaneous relief of obstruction occurs before examination.

Urinalysis typically reveals blood and struvite crystals.

Blood work reveals elevated urea, creatinine, potassium and phosphorus.

Differential diagnosis

If the owner has only noted non-specific signs, then most other causes of acute depression must be considered. The diagnosis is usually straightforward on the basis of physical examination.

Treatment

Intravenous fluids and correction of hyperkalemia (see Acute renal failure, below).

Urethral catheterization.

Management of urethral spasm, detrusor atony.

Dietary management.

GASTROINTESTINAL FOREIGN BODY AND INFLAMMATION***

Classical signs

- Vomiting and diarrhea.
- Anorexia and depression.

See main reference on page 636 for details (The Cat With Signs of Acute Vomiting), page 713 (The Cat With Signs of Acute Small Bowel Diarrhea), page 765 (The Cat With Signs of Large Bowel Diarrhea), page 792 (The Constipated or Straining Cat).

Clinical signs

Cats with acute gastritis, acute gastroenteritis or acute gastrointestinal foreign bodies typically have vomiting and diarrhea. However, these signs may be intermittent, so that only non-specific signs such as anorexia and depression are reported by the owners.

Variable more specific findings include **abdominal pain, vomiting following abdominal palpation, dilated loops of intestine** and an **intestinal mass**. A linear foreign body may be evident around the base of the tongue.

Diagnosis

If only non-specific signs are reported, **observation for vomiting and diarrhea** may be of value.

Rule out extra-intestinal causes of vomiting and diarrhea with routine laboratory work.

Diagnostic imaging is required to identify foreign material and intestinal obstruction.

Differential diagnosis

Pancreatitis.

Other causes of acute vomiting and diarrhea. See The Cat With Signs of Acute Vomiting (page 630) and The Cat With Signs of Acute Small Bowel Diarrhea (page 697).

Treatment

Treatment of the underlying cause.

Antiemetic agents will decrease nausea, and thereby reduce depression and anorexia.

DRUG THERAPY***

Classical signs

- Anorexia.

Clinical signs

Anorexia is a side effect of many drugs, including antibiotics, anti-thyroid medications and anti-cancer agents. Anorexia typically develops within the first week of therapy.

Vomiting and diarrhea are the most common concurrent signs.

Some drugs also cause oral irritation.

Diagnosis

Rule out other causes of anorexia.

Improved appetite upon withdrawal of the drug.

PAIN***

Classical signs

- Depression, anorexia and localizing sign of pain.

Clinical signs

Pain may contribute to the depression and anorexia seen in many disorders. Other signs of pain include vocalization (spontaneous and evoked by palpation), defensive aggression evoked by palpation, lameness, hunched posture (abdominal pain) and reluctance to move.

Diagnosis

A cat with acute depression and anorexia should be carefully examined for signs of pain, which may help identify a causative disorder.

ACUTE INTRANASAL, ORAL OR PHARYNGEAL INFLAMMATION

Classical signs

- Partial or complete anorexia and depression.
- Sneezing, nasal discharge.
- Stertor.
- Halitosis, ptyalism.

See main reference on page 5 for details (The Cat With Acute Sneezing or Nasal Discharge), page 32 (The Cat With Stridor).

Clinical signs

Cats with **foreign material** (e.g. **kitty litter, plant material**) in the nose or nasopharynx may be acutely depressed and refuse to eat. Typically there is an acute onset of sneezing or serous nasal discharge. Foreign material in the nasopharynx may result in stertorous respiration.

Cats with **acute viral rhinitis** may also be depressed and anorexic, but these cats usually have a fever. Anosmia may contribute to anorexia; so may concurrent oral inflammation with calicivirus infection. Conjunctivitis may be present.

Cats with oral and oropharyngeal foreign bodies (e.g. needle) will be acutely depressed and refuse to eat. More specific signs include halitosis, ptyalism, unusual jaw motions, gagging, pawing at the mouth and stertorous respiration.

Oral ulcers, acute anorexia and salivation may occur following **exposure to a corrosive substance**.

Uremic ulceration contributes to anorexia in cats with renal failure.

Diagnosis

Acute viral rhinitis is usually diagnosed on the basis of clinical findings.

Foreign material may be evident adhered to the external nares. The nasal cavity may be examined for foreign material by means of an otoscope, rigid endoscope or radiographically. The nasopharynx may be examined under anesthesia with a dental mirror or flexible endoscope.

Ulcers and foreign material in the oral cavity are usually obvious, except for those under the tongue. Anesthesia is often required for thorough evaluation of the tongue and oropharynx.

Differential diagnosis

Other causes of acute depression need to be ruled out.

Treatment

Foreign material should be removed by extraction or lavage.

Antibiotics (e.g. ampicillin or amoxicillin at standard doses) are indicated when secondary bacterial infection is evident with viral, foreign body, corrosive or uremic ulceration.

BACTERIAL SEPSIS**

Classical signs

- Acute anorexia and depression.
- Fever and localizing signs of infection.
- Hypothermia and bradycardia with severe sepsis.

See main reference on page 112 for details (The Fading Kitten and Neonate).

Clinical signs

Cats with a bacterial infection usually have a **fever and localizing signs of infection**, in addition to depression and anorexia.

- Sepsis is defined as presence of a systemic inflammatory response syndrome (SIRS) due to a disseminated bacterial infection. Signs of SIRS include high fever or hypothermia; tachycardia or bradycardia; polypnea; and moderate to marked neutrophilia, neutropenia or left shift.
- Severe sepsis is defined as sepsis accompanied by organ dysfunction, hypoperfusion or hypotension.
- Septic shock is defined as severe sepsis with hypotension that is refractory to adequate fluid resuscitation.

Febrile responses may be blunted in older cats, and the severity of infection may be underestimated based on the magnitude of the fever.

In some cases fever is absent, and this should not be used to rule out bacterial infection. Septic cats without a fever are more likely to have severe sepsis and impending septic shock.

In some cats, the **localizing signs of infection are not readily detectable** on physical examination. This most often occurs when there is **primary neutropenia and secondary infection**.

- Severe sepsis or septic shock should always be considered in the differential diagnoses of cats with acute depression and anorexia without more specific signs.
- Other common signs of severe sepsis are bradycardia, pale mucous membranes, weak pulses, polypnea, diffuse abdominal pain and icterus.

Diagnosis

A complete blood count may reveal **neutrophilia** and a **left shift**. Alternatively, neutropenia may be present from primary bone marrow failure (e.g. FeLV infection) or exhaustion of marrow granulocyte reserve.

Meticulous physical examination, serum chemistries, diagnostic imaging and fine-needle aspiration will help localize the infection (e.g. deep subcutaneous abscess, pyometra, pyelonephritis, peritonitis, pyothorax, pneumonia).

Differential diagnosis

In the absence of a fever and localizing signs, all other causes of acute depression and anorexia should be considered.

Treatment

Treatment is supportive pending a diagnosis.

Systemic antibiotic therapy and **local treatment** of infection if indicated (e.g. drainage of abscess).

Empirical therapy with **broad-spectrum, bactericidal antibiotics** (e.g. cefazolin plus gentamicin, ceftiofur) should be started at standard doses in depressed neutropenic cats.

ACUTE ANEMIA**

Classical signs

- Pale mucous membranes.
- Acute onset of anorexia, depression and physical inactivity.

See main reference on page 526 for details (The Anemic Cat).

Clinical signs

The degree of depression, anorexia and dehydration correlates with the severity and acuteness of the anemia.

Tachypnea and tachycardia may be evident.

Pale mucous membranes with or without splenomegaly or icterus.

If the anemia is due to infectious causes, e.g. *Mycoplasma haemofelis* (*Haemobartonella felis*), the cat may be pyrexemic.

Diagnosis

Routine hematology will confirm anemia.

The cause of the anemia can usually be determined by routine work-up (see The Anemic Cat).

Differential diagnosis

Pale mucous membranes due to shock.

Treatment

Treat the cause of anemia; transfusion. See The Anemic Cat.

SEPARATION OR SITUATION ANXIETY**

Classical signs

- Withdrawal or hiding and/or anorexia.

Pathogenesis

Removal of significant persons, or other pets from the cat's environment, or removal of the cat from **familiar surroundings** may **trigger separation or situation anxiety**.

Introduction **to new persons, pets or surroundings** may also trigger anxiety.

The cat's personality is an important risk factor.

Separation/situation anxiety **may exacerbate secondary anorexia** and depression in a hospitalized cat.

Clinical signs

Variable withdrawal, inactivity, anorexia and dehydration.

Other behavioral signs may occur, such as aggression to other pets or persons, and inappropriate elimination.

No signs of another disorder causing depression and anorexia.

Weight loss is dependent on degree and duration of anorexia. Complete anorexia will result in detectable lumbar muscle wasting within one week.

Diagnosis

History of change in environment.

Ruling-out other causes of depression and anorexia.

Differential diagnosis

Other causes of depression and anorexia.

Treatment

No treatment is necessary if signs are mild and it is likely that the cat will adapt.

Return cat to previous environment if possible.

Offer a variety of foods, warm the food, increase palatability of food with clam juice, or canned tuna or salmon juice.

Anxiolytic and/or appetite-stimulant drugs or herbal remedies may be useful if anorexia or anxiety cannot be quickly resolved. **Tricyclic antidepressants** (amitripty-

line, clomipramine) or **selective serotonin re-uptake inhibitors**, together with environmental changes may be effective (see The Cat With Anxiety-Related Behavior Problems, page 1014, for doses). Other treatments that have been used (but some may have undesirable side effects) include hydroxyzine, phenobarbital, megestrol acetate, prednisone, diazepam, oxazepam, cyproheptadine at standard doses and catnip. Dependency can develop with some treatments.

Nasoesophageal, esophagostomy or gastrostomy tube feeding or parenteral nutrition should be instituted for hospitalized cats if anorexia persists for more than 3 days.

Prognosis

The ability of the cat to adapt is dependent upon personality.

Hepatic lipidosis may complicate primary anorexia, especially in an obese cat anorexic for more than two weeks.

ACUTE HYPOKALEMIA**

Classical signs

- Ventroflexion of the neck
- Stilted forelimb gait.

Pathogenesis

Hypokalemia results from **insufficient potassium intake** and/or **excessive urinary or gastrointestinal potassium loss** and/or **translocation** from extracellular to intracellular fluid.

Hypokalemia may be seen in **numerous disorders** including chronic renal failure, post-obstructive diuresis, intravenous fluid therapy with potassium-poor fluids, furosemide therapy, vomiting, hyperaldosteronism (rare) and the treatment of diabetic ketoacidosis. Anorexia may contribute to hypokalemia, which in turn may exacerbate anorexia and depression.

Clinical signs

Lethargy, muscle weakness, anorexia – increasing risk with decreasing potassium level.

Ventroflexion of the neck and stilted forelimb gait. Severe muscle weakness may lead to respiratory muscle failure (rare).

Polyuria and polydipsia – this is usually due to the underlying disorder, but hypokalemia may impair concentrating ability (hypokalemic nephropathy).

Arrhythmias – increasing risk with decreasing potassium level.

Diagnosis

Serum potassium level < 3.5 mmol/L.

Ruling-out other causes of depression, weakness and anorexia.

Differential diagnosis

Other causes of depression, weakness and anorexia related to the primary disorder.

Other causes of cervical ventroflexion include thiamine deficiency and other causes of muscle weakness (including motor neuron disease and myasthenia gravis, which do not cause anorexia).

Treatment

Potassium-rich intravenous fluids. See Diabetic ketoacidosis in The Cat With Polyuria and Polydipsia.

Cats with mild hypokalemia (3.0–3.5 mmol/L) may be treated as outpatients with **potassium gluconate**, 1.0–3.0 mEq/kg/day q 8 h, followed by a maintenance dose of 1.0 mEq/kg/day q 12 h once serum potassium has normalized.

Prognosis

The prognosis for correction of hypokalemia is good and overall prognosis is determined by the underlying disorder.

PANLEUKOPENIA**

Classical signs

- Acute depression, anorexia, dehydration, and fever in kittens or unvaccinated cats.
- Vomiting usually precedes diarrhea.

See main reference on page 650 for details (The Cat With Signs of Acute Vomiting).

Clinical signs

Most common in cats 2–6 months of age.

Typically, there is acute onset of depression and anorexia. Vomiting then appears, followed by the onset of fetid and often bloody diarrhea in 1–2 days. Cats may stand hunched-up, sometimes with the face over a water bowl, but refuse to drink. Dehydration develops with vomiting and diarrhea.

Pain is often evident on abdominal palpation, and loops of intestine may be thickened and contain excess gas and fluid.

Affected kittens are initially **febrile**, but if signs are severe, this progresses rapidly to **hypothermia**. Coma and death usually follow in a few hours.

Diagnosis

Diagnosis is usually suspected when there are consistent clinical signs in a kitten or cat with no history of vaccination.

Complete blood count reveals severe neutropenia and lymphopenia. Fecal tests for parvovirus antigen are sometimes useful.

Differential diagnosis

No other disease mimics classic severe panleukopenia, and this should be the first differential diagnosis in any unvaccinated kitten presented for acute depression.

Many other diseases mimic mild panleukopenia clinically. However, leukopenia is usually present, even in mild cases, which supports the diagnosis.

Treatment

Intravenous fluids and bactericidal antibiotics (e.g. ampicillin plus gentamicin, ceftiofur) at standard doses are required.

PANCREATITIS*

Classical signs

- Acute depression and anorexia.

Pathogenesis

Pancreatitis is typically **classified based on post-mortem pancreatic histopathology**. Classification schemes vary in different reports, but in general the degree of fibrosis and mononuclear cell infiltration correlates with chronicity.

- **Acute pancreatitis is characterized** by variable neutrophil infiltration, edema, hemorrhage, acinar necrosis and peripancreatic fat necrosis, inflammation (steatitis) and saponification. In one series of 40 cats, acute pancreatitis was categorized as necrotizing pancreatitis (some with fibrosis) and suppurative pancreatitis.
- Both acute and chronic pancreatitis can be severe and no clinical, laboratory or diagnostic imaging finding reliably distinguishes the two.

Pancreatitis may occur with or without concurrent disorders. In the absence of a concurrent condition, a specific cause is usually not identified.

- Identified causes of acute pancreatitis include pancreatic neoplasia, hypothermia, virulent systemic feline calicivirus strains, ascending bacterial infection, toxoplasmosis, abdominal trauma and organophosphate intoxication. Ingestion of a high-fat meal is not a cause, unlike in dogs. Pancreatic flukes (*Eurytrema procyonis*) and liver flukes (*Amphimerus pseudofelineus*) have been associated with chronic, but not acute, pancreatitis. The cat has been used extensively as an experimental model of acute pancreatitis, but the methods of inducing pancreatic inflammation have little relevance to the etiology of naturally occurring disease.
- **Associated disorders** include hepatic lipidosis, cholangiohepatitis, inflammatory bowel disease, diabetes mellitus, diabetic ketoacidosis and acute renal failure. Cause and effect between these conditions and pancreatitis is not known, but the disorders are probably related. Other concurrent disorders include chronic renal diseases and neoplasia, which may be related to age rather than pancreatitis. If a concurrent disorder is not identified, pancreatitis is more likely to be acute based on histopathology.
- Obesity is not an independent risk factor, but is a risk factor for conditions associated with pancreatitis, such as hepatic lipidosis and diabetes mellitus. Cats with pancreatitis may be thin, but it is not clear if this is a risk factor or consequence of anorexia.

The **pathogenesis** of acute pancreatitis is believed to be similar to that in other species:

- **Premature zymogen activation occurs** within the pancreas leading to local inflammation, circulating pancreatic enzymes, and systemic inflammatory response syndrome (SIRS). **Potential sequelae include** hypotension, disseminated intravascular coagulation (DIC), pulmonary edema, pleural effusion, pulmonary thromboembolism, encephalopathy, systemic lipodystrophy, acute renal failure and multi-organ failure.
- Neither bacterial infection of the inflamed pancreas nor bacteremia appears to be common in naturally occurring pancreatitis.

Clinical signs

Cat may be of **any age, with no sex or breed predilection**, except perhaps for Siamese cats.

Duration of clinical signs prior to presentation varies from **several days to more than 3 weeks**. Both acute and chronic pancreatitis may present with acute signs, but cats presenting with a longer clinical history are more likely to have pancreatic fibrosis.

Clinical findings are often more subtle than expected for the degree of pancreatic injury. This may explain in part the delay in presentation to a veterinarian.

Depression and/or anorexia are the most common historical signs and may be the only signs present. The **most common physical abnormalities are dehydration and hypothermia** (68% in one study). Fever is uncommon.

Other inconsistent signs include weight loss, vomiting, diarrhea, cranial abdominal pain, cranial abdominal mass, abdominal distention due to ascites, dyspnea, ataxia and disorientation and shock. Polydipsia may be present, but is usually due to concurrent diabetes mellitus. Systemic lipodystrophy is a rare complication of acute pancreatitis, characterized by subcutaneous nodules that may ulcerate.

Diagnosis

Because clinical and laboratory findings are non-specific, diagnosis requires a high index of suspicion.

Pancreatitis should be considered in any cat with unexplained acute depression. Acute pancreatitis

should also be considered in any critically ill cat developing pleural effusion, ascites or hypothermia.

Laboratory findings are variable and are most valuable in ruling out other causes of depression and anorexia.

Hematology abnormalities include:

- Mild non-regenerative anemia.
- Neutrophilia, with or without a left shift (inflammatory leukogram).
- Neutropenia.
- Lymphopenia (stress leukogram).
- Thrombocytopenia (consumption).

Serum biochemistry abnormalities include elevations in liver enzymes (with a tendency to be higher in chronic pancreatitis), bilirubin, cholesterol, urea and creatinine, and decreases in potassium, calcium and albumin. Lower concentrations of ionized calcium have been associated with a poor prognosis in acute pancreatitis. Low serum cobalamin levels may be present.

Blood glucose concentration may be increased, normal or low. Mild coagulation abnormalities may be present.

- Serum **amylase and lipase** levels are infrequently elevated in naturally occurring pancreatitis (poor sensitivity).
 - Serum amylase levels may be elevated by **dehydration**, and **amylase and lipase levels may be elevated by renal failure**. An elevated lipase level in the presence of normal renal function is probably highly specific for pancreatitis.
 - There may be a greater likelihood of detecting an elevated lipase level if measured immediately after the onset of clinical signs.
 - In one model of experimental pancreatitis, amylase levels actually decreased from baseline values during the first week of illness.
 - Decreased lipase level usually rules out pancreatitis in the dog; it is not known if this is also true for the cat.
 - The utility of measuring amylase and lipase in peritoneal effusion has not been evaluated in clinical cases.
- A more useful laboratory test is **feline trypsin-like immunoreactivity (fTLI)**.
 - **fTLI is a more sensitive test** than amylase or lipase for pancreatitis, but a normal value does not rule out pancreatitis.

- Elevated fTLI is not specific for pancreatitis. Elevations may also be seen in inflammatory bowel disease, intestinal lymphoma and renal failure.

- fTLI is not as widely available as other laboratory tests, and delays in reporting reduce its utility.

- The measurement of trypsinogen activation peptide may be useful in the future.
- **Feline pancreatic lipase immunoreactivity (fPLI)** appears to be a very sensitive test for acute pancreatitis, but is currently not widely available.
- Abdominal fluid is usually a modified transudate but may be a non-septic exudate. Pleural fluid is usually a modified transudate.

Diagnostic imaging findings are also variable.

Abdominal **radiography** is most useful in ruling out other causes of vomiting.

- Radiographic findings are often normal and do not rule out pancreatitis.
- If abnormalities are present, they are similar to those of acute pancreatitis in dogs: **decreased cranial abdominal contrast** (due to effusion), a mass effect (displacement of organs) in the right cranial quadrant due to the swollen pancreas, and **localized dilation of loops of intestine** (due to ileus).

Abdominal **ultrasonography** is more useful than radiography. Ideally high-resolution equipment should be used. (Abdominal ultrasonography, fTLI and fPLI are the best non-invasive tests for pancreatitis.)

- Normal findings do not rule out pancreatitis (reported sensitivity is 11–80%).
- **Abnormalities with a high specificity for pancreatitis** include pancreatic regular or irregular enlargement, pancreatic hypoechogenicity, hyperechogenicity of peripancreatic fat (may be difficult to appreciate), dilation of the pancreatic duct in the left lobe and accumulation of peritoneal fluid around the pancreas. Less specific changes include dilated common bile duct and gall bladder, cranial abdominal mass effect, generalized peritoneal effusion and mesenteric lymphadenopathy. If a pancreatic mass is identified, it is most likely a neoplasm, followed by a pseudocyst. Pancreatic abscesses are rare. Hepatic parenchymal and gastrointestinal changes may also be present because of associated conditions.

- CT-scanning has low sensitivity. The diagnostic utility of magnetic resonance imaging is not known. Some cases have had no changes.

Thoracic radiographs should be obtained in dyspneic cats to rule out pleural effusion, which may be caused by pancreatitis. Dyspnea may rarely be due to pulmonary thromboembolism.

Definitive ante-mortem diagnosis requires **biopsy** obtained by exploratory laparotomy or laparoscopy. The pancreas may appear grossly normal (or show only nodular hyperplasia in the older cat).

A cat with pancreatitis may be a poor anesthetic risk. Acute exacerbation of pancreatitis occasionally occurs following biopsy.

Inflammation may be irregularly distributed in dogs and multiple biopsies are recommended; the situation may be the same in cats.

Ultrasound-guided fine-needle aspiration may be used to biopsy pancreatic masses. Amylase and lipase should be measured in cystic fluid – levels above serum levels support a diagnosis of pseudocyst; levels equivalent to serum levels do not rule out a pseudocyst.

Differential diagnosis

Acute anemia.

- Some cats with acute pancreatitis will have **pale mucous membranes** from shock. Routine haematology will confirm severe anemia. Anemia is usually only mild in pancreatitis.

Urethral obstruction.

- A **painful turgid bladder** is palpable. Rarely the obstruction has spontaneously resolved by the time the cat is presented for examination. In the latter case, diagnosis is established by history, prepuccial crystal deposits, urinalysis and azotemia.

Acute renal failure.

- Both acute renal failure and pancreatitis may cause depression, anorexia, dehydration, vomiting, azotemia and reduced urine production. In acute renal failure urine will be isosthenuric to minimally concentrated, while in acute pancreatitis urine should be well-concentrated, unless there is pre-existing chronic renal failure. Azotemia is more

severe in acute renal failure and will not normalize with rehydration. Acute renal failure may be a complication of acute pancreatitis.

Liver disease.

- Elevations in liver enzymes, bilirubin and cholesterol may characterize both pancreatitis and liver diseases. Furthermore, hepatic lipidosis and cholangiohepatitis are common concurrent disorders with acute pancreatitis. It is often difficult to establish if one disorder preceded the other, and to establish if one is more responsible for clinical signs. Moderate to marked liver enzyme elevations are suggestive of primary hepatic disease, and a disproportionate elevation of ALP compared to ALT and GGT is suggestive of hepatic lipidosis. Elevations in serum bile acids in the absence of cholestasis confirm the presence of hepatocellular dysfunction. Elevated plasma ammonia levels are diagnostic for hepatic encephalopathy. Marked coagulation abnormalities are suggestive of liver disease. Abdominal ultrasound examination of cats with liver disease is recommended in an effort to detect pancreatitis. If laparotomy is performed to obtain a liver biopsy, then a pancreatic biopsy should also be obtained, and vice versa.

Diabetic ketoacidosis (DKA).

- Confirmation of DKA requires demonstration of **hyperglycemia, ketonuria or ketonemia, and acidosis**. DKA may be confused with pancreatitis because urine test strips measure oxaloacetate or acetone, which may be produced in minimal quantities by cats, and cats with pancreatitis may be hyperglycemic. Several drops of hydrogen peroxide may be added to the urine sample in an effort to convert β -hydroxybutyrate to oxaloacetate to increase the concentration of oxaloacetate in urine. Alternatively, β -hydroxybutyrate may be measured in serum using a point-of-care test, or the urine test strip may be used to detect oxaloacetate in heparinized plasma. Using a standard urine test strip, a **negative plasma test rules out ketosis**, and a **positive urine test rules in ketosis**, in cats. It should be remembered that acute pancreatitis and DKA may occur concurrently. Acute pancreatitis, DKA and hypoglycemia should always be considered in an acutely depressed diabetic cat.

Hypoglycemia.

- Cats with acute pancreatitis may be hypoglycemic, but it is not known if this contributes to depression. Clinical hypoglycemia usually results from **insulin overdose**. This is confirmed by measuring blood glucose levels and by prompt resolution of clinical signs following intravenous dextrose or intramuscular glucagon. Portable glucose meters have a tendency to measure falsely low values, so a diagnosis of hypoglycemia should be reconsidered if the cat does not respond to intravenous glucose or glucagon. Lack of response to sugar solutions rubbed on the gums or given by stomach tube does not rule out hypoglycemia, because most absorption of glucose occurs in the small intestine.

Acute gastritis/gastroenteritis.

- This is a differential diagnosis for cats with pancreatitis that are **vomiting**. Indeed, some cases diagnosed with acute gastritis probably have acute pancreatitis. If signs are mild, then distinguishing the two diseases is not important, because both are similarly treated (short-term withholding of food and fluid therapy). The most useful test for distinguishing the two is abdominal ultrasound examination. Abdominal radiography will help rule out foreign material and obstruction as a cause of acute vomiting.

Acute heart failure.

- Potential **overlapping signs** of acute heart failure and pancreatitis include pale mucus membranes, hypothermia, weak pulses, tachycardia, bradycardia, dyspnea and vomiting. Clinical findings of a heart murmur, irregular heart rate, and pulmonary crackles, and radiographic findings of pulmonary edema and cardiomegaly help establish the diagnosis of heart failure. (Note that both heart failure and pancreatitis may be associated with pleural effusion.) Definitive diagnosis of cardiomyopathy requires echocardiography.

Panleukopenia.

- Severe panleukopenia usually affects **immature cats** while pancreatitis usually affects mature cats. A complete blood count will usually reveal severe **neutropenia**. **Depression and vomiting** are early signs. **Marked diarrhea** typically develops later, but may not be evident at the time of presentation.

Severe sepsis without an externally obvious source of infection.

- Septic cats may not have a **fever**. Meticulous physical examination, serum, chemistries, diagnostic imaging and fine-needle aspiration will help localize the infection (e.g. deep subcutaneous abscess, pyometra, pyelonephritis, peritonitis, pyothorax, pneumonia).

Toxoplasmosis.

- Acute systemic toxoplasmosis typically **affects kittens or immunosuppressed cats**, causes a fever, and uveitis is a common finding. Confirmation is by measuring serum IgM antibodies or demonstrating rising serum IgG antibodies.

Ethylene glycol poisoning.

- The diagnosis of acute poisoning relies on history of ingestion or a high index of suspicion. Both cats with pancreatitis and cats with acute ethylene glycol poisoning may have acute depression without other signs, but cats with acute ethylene glycol poisoning should be **isosthenuric**, while cats with pancreatitis should have well-concentrated urine, unless there is a concurrent disorder causing dilute urine, such as chronic renal failure. Metabolic acidosis, increased anion gap and increased osmolal gap will be more severe than in pancreatitis. Definitive diagnosis relies on measuring ethylene glycol in serum or urine or seeing **oxalate crystals in urine or in a kidney biopsy**.
- In the later stage of poisoning (renal failure), kidneys may be firm and painful on palpation, and the bladder is usually small because of anuria. The elevations in urea and creatinine will be marked.

Lily poisoning.

- The diagnosis of acute poisoning relies on history of ingestion or a high index of suspicion. Cats in the acute stage of lily poisoning should have **poorly concentrated urine**, while cats with pancreatitis should have well-concentrated urine, unless there is a concurrent disorder causing dilute urine, such as chronic renal failure.
- In the later stage of poisoning (renal failure), kidneys may be firm and painful on palpation, and the bladder is usually small because of anuria. The elevations in urea and creatinine will be marked.

Acetaminophen (paracetamol) poisoning.

- Probing for a history of ingestion, and careful observation for appearance of **brown mucous membranes**, and **facial and paw edema**, will establish the diagnosis.

Anticoagulant rodenticide poisoning.

- A careful search for **subcutaneous or internal bleeding** will help establish that a bleeding disorder is present. Clotting times are likely to be normal to minimally elevated in acute pancreatitis, and markedly prolonged in rodenticide poisoning. Note that markedly prolonged clotting times and vitamin K deficiency have been recognized in chronic pancreatitis.

Snake bite envenomation.

- A high index of suspicion should be maintained for cats at risk because of geographical location and season. For North American snakes with cytotoxins, a thorough physical examination should reveal a **bite wound**; there may be associated tissue necrosis. For Australian snakes, acute onset of weakness and depression are early findings. Dilated pupils with slow or absent papillary light reflexes, ataxia and elevated creatine kinase concentration or evidence of a bleeding tendency are frequent findings. Paresis may progress to flaccid paralysis.

Trauma.

- Subtle **external signs of trauma** include car grease on the fur, shorn nails, dried blood around the external nares, blood seen on otoscopic examination, small scleral hemorrhages and lacerations on the ventral surface of the tongue.

The above differential diagnoses are applicable to cats with acute onset of signs. Other than liver diseases, most of the above differential diagnoses will not be applicable to cats with pancreatitis with a longer duration of clinical signs and weight loss. For cats with **pancreatitis and subacute or chronic signs**, the **primary differential diagnoses are neoplasia, chronic renal failure, and inflammatory bowel disease**. Concurrent diabetes mellitus may confuse the clinical picture. See The Thin, Inappetent Cat (page 355).

Treatment

Address the inciting cause if one is identified.

The remainder of therapy is largely **supportive**.

Fluid therapy to correct dehydration and hypotension.

- If crystalloid solutions are insufficient, or pulmonary or peripheral edema is present, colloid solutions should be considered (e.g. plasma, dextrans, hetastarch, pentastarch).

Nutritional support.

- The optimal approach is not known. The tendency to withhold food based on treatment of acute pancreatitis in dogs is tempered by the overlap between acute and chronic pancreatitis in cats, the presence and risk of hepatic lipidosis in cats, the observation that most cats are not vomiting, and the observation that feeding does not appear to aggravate pancreatitis in cats.
- **Cats that are willing to eat should be fed.** Food should be withheld for 2–3 days for cats that are vomiting. For anorexic cats that are not vomiting, an appetite stimulant may also be considered – these include cyploheptidine (may cause unusual behavior), intravenous diazepam and oral oxazepam at standard doses.
- **Parenteral nutrition** may be used if available, especially for cats that are vomiting.
- If exploratory laparotomy is used to make a diagnosis, **a jejunal feeding tube should be placed**. This is best placed as a jejunostomy tube. Transpyloric tubes may also be used, either threaded through a gastrostomy tube, or as a nasojejunosomy tube, but preliminary experience is that such tubes tend to back out into the stomach.
- If laparotomy is not performed, **a gastrostomy or esophagostomy tube** may be placed once the cat has stopped vomiting. Endoscopic placement of a transpyloric tube is difficult.
- If it is desired to avoid anesthesia, a nasoesophageal tube should be used.
- The optimal diet is not known. Low-protein, low-fat and high-carbohydrate diets are recommended for dogs, but may not be appropriate for cats, especially if there is concurrent diabetes mellitus, and may not be sufficiently calorie-dense. Another problem is that the fat content on an energy basis is not provided for many foods. A food with a moderate fat content is a reasonable initial choice, which includes most commercial cat foods.

- **Supplemental B vitamins** should be considered. Specifically, cobalamin treatment should be given (0.5–1 mg SC q 2–3 weeks) if serum level is low.
- **Antiemetics.** Metoclopramide, ondansetron, prochlorperazine and chlorpromazine given at standard doses may be used to control vomiting. The latter two should not be given if the cat is hypotensive.
- **Analgesics.** Although many cats do not show evidence of abdominal pain, it is likely present, and may contribute to depression. Opioid analgesics should be considered at standard doses.
- **Antibiotics** are not indicated in most cases. Antibiotics are recommended if there is a marked inflammatory leukogram or fever (blood culture is recommended), or evidence of pancreatic infection on biopsy (pancreatic and liver biopsies should be cultured). Empirical choices include ampicillin, cefazolin and cefoxitin at standard doses.
- **Corticosteroids** should only be used if needed to treat a concurrent disorder (e.g. inflammatory bowel disease). They may be considered if the cat is presented in shock, but the value of such therapy has been overstated.
- **Fresh-frozen plasma** (10–20 ml/kg) has been advocated in acute pancreatitis to replenish coagulation factors and anti-thrombin III consumed in DIC, and to replenish α -macroglobulins, which are involved in clearing pancreatic enzymes from the circulation. There is no evidence of a beneficial effect in humans, and there are too few reports in dogs or cats to make an assessment. Transfusions are expensive, and any benefit is probably as a colloid solution. (It should be noted that **α -macroglobulins and anti-thrombin III are stable in regular plasma**. The main difference in regular plasma and fresh-frozen plasma are the concentrations of factor VIII and von Willebrand's factor. Fresh-frozen plasma is potentially more beneficial in DIC only if the aPTT is prolonged.)
- **Dopamine** 5 μ g/kg/min as a constant rate infusion is beneficial in experimental acute pancreatitis when given within the first 12 hours of injury, but not after that time. Most cats with naturally occurring disease are presented after 12 hours, and it is unknown if there is any benefit.
- **Vitamin K** – see The Bleeding Cat (page 499).

Surgical debridement of grossly necrotic tissue and abdominal lavage may be performed if a diagnostic

laparotomy reveals abnormal pancreatic tissue. For cats with a non-surgical presumptive diagnosis of pancreatitis, similar to dogs, **surgery should be considered if the cat is not improving with conservative management**, if there are worsening pancreatic changes on ultrasound examination, or if peritoneal effusion is an exudate, but there are no firm guidelines. Closed therapeutic abdominal lavage may also be considered if peritoneal effusion is an exudate. Therapeutic abdominocentesis should be considered if there is large-volume ascites, and it should definitely be performed if there is a problem secondary to a volume effect (e.g. dyspnea from diaphragmatic compression), but the benefit of the procedure on the course of the disease is not known.

Prognosis

The true prognosis is not known because of under-diagnosis, mortality due to concurrent disorders, and euthanasia because of the prevailing attitude that feline pancreatitis carries a poor prognosis. **Prognosis is related to the severity of the pancreatitis.**

Cats with mild acute pancreatitis probably have a good prognosis, while cats with severe pancreatitis and an associated disorder have a poor prognosis. Chronic pancreatitis may be subclinical.

In one series of 13 cats with acute pancreatitis and hepatic lipidosis, recovery rate was 20%, versus 50% for cats with hepatic lipidosis alone. In another series of 40 cats with severe acute pancreatitis, all cats died or were euthanized. Successful management of acute pancreatitis has been anecdotally reported and reported in individual case reports and small case series.

ACUTE RENAL FAILURE*

Classical signs

- Progressive depression and anorexia.
- Vomiting.
- Polyuria, oliguria or anuria.

Pathogenesis

Acute renal failure is a syndrome characterized by an abrupt reduction in glomerular filtration rate and result-

ant dysregulation of water, acid–base and electrolyte balance, and accumulation of uremic toxins. Acute renal failure may be non-oliguric (polyuric), oliguric or anuric.

- **Oliguria** is defined as $< 0.27 \text{ ml/kg/h}$, and **anuria** $< 0.08 \text{ ml/kg/h}$ and these definitions may be used as guidelines for cats.

The **central pathophysiological event** in acute renal failure is **acute tubular necrosis**. This is initiated by **altered hemodynamics** (ischemia), **nephrotoxins** or **miscellaneous primary renal diseases**. In some cases more than one mechanism is involved.

- **Ischemia may be caused by hypotension** (e.g. prolonged anesthesia, shock), **thromboembolism** (e.g. cardiomyopathy), or **acute hydronephrosis** (e.g. prolonged urethral obstruction).
 - **Hemodynamically mediated** acute renal failure may be caused by the same factors that cause pre-renal azotemia, but the reduced perfusion of the kidney is so profound that it leads to acute tubular necrosis.
- **Nephrotoxins** include ethylene glycol and lilies; mercury, lead and other heavy metals; aminoglycoside antibiotics and amphotericin B; NSAIDs, and cholecalciferol (vitamin D₃) rodenticides. The mechanism of NSAID nephrotoxicity is ischemia from vasoconstriction. The chemotherapeutic agents doxorubicin, epirubicin and carboplatin are also nephrotoxic, although the clinical importance of this appears to be low.
- **Primary renal diseases** do not commonly cause acute renal failure in the cat. Glomerulonephritis, amyloidosis, feline infectious peritonitis, bacterial pyelonephritis and bilateral renal lymphoma may cause renal failure with a more acute clinical course than typical chronic renal failure due to age-related chronic tubulointerstitial disease, but true acute renal failure is rare. It is most likely to occur with acute bacterial pyelonephritis. Acute exacerbation of chronic renal failure (“acute on chronic renal failure”) may also occur; the mechanism in most cases is probably ischemia.

Acute oliguric renal failure is classically **divided into initiation, oliguric, polyuric and recovery stages**.

The **oliguric stage** is maintained by various factors, including:

- Arteriolar vasoconstriction.

- Intratubular obstruction from desquamated tubular epithelial cells.
- Tubular backleak, where filtrate leaks across the injured tubular epithelium and is thus shunted directly to the peritubular capillaries.
- Reduced glomerular permeability.

Clinical signs

The salient historical findings are **acute depression and anorexia**, which are progressive in nature. Most cats will **vomit**; diarrhea may also occur.

Physical examination findings are variable. **Hypothermia** typically develops within 24–48 hours of the development of oliguria or anuria. **Bradycardia** may be present.

- Body condition is normal in a cat without pre-existing chronic renal failure or other disorder-promoting weight loss.
- **Renal size is normal to large** in a cat without pre-existing renal disease, and kidneys may be painful on palpation. Kidneys are likely to be small in cats with chronic renal failure. Kidneys may also be enlarged in FIP, lymphoma, polycystic kidney disease, chronic hydronephrosis and amyloidosis, but are not painful. It should be noted that hydration status and the quantity of peri-renal fat affects renal size on palpation. Kidneys may feel larger upon rehydration.
- **The bladder is small with oliguria and anuria**, may be large with polyuria, and is large and turgid with urethral obstruction. Owners should be queried as to when the cat was last seen to urinate.
- Halitosis and oral ulceration and dehydration are common findings.

Diagnosis

The diagnosis of acute renal failure is based on:

- **Acute onset** of clinical signs.
- **Elevated serum urea, creatinine and phosphorus levels**.
- Increased (**polyuria**), or reduced (**oliguria/anuria**) production of **inappropriately concentrated urine**.
 - In cats with pre-renal azotemia, urine specific gravity should be > 1.035 unless there is another mechanism present for reducing specific gravity

(e.g. therapy with a diuretic). In **acute renal failure, urine is usually isosthenuric or minimally concentrated**. Some cats with chronic renal failure maintain adequate urine concentrating ability, but this does not appear to happen in acute renal failure.

- If urine specific gravity was not measured prior to initiating fluid therapy, monitoring serum biochemistry abnormalities will help in distinguishing pre-renal from renal azotemia. If azotemia is **pre-renal** in origin, it **will normalize within 24–48 hours upon rehydration** and/or correction of hypotension, whereas renal azotemia will remain elevated during this period (although it may improve).
- In animals with pre-renal azotemia, urine production will increase as the animal becomes rehydrated and/or hypotension is corrected. The volume of urine produced and time to do so will depend on the rate of fluids. Because these animals are usually acutely dehydrated, rehydration is typically performed quickly, so within a few hours urine production is expected. A method **to rapidly detect oliguria or anuria** is to **give a 10 ml/kg bolus of intravenous fluids over 10 minutes**. This should cause sufficient volume expansion and increase in blood pressure to initiate urine production within 10–30 minutes. If there is no urine produced after 30 minutes, another fluid bolus may be considered. **If there is no urine production after two fluid boluses**, then it is likely that **intrinsic oliguric renal failure** is present. Ideally blood pressure should be measured to confirm that reduced urine production is not due to persistent hypotension that is still causing pre-renal azotemia. A normotensive cat receiving maintenance fluid therapy should produce urine at **0.5–2 ml/kg/h**.
- The diagnosis of acute oliguric/anuric renal failure is usually straightforward. Acute non-oliguric renal failure is more difficult to distinguish from subacute chronic renal failure and acute-on-chronic renal failure.

A hemogram typically reveals **hemoconcentration** and a **stress leukogram**. Cats with **acute-on-chronic renal failure may have anemia**, and this finding is highly suggestive of pre-existing chronic renal failure. The anemia may not be evident until the cat is rehydrated.

Other variable serum biochemistry abnormalities include hyperglycemia, hyperkalemia, hyponatremia, hypocalcemia and decreased bicarbonate (total CO_2).

Other variable urinalysis findings include glucosuria, proteinuria, tubular casts, crystaluria, pyuria and bacteruria.

Diagnostic imaging of the kidneys, urinalysis, urine culture and kidney biopsy may be needed to rule in and rule out causes of renal failure. See Ethylene glycol poisoning and Lily poisoning, below.

- **Renal biopsy** may also help determine the **severity and reversibility of the injury**, but there is poor correlation between histopathologic findings and renal function.

Differential diagnosis

Pre-renal azotemia and reduced urine production.

Causes of acute depression, anorexia, dehydration and vomiting may cause pre-renal azotemia and reduced urine production. These causes include acute gastritis, gastroenteritis and **pancreatitis**. In acute renal failure, urine will be isosthenuric to minimally concentrated, while in the other disorders urine should be well-concentrated, unless there is pre-existing chronic renal failure. Azotemia is more severe in acute renal failure and will not normalize with rehydration. Acute renal failure may be a complication of a primary disorder, due to the progression from pre-renal to renal azotemia.

Pre-renal azotemia and increased urine production.

- Both acute renal failure and **diabetic ketoacidosis** may cause acute depression, polyuria, vomiting, dehydration, hyperglycemia and glucosuria, and both may be preceded by a history of chronic polyuria and polydipsia (due to chronic renal failure and diabetes mellitus, respectively). Diabetic ketoacidosis is confirmed by detecting ketones in the blood or urine. Acute renal failure is also an uncommon complication of diabetic ketoacidosis. Cats with diabetic ketoacidosis may have concurrent chronic renal failure.
- Other disorders that cause polyuria and polydipsia in the cat include hyperthyroidism (common), and hepatic encephalopathy and central diabetes insipidus (rare) (see The Cat With Polyuria and

Polydipsia, page 231). Dehydrated animals with such a condition will appear to be in renal failure because of concurrent azotemia and poorly concentrated urine ($SG < 1.035$).

- Cats with hypovolemia from hypoadrenocorticism may also present with pre-renal azotemia, hyperphosphatemia and poorly concentrated urine.

Post-renal azotemia. The conditions will result in azotemia, hyperkalemia and reduced urination.

- **Urethral obstruction.** A painful turgid bladder is palpable. Rarely the obstruction has spontaneously resolved by the time the cat is presented for examination. In the latter case, diagnosis is established by history, preputial crystal deposits, urinalysis and azotemia. Note that prolonged urethral obstruction may rarely lead to acute renal failure.
- **Ruptured bladder.** The bladder is not palpable or, rarely, is palpable but small, and abdominal fluid is present. Creatinine or potassium concentrations higher in the abdominal fluid than that of serum are strongly suggestive of uroperitoneum. A ruptured bladder may be confirmed by a positive contrast cystogram. See page 464, The Cat With Abdominal Distention or Abdominal Fluid.

Treatment

Remove or correct the primary cause. Avoid any nephrotoxic drugs.

Administer intravenous fluid therapy.

- **Weigh the cat prior to fluid therapy** and monitor weight throughout treatment. Weight is one of the most important markers of hydration status. **Daily weight loss of 0.5–1% is expected in anorexic animals**, and this should be taken into account when judging hydration based on weight.
- Establish a **jugular catheter** if possible. This will facilitate fluid therapy, repetitive blood sampling and measurement of central venous pressure.
 - If direct measurement of central venous pressure is not possible, **observe the jugular veins**. Progressive distention of these veins and/or increase in the jugular pulse indicates rising central venous pressure. The medial saphenous veins may also be observed while the hind legs are raised and lowered. **Decreased emptying and increased refilling of the medial saphenous veins indicates volume expansion.**

Monitor for changes in respiratory pattern and auscultate lungs frequently for evidence of pulmonary edema. Observe extremities and intermandibular space for subcutaneous edema.

- Normal saline, lactated Ringer's or other balanced electrolyte solutions.
 - Rehydration. The goal of initial fluid therapy is to **correct dehydration and achieve 3–5% volume expansion**. Replace fluid deficits over 4–6 hours. An initial fluid bolus may be given in an effort to overcome renal arteriolar vasoconstriction. Use **10 ml/kg over 10 minutes in cats with anuria** or rapidly progressive oliguria, and **7–10 ml/kg/h for 4–6 hours** if there is increased concern for pulmonary edema or oliguria is less severe.

The goal of fluid therapy after rehydration is to **maintain 3–5% volume expansion above normal hydration**. More aggressive fluid therapy will not “flush out” or “open up” the kidneys, and overzealous treatment will result in pulmonary edema. Fluid rate must be adjusted based on body weight, central venous pressure, PCV and total protein levels and urine output.

- In cats with anuria or oliguria, place a urinary catheter and attach to a closed collection bag. **Always palpate the bladder** whenever checking urine production because the **catheter may kink**. The **urine should be cultured periodically** to monitor for urinary tract infection.
- In cats with polyuria, while a urinary catheter may be used, frequent palpation of the bladder and measurement of voided urine by weighing the litter pan is usually adequate to estimate urine production.

Monitor electrolytes and acid–base status (initially three times daily) and adjust fluids accordingly.

- **Hyperkalemia** is a potentially life-threatening complication of acute renal failure. Signs of significant hyperkalemia include bradycardia and weakness, which may progress to shock and a moribund state. ECG findings include loss of P waves, spiked T waves, and shortened Q–T interval.
- **Mild hyperkalemia** (above reference range to 6.5 mEq/L) may not require immediate treatment. If no clinical signs are present, one or more of the following treatments will usually suffice: reducing potassium concentration in the fluids, changing fluids to a more alkalinizing fluid, adding 5% dextrose to the fluids, and furosemide (see below).

- **Moderate hyperkalemia** (6.5–8.0 mEq/L) should always be treated promptly.
- **Severe hyperkalemia (> 8.0 mEq/L) may be life-threatening** and usually requires aggressive treatment. The higher the potassium level and the worse the clinical signs, the more rapid and aggressive should be the treatment. Treatments include:
 - **Dilution of potassium concentration** by rapid infusion of intravenous fluids (60 ml/kg/h). Potassium-free solutions have the most dilutional effect. Saline is beneficial for this reason although it is acidifying. Note that life-threatening hyperkalemia in acute renal failure is most likely to occur in anuric animals, which may not tolerate a large fluid bolus.
 - **Protect the heart** against the membrane effects of hyperkalemia with 10% calcium gluconate, 0.5–1.0 ml/kg IV, over 5–15 minutes. This should be given if there is a life-threatening arrhythmia. Monitor the ECG during therapy.
 - **Translocate** potassium from the blood into the intracellular fluid. Usually only one of the following treatments is necessary.
 - **NaHCO₃**, 0.5 mEq/kg IV over 5 minutes, followed by another 0.5 mEq/kg over the next 30–60 minutes. This treatment is best reserved for cats with HCO₃[−] or total CO₂ < 12 mmol/L, if measurements are available.
 - **Dextrose:** Severe hyperkalemia or moderate hyperkalemia with clinical signs – give 50% dextrose, 1.0–2.0 ml/kg IV (ideally diluted 1:1 with sterile water or saline), over 30–60 minutes. Moderate hyperkalemia without clinical signs – add 5–10% dextrose to the fluids (100–200 ml 50% dextrose/L). Monitor blood glucose. Note that dextrose may also serve as a diuretic.
 - **Insulin-dextrose:** regular insulin 0.1–0.5 units/kg IV followed by 2–4 ml of 50% dextrose/unit of insulin given (ideally diluted 1:1 with sterile water or saline) and then followed by adding 2.5% dextrose to the fluids (50 ml of 50% dextrose/L of fluids). Monitor blood glucose. Note that NaHCO₃ and dextrose should be avoided if effective serum osmolality is > 330 mOsm/kg. (Effective osmolality is calculated as $[1.86(\text{Na}^+ + \text{K}^+)] + \text{glucose} + 9$, with all units in mmol/L.) If the cat is hyperosmolar and dehydrated, increase the fluid rate. If dextrose therapy is needed, then

it is best used in conjunction with insulin to minimize exacerbation of hyperosmolality.

- Enhance potassium secretion. Give furosemide as discussed below. This may be used in the management of mild hyperkalemia, or subsequent to emergency management of moderate to severe hyperkalemia, but it will not act rapidly enough to correct hyperkalemia that is causing clinical signs, especially in the presence of oliguria or anuria where the drug may not promote urine production.

Diuretics.

- **If anuria or oliguria persists after fluid replacement**, administer **furosemide** 2 mg/kg. If diuresis does not occur within 30 minutes, repeat once. Furosemide will not improve glomerular filtration rate, but diuresis **may reduce tubular blockage and tubular back-leak**, and a polyuric animal is easier to manage than an oliguric one. If diuresis does occur, treatment may be given two to three times a day if needed to maintain diuresis. Fluid requirements will be increased. Constant-rate infusions of furosemide have been used in the management of acute renal failure in dogs but there is limited experience with cats. Constant rate infusions of furosemide at 0.25 mg/kg/h have been used in the management of congestive heart failure in cats and may be considered in the management of acute renal failure.
- Osmotic diuretics.
 - **If furosemide fails to induce a diuresis**, consider using **10–20% dextrose** as an osmotic diuretic, **25–50 ml/kg over 1–2 hours**. Monitor urine for glucosuria indicating adequate dosage. Diuresis should occur within 60 minutes of completing infusion. If diuresis results, the treatment may be repeated every 8–12 hours.
 - Mannitol may also be used as an osmotic diuretic at a dose of **0.25–0.5 g/kg over 10 minutes**. Diuresis should occur within 60 minutes of completing infusion. If diuresis results, the treatment may be repeated every 4–6 hours. Mannitol is a more potent osmotic agent than dextrose, but can **only be eliminated by renal excretion**, and carries a **higher risk of causing pulmonary edema**.

- **Osmotic diuretics should not be used in the presence of hyperosmolality** (e.g. ethylene glycol poisoning, diabetic ketoacidosis), dehydration or overhydration.

Monitor urea, creatinine and phosphorus levels (initially once daily).

- **A rapid fall in serum urea and creatinine levels** in the first 24–48 hours of fluid therapy indicates that there was a substantial **pre-renal component** to azotemia. Mild decreases in urea and creatinine levels during the following week are usually due to mild ongoing volume expansion and the cat should be watched closely for over-hydration. **Decreases in urea and creatinine levels due to improved renal function usually take 10–14 days** to appear. After renal function improves and then stabilizes, fluids may be tapered. Urea and creatinine levels will rise when fluids are tapered.

Obtain minimum blood sample sizes. Frequent blood sampling may lead to anemia and hypoproteinemia that will affect use of PCV and total protein values to monitor hydration. Anemia may require correction by transfusion.

Dopamine is not recommended as its effects are uncertain in cats and its benefit in acute renal failure in humans is being questioned.

Antiemetics. Prochlorperazine, chlorpromazine, yohimbine, metoclopramide and ondansetron may be used to control vomiting. Metoclopramide is a less effective antiemetic in the cat than in the dog. It is eliminated via the kidney so an initial dose of 0.2 mg/kg, SC, twice daily is recommended (dose range 0.2–0.5 mg/kg three times a day). It may also be given by constant rate infusion at a dose of 0.005–0.02 mg/kg/h (lower end of the range recommended initially). Prochlorperazine and chlorpromazine may cause hypotension.

Gastrointestinal protectants. Ranitidine and famotidine (H₂ blockers) are eliminated via the kidney (about 2/3–3/4 of the dose) so an initial dose of 0.5 mg/kg IV once daily is recommended. Sucralfate 0.25–0.5 g PO three times a day may be used if it does not increase vomiting.

Nutritional support. This may include **naso-esophageal or esophageal feeding** in cats that are not vomiting, and parenteral nutrition.

Opioid **analgesics** should be considered at standard doses for cats with swollen and painful kidneys or oral ulceration.

Peritoneal dialysis, pleural dialysis, hemodialysis or transplantation should be considered for cats with anuria or severe oliguria.

Prognosis

There are few reports of acute renal failure in cats due to causes other than ethylene glycol or lily poisoning (see below). Most cats with hemodynamically mediated non-oliguric acute renal failure and cats with pyelonephritis will probably recover with appropriate critical care, but may have **residual or worsened chronic renal failure**. In general, the prognosis for non-oliguric renal failure is better than for oliguric or anuric renal failure. Without dialysis, the **prognosis is typically considered poor if there is persistent oliguria or anuria**.

Prevention

Minimize prolonged renal hypoperfusion. Correct fluid deficits and hypotension promptly in cats with chronic renal failure.

Begin intravenous fluids preoperatively in elderly cats undergoing surgery, to prevent acute exacerbation of chronic renal failure.

Minimize exposure to ethylene glycol and lilies. Use aminoglycosides and other nephrotoxic drugs judiciously and avoid in elderly cats and in cats with chronic renal failure.

ACUTE POISONING AND EVENOMATION*

Classical signs

- Acute depression.
- Other specific signs: weakness, tremor, GIT signs.

See main reference on page 594 for details (The Cat With Salivation) and page 481 (The Bleeding Cat) and page 381 (The Pyrexia Cat), page 812 (The Cat With Seizures, Circling and/or Changed Behavior for

bromethalin, lead, methaldehyde, strychnine, organophosphates, carbamates, organochlorines, pyrethrins, pyrethroids), page 833 (The Cat With Stupor or Coma for lead), page 850 (The Cat With a Head Tilt, Vestibular Ataxia or Nystagmus for blue-tailed lizard), page 861 (The Cat With Tremor or Twitching for hexachlorophene, organophosphate) and pages 947, 950 (The Cat With Generalized Weakness for OP, snakes, spiders, ticks).

Clinical signs

Acute depression and anorexia are signs of most poisonings and envenomations and are not listed with every poison below. Other common signs include hypersalivation, vomiting, diarrhea, polypnea, arrhythmias, pale mucous membranes, hypothermia, tremors (which may cause hyperthermia), excitability, agitation and other behavior changes, seizures, and generalized weakness.

Rodenticides.

- **Anticoagulants:** signs include pale mucous membranes and signs referable to localized bleeding. Acute depression may be the only initial sign of internal bleeding, occurring prior to pale mucous membranes. See page 522, The Bleeding Cat.
- **Cholecalciferol:** signs include vomiting, diarrhea and polydipsia.
- **Bromethalin:** signs include mydriasis, paresis, tremors, hyperthermia, excitability and seizures.
- **Strychnine:** signs include muscle stiffness, extensor rigidity and opisthotonus, and tetanic seizures that may be initiated by physical, visual or auditory stimulation.

Anthelmintics.

- **Ivermectin:** signs include tremors, abnormal behavior, ataxia, blindness, bradycardia, hypothermia, seizures and coma.
- **Piperazine:** signs include weakness, tremors, ataxia, behavior changes, seizures and vomiting and diarrhea.

Insecticides.

- **Organophosphates and carbamates:** signs variably include systemic **parasympathetic** (muscarinic) signs (salivation, lacrimation, urination, defecation, miosis, dyspnea, bradycardia); **sympathetic** (ganglionic) signs (tachycardia, mydriasis); **neuromuscular** (nicotinic) signs (muscle stiffness, tremors, weakness, paralysis); and **CNS cholinergic signs** (hyperactivity, seizures, marked depres-

sion). Chlorpyrifos may cause a delayed toxicosis characterized by cervical ventroflexion and marked hind limb ataxia.

- **Pyrethrins, pyrethroids (phenothrin, etofenprox, and especially permethrin) and rotenone:** signs include hypersalivation, vomiting and agitation from oral irritation and tremors, ataxia, and seizures from systemic toxicoses.
- **Organochlorines (e.g. lindane):** signs include ataxia, tremors and seizures.

Slug and snail bait.

- **Metaldehyde:** signs include hypersalivation, vomiting, diarrhea, tachycardia, polypnea, mydriasis, ataxia, excitability, hyperesthesia and marked muscle tremors progressing to convulsions, with resultant hyperthermia.

Analgesics.

- **Acetaminophen:** signs include depression, anorexia, salivation, vomiting, abdominal pain, polypnea, dark mucous membranes, edema of the face and paws, and dark discolored urine. See page 595, The Cat With Salivation.
- **Aspirin:** signs include hematemesis, melena, polypnea and fever.
- **Ibuprofen** and other non-selective NSAIDs: signs include depression, hematemesis, melena, diarrhea, abdominal pain, polydipsia (renal failure), and seizures and coma with very high doses.

Plants (partial list).

- **Lilies:** signs are described in a separate heading below.
- **Marijuana:** signs include acute depression, ataxia, hypothermia and polyphagia.
- **Azaleas and oleander:** signs include arrhythmias, shock and acute heart failure.
- **Daffodils:** signs include vomiting, hypothermia, hypotension and bradycardia.
- Many other plants result in oropharyngeal and gastrointestinal irritation. **English ivy (*Hedera helix*)** and ***Cyclamen*** species may cause severe, potentially life-threatening, vomiting (including hematemesis) and diarrhea.
- **Pine** (water in Christmas tree reservoir): signs include vomiting, abdominal pain and icterus.

Heavy metals.

- **Lead:** Anorexia may be the only sign. Other signs include vomiting, diarrhea, abdominal pain, excitability, seizures and blindness.

Miscellaneous.

- **Ethylene glycol:** signs are described in separate headings below.
 - **Venlafaxine** is a human antidepressant medication (serotonin and noradrenaline reuptake inhibitor). It is an emerging toxicosis in that it is one of the few human medications that cats voluntarily ingest. Clinical signs include vomiting, polypnea, tachycardia, ataxia, mydriasis and agitation.
 - **Glow-in-the-dark items** contain dibutyl (n-butyl) phthalate as a luminescent. It is extremely unpalatable and when a cat bites into a glow-in-the-dark item it causes marked hypersalivation, frothing, head-shaking, agitation, hyperactivity, aggression and other behavioral changes. The luminescent is of low toxicity and a sufficient quantity to cause systemic toxicosis would not be ingested.
 - **Liquid potpourri** causes poisoning when there is accidental skin contact and the product is licked off. The product may contain essential oils (irritants and central nervous system depressants), and/or cationic detergents (corrosives) that cause more severe signs. Cutaneous and oral cavity signs vary from erythema to ulceration. Marked hyperthermia may accompany oral inflammation and precede ulceration. Gastrointestinal signs include dysphagia (esophagitis) and vomiting, hematemesis, melena, and abdominal pain (gastritis). Esophageal and gastrointestinal ulceration and perforation may occur.

Envenomation.

- **Tick bite paralysis:** Cats do not appear to be affected by North American ticks. *Ixodes holocyclus* in Australia causes rapidly progressive motor weakness, megaesophagus, mydriasis, tachyarrhythmias and dyspnea (various causes).
- **Spider bites:** *Latrodectus* spp. (black widow spider in North America, red back spider in Australia) live in warm and temperate regions in all continents. Cats are very sensitive to the venom. Signs of envenomation include loud vocalization from pain; restlessness and polypnea; salivation, vomiting and diarrhea; and muscle tremors and spasms that progress to flaccid paralysis.
- **Wasp and bee stings:** Local angioedema and pain are common signs. Anaphylaxis is rare.

- **Toad poisoning:** *Bufo marinus* (cane toad) is found mostly in South America, southeast United States and Hawaii, and Australia. *Bufo alvarius* is found in the southwest United States and northern Mexico. Signs of poisoning include profuse salivation, vomiting, arrhythmias, hindlimb weakness, a fixed trance-like stare and collapse.
- **Poisonous lizards:** Gila monster (*Heloderma suspectum*) and Mexican beaded lizard (*Heloderma horridum*) are found in the southwest United States and Mexico. Envenomation occurs during a tenacious bite with chewing action. Signs of envenomation include painful bite wound, salivation, lacrimation, urination, defecation, and loss of voice. Ingestion of a blue-tailed lizard skink (*Eumeces elegans*) found in the southeast United States may cause vestibular signs.

Diagnosis

History is often critical to the diagnosis of intoxication.

Definitive diagnosis can be made by measuring poisonous principles in vomitus, serum or urine.

Anticoagulant rodenticide: prolonged prothrombin, activated partial thromboplastin times, and activated clotting time.

Cholecalciferol rodenticide: hypercalcemia and hyperphosphatemia.

Black widow spider (*Latrodectus*) envenomation: marked elevation in creatinine kinase and aspartate aminotransferase, and myoglobinuria.

Differential diagnosis

Other causes of acute depression are differential diagnoses. Other differential diagnoses should be considered for the more specific signs (e.g. hypocalcemia as a cause of tremors).

Treatment

The most effective treatments vary with the toxin, and **consultation with a toxicology service** is recommended.

Minimize further absorption (cutaneous and gastrointestinal decontamination).

- Bath the cat if there is poison on the skin (e.g. permethrin)
- Remove the source of the poison.
- **Irrigate oral cavity** if there is poison in the mouth (e.g. after mouthing a *Bufo* toad). If clinical signs are due to unpleasant taste or oral irritation (hyper-salivation, agitation +/- vomiting) after milk or liquid from a can of tuna.
- **Induction of emesis.** **Xylazine** 0.44 mg/kg IM reliably causes vomiting in 5–20 minutes. The effect can be reversed with yohimbine 0.1–0.5 mg/kg IV. If xylazine is not available, or for induction of vomiting at home, use fresh 3% **hydrogen peroxide**, 2 ml/kg PO, or syrup of **ippecac**, 3–6 ml/kg diluted 1:1 with water, PO or by gavage (i.e. via stomach tube). Vomiting should occur within 10–30 minutes. Hydrogen peroxide and syrup of ippecac treatments may be repeated once if the initial treatment is ineffective.
- **Induction of emesis is absolutely contraindicated** in the presence of a caustic or volatile poison, impaired gag reflex, laryngeal paralysis, extreme weakness or unconsciousness, and is relatively contraindicated in the presence of seizures or dyspnea.
- **If induction of emesis is ineffective or contraindicated**, perform **gastric lavage**. Establish light general anesthesia if the cat is not unconscious and place a cuffed endotracheal tube extending 2–3 cm beyond the teeth. Position the cat with the head and thorax slightly lowered. Pass a tube the same size or slightly larger than the endotracheal tube into the stomach, deliver 5–10 ml/kg tepid water, and aspirate with a 60 ml syringe or aspiration bulb. Repeat the procedure 10–15 times. Kink the stomach tube as it is removed from the stomach. Addition of activated charcoal at the dose below to the lavage solution will increase its effectiveness.
- Solid poisons (e.g. lead) may be removed by **endoscopy** or **gastrotomy/enterotomy**.
- **Absorption of remaining poison.** Give a slurry of **activated charcoal** by gavage, 1–5 g/kg dissolved in 3–5 ml of tepid water/g charcoal, after induction of emesis or when gastric lavage is complete. Treatment may need to be repeated every 4–6 hours for 2–3 days because the poison may return to the intestinal tract by enterohepatic circulation.

Activated charcoal is an effective absorbent for many poisons including vitamin K antagonist rodenticides, ethylene glycol, alkaloids, organophosphate and other insecticides, acetylsalicylic acid, NSAIDs and barbiturates. It is not effective with most caustic or corrosive agents.

- **Catharsis** is used to promote elimination of the toxin in the stool. It should always be used following the use of activated charcoal and should not be used in the presence of diarrhea. Catharsis may have to be repeated every 4–6 hours as with activated charcoal. Catharsis using non-absorbed salts or sugars will cause dehydration that must be addressed with fluid therapy.
 - Salts: **sodium sulfate** (Glauber's salts, preferred) or **magnesium sulfate** (Epsom salts), 1/2 level teaspoon per kg in 5–10 volumes of tepid water, by gavage. Magnesium sulfate may cause central nervous system depression, should not be repeated, and must be used cautiously in renal failure. These salts are the preferred cathartics in lead poisoning as lead will precipitate as unabsorbable lead sulfate.
 - **Sugars: sorbitol 70% solution** (preferred) or **lactulose**, 3 ml/kg. The **most practical product** to use in the non-specific treatment of poisoning is a commercial product that combines activated charcoal and sorbitol in a suspension.
 - **Colonic lavage** ("high enema"), 20 ml/kg tepid water.

Enhance elimination.

- **Diuresis.** Diuresis will hasten renal elimination of a toxin only if it is reabsorbed by the renal tubules, e.g. ethylene glycol. Diuresis may be achieved with fluid therapy, furosemide, mannitol or dextrose (see Acute renal failure, page 282).
- **Ion trapping.** A toxin must be unionized to be reabsorbed by the renal tubules. Elimination of **acidic toxins** (e.g. aspirin) may be hastened by alkalinizing the urine using sodium bicarbonate. Elimination of **alkaline toxins** (e.g. strychnine) may be hastened by acidifying the urine using saline or ammonium chloride.
- Peritoneal dialysis or hemodialysis.

Specific therapy.

- **Anticoagulant rodenticide** – vitamin K (see page 509, The Bleeding Cat).

- Cholecalciferol rodenticide – treatment of hypercalcemia (saline, furosemide, calcitonin, prednisone, ± biphosphonates).
- Organophosphates and carbamates – atropine (both), pralidoxime chloride (organophosphates only).
- Acetaminophen – acetylcysteine, ascorbic acid, transfusion (see page 596, *The Cat With Salivation*).
- Aspirin and NSAIDs – Treatment of gastric ulceration (H2 blockers, sulcralfate), treatment of acute renal injury with fluids.
- **Lilies** – see separate heading below.
- Lead – CaNa₂EDTA, D-penicillamine (contraindicated if lead present in intestinal tract), succimer (preferred treatment).
- Ethylene glycol – see separate heading below.
- Venlafaxine – cyproheptadine 2–4 mg/cat PO or per rectum may counteract serotonin effects.
- Ixodid tick paralysis and *Lactrodectus* spider bites – specific antivenin (see pages 954, 975, *The Cat With Generalized Weakness*).

Treat arrhythmias, e.g. atropine for daffodil-induced bradycardia (see page 160, *The Cat With Tachycardia, Bradycardia or an Irregular Rhythm*).

Treat tremors and seizures – diazepam, methocarbamol, phenobarbital, pentobarbital (see page 801, *The Cat With Seizures, Circling, and/or Changed Behavior*). Beware of hypothermia following correction of hyperthermia, which may cause renewed tremors.

Treat agitation – consider acepromazine (ensure cat is not hypotensive).

Supportive care.

ETHYLENE GLYCOL POISONING*

Classical signs

- Acute depression and anorexia.

Pathogenesis

Ethylene glycol is a solvent used in paints, polishes, inks and antifreeze, which is the most common source of poisoning. It is a colorless liquid – the yellow-green appearance of antifreeze is due to the addition of fluorescein.

It tastes sweet to humans, and is palatable to cats. The **minimum lethal dose of undiluted ethylene glycol in cats is only 1.4 ml/kg**.

Ethylene glycol is **rapidly absorbed from the intestinal tract**.

- **Peak plasma concentration is achieved 1 hour post ingestion** in a fasted cat. Food probably delays peak plasma concentrations, but by at most 1–2 hours.

Following absorption, ethylene glycol is excreted about **50% unchanged in the urine** (peak urine concentration is achieved at 6 hours). Some passive reabsorption occurs in the distal convoluted tubules and collecting ducts. The other **50% is metabolized in the liver** by alcohol dehydrogenase to glycoaldehyde, which in turn is metabolized by aldehyde dehydrogenase to glycolic acid. Glycolic acid is further metabolized to glyoxylic acid, which is then metabolized to final metabolites including **oxalic acid**. Oxalic acid combines with calcium to form **calcium oxalate crystals**. The serum half-life of ethylene glycol in untreated cats is 2–5 hours.

- Acute tubular necrosis is caused by **cytotoxic effects of glycolic, glyoxalic and oxalic acids**. Deposition of crystals in the kidneys has a minor role.

Clinical signs

Signs of **acute ethylene glycol poisoning** (<12 hours) are due to direct effects of the poison and metabolites on the central nervous system and gastrointestinal tract, and include **depression, ataxia, tremors, vomiting, and a sweet odor to the breath**. Polyuria occurs due to osmotic diuresis. Polydipsia is uncommon in cats.

Later signs (> 12 hours) are due to acute renal failure and include progressive depression, anorexia, oral ulceration, hypothermia, painful and swollen kidneys, seizures, oliguria and anuria.

Diagnosis

The **diagnosis** of acute poisoning **relies on history of ingestion or a high index of suspicion**.

- Acute ethylene glycol poisoning should be considered in **any cat at risk with acute depression**.

A **hemogram** typically reveals hemoconcentration and a stress leukogram.

A **serum biochemistry** profile will reveal **decreased bicarbonate (total CO₂)** and an **increased anion gap**. Blood gases, if available, will reveal **severe metabolic acidosis** with or without partial respiratory compensation. Measured osmolality, if available, will be increased in parallel with ethylene glycol concentration, resulting in an increased **osmolal gap**. Other variable findings are **hyperglycemia** (stress and reduced metabolism by aldehydes), **hypocalcemia** (chelation by oxalic acid), and **hypophosphatemia** (binding by rust-inhibitors in antifreeze). In the later stage of poisoning serum chemistry findings are typical of acute renal failure.

Urinalysis will reveal persistent **isosthenuria to minimally concentrated urine** and aciduria within 3 hours of ingestion. **Oxalate crystals** are usually present at some point during the acute phase of intoxication, and may appear as early as 3 hours. Glucosuria and proteinuria may be present. A **Wood's lamp** may be used in an effort to detect **fluorescence** from fluorescein in stomach contents and on the muzzle and paws. However numerous products contain fluorescents and absence of fluorescence does not rule-out exposure, so the diagnostic utility of fluorescence may be limited. Similarly examination of urine for fluorescence is likely of limited values as cat's urine normally fluoresces and a potential increase in fluorescence from a small amount of excreted fluorescein may be difficult to detect.

Definitive diagnosis can be made by **measuring ethylene glycol in serum or urine**, but cats are very sensitive to ethylene glycol poisoning and may develop signs at concentrations below that detected by the assays. Serum is preferred because concentration of the poison is higher than in urine. Ethylene glycol is usually not detectable in serum or urine after 72 hours. Propylene glycol (present in diazepam injection) causes a false positive reaction in some assays.

Ultrasound may reveal hyperechoic renal cortices. The kidney may feel very firm when advancing a percutaneous biopsy needle.

- **Kidney biopsy** will reveal acute tubular necrosis, with the presence of oxalate crystals.

Differential diagnosis

Both ethylene glycol and **lily intoxication** cause acute depression and acute renal failure. The laboratory features of lily poisoning have not been as well characterized as those of ethylene glycol poisoning therefore it is difficult to use these to differentiate the two poisonings.

Ethylene glycol poisoning is more **likely in outdoor cats and lily poisoning in indoor cats**. Vomiting is more consistent in lily poisoning and there is evidence of plants being chewed. Detectable serum or urine **concentrations of ethylene glycol, oxalate crystalluria, and oxalates on kidney biopsy are diagnostic for ethylene glycol poisoning**. If these findings are absent, other causes of acute renal failure must be ruled out.

- Both cats with **pancreatitis** and cats with acute ethylene glycol poisoning may have acute depression with or without vomiting, but cats with acute ethylene glycol poisoning will be **isosthenuric**, while cats with **acute pancreatitis should have well-concentrated urine**. Azotemia, metabolic acidosis, increased anion gap and increased osmolal gap will be more severe than in pancreatitis. Definitive diagnosis relies on measuring ethylene glycol in serum or urine or seeing **oxalate crystals** in urine or a kidney biopsy.
- Both ethylene glycol poisoning and **diabetic ketoacidosis** may cause acute depression, polyuria, vomiting, dehydration, hyperglycemia, azotemia, increased anion gap metabolic acidosis, and increased osmolality. The former is confirmed by detecting ethylene glycol in serum or oxalate crystals and the latter by **detecting ketones in the blood or urine**. Ethylene glycol poisoning invariably causes acute renal failure (unless treated within 3 hours), while acute renal failure is an uncommon complication of diabetic ketoacidosis, although cats with diabetic ketoacidosis may have concurrent chronic renal failure.

Ethanol ingestion may cause depression, polyuria, ataxia and increased osmolality. Diagnosis relies on history of ingestion and **measurement of ethanol in the serum**.

Certain abnormalities in the acute phase of ethylene glycol poisoning (depression, tremors, hypocalcemia) may resemble acute hypoparathyroidism. Other historical and physical abnormalities, and the presence of hyperphosphatemia in the latter, will distinguish the two.

Treatment

Immediate **induction of emesis and activated charcoal or gastric lavage** if ingestion is witnessed. Ethylene glycol is rapidly absorbed and intestinal decontamination is unlikely to be of any benefit after two hours or once clinical signs have appeared.

Prevent ethylene glycol metabolism. This may be achieved using either ethanol or fomepizole as competitive inhibitors of alcohol dehydrogenase. Treatment must be initiated within 3 hours of ingestion to prevent acute renal failure. The unmetabolized ethylene glycol is eliminated via the kidneys.

- Cats are usually treated with **ethanol**; several protocols exist. Prepare 20% (20 g/100 ml, 200 mg/ml) ethanol by mixing 1 part of 95–100% ethanol with 4 parts saline. (An alternative is to mix 1 part vodka [40% ethanol] with 1 part saline.) Give 3 ml/kg 20% ethanol (600 mg/kg) over 1 hour further diluted to a minimum of 1 part 20% solution and 2 parts saline for a final $\approx 7\%$ maximum concentration solution. (Additional dilution is needed in these protocols as the ethanol solutions are hyperosmolar). This is followed by a constant rate infusion of 20% ethanol, 0.5 ml/kg/hr (100 mg/kg/hr), in a minimum of 2 ml/kg/hr saline (again for a final $\approx 7\%$ maximum concentration). (The dose may be increased with close monitoring up to 1.0 ml [200 mg]/kg/hr in 4 ml/kg/hr fluids.) Treatment is continued for 10 hours after a negative serum ethylene glycol test, or 18 hours after correction of metabolic acidosis without ongoing need for NaHCO_3 treatment. An alternative protocol is to give 5 mL/kg 20% ethanol, diluted into IV fluids, by constant rate infusion over 6 hours for 5 treatments, then over 8 hours for 4 treatments. (The serum half-life of ethylene glycol for cats receiving ethanol is 29 hours.)
- **Begin IV fluids** (do not use Ringer's or lactated Ringer's) at **1.5–3 times maintenance** based on patient requirements and adjusted to account for volume delivered with ethanol solutions. Monitor hydration status, body weight, and urine output; observe respiration and auscultate lungs frequently to monitor for pulmonary edema.
- Ideally **measure serum ethanol concentrations** and maintain at 100 mg/dL. **Treatment will increase central nervous system depression and serum osmolality.** The cat may become comatose

during therapy. Observe very closely for life-threatening respiratory depression, which should prompt reduction of ethanol treatment. Monitor body temperature and rewarm if hypothermia develops.

- Ideally monitor **acid-base status**. If $\text{pH} < 7.25$ and/or $\text{HCO}_3^- < 8$ mmol/L, give NaHCO_3 (mmol = $0.2 \times \text{kg} \times \text{base deficit}$) over 4 hours IV. Repeat as necessary.
- **If intravenous therapy is not possible**, give the ethanol doses above intraperitoneally, and additional fluids subcutaneously.
 - If the cat cannot be hospitalized immediately for ethanol therapy, the owner can attempt to give a **40% alcoholic beverage by mouth** (e.g. rum, vodka), 2.5 ml/kg, although a cat is less likely to tolerate this than a dog.
- **Fomepizole (4-methylpyrazole)** is the treatment of choice in dogs. The drug causes minimal central nervous system depression and does not increase serum osmolality or metabolic acidosis. Although initially considered ineffective in cats, recent studies suggest that higher doses are effective.
 - Give 125 mg/kg 5% solution IV initial dose, followed by 31.25 mg/kg IV at 12, 24 and 36 hours post-ingestion. The dose should be given over 15–30 minutes.

Multiple B-vitamins containing pyridoxine and thiamine may enhance the metabolism of glyoxylic acid to non-toxic metabolites and protect the nervous system during ethanol therapy. Compatibility of B-vitamins with ethanol solutions is not known, so administration via a separate IV line is recommended.

See Acute renal failure, above.

- Most ingestion is not witnessed, and, without dialysis, the prognosis for cats with oliguric or anuric renal failure is grave. Hemodialysis has been used successfully to support cats through oliguric and anuric renal failure until tubular regeneration occurred. **Peritoneal dialysis** may be considered, especially if oliguria has not progressed to anuria, as the chances for recovery of renal function are perhaps somewhat better with oliguria than with anuria.
- **Renal transplantation** may be considered in cats with oliguric or anuric renal failure.

LILY POISONING*

Classical signs

- Acute depression and anorexia.
- Vomiting.

Pathogenesis

Lily poisoning is caused by ingestion of plants in the genera *Lilium* and *Hermercallis*, and all plants within these genera should be considered potentially toxic. Plants with proven toxicity include the Easter lily (*L. longiflorum*), tiger lily (*L. tigrinum*), rubrum lily (*L. speciosum*), Japanese show lily (*L. lancifolium*), *Lilium* hybrids and daylilies (all *Hermercallis* spp.). Calla lilies (*Zantedeschia aethiopia*) and peace lilies (*Spathiphyllum wallis*) are not toxic.

Leaves, flowers and stems are toxic; only small quantities have to be ingested to result in intoxication. The flowers are most toxic.

The toxic principles have not been fully characterized and it is not known if *Lilium* and *Hermercallis* toxins are the same.

Poisoning results in acute renal failure, which initially is non-oliguric.

Dehydration appears to be a critical factor in the progression of non-oliguric to oliguric renal failure.

Clinical signs

Signs of **acute lily poisoning** (< 24 hours) are probably due to direct effects of the uncharacterized poison and include **depression, anorexia, polyuria with or without polydipsia, hypersalivation and acute vomiting**. Hypersalivation and vomiting typically **begin within 3 hours of ingestion and lasts for 4–6 hours**. Cases have been presented without a history of vomiting. Polyuria typically begins within 12–30 hours and lasts for 12–24 hours. Ataxia, tremors and seizures have also been reported.

Later signs (> 24 hours) are due to acute renal failure and include persistent depression and anorexia, hypothermia, recurrent vomiting, painful and swollen kidneys, and polyuria, oliguria or anuria.

Diagnosis

The diagnosis of acute poisoning relies on history of ingestion or a high index of suspicion.

- Acute lily poisoning should be considered in any cat at risk with acute depression and vomiting. Indoor cats with access to newly introduced plants are at highest risk.
- Vomitus should be examined for plant material. Plants should be examined for evidence of having been chewed.

A **hemogram** typically reveals hemoconcentration and a stress leukogram.

Acid-base and osmolality values in the acute phase of poisoning have not been well characterized. In the later phase of poisoning serum chemistry findings are typical of acute renal failure, but there may be a **disproportionate elevation in creatinine compared to urea**. **Liver enzyme and creatinine kinase values may also increase.**

Urinalysis will reveal **isosthenuria to minimally concentrated urine**. Glucosuria and proteinuria may be present.

Ultrasound may reveal **hyperechoic renal cortices**. The kidney may feel very firm when advancing a percutaneous biopsy needle.

Kidney biopsy will reveal acute tubular necrosis and intact basement membranes. Low numbers of birefringent crystals may be present.

Differential diagnosis

Other causes of acute renal failure.

Other causes of **acute vomiting**.

- Both cats with **acute pancreatitis** and cats with acute lily poisoning may have acute depression and vomiting, but cats with **lily poisoning** will have **minimally concentrated urine**, while cats with acute pancreatitis should have **well-concentrated urine** unless there is a concurrent disorder causing dilute urine, such as chronic renal failure.

Treatment

Induction of emesis, activated charcoal and catharsis if recent ingestion.

Prompt intravenous fluid therapy. This is critical for a good prognosis.

Dehydration is an important mechanism in the development of renal failure. Prompt initiation of intravenous fluids will halt progression of non-oliguric to oliguric/anuric renal failure and hasten recovery. Deliver **fluids at 2–3 times maintenance** for a minimum of 24 hours (48 hours preferred).

Gastrointestinal decontamination and intravenous fluid therapy within 6 hours of ingestion is likely to prevent renal failure. If such treatment is delayed for more than 18–24 hours, acute renal failure will likely occur.

If renal failure occurs, see Acute renal failure, above.

- Hemodialysis and peritoneal dialysis have been used to support cats through oliguric/anuric renal failure until tubular regeneration occurs. Without dialysis, the prognosis for oliguric/anuric renal failure is grave. Cats with non-oliguric acute renal failure may develop chronic renal failure.

SNAKE BITE ENVENOMATION*

Classical signs

- Flaccid paresis/paralysis with mydriasis (most Elapidae, some Crotalidae and Viperidae snakes).
- Bleeding tendency (some Elapidae and Viperidae snakes).
- Bite wound on cranial half of body \pm local swelling or bleeding (Viperidae snakes).

See main reference on page 950 for details (The Cat With Generalized Weakness).

Clinical signs

Cats are less likely to be bitten than dogs.

Venoms from **Elapidae** snakes (all Australian snakes) are predominantly **neurotoxic**. Initial signs may be acute depression and weakness. More specific signs include areflexic dilated pupils, dysphagia (salivation), dyspnea (respiratory paralysis), hindlimb ataxia and flaccid quadraplegia. Local reaction to the bite is minimal, and the bite wound is rarely located. Some

Elapidae also have hematoxins that activate and deplete clotting factors resulting in bleeding, myotoxins that cause rhabdomyolysis, or hemolysins that cause intravascular hemolysis.

Venoms from **Viperidae** are predominantly **hematoxic**, although some have **neurotoxic properties**. **Edema \pm bleeding/bruising around the bite is typical**.

Venoms from **Crotalidae** are predominantly **hematoxic**, although some are **potent neurotoxins**. Acute depression may occur from hypotension or neurotoxicity.

Venoms from most **Colubridae** are mild and clinical reports of bites to cats lacking.

Diagnosis

Diagnosis is based on **history of possible exposure** to a snake and physical examination findings.

CBC may reveal hemoconcentration, echinocytosis and thrombocytopenia. Serum chemistry profile may reveal hypokalemia and elevated CK, ALT, urea and creatinine levels. Urinalysis may reveal myoglobiunuria or hemoglobinuria and glucosuria.

Differential diagnosis

See The Cat With Generalized Weakness (page 952) and for differential diagnosis of neurologic signs and The Bleeding Cat (page 503) for differential diagnosis of hematologic signs.

Differential diagnoses for the local reaction include angioedema from insect envenomation, animal bite wounds, sharp and blunt trauma.

Treatment

Keep the animal calm.

Supportive care. See page 953, The Cat With Generalized Weakness.

Specific antivenin therapy.

Transfusions for clinically significant hemostatic or hematologic abnormalities.

ACUTE HEART FAILURE*

Classical signs

- Acute dyspnea.
- Lethargy and inappetence.

See main reference on page 124 for details (The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

Clinical signs

Acute onset of depression, anorexia and dyspnea. In severe cases, collapse may occur, especially if stressed.

Pulmonary crackles, a heart murmur, arrhythmia and/or weak pulses may be found on physical examination.

Some cats have a history of vomiting.

Diagnosis

Pulmonary edema and cardiomegaly are evident on radiographs. The radiographic appearance of pulmonary edema is variable in cats.

Furosemide may be given and radiographs repeated in one hour to see if the pulmonary changes have improved. Definitive diagnosis of cardiomyopathy requires echocardiography.

Differential diagnosis

Other causes of depression and dyspnea. See The Dyspneic or Tachypneic Cat (page 47).

Treatment

Furosemide and nitroglycerin ointment at standard dosages. See details of additional treatment page 130 (The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

DIABETIC KETOACIDOSIS*

Classical signs

- Polyuria, polydipsia, and weight loss.
- Recent onset of acute depression and anorexia.

See main reference on page 236 for details (The Cat With Polyuria and Polydipsia).

Clinical signs

Typically there is a history of **weight loss, polyuria and polydipsia**, together with a normal appetite or polyphagia in the preceding weeks or months prior to an acute onset of anorexia, vomiting, dehydration, and depression. Other signs that may be evident with the onset of depression include icterus and dyspnea.

Diagnosis

Diagnosis requires **demonstration of ketonemia or ketonuria, and hyperglycemia**. Ketones may be falsely negative in urine because urine test strips measure primarily oxaloacetate (and to a lesser extent acetone), which may be present in concentrations in urine below the limit of detection by the test strip in cats. Several drops of hydrogen peroxide may be added to the urine sample in an effort to convert β -hydroxybutyrate to oxaloacetate to increase the concentration of oxaloacetate in urine. Alternatively, β -hydroxybutyrate may be measured in serum using a point-of-care test, or the urine test strip may be used to detect oxaloacetate in heparinized plasma. Using a standard urine test strip, a **negative plasma test rules-out ketosis**, and a **positive urine test rules-in ketosis**, in cats. Finally, bicarbonate (total CO_2) concentrations in plasma may be used to demonstrate acidosis.

Differential diagnosis

Acute pancreatitis or sepsis (depression), hepatic lipidoses or cholangiohepatitis (depression and icterus), ethylene glycol or lily intoxication (depression and polyuria), acute heart failure (depression and dyspnea) may all cause vomiting and dehydration and appear similar to diabetic ketoacidosis.

Treatment

Intravenous fluids are required to correct dehydration and electrolyte imbalances.

Regular insulin should be administered using intravenous, intramuscular or subcutaneous administration protocols depending on the status of the cat's peripheral perfusion.

Appropriate antibiotics should be administered if urine has evidence of bacteria or inflammation. Many diabetic

cats have urinary tract infection at the time of admission (culture urine).

NEOPLASIA*

Classical signs

- Usually chronic depression, anorexia and weight loss.
- Occasionally acute signs.

Clinical signs

Neoplasia **typically causes chronic signs**, but depending on location and growth rate, a **tumor may cause acute signs**, which may include acute depression, anorexia, and dehydration.

Diagnosis

Routine **history-taking, physical examination, and diagnostic work-up** is required to identify specific signs and localize organ involvement. Definitive diagnosis requires biopsy.

Differential diagnosis

Other causes of acute depression and anorexia.

Treatment

Surgery, radiation therapy, chemotherapy and other treatment modalities may be indicated, depending upon the neoplasm.

NUTRITIONAL SUPPORT

TOXOPLASMOSIS*

Classical signs

- Fever, anorexia and depression.
- Uveitis, dyspnea, icterus, or neurologic signs.

See main reference on page 432 for details (The Yellow Cat or Cat With Elevated Liver Enzymes), page 375 (The Pyrexia Cat).

Clinical signs

Cats of any age may be affected, but **70% of cats are less than 2 years of age**.

Toxoplasmosis may affect any organ system resulting in a wide variety of clinical signs. Uveitis, **pneumonia, hepatitis and encephalitis** are the most common syndromes. Most cats with systemic toxoplasmosis have a fever.

Lethargy, anorexia and fever are early signs.

Uveitis or other forms of intraocular inflammation are present in about 80% of cases.

Dyspnea is present in the majority of cats, and associated with increased respiratory sounds over the chest.

Abdominal signs may occur associated with hepatitis or pancreatitis and include abdominal pain on palpation, infrequent vomiting, and enlarged mesenteric lymph nodes.

Neurologic signs are more common in older cats.

Diagnosis

Acute systemic toxoplasmosis typically affects kittens, or immunosuppressed cats, which usually have a history of chronic disease.

Confirmation is **by measuring serum IgM antibodies or demonstrating rising serum IgG antibodies**.

The organism occasionally may be seen in airway wash cytology of cats with pneumonia.

Differential diagnosis

Rule out **other diseases** causing **acute lethargy, anorexia and fever**, which in the cat are usually **infectious causes**. Physical examination will often identify localizing signs, which can be pursued diagnostically.

Treatment

Clindamycin at standard doses (10–12 mg/kg orally q 12 h for 4 weeks).

Other drugs with potential efficacy include trimethoprim-sulfas, doxycycline, minocycline, azithromycin and clarithromycin.

UPALATABLE FOOD*

Classical signs

- Partial anorexia.

Pathogenesis

Change in diet to unpalatable food may precipitate total or partial anorexia.

Stale food or spoiled food may cause anorexia.

Clinical signs

Complete or partial anorexia.

Diagnosis

History of change in diet.

History of feeding from a large, slowly consumed bag of dry food, or providing several days of rations in one meal.

Ruling out other causes of anorexia.

Differential diagnosis

Other causes of depression and anorexia.

Treatment

Resume previous diet or offer other more palatable food.

Prognosis

Excellent provided anorexia is not protracted in obese cats resulting in hepatic lipidosis.

ALTERNATE FOOD SOURCE*

Classical signs

- Partial anorexia.

Pathogenesis

The cat has another food source in addition to its usual source, causing physiologic anorexia.

Clinical signs

Partial or complete anorexia is observed with respect to the cat's normal food source.

No weight loss or other signs of illness are apparent.

Diagnosis

Diagnosis is based on confirming that another food source is being used, e.g. neighbors, successful hunting.

Ruling out other causes of anorexia.

Differential diagnosis

Other causes of anorexia.

Treatment

Eliminate the alternate food source if indicated.

ENVIRONMENTAL STRESS*

Classical signs

- Inactivity and/or anorexia.

Pathogenesis

Hot weather may cause inactivity and withdrawal to cool locations.

Cold weather may cause withdrawal to warm locations.

The cat may not be eating because of discomfort or because of inactivity and withdrawal.

Clinical signs

Variable withdrawal, inactivity, anorexia and dehydration.

During hot weather periods the cat may be more active than usual at night when it is cooler.

No signs of another disorder causing depression and anorexia.

Diagnosis

History of temperature extremes.

Ruling-out other causes of depression and anorexia.

Differential diagnosis

Other causes of depression and anorexia.

Treatment

Provide a thermoneutral environment.

Place food in withdrawal location.

Prognosis

This is usually a short-term problem with no adverse consequences.

HYPOPHOSPHATEMIA*

Classical signs

- Weakness.
- Pallor and hemoglobinuria (hemolysis).

Pathogenesis

Hypophosphatemia results from **insufficient phosphorus intake** and/or **excessive urinary phosphorus loss** and/or **translocation** from extracellular to intracellular fluid.

Mild to moderate hypophosphatemia (serum phosphorus level 0.5–0.8 mmol/L) may be seen in **numerous disorders** where anorexia is a feature. It is seen most often with hepatic lipidosis and chronic renal failure. Anorexia may contribute to hypophosphatemia, which in turn may exacerbate anorexia and depression.

Severe hypophosphatemia (serum phosphorus level < 0.5 mmol/L) is most likely to be seen in the **treatment of diabetic ketoacidosis** and within 3 days of initiating tube feeding in an anorexic cat.

Clinical signs

Lethargy, muscle weakness, anorexia – increasing risk with decreasing phosphorus level.

Severe muscle weakness may lead to respiratory muscle failure (rare).

Pale mucous membranes, hemoglobinemia and hemoglobinuria from **hemolysis** – most likely to occur with

serum phosphorus level < 0.3–0.5 mmol/L, but has occurred at higher levels.

Diagnosis

Serum phosphorus level < 0.8 mmol/L.

Ruling out other causes of depression, weakness, anorexia and hemolysis.

Differential diagnosis

Other causes of depression, weakness and anorexia related to the primary disorder.

Treatment

Intravenous **potassium phosphate** or sodium phosphate. See Diabetic ketoacidosis in The Cat With Polyuria and Polydipsia (page 236).

Transfusion with fresh red blood cells if hemolysis occurs.

Prognosis

The prognosis for correction of hypophosphatemia is good and overall prognosis is determined by the underlying disorder.

HYPOPARATHYROIDISM*

Classical signs

- Anorexia and depression.
- Muscle tremors and seizures.
- History of thyroidectomy.

Clinical signs

Anorexia and depression are consistent findings.

Muscle tremors have been reported in 83%, and **seizures** in 50%, of cases of idiopathic hypoparathyroidism.

Diagnosis

Hypocalcemia (serum calcium level usually < 1.6 mmol/L in the presence of normal serum albumin level) and hyperphosphatemia.

History of **thyroidectomy** within the previous 2 weeks.

Differential diagnosis

Acute poisoning is main differential diagnosis for acute anorexia and depression progressing to muscle tremors and seizures.

Hypoglycemia may cause similar signs.

Treatment

Tremors or seizures:

- 10% calcium gluconate 0.5–1.0 ml/kg, or 10% calcium chloride 0.15–0.5 ml/kg, given IV over 10–15 min. Temporarily stop administration if bradycardia, QT-interval shortening or vomiting occur. Both solutions are caustic (calcium chloride >> calcium gluconate) if extravasated.
- If severe initial signs or recurrent signs, follow with 10% calcium gluconate 0.25–0.375 ml/kg/h CRI.

Long-term management:

- Vitamin D and oral calcium preparations – see The Cat With Tremor or Twitching (page 864).
- Cats with post-thyroidectomy hypoparathyroidism typically regain parathyroid function within 2 weeks to 6 months.

ACUTE HYPOGLYCEMIA

Classical signs

- Acute depression in an insulin-treated cat.
- Weak wobbly gait.
- Muscle fasciculations.
- Dilated pupils.

See main reference on page 236 for details (The Cat With Polyuria and Polydipsia).

Clinical signs

Clinical signs of hypoglycemia most often occur in insulin-treated diabetic cats.

Signs may be mild and include lethargy or increased somnolence, a weak wobbly gait and mydriasis, or be more severe and include **seizures**, stupor or coma.

Other signs that are sometimes observed include muscle tremors, vomiting, vocalizing, circling, panting, diarrhea or urination.

Hypoglycemia is unlikely to stimulate eating behavior in a cat; it is more likely to cause anorexia.

Diagnosis

Clinical hypoglycemia usually results from insulin overdose in a diabetic cat. This is confirmed by measuring blood glucose levels and by prompt resolution of clinical signs following intravenous dextrose or intramuscular glucagon.

Portable glucose meters have a tendency to measure falsely low values. A diagnosis of hypoglycemia should be reconsidered if the signs do not improve once blood glucose increases in response to intravenous glucose or glucagon. **Lack of response to sugar solutions rubbed on the gums or given by stomach tube does not rule out hypoglycemia**, because most absorption of glucose occurs in the small intestine. Cats with severe signs such as coma may not respond if there is irreversible brain damage.

Differential diagnosis

Other causes of neurologic disease. See The Cat With Stupor or Coma (page 821) and The Cat With Seizures, Circling and/or Changed Behavior (page 809).

Some poisonings may cause similar signs, e.g. vocalizing, mydriasis, vomiting, diarrhea, polypnea, tremors, seizures and stupor (see Acute poisoning and envenomation, above).

Hypocalcemia may also cause lethargy and anorexia progressing to muscle tremors and seizures.

Hypoglycemia may also be a finding in acute pancreatitis, porto-systemic shunts, hepatic lipidosis, cholangiohepatitis, and overwhelming sepsis, but it is usually a marker of disease rather than a cause of clinical signs.

Treatment

A Somogyi reaction should not be relied upon to rescue a cat from hypoglycemia.

Give **50% dextrose** at 0.5–1.0 ml/kg IV.

If intravenous access is not possible, 50% dextrose (0.5–1.0 ml/kg) or corn syrup (0.25–0.5 ml/kg) PO and rubbed on the gums may be effective, but **glucagon 0.25–1.0 mg IM is superior**. Glucagon must be followed by intravenous dextrose once seizures have stopped and intravenous access is possible.

CENTRAL NERVOUS SYSTEM NEOPLASIA OR INFLAMMATION

Classical signs

- Acute depression and anorexia.
- Stupor, coma, and specific neurological signs.

See main reference on page 795 for details (The Cat With Seizures, Circling and/or Changed Behavior), page 821 (The Cat With Stupor or Coma), page 835 (The Cat With a Head Tilt, Vestibular Ataxia or Nystagmus), page 852 (The Cat With Tremor or Twitching) and page 941 (The Cat With Generalized Weakness).

Clinical signs

Acute meningitis, encephalitis or central nervous system neoplasia may initially be characterized by non-specific signs such as acute onset of anorexia and depression.

Depression may then progress to stupor, coma, behavior change or other specific neurological signs. See The Cat With Stupor or Coma, The Cat With Seizures, Circling and/or Changed Behavior, and The Cat With a Head Tilt.

- Acute depression may be the only finding in a cat in the prodromal phase of clinical rabies, but fever spikes are typical. The prodromal phase typically only lasts one to two days in cats before proceeding to the furious phase (most often) or the paralytic phase. Rabies is highly unlikely if there is persistent depression and anorexia without the development of other behavior changes or specific neurologic signs.
- Acute depression is a consistent initial sign in pseudorabies (Aujeszky's disease, mad itch), but typically progresses to severe pruritis, voice change and anisocoria with 1–2 days.

Diagnosis

The cat with unexplained acute depression should be carefully examined repetitively for neurological signs.

Differential diagnosis

In the absence of specific neurologic signs, all other causes of acute depression and anorexia should be considered.

If neurologic signs develop, poisoning should be considered.

Treatment

Treat the underlying disease.

In the absence of a specific diagnosis, treatment should be supportive.

HEPATIC ENCEPHALOPATHY

Classical signs

- Disorientation and ptialism.
- Intermittent central nervous system (CNS) signs often associated with eating.
- Usually in young cats (< 1 year).
- Affected cats are often stunted in size.

See main reference on page 588 for details (The Cat With Salivation) and page 425 (The Yellow Cat or Cat With Elevated Liver Enzymes).

Clinical signs

Porto-systemic shunts usually cause signs in young cats that are small in size. Copper-colored irises may be evident. Intermittent central nervous system signs including disorientation and behavioral changes, and occasionally seizures occur, often associated with eating. Ptyalism may occur alone or associated with neurological signs. Occasionally urethral obstruction results from ammonium biurate uroliths. Prolonged post-anesthetic recovery may be reported.

Mature cats with hepatic lipidosis and cholangio-hepatitis typically have anorexia, weight loss, vomiting and icterus. In severe cases, collapse, disorientation and ptyalism may occur.

Diagnosis

Elevated plasma ammonia level confirms hepatic encephalopathy; but a normal fasting concentration does not rule it out.

Porto-systemic shunts have variable hematologic and biochemical findings, which may include low normal to low MCV, low urea, albumin, glucose and cholesterol concentrations, and elevated globulin and bile acid concentrations. Imaging may reveal a small liver and the shunt. Definitive diagnosis may require an exploratory laparotomy.

Hepatic lipidosis and cholangiohepatitis are typically associated with increased ALT and/or ALP. A disproportionate elevation of ALP compared to ALT and GGT is suggestive of hepatic lipidosis. Elevations in serum bile acids in the absence of cholestasis confirm the presence of liver dysfunction. Coagulation abnormalities may be present. Imaging may reveal an enlarged, hyperechoic liver. Definitive diagnosis relies on liver biopsy.

Differential diagnosis

The main differential diagnosis for ptyalism is oral cavity ulceration.

The main differential diagnoses for icteric depressed cats are acute pancreatitis and diabetic ketoacidosis.

The main differential diagnosis for transient depression and disorientation is poisoning.

Treatment

Hepatic encephalopathy treatment includes lactulose, enema, lactulose retention enema, correction of hypokalemia, and antibiotics (neomycin, metronidazole, ampicillin/amoxicillin).

Porto-systemic shunts can often be reduced or closed by partial or complete surgical ligation or placement of an ameroid constrictor.

Hepatic lipidosis requires nutritional support.

Cholangiohepatitis treatment includes nutritional support, antibiotics if an organism is cultured, and corticosteroids if lymphocytic-plasmacytic inflammation is evident on biopsy.

HYPERNATREMIA

Classical signs

- Coma, twitching, seizures.

Pathogenesis

Hypernatremia results from excessive sodium intake and/or inadequate water intake and/or excessive water loss.

Hypernatremia in cats is most likely to occur in critically ill cats receiving sodium-rich fluids that have concurrent sodium-poor water loss (e.g. diabetes mellitus, head-trauma induced central diabetes insipidus).

Clinical signs

Acute progressive lethargy in a critically ill cat.

May progress to coma, twitching, and seizures.

Dehydration.

Weak pulse, prolonged capillary refill time and hypothermia may be present.

Diagnosis

Serum sodium level > 160 mmol/L.

Ruling out other causes of depression and anorexia.

Urine specific gravity < 1.035 may indicate diabetes insipidus.

Differential diagnosis

Other causes of depression and anorexia related to the primary disorder causing critical illness.

Treatment

Sodium-poor intravenous fluids. Hypernatremia should be corrected at the same rate at which it developed, i.e. serum sodium concentration should be lowered rapidly in acute hypernatremia, and slowly in chronic hypernatremia. Overly rapid correction of hypernatremia will result in signs similar to hyponatremia.

tremia. Idiogenic osmols form in hypernatremia to protect the brain against dehydration; these osmols result in cerebral edema if serum sodium concentration is lowered too quickly. Because the rate at which hypernatremia developed is often not known, a general recommendation is to **lower serum sodium level by 1–2 mmol/L/h**.

Assess percent dehydration and replace using 0.9% saline over 4–8 hours if acute dehydration and over 8–12 hours if chronic dehydration.

Once the cat is rehydrated, **calculate free water deficit**:

Deficit (L) = $0.6 \times \text{body weight (kg)} \times ([\text{Na} \div 140] - 1)$.

Give this volume over 12–24 h if the cat's mentation is normal, and over 24–48 h if mentation is abnormal.

Give furosemide 0.5 mg/kg IV if hypernatremia persists and the cat is normally hydrated.

Consider antidiuretic hormone therapy (e.g. DDAVP) if there is diabetes insipidus (see *The Cat With Polyuria and Polydipsia*, page 231).

Prognosis

The prognosis for hypernatremic cats with head trauma is poor; the prognosis for uncomplicated correction of hypernatremia with other disorders is good and overall prognosis is determined by the underlying disorder.

ESOPHAGEAL FOREIGN BODY AND INFLAMMATION

Classical signs

- Regurgitation.
- Anorexia and depression.

See main reference on page 616 for details (*The Cat With Signs of Regurgitation (Acute or Chronic)*).

Clinical signs

Cats with esophageal foreign bodies or esophagitis (e.g. secondary to treatment with tetracyclines) are typically presented for **regurgitation** (or vomiting as perceived by the owner), **dysphagia** or **gagging**. However, this may be intermittent, so that only non-specific signs such as

anorexia and depression are reported by the owners. Anorexia and depression may be due to esophageal pain.

Diagnosis

Diagnostic imaging or endoscopy is required to identify foreign material. The latter is required to identify esophagitis.

PRIMARY ANOSMIA

Classical signs

- Anorexia.

Clinical signs

Anorexia and cat may sniff less.

Diagnosis

History of olfactory tractotomy for inappropriate elimination behavior.

No reaction to placement of noxious stimuli in front of nose.

FELINE LEUKEMIA VIRUS INFECTION

Classical signs

- Fever.
- Signs of secondary infections, hematologic disorders, or neoplasia.

Clinical signs

Feline leukemia virus infection usually causes fever; anemia and other hematologic disorders; immunosuppression leading to secondary infections; lymphoma, myeloproliferative disorders, and fibrosarcomas and neurologic disorders.

Occasionally the only sign of infection is acute depression, anorexia and dehydration.

Diagnosis

A feline leukemia virus test should be considered in the work-up of a cat with acute depression and anorexia.

PART 6

Cat with weight loss or chronic illness

17. The cat with weight loss and a good appetite

Daniëlle Gunn-Moore and James B Miller

KEY SIGNS

- Thin cat eating well.
- Weight loss and a good appetite.

MECHANISM?

- Weight loss with a good appetite occurs when the cat is unable to gain sufficient nutrition from its diet.

WHERE?

- Diseases involving many body systems can lead to weight loss with a good appetite.

WHAT?

- In older cats the most common causes of weight loss with a good appetite are hyperthyroidism, diabetes mellitus and inflammatory bowel disease. In younger cats, inflammatory bowel disease and intestinal parasites are the most common causes.

QUICK REFERENCE SUMMARY

Diseases causing weight loss and a good appetite

METABOLIC

- **Hyperthyroidism*** (p 304)**

Usually seen in cats greater than eight years of age. Weight loss, good appetite, tachycardia, restlessness and/or intermittent vomiting and diarrhea.

- **Diabetes mellitus** (p 310)**

Usually seen in older cats. Increased risk in fat cats and some Burmese. History of polyuria, polydipsia and polyphagia, plus variable weight changes.

- **Acromegaly (p 322)**

Rare condition of older, typically males, cats. Slow increase in body size, especially affecting the head and feet. Usually diabetic; so polyuric, polydipsic and polyphagic.

- **Hyperadrenocorticism (p 324)**

Rare condition of middle-aged and older cats. Poor coat condition and pot-bellied appearance. Often diabetic; so polyuric, polydipsic and polyphagic.

- **Glomerulonephritis (protein-losing nephropathy) (p 326)**

Weight loss with a good appetite may be seen early in disease, accompanied by ascites, subcutaneous edema, polydipsia and polyuria, \pm vomiting and diarrhea.

NEOPLASTIC

- **Alimentary lymphosarcoma* (p 317)**

Usually older cats. Weight loss with variable appetite. History of acute, or more commonly, chronic vomiting and/or diarrhea.

NUTRITIONAL

- **Inadequate nutrition** (p 316)**

Weight loss with a good appetite, few other signs. History of inadequate or inappropriate diet. Seen in kittens from poor conditions or cats that have recently changed environment.

INFLAMMATORY

- **Inflammatory bowel disease*** (p 307)**

Can affect any age but most typically seen in middle-aged cats. Any combination of chronic weight loss, vomiting and/or diarrhea.

- **Chronic pancreatitis/exocrine pancreatic insufficiency* (p 318)**

Typically seen in middle-aged to older cats with a history of episodic anorexia, lethargy, vomiting and/or diarrhea. If also diabetic; polyuria and polydipsia.

- **Lymphocytic cholangiohepatitis* (p 320)**

Typically seen in younger to middle-aged cats. Often polyphagic, may have mild generalized lymphadenopathy. May be associated with inflammatory bowel disease.

INFECTIOUS

- **Intestinal parasites** (p 314)**

Usually seen in young cats from poorly cleaned multi-cat environments. Weight loss or failure to gain weight, usually with a good appetite, may have diarrhea and/or vomiting.

INTRODUCTION

MECHANISM?

While weight loss is a common presenting problem in feline medicine, weight loss in association with a good appetite is seen less frequently. This occurs when the cat is unable to gain sufficient nutrition from its diet.

This can result from **inadequate nutrition** (feeding insufficient food or a diet of inadequate nutritional content), or **an inability to derive nutrient from the diet**. The latter can result from:

- **Inability to digest or absorb nutrients** (malassimilation syndromes), e.g. parasitism, inflammatory bowel disease, pancreatitis/exocrine pancreatic insufficiency, lymphocytic cholangiohepatitis, alimentary lymphosarcoma or lymphangectasia.
- **Inability to utilize absorbed nutrients** – as seen with diabetes mellitus, or endocrinopathies which result in diabetes, e.g. acromegaly or hyperadrenocorticism.
- **Increased utilization of absorbed nutrients** (hypermetabolic states), e.g. hyperthyroidism, pregnancy, lactation, congestive heart failure, excessive physical activity or neoplasia.
- **Excessive nutrient loss**, e.g. diabetes mellitus, protein-losing nephropathy or lymphangectasia.

WHERE?

Weight loss with a good appetite may be seen when the **intestinal tract is unable to digest and/or absorb food** (malassimilation syndromes, hyperthyroidism), **the body tissues are unable to utilize nutrition** that has been absorbed (diabetes mellitus), the **body loses essential nutrients** through the **intestines or kidneys** (diabetes, protein-losing nephropathy, lymphangectasia), or the **demands of the body have been raised** beyond the level that the diet can supply (hyperthyroidism, pregnancy, lactation).

Weight loss with a good appetite **indicates a gastrointestinal problem, renal problem or a problem-involving tissue metabolism** (either metabolic demands have increased, or the tissues are unable to utilize nutrients).

WHAT?

The **most common cause** of weight loss with a good appetite is **hyperthyroidism**. Other common causes include various **malassimilation syndromes** including combinations of inflammatory bowel disease, pancreatitis and/or lymphocytic cholangiohepatitis (in combination termed “**triaditis**”). **Intestinal parasitism, diabetes** and **alimentary lymphosarcoma** are seen reasonably commonly, while hyperadrenocorticism, acromegaly, protein-losing nephropathy and lymphangiectasia are seen very rarely.

Disorders which may occasionally present with weight loss with a good appetite, but more typically present with a poor appetite are discussed elsewhere, e.g. congestive heart failure, congenital portosystemic shunts.

DIAGNOSIS

Initial diagnostic evaluation should include history, physical examination, hematology, serum biochemistry, serum thyroxin if > 8 years of age, urinalysis, and fecal examination for parasites.

Age of cat is an important consideration. **Younger cats** are more likely to develop parasitism, inappropriate nutrition, or protein-losing nephropathy. **Middle-aged cats** have a greater risk of hyperadrenocorticism, while **older cats** develop hyperthyroidism, diabetes mellitus, alimentary lymphosarcoma or acromegaly. Inflammatory bowel disease can affect cats of any age, but most typically affects middle-aged or older individuals.

The history is essential. Determine the cat’s environment (inside or outside, competition over food supplies), what and how much is fed, whether nutritional requirements have changed (pregnancy, going outside in cold weather), or whether diabetogenic drugs have been given.

Other clinical signs are important to consider. These signs may result from underlying or concurrent disease processes. **Polyuria and/or polydipsia** are suggestive of an endocrinopathy or protein-losing nephropathy. **Vomiting and/or diarrhea** are suggestive of enteric disease, hyperthyroidism, lymphocytic cholangiohepatitis or protein-losing nephropathy. **Feces becoming bulky or fatty** suggest malassimilation syndromes or hyperthyroidism, and increased **aggression or restlessness** are suggestive of hyperthyroidism.

Careful physical examination is essential for diagnosis. Careful palpation of the ventral cervical region is required to detect thyroid mass(es). **Thorough abdominal palpation** is essential to detect anterior **abdominal pain** (pancreatitis, hepatopathy), **liver enlargement** (diabetes-associated hepatopathy, hyperadrenocorticism, lymphocytic cholangiohepatitis), **thickened bowel loops** (inflammatory bowel disease, alimentary lymphosarcoma), **mesenteric lymphadenopathy** (alimentary lymphosarcoma, occasionally eosinophilic or suppurative inflammatory bowel disease), **ascites** (lymphocytic cholangiohepatitis, protein-losing nephropathy) or an **enlarged uterus** (late pregnancy). **General physical examination** is important to detect mild **generalized lymphadenopathy** (lymphosarcoma, lymphocytic cholangiohepatitis), an **ill-kept coat** (hyperthyroidism), a **greasy coat** (exocrine pancreatic insufficiency), **alopecia and thin skin** (hyperadrenocorticism), **subcutaneous edema** (protein-losing nephropathy), or **extremities that appear disproportionately enlarged** (acromegaly).

DISEASES CAUSING SIGNS OF A THIN CAT WITH A GOOD APPETITE

HYPERTHYROIDISM***

Classical signs

- Older cats (usually > 8 years).
- Progressive weight loss, often with a ravenous appetite.
- May also show restlessness, a lack of grooming, vomiting \pm diarrhea, \pm polyuria/polydipsia.

Pathogenesis

99% of cases of hyperthyroidism result from benign nodular hyperplasia/adenoma.

- Disease results from autonomous secretion of thyroxine (T4) and triiodothyroxine (T3). Negative feedback on the pituitary suppresses release of thyroid-stimulating hormone (TSH) and normal thyroid tissue atrophies.
- **Cause is unknown** but may involve diet (iodine content, frequent changes, food additives), environmental causes (in cat litter, toxins, pollution,

exposure to allergens), genetic mutation, abnormal immune and/or hormonal responses.

- **70% of the cats have both thyroid glands affected.**

1% of cases result from mild to moderately malignant thyroid carcinoma.

GIT signs may result from polyphagia, malabsorption or intestinal hypermotility.

Polyuria/polydipsia may result from diuretic effects of T4, increased renal blood flow, associated renal insufficiency or compulsive polydipsia.

Cardiac effects result from a high output state, induced, in part, by a demand for increased tissue perfusion to meet the needs of increased tissue metabolism. Cardiovascular changes include left ventricular hypertrophy, left atrial and ventricular dilation, increased myocardial contractility, and decreased peripheral vascular resistance. Other contributors are the direct effect of thyroid hormones on cardiac muscle and the nervous system.

Associated cardiac hypertrophy may cause congestive heart failure with tachycardia, a gallop rhythm, systolic murmurs, dyspnea, apathy, hindlimb weakness due to aortic thromboemboli or collapse.

Associated hypertension may be seen as ocular hemorrhage, or may cause clinical signs associated with cerebrovascular accidents, dementia and/or renal failure.

- Up to 85% of cats with hyperthyroidism may develop systemic hypertension, either initially or even some time after apparently successful treatment.

Clinical signs

Hyperthyroidism is the most common endocrinopathy in cats; affecting ~1 in 300 pet cats.

It is seen mainly in older cats (>8 years of age); it is occasionally seen in cats as young as 4 years, and has even been documented in an 8-month-old kitten.

There is no sex or breed predisposition, but Siamese cats appear to be under-represented.

Most cats have a history of weight loss and polyphagia.

Weight loss usually occurs over several months.

10–20% of cats will present with signs of inappetence with weight loss.

Cats may have a **history of restlessness, aggression and a lack of grooming.**

Cats may also show **tachycardia ± a gallop rhythm, vomiting and/or diarrhea** (feces may become bulky) and/or **polyuria/polydipsia.**

GIT signs may result from polyphagia, malabsorption or intestinal hypermotility.

Polyuria/polydipsia may result from diuretic effects of T₄, increased renal blood flow, associated renal insufficiency or compulsive polydipsia.

Associated cardiac hypertrophy may cause congestive heart failure with tachycardia, a gallop rhythm, systolic murmurs, dyspnea, apathy, hindlimb weakness due to aortic thromboemboli or collapse.

Associated hypertension may be seen as ocular hemorrhage, or may cause clinical signs associated with cerebrovascular accidents, dementia and/or renal failure.

- Up to 85% of cats with hyperthyroidism may have signs of systemic hypertension.

Many hyperthyroid cats are presented for their routine vaccination with no owner complaints.

Diagnosis

Hyperthyroidism should be suspected when any older cat presents with weight loss, and especially when the weight loss is associated with a good appetite. However, inappetence should not rule out hyperthyroidism.

Physical examination usually reveals a thyroid nodule on either or both sides of the trachea in the ventral cervical region (80–90%).

Tachycardia and/or a gallop rhythm are usually present.

Liver enzymes (ALT and/or SAP) are often raised. Hepatopathy may be secondary to a direct toxic effect of thyroid hormones, hepatic lipidosis, malnutrition or hepatic hypoxia resulting from cardiac failure.

Definitive diagnosis is based on detecting elevated serum concentrations of total T₄ (and/or T₃).

Some cats with hyperthyroidism have a T₄ concentration that is within the normal range. This may be due to:

- Early or mild hyperthyroidism.

- T₄ concentrations varying during the day.
- Severe systemic illness causing a reduction in T₄ (euthyroid sick syndrome).

If hyperthyroidism is suspected despite a high normal T₄ concentration:

- **Retest the cat** – either immediately, or in a few weeks time.
- **Check free T₄** – by equilibrium dialysis.
- **T₃ suppression test** – Collect blood sample, give 7 × 25 mg doses of T₃ PO every 8 h, then collect blood 2–4 h after the 7th dose (i.e. on day 3). An increase in T₃ concentration confirms successful medication. Suppression of T₄ concentration (below 50% of baseline, <20 nmol/l [1.5 ug/dl]) does not usually occur in hyperthyroid cats.
- **Thyrotropin-releasing hormone (TRH) stimulation test** – Collect blood, give 0.1 mg/kg TRH IV, then collect second blood sample 4 hours later. Assess both samples for serum T₄ concentration. Stimulation to > 50% does not occur in hyperthyroid cats. Side effects of TRH include transient salivation, vomiting, tachypnea and defecation.
- **Thyroid-stimulating hormone (TSH) response test** – The usefulness of this test has been questioned and TSH may be difficult to obtain.
- **Nuclear isotope scanning** detects hyperactive thyroid tissue. Procedure is relatively safe and simple to perform, but requires access to a licensed facility, which is not always available.
- **Trial course of anti-thyroid therapy** (see below) of approximately 30 days is not without risk of toxic side effects.

Differential diagnosis

These include most other causes of weight loss with a good appetite. However, hyperthyroidism typically occurs in older cats and presents with polyuria, polydipsia, vomiting and/or diarrhea, so diabetes, renal disease, malassimilation syndromes (including IBD, pancreatitis/exocrine pancreatic insufficiency, and early intestinal lymphosarcoma), acromegaly and hyperadrenocorticism are perhaps the most important differentials.

Treatment

Hyperthyroidism can be treated medically, surgically, or with radioiodine (¹³¹I).

Prior to deciding which treatment to use the cat should be assessed for concurrent disease, especially renal disease, systemic hypertension and heart disease, all of which occur commonly in association with hyperthyroidism.

- The interplay between systemic blood pressure and renal function is complex. While **systemic hypertension is detrimental to kidney function**, a sudden fall in blood pressure or a reduction in glomerular filtration rate (e.g. associated with a sudden fall in T4) can exacerbate renal dysfunction by causing a sudden fall in renal blood flow. **Changes in T4 need to be made gradually** so there are no sudden changes in renal blood pressure.
- By maintaining renal blood pressure, hyperthyroidism can mask low-grade renal insufficiency. It is essential to check serum urea and creatinine concentrations and urine specific gravity prior to inducing irreversible reduction of T4 (i.e. by thyroidectomy or I^{131} treatment). A short course of medical therapy may reveal the presence of masked renal insufficiency.

Medical therapy tends to be given to stabilize the cat prior to surgical treatment, to check for masked renal disease prior to thyroidectomy or I^{131} treatment, or when neither I^{131} nor surgery are possible.

Methimazole and carbimazole block T3 and T4 synthesis. It takes 1–3 weeks before a significant decrease in T4 concentrations occur after beginning treatment.

- Carbimazole is broken down to methimazole in vivo. Bioavailability and volume of distribution of methimazole is highly variable between cats.
- Dose for both is 1.25–5.0 mg PO every 8–24 hours initially, reducing to every 12–24 hours. If the cat has concurrent renal insufficiency, start with a low dose and monitor renal values as dose is gradually increased. Preliminary studies with topical transdermal applications show promise.
- When cat and owner compliance is good, the successful response rate is approximately 85% with medical treatment.
- **Poor compliance results** from:
 - The need for **frequent medication**.
 - The need for **frequent blood samples** to look for possible side effects. Blood dyscrasias occur in 2–10% of cats and include eosinophilia, lymphocytosis, leukopenia, thrombocytopenia

and/or agranulocytosis, hepatopathy and, rarely, immune-mediated hemolytic anemia (IMHA).

- **Frequent side effects.** Up to approximately 20% of cats develop anorexia, vomiting, lethargy, hepatopathy \pm jaundice, cutaneous reactions (typically pruritus of the head and neck), bleeding tendencies or, very occasionally, myasthenia gravis, or IMHA.
- Mild side effects may resolve despite continued treatment.

Other medical therapies include:

- **Atenolol** (selective β_1 adrenoceptor blocking agent) may be added to reduce tachycardia, arrhythmias and hypertension (6.25 mg/cat PO every 24 hours).
- **Stable iodine** helps to decrease T3 and T4 synthesis and reduce thyroid gland vascularity, but the effect can be transient and inconsistent. Give potassium iodide 30–100 mg/cat/day PO for 10–14 days prior to surgery using 100 g potassium iodide/100 ml solution, or potassium iodate ~20 mg/cat every 12 hours PO.
- **Calcium or sodium ipodate** is a radiopaque iodine agent that reduces T3 concentrations. Its effect can be transient, and it may be difficult to obtain (15 mg/kg PO every 12 hours).

Surgical thyroidectomy. The success depends on the stability of the patient, the expertise of the surgeon (a bilateral thyroidectomy is usually performed), and the expertise of the anesthetist (e.g. do not give atropine).

- Successful response rate is > 95%. Ectopic overactive thyroid tissue is a cause of failure, as it is usually missed at surgery.
- Reduce the risks of surgery by making the cat euthyroid prior to surgery (see Medical therapy, above).
- Surgical risks include anesthetic risks in older patients (often with concurrent renal \pm cardiac disease), iatrogenic damage to parathyroid tissue leading to transient or permanent hypocalcemia, or to the local nerves leading to laryngeal paralysis or Horner's syndrome.

Radioiodine (I^{131}) is taken up by and destroys the overactive thyroid tissue, but spares the normal tissue.

- Successful response rate is > 95%, but it may take a few weeks, or occasionally months, for the normal tissue to recover function.

- Availability of facilities and length of stay in hospital varies from 2 days to 4 weeks depending on country and state, as it often depends on the interpretation of radiation safety laws.
- Side effects are few and include transient dysphagia or dysphonia, or permanent hypothyroidism (~2%).

Prognosis

Without treatment, cats with hyperthyroidism will usually die of concurrent renal disease, heart disease, liver disease or systemic hypertension.

With **treatment, prognosis varies from very good to guarded**, dependent on the presence of heart disease, renal disease and systemic hypertension, whether or not any damage has become permanent prior to treatment of the hyperthyroidism, and which treatment options are available.

Prevention

Since it is not known what triggers the development of hyperthyroidism, it is currently not possible to prevent its onset.

INFLAMMATORY BOWEL DISEASE***

Classical signs

- Any age, sex or breed of cat.
- Any combination of progressive weight loss, vomiting and/or diarrhea.

Pathogenesis

Inflammatory bowel disease (IBD) is a group of chronic idiopathic gastrointestinal tract disorders that are characterized by **infiltration with inflammatory cells**. The infiltration may consist of lymphocytes, plasma cells, neutrophils, eosinophils and/or macrophages, and the inflammation may involve the stomach, small intestine and/or colon.

The etiology is probably multifactorial and appears to involve host hypersensitivity responses to antigens within the bowel lumen or mucosa. Suspected antigens include food, bacteria, parasites or self-antigens.

- The hypersensitivity may result from a primary, possible genetic, disorder, or arise secondary to mucosal injury incurred by a number of different disorders including bacterial, viral, protozoal or fungal infections, bacterial overgrowth, food hypersensitivity, drug administration, metabolic disease, neoplasia, pancreatitis or cholangiohepatitis.
- Regardless of the initial cause of the hypersensitivity, it results in **increased mucosal permeability** which allows **luminal antigens to cross the mucosa**, leading to inflammation and further mucosal damage.

Clinical signs

IBD can occur in any age, sex or breed of cat. While it is most commonly seen in middle-aged to older cats, a third of cases occur in cats of less than 2 years of age. Some purebred cats may be predisposed.

Clinical signs include any combination of progressive weight loss, and/or vomiting and/or diarrhea.

Weight loss may result from malabsorption and/or inappetence (which usually occurs late in the disease). Not all cases show significant enteric signs, so some cats present with only weight loss and a variable appetite.

Vomiting is often intermittent and may occur every few days to weeks, often accompanied by anorexia and lethargy. Vomiting is rarely associated with feeding. It may contain froth, bile-stained fluid and food or, occasionally, blood.

Diarrhea can vary in consistency from almost well formed to liquid. Some cats may show evidence of large bowel involvement with mucus and/or blood and increased frequency.

Clinical signs may wax and wane, and tend to vary with the type and severity of inflammation.

Physical examination is often unremarkable, but may reveal a thin cat, palpably thickened intestines, enlarged mesenteric lymph nodes and/or abdominal discomfort.

Concurrent pancreatitis and/or cholangiohepatitis may result in jaundice, a palpably enlarged liver and/or anterior abdominal discomfort.

When lymphangectasia is present, severe hypoproteinemia may lead to subcutaneous edema and/or ascites.

Diagnosis

Before a diagnosis of IBD can be made, all other causes of enteropathy must be ruled out. These include bacterial enteritis (*Helicobacter* spp., *Salmonella* spp., *Campylobacter* spp., *Clostridium perfringens*, *E. coli*), intestinal parasites (helminths, cestodes, protozoans), fungal enteritis, GI neoplasia (lymphosarcoma, adenocarcinoma) and viral enteritis (feline leukemia virus, feline immunodeficiency virus, feline coronavirus, feline panleukopenia). **IBD is diagnosed by documenting histopathological evidence of GI inflammation and excluding all of other causes of it.**

Baseline laboratory tests include hematology, serum biochemistry (including total T4 concentration in older cats), FeLV and FIV tests, urinalysis, fecal culture for pathogenic bacteria and a full examination for fecal parasites.

- Performing all of these investigations can be expensive so the investigation should, where possible, be tailored to the patient, and many clinicians start with a dietary trial (see below).
- Since the investigations are being performed to rule out other causes of enteropathy they are frequently unremarkable. However, IBD may be associated with a number of non-specific findings:
 - **Hematology** may reveal an inflammatory response; neutrophilia, eosinophilia, lymphopenia or monocytosis. Microcytic anemia may result from chronic blood loss associated with severe IBD.
 - **Hyperglobulinemia** may result from chronic inflammation. **Panhypoproteinemia** may be seen with severe protein-losing enteropathies.
 - **Increases in liver enzymes** may result from associated hepatic inflammation (see below).

Non-invasive screening tests may provide additional information. These include abdominal radiography, ultrasound examination, assessment of serum folate and cobalamine (B12) levels, examination of fecal smears for the presence of undigested fats or starch, fat absorption tests, breath hydrogen analysis and sugar permeability studies (where available).

- **Survey radiographs** tend to be unrewarding, but may reveal gas- or fluid-filled loops of intestines. **Barium studies** may reveal flocculation or persistent adherence of the barium to the mucosa, irregular mucosal surfaces or delayed transit times.
- **Ultrasound examination** may reveal intestinal wall irregularity or echogenicity. It may also be used to examine the mesenteric lymph nodes and other intra-abdominal structures.
- **Serum folate and cobalamin** levels may be reduced because of malabsorption.
- **Serum feline trypsin-like immunoreactivity** (FTLI) and **feline pancreatic lipase immunoreactivity** (fPLI) may be helpful in the diagnosis of exocrine pancreatic insufficiency (EPI) and pancreatic inflammation, respectively.
- **Breath hydrogen analysis and sugar permeability studies** may be used to try to demonstrate malabsorption and/or small intestinal bacterial overgrowth (SIBO)/antibiotic-responsive diarrhea.

A dietary trial should be performed in all except very ill patients prior to more invasive investigation.

- Feed a single highly digestible source of protein for at least 3–4 weeks and see if the clinical signs resolve.

It is inadvisable to carry out treatment trials with antibiotics or corticosteroids prior to making a definitive diagnosis.

- This delays making the correct diagnosis, and may cause complicating intestinal bacterial overgrowth (antibiotics) or potentiate secondary infections (corticosteroids).

Definitive diagnosis requires the collection of intestinal biopsies.

- **Mucosal biopsies** may be collected by endoscopy. Unfortunately, it is not always possible to make a definitive diagnosis from these biopsies, so in some cases, full-thickness biopsies must be collected via laparotomy or laparoscopy.
- IBD often causes no gross mucosal changes, but changes that may be seen include increased granularity and friability, the presence of erythema, ulcerations, and/or mass lesions and poor distensibility.
- **Multiple biopsies should be taken** since the inflammatory infiltrates may not be spread diffusely throughout the gastrointestinal tract.

- When performing laparotomy or laparoscopy it is advisable to **collect biopsies of the mesenteric lymph nodes, liver** and, if possible, **pancreas**, as well as from **multiple intestinal sites**. Part of the liver and/or mesenteric lymph node biopsy, and bile aspirated from the gall bladder can be sent for culture.
- Collection of **duodenal aspirates for quantitative culture** may help to determine the bacterial load of the small intestine.
- **Gastric biopsies** should always be assessed for the presence of *Helicobacter* spp.
- **Histopathology reveals inflammatory cells infiltrating the lamina propria**, plus variable degrees of epithelial abnormality and glandular distortion.
 - **Lymphocytic-plasmacytic IBD** is the most common form of IBD in the cat. It may occasionally progress to intestinal lymphosarcoma.
 - **Granulomatous enterocolitis** is less common, and often presents as GI obstruction.
 - **Eosinophilic IBD** is rare. It may be associated with eosinophilia and/or hypereosinophilic syndrome where tissues other than the GI tract are also affected.
 - **Suppurative IBD** is usually associated with an infectious etiology.
 - Other forms also exist and many cats have mixed populations of inflammatory cells.
- Unfortunately, when lymphangectasia is present, severe hypoproteinemia may render these patients a poor anesthetic and surgical risk. It may therefore be necessary to make a presumptive diagnosis based on the presence of diarrhea, panhypoproteinemia and lymphopenia in the absence of finding other diseases on hematology, serum biochemistry, fecal evaluation, abdominal ultrasound examination \pm mucosal biopsies.

Differential diagnosis

These include most of the other causes of weight loss with a good appetite. However, since cats with IBD usually develop vomiting and/or diarrhea, **other causes of enteropathy, cholangiohepatitis, pancreatitis, hyperthyroidism and the other malassimilation syndromes** (including alimentary lymphosarcoma) should be considered as important differentials.

Treatment

The basic aims of treatment are to remove the source of antigenic stimulation and to suppress the inflammatory response within the GI tract.

- **Treatment typically involves dietary management, \pm metronidazole, \pm prednisolone.**
- Treatment should be tailored to each patient.
- Relapses warrant critical reassessment of the case, and often require repeated intensification of treatment and/or the addition of more potent immunosuppressive drugs.

The diet should contain a single highly digestible source of protein, ideally that the cat has not eaten before.

- The diet should preferably contain few food additives, be gluten-free, lactose-free, low residue, not too high in fat, and adequately supplemented with vitamins and minerals, especially B vitamins and potassium.
- High-fiber diets may help when the large bowel is affected.
- No other foods should be fed concurrently.
- During the **initial phase of treatment**, when the bowel is recovering, it may be preferable to **feed either a home-cooked diet, a “sacrificial protein”** which the cat will then not be fed again, or **protein hydrolysate** which has reduced molecular weight protein and is supposed to be less antigenic. This should be fed for 1–2 months, after which time the cat can then be fed a commercial “hypoallergenic” diet, or further protein sources can be gradually reintroduced. If feeding homemade diets long-term, great care should be taken to ensure they are balanced.

Metronidazole often forms the mainstay of treatment. Its effect against **anaerobic bacteria** helps to reduce secondary bacterial overgrowth. It is also effective against **protozoa** (e.g. *Giardia* spp.), has positive effects on **brush border enzymes levels**, and is believed to **alter the immune function** of the GI tract, perhaps by altering neutrophil chemotaxis and inhibiting cell-mediated immunity. Administer 7.5–15 mg/kg PO q 8–12 hours for 2–4 weeks, then taper gradually over 1–2 months. Some authors suggest that it is inadvisable to give very prolonged courses.

Immunosuppressive agents:

- **Immunosuppressive doses of corticosteroids** are usually required. Administer prednisolone 2–4 mg/kg q 12–24 hours PO, then taper over 1–3

months and maintain on every other day doses, if needed. Use of budesonide (1 mg/cat PO q 24 hours) instead of prednisolone may help to reduce systemic signs of corticosteroid administration.

- Other immunosuppressive agents may be considered. While they all have potential side effects and warrant regular monitoring **chlorambucil** (2–5 mg/m² PO up to once every 48 h) is often very well tolerated. Other less favorable options include **cyclophosphamide** (50 mg/m² PO up to four times a week), **cyclosporine** (0.5–8.5 mg/kg every 12–24 hours, indefinitely) or, in the cases of **colonic disease**, **sulfasalazine** (10–20 mg/kg/day PO for 7–10 days).

Supportive therapies are often recommended. However, few have been assessed using controlled studies in cats.

- **Tylosin** may be effective for its antibiotic actions as well as other, as yet undefined, effects (5–20 mg/kg every 6–12 hours PO).
- **Motility modifiers** may give short-term palliative relief in cases of very watery diarrhea (**loperamide** 0.04–0.2 mg/kg every 8–12 hours PO).
- **Metoclopramide** may be useful for its anti-emetic and prokinetic effects (0.2–0.5 mg/kg PO up to four times a day, being given just prior to feeding, or as a constant IV infusion 1–2 mg/kg over 24 hours).
- **Cisapride** is a good prokinetic, but it is now more difficult to obtain (0.3–1.0 mg/kg every 8–12 hours PO).
- **Cobalamin and folate** may be needed as they are often reduced by malabsorption (cobalamin 125–250 µg/week SC or IM for 6–8 weeks then q 2–4 weeks [50–100 µg/cat/day PO]; folate 0.5–1.0 mg/cat/day PO for 1 month).
- **Vitamin K1** is often required because fat malabsorption results in poor absorption of fat-soluble vitamins like vitamin K, and this can result in abnormal hemostasis (0.5 mg/kg/day SC for 3–4 days, then once weekly).
- **Glutamine** may be given as an energy source for the GI mucosal cells (250–5000 mg/cat/day PO, indefinitely).
- **Lactobacillus acidophilus** may be given as a probiotic to help restore intestinal flora (50–500 M organisms/cat/day PO until feces return to normal).
- Various nutritional supplements may be given for their potential anti-inflammatory properties. These

include **vitamin E** (50–200 IU/cat/day PO), **vitamin A** (1000–5000 IU/cat/day PO), **vitamin C** (50–80 mg/kg/day PO), **zinc** (7.5 mg/cat/day PO), and **N-acetyl glucosamine** (125–1500 mg/cat/day PO).

Prognosis

The prognosis depends on the nature and severity of the GI infiltration, and the presence of concurrent and/or associated disease, such as pancreatitis or cholangiohepatitis. In general, the prognosis for control is reasonably good, but the condition cannot be cured, and many cats will need treatment for the rest of their life.

Prevention

Since it is not known what triggers IBD to develop, it is not currently possible to prevent its onset.

DIABETES MELLITUS**

Classical signs

- Usually seen in older, obese, neutered male cats, and Burmese cats may be over-represented.
- History of polyuria, polydipsia and polyphagia.
- Possible initial weight gain, followed by weight loss.

Pathogenesis

Diabetes results from a variety of mechanisms that cause an absolute or relative lack of insulin.

Classification of diabetes in cats is best made by cause, rather than whether or not they require exogenous insulin.

Type 1 diabetes, previously called juvenile-onset diabetes, is due to **immune-mediated destruction** of pancreatic islet beta cells. It appears to be very rare in cats.

Type 2 diabetes results from impaired insulin secretion, and peripheral resistance to the action of insulin. Hyperglycemia results from decreased glucose uptake in tissues and increased hepatic glucose production. Many cats with diabetes appear to have type 2 diabetes.

- This is often associated with **accumulation of islet-specific amyloid polypeptide** (IAPP), which occurs in aggregates around pancreatic islets. While

IAPP is co-secreted and accumulates as amyloid in normal cats as they age, it accumulates more extensively in cats with diabetes. The accumulation of islet amyloid eventually leads to loss of beta cells.

- **Obesity** is a significant risk factor for diabetes because it results in peripheral insulin resistance.

Other specific types of diabetes, previously called **type 3** or secondary diabetes, results from diseases which destroy beta cells or cause marked insulin resistance, such as:

- Beta cell destruction due to **pancreatitis** or neoplasia. Pancreatitis may be more common than previously thought, as >50% of diabetic cats have evidence of past or current pancreatitis at necropsy (see below under pancreatitis/exocrine pancreatic insufficiency).
- Insulin resistance resulting from unrelated endocrinopathies, e.g. **acromegaly** or **hyperadrenocorticism** (see below under Acromegaly and Hyperadrenocorticism).
- Insulin resistance from **drug administration**, e.g. corticosteroids, megestrol acetate.

60–70% of cats with diabetes require exogenous insulin, at least temporarily.

10–80% of cats with diabetes may lose the need for exogenous insulin. This may result from:

- Correction of ‘**glucose toxicity**’. Prolonged hyperglycemia causes impaired insulin and increased peripheral insulin resistance, termed glucose toxicity. Exogenous insulin administration and reduction of hyperglycemia can result in resolution of this toxicity and return of sufficient insulin secretion to maintain normoglycemia. Long-acting insulin administered twice daily and a low-carbohydrate, high-protein diet appear to facilitate this.
- Reduction of obesity which decreases insulin resistance.
- Resolution of pancreatitis.
- Treatment of underlying disease, e.g. acromegaly or hyperadrenocorticism.
- Removal of diabetogenic drugs, e.g. progestogens (megestrol acetate) or exogenous corticosteroids.

Clinical signs

Diabetes is the second most common endocrinopathy in cats following hyperthyroidism. However, while it used to affect ~1 in 400 pet cats, in Great Britain this has risen to ~1 in 200.

It can occur in any age, sex or breed of cat, but is seen most frequently in older obese neutered male cats.

In Australia, New Zealand and Great Britain, Burmese cats appear to be predisposed, with ~1 in 50 affected.

The most consistent signs are polyuria, polydipsia and polyphagia. In the early stages these signs may go unnoticed by the owners, possibly because of free choice feeding and outdoor toileting habits.

Possible initial weight gain is followed by weight loss.

Urinary tract infections are common, and cats may present with signs of cystitis and/or renal failure.

The coat may be ill kept and a pot-bellied appearance may result from hepatomegaly.

Hindlimb weakness and a plantigrade stance due to diabetic neuropathy are seen quite frequently, but cataracts occur rarely.

Cats are frequently presented only when they become systemically ill with signs of anorexia, vomiting and/or diarrhea, jaundiced and depression (see page 261, The Cat With Depression, Anorexia or Dehydration).

Cases of diabetes that result from chronic pancreatitis may have a history that includes episodes of depression, anorexia, vomiting, diarrhea and/or abdominal pain. Since diabetes is most likely to occur when most of the pancreatic mass has been destroyed, it may be accompanied by signs of exocrine pancreatic insufficiency, evidenced by large quantities of voluminous fatty feces and a voracious appetite (see below under pancreatitis/exocrine pancreatic insufficiency).

Diagnosis

Diagnosis of diabetes mellitus is based on documenting persistent fasting hyperglycemia (> 11 mmol/l [200 mg/dl]) and glucosuria in a cat with appropriate clinical signs (polyuria, polydipsia and polyphagia).

Stress-induced hyperglycemia can result in glucose levels above the renal threshold and hence glucosuria, so a single documentation of these findings is not diagnostic of diabetes.

Allowing the cat to settle down then re-testing it after a few hours may help to determine whether or not the

hyperglycemia is stress-induced. Alternately, the owner can be asked to test the cat's urine for the presence of glucose when it is at home.

Assessing serum fructosamine or glycosylated hemoglobin concentrations will give an indication of how high the blood glucose concentration has been during the preceding 2–3 weeks, and 1–2 months, respectively.

Many cats with diabetes have mild to moderate increases in serum concentrations of cholesterol and liver enzymes. However, more severe changes such as bilirubinemia, acidemia, uremia and electrolyte disorders are unlikely to be present in a cat that is maintaining a good appetite, that is, a cat with uncomplicated diabetes.

Ketones may or may not be present in the urine. Their presence further confirms the diagnosis of diabetes. By the time a cat has developed diabetic ketoacidosis it is unlikely to be maintaining a good appetite (see page 355, The Thin, Inappetent Cat).

Differential diagnosis

These include most of the other causes of weight loss with a good appetite. However, since cats with diabetes develop polyuria and polydipsia, hyperthyroidism and renal disease (particularly protein-losing nephropathies) should be considered as important differentials, as should underlying causes of diabetes, such as acromegaly and hyperadrenocorticism.

Treatment

Treatment consists of various combinations of weight loss, dietary modification, oral hypoglycemic agents and insulin administration.

- While the signs of diabetes in obese cats may resolve with dietary modification alone, most cats need at least temporary medical intervention.
- Oral hypoglycemic agents may be successfully used in some cases of uncomplicated diabetes, or once glucose toxicity has resolved following insulin therapy.
- Insulin is required for most diabetics, at least initially.

Obese cats usually benefit from weight loss. However, this should be done very gradually, restricting

calorie intake to no more than 75% of maintenance requirements and monitoring for changes in insulin requirement. Aim for no more than 2% weight loss per week.

Dietary modification – all cats with diabetes benefit from being fed a well-balanced diet on a regular, consistent, feeding schedule.

- Obese cats may benefit from being fed a low-calorie, high-fiber diet to help them lose weight. However, a low-carbohydrate, high-protein diet may be more beneficial to minimize demand for insulin secretion and minimize post-prandial hyperglycemia.
- Non-obese cats benefit from being fed a low-carbohydrate, high-protein diet. The choice of diet may be affected by concurrent illness, especially renal disease.
- Regular feeding is essential. Cats on once-daily insulin are usually fed just before their morning insulin, then again in the early evening. Cats on twice daily insulin are usually fed just before both insulin injections. Free-choice feeding can be beneficial, but it is important to monitor the amount of food eaten on a daily basis.

Oral hypoglycemic agents act to increase insulin secretion, decrease peripheral insulin resistance, and/or decrease absorption of glucose from the intestinal tract. They may successfully control some non-ketotic, uncomplicated diabetic cats, either temporarily or longer term, particularly when given in conjunction with dietary modification. There are several different types of drugs that have been shown to be at least somewhat effective in cats.

- **Sulfonylureas, e.g. glipizide** (0.25 mg/kg PO q 8–12 h, adjust dose as needed). Side effects include vomiting, anorexia and hepatopathy. Periodic checks for serum biochemistry and hematology are recommended. It may take a few weeks of medication to see the full effect of the drug.
- **Alpha-glucosidase inhibitors, e.g. ararbose** (12.5–25 mg/cat with meals). Side effects include flatulence, soft feces and diarrhea.
- **Transition metals, e.g. vanadium** (0.2 mg/kg/day in food). Side effects include anorexia, vomiting, diarrhea and renal disease; **chromium** (200 µg/cat/day PO). Side effects are unknown.

Insulin: There are a number of different types of insulin, and the choice is often based on personal preference.

- **Most cats with uncomplicated diabetes respond well to once- or twice-daily subcutaneous administration of lente, protamine zinc insulin (PZI) or glargine.**
- The source of the insulin does not appear to be important in cats, as anti-insulin antibodies do not cause many problems.
- The duration of action of the different preparations varies between cats (lente – peak 2–10 h, duration of action 6–16 h; PZI – peak effect at 3–12 h, duration of action 6–24 h; glargine peak effect at 16 h, duration of action > 24 h). In general, PZI and glargine are preferred because of their longer duration of action, improved glycemic control and increased remission rates.
- Start at ~0.25–0.5 IU insulin/kg/per injection, then adjust as necessary, usually by 0.5–1.0 IU per dose. See page 239, Diabetes mellitus in The Cat With Polyuria or Polydipsia, for detailed criteria for adjusting the insulin dose.
- The aim of therapy is to prevent the clinical signs of diabetes and, if possible, maintain blood glucose concentration between 5.5–14 mmol/l (100–250 md/dl).
- It takes 2–3 days for glucose homeostasis to adjust after starting or altering insulin doses. Any changes in dose should therefore be based on recurring effects, not a single urine (or blood) glucose determination. Owners can monitor water intake, urine glucose and ketone levels at home. Ideally glucose will be negative or trace, and ketones will be negative. Glucose curves can also be performed at home by obtaining a drop of blood for glucose testing via ear vein pricking.
 - It is generally recommended that glucose curves be performed every 1–2 weeks until the diabetes is stable. After this time they need be performed less frequently, and the dosage can be adjusted in response to changed clinical signs, \pm serum fructosamine concentrations.
 - The usefulness of glucose curves can be very limited in easily stressed cats that become hyperglycemic whenever they are hospitalized. Anorexic cats may have a lower blood glucose concentration in the hospital than at home when eating.
 - A glucose curve is performed by giving the cat its usual breakfast and dose of insulin, then determining blood glucose level every 1–2 h

during a 12–24 h period. The level of the blood glucose at its nadir (lowest point) determines whether or not the dose of insulin needs to be changed, while the duration of insulin action determines how frequently it needs to be given.

Water drunk measured at home on at least two consecutive days is better correlated with mean blood glucose than is fructosamine concentration. If water intake is < 20 ml/kg on wet food or < 70 ml/kg on dry food, it indicates good glycemic control.

At all times, but especially after altering the insulin dosage, the owners should be warned to look for signs of hypoglycemia (weakness, lethargy, shaking, ataxia, collapse and coma). If these signs occur, the cat's gums should be rubbed with sugar water, jam or honey, and immediate veterinary attention sort.

- **Reasons for apparent insulin resistance** include ineffective insulin (out of date, poor storage, incomplete mixing), poor injection technique, out-of-date urine test strips and insulin overdose leading to insulin-induced hyperglycemia. The Somogyi over-swing occurs when hypoglycemia induces counter-regulatory hormones such as epinephrine and glucagon to induce hyperglycemia. True insulin resistance can result from recent weight gain, infection, acromegaly, hyperadrenocorticism, hyperthyroidism, the administration of diabetogenic drugs, renal or hepatic insufficiency, anti-insulin antibodies or presence of certain types of tumor.

Prognosis

The prognosis is very variable. It depends on the owner's commitment, the presence of concurrent and interacting disease and the ease of glycemic control. If diabetes arises secondary to chronic pancreatitis it can be particularly difficult to control.

Prevention

The risk of developing diabetes can be reduced by not allowing cats to become obese or physically inactive and not giving long courses of diabetogenic drugs. A low-carbohydrate, high-protein diet may also help to reduce the demand on beta cells to produce insulin.

INTESTINAL PARASITES**

Classical signs

- Usually in kittens or young adult cats.
- Weight loss or failure to gain weight, usually with a good appetite.
- Diarrhea and/or vomiting may be present.

Pathogenesis

Intestinal parasites that can infect cats and, at least occasionally, cause weight loss associated with a good appetite include **nematodes** (large ascarid roundworms *Toxocara cati* and *Toxascaris leonina*), and **hookworms** (*Ancylostoma braziliense*, *A. tubaeforme* and *Uncinaria stenocephala*), cestodes (tapeworms *Dipylidium caninum* and *Taenia taeninaeformis*), and **protozoans** (coccidians, *Isospora felis*, *I. rivolta*, and *Cryptosporidium parvum* and flagellates *Giardia lamblia* and *Tritrichomonas foetus*).

***T. cati* and *Isospora* spp. are the most common parasites of kittens. *D. caninum*, *T. taeninaeformis* and *G. lamblia* are the most common parasites of adult cats.**

Adult *T. cati* live in the **small intestine** of cats. Eggs are passed into the environment with the feces to be ingested by other cats, in which they **migrate via the liver and lungs** to the small intestine.

- Larvae can be **transmitted lactationally** to kittens, but prenatal infection does not occur.
- Rodents can act as transport hosts.
- Infection can cause **visceral larva migrans in humans**.

Adult *T. leonina* live in the **small intestine of cats**. Eggs are passed into the environment with the feces to be ingested by other cats where they **mature in the wall of the small intestine**.

- Lactational and prenatal infections do not occur.
- Rodents can act as transport hosts.
- Does not cause **visceral larva migrans** in humans.

The prevalence of **hookworms** varies. *Ancylostoma* spp. **prefer warm, humid climates**, while *U. stenocephala* can live in **colder climates**. Severe hookworm infections are usually seen in warm, moist climates.

- Adults hookworms live in the **small intestine** of cats. Eggs are passed into the environment with the feces and then hatch. They can be ingested by other cats or infect them by **skin penetration**.

- Lactational and prenatal infections do not occur.
- Rodents can act as transport hosts.
- Infection can cause **cutaneous larva migrans in humans**.

Adult **tapeworms** live in the **small intestine** and both *D. caninum* and *T. taeninaeformis* require an **intermediate host** to complete their life cycle. Gravid proglottids containing many eggs are released from the adult worms. They may rupture within the intestines, or remain intact and pass out in the feces and be seen around the cat's anus.

- **Dog and cat fleas are the intermediate hosts for *D. caninum*.**
- **Rodents are the intermediate hosts for *T. taeninaeformis*.**

***Isospora* spp.** live in **intestine** of cats and shed oocysts into the environment via the feces. Sporulated oocysts can be directly ingested by other cats.

- Rodents harboring cyst stages can act as transport hosts.
- Infection and clinical disease is seen most commonly in cats kept in large unhygienic groups.

C. parvum lives in the **small intestine** and sheds oocysts that can either break open to release sporozoites into the intestine resulting in chronic infection or be passed out into the environment where they can remain viable for many months.

- Infection can cause severe disease in immuno-deficient humans.

In cats, ***G. lamblia*** lives in the **jejunum and ileum**. Environmentally resistant cysts are shed in feces, contaminate drinking water or food, and are then ingested by other cats.

- Infection and clinical disease are seen most commonly in **cats kept in large unhygienic groups**.
- *Giardia* spp. do not appear to be host-specific and have a world-wide distribution in tropical and temperate areas.

In cats, ***T. foetus*** lives in the **colon** and sheds flagellated protozoa into the feces. Infection and clinical disease are seen most commonly in young cats kept in large unhygienic groups.

Clinical signs

The prevalence of intestinal parasites varies with geographic location, the level of sanitation, whether or

not the cat is an indoor or outdoor animal, and whether or not it **hunts and eats its prey**.

While infection is common, disease is seen most commonly in **young cats living in poorly cleaned multi-animal environments**.

In these situations, episodes of **disease** may be seen in kittens or cats of similar ages, and may **be preceded by a stressful event** such as an environment change, addition of new cats, or weaning, etc.

Clinical signs vary but typically include **diarrhea and vomiting** (especially with *T. cati* infections), but anorexia is not often present.

- **Ascarids:** In adult cats, infections are usually subclinical, but kittens and young cats may develop vomiting, small bowel diarrhea, a pot-bellied appearance, poor coat condition and a failure to thrive.
- **Hookworms:** Infections cause less disease in cats than dogs, and most disease is seen in young adult cats that live in poorly cleaned, crowded conditions. A heavy infection can cause weight loss, poor coat condition and melena.
- **Tapeworms:** Infections are usually subclinical, but heavy infections can cause anal pruritus, vomiting, diarrhea, weight loss and, occasionally, intestinal obstruction.
- ***Isospora* spp.:** Infections rarely cause clinical disease in adult cats unless they are stressed or immunocompromised. In kittens, infections can range from subclinical through to severe hemorrhagic diarrhea.
- ***C. parvum*:** Infections are usually subclinical, but can also cause acute or chronic small bowel diarrhea, or result in lymphocytic-plasmacytic duodenitis.
- ***G. lambia*:** Infections can be subclinical, or cause acute, chronic or episodic small bowel diarrhea where intestinal malabsorption may result in mucoid, soft, foul-smelling feces.
- ***T. foetus*:** Infections can be subclinical or cause chronic large bowel diarrhea.

Diagnosis

Intestinal parasites should be suspected in any cat, but especially those coming from a poorly cleaned multi-animal environment in a geographic region with a high prevalence of intestinal parasites.

Since some parasites can be transmitted lactationally (*T. cati*), and infections are frequently more severe in young cats, all young cats should be evaluated for intestinal parasites or treated against the common parasites of the region.

Infection rarely causes systemic changes. However, hematology may reveal an eosinophilia and, in severe cases, low serum proteins may be found on serum biochemistry.

With the exception of tapeworm segments, most intestinal parasites are not noticed in the feces.

Fecal floatation techniques are used to diagnose most intestinal parasites (round worms, hook worms and *Isospora* spp.). However, special techniques may be necessary for some parasites, such as *C. parvum* (special stains or, possibly, fecal antigen tests), *Giardia* spp. (direct saline fecal smears or fecal antigen tests), or *T. foetus* (PCR, 'In Pouch' culture or direct saline fecal smears).

Rather than confirming the presence of an infection with fecal tests, a therapeutic trial with a suitable drug may be considered.

Differential diagnoses

Differential diagnoses include most of the other causes of weight loss with a good appetite. **Inadequate nutrition** becomes the most likely differential when there are no signs other than weight loss. However, the variable presence of **gastrointestinal signs is more suggestive of some of the malassimilation syndromes such as IBD, exocrine pancreatic insufficiency, or early alimentary lymphosarcoma**.

Treatment

Roundworms and hookworms may be treated with **pyrantel pamoate** (20 mg/kg/day – two doses need to be given 2–3 weeks apart) or **fenbendazole** (20–50 mg/kg/day usually given for 3–5 days, then repeated 2–3 weeks later) which are both safe and effective in cats.

Tapeworms may be treated with **praziquantel** (3.5–7.5 mg/kg SC, PO) or **epsiprantel** (2.75 mg/kg PO). One dose is effective against *D. caninum* and *T. taeninaeformis*.

***Isospora* spp.** may be treated with **trimethoprim/sulfonamide** (15 mg/kg q 12 hours PO for 10–14 days), plus improved sanitation.

C. parvum can be difficult to treat, but **tylosin** (10–15 mg/kg q 12 hours PO for 28 days, but may need higher doses), **paromycin** (125–165 mg/kg q 12 hours PO for 5 days), or **azithromycin** (7–15 mg/kg q 12 hours PO for 5–7 days) may be effective.

Giardia spp. may be treated with **fenbendazole** (10–30 mg/kg/day PO for 5 days) or **metronidazole** (10–25 mg/kg q 12–24 hours PO for 5–7 days). Repeated treatment may be needed. The possibility of vaccination is currently being studied.

T. foetus may be treated with **ronidazole** (10–30 mg/kg q 12 hours PO for 14 days).

Prognosis

If given the correct treatment, the prognosis for full recovery is usually very good.

Severe infections can occasionally result in permanent intestinal damage and chronic clinical signs.

Resistant *C. parvum*, *Giardia* spp. and/or *T. foetus* infections can occasionally result in chronic disease.

Prevention

Severe infections can usually be prevented by having a good preventative worming policy, giving prompt and effective treatment to any animals found to be infected or carrying these organisms, improving sanitation, and reducing stocking densities.

INADEQUATE NUTRITION**

Classical signs

- Seen in any age, sex or breed of cat, but mostly typically in kittens from poor environments.
- Weight loss, often in association with a voracious appetite.
- Few other signs until terminal stages of malnutrition.

Pathogenesis

Disease due to inadequate nutrition is caused by feeding an inadequate or inappropriate diet.

Clinical signs

Disease can be seen in any age, sex or breed of cat, but is seen **most commonly in kittens from poor environments**.

It may also be seen in **pregnant or lactating queens**, or in **cats that have recently changed environments**: e.g. changed from having a sedentary life in a warm environment, to having an active life in adverse weather conditions.

Affected cats show a **generalized loss of body condition** despite a good appetite.

They are usually bright and active until terminal stages of malnutrition.

There are few specific findings, but severe cases may show lethargy, muscle weakness, depression, diarrhea, neurological signs, blindness and/or ascites.

Diagnosis

Diagnosis is based on resolution of clinical signs following correction of diet. If necessary, rule out other likely differentials.

Differential diagnosis

These include most other causes of weight loss with a good appetite. However, given the lack of other clinical signs, the most likely differentials include **intestinal parasites** and **some of the malassimilation syndromes including IBD, exocrine pancreatic insufficiency, early alimentary lymphosarcoma**.

Treatment

Changing the diet to a suitable well-balanced diet is usually all the treatment that is necessary. Very severe cases may need supportive care and nursing.

Prognosis

Provided that the malnutrition was not too severe or prolonged, the prognosis for recovery is very good.

Prevention

Cats should always be fed appropriate amounts of a suitable well-balanced diet that has been designed to be fed to cats.

ALIMENTARY LYMPHOSARCOMA*

Classical signs

- Usually older cats.
- Anorexia and weight loss, \pm vomiting, \pm diarrhea.
- Early in disease may have a good appetite.

Pathogenesis

Lymphosarcoma is the most common GI neoplasia of cats.

Alimentary lymphosarcoma can occur isolated to the intestine, or as part of multicentric disease.

It can occur as a **focal lesion or diffuse intestinal thickening**. It can arise in the stomach, small intestines and/or colon, and involvement of the ileocolic junction is common.

- Concurrent involvement of mesenteric lymph nodes, liver and/or spleen is not uncommon.

The cells may be lymphocytic, lymphoblastic, of B or T cell origin or, occasionally, large granular lymphocytes or globular leukocytes.

Lymphoblastic lymphosarcoma are more likely than lymphocytic lymphosarcoma to present as an abdominal mass.

Alimentary lymphosarcoma may arise secondary to chronic lymphocytic-plasmacytic IBD.

Clinical signs

Typically seen in older cats of any sex or breed.

History usually includes anorexia and weight loss, but early in the disease the appetite may be good. Vomiting and/or diarrhea may or may not be present.

Some cats develop fever, ascites or jaundice, and at this stage they rarely maintain a good appetite.

Physical examination typically reveals a thin cat with a palpable abdominal mass(es) and/or thickened intestines.

Diagnosis

Hematology may reveal non-specific changes including neutrophilia and lymphopenia. Lymphoblasts may occasionally be seen in the circulation.

Serum biochemistry may reveal panhypoproteinemia and/or hyperbilirubinemia.

Most cats test negative for FeLV infection.

Survey radiographs may reveal gas- or fluid-filled loops of intestines. Barium studies may reveal flocculation or persistent adherence of the barium to the mucosa, irregular mucosal surfaces, luminal narrowing or intramural thickening.

Ultrasound examination may reveal intestinal wall irregularity, thickening, or altered echogenicity, and/or enlarged mesenteric lymph nodes, liver or spleen.

Diagnosis is made by examination of a **GI tract fine-needle aspirate or biopsy**, with or without biopsies from mesenteric lymph nodes and/or other abdominal organs.

Differentiating lymphocytic (small cell) alimentary lymphosarcoma from lymphocytic-plasmacytic IBD can be very difficult.

Determining which types of cells are involved can aid in treatment and prognosis (see below).

Differential diagnosis

These include most of the other causes of weight loss with a good appetite. However, since cats with alimentary lymphosarcoma usually develop vomiting and/or diarrhea, **other causes of enteropathy, IBD, cholangiohepatitis, pancreatitis, hyperthyroidism** and the **other malassimilation syndromes** should be considered as important differentials.

Treatment

Localized alimentary lymphosarcoma may respond to **surgical resection** and adjunct chemotherapy.

- Large masses involving the entire thickness of the bowel wall should not be treated with chemotherapy alone as this may result in **gut perforation**.

Diffuse lymphosarcoma are best treated with combination chemotherapy.

- Lymphoblastic lymphosarcoma and lymphosarcoma affecting more than just the GI tract are best treated with combinations of cyclophosphamide, vincristine and prednisolone, \pm doxorubicin, \pm l-asparaginase (see page 676, for protocols and doses).
- Lymphocytic lymphosarcoma may respond more favorably to a combination of only prednisolone (10 mg/cat/day PO) and chlorambucil (2–5 mg/m² PO up to once every 48 h or 15 mg/m²/day for 4 days PO, every 3 weeks).

Prognosis

The prognosis is guarded. The best prognostic indicators are response to therapy and the duration of the first remission.

Response rates to chemotherapy range from 30–70%, with median remissions of 4–23 months.

Being **FeLV positive or having lymphoblastic lymphosarcoma are negative indicators**, while having lymphocytic lymphosarcoma is a positive indicator.

- **Lymphoblastic lymphosarcoma** has a complete remission rate of 18%, and median survival time of 2.7 months.
- **Lymphocytic lymphosarcoma** has a complete remission rate 69%, median survival time 22.8 months.

Prevention

Since it is not known what triggers lymphosarcoma to develop, it is not currently possible to prevent its onset. However, since lymphocytic IBD has been seen to progress to lymphosarcoma, it would appear sensible to try to control lymphocytic IBD as well as possible, to try to prevent its progression.

CHRONIC PANCREATITIS/EXOCRINE PANCREATIC INSUFFICIENCY*

Classical signs

- Typically seen in middle-aged to older cats.
- History of episodic anorexia, lethargy, vomiting and/or diarrhea.
- If also diabetic; polyuria and polydipsia.

Pathogenesis

Pancreatitis develops when there is **activation of digestive enzymes** within the pancreas, which results in some degree of auto-digestion. While there are many possible causes of pancreatitis in cats, over 90% are idiopathic.

In cats, the **most common forms** of pancreatic disease are **chronic non-suppurative** (lymphocytic/plasmacytic or, occasionally, eosinophilic) pancreatitis and **suppurative** (neutrophilic) pancreatitis, while acute septicemic pancreatitis and exocrine pancreatic insufficiency (EPI) are seen less frequently.

It is the presence of exocrine pancreatic insufficiency that results in weight loss with a good, often ravenous, appetite.

- Primary exocrine pancreatic insufficiency is uncommon in cats. However, exocrine pancreatic insufficiency secondary to chronic, often episodic, pancreatitis is being recognized more frequently.
- In exocrine pancreatic insufficiency the lack of pancreatic digestive enzymes leads to maldigestion and malabsorption.

In cats, pancreatitis is often seen in association with idiopathic inflammatory bowel disease (IBD), cholangitis/cholangiohepatitis complex, or both (termed “triaditis”).

- This association may occur because the **pancreatic duct in some cats enters the common bile duct** before it opens into the duodenum. In other cats, the pancreatic and bile ducts enter the duodenum separately.
- When disease occurs in the small bowel it may ascend the common bile duct and from there affect the pancreas and the rest of the biliary tree, or it may ascend both ducts from their opening in the duodenum. For the same reason, disease of the biliary tree or pancreas may affect the other two regions.
- Regardless of which organ is affected first, the other two organs tend to become involved as inflammatory mediators, infectious agents, bile and/or pancreatic secretions pass from one area to another.

Clinical signs

Chronic pancreatitis can occur in **any sex or breed of cat**, and is typically seen in middle-aged or older cats.

Burmese cats in Great Britain may be predisposed to pancreatitis.

History and clinical signs of chronic pancreatitis tend to be **very variable and non-specific**.

They usually include **episodes of anorexia or variable appetite, with or without vomiting and/or diarrhea, weight loss and/or possible abdominal pain**.

Once exocrine pancreatic insufficiency develops the cat is usually **thin, has a greasy coat** and produces large quantities of voluminous, fatty, foul-smelling feces or has severe diarrhea.

Cats with chronic pancreatitis **may also develop episodic or persistent diabetes mellitus**, which is seen as polyuria and polydipsia.

When both exocrine pancreatic insufficiency and diabetes occur concurrently the **polyphagia** can be profound.

Physical examination is often unremarkable, but may reveal anterior abdominal discomfort, a palpably irregular and enlarged pancreas, or hepatomegaly associated with cholangitis/cholangiohepatitis complex.

Diagnosis

Chronic pancreatitis is very difficult to diagnose.

Hematology and serum biochemistry may reveal non-specific changes.

- **Hematology** may show neutrophilia, neutropenia (associated with sequestration during acute exacerbation), monocytosis and/or a mild non-regenerative anemia.
- **Serum biochemistry** may show hyperglobulinemia, bilirubinemia and raised liver enzymes (depending on the degree of associated cholangitis/cholangiohepatitis complex), and/or hypercholesterolemia, hypertriglyceridemia and hyperglycemia (often associated with concurrent diabetes). Hypocalcemia may be associated with severe disease.
- **Serum amylase and lipase tests** are **rarely useful** in the diagnosis of pancreatitis in cats, although a raised lipase level may be seen occasionally.

Serum cobalamin and folate levels are usually decreased.

A number of older tests are very unreliable and are now rarely used. These include staining fecal smears to

demonstrate undigested fat (Sudan III or IV stain) and starch (iodine stain), and fat absorption tests.

Abdominal radiographs are usually unremarkable.

Ultrasound examination may reveal pancreatic enlargement, irregularity or heterogeneity, evidence of peripancreatic fat necrosis, enlargement of mesenteric lymph nodes, and/or evidence of post-hepatic biliary obstruction (enlarged gall bladder, thickened bile or tortuous common bile duct).

Evaluation of serum **trypsin-like immunoreactivity (TLI)** may be helpful.

- The species-specific assay must be performed on a fasted serum sample.
- Serum TLI may be increase with pancreatitis and decrease with exocrine pancreatic insufficiency.
- While it consistently diagnoses exocrine pancreatic insufficiency, it often fails to confirm pancreatitis, possibly because chronic inflammation has reduced the overall ability of the pancreas to produce TLI.

Evaluation of serum **pancreatic lipase immunoreactivity (PLI)** may be helpful.

- The species-specific assay must be performed on a fasted serum sample.
- Serum PLI may increase with pancreatitis and appears to be more sensitive than TLI.

A therapeutic trial with replacement pancreatic enzymes may be considered (see under treatment).

- Providing that any associated IBD and/or cholangitis/cholangiohepatitis complex has been addressed, the response to treatment may be dramatic. However, a positive response is not diagnostic of chronic pancreatitis and/or exocrine pancreatic insufficiency.

Pancreatic biopsy is required to confirm a diagnosis of pancreatitis.

- Because triaditis is common, it is advisable to collect liver and intestinal biopsies at the same time, and send part of the liver biopsy and a sample of bile for culture.

Differential diagnosis

These include most of the other causes of weight loss with a good appetite. However, since cats with chronic pancreatitis and exocrine pancreatic insufficiency usually develop diarrhea and/or vomiting, other **causes of enteropathy, IBD, cholangiohepatitis, alimentary**

lymphosarcoma, hyperthyroidism and the other malassimilation syndromes should be considered as important differentials.

Treatment

(For treatment of acute pancreatitis see page 277, The Cat With Depression, Anorexia or Dehydration)

Replace pancreatic enzymes by adding pancreatic enzyme replacement to food (~ half a teaspoonful of powder per meal, or to effect), or add fresh-frozen then defrosted pig pancreas (~20–40 g per meal, or to effect).

Immunosuppression: In the non-suppurative form of pancreatitis, immunosuppressive doses of **corticosteroids** may be needed to reduce ongoing inflammation (prednisolone 1–4 mg/kg q 12–24 hours PO, then taper over 1–3 months and maintain on every other day doses if needed). Alternately, **chlorambucil** could be considered (2–5 mg/m² PO up to once every 48 h).

Supportive therapies:

- **Feed a highly digestible, “bland enteric diet”**, which is low in fat. Feed small meals frequently.
- **Cobalamin** is often reduced by lack of pancreatic intrinsic factor and malabsorption and should be supplemented (125–250 µg/week SC or IM for 6–8 weeks or 50–100 µg/cat/day PO).
- **Vitamin K1** is often required because fat malabsorption results in poor absorption of fat-soluble vitamins like vitamin K, and this can result in abnormal hemostasis (0.5 mg/kg/day SC for 3–4 days, then once weekly).
- **Vitamin E** may be given for its anti-oxidative properties (50–200 IU/cat/day PO).

Surgical intervention may be required if complete biliary obstruction occurs (cholecystotomy or cholecystoduodenostomy), or if a focal pancreatic mass is detected (partial pancreatectomy to remove a pancreatic pseudocyst, abscess, fibrotic mass or tumor).

Diabetes that develops secondary to chronic pancreatitis can be very difficult to stabilize. Insulin requirements may vary widely because of the ongoing pancreatic pathology, and treatment is complicated further when corticosteroids also need to be given.

It is essential to diagnose and treat any concurrent disease (e.g. IBD and/or cholangitis/cholangiohepatitis complex).

Prognosis

Prognosis depends on the severity of damage. Many cats live with low-grade smoldering pancreatitis for many years, however, once exocrine pancreatic insufficiency and/or diabetes has developed the prognosis is worse.

In rare cases of congenital exocrine pancreatic insufficiency, the prognosis is good, as long as the cat receives pancreatic supplementation.

Prevention

Since it is not known what triggers pancreatitis to develop, it is not currently possible to prevent its onset. However, since chronic pancreatitis can progress to exocrine pancreatic insufficiency, it would appear sensible to try to control it as well as possible to try to prevent its progression.

LYMPHOCYTIC CHOLANGIOHEPATITIS*

Classical signs

- Typically seen in middle-aged cats, and Persian cats may be over-represented.
- Weight loss, inappetence, some cats may be polyphagic,
- ± mild generalized lymphadenopathy,
- ± vomiting and/or diarrhea.
- In some cats, is associated with IBD and/or pancreatitis.

Pathogenesis

The **cholangitis/cholangiohepatitis complex** comprises chronic non-suppurative (lymphocytic) cholangitis/cholangiohepatitis, suppurative cholangitis/cholangiohepatitis and biliary cirrhosis.

- The pathogenesis and interaction of the three conditions is poorly understood and it is highly probable that each of these conditions incorporates a number of different diseases.
- Cholangitis describes inflammation of the biliary tract, while cholangiohepatitis describes inflammation of the peribiliary hepatocytes as well as the biliary tract.

- **The only condition that may be associated with polyphagia is lymphocytic cholangitis/cholangiohepatitis.**

Pathogenesis of lymphocytic cholangitis/cholangiohepatitis complex is unknown. It is probably immune-mediated, but is possibly associated with progression of the suppurative form. **It is often associated with IBD and/or pancreatitis, and when all three occur together it is termed “triaditis”.**

Clinical signs

Cats of any age may be affected, but disease is seen most typically in **middle-aged cats**. **Persian cats** may have an increased risk.

Clinical signs are usually chronic and insidious in nature.

Affected cats are **typically jaundiced, but bright, and are often polyphagic.**

Vomiting and/or diarrhea may be present.

Cats may have a **palpably enlarged liver and mild generalized lymphadenopathy.**

Cats may show **intermittent signs of systemic illness**, with **fever, anorexia**, weight loss, and vomiting. Systemic signs are sometimes associated with secondary infections, typically of the liver and/or pancreas.

The disease may progress to causing chronic biliary cirrhosis with ascites, hepatic encephalopathy, and bleeding tendencies.

Diagnosis

Serum biochemistry often reveals mild to moderately (occasionally severely) increased liver enzymes, increased bile acids, hyperbilirubinemia, hyperglobulinemia and hypoalbuminemia.

Hematology may reveal mild anemia, lymphopenia or lymphocytosis, monocytosis and/or thrombocytopenia. **Blood clotting times are frequently prolonged.**

Ascitic fluid, if present, is typically high in protein.

Radiographs typically reveal **hepatomegaly** and occasionally choleliths (gallstones), while **ultrasound** examination may also show blotchy hepatic hyperechogenicity, “sludging” of bile, and evidence of com-

mon bile duct obstruction. Associated findings may include enlarged mesenteric lymph nodes, pancreatic irregularity, and/or thickening of the duodenal walls.

A **definitive diagnosis** is made by **histopathological examination of a liver biopsy.**

- A fine-needle aspirate is rarely diagnostic, so a **percutaneous needle biopsy or surgical wedge biopsy** is required. Blood clotting times and/or a PIVKA test (protein induced by vitamin K absence or antagonism) should be assessed first, and a platelet count should be performed.
- Typical gross findings include a **very firm often rather irregular liver**, and a thickened and distended gallbladder and common bile duct, which often contains inspissated bile. Enlarged mesenteric lymph nodes, pancreatic irregularity and/or thickening of the duodenal walls may also be present.
- If performing an exploratory laparotomy, it is sensible to check the patency of the biliary outflow, then collect biopsies from the mesenteric lymph nodes, small intestines and pancreas as well as liver. Send bile and part of the liver biopsy for culture.
- Histopathology of the liver reveals **lymphocytic and/or plasmacytic periportal inflammation, bile ductule hyperplasia, and periportal fibrosis.** Very chronic cases may have biliary cirrhosis.

Differential diagnosis

These include most of the other causes of weight loss with a good appetite. However, since cats with lymphocytic cholangitis/cholangiohepatitis complex often develop vomiting and/or diarrhea enteropathies (including IBD), **pancreatitis, and the other malassimilation syndromes** should be considered as important differentials. In cases that develop ascites, the **wet form of feline infectious peritonitis (FIP)** should also be considered. This is because both conditions produce a protein-rich ascitic fluid and have similar biochemical and hematological changes. However, the presence of polyphagia usually differentiates the two conditions as cats with FIP are usually anorexic.

Treatment

Treatment is largely empirical.

Antibiotics, if needed:

- Ampicillin (10–40 mg/kg q 8 hours PO), amoxicillin (11–22 mg/kg q 8–12 hours PO), or cephalexin (10–35 mg/kg q 8–12 hours PO)
- Add **metronidazole** for its effect against anaerobes and its immune-modulating effects (7.5–10 mg/kg every 12 hours PO). Do not use higher doses, as these can be hepatotoxic.

Immunosuppressive agents:

- Immunosuppressive doses of **corticosteroids** (prednisolone 2–4 mg/kg q 12–24 hours PO), then taper over 1–3 months, and maintain on every other day doses if needed.
- Other immunosuppressive agents may be considered, e.g. **methotrexate** (0.13 mg/cat every 12 hours × 3 doses PO, repeated once weekly) or **chlorthalidone** (2–5 mg/m² PO up to once every 48 h).

Supportive therapies:

- **Ursodeoxycholic acid** aids bile flow and is believed to have hepatoprotective effects (10–15 mg/kg q 24 hours PO).
- **Vitamin K1** is often required because fat malabsorption results in poor absorption of fat-soluble vitamins like vitamin K and this can result in abnormal hemostasis (0.5 mg/kg q 24 hours SC for 3–4 days, then once every 7–14 days).
- **Vitamin E** may be given for its anti-oxidative properties (50–200 IU/cat/day PO).
- **S-adenosylmethionine** (SAME) may be given for its hepato-protective and anti-oxidative properties (18 mg/kg/day PO).
- Some authors suggest feeding either hypoallergenic or high-fiber diets.
- **Milk thistle**, 7–50 mg/kg q24h PO.

Surgery will be required where **complete biliary obstruction** occurs (cholecystotomy or cholecystoduodenostomy).

It is important to address any associated or underlying conditions, such as IBD, pancreatitis, extrahepatic bile duct obstruction or cholecystitis.

Prognosis

Prognosis is **very variable and often unpredictable**. Some cases respond well and only need temporary treatment, others require continued therapy to maintain remission, while others progress relatively rapidly and

require euthanasia. Once severe fibrosis, cirrhosis or ascites has developed the prognosis is usually guarded.

Prevention

Since it is not known what triggers the development of lymphocytic cholangitis/cholangiohepatitis complex, it is currently not possible to prevent its onset.

ACROMEGALY

Classical signs

- Rare condition of older, typically, male cats.
- Slow increase in body size, especially affecting head and feet.
- Variable weight change with a good appetite.
- Usually diabetic; so polyuric and polydipsic.

Pathogenesis

In cats, most cases of acromegaly are caused by the development of a **growth hormone-secreting tumor within the pituitary gland**.

Unlike the situation in the dog, increased levels of circulating progestogens or progesterone do not stimulate growth hormone secretion in the cat.

Clinical signs

Acromegaly is seen most typically in older, male, mixed-breed cats.

Affected cats slowly increase in size, with somewhat disproportionate enlargement and thickening of the head and feet.

- Growth of the jaw bones may result in obvious interdental spaces and/or prognathism.
- A mild increase in respiratory noise may result from increased soft tissue thickness around the airways.
- Distortion of the joints can lead to destructive arthritis.

Acromegalic cats develop insulin-resistant diabetes because excess growth hormone causes peripheral insulin resistance. However, early cases may have unstable diabetes rather than being truly resistant.

- They therefore develop polyuria, polydipsia and polyphagia.
- They may either gain or lose weight.

While all organs undergo growth and hypertrophy, hepatomegaly and renomegaly are the easiest to detect on palpation. Enlargement of the abdominal organs often results in a pot-bellied appearance.

Organ enlargement may lead to organ failure. The clinical signs will therefore reflect the particular organ systems that have been affected; e.g. cardiac hypertrophy and eventual congestive heart failure, liver failure and/or kidney failure.

Concurrent hypertension may result in clinical signs, typically ocular hemorrhages, sudden blindness and/or neurological signs.

Only rarely do neurological signs result from the pituitary tumor compressing and invading the hypothalamus.

Diagnosis

Acromegaly should be considered in any large-sized cat which develops insulin-resistant or unstable diabetes.

- Hyperglycemia and glycosuria will be present, but ketosis is rare.
- Affected cats may also show azotemia, hypercholesterolemia, hyperphosphatemia, hyperproteinemia, erythrocytosis and mildly raised liver enzymes.

Comparing the cat to a previous photograph of itself can be helpful in confirming the disproportionate enlargement and thickening of its head.

A definitive diagnosis can be made by measuring growth hormone levels (where available) **or insulin-like growth factor-1** (IGF-1) assay, which gives similar results. Unfortunately, the degree of elevation does not always correlate with the clinical signs, and IGF-1 will also be increased in most cats treated long-term with insulin.

The presence of acromegaly can be confirmed by evaluating the **growth hormone response** to a **glucose suppression test**.

Other tests can be used to gain supportive evidence.

- Radiography may show organomegaly, increased interdental spaces, hyperostosis of the skull and/or degenerative arthritis.

- Ultrasonography and, where available, computed tomography (CT) or magnetic resonance imaging (MRI) can also be used to detect organomegaly. CT and MRI may be used to determine the location and extent of the tumor within the brain.

Differential diagnosis

Differential diagnoses include most of the other causes of weight loss with a good appetite. However, since all cats with acromegaly develop diabetes with polyuria and polydipsia, other causes of **diabetes, hyperadrenocorticism, hyperthyroidism and renal insufficiency** are the most important differentials.

Treatment

Acromegaly can be treated three ways; surgery, external-beam radiotherapy or medically.

- **Surgical excision of the growth hormone-secreting tumor** is usually a rapid and effective treatment for affected humans. However, the procedure has rarely been performed in cats, and mapping of the tumor is essential prior to considering surgery.
- **In humans, external-beam radiotherapy is often effective**, although clinical improvement may be slow to develop. The few cats that have been treated in this way have shown variable results. Treatment requires repeated anesthetics and suitable facilities are limited.
- Although they require frequent administration and usually cause side-effects, **somatostatin analogs** (e.g. octreotide) and **dopamine agonists** (e.g. bromocriptine) are sometimes used in the treatment of humans with acromegaly. Unfortunately, limited trials with octreotide in acromegalic cats have not been promising, and dopamine agonists have not yet been evaluated in this species.

Temporary management consists of **trying to treat the diabetes** and any other concurrent or related diseases (e.g. hypertension, heart failure, renal disease).

- Control of the diabetes can usually be achieved by giving extremely **high doses of exogenous** insulin (20–130 IU/day), sometimes in various combinations of short-, intermediate- or long-acting insulin. However, because the severity of the insulin resistance can fluctuate, the dose should not exceed 12–15 IU/injection so the risk of iatrogenic hypoglycemia is reduced.

- Very rarely, spontaneous necrosis of the tumor can result in temporary or permanent remission of clinical signs.

Prognosis

The long-term prognosis is poor. However, because the tumors grow very slowly, the short-term prognosis may be good to guarded with **survival times of 4–48 or more months reported**.

Prevention

Since acromegaly is usually caused by a slow growing pituitary tumor, its development cannot be prevented.

HYPERADRENOCORTICISM

Classical signs

- A rare condition of middle-aged and older cats.
- Poor coat condition and pot-bellied appearance.
- Polyuric, polydipsic, polyphagic and often diabetic.

Pathogenesis

In cats, hyperadrenocorticism, more correctly termed **hypercortisolism**, can be caused by:

- **Adrenocorticotropin (ACTH)-secreting pituitary tumors;**
 - Approximately 80% of cats with hyperadrenocorticism have a pituitary tumor and most are microadenomas.
- **Adrenal tumors that autonomously secrete cortisol;**
 - Represent about 20% of cases, and approximately 50% of adrenal tumors are benign adenoma, and 50% are malignant.
- **Iatrogenic hyperadrenocorticism** can be caused by giving long courses of exogenous corticosteroids (parenteral, oral or topical) or megestrol acetate.

Clinical signs

Hyperadrenocorticism is typically seen in middle-aged to older cats. Females may be over represented.

History is often vague, but usually includes **polyuria, polydipsia, polyphagia, weight loss and lethargy**, and affected cats may have a history of recurrent infections and/or abscesses.

Since cortisol antagonizes insulin, **approximately 80% of cases develop diabetes**, which may or may not be insulin resistant, based on the insulin dose administered.

Cats with hyperadrenocorticism typically have **poor coat condition, spontaneous alopecia, very fragile thin skin that bruises easily** and a **pot-bellied appearance**. Hepatomegaly is often palpable.

Diagnosis

Hyperadrenocorticism should be suspected in any cat with the clinical signs described above, particularly if it has **unstable diabetes**, and/or a **long history of exogenous corticosteroids administration**.

Since hyperadrenocorticism is frequently associated with diabetes, serum biochemistry and urinalysis often reveal persistent **hyperglycemia, glucosuria ± ketonuria**.

Unlike in dogs, a stress leukogram is rarely present, although lymphopenia may be seen.

Increased liver enzymes and **hypercholesterolemia** may be seen regardless of whether or not the cat has diabetes.

Making a diagnosis of hyperadrenocorticism can be very difficult:

- Few of the tests have well-established specificity and sensitivity in cats.
- It is usually necessary to use a combination of tests.

In cats, the **most useful screening tests** are:

- **Adrenocorticotropin hormone (ACTH) stimulation test** – Collect baseline blood sample, give 0.125 mg of synthetic ACTH IV, collect blood after 1 ± 2 hours. Normal basal serum cortisol concentration is 10–110 nmol/L (0.36–3.6 µg/dl); at 1 h and/or 2 h after ACTH is 210–330 nmol/L (7.6–11.9 µg/dl); > 330 nmol/L (> 11.9 µg/dl) is

consistent with hyperadrenocorticism. False negatives and positives occur.

- **Low-dose dexamethasone suppression test** – Collect baseline blood sample, give dexamethasone 0.01 mg/kg IV, collect blood after 4 and 8 hours. In normal cats serum cortisol should be < 30 nmol/L (< 1.0 µg/dl) at 4 h and 8 h after dexamethasone. Lack of suppression is seen in most cats (95%) with hyperadrenocorticism, and some cats with non-adrenal illness.
- **Urine cortisol to creatinine ratio (UC/CR)** – Collect urine sample, centrifuge and submit supernatant. A normal ratio almost always rules out hyperadrenocorticism. Unfortunately, an increased ratio is commonly caused by non-adrenal illness. The test is more reliable if the sample is collected at home.

Additional tests may be used to try to differentiate pituitary-dependent hyperadrenocorticism (PDH) from adrenal neoplasia. These include:

- **High-dose dexamethasone suppression test** – Performed as low-dose dexamethasone suppression test but give 0.1 mg/kg. Lack of suppression at 8 h is seen in most cats (80%) with hyperadrenocorticism. Suppression at 4 h but not at 8 h is consistent with PDH. False negatives may occur in mild cases of hyperadrenocorticism.
- **Ultra-high-dose dexamethasone suppression test** – Performed as low-dose dexamethasone suppression test but give 1.0 mg/kg. Suppression at 4 h or 8 h to < 30 nmol/l (< 1.0 µg/dl) or <50% of baseline is consistent with PDH, but lack of suppression may be seen with PDH and adrenal tumors.
- **Combination test** – Collect blood sample, give 1.0 mg/kg dexamethasone IV, collect blood after 4 h, then immediately perform ACTH stimulation test as above. Interpretation is as for ACTH stimulation test and ultra-high-dose dexamethasone suppression test (taking ultra-high-dose dexamethasone suppression test result as result at 4 h).
- **‘At home’ protocol** – Collect urine on the morning of Days 1 and 2; give two oral doses of dexamethasone at 8 hour intervals at 4 pm and 12 pm; then collect a third urine sample on the morning of Day 3. All three samples are assessed for UC/CR. The mean of the first two UC/CR = basal value and acts as a screening test. Suppression < 50% basal on Day 3 is not seen in cats with adrenal-

dependent hyperadrenocorticism, but may be seen in cats with PDH.

- **Measurement of endogenous ACTH** – Collect blood sample in EDTA, spin immediately, transfer plasma to a plastic tube, ship overnight on ice or freeze for storage. Plasma ACTH is high normal or above (>15 pg/ml) with PDH, and low (<10 pg/ml) with adrenal tumors.
- **Radiography, ultrasonography and, where available, CT or MRI.** Use to determine adrenal size and shape. The presence of adrenal mineralization should not be over-interpreted as it occurs in ~30% of normal cats. Unilateral adrenal enlargement is typical of an adrenal tumor. While bilateral enlargement usually indicates PDH, it can occasionally result from bilateral adrenal tumors. Hepatomegaly is found in ~75% of all cats with hyperadrenocorticism. CT and MRI can be used to image the pituitary gland as well as the adrenal glands.

Differential diagnoses

Differential diagnoses include most of the other causes of weight loss with a good appetite. However, since most cats with hyperadrenocorticism develop polyuria, polydipsia and diabetes, **other causes of diabetes, acromegaly, hyperthyroidism and renal insufficiency** are the most important differentials.

Treatment

While there are a number of different treatment options, there have been few good studies into their use in cats.

Medical therapies have generally given poor results, and safe dosages have not been established. They may be given pre-surgically to reduce the operative risks.

- **Trilostane** has produced promising results in a very small number of cases and warrants further investigation, particularly given that side effects have not been significant.
- **Mitotane** gave poor results in early trials, and it has been suggested that higher doses and/or longer courses may be needed.
- **Ketoconazole** has given mixed results and considerable toxicity.

- **Metypapone** has given mixed results and is difficult to obtain.
- **L-depronyl** has little information available on use in cats, and no proven efficacy.

Radiation therapy with ablation of the pituitary tumor has given mixed results.

Adrenalectomy. Because of the difficulties of medical therapy, **surgery has been considered the treatment of choice.** However, this is changing with the success of trilostane treatment. Where a single adrenal tumor is present, the removal of the affected adrenal gland is recommended. With PDH or bilateral adrenal tumors, bilateral adrenalectomy is recommended. While surgery can provide successful treatment, the **risk of a fatal peri-operative hypoadrenal crisis, renal failure or surgical complications are great.** The procedure should only be performed by an **experienced surgeon.** Consideration of the diabetic state must be given, and peri-operative and post-operative treatment with glucocorticoids is essential. **Glucocorticoids are needed in all cases.** Short-term treatment will be needed after unilateral adrenalectomy, because the contralateral gland will be temporarily atrophied. Long-term treatment will be needed after bilateral adrenalectomy, and should also include mineralocorticoids.

Prognosis

Without successful treatment, the prognosis is poor. Where PDH is present, successful bilateral adrenalectomy will reduce the signs of hyperadrenocorticism, but the risk of a hypoadrenal crisis is high and tumor expansion will eventually lead to neurological signs. If adrenal tumors are successfully removed the hyperadrenocorticism should resolve, and the diabetic state may become less insulin resistant or even resolve. Early studies with trilostane appear to show that while it may ameliorate signs of hyperadrenocorticism, it may not alter the need for exogenous insulin in cats that are also diabetic.

Prevention

Since hyperadrenocorticism is usually caused by pituitary or adrenal tumors, its development cannot be prevented. Iatrogenic hyperadrenocorticism can be

prevented by not giving long courses of exogenous corticosteroids.

GLOMERULONEPHRITIS (PROTEIN-LOSING NEPHROPATHY)

Classical signs

- Rare disease seen most frequently in young male cats.
- Weight loss with a good appetite early in disease.
- Often marked subcutaneous edema and ascites.
- \pm polydipsia and polyuria.
- \pm vomiting and/or diarrhea.

Pathogenesis

Glomerulonephropathy can arise from **one of two mechanisms:**

- **Primary glomerulonephritis** has **antibodies** targeted directly against the **glomerular basement membrane.**
- **Secondary glomerulonephritis** has **deposition of immune complexes** within the glomeruli that have arisen elsewhere in the body.
 - This is the most common form in cats.
 - It tends to be **membranous or membrano-proliferative** in nature.
 - It may be associated with many different conditions (see below), but in most cases the underlying cause cannot be found.
- **Diseases that may be associated with secondary glomerulonephritis** in cats include infection with FeLV, FIV, FIP, *Mycoplasma* spp., or *Ehrlichia* spp., chronic pyoderma, chronic gingivitis, dirofilariasis, endocarditis, pancreatitis, pyometra, neoplasia or other immune-mediated diseases.

Deposition of immune complexes within the glomerulus leads to the initiation of inflammation and this results in proteinuria (protein-losing nephropathy).

Clinical signs

Rare condition seen most typically in **young male cats.**

Clinical signs may be non-specific. Typically in the later stages there is anorexia, depression, weight loss, lethargy and poor coat condition. More specific signs include **subcutaneous edema, ascites, and polyuria and polydipsia.**

It tends to take one of two clinical forms:

- **Nephrotic syndrome** with ascites and subcutaneous edema, usually affecting the hind legs, ventral body wall and neck. This form may or may not be associated with signs of renal failure (polyuria, polydipsia).
- **Renal failure with no signs of nephrotic syndrome.**

Cats with early nephrotic syndrome may present with weight loss with a good appetite.

Edema affecting the intestines can exacerbate the protein loss and result in **malabsorption, diarrhea, vomiting and weight loss.**

Systemic hypertension may arise secondary to the renal dysfunction and result in **acute blindness, ocular hemorrhages** or signs of CNS dysfunction.

Other clinical signs may result from any primary disease conditions.

On abdominal palpation, the **kidneys may appear small and/or irregular or, occasionally, enlarged.**

Diagnosis

Cats with nephrotic syndrome have marked proteinuria, hypoalbuminemia and hypercholesterolemia.

Other findings may include hypertriglyceridemia, hypocalcemia, non-regenerative anemia and neutrophilia.

Increased concentrations of blood urea and creatinine (azotemia) and a low urine specific gravity (<1.035) will indicate whether or not renal insufficiency is present.

Persistent proteinuria is the hallmark of glomerulonephritis.

- This should be quantified by determining the **urine protein to creatinine ratio (UPC ratio).**
- UPC ratio: < 0.4 = normal, > 0.4–2 suggestive of glomerulonephropathy or tubular disease, > 2 consistent with glomerulonephropathy.

Urinalysis may reveal an inactive sediment, with or without hyaline and/or granular casts.

It is important to try to determine an underlying cause. This may involve screening radiography and ultrasonography, tests for immune-mediated disease, and numerous tests for infectious disease (see above for the list of possible diseases).

Systemic blood pressure should be assessed.

Abdominal radiographs and ultrasound examination rarely reveal obvious renal changes.

Renal biopsy is necessary to confirm the diagnosis and find which type of glomerular disease is present.

- Blood clotting times, platelet number, and systemic blood pressure should be assessed prior to biopsy.
- **Ultrasound-guided percutaneous biopsy** is relatively safe but **laparotomy or laparoscopy** reduces the risk of post-operative bleeding. Renal hemorrhage is a risk, especially if hypertensive.
- Sample must **contain >5 glomeruli** to make a diagnosis; this usually means **multiple needle biopsies or a wedge biopsy** are required.
- Routine **histopathology** (fix sample in buffered normal formalin), **electromicroscopy** (fix sample in paraformaldehyde-glutaraldehyde), ± **immunohistochemistry** (keep fresh and paraffin embed) are needed to confirm a diagnosis.
- **On gross inspection** kidneys may appear normal, be slightly small, firm and pale, or show irregular pitting and fibrosis.
- Light microscopy typically shows **diffuse thickening of the glomerular basement membrane**, with variable degrees of **cellular proliferation** in the affected glomeruli. Special stains can help to define the changes, but electromicroscopy and immunohistochemistry are needed to define the exact nature and extent of the disease.

Differential diagnosis

Chronic renal failure, diabetes, acromegaly, hyperadrenocorticism and hyperthyroidism are important differentials in those cats that develop polyuria and polydipsia. However, the presence of ascites in combination with polyphagia is suggestive of **lymphocytic cholangitis/cholangiohepatitis complex.** Once hypoalbuminemia is detected, then a **protein-**

losing enteropathy or severe liver failure should be considered.

Treatment

Treatment for nephrotic syndrome is controversial and usually empirical.

Monitor response to treatment by assessing changes in body weight, serum and urinary protein levels.

Where an underlying cause can be found it should be treated.

Alter the level of dietary protein:

- High protein diets may help to correct hypoalbuminemia and reduce protein malnutrition.
- However, they may exacerbate proteinuria, glomerular hypertension and glomerular damage.
- High-protein diets **should not be fed if serum urea is elevated.**
- Some cats benefit from mild protein addition while others benefit from mild protein restriction. Feed the chosen diet for ~ 2 weeks then reassess.

Angiotensin-converting enzyme (ACE) inhibitors help to reduce proteinuria and any associated systemic hypertension (e.g. benazepril 0.25–0.5 mg/kg/day PO).

If systemic hypertension is significant, the **calcium channel antagonist amlodipine** (0.625 mg/cat/day PO) should be given.

Use of corticosteroids and immunosuppressive drugs is controversial. They may or may not help to reduce immune complex formation, will worsen any azotemia, and are contraindicated once renal failure is evident.

Very careful use of diuretics can help to reduce fluid retention and improve the patient's well-being (e.g. frusemide 1–2 mg/kg q 8–12 hours PO, reducing to as low dose as possible and monitoring closely for side-effects).

Thromboembolic disorder is rare in cats, but if present consider giving low doses of aspirin (10–25 mg/kg every 3 days PO).

Prognosis

Very variable and often unpredictable. Some undergo **spontaneous complete or partial remissions** (~30%), others need temporary or continuous therapy, while others progress relatively rapidly to require euthanasia.

Approximately 50% survive for 2.5–6 years.

Cats with nephrotic syndrome that do not originally have renal insufficiency, **may or may not progress to develop renal insufficiency.**

Prognosis is poor with worsening clinical signs or progression to renal failure.

Prevention

Prompt recognition and treatment of underlying disease may prevent the development of secondary glomerulonephritis. However, since it is not usually possible to detect the underlying cause, it is not usually possible to prevent the onset of glomerulonephritis.

18. The thin, inappetent cat

Penny Barber[†], James B Miller and Jacquie Rand

KEY SIGNS

- Thin cat or cat with weight loss and a poor appetite.

MECHANISM?

- Weight loss occurs when nutrient loss or metabolic utilization exceeds intake. Weight loss results from one or more of the following mechanisms: inadequate intake; impaired ability to digest or absorb; inability to utilize; increased utilization or the increased loss of nutrients.
A lack of appetite is associated with suppression of the appetite center in the hypothalamus.

WHERE?

- Diseases involving most body systems can cause weight loss and affect appetite.

WHAT?

- The most common causes of a thin, inappetent cat are chronic renal failure, neoplasia and several of the viral diseases (FIV, FeLV, FIP). Many other diseases will cause weight loss, but inappetence will frequently occur late in the disease process.

QUICK REFERENCE SUMMARY

Diseases causing signs of a thin, inappetent cat

ANOMALY

- Portosystemic shunts (p 361)
May be congenital or acquired. In congenital portosystemic shunts, growth may be stunted. Neurological signs of hepatic encephalopathy (behavioral, seizures, blindness) may occur and hypersalivation is a frequent sign.

METABOLIC

- **Chronic renal failure*** (p 333)**
Chronic history of gradual weight loss, polyuria and polydipsia. Systemic signs such as inappetence and vomiting are common.

- **Septic focus/persistent fever ** (p 344)**

Anorexia is associated with the pyrexia. Anorexia and a hypermetabolic state lead to weight loss. Fluctuating pyrexia, poor appetite and weight loss are present, along with other clinical signs dependent on the etiology of the pyrexia. Common sites of bacterial infection include pyothorax, upper urinary tract infections and bite wounds, with peritonitis, osteomyelitis, endocarditis and pneumonia occurring less commonly.

- **Apathetic hyperthyroidism* (p 346)**

Weight loss, poor appetite, tachycardia and intermittent vomiting and diarrhea are common. Usually affects cats greater than 6 years of age.

- **Cholangiohepatitis complex* (p 348)**

Anorexia or poor appetite, weight loss and depression. Icterus and hepatomegaly are common. Ascites occasionally occurs.

- **Cardiac cachexia (p 356)**

Clinical signs relating to the cardiac disease including murmurs, gallop rhythm and arrhythmias. Dyspnea caused by pleural effusion or pulmonary edema may also be present.

- **Diabetes mellitus (p 355)**

Polyuria and polydipsia. Frequently history of good appetite with weight loss prior to inappetence.

NEOPLASTIC

- **Cancer cachexia** (p 342)**

Paraneoplastic syndrome characterized by anorexia, wasting and weight loss. Occurs with a variety of malignancies, and more specific signs will relate to the site of the neoplasm.

INFECTIOUS

- **Feline immunodeficiency virus (FIV)*** (p 339)**

Chronic weight loss, stomatitis, lymph node enlargement and neurologic signs. Signs may be vague and variable. Immunosuppression resulting in secondary, opportunistic infections is common.

- **Feline leukemia virus (FeLV)* (p 350)**

A variety of clinical signs depending on the system(s) of the body affected. Neoplasia, particularly lymphoma, and chronic anemia or pancytopenia occur. Immunosuppression resulting in secondary, opportunistic infections is common.

- **Feline infectious peritonitis (FIP)* (p 352)**

Chronic, fluctuating pyrexia with anorexia and weight loss. The non-effusive (“dry”) form frequently leads to clinical signs associated with the organs involved (liver, kidney, ocular or central nervous system). The effusive (“wet”) form of the disease causes ascites, pleural or occasionally pericardial effusions.

- **Chronic bacterial rhinitis and sinusitis (p 356)**

Chronic sneezing, and mucopurulent nasal discharge may be associated with a poor appetite and weight loss.

- **Toxoplasmosis (p 359)**

Muscle hyperesthesia, respiratory distress, fever, uveitis and neurological signs including seizures occur variably.

continued

continued

- Cryptococcosis (p 360)

Chronic mucopurulent or hemorrhagic nasal discharge, sneezing and distortion of the dorsum of the nose are typical. Central nervous system signs including seizures are less common.

- Systemic mycoses (p 361)

Blastomycosis and histoplasmosis may cause depression, anorexia and weight loss in endemic areas. The most common clinical sign is dyspnea, but signs vary with the organ systems affected.

INFLAMMATION

- **Oral inflammatory disease* (p 353)**

Usually lymphocytic-plasmacytic in nature. Causes reluctance to eat, dysphagia and drooling of saliva with associated weight loss.

- **Inflammatory bowel disease* (p 349)**

Chronic weight loss, intermittent vomiting and/or diarrhea. Cats may have minimal clinical signs other than weight loss.

- Protein-losing nephropathy (p 358)

Results from glomerulonephritis (rare) and amyloidosis (familial disease in Abyssinian). Marked weight loss occurs initially, followed by decreased appetite, polyuria and polydipsia associated with the development of renal failure. Ascites and peripheral edema occur if protein loss is severe.

IDIOPATHIC

- Chylothorax (p 357)

Respiratory distress. Decreased appetite may occur late in the disease.

INTRODUCTION

MECHANISM?

Weight loss of greater than 10% of body weight is significant and should be investigated.

Any cause of weight loss may present as failure to grow or stunting if affecting an immature cat.

Weight loss occurs when there are one or more of the following:

- Inappetence (inadequate caloric intake).
- Inability to digest or absorb nutrients (e.g. pancreatic exocrine insufficiency, inflammatory bowel disease).
- Inability to utilize absorbed nutrients (e.g. diabetes mellitus).
- Increased utilization of absorbed nutrients (e.g. hyperthyroidism, fever).

- Increased loss of nutrients (e.g. protein-losing enteropathy or nephropathy).

Maintenance energy requirements in the adult cat are approximately 50–70 kcal/kg body weight/day. Intakes below maintenance will result in weight loss.

Anorexia has a diverse etiology including stress, pain, fear, trauma, disease or neoplasia.

Causes of anorexia may broadly be categorized as:

- Pseudoanorexia (e.g. oral cavity disease, dental pain).
- Primary anorexia (e.g. central nervous system disorders affecting appetite center).
- Secondary anorexia (e.g. metabolic diseases such as renal failure).

It is important to note that many diseases leading to a thin inappetent cat involve more than just loss of appetite. When weight loss appears to exceed that which can be accounted for by decreased intake, other mechanisms need to be considered.

WHERE?

Signs of a thin inappetent cat may be the result of any disease process that can cause decreased body weight and/or suppression of appetite.

The appetite center is in the hypothalamus.

Diseases affecting the oral cavity and pharynx may cause pain or dysphagia and so decrease nutrient intake. Such animals will often show interest in food but cannot eat. Inability to smell food (anosmia) will frequently cause anorexia (e.g. chronic nasal disease).

Diseases of the gastrointestinal tract, liver and pancreas may cause anorexia, maldigestion or malabsorption of nutrients, and therefore weight loss.

Careful history taking regarding the animal's environment (inside, outside; single-, multiple-cat household) may aid in deciding a diagnostic approach.

Good history taking and complete physical examination are essential, due to the lack of specificity of these clinical signs.

WHAT?

The most common causes of the thin inappetent cat with few other clinical signs are chronic renal failure, neoplasia and, depending on geographical location, several viral diseases (FIV, FeLV and FIP).

Weight loss followed by inappetence tends to be a terminal event in many disease processes.

Many other causes will usually have other significant clinical problems that will aid the clinician in formulating a diagnostic plan.

DISEASES CAUSING SIGNS OF A THIN INAPPETENT CAT

CHRONIC RENAL FAILURE***

Classical signs

- Polyuria, polydipsia.
- Weight loss, inappetence.
- Vomiting.

PATHOGENESIS

Chronic renal failure is defined as primary renal failure that has persisted for an extended period (usually greater than 2 weeks).

Chronic renal failure is associated with irreversible structural lesions in the kidney.

Chronic renal failure is the end result of many disease processes affecting the kidney:

- Anomalous: Familial renal disease, polycystic kidney disease.
- Metabolic: Hypercalcemia (from cholecalciferol rodenticide, granulomatous disease or neoplasia), ischemic injury.
- Mechanical: Chronic urinary tract obstruction (e.g. urolith) resulting in hydronephrosis.
- Neoplastic: Lymphoma, primary neoplasia.
- Infectious: Feline infectious peritonitis, upper urinary tract infection (pyelonephritis).
- Immune: Secondary to glomerulonephritis, amyloidosis.
- Toxic: Therapeutic agents (e.g. gentamicin, amphotericin B, NSAIDs), intravenous contrast agents, heavy metals (e.g. lead), hemoglobin, ethylene glycol and plants (lilies).

The initiating cause of chronic renal failure is often not identified.

At the time of diagnosis there is usually diffuse pathology of the renal parenchyma termed chronic generalized nephropathy.

Polycystic kidney disease is a common cause of renal failure in some breeds of cats and has the following characteristics:

- Renal cysts may be congenital or acquired and may affect one or both kidneys.
- Polycystic kidney disease is characterized by multiple cysts occurring in both kidneys.
- **Polycystic kidney disease occurs as an autosomal dominant inherited renal disease of Persian and Persian-related cats**, with a prevalence of at least 45% in some Persian populations.
- Renal cysts are fluid-filled sacs lined with epithelium, that generally originate in existing nephrons and may therefore occur in the renal cortex or medulla. Cystic structures have also been noted in other organs, such as the liver, in cats with polycystic kidney disease.

- Cysts vary in size and tend to increase in number and size with time. Eventually progressive cyst enlargement compresses the adjacent renal parenchyma and if sufficient renal mass is affected renal failure will develop. **Renal failure may occur at any age**, however affected Persian cats typically present at approximately 7 years.
- Renomegaly may be obvious with the kidneys being irregular in outline. Laboratory evaluation is necessary to determine the extent of the renal dysfunction. Ultrasonographic examination is non-invasive and a very sensitive diagnostic technique for this condition. Cysts are seen as multiple, round anechoic regions.

In chronic renal failure resulting from many of the disease processes, **renal function often slowly deteriorates over months or years**, but the rate of deterioration is very variable between cats. Deterioration is not necessarily linear and many cats are stable for long periods of time with intermittent acute decrements. The postulated causes of progression include:

- Primary disease process; the inciting cause may lead to ongoing renal damage.
- Systemic and metabolic derangements of chronic renal failure.
- Renal compensatory mechanisms (increase in single nephron glomerular filtration rate).

In chronic renal failure, **surviving functional nephrons undergo compensatory changes** including glomerular hypertension, hypertrophy and hyperfiltration (leading to an increase in single nephron glomerular filtration rate).

- These adaptive mechanisms compensate for the loss of nephrons and so minimize the overall decrease in glomerular filtration rate.
- However, it is postulated, based on extrapolation from other species, that these compensatory changes are maladaptive and represent a final common pathway for the progression to eventual glomerular sclerosis and end stage renal failure.

Clinical signs

Chronic renal failure is mainly a disease of older cats, with Persian, Abyssinian, Maine coon, Siamese and Burmese breeds of cat being identified to be at increased risk.

Early cases may be asymptomatic.

Signs associated with chronic renal failure result from failure of excretory, regulatory and synthetic functions of the kidney.

Polydipsia is the most commonly reported clinical sign. The polydipsia is compensatory to an obligatory polyuria. If fluid intake is insufficient, dehydration will result. Polyuria results from:

- Increased solute load in surviving functional nephrons (solute diuresis).
- Disruption of medullary anatomy.
- Impaired response to antidiuretic hormone.

Inappetence or anorexia, weight loss and poor body condition are common clinical signs as the disease progresses.

Lethargy, weakness and depression.

Vomiting (with possible hematemesis) is usually **intermittent and often low grade**. Vomiting and nausea may be associated with:

- The action of uremic toxins on the medullary emetic chemoreceptor trigger zone.
- Uremic gastritis and gastrointestinal ulceration.

Constipation is common and results from dehydration.

Severe uremia associated with an acute exacerbation of chronic renal failure (acute on chronic) or end-stage chronic renal failure may be associated with extreme clinical signs including:

- **Halitosis, ulceration of oral mucosa or tongue** and brownish discoloration of dorsal surface and sloughing of anterior tip of tongue (due to fibrinoid necrosis, arteritis and bacterial degradation of urea to ammonia).
- Occasionally diarrhea, which may be hemorrhagic from uremic enterocolitis.
- Terminally, seizures, stupor or coma may occur.

Clinical signs relating to systemic arterial hypertension are common. **Hypertension is reported in 29–61% of cats with chronic renal failure.** Clinical signs which may be associated with hypertension include:

- **Ocular signs** include sudden blindness with dilated pupils, **hyphema or retinal hemorrhage**, retinal edema, retinal vessel tortuosity, retinal detachment.
- Systolic **heart murmurs** and a gallop rhythm.
- **Neurological signs** including seizures and stupor.

Small and/or irregular kidneys may be palpable, occasionally kidneys are enlarged (for example in neoplastic or cystic kidney disease).

Diagnosis

Diagnosis is based on demonstration of persistently decreased renal excretory function.

- **Persistently elevated blood urea and creatinine concentrations (azotemia) are indicative.**
- **Chronicity and stability is based on two assessments, ideally at a 2–4 week interval.**

Diagnosis is further supported by demonstration of tubular dysfunction:

- **Urine specific gravity of less than 1.030 (typically less than 1.020).**

Any factors contributing to the progression of the renal failure, including the initiating disease, and any systemic complications of renal failure should be identified by diagnostic tests.

Attempt to identify the renal disease initiating the failure using all or any of the following tests:

- Routine hematology and biochemistry.
- Routine urinalysis (including microscopic sediment examination).
- Assessment of proteinuria by urine protein:creatinine ratio. Proteinuria is typically very low (1.5–2 times increase in protein excretion), unless there is significant glomerular disease.
- Quantitative urine bacterial culture.
- Imaging, either radiography to assess renal size and shape, and/or ultrasound examination to assess renal architecture.
- Renal cytology (fine needle aspiration biopsy) and biopsy.
 - However, due to the high risk and low diagnostic yield of histopathology in CRF, biopsy is rarely indicated unless atypical features such as renomegaly, proteinuria or hematuria are present. **Biopsy is only indicated in cases where the result of histopathology will influence the treatment options and therefore, outcome of the case.**

Secondary hyperparathyroidism, hypokalemia, anemia and systemic hypertension are all possible complications of chronic renal failure.

Renal secondary hyperparathyroidism is characterized by excess circulating concentrations of parathyroid hormone (PTH) resulting from altered mineral homeostasis in renal failure, and is present in approximately 80% of cats with chronic renal failure.

- Chronically increased PTH concentrations are toxic to the kidney and contribute to ongoing loss of renal function.
- Factors involved in the pathogenesis of renal hyperparathyroidism leading to increased PTH concentrations include phosphate retention with declining glomerular filtration rate, hypocalcemia and decreased synthesis of 1,25-dihydroxycholecalciferol (calcitriol) by proximal tubular cells.
- Diagnosis is based on elevated PTH concentrations in a cat with chronic renal failure, and normal or slightly low serum calcium concentrations. Measurement of ionized calcium is a better indicator of calcium levels than total calcium. Cats with chronic renal failure and hyperphosphatemia will be hyperparathyroid.
 - Samples for PTH assay require special handling, therefore contact the diagnostic laboratory.
- **Hypokalemia occurs in many cats (20–30%) with polyuric renal failure.**
- Hypokalemia may be a consequence or cause of chronic renal failure in the cat.
- The mechanism is unknown but increased renal losses of potassium, decreased dietary intake and decreased gastrointestinal absorption are implicated.
- Clinical signs of inappetence and generalized muscle weakness (such as ataxia, inability to jump, stiff, stilted gait and ventroflexion of the neck) may occur.

Normochromic, normocytic, nonregenerative anemia is common when chronic renal failure is advanced.

- Occurs mainly from relative erythropoietin deficiency, but other factors contribute, such as decreased red cell life span, uremic suppression of erythropoiesis and gastrointestinal blood loss.
- Routine hematology should be used to monitor anemia and rule out other causes.

Systemic hypertension is present in many cats with chronic renal failure.

- Diagnosis is based on serial blood pressure measurements.

- **Systemic hypertension is usually measured using a Doppler technique (Doppler ultrasonic sphygmomanometry) to assess systolic blood pressure.**
- Normal range is technique dependent, however systolic pressures > 200 mmHg indicate severe hypertension.
- Retinal examination to detect end organ damage should also be carried out.

Proteinuria is a risk factor for progression of chronic renal insufficiency in cats, and may be a marker of glomerular hypertension. Median survival times are significantly reduced if the urine protein/creatinine ratio is > 0.43.

All chronic renal failure cases should receive regular monitoring, involving full clinical examination (including assessment of body weight), measurement of systemic arterial blood pressure and analysis of blood and urine samples. This allows early detection of problems, and assessment of efficacy of therapy and tailoring of treatment to the individual.

Differential diagnosis

Pre-renal azotemia occurs secondary to dehydration or circulatory collapse, and the azotemia results from reduced renal perfusion.

- Typically urine specific gravity is greater than 1.035.
- Pre-renal azotemia concurrent with primary disease affecting renal concentrating ability can mimic renal failure, for example a dehydrated cat with diabetes insipidus.

Acute renal failure.

- Therapeutically and prognostically it is important to distinguish between chronic and acute renal failure.
- Evidence of chronicity is usually obvious from the history (polydipsia, weight loss), physical examination (small kidneys), and diagnostic tests (non-regenerative anemia).
- Due to the gradual decline in glomerular filtration rate in chronic compared to acute renal failure, clinical signs in chronic renal failure tend to be less dramatic relative to the metabolic derangements.

Treatment

Treatment of chronic renal failure is aimed at:

- **Ameliorating the clinical signs and systemic complications associated with renal dysfunction.**
- **Prevention of further deterioration of renal function (progression).**
 - Management of end-stage renal failure by renal replacement therapy (dialysis or transplant) is generally prohibitive because of cost, technical and ethical considerations.

Although chronic renal failure is irreversible, many cats presented in a uremic crisis have superimposed prerenal azotemia or acute renal failure (so called acute on chronic).

- It is very important that appropriate therapy be used to correct reversible azotemia.
- Once reversible azotemia is corrected, more accurate assessment of the severity of the underlying irreversible chronic renal failure can be made.

Treatment of progression of chronic renal failure involves:

- **Identifying and eliminating the inciting cause of the renal damage.**
- **Correcting the systemic and metabolic derangements of chronic renal failure.**
- **Preventing the intrinsic progression of renal failure** (if such progression occurs in the cat).
 - A number of therapeutic maneuvers **may be** effective slowing intrinsic progression. These include dietary protein restriction, angiotensin-converting enzyme (ACE) inhibitors, modification of dietary lipid intake and phosphate restriction. Evidence for a beneficial effect on survival for each of these treatments is limited and therefore currently each case should be assessed on an individual basis.

Maintenance of hydration.

- Unrestricted access to water is essential in any cat with chronic renal failure to allow thirst to compensate for the obligatory polyuria. Additional fluids (oral, subcutaneous or intravenous) may be required when intake fails to keep pace with diuresis. Home administration of subcutaneous fluids are indicated when the cat is unable to maintain hydration. Typically, cats require 75–150 ml SQ q 12–72 h. Begin a 4–5 kg cat on 150 ml twice weekly, and use normal saline with 35 mmol (mEq)/L of KCl added. Education of the owner on proper administration and sterile technique is vital.

Dietary management of chronic renal failure.

- Treatment of cats with chronic renal failure by dietary modification has been proven to significantly increase survival. Generally, commercially available “renal diets” are recommended. These diets have restricted protein, calcium, sodium, phosphorus and acid-load, and added potassium.

Dietary protein restriction is frequently advocated.

- In moderate to severe chronic renal failure, controlled restriction of non-essential protein will reduce the accumulation of nitrogenous waste products that are believed to contribute to the uremic syndrome.
- More controversially, the use of a restricted protein diet in early CRF may slow the rate of progression to end-stage renal failure by preventing maladaptive changes in surviving nephrons. However, evidence for a beneficial effect of protein restriction on renal function in cats with early renal failure is not available.
- Poor appetite and the decreased palatability of restricted protein diets make mal-nutrition a serious problem in renal-failure patients. Monitor carefully for weight loss and decreasing muscle mass.
- Dietary protein intake should be tailored to the metabolic needs of the individual cat. Usually a diet containing at least 21% of gross energy as protein is required (usual maintenance diets contain 35–55% gross energy as protein). The goal is to maintain a BUN of ≤ 29 mmol/L (80 mg/dl). In general, the more severe the renal dysfunction, the greater the protein restriction required, but protein should not be decreased below 19–20% of gross energy (metabolizable energy).

A number of other dietary components have been studied for their effect to modify the rate of progression including calorie intake and fatty acid composition. Dietary phosphate restriction is discussed under the section on renal secondary hyperparathyroidism.

Angiotensin-converting enzyme (ACE) inhibitors may have a renoprotective effect, which is independent of any effect on systemic blood pressure. **ACE inhibitor therapy may also be useful in reducing the degree of proteinuria in cats with chronic renal failure.** benazepril 0.25–0.5 mg/kg PO q 24 h.

- The mechanisms of these effects are unclear, but may be hemodynamically mediated by causing renal vasodilation especially of the efferent arteriole, and reducing glomerular capillary pressure.
- Preliminary studies of ACE inhibitor use in naturally occurring chronic renal failure in cats have shown significantly increased survival times for the subgroup of renal-failure cats with urine protein/creatinine ratios > 1 .
- By reducing glomerular pressure, ACE inhibition would be expected to cause a decrease in glomerular filtration rate and so may increase azotemia. A rise in creatinine of $> 50\%$ warrants withdrawal of the drug.

Treatment of renal secondary hyperparathyroidism should be instituted in a staged manner.

The cornerstone of therapy is dietary phosphate restriction.

- After initiation of phosphate restriction, plasma phosphate levels usually stabilize at a lower level by 2–8 weeks, however PTH concentrations may continue to decline without additional intervention.
- Proteinaceous foods are the main source of phosphate in the diet, so phosphate restriction is generally combined with protein restriction.
- The aim of dietary phosphate restriction is to reduce plasma phosphorus to the lower limit of the reference range, the point at which the most effective control of PTH secretion is usually attained.

If after 4 weeks dietary management alone is not achieving this, or if PTH concentrations are not decreasing, then **intestinal phosphate-binding agents should be introduced to further restrict phosphate intake.**

- Intestinal phosphate-binding agents form non-absorbable salts of phosphate, binding phosphate in both the diet and intestinal secretions. To achieve efficient phosphate binding, the medication should be given, ideally mixed through the food or immediately before feeding.
- **Aluminum hydroxide** should be dosed at 30–100 mg/kg/day PO in divided doses with each meal, titrated to effect based on plasma phosphate concentrations. Dose can be increased to 200–300 mg/kg if necessary to control phosphate. If the cat refuses to eat it with food, a compounding pharmacy can formulate

it in capsules to administer immediately after a meal. Calcium-containing phosphate binders such as calcium acetate (60–90 mg/kg/day divided with meals) or calcium carbonate (90–150 mg/kg/day divided with meals) can be used, but serum calcium must be monitored carefully. Do not use if there is hypercalcemia.

- High dietary phosphate limits the effectiveness of phosphate-binding agents, so preferably these should be used in combination with a low-phosphate diet.

Treatment with an active form of vitamin D directly inhibits PTH secretion. This group of drugs has a **very narrow therapeutic index.**

- **Calcitriol or alphacalcidol** 1.5–3.5 ng/kg/day PO on an empty stomach (maximum 10 ng/kg/day). Because of the very low dose, the human preparations must be re-formulated by a compounding pharmacy for use in cats.
- All active vitamin D preparations enhance intestinal absorption of calcium and phosphorus, and so are contraindicated unless plasma concentrations of calcium and phosphate are normal. In addition, they are ineffective in decreasing PTH concentrations if phosphorus is elevated. Phosphorus concentration must be below 2 mmol/L (6 mg/dl) before calcitriol use is optimal. Between serum phosphorus of 2–2.25 mmol/L (6–7 mg/dl), the effectiveness of calcitriol is decreased, and above a phosphorus of 2.5 mmol/L (8 mg/dl) it is ineffective in reducing PTH concentration.
- Plasma calcium must be closely monitored, initially weekly. If possible measure ionized calcium rather than total calcium. The dosage should be titrated to maintain normocalcemia, not merely to decrease PTH concentrations, and therapy should be discontinued if hypercalcemia occurs. If hypercalcemia does not resolve within 7–10 days of stopping calcitriol, begin intermittent dosing of calcitriol. For cats with mild hypercalcemia based on the ionized calcium concentration, give calcitriol every other day at twice the daily dose, so the total amount per week is the same. If calcium levels do not decrease, try twice weekly dosing at 3.5 times the daily dose (8 pm one day and 8 am 4 days later). Do not use less than twice weekly. PTH concentrations should be measured to document successful control of renal secondary hyperparathyroidism.

- The long-term advantages of this form of therapy are as yet unproven. The aim is to decrease progression of renal failure through a reduction in PTH concentrations. If there is marked hypercalcemia based on measurement of ionized calcium, care should be taken to rule out other causes of hypercalcemia, because the hypercalcemia of renal failure is usually only mild to moderate in severity (total calcium <3.4 mmol/L or 13.5 mg/dl).

Treatment of hypokalemia.

Hypokalemia may be treated with oral potassium gluconate (2–6 mmol/cat/day PO). The exact dose is dependent on the response to therapy, determined by monitoring plasma potassium concentrations.

Treatment of the anemia.

Management of the anemia of CRF should include an initial assessment of the cat to rule out and treat other potential causes of anemia, such as flea infestation and gastrointestinal ulceration.

Nutritional and iron deficiencies will impair the erythropoietic potential, and should be corrected prior to initiating other treatment.

Blood transfusions (limited availability), androgen (poor efficacy) and recombinant erythropoietin therapy have all been used to treat the anemia of CRF.

Recombinant human erythropoietin (rHuEPO) is the most effective therapy.

- Therapy should be started only if clinical signs relating to the anemia are present, such as weakness, inactivity or lethargy, which is usually when the packed cell volume (PCV) is less than 18%. Because of potential side effects of treatment, it is usually only commenced once PCV is <15%.
- Initial dosage is 50–100 U/kg injected subcutaneously three times weekly, with PCV monitored at least twice weekly. Once the PCV has increased to the lower end of the reference range, the dosage is usually reduced to once or twice weekly.
- Adverse effects of rHuEPO include polycythemia, seizures, hypersensitivity reactions and systemic hypertension. Absolute failure to respond to rHuEPO is usually due to iron deficiency.
- After an initial response, many treated cats develop antibodies to rHuEPO, which leads to a severe refractory anemia greater than that present prior to

treatment. This anemia is usually reversible when therapy is discontinued. For this reason rHuEPO should not be initiated too early in the course of progressive CRF.

Treatment of systemic hypertension.

- Treatment is usually carried out on a trial basis, monitoring for a decrease in blood pressure without adverse effects or the development of hypotension. Generally a period of about 2 weeks is sufficient to document a response. If severe clinical signs are present, therapy may need to be more aggressive.
- Classically, a staged therapeutic response is recommended, starting with dietary sodium restriction, followed by the use of various pharmacological agents.

The current treatment of choice for the cat is amlodipine besylate. An initial dose of 0.625 mg/cat PO q 24 h is recommended and may be increased cautiously if the response is poor, to 1.25 mg daily.

Combination therapy is required in some cases, with the addition of an ACE inhibitor or beta blocker.

Treatment of proteinuria involves protein restriction to maintain a BUN of ≤ 29 mmol/L (80 mg/dl) and use of an ACE inhibitor to reduce glomerular pressure.

Treatment of anorexia associated with chronic renal failure.

- Anorexia is usually associated with moderate to severe uremia, and contributes to further uremia by resulting in catabolism of tissue protein for energy.
- Change food gradually over 1–2 weeks in a renal diet, and increase palatability by warming to just below body temperature.

Reduce gastric hyperacidity from hypergastrinemia.

- H₂-receptor antagonists such as famotidine (0.5–1 mg/kg PO q 24 hours).
- Gastric mucosal protectant, sucralfate (250 mg/cat q 8–12 hours, on an empty stomach).

Modify doses of drugs if excreted by kidneys.

Prognosis

Chronic renal failure tends to be progressive and the long-term prognosis is poor, although with careful management some cats will live for years.

Prevention

Since the majority of cases of chronic renal failure are of unknown primary cause, there are currently no preventative recommendations.

Avoid any potential renal insults, particularly in cats with pre-existing compromise of renal function or renal perfusion. For example, avoid using NSAIDs in dehydrated cats, and use intravenous fluids prior to induction of anesthesia and during surgery, to maintain renal perfusion in elderly cats and cats with compromised renal function. Remember that minor renal insults may summate to cause clinically significant renal damage.

- Promptly and appropriately treat conditions causing decreased renal perfusion including dehydration, shock and hypotension associated with anesthesia and surgery.

Pre-renal and post-renal azotaemia, if not corrected, may lead to renal damage and renal failure.

FELINE IMMUNODEFICIENCY VIRUS (FIV)***

Classical signs

- Middle-aged to older cats, particularly entire males and feral cats.
- Clinical signs variable, often vague.
- Weight loss, inappetence.
- Pyrexia, lymphadenopathy.
- Immunosuppression (cat flu, diarrhea, neoplasia).
- Gingivitis/stomatitis.

Pathogenesis

Feline immunodeficiency virus (FIV) is a lymphotropic lentivirus, which causes an acquired immunodeficiency syndrome (AIDS) in cats.

- FIV is morphologically and biochemically similar to human immunodeficiency virus (HIV), however it is antigenically distinct and the viruses are species specific.

Infectious virus is found in the saliva of FIV-positive cats and transmission occurs primarily though inoculation of the virus through saliva or blood.

- **Bite wounds are considered a primary source of infection.**
- Vertical transmission either transplacentally or via infected milk occurs experimentally but is of questionable significance in natural settings.
- Horizontal transmission in multiple cat households via food bowls, mutual grooming appears rare.
- Sexual transmission is not thought to be a significant route of infection.

The prevalence of FIV infection varies with the population studied:

- FIV infection in healthy cats in the United States and United Kingdom ranges from 2–3%, compared to rates approaching 30% in sick cats or cats with a high risk of exposure.
- **Male cats are three times more likely to be infected than female, especially male entire cats.**
- **Risk of infection is greater in free-roaming and feral cats than indoor cats.**

FIV has a worldwide distribution in domestic cats.

The course of the disease following FIV infection is dependent on a number of host- and virus-related factors, such as the age and health status of the cat and the strain and dose of the virus.

Acute infection involves rapid replication of virus in lymphoid organs and salivary glands.

Although CD4+ (helper) and CD8+ (cytotoxic) T lymphocytes may be infected by FIV, FIV selectively destroys CD4+ cells.

- The ratio of CD4+ to CD8+ becomes “inverted” in cats with FIV because of the relative lack of CD4+ cells.
- The lack of CD4+ leads to the immunosuppression associated with many of the clinical signs of FIV infection.

Many cats remain completely asymptomatic for years, despite severe lack of CD4+ lymphocytes.

Clinical signs

Clinical signs are very variable from cat to cat, and may be a direct effect of the virus or secondary to immunosuppression.

The infection can be divided into stages: acute, asymptomatic carrier, persistent generalized lymph-

adenopathy, AIDS-related complex (ARC), and AIDS. However it may be difficult to distinguish these stages clinically.

- The **acute** phase begins about 4 weeks following infection and may persist for up to 4 months.
 - Mild lymphadenopathy, neutropenia, fever, malaise and diarrhea may occur.
 - These signs may be mild and go completely unnoticed by the owner.
 - These cats will usually test seronegative for the virus.
- The **asymptomatic carrier** phase may last for months to years.
 - Despite being asymptomatic, significant immune aberrations may be present
- **Persistent generalized lymphadenopathy** lasts for less than 2–4 months.
 - Poor hair coat, fever and leukopenia may be noted.
- **The terminal clinical phase can sometimes be divided into ARC and AIDS.**
- ARC is the presence of clinical disease that does not fulfill the criteria for AIDS.
- **AIDS is the final stage of the infection.**
 - **Profound weight loss (> 20% of body weight) and a variety of opportunistic infections.**
 - **Frequently there is persistent leukopenia and anemia.**
 - **Additionally, cats may have neurological disease or malignancy.**
 - **Average life expectancy is less than 1 year.**

Many diseases found in the asymptomatic phase may or may not be related to the virus.

Immunosuppression leads to opportunistic infections with bacterial, fungal or protozoal agents.

- Little good statistical evidence is available to show that there is a higher incidence of many of these diseases in FIV-infected cats.
- Some studies indicate that these diseases may be more severe in the FIV-infected cat.

Certain disease processes have been directly associated with the terminal clinical phase of the disease.

- **Chronic ulceroproliferative stomatitis is common**, and may be associated with concurrent calicivirus infection.
- **Ocular disease** including uveitis, glaucoma, infiltration of inflammatory cells in the posterior chamber

(pars planitis), focal retinal chorioretinitis and retinal hemorrhages have been reported.

- **Neoplasia** including lymphoma (often extra-nodal), leukemia, and several others have been associated with the terminal stage of the disease. However, the exact role of FIV in the neoplastic process is unclear.
- **Central and peripheral nervous system disease** has been associated with FIV infections. These signs may be transient. Clinical signs include behavior changes, seizures, paresis and anisocoria. Concomitant infections (cryptococcosis, toxoplasmosis or FIP) may contribute to neurologic signs.
- **Renal disease** and failure may have an association with the FIV virus. Since many older cats suffer from chronic renal failure, the exact association between the virus and renal failure has yet to be determined.

Diagnosis

Diagnosis of FIV infection is based on serological evidence of the presence of FIV specific antibodies.

- **In practice, diagnostic kits are available to detect antibody to either p24 core protein or gp41 envelope protein using enzyme-linked immunosorbent assay (ELISA) or rapid immunomigration (RIM).**

Interpretation of a positive antibody result:

- Vaccinated cats will test positive with all current testing methods.
- In unvaccinated cats, FIV antibodies are associated with lifelong viral infection. A positive test implies a persistently infected cat.
- Passive transfer of antibody via milk will result in a positive test in kittens nursed by an infected queen. Such kittens should not be tested until at least 6 months of age.
- False-positive results occur with ELISA or RIM tests, but at a low frequency. A positive test should be confirmed using a western blot if it will influence management of the cat.

Interpretation of a negative antibody result:

- The cat is not infected with FIV.
- The cat is infected but no antibodies are present.
 - This occurs in early stages of infection, usually 2–4 weeks after infection.

- Small numbers of cats (up to 10–20%) have delayed seroconversion or may never seroconvert.
- The cat is in the terminal stages of the disease, when antibody production declines.

Detection of FIV infection does not prove that the clinical signs are necessarily related to the infection.

- Since cats can live for years in the “asymptomatic” stage of the disease, the clinician should try to decide if the virus is a cause, contributing factor, or just incidental to the cat’s problem.

Immunofluorescent antibody or western blot techniques may be used to confirm the presence of FIV antibody, particularly in ELISA-positive cats from low-risk populations, or if initial test results were equivocal.

Non-specific findings on routine hematology and biochemistry include:

- Various cytopenias including neutropenia, thrombocytopenia, lymphopenia, and anemia.
- Mild non-regenerative anemia.
- A polyclonal hyperglobulinemia.

Differential diagnosis

Feline leukemia virus infection (FeLV) may be clinically very similar to FIV infection, as many signs are associated with the immunosuppression which is common to both conditions.

- Most cats that are tested for FeLV probably should be tested for FIV.

The dry form of feline infectious peritonitis (FIP) may lead to signs of wasting, neurologic signs, renal failure and ocular disease. The “dry” form of FIP is extremely difficult to diagnose without histologic examination of tissue.

Toxoplasmosis causes neurologic and ocular signs as well as wasting. FIV and toxoplasmosis may also occur concurrently.

Treatment

The FIV status of the cat should not necessarily preclude treatment for other diseases.

No specific therapy has proven effective against the virus in the long term, but reverse transcriptase inhibitors and immunomodulating drugs may provide some benefit in rescuing severely ill cats in the short-term. Although some drugs can reduce viral load (AZT and PMEA), there are no studies showing a proven clinical benefit long term, or resolution of infection, and long-term use is hindered by side effects.

Reverse transcriptase inhibitors may suppress viral replication.

- **Zidovudine (3'-azido-3'-deoxythymidine, AZT)** (5–15 mg/kg PO or 5 mg/kg subcutaneously q 12 hours) has been shown to improve clinical signs, but does not eliminate the virus.
 - Increased numbers of CD4+ cells and improvement in CD4+:CD8+ ratios have occurred in naturally infected FIV cats.
 - Remission in stomatitis has been reported.
 - The virus may become resistant to AZT
 - Anemia and hepatotoxicity are potential side effects.

Immunomodulating drugs to potentiate the immune response against the virus include:

- **Evening primrose oil (550 mg PO q 24 hours).**
- **Low-dose oral human recombinant alpha interferon** (30 IU/cat PO q 24 hours, 7 days on, 7 days off).
- **Acemannan, *Propionibacterium acnes* and staphylococcal protein A** have been suggested as immunomodulating agents in FIV infection.

Aggressive supportive care and management of secondary infections are essential in FIV-positive cats. All infections should be fully assessed in terms of extent and appropriate treatment administered, ideally based on culture and sensitivity results. Response to treatment may be slower in FIV-infected cats, and so sufficient duration of antibiotic must be administered.

Appropriate preventative medicine is important in immunosuppressed cats.

- Inactivated vaccines should be used against respiratory or enteric pathogens.
- However the ability of an FIV-infected cat to produce an adequate immune response to a vaccine is unknown.

Prognosis

In the acute or asymptomatic phases of the disease, it is not possible to predict the short- or long-term prognosis.

Many cats appear to live for years with no or minimal problems.

In the terminal clinical phase, the prognosis is poor to grave with average life expectancy of less than 1 year.

Prevention

One vaccine has been approved for the prevention of FIV. There are still questions on its efficacy and the American Association of Feline Practitioners (AAFP) has yet to recommend its use.

Until a proven effective vaccine is developed and the ability to differentiate a false positive vaccine titer from infection, prevention is achieved by avoiding exposure to infected cats.

- FIV-positive cats should be neutered to reduce the tendency to fight.
- Confinement of FIV-positive cats to indoors will reduce the spread of the virus, and will also reduce the exposure of the affected cat to secondary infectious diseases.
- In single-cat households or multiple-cat households where all cats are seronegative for the virus, the animals are at negligible risk if they are kept as indoor cats.
- FIV is readily killed by disinfectants and survives only a few hours in the environment, so risk of fomite transmission is low.

The FIV status of new cats should be determined prior to introduction to a group. Ideally these cats should be rechecked in 4–6 weeks because of the latency period between exposure and production of antibody.

CANCER CACHEXIA**

Classical signs

- Anorexia, muscle wasting and weight loss.
- Weakness, lethargy.
- Clinical signs associated with the neoplastic lesion.

Pathogenesis

Cancer cachexia is probably the most common paraneoplastic syndrome.

It is associated with a variety of malignancies.

Although many cats with neoplasia are cachexic, little information is available on the metabolic derangements present. Care must be taken extrapolating data from the dog and man, given the differing nutritional requirements of these species.

Weight loss occurs in patients with neoplasia because:

- **Nutrient intake is reduced.**
 - This is related to tumor size and location. For example, intraoral masses cause dysphagia, and infiltrative intestinal neoplasia may reduce nutrient assimilation.
 - Decreased appetite may be a consequence of therapy.
- **Metabolic and hormonal changes secondary to neoplasia lead to inefficient energy utilization.**

Clinical signs

Inappetence and weight loss are common clinical findings in many cats with varying malignancies.

Weight loss is frequently associated with muscle wasting, and consequent lethargy and weakness.

Poor hair coat, delayed wound healing and impaired immune function are associated with cachexia.

Other clinical signs will vary with the nature and location of the neoplasia.

Diagnosis

Neoplasia should be suspected in any cat showing inappetence and weight loss, with no obvious other cause.

A thorough clinical examination, including palpation of all lymph nodes, may provide an indication of the site of the lesion and direct further investigation.

Principal diagnostic efforts are aimed at establishing the nature and extent of the neoplastic lesion. The exact diagnostic investigation will depend on the location and type of lesion being investigated but may include:

- **Diagnostic imaging** (radiography, ultrasound examinations and computed tomography) of the thorax and abdomen.
 - Evaluation of pulmonary neoplasia should include two lateral and ventrodorsal radiographic views.
- Cytological or histopathological evaluation of tissue is required to confirm the diagnosis.

Cats with neoplastic lesions should be monitored closely for evidence of malnutrition. A detailed dietary history and physical examination are important for monitoring. Regularly assess body weight and use a body condition scoring system.

Hematological and biochemical parameters are relatively insensitive markers of nutritional status, but may provide additional information. However these markers may be affected by the neoplasia itself.

- Creatine kinase concentrations may increase rapidly in response to anorexia.
- Protein malnutrition may lead to hypoalbuminemia.
- Malnutrition may also cause anemia and lymphopenia.

Differential diagnosis

Differential diagnoses include **most causes of inappetence and weight loss.**

Other differentials to be considered depend on the site, location and nature of the tumor.

Treatment

Treatment specific to the neoplastic lesion will depend on the nature, extent and location of the tumor, but may include excisional surgery, radiotherapy or chemotherapy.

Dietary recommendations postulated to prevent or ameliorate cancer cachexia include:

- **Palatable, highly digestible, complete and balanced diets.**
- Tumor cells have an obligate requirement for glucose and are unable to utilize significant amounts of lipid for energy. Therefore, **energy-dense diets, which are relatively high in fat** and restricted in carbohydrate, may theoretically have beneficial effects.

Appropriate treatment of associated symptoms such as nausea, diarrhea or vomiting.

Pharmacological appetite stimulation may be considered but objective evidence of their efficacy is not available.

In cats which are unable or unwilling to eat, enteral or parenteral feeding may be considered.

- **Enteral nutrition should be used wherever possible**, as this prevents intestinal mucosal atrophy
 - Nasoesophageal, esophageal, gastrostomy and jejunostomy tubes may be used
 - Esophagostomy and gastrostomy tubes are preferable in cats requiring more long-term nutrition.
- Parenteral feeding is more technically complex and expensive, and should only be used when feeding via the gastrointestinal tract is impossible.

Prognosis

The prognosis for each individual case will be dependent on the nature of the neoplasm and the response to therapy.

Cachexia and hypoalbuminemia tend to be poor prognostic indicators.

Prevention

Cats with neoplastic lesions should **be monitored closely for evidence of malnutrition**.

SEPTIC FOCUS/PERSISTENT FEVER**

Classical signs

- Fluctuating pyrexia and associated inappetence.
- Weight loss.
- Clinical signs associated with the etiology of the fever.

See main references on page 364 for details (The Pyrexia Cat).

Pathogenesis

The thermoregulatory center is located in the preoptic region of the anterior hypothalamus.

Hyperthermia describes a core body temperature above that considered normal in the cat. **In fever, the set point of the thermoregulatory center is increased.**

Fever may be caused by exogenous pyrogens such as infectious agents, immune complexes and tissue inflammation or necrosis.

- **Exogenous pyrogens** principally act by causing the host to release endogenous pyrogens.
- **Endogenous pyrogens** act on the thermoregulatory center, alter the set point and induce a febrile response.

Weight loss frequently occurs in cats with prolonged fever because:

- **Febrile cats are frequently inappetent.**
- **A febrile cat is in a hypermetabolic state.**
- **Weight loss may be associated with the fever per se, or more often with the disease causing the fever.**

The differential diagnosis list for causes of fever is extensive but may be broadly categorized:

- **Localized infection.**
 - Including urinary tract infection, pyometra, pyothorax, peritonitis, abscess, bronchopneumonia, endocarditis, suppurative cholangitis/ cholangiohepatitis, dental disease, retrobulbar or pulmonary abscess and osteomyelitis.
- **Systemic infection.**
 - Including FeLV, FIV, feline infectious peritonitis (FIP), feline panleukopenia, respiratory tract virus infection, bacteremias, toxoplasmosis, mycobacterial infection and systemic mycoses.
- **Immune-mediated disorders.**
 - Including primary immunodeficiencies, systemic lupus erythematosus, polyarteritis nodosa, chronic progressive polyarthritis, immune-mediated hemolytic anemia and immune-mediated thrombocytopenia.
- **Neoplasia.**
 - Including lympho- and myeloproliferative diseases and large neoplastic lesions with central necrosis.
- **Miscellaneous conditions.**
 - Including drug reactions.

Clinical signs

Principal clinical signs will be **fever, weight loss and inappetence**.

Fever may be **sustained or fluctuating**.

Other clinical signs will vary with the nature of the disease causing the fever.

Diagnosis

A thorough history and clinical examination is vital to identify any localizing signs that would narrow the differential diagnosis list.

Monitoring the cat's temperature **three or four times daily** over a period of 48–72 hours confirms the presence and nature of the fever.

Routine hematology often reveals a **neutrophilia with or without a regenerative left shift**.

- Occasionally a degenerative left shift occurs when the bone marrow is unable to make an adequate response, and neutropenia develops in the face of a left shift. This has a poor prognosis.

In the absence of localizing signs a series of initial screening tests are carried out to identify the septic focus:

- Routine hematology and biochemistry.
- Routine urinalysis including bacterial culture and sensitivity.
- Thoracic and abdominal radiographs.
- Fecal analysis and culture for enteric pathogens.

Further diagnostic investigation may be required depending on the cause of the fever, this may include:

- Blood culture.
- Synovial fluid aspirates.
- Echocardiography.
- Bone marrow aspirates.
- Immunological tests such as Coomb's, antiplatelet antibody and antinuclear antibody tests.
- Serum protein electrophoresis.
- Serology.

If a bacterial cause is suspected, strenuous attempts should be made **to obtain a sample of infected material for bacterial culture and sensitivity testing prior to administering antibiotics**.

Differential diagnosis

Differential diagnoses include **most causes of inappetence and weight loss**.

Other differentials to be considered depend on the site, location and nature of the disease causing fever.

Treatment

Effective treatment is based on accurate assessment of the cause of the fever, followed by appropriate management.

Use of antibiotics, corticosteroids and NSAIDs prior to diagnosis should be avoided where possible, as it will mask the clinical signs and interfere with diagnostic testing.

If a septic focus is identified, treatment involves **drainage where appropriate (e.g. placement of thoracic drains in pyothorax) and use of antibiotic therapy based on the results of culture and sensitivity testing**.

Mild fever is unlikely to be fatal and may be beneficial in inhibiting viral and bacterial replication and increasing leukocyte function.

Fever in excess of 41.0°C often results in significant organ damage and may initiate disseminated intravascular coagulation.

Symptomatic therapy for fever includes:

- Oxygen.
- Crystalloid fluid therapy.
- **Antipyretic drugs** (NSAIDs) – these act directly on the thermoregulatory center and should be tried before surface cooling, unless the fever is life-threatening, when they may be instituted together.
- **Surface cooling.** Core temperature will continue to decrease after surface cooling has ceased, so to avoid large oscillations in temperature, aggressive cooling should stop just prior to reaching the desired temperature.
 - With cool, not cold, water (avoid inducing shivering).
 - Fans.
 - Ice packs over large blood vessels.

Prognosis

The prognosis for each individual case will be dependent on the etiology of the fever and the response to therapy.

APATHETIC HYPERTHYROIDISM*

Classical signs

- Older cats (usually > 8 years).
- Weight loss and inappetence.
- Weakness and depression.
- Palpable goiter.
- Tachycardia ± gallop rhythm.

See main references on page 304 for details (The Cat With Weight Loss and a Good Appetite).

Clinical signs

Hyperthyroidism is a disease of older cats, with only 5% being under 10 years of age at first diagnosis.

The majority of cats with hyperthyroidism present with weight loss and polyphagia.

In approximately 5% of cases, apathetic or masked hyperthyroidism occurs.

- **Weight loss is accompanied by a decreased appetite.**
- Cats tend to be depressed.
- Muscle weakness may be evident as ventroflexion of the neck.
- Cats with apathetic hyperthyroidism may show **signs of concurrent disease including congestive cardiac failure, renal failure or neoplasia.**

Other clinical signs are those typical for hyperthyroidism.

- **Unilateral or bilateral palpably enlarged thyroid (goiter).**
- Polyuria and polydipsia.
- Vomiting and diarrhea (bulky feces).
- Tachycardia, gallop rhythm, murmur and arrhythmia may be noted.
- Poor coat condition with decreased grooming.

Diagnosis

Although clinical signs of inappetence and depression are atypical for hyperthyroidism, **the presence of a thyroid goiter or tachycardia** should alert the clinician to the possibility of hyperthyroidism.

As apathetic hyperthyroidism typically **occurs in hyperthyroid cats with significant concurrent disease**, a thorough investigation is required to establish the presence of such disease.

Routine hematology may reveal a mild erythrocytosis.

Serum biochemistry frequently shows elevations of hepatic enzymes (alanine amino transferase and alkaline phosphatase).

A definitive diagnosis of hyperthyroidism is made on the basis of **high serum basal total thyroxine (T₄) concentrations.**

Normal serum thyroid hormone concentrations are occasionally found in hyperthyroid cats due to:

- Day-to-day fluctuation in hormone levels.
- Early or mild hyperthyroidism.
- The presence of concurrent non-thyroidal disease that suppresses serum thyroid levels.

Given that concurrent disease is common in cats with apathetic hyperthyroidism, suspect hyperthyroidism despite normal Total T₄ concentrations if the cat is older than 8 years and has signs consistent with hyperthyroidism. e.g. tachycardia or thyroid goitre.

If hyperthyroidism is suspected despite normal total T₄ concentrations, diagnostic possibilities include:

- **Repeat basal total T₄ measurement in 1–2 weeks.**
- **Identify and treat concurrent disease, then repeat basal total T₄ measurement.**
- Measure basal free T₄ concentrations, although euthyroid cats with non-thyroidal illness may have an elevated concentration.
- Dynamic thyroid testing may also be used:
 - Triiodothyronine (T₃) suppression test.
 - Thyrotropin (TRH) stimulation test, although the usefulness of this test in cats with non-thyroidal illness to distinguish those with and without hyperthyroidism has recently been questioned.
- Radionucleotide uptake and imaging.

Concurrent disease may be present and should be investigated, in particular:

- Evidence of concurrent renal failure with increased creatinine and urea concentration may also be present. Urine specific gravity will also provide further information regarding renal function.
- Hypertrophic cardiomyopathy secondary to hyperthyroidism (thyrotoxic cardiac disease) is frequently seen on echocardiography. This may be reversible with resolution of the hyperthyroid state but may progress to congestive cardiac failure.

Differential diagnosis

These include most other causes of inappetence and weight loss.

As tachycardia (with or without cardiac failure) is often present, cardiac disease should be placed high on the differential diagnosis list.

For cats with polydipsia and polyuria in addition to inappetence and weight loss, the main differential diagnoses would include chronic renal failure and diabetes mellitus.

Treatment

Hyperthyroid cats may be treated by surgical thyroidectomy or radioactive iodine (^{131}I), which are curative, or alternatively the condition may be controlled using antithyroid therapy.

The ideal form of treatment for each case will depend on a number of factors:

- Age of the cat.
- Presence of concurrent disease, particularly chronic renal failure or cardiovascular disease.
- Availability of appropriate nuclear medicine facilities.
- Owner's wishes, including ability to medicate cat and cost.

Cats with apathetic hyperthyroidism frequently have concurrent disease, and it is essential that this is thoroughly investigated and considered prior to embarking on therapy.

- Cardiac disease may preclude safe anesthesia and surgical thyroidectomy.
- **Glomerular filtration rate declines with resolution of the hyperthyroid state.** Therefore, any cat suspected of having underlying renal disease (azotemia, creatinine and urea concentrations in the upper part of the reference range, or lack of urine-concentrating ability) should be treated with antithyroid medication until it can be determined if induction of euthyroidism would have detrimental effects.

Medical therapy for hyperthyroidism is used in the short term to stabilize a hyperthyroid cat prior to surgical thyroidectomy, as trial therapy assesses the effect on renal function prior to curative treatment, or for long-term management if surgery or radioactive iodine therapy are not suitable.

- Medical management merely blocks thyroid hormone synthesis and so requires continuous life-long treatment.
- **Carbimazole** (5 mg PO q 8 hours for 2–3 weeks, then 5 mg PO q 12 hours to maintain euthy-

roidism) and **methimazole** (10–15 mg/day PO divided q 8–12 hours for 2–3 weeks, then 7.5–10 mg/day PO divided q 12 hours to maintain euthyroidism) are the drugs of choice for both short- and long-term medical management of hyperthyroidism. Transdermally absorbed methimazole may be obtained from a compounding pharmacist, and may be useful if the owners are unable to give oral medication.

- Exact dosage should be adjusted on the basis of basal total T_4 concentrations.
- Failure of efficacy is usually due to poor compliance.
- Adverse effects appear to be less common with carbimazole than methimazole and usually occur in the first 3 months of therapy.
- Transient vomiting, anorexia and lethargy have been reported, and usually resolve without withdrawal of the drug.
- Serious hematological adverse effects may occur, and so routine monitoring is required.
- Hepatopathy and self-induced facial excoriation may rarely occur.
- Other medical therapies may be considered including atenolol (to reduce the cardiac effects of hyperthyroidism), **stable iodine** (preoperatively to reduce gland vascularity) and **ipodate**.

Surgical thyroidectomy is curative when it is possible to remove all abnormal thyroid tissue.

- **Medical stabilization, ideally for 3 weeks preoperatively significantly reduces the anesthetic and surgical complications.**
- The most common complication is post-operative hypoparathyroidism, although Horner's syndrome and laryngeal paralysis may also occur.

Radioactive iodine therapy is the treatment of choice for most hyperthyroid cats when suitable facilities for treatment are available.

- This is the treatment of choice for cats with hyperthyroidism induced by thyroid carcinoma.
- Complications include the induction of permanent hypothyroidism and incomplete ablation requiring an additional treatment.
- The principal disadvantage is a period of isolation is required to comply with local radiation safety regulations. This makes treatment of intercurrent disease difficult or impossible during this time.

CHOLANGIOHEPATITIS COMPLEX*

Classical signs

- Inappetence and weight loss.
- Lethargy.
- Jaundice.
- Hepatomegaly and/or ascites.

See main references on page 427 for details (The Yellow Cat or Cat With Elevated Liver Enzymes).

Clinical signs

The most consistent clinical signs in these cases are **weight loss, variable anorexia, lethargy and depression**.

Fever may occur, particularly in the acute or suppurative form of the disease.

Vomiting, diarrhea and abdominal pain may also occur.

Clinical signs more specific to hepatic disease such as **hepatomegaly and jaundice** are common, particularly in the early stages of the condition.

Occasionally polyphagia or a normal appetite may be seen, particularly associated with lymphocytic cholangiohepatitis.

Ascites, hepatic encephalopathy and a generalized lymphadenopathy are uncommon clinical signs.

In some cats, cholangiohepatitis is associated with inflammatory bowel disease and pancreatitis.

Diagnosis

Routine serum biochemistry findings include **mild to severe elevations in hepatic enzymes** (especially **alanine amino transferase (ALT)**). Hyperbilirubinemia and elevated bile acids are often also present.

Elevated **serum globulin concentrations** are common in the chronic stage of the disease.

A **neutrophilia**, often with **left shift** may be present in acute cases on routine hematology. More chronic cases often have a lymphocytosis.

If there is significant biliary stasis, intestinal absorption of vitamin K may be impaired leading to impaired secondary hemostasis and a **coagulopathy**.

Abdominal radiography may be normal or reveal:

- Hepatomegaly.
- Loss of abdominal contrast due to the presence of ascites, or if more localized, due to pancreatitis.
- Occasionally, choleliths may be noted.

Hepatic parenchymal changes on **abdominal ultrasound** are not specific to cholangiohepatitis, varying from normal parenchymal architecture, to diffuse increases (particularly if cirrhosis is present), or decreases (especially in acute or suppurative inflammatory disease) in echogenicity. Ultrasonography is helpful to demonstrate:

- Abnormalities of the biliary tract including biliary stasis or sludging, cholecystitis, biliary tract distention and obstruction.
- Concurrent pancreatic or intestinal disease.

A definitive diagnosis requires histopathological examination of hepatic tissue. Although as a diffuse disease, cholangiohepatitis should be amenable to diagnosis by percutaneous fine-needle aspiration techniques, blood contamination and the inability to assess hepatic architecture make definitive diagnosis of inflammatory disease difficult. Tissue core biopsy or surgical wedge biopsy yield improved diagnostic accuracy.

- Surgical exploration and wedge biopsy are required if there is evidence of extra-hepatic biliary stasis, severe biliary sludging or clinically significant choleliths.
- In addition, surgical exploration permits a complete evaluation of the biliary tree and pancreas, aspiration of bile for culture (although this may be carried out percutaneously by ultrasound guidance), biopsy of pancreas, and intestine and placement of feeding tubes.

Differential diagnosis

Differential diagnoses for inappetence and weight loss associated with suspicion of hepatic pathology includes hepatic lipidosis, hepatic neoplasia, feline infectious peritonitis affecting the liver and hyperthyroidism.

Feline infectious peritonitis is an important differential diagnosis for cholangiohepatitis, as both may present with hyperglobulinemia or ascites.

Treatment

Acute or suppurative cholangiohepatitis is treated primarily with antibiotics, ideally based on the results of culture and sensitivity testing.

- Ampicillin (10–40 mg/kg PO q 8 hours), amoxycillin (11–22 mg/kg PO q 8–12 hours), amoxycillin clavulanate (12.5–25 mg/kg PO q 12 hours), or cephalexin (10–30 mg/kg PO q 8–12 hours) are good empirical choices.
- Metronidazole in combination with the above antibiotics, provides broader anaerobic cover. Use at a lower dose (7.5–10 mg/kg PO q 12 hours) because of hepatotoxicity and the increased potential for neurological signs in animals with pre-existing hepatic disease. In addition it may have immunomodulating properties.

Immunosuppressive therapy is used if there is a lymphocytic component to the pathology, and in more chronic cases, although definitive evidence of efficacy is lacking.

- Prednisolone (2–4 mg/kg q 12–24 hours), gradually tapering the dose.
- Other immunosuppressive agents may be considered in non-responsive cases.

Fluid therapy and nutritional support will be required if anorexia is present.

Supportive and adjunctive therapy is often recommended on an empirical basis.

- **Ursodeoxycholic acid** (10–15 mg/kg PO q 24 hours) is a hydrophilic bile acid which has cytoprotective properties.
- **Parenteral vitamin K1** (0.5 mg/kg SC q 12 hours for 3 days) may be provided for those cases showing evidence of a coagulopathy.
- **S-adenosylmethionine** (18 mg/kg PO q 24 hours) and **vitamin E** have antioxidant properties and may be useful supplements.

INFLAMMATORY BOWEL DISEASE*

Classical signs

- Weight loss.
- Chronic vomiting and/or diarrhea.
- Variable appetite.

See main references on page 307 for details (The Cat With Weight Loss and a Good appetite).

Clinical signs

Clinical signs vary with the type and severity of the inflammation, and with the anatomical extent of the disease, although the correlation is poor.

Characteristically, any combination of **weight loss, vomiting or diarrhea** may be seen.

Vomiting is particularly evident **if the pathology involves the stomach or proximal small intestine** and may occur every few days to weeks. Vomiting is usually **unrelated to feeding**, and is more frequently composed of **fluid** rather than food.

Diarrhea may be soft and semi-formed to watery in consistency, with or without steatorrhea. Occasionally large bowel diarrhea with tenesmus, mucus and hematochezia may be present.

Clinical signs are usually chronic and may initially be intermittent.

Weight loss initially results from malabsorption and later from inappetence. In some cases, progressive weight loss is the only clinical sign.

Flatus and borborygmi may be reported.

Initially, **polyphagia or a normal appetite** may be seen, but this frequently **progresses to inappetence** as the disease increases in severity.

Intestinal thickening, mesenteric lymphadenopathy or abdominal pain may be revealed by abdominal palpation.

Occasionally, severe small intestinal disease leading to protein leakage into the gut lumen (**protein-losing enteropathy**) leads to extreme weight loss and hypoproteinemia. Although usually polyphagic, if the condition is associated with severe inflammatory or malignant disease, anorexia may occur. Vomiting and diarrhea may rarely be accompanied by ascites and peripheral edema.

Diagnosis

The diagnosis of inflammatory bowel disease is made based on exclusion of all other causes of the clinical signs in association with appropriate histopathology.

- Intestinal infiltration with inflammatory cells is non-specific.

- Inflammatory bowel disease is an idiopathic condition.

Initial diagnostic investigation should aim to exclude other causes of gastrointestinal signs and may include:

- Routine hematology and biochemistry and serum basal total T_4 concentrations.
 - Stress leukogram and occasionally eosinophilia.
 - Serum globulins may be increased as part of the chronic immune stimulation. In severe cases hypoproteinemia may result from protein-losing enteropathy.
- Fecal analysis and culture to exclude fecal parasites and enteric pathogens.
- Radiography and ultrasonography should be performed.
 - Radiography is frequently unremarkable, although increased gas may be present in intestinal loops.
 - Ultrasonography may show evidence of thickened or abnormal intestinal walls. Abdominal lymph node enlargement may be present.
- A dietary trial is a valuable tool to determine if signs resolve when the cat is fed a novel single protein and carbohydrate diet.

Assessment of serum cobalamin and folate concentrations, breath hydrogen analysis and sugar permeability studies may be supportive of inflammatory bowel disease.

Definitive diagnosis requires multiple intestinal biopsies either by endoscopy, laparoscopy or laparotomy:

- Gastrointestinal endoscopy permits visual evaluation of the mucosa, but the superficial nature of the mucosal biopsies obtained by this technique limits their diagnostic value.
- Laparotomy allows the collection of full-thickness biopsies, and gross evaluation and biopsy of other abdominal organs if required.

Differential diagnosis

The principal differential diagnoses are those conditions causing inappetence and weight loss in conjunction with gastrointestinal signs, namely other causes of enteropathy, chronic pancreatitis, cholangiohepatitis, gastrointestinal neoplasia and apathetic hyperthyroidism.

Treatment

As the etiology of the immune response in inflammatory bowel disease is unknown, the **principal form of**

treatment involves immunosuppressive therapy in combination with dietary management.

A therapeutic dietary trial may be undertaken as part of the diagnostic evaluation (to eliminate dietary sensitivity), as the initial stage of treatment, or in combination with immunosuppressive therapy, depending on the severity of the clinical signs.

- A nutritionally balanced, highly digestible diet should be used.
- Usually a single protein, single carbohydrate source diet is used (hypoallergenic), preferably one to which the cat has not previously been exposed.
- Use of diets with hydrolyzed protein (e.g. Hill's z/d or Royal Canin HA) may be efficacious in some cats. Hydrolyzation reduces the molecular weight of dietary proteins to < 10 000 so they are not detected by the immune system.
- A high-fiber diet has proven beneficial in cases with large intestinal involvement.
- Minimum duration of the trial should be 3 weeks, but may be longer. If an improvement is seen, the cat should then be challenged with the original diet to confirm sensitivity.

Immunosuppressive therapy is required in the majority of cases:

- Prednisolone (2–4 mg/kg PO q 12–24 hours) is used at higher initial doses, which are gradually reduced to the lowest maintenance dose.
- Metronidazole (7.5–15 mg/kg PO q 12 hours) is used either as sole therapy in mild cases, or in addition to prednisolone for those cats in which the response to prednisolone is inadequate. Metronidazole has activity against anaerobic bacteria, protozoa and may be anti-inflammatory and influence cell-mediated immunity.
- Other more potent immunosuppressive therapy may be required in some cases.

FELINE LEUKEMIA VIRUS (FELV)*

Classical signs

- Younger cats, often less than 6 years of age, clinical signs variable.
- Inappetence, weight loss and lethargy.
- ± Neoplasia (lymphoma) – lymph node enlargement, organomegaly, solid masses.
- ± Anemia – pica, lethargy, pale mucous membranes, tachycardia.

Classical signs—Cont'd

- Immunosuppression – abscesses, cat flu, vomiting, diarrhea, neoplasia.
- Ocular signs – uveitis.
- Neurological signs – ataxia, behavioral changes.

See main references on page 540 for details (The Anemic Cat).

Clinical signs

There are no “classical signs” in a FeLV infection. A variety of clinical signs may be noted dependent on the body system affected. No one clinical sign is found in all cats with persistent viral infection.

The most consistent clinical signs are **weight loss, variable anorexia, lethargy and depression.**

Early infection with the virus is usually characterized by **submandibular lymph-adenopathy and fever.** This usually resolves in several days to weeks.

Pale mucous membranes, weakness and anorexia are seen if the virus causes anemia or bone marrow suppression. Hematological disease may be a primary viral effect on the bone marrow or secondary (e.g. neoplastic infiltration, hemobartonellosis)

Respiratory distress occurs if the virus leads to development of an **anterior mediastinal lymphoma** with or without pleural effusion.

Signs of **vomiting, diarrhea, and weight loss** may be evident if there is **gastro-intestinal infiltration** with malignant lymphocytes.

Signs of **liver or renal failure** occur if these organs are involved in lymphoma.

Gingivitis/stomatitis.

Ocular signs are relatively common, primarily uveitis, although neuro-ophthalmic signs, such as anisocoria may occur.

Various neurological signs may also be noted including ataxia and behavioral changes.

Immunosuppression may cause recurrent bacterial infections, especially subcutaneous abscesses, which recur or fail to respond to appropriate therapy.

Many of the clinical signs relate to the presence of concurrent disease such as toxoplasmosis or hemobartonellosis.

Diagnosis

When clinical disease warrants evaluation for FeLV, testing should be performed.

- **However a positive test does not prove that the disease process is caused by the virus.**

Diagnosis is usually based on the detection of viral antigen (usually the p27 core protein) by immunoassay. The ELISA test is recommended by the American Association of Feline Practitioners.

- **Serum or plasma** is preferred over whole blood when ELISA testing because there are reported to be fewer false positives.

A **positive result may indicate:**

- **Transient viremia** in the early viremic state; the cat may become negative later if a successful immune response is mounted.
- **Persistent viremia;** such cats are likely to develop FeLV-related disease.
- **Discordant results** (positive antigen test and negative on virus isolation) may occur early in the course of the infection or may indicate focal infection with no virus present in the circulation.
- **False-positive result.**

Confirmatory tests should be considered in cats with a positive ELISA result, especially if the cat is asymptomatic.

- **Immunofluorescent antibody test (IFA)** detects **p27 antigen** within **neutrophils and platelets.**
 - A positive result indicates that the **bone marrow is infected** and such cats are likely to be persistently infected. The **IFA** test is considered **more specific,** although slightly **less sensitive,** than the ELISA.
- **Virus isolation is considered the gold standard test for confirmation of FeLV infection.**
- Polymerase chain reaction (PCR) assays have been recently developed, however testing protocols require further validation.

Certain forms of diseases (abdominal visceral lymphoma) may be negative for the virus, although FeLV may have played a role in their development.

Other diagnostic tests should be carried out as required to investigate the presenting signs.

Differential diagnosis

The differential diagnoses will vary depending on the clinical manifestation(s) of the FeLV-related disease.

Because the clinical signs in a cat having disease caused by this virus are so extremely diverse, FeLV-associated disease must be considered in any chronically ill cat.

FIV infection is a principal differential diagnosis, as this may also be a cause of immunosuppression and neoplasia.

Treatment

The FeLV status of the cat should not necessarily preclude treatment for other diseases.

Chemotherapy has been used to treat a variety of lymphomas caused by the FeLV virus. Certain forms (mediastinal) seem to be more chemoresponsive than others (abdominal visceral).

Blood transfusions can give temporary help for the anemic patient.

Aggressive supportive care and management of secondary infections are essential in FeLV-positive cats.

All infections should be fully assessed in terms of extent, and appropriate treatment administered, ideally based on culture and sensitivity results. Response to treatment may be slower in FeLV-infected cats, and so sufficient duration of antibiotic must be administered.

A variety of immunomodulator and antiviral therapies have been tried. As with FIV, the efficacy of these agents to clear the virus completely is questionable, although there is evidence that they may decrease total viral load.

FELINE INFECTIOUS PERITONITIS (FIP)*

Classical signs

- Younger cats, pedigree cats with variable clinical signs.
- Inappetence, weight loss and depression.

Classical signs—Cont'd

- Fever.
- Pleural and/or peritoneal effusions (abdominal enlargement and respiratory difficulties).
- Uveitis and neurological signs.

See main references on page 372 for details (The Pyrexia Cat).

Clinical signs

Most common in pure-bred cats from multi-cat households.

FIP is primarily seen in cats from 3 months to 3 years of age, although a second peak in incidence may occur in geriatric cats.

FIP occurs in two main forms, wet (or effusive) and dry (non-effusive). Weight loss, variable appetite, fever, lethargy and depression occur in both forms and may be the only clinical signs in early disease.

The **wet form** tends to progress more rapidly, and is characterized by combinations of **abdominal, pleural or pericardial effusions**.

- Non-painful abdominal enlargement is the main clinical sign if ascites is present. Vomiting and diarrhea may occur as the disease advances.
- **Dyspnea** is characteristic of pleural effusions.

The **dry form** leads to clinical signs associated with **pyogranulomatous perivascular disease in multiple organs** and clinical signs vary with the affected body system.

- This form of the disease tends to be more chronic (months) and progressive.
- **Neurological** (seizures, nystagmus, behavioral changes, peripheral neuropathies) and **ocular** (posterior and anterior uveitis) involvement is common.
- The liver, kidney and abdominal lymph nodes may also be involved.

Diagnosis

Definitive diagnosis is difficult, if not impossible, without histopathological examination of affected tissues.

- Histologic evaluation revealing typical pyogranulomatous is diagnostic.

By combining clinical signs with other testing, a high suspicion of FIP may be obtained.

In the wet form, **evaluation of the fluid is helpful.**

- Fluid is typically yellow, viscous, and may have fibrin clots.
- Fluid is high in protein (> 35g/L or 3.5 g/dl and usually 50–120g/L or 5–12 g/dl) with moderate numbers of non-degenerate neutrophils and macrophages, although lower than usual for an exudate.
- If the albumin:globulin ratio of the fluid is > 0.81, FIP is an extremely unlikely diagnosis.

Aspiration of affected organs (liver, lymph nodes, kidney) will often reveal a pyogranulomatous response.

Increased serum globulin concentration (polyclonal gammopathy) is present in the majority of cats with FIP.

- Other biochemical findings will vary, dependent on the organ system involved.

Complete blood count usually often reveals a normocytic, normochromic, nonregenerative anemia, a neutrophilic leukocytosis and lymphopenia.

“FIP titers” reported by laboratories are either **coronavirus titers** or **titers to the 7B protein in coronavirus**. Neither are specific for the mutated FIP-coronavirus virus. Although claimed that 7B protein was specific for FIP strains, subsequent studies have shown that it is not present in some FIP strains, and that non-FIP coronavirus may have an active 7B component. Currently there is no serological test that is specific for FIP-coronavirus.

Differential diagnosis

FIV, FeLV and toxoplasmosis are the three most common differentials for the non-effusive form of FIP. All three can lead to fever, inappetence and weight loss. Toxoplasmosis and FeLV can both present with ocular and neurological signs.

Abdominal neoplasia, liver disease (especially cholangiohepatitis), **pancreatitis, peritonitis** and **diseases causing hypoproteinemia** can lead to abdominal effusion. Fluid analysis and cytology of the fluid can frequently distinguish between these diseases.

Heart failure, diaphragmatic hernias, neoplasia and chylothorax may all present signs similar to effusive FIP in the thorax. Fluid analysis and thoracic radiographs will help in differentiating the cause of fluid accumulation.

Treatment

Clinical FIP is invariably fatal, and no effective treatment has been found in cats.

Anti-inflammatory and immunosuppressive therapy may increase life span by controlling the complement mediated vasculitis, but will not cure the condition.

- **Prednisolone** (2–4 mg/kg PO daily).
- **Cyclophosphamide** and **chlorambucil** may be used for more potent immunosuppression, but cytotoxic agents should be avoided in debilitated cats.
 - Broad-spectrum antibiotic cover should be given if immunosuppressive drugs are used to prevent secondary infections.
 - Therapy should be re-evaluated regularly, including monitoring for myelosuppression.

Other immunomodulating drugs (recombinant **human interferon- α**) and **anti-viral agents** have been promising *in vitro* but have limited efficacy in *in vivo* studies.

Supportive care should be provided if the cat is not euthanized.

ORAL INFLAMMATORY DISEASE*

Classical signs

- Inappetence associated with dysphagia.
- Weight loss.
- Ptyalism, halitosis and oral pain.
- Oral inflammatory, ulcerative and proliferative lesions.

See main references on page 585 for details (The Cat With Salivation).

Clinical signs

Pure-bred cats may be predisposed.

Continuum of disease from mild gingivitis to chronic, severe, intractable oral inflammation.

- **Most cases are due to lymphoplasmacytic gingivitis/stomatitis.**

The condition may be waxing and waning in nature but in some cases is progressive.

Oral examination reveals erythema, swelling, ulceration and proliferative lesions (giving a cobblestone appearance) of varying severity. The tissue is friable and therefore tends to bleed easily.

- These lesions may involve the **gingiva, glossopalatine arches** (fauces), **pharynx, buccal mucosa** and less commonly the tongue, hard palate and lips.
- Many cats have significant dental disease but it is not clear whether the inflammation precedes, contributes to, or results from this.

Submandibular lymphadenopathy is also common.

A poor hair coat may be noted due to decreased grooming. It is usually accompanied by varying degrees of dental disease.

A particular form of oral inflammatory disease is **feline juvenile hyperplastic gingivitis**.

- This condition affects young cats at the **time of eruption of adult teeth**. Abyssinian and Persian cats may be predisposed.
- There is a tendency for spontaneous remission with maturity.
- Lesions consist of a very proliferative, hyperemic gingivitis.

Diagnosis

The identification of this condition is usually obvious on **oral examination**.

- A complete history and clinical examination is essential to ensure evidence of concurrent disease or additional lesions are not overlooked.

The investigation should aim to identify any possible predisposing causes of oral inflammation.

- Perform routine hematology, biochemistry and urinalysis to assess for systemic predisposing disease.
 - Approximately half the cats have a polyclonal gammopathy.
- Test for FeLV, FIV and respiratory tract viruses.

- Perform a full oral examination under general anesthesia to assess for periodontal disease and feline odontoclastic resorptive lesions, including a full mouth radiographic dental survey.

Biopsy and histopathological examination of affected areas is required for **definitive diagnosis** of the lymphoplasmacytic nature of the lesions.

Differential diagnosis

Other diseases that may appear clinically similar on examination include neoplasia (squamous cell carcinoma and fibrosarcoma), eosinophilic granuloma complex and autoimmune disease (pemphigus vulgaris and systemic lupus erythematosus).

FIV, FeLV and the respiratory tract viruses, particularly feline calicivirus, may be associated with oral ulceration or stomatitis.

Stomatitis may be found in association with severe uremia.

Dental disease may be associated with oral inflammatory lesions. If the oral inflammation does not resolve with treatment of the dental disease, lymphoplasmacytic gingivitis/stomatitis should be considered.

Treatment

Initial management involves removing or treating any underlying etiology identified.

Attention should be given to the nutritional status of the cat, including other forms of feeding, if the severity of the lesions is preventing the oral intake of food.

- A dietary trial of a novel protein source should also be considered to exclude hypersensitivity as a cause.

Pivotal to management is thorough dental management. The aim is to improve the overall oral hygiene by scaling and polishing, followed by extraction of any anatomically compromised teeth which may be acting as foci of inflammation.

- Repeated dental prophylaxis may be required to maintain oral hygiene.
- In a number of cases the condition resolves or can be more effectively managed after extraction of all

the teeth caudal to the canines. Occasionally removal of the canines and incisors is also required.

Systemic antibiotics frequently produce only a transient improvement.

- Effective antibiotics include clindamycin, clavulanate potentiated amoxycillin, metro-nidazole and spiramycin (which is concentrated in saliva).

Immunosuppressive therapy appears to produce the most reliable responses in chronic cases.

- Prednisolone (2–4 mg/kg PO once daily) on a tapering regime to the lowest maintenance dose.
- In cases failing to respond to corticosteroid therapy, alternative immunosuppressive or immunomodulating therapies should be considered.
 - Including chlorambucil, cyclosporin A, gold salts, human recombinant interferon alpha and topical application of bovine lactoferrin. There have been few studies evaluating these drugs and most have more potential side effects, requiring closer monitoring.

DIABETES MELLITUS

Classical signs

- More common in older cats, especially neutered males.
- Polyuria and polydipsia.
- Usually polyphagia and weight loss.
- May progress to decreased appetite.

See main references on page 236 for details (The Cat With Polydipsia and Polyuria).

Clinical signs

Although diabetes mellitus may occur in any cat, it is more frequent in older cats, especially neutered males.

- In some regions Burmese cats may be predisposed.

The classic clinical signs are those of polydipsia, polyuria, polyphagia and weight loss.

- These signs are frequently unnoticed by cat owners.
- Therefore many cats do not present until the cat develops more severe clinical signs such as inappetence, vomiting and depression.
 - These clinical signs may be associated with the development of ketoacidosis.

Body condition varies from obese to thin.

Coat condition is often poor, with seborrhea and scales.

Hepatomegaly is common. If diabetes mellitus is associated with pancreatitis, abdominal discomfort may be present.

A plantigrade stance may be noted due to diabetic neuropathy.

If the diabetic cat is ketoacidotic, dehydration, depression and weakness may also be present.

Diagnosis

Documenting a persistent fasting hyperglycemia (blood glucose > 12 mmol/L, 217 mg/dl) and glucosuria in a cat with appropriate clinical signs is required to establish a diagnosis of diabetes mellitus.

- It is important to distinguish diabetes mellitus from stress hyperglycemia.
 - Glucosuria rarely results from stress hyperglycemia because the hyperglycemia is usually below the renal threshold or only transient, however glucosuria does not exclude this possibility.
 - Monitoring for glucosuria at home may aid differentiation.

Blood glycosylated hemoglobin and serum fructosamine concentrations represent the average blood glucose concentrations over the preceding 4–6 weeks and 2–3 weeks respectively.

- They may be helpful to distinguish diabetes mellitus from stress hyperglycemia.
- They also provide further information regarding glycemic control when monitoring patients under treatment.

Further investigation is required to assess for concurrent disease or systemic complications of diabetes mellitus.

- Routine hematology and biochemistry, including assessment of electrolytes.
 - Diabetic cats frequently have mild to moderate increases in hepatic enzymes and cholesterol.
 - Concurrent renal failure or pre-renal azotemia may be present.
- Complete urinalysis should be carried out.
 - The presence of ketones in the urine confirms the diagnosis of diabetes mellitus. Sick ketoacidotic cats require aggressive monitoring and management.

- Symptomatic or asymptomatic **urinary tract infections** are frequently present in diabetes mellitus.

CARDIAC CACHEXIA

Classical signs

- Decreased appetite and weight loss.
- Lethargy.
- Signs relating to cardiac disease – tachycardia, cardiac murmurs and arrhythmias.
- Dyspnea if pleural effusion or pulmonary edema present.

See main references on page 124 for details (The Cat With Abnormal Heart Sounds and/or an Enlarged Heart).

Clinical signs

Inappetence and weight loss may occur, associated with cardiac disease.

- The remaining clinical signs will vary with the nature of the cardiac disease, although cardiac cachexia usually only occurs in cats with cardiac disease sufficient to cause failure.
- **Generally it is seen in cats with chronic, severe right-sided congestive cardiac failure.**

Lethargy and exercise intolerance are present.

Dyspnea due to the presence of pleural effusion or pulmonary edema may be present.

Rarely **ascites** may be present.

Physical examination may reveal poor peripheral pulses or evidence of venous congestion (jugular distention and pulses, hepatojugular reflux).

Cardiac auscultation may reveal tachycardia, arrhythmias or cardiac murmurs.

Diagnosis

Diagnosis is based on documenting the presence of severe cardiac disease in a cat with weight loss.

Evidence of cardiac disease may be provided by thoracic radiography, electrocardiography, measurement of systemic blood pressure and echocardiography.

- Thoracic radiography may show cardiomegaly, vascular congestion and possibly pleural effusion or pulmonary edema.
- **Echocardiographic examination is usually required to make a definitive diagnosis of the type of cardiac disease.**

CHRONIC BACTERIAL RHINITIS AND SINUSITIS

Classical signs

- Chronic sneezing and snuffling.
- Chronic, persistent or intermittent, mucopurulent nasal discharge.
- Stertorous respiration.

See main references on page 21 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Usually there is a history of chronic upper respiratory tract disease following an acute episode of signs.

- Typically there is serous to mucopurulent, unilateral or bilateral oculonasal discharge, often associated with sneezing.
 - Signs may be persistent or intermittent, but are usually gradually progressive.
 - Rarely epistaxis may be noted, but this is more frequently associated with neoplasia.
- Stertorous respiration may be audible.

If chronic and severe, in rare cases, bone destruction may lead to nasal distortion.

Inappetence, which is often associated with inability to smell food, and weight loss may occur.

Systemic signs such as depression and anorexia are often associated with intermittent exacerbation of disease.

Diagnosis

Appropriate clinical signs and a history of previous acute upper respiratory tract disease are supportive of the diagnosis, however a full investigation is required to exclude other causes of nasal discharge including neoplasia and fungal disease.

- Neoplasia and fungal causes are unlikely if the clinical signs have been constant for a protracted period (1–2 years).

A **thorough examination of the oral cavity** and pharynx should be made whilst the cat is anesthetized to exclude congenital and traumatic palate defects, dental disease, nasopharyngeal polyps and neoplasia as a cause.

Radiographic evidence of bilateral fluid density in nasal passages often extending into the frontal sinuses is typical.

- Occasionally bone destruction is seen on radiographs.

Cytology of the nasal discharge reveals neutrophils, bacteria, and the absence of neoplastic or fungal elements.

Rhinoscopy (anterior and posterior) will permit visual examination and flushing of the nasal cavity, and facilitate nasal biopsy.

- Blind biopsy or traumatic flushing may be used to obtain biopsy material from the nasal cavity.
- **It is extremely difficult to definitively exclude neoplasia in these cases.**
 - A diagnosis should not be made on cytology alone, because both neoplasia and fungal disease frequently reveal only neutrophils and bacteria on cytologic examination.
 - Rhinotomy and biopsy may be necessary to definitively exclude neoplasia, particularly in cases with suggestive clinical signs.

Respiratory virus status may be evaluated by virus isolation from oropharyngeal and nasal swabs.

FeLV and FIV status should be assessed and other causes of immunosuppression should be excluded.

CHYLOTHORAX

Classical signs

- Respiratory distress – tachypnea, dyspnea and open mouth breathing.
- Weight loss.
- Inappetence.

See main references on page 77 for details (The Cat With Hydrothorax).

Clinical signs

Although signs of respiratory distress may appear acute, the disease process is often more chronic.

Clinical signs will vary with the quantity of fluid present.

- Cats adjust to the decreased lung volume, and distress is not usually apparent until late in the disease.
- **Tachypnea and dyspnea** are often present.
- If ventilation is severely impaired, cyanosis may be noted.

Auscultation usually reveals **decreased breath sounds** (muffled and dull) ventrally.

- Occasionally fluid may accumulate in focal areas, and unilaterally rather than bilaterally.
- Heart sounds may be muffled.

The thorax may be dull on percussion.

Weight loss is usually present, accompanied by inappetence as the respiratory difficulty increases.

Clinical signs to a certain degree will depend on the underlying cause of the pleural effusion.

- **Possible causes of chylothorax include** neoplasia, heart failure, trauma and hyperthyroidism, although in many cases the underlying etiology is not determined despite extensive investigation (termed idiopathic chylothorax).

Diagnosis

The presence of a pleural effusion may be confirmed radiographically or ultrasonographically.

- **Care should be taken in handling and positioning cats with respiratory distress, and thoracocentesis may be required to stabilize the cat prior to these procedures.**
- Radiographic evidence of a pleural effusion includes:
 - Presence of pleural fissure lines.
 - Separation of lung borders from the thoracic wall and rounding of edges of the lung lobes.
 - Loss of cardiac silhouette.

Thoracocentesis with biochemical and cytological analysis of thoracic fluid is required for definitive diagnosis:

- Chylous fluid is usually a white “milky” fluid.
 - It may be slightly pink on repeated aspirations.

- If the cat has not eaten recently, the fluid may appear only slightly opaque.
- Lymphocytes are usually the predominant cell type, with some non-degenerate neutrophils.
- **The concentration of triglycerides in the fluid exceeds that of the serum in a true chylous effusion.**

It is important that, where possible, the underlying cause is investigated, as this will influence the treatment and prognosis.

PROTEIN-LOSING NEPHROPATHY

Classical signs

- Marked weight loss.
- Initially polyphagia may be present but progresses to inappetence.
- Polydipsia and polyuria.
- Subcutaneous edema and/or ascites.

Pathogenesis

The most common causes of protein-losing nephropathy are glomerulo-nephritis and renal amyloidosis.

Renal amyloidosis is characterized by the extracellular deposition of fibrillar proteins arranged in a beta-pleated sheet configuration.

- **Reactive (secondary) systemic amyloidosis is the form of amyloidosis occurring in cats.**
 - It is considered to be **secondary to inflammatory, neoplastic and chronic infectious** disease, although in many cases the predisposing disease is not found.
- Severe proteinuria occurs when amyloid deposits in the glomerulus cause glomerular damage.
 - Most domestic cats with amyloidosis and at least 25% of Abyssinian cats with familial amyloidosis have medullary amyloid deposits, without significant glomerular deposits.
 - In cases of medullary amyloidosis, proteinuria may be mild or absent, although the deposits will interfere with renal concentrating ability.

Glomerulonephritis is caused by antibody–antigen complexes present in the glomerulus that lead to immune-mediated glomerular damage.

- Initially the glomerular injury is characterized by proteinuria, but as the condition progresses, the entire nephron may become non-functional, with decreased glomerular filtration rate and azotemia.
- **Glomerulonephritis** may be found in association with any **chronic antigenic stimulus**, including **infectious, inflammatory and neoplastic diseases.**
 - In the cat, glomerulonephritis has been particularly associated with infectious diseases including FeLV, FIV and FIP, and hemolymphatic neoplasia.
 - In the majority of cases an underlying antigen source is not identified and the disease is classed as idiopathic.

Glomerular proteinuria is characteristically massive, and in many cases may lead to clinical signs related to protein loss and eventually the nephrotic syndrome.

The nephrotic syndrome is characterized by massive proteinuria, hypoalbuminemia, hyperlipidemia and subcutaneous edema and/or ascites.

- The proteinuria leads to hypoalbuminemia and subsequent development of edema.

Clinical signs

Protein-losing nephropathies are uncommon conditions in the cat.

- **Glomerulonephritis** usually affects **young adult cats** (average age 3–4 years), with males being predisposed. The condition is rare.
- Most cats with **amyloidosis** are **over 5 years** of age at diagnosis. Systemic reactive amyloidosis occurs as a familial disease in Abyssinian cats.

Clinical signs in early disease are principally weight loss with a good appetite and even polyphagia.

- Signs frequently progress to inappetence and depression.
- Continued protein loss eventually leads to the **nephrotic syndrome** with subcutaneous edema and/or ascites.

Polyuria and polydipsia are common if the condition progresses to renal failure and uremia.

- Polyuria and polydipsia are also common if there are medullary amyloid deposits.
- Clinical signs of uremia may also be noted (see page 334, chronic renal failure).

The **kidneys** are usually **small, firm and irregular on palpation**.

Both conditions are associated with an underlying chronic antigenic stimulus, including infectious, inflammatory and neoplastic diseases. Clinical signs may also relate to the underlying disease.

Systemic hypertension may occur and result in hypertensive retinopathy, acute-onset blindness or neurological signs.

The prognosis is variable depending on the cause of the protein-losing nephropathy, although is generally considered poor if actual renal failure is present.

- Clinical signs in glomerulonephritis may wax and wane, and occasionally undergo complete or prolonged periods of remission.
- Amyloidosis tends to be slowly progressive, and is generally fatal.

Diagnosis

Diagnosis of protein-losing nephropathy is made on the documentation of proteinuria, in the absence of pre- and post-renal causes. A complete urinalysis should therefore be carried out.

- **Urinalysis typically reveals proteinuria with a benign sediment.** A benign sediment excludes lower urinary tract disease as a cause of the proteinuria.
- Hyaline casts may be noted on sediment examination.
- In the early stages of disease, urine-concentrating ability may be retained.
- Proteinuria is usually detected on qualitative screening tests, such as urine dipstick reagent strips.

The protein:creatinine ratio should be evaluated to further quantify the urinary protein loss.

- Although the magnitude of the proteinuria can be used to predict the site of protein loss, there is great variability in ratios with different diseases.
- The quantity of protein loss in glomerular disease is massive compared with that in pre-renal and post-renal proteinuria. Protein:creatinine ratios of greater than 13 commonly occur in glomerular proteinuria, although ratios generally range from mild to severe (ratio of 5–13).

Routine biochemistry should be evaluated.

- **Plasma protein concentrations** may be variable, with hypoalbuminemia occurring if the protein loss is severe. Conversely, hyperglobulinemia may occur associated with the chronic inflammatory focus initiating the lesion.
- **Hypercholesterolemia** is reported as a characteristic feature of the nephrotic syndrome, however it is a common non-specific finding in cats with any form of renal disease.
- **Azotemia** and a **low urine specific gravity** will indicate the presence of **renal failure**.

Abdominal radiography and ultrasound may provide information on renal architecture and size.

Renal biopsy is the only definitive method of distinguishing between glomerulonephritis and amyloidosis.

- Complete morphological classification of glomerular lesions may require light, electron and immunofluorescence microscopy.
- Amyloid deposits demonstrate characteristic green birefringence after Congo red staining when viewed under polarized light.
 - The diagnosis is frequently difficult to achieve if glomerular involvement is minimal or absent, requiring medullary biopsies.

A thorough investigation for an underlying inflammatory focus should be made, including assessment of FeLV and FIV status.

TOXOPLASMOSIS

Classical signs

- Especially in immuno-compromised individuals, particularly free-roaming cats.
- Weight loss, lethargy and inappetence.
- Fever.
- Respiratory distress.
- Icterus.
- Uveitis.
- Neurological signs including ataxia and seizures.
- Muscle hyperesthesia.

See main references on page 376 for details (The Pyrexia Cat).

Clinical signs

Self-limiting small bowel diarrhea is common after primary exposure, although it is often unrecognized.

Acute fatal toxoplasmosis is recognized in kittens and immuno-compromised cats.

Chronic toxoplasmosis is characterized by diverse clinical signs depending on the tissue affected.

Respiratory distress due to pneumonia is common in kittens and cats with acute infection.

Central nervous system disease, including ataxia and seizures, may occur either with acute or chronic infection.

Icterus is common due to infection involving the liver.

Anterior or posterior uveitis may be the only obvious sign present in some cats.

Muscle stiffness or hyperesthesia.

The disease may be chronic with weight loss and lack of appetite. Occasionally, toxoplasma granulomas (tissue cysts) form in the gastrointestinal tract or pancreas causing chronic vomiting.

Diagnosis

Routine laboratory testing is not specific for toxoplasmosis.

Diagnosis of toxoplasmosis may be made on:

- **Rarely tachyzoites or bradyzoites may be identified in tissues, broncho-alveolar lavage fluid, cerebrospinal fluid and effusions.**
- Oocysts in the feces do not provide definitive diagnosis due to difficulties of identification.
 - **Shedding** only occurs for **1 or 2 weeks** following initial infection, **usually prior to illness.**
- Serologic testing for antibodies is helpful, but not definitive because clinically normal cats frequently have significant titers. The magnitude of the titers is not proportional to severity of the disease.
 - **IgG titers may last for years and are common in normal cats indicating previous infection.** A four-fold rise in IgG titer over 2–4 weeks suggests active infection.
 - **A positive IgM titer persists for approximately 3 months, so tends to indicate recent infection** but may persist for much longer.

- A positive response to appropriate treatment provides a presumptive diagnosis.

Routine hematology and biochemistry findings are variable dependent on the tissues affected.

Thoracic radiography may reveal a pleural effusion and diffuse interstitial or alveolar patterns.

CRYPTOCOCCOSIS

Classical signs

- **Progressive chronic nasal discharge and sneezing.**
- **Soft tissue swelling over the nose, polypoid masses in the nasal cavity.**
- **Neurological and ocular signs.**

See main references on page 25 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Cryptococcosis is the most common systemic fungal disease of the cat, and has a worldwide distribution.

It is most commonly **acquired by inhalation**, and so clinical signs are often localized to the respiratory tract.

- Immune response leads to **granuloma formation**, leading to **facial swellings** and **polypoid mass** lesions within the nasal cavity.
- Stertor and inspiratory dyspnea may occur.
- Typically there is **sneezing and mucopurulent nasal discharge** (unilateral and bilateral), which is commonly blood tinged.

The **central nervous system and eyes** may be affected by direct extension from the nose.

- Signs include depression, behavior changes, ataxia and seizures.
- Ocular signs include granulomatous chorioretinitis and uveitis.

Depression, inappetence (which occurs as a result of the inability to smell the food) and weight loss are common.

Skin involvement (papules and draining nodules) with peripheral lymphadenopathy may occur.

Diagnosis

Diagnosis based on cytological identification of cryptococcal organisms in nasal discharge, exudates, fine-needle aspiration of masses and lymph nodes and cerebrospinal fluid.

Histopathology may be required if cytology is not diagnostic.

Using a latex agglutination test to identify cryptococcal capsular antigen (on serum, urine or cerebrospinal fluid) provides a non-invasive, sensitive and specific diagnostic test.

Nasal radiography may reveal increased soft tissue density and bone destruction.

PCR (polymerase chain reaction) assays are now available to detect cryptococcal antigens in biopsy material.

SYSTEMIC MYCOSES

Classical signs

- Vague, non-specific signs of weight loss, inappetence and depression.
- Dyspnea.

See main references on pages 371, 388 for details (The Pyrexia Cat).

Clinical signs

The most common systemic mycoses (excluding cryptococcosis) are **histoplasmosis** and **blastomycosis**.

- Both are geographically restricted infections.
 - *Histoplasma capsulatum*, the agent causing histoplasmosis, is endemic throughout large areas of the temperate and subtropical regions of the world.
 - Blastomycosis (caused by *Blastomyces dermatitidis*) is principally a disease of North America, but has occurred in Africa and Central America.

History tends to be vague and chronic, including weight loss, inappetence and weakness.

Mild to moderate **fever**.

Infection is commonly acquired by inhalation, and so clinical signs are often localized to respiratory tract.

- **Dyspnea** and occasionally coughing may occur, with increased respiratory noise on auscultation.
- Absence of respiratory signs does not exclude significant lung involvement.

Involvement of the gastrointestinal tract causes **diarrhea and weight loss**.

Peripheral lymphadenopathy and granulomatous, ulcerating skin lesions may be noted.

Ocular involvement is common, and may cause a granulomatous retinitis, uveitis and panophthalmitis.

Hepatomegaly, splenomegaly and neurological signs may also be seen.

Cats with disseminated disease are generally extremely ill.

Diagnosis

Diagnosis is based on cytological identification of the organisms in exudates, fine-needle aspiration of lesions and lymph nodes, cerebrospinal fluid and bronchoalveolar lavage fluid.

- Fungal culture may assist, but is not required for identification of the organism.

Histopathology may be required if cytology is not diagnostic, and shows pyogranulomatous lesions.

Serology may be useful in the diagnosis of blastomycosis, but false-negative results may occur both early and late in the infection. It should be used in cases where there is a high level of suspicion of the disease, but organisms can not be demonstrated.

Thoracic radiography may show varying changes, however a **diffuse interstitial or nodular interstitial pattern** is most commonly seen.

Hematological changes tend to be non-specific, and include the presence of a mild non-regenerative anemia in some cases.

PORTOSYSTEMIC SHUNTS

Classical signs

- Congenital shunts usually show clinical signs by 6 months of age.
- Weight loss or stunting (congenital shunts).

continued

Classical signs—Cont'd

- **Neurological signs – hypersalivation, seizures, ataxia, blindness and behavioral changes.**
- **Inappetence, vomiting or diarrhea.**

See main references on page 588 for details (The Cat With Salivation).

Clinical signs

Portosystemic shunts are vascular **communications between the portal and systemic** venous circulation, and may be a congenital anomaly or acquired.

- **Congenital portosystemic shunts** in cats are usually **single extrahepatic shunts** resulting from developmental anomalies of the vitelline system.
 - Persian and Himalayan cats are predisposed.
 - A predilection for male cats has been suggested, and such cats are often crypt-orchid.
 - Cats with congenital shunts will usually show clinical **signs by 6 months of age**, however a congenital portosystemic shunt should not be excluded on the basis of age alone.
- Multiple **extrahepatic acquired portosystemic shunts** are formed secondary to portal hypertension, and are extremely uncommon in the cat.
 - Acquired shunts usually occur in cats with chronic, severe, diffuse hepatic disease.

Signs are often vague or non-specific and episodic.

Cats with congenital shunts may show **stunting** (smaller than littermates) or **weight loss**.

Clinical signs of **hepatic encephalopathy predominate** in cats with portosystemic shunts.

- Vague anorexia, depression and weakness.
- Ataxia, behavioral changes (bizarre and aggressive behavior), aimless pacing, blindness and seizures may occur.
- **Hypersalivation**, often profuse, is also common.

There are often intermittent episodes of vomiting, diarrhea and inappetence with normal periods between.

Lower urinary tract signs are present in cats with concurrent urate urolithiasis.

Copper- or golden-colored irises have been noted in some cats with portosystemic shunts.

Heart murmurs have also been noted in some affected cats.

Ascites and signs of primary hepatic disease may be seen in cats with acquired portosystemic shunts.

Diagnosis

Routine hematology and biochemistry may be unremarkable in cats with congenital portosystemic shunts however:

- Routine hematology may reveal a **mild non-regenerative, microcytic anemia** often with **poikilocytosis**.
- **Hypoglycemia, hypoalbuminemia, hypocholesterolemia and decreased blood urea concentrations** may indicate hepatic dysfunction.

Pre- and post-prandial serum bile acids should be assessed.

- Pre-prandial bile acid concentrations may be normal or elevated.
- **Post-prandial bile acids are typically elevated, frequently exceeding 100 $\mu\text{mol/L}$ (39.2 mg/L).**

Hyperammonemia, particularly post prandial is commonly present.

Abdominal radiographs may demonstrate microhepatica, but in many cats hepatic size is normal.

Ammonium biurate crystals may be present on urine sediment examination.

- Ammonium urate calculi are often radiolucent.

Portosystemic shunts may be identified and localized on abdominal ultrasound.

Other techniques may be required to definitively demonstrate the presence of shunting vessels.

- Transcolonic portal scintigraphy is a non-invasive technique but requires specialist equipment.
 - It may produce false-negative results when the shunt connects the gastric vein to the caudal vena cava, a common type of shunt in the cat.
- **Venous portography, although requiring surgery, is the definitive method for identifying shunts.**

PART 7

Sick cat with specific signs

19. The pyrexic cat

Kristy L Dowers and Michael R Lappin

KEY SIGNS

- Temperature > 39.2°C (102.5°F).

MECHANISM?

- True fever results from a cascade of events, which starts with activation of leukocytes. Pyrogenic factors released from the leukocytes increase the thermoregulatory set point in the hypothalamus.
Signs that may be associated with fever include:
- Elevated body temperature.
- Reluctance to move.
- Anorexia.
- Depression.
- Hyperpnea.
- Muscle or joint stiffness/discomfort.
- Shivering.

WHERE?

- Inflammation anywhere in the body can result in elevation of core body temperature above 39.2°C (102.5°F).

WHAT?

- The most common etiology for fever in the cat is percutaneous cellulitis or abscess. Viral diseases such as FIV, FeLV and FIP are important diseases to consider.

QUICK REFERENCE SUMMARY

Diseases causing a pyrexia cat

METABOLIC

- Hyperthyroidism (p 389)

Occasionally mild fever occurs from the increased metabolic rate. Typical signs are history of weight loss despite good appetite, unkempt hair coat, change in temperament and vomiting/diarrhea.

NEOPLASTIC

- Neoplasia (p 385)

Fever associated with antibody stimulation from tumor antigens, tissue necrosis or destruction of bone marrow. Lymphoma is the most common neoplasia in cats.

INFLAMMATION

INFECTIOUS

Viral:

- **Feline leukemia virus (FeLV)***** (p 374)**

Fever may occur in any age cat but is primarily seen initially in the viremic stage or later in response to neoplastic, inflammatory or immunosuppressive effects. Signs include chronic infections, anemia, thrombocytopenia, elevated MCV and lymphoma.

- **Feline immunodeficiency virus (FIV)** (p 378)**

Fever in adult cats is associated with the acute stage and in older cats with the chronic terminal stage. Signs include chronic infections, especially upper respiratory and skin infections, gingivitis, weight loss and diarrhea.

- **Feline infectious peritonitis (FIP)***** (p 372)**

Tends to occur in very young or very old cats. Signs include fever, anorexia, lethargy, weight loss, pleural effusion and dyspnea, peritoneal effusion, vomiting/diarrhea, ocular changes (uveitis, in particular), neurologic signs, hyperglobulinemia, leukopenia.

- **Panleukopenia* (p 382)**

Acute onset of fever in young cats with vomiting, anorexia, depression, dehydration and profound leukopenia. Diarrhea usually follows 1–2 days later.

- **Feline viral rhinotracheitis (herpesvirus-1)*** (p 370)**

Paroxysms of sneezing followed by severe conjunctivitis with serous to mucopurulent nasal discharge, fever, anorexia and lethargy. Ocular signs (corneal ulcerations) may follow 1–2 weeks later.

- **Calicivirus*** (p 370)**

Inconsistent fever, anorexia, lethargy, mild upper respiratory signs with a serous to mucopurulent oculonasal discharge, oral ulcers predominately on the anterior or lateral margins of the tongue and salivation.

Bacterial/rickettsial:

- **Percutaneous cellulitis/abscess*** (p 368)**

Fever, anorexia, depression, localized swelling/pain in area of abscess.

continued

continued

- ***Chlamydophila felis** (p 381)**

Conjunctivitis is the predominant sign and is often initially unilateral and becomes bilateral. Ocular discharge is serous initially then mucopurulent, but is usually mild. Fever, anorexia and lethargy may occur.

- ***Yersinia pestis* (feline plague)* (p 383)**

Acute onset of a high fever, anorexia and depression. Lymphadenopathy, with marked swelling over submandibular or cervical lymph nodes, which may abscess. Pneumonic form is less common and may have upper and lower respiratory signs with sneezing, nasal discharge, dyspnea or cough.

- ***Salmonella* spp. (songbird fever)**

Signs occur in outdoor cats which hunt. Acute onset of fever, anorexia and depression, and 50% of cats have GI signs with vomiting and diarrhea.

- ***Francisella tularensis* (tularemia)* (p 382)**

Occurs in outdoor cats which hunt and have recent exposure to rabbits. Signs include fever, depression, anorexia, peripheral lymphadenopathy, oral ulcerations and hepatomegaly.

- ***Ehrlichia* spp. and *Anaplasma phagocytophilum** (p 385)**

Chronic intermittent fever, weight loss and anorexia occur. Hyperesthesia, joint pain or irritable disposition is common. Exposure to ticks may or may not be documented.

- ***Mycoplasma haemofelis* and *Candidatus 'M. haemominutum'* (*Haemobartonella felis*)** (p 374)**

Pale mucous membranes, anorexia and depression. Fever occurs in approximately 50% of cats and icterus may be evident.

- ***Bartonella henselae* (cat-scratch fever)**

Mild, self-limiting fever occurs in experimentally infected cats. Naturally infected cats are usually subclinical and fever is not well documented.

Parasitic/protozoal:

- ***Toxoplasma gondii*** (p 375)**

Fever, anorexia and depression are often present. Dyspnea is common. Kittens and cats may also have icterus, abdominal distension or pain/discomfort, ocular signs (uveitis, retinochoroiditis) or neurologic signs.

- **Cytauxzoon felis**

Rapid onset of fever with lethargy, anorexia, pale mucous membranes, dehydration, icterus and splenomegaly.

Fungal:

- ***Blastomyces dermatitidis* (blastomycosis)**

Fever, anorexia, depression and lymph-adenopathy occur together with respiratory signs (dyspnea, coughing). Ocular signs are frequent. Signs are more common in dogs than cats.

- ***Coccidioides immitis***

Clinical disease is uncommon in cats. Fever, anorexia and depression are common. Skin lesions occur in 50% of cats with nodules progressing to abscesses. Respiratory, musculoskeletal and ocular signs are less common.

- ***Cryptococcus neoformans* (cryptococcosis)** (p 379)**

Low-grade fever, malaise, anorexia and weight loss are typical. Most common form presents with chronic mucopurulent or hemorrhagic nasal discharge, sneezing, stertorous respiration, distortion over bridge of nose (Roman nose) or polyp-like mass in nasal opening.

- ***Histoplasma capsulatum* (histoplasmosis)** (p 371)**

Signs are often non-specific with fever, depression, and weight loss. Dyspnea, lymphadenopathy, pale mucous membranes, gastrointestinal signs or ocular signs may be present.

Non-infectious:

- **Pancreatitis** (p 377)**

Signs are often vague and non-specific with anorexia and depression predominating. Fever is inconsistent and may be accompanied by abdominal pain, vomiting and dehydration.

- **Cholangiohepatitis** (p 378)**

Typically anorexia and depression are present together with icterus or increased liver enzymes. Vomiting may be evident and fever is present in about 1/3 of cats.

- **Non-suppurative meningoencephalitis** (p 379)**

Signs are chronic, of 1–4 weeks duration and include fever in some cats and variable CNS signs, especially seizures and focal or multifocal neurologic signs.

- **Myocarditis/diaphragmitis** (p 380)**

Uniphasic or biphasic fever together with depression and lethargy are typical. Mild generalized lymphadenopathy may be present and in a few cats overt cardiac failure occurred.

- **Immune-mediated disease**

Primary immune-mediated disease, such as systemic lupus erythematosus, is extremely rare in cats. Secondary immune-mediated disease can occur due to primary infection, vaccination or neoplasia. Anorexia, weight loss, fever and signs specific for the disease occur, such as bleeding, pale mucous membranes, skin lesion or lameness.

Toxins/drugs:

- **Drug-induced fever* (p 381)**

Tetracyclines, amphotericin B and other drugs may cause a fever. The severity of fever is out of proportion with the mild clinical signs. There is a history of antibiotic or antifungal therapy.

Trauma:

- **Trauma** (p 380)**

Mild fever associated with pain and inflammation often occurs 10–14 h after injury. There is evidence of external or internal trauma. Sterile surgical trauma causes fever in some cats for 24 hours post-surgery.

INTRODUCTION

MECHANISM?

True fever must be differentiated from hyperthermia, which can be caused by increased muscle activity, increased environmental temperature and stress.

True fever results from **activation of leukocytes** that release factors (pyrogens) such as interleukin-1 and tumor necrosis factor.

- These factors cross the blood–brain barrier and increase the **thermoregulatory set point** in the hypothalamus.

- Leukocytes are activated by a multitude of **infectious agents, neoplasia, tissue necrosis** and **immune-mediated diseases**.

WHERE?

Fever is defined as systemic elevation of **core body temperature above 39.2°C (102.5°F)**.

The most accurate measurement of core body temperature is obtained **rectally**.

Aural temperature is approximately -17.2°C (0.5°F) lower than the rectal temperature.

WHAT?

Fever is a general clinical sign that can be associated with many different diseases.

The **most common** disease causing fever in the cat is **percutaneous cellulites or abscess**.

Many **viral and bacterial diseases** cause fever because leukocytes are recruited and activated as part of the general immune response.

Organ inflammation, such as pancreatitis, cholangiohepatitis and myocarditis, can be associated with an elevated temperature even when an infectious agent is not present.

DISEASES CAUSING AN ELEVATED TEMPERATURE

PERCUTANEOUS CELLULITIS/ABSCESS***

Classical signs

- Fever.
- Anorexia (partial or complete).
- Reluctance to move, lethargy and depression.
- Pain, heat or swelling at site of abscess or cellulitis.

Pathogenesis

Percutaneous abscesses and cellulitis are caused by puncture wounds, most typically from cat bites or

scratches, but can be from other animal bite wounds, or foreign bodies such as grass awns.

Tissue trauma results in decreased blood flow to the area, and therefore selects for those bacteria which are facultative or obligate anaerobes.

Common bacteria isolated from cat abscesses are **obligate anaerobes** (*Fusobacterium*, anaerobic cocci, *Bacteroides*, *Eubacterium*, *Peptococcus* and *Peptostreptococcus*) **and/or microaerophilic or facultative organisms** (*Pasteurella*, *Corynebacterium*, *Actinomyces* and *Micrococcus*); abscesses commonly contain more than one isolate.

Abscesses resulting from cat bites are often infected with *Pasteurella* spp.; L-forms and *Mycoplasma* spp. are occasionally involved.

Proliferation of injected organism results in infiltration of tissue by neutrophils and other phagocytes and eventual pus production.

The body generally walls off infection, and purulent products build up to form a soft, fluccuant swelling, usually associated with hair loss over the area.

The abscess may **rupture spontaneously**.

Persistent cellulitis can be a consequence of long-standing abscess.

Bone involvement may also occur with long-standing abscesses. Osteomyelitis should be suspected if the abscess heals but repeatedly breaks as a draining tract.

Clinical signs

Owners will report that cats are **indoor/outdoor** or recently escaped up to a week prior to appearance of the clinical signs.

Pyrexia may occur within 12 hours of a fight. Cats may be quite depressed following a fight, even prior to the onset of fever.

Some cats present without systemic signs and only a mild swelling in the fore- or hindlimbs, neck, face or head.

If limbs are involved, the only complaint may be progressive lameness.

Reluctance to move and anorexia may be a consequence of pain, fever or systemic response to infection.

Cellulitis usually precedes an abscess, and if treated appropriately, the abscess may not even form. **Cellulitis** may be the only evidence of a previous abscess.

An abscess may rupture spontaneously, and the owner may notice **foul-smelling, purulent discharge** on the fur.

- Some abscesses resolve on their own with or without rupture, if they have been present long enough.

Regional lymphadenopathy may occur near the affected site.

L forms produce cellulitis 4–5 days after injury. Cellulitis spreads rapidly with the development of multiple fistulae and a febrile response.

- Lameness from septic arthritis is a common sequelae to infection with L forms. Joints are affected by the hematogenous route and may be distant to the initial site. Lower limbs (tarsus and carpus) are most commonly affected. The joints often ulcerate with a grayish mucinous exudate. Infection remains confined to subcutaneous tissues and joints without systemic spread to internal organs.

Diagnosis

History supports access to outdoors or conflict with other cats indoors.

Palpation reveals a tender area or fluctuant swelling, with or without evidence of puncture wounds.

Microscopic examination of a fine-needle aspirate of the abscess **reveals a heterogeneous population of bacteria**, numerous degenerate neutrophils and intracellular bacteria.

A complete blood count will generally show neutrophilia.

L forms are not visible in tissue samples even with special stains, nor do they grow on culture. On electromicroscopy, organisms are visible intracellularly within phagocytes. Diagnosis is often made by response to tetracyclines in a therapeutic trial (doxycycline 10 mg/kg PO, q 24 h). Response is rapid and evident within 48 h.

Non-healing abscesses should have **histopathology and culture of tissue**. Causes include nocardia, fungi,

mycobacteria, and tumors. See page 1081, The Cat With Non-Healing Wounds.

Differential diagnoses

In plague-endemic regions, *Yersinia pestis* (**plague**) **must be considered**, if the swelling is predominately in the neck region and the cat's fever is in the region of 40.5°C (105°F). Cautionary measures such as gloves, masks and isolation of the suspect cat should be taken until diagnosis established. (See below for discussion of *Y. pestis* infections).

Fracture.

Ligament/tendon injury.

Cellulitis.

Neoplasia.

Treatment

Clip area looking for evidence of puncture wounds.

Drainage of the purulent material is the key to treatment. Surgical drainage can be done under sedation or general anesthesia with a #15 blade. Make a 1/4–1/2" incision over the dependent area, or the area most likely to allow for continued drainage.

Flush the wound thoroughly with sterile saline or a saline/betadine mixture.

Explore the wound with a sterile cotton swab or hemostats to assess the extent of dead-space and to look for a possible foreign body.

Leave the wound open to allow drainage of further purulent material. Do not suture incision closed, as this will only allow the abscess to reform. A Penrose drain may be placed for 2–3 days to allow maximum drainage for abscesses that close too early.

Antibiotic therapy for 7–10 days directed against anaerobes: penicillins, cephalosporins, clindamycin and metronidazole are reasonable choices. Most abscesses respond extremely well to drainage and amoxicillin at 10–20 mg/kg PO q 12 hours for 7 days or amoxicillin/clavulonic acid (12.5 mg/kg PO q 12 hours).

L-forms and *Mycoplasma* spp. respond to doxycycline or tetracycline within 48 hours, but not other antibiotics.

If the wound is not healing well, or the cat has had recurrent abscesses, FeLV/FIV testing is recommended to rule out an underlying immunodeficiency. Further considerations are inappropriate antibiotics (consider culture and sensitivity testing) or the presence of an undetected foreign body (consider surgical exploration of the area) or involvement of underlying bone (osteomyelitis).

Prognosis

Prognosis is good unless there is an underlying immunodeficiency.

Prevention

Restrict the cat to an **indoor environment** only; although less effective, confine cat indoors at least from dusk to dawn.

Neuter male intact animals to decrease territorial behavior.

FeLV and FIV serology should be repeated 2–4 months following bite wounds.

FELINE VIRAL RHINOTRACHEITIS (FVR)*** (FELINE HERPESVIRUS INFECTION (FVH-1))

Classical signs

- Sneezing.
- Conjunctivitis.
- Punctate corneal ulceration.
- Ocular discharge.
- Anterior uveitis.
- Nasal discharge.
- Fever, anorexia and depression.

See main reference on page 7 for details (The Cat With Acute Sneezing or Nasal Discharge).

Clinical signs

Acute onset of sneezing followed by oculonasal discharge.

Discharge progresses from **serous to mucoid to mucopurulent**.

Severe **conjunctivitis** with tearing, photophobia and chemosis.

Hypersalivation may occur as an initial sign before the classic signs of upper respiratory tract appear.

Punctate corneal ulcers that may coalesce to larger ulcers or perforation.

Fever of 1–2 days duration, anorexia and depression.

Retching or coughing may occur.

Cats with anterior uveitis have occasionally have herpesvirus 1 in the aqueous humor.

Diagnosis

Presumptive diagnosis can be made on the basis of history and clinical signs because treatment for feline herpes virus-1 and calicivirus are similar.

Ocular ulcerations and chemosis are more suggestive of **FHV-1**.

Definitive diagnosis is by **direct IFA** of cells obtained from conjunctival or nasal scrapings, or by **viral isolation or polymerase chain reaction assays** from oropharyngeal or nasal swabs.

CALICIVIRUS***

Classical signs

- Mild conjunctivitis and ocular discharge.
- Serous to mucoid nasal discharge.
- Stomatitis, oral ulcerations.
- Fever.
- Signs associated with pneumonia.
- Rarely, facial and paw edema, hemorrhage, icterus and rapid death.

See main reference on page 11 for details (The Cat With Acute Sneezing or Nasal Discharge).

Clinical signs

Sudden onset of **serous ocular discharge and mild conjunctivitis**; these signs may begin unilaterally, but often progress bilaterally.

Initial signs are rapidly followed by **sneezing**, which are not paroxysmal and are less prominent than in herpesvirus.

Nasal discharge is primarily serous to mucoid and rarely progresses to purulent.

Oral ulcerations are common, especially on the tongue, and may be associated with drooling or hypersalivation. Ulcers may also occur at the mucocutaneous junction, hard palate and nose.

Fever generally spikes initially after infection prior to onset of signs, and returns with onset of clinical signs.

Viral pneumonia occurs occasionally with certain strains, and may produce significant mortality. Death is often sudden and preceded by **laboured respiration**.

A **rare variant strain (FCV-Ari)** reported from the United States, produces a high fever, facial and paw edema (50% of cats), ocular and nasal discharge, conjunctivitis and ulcerative stomatitis (50% of cats), hemorrhage from the nose, GIT, etc. (30–40% of cats), icterus (20% of cats) and rapid death. Mortality is high (30–50%).

Diagnosis

Presumptive diagnosis can be made on basis of **history and clinical signs** because treatment for feline herpes virus-1 and calicivirus are similar.

Oral ulcerations or clinical signs of **pneumonia** are more suggestive of calicivirus.

Definitive diagnosis is by **viral isolation or reverse transcriptase polymerase chain reaction** assays from swabs taken from the **oropharynx**, ideally in the first week of illness.

Demonstration of **increasing serum antibody titers** to feline calicivirus in paired samples is also useful, whereas measurement of a single titer is not useful because many cats have titers from vaccination.

Identification of FCV-Ari is based on the clinical syndrome, pathology and culture of virus from blood, nasal or ocular discharge, spleen or lungs.

HISTOPLASMA CAPSULATUM (HISTOPLASMOSIS)*-***

Classical signs

- Fever.
- Weight loss.
- Anorexia.
- Pale mucous membranes.
- Dyspnea.
- Lymphadenopathy.

See main reference on page 755 for details (The Cat With Signs of Chronic Small Bowel Diarrhea).

Clinical signs

Clinical signs are often non-specific and include fever, anorexia and weight loss.

Dyspnea and harsh lung sounds without coughing is common.

Peripheral and visceral **lymphadenopathies** are frequently present.

Pale mucous membranes, icterus, hepatomegaly or splenomegaly may be evident.

Ocular signs are uncommon, but can occur.

Gastrointestinal signs are uncommon in cats compared to dogs, and include chronic diarrhea, mesenteric lymphadenopathy and anorexia.

Osseous lesions produce soft tissue swelling and lameness.

Diagnosis

Diagnosis is by **demonstration of the organism** in lymph nodes, draining tracts, bone lesions or vitreous humor.

The organism has a **thin capsule** and is **intracellular within macrophages**.

No reliable serologic test available.

FELINE INFECTIOUS PERITONITIS (FIP)*-***

Classical signs

- Fever.
- Weight loss, anorexia.
- Lethargy.
- Abdominal effusion.
- Dyspnea from pleural effusion.
- Ocular and/or neurologic signs.
- Hepatic, intestinal and/or renal signs.

Pathogenesis

Feline coronaviruses (FCoV) are divided into:

- **FIP-inducing strains**, which are **mutated strains** that infect macrophages and can be distributed to many organ systems.
- **Feline enteric coronavirus (FECV)** which are mildly pathogenic strains producing signs limited to the intestinal lumen.

Mutations of FECV that lead to FIP can **occur in the host within about 18 months** of contracting the virus.

The chance of developing FIP decreases the longer the cat has high coronavirus titers.

Immune responses play a large role in the development of this disease:

- If a **cell-mediated response is not mounted** to mutated FCoV, **effusive FIP** generally results, producing abdominal, thoracic, pericardial and/or scrotal effusions.
- A **partial cell-mediated response** to mutated FCoV generally results in non-effusive FIP, and clinical signs are due to formation of **granulomas**, with signs depending on the organ affected.
- A strong cell-mediated response results in clearance of the virus.

Stress may contribute to development of disease, as stress can interfere with the immune response. Multiple-cat households, surgery, illness and pregnancy may be part of the history in a cat with clinical signs of FIP.

Typically, cats have been in **multi-cat environments** (cat breeders or rescue facilities) within the previous year.

Genetic predisposition appears to play a role.

FIP is most common in catteries and multi-cat households.

Clinical signs

There are **two clinical forms of FIP, effusive or wet form and non-effusive or dry form**. Both are characterized by a **fluctuating fever unresponsive to antibiotics, anorexia, lethargy** and weight loss.

Typical age of onset is **6 months to 2 years**, but any age can be affected.

The effusive form may have any of the following signs:

- **Abdominal effusion** that is non-painful but progressive. The amount of effusion varies from volumes causing abdominal enlargement, to amounts only detectable by abdominocentesis. **Fluid is straw-colored and highly viscous**, like egg white.
- **Pleural effusion** resulting in **dyspnea** occurs in 30% of cats with the effusive form. **Pericardial fluid** may be evident on ultrasound. Usually it not associated with clinical signs, but occasionally can produce cardiac tamponade.
- Male cats may present with **scrotal swelling**.

The non-effusive form may have any of the following signs:

- **Ocular signs** result from pyogranulomatous inflammation of the iris and ciliary body. They include bilateral uveitis, perivascular exudates (cuffing), retinal hemorrhage, retinal detachment.
- **Neurologic signs** include **cerebral and cerebellar-vestibular signs** such as seizures, personality changes, nystagmus, head tilt, circling, head tremor and hyperesthesia.
- **Dysfunction of any organ system** may result from **granuloma formation** within the tissue of that organ, e.g., **liver, kidney, spleen, intestines, lungs**, etc., however, organ failure producing clinical signs only rarely occurs, and most dysfunction is only detected on biochemical tests.
- **Granulomatous masses may be palpable** in abdominal viscera especially mesentery, mesenteric lymph nodes and omentum as tender, irregular masses. **Occasionally vomiting or diarrhea** results from extensive lesions on the bowel wall.

Jaundice may occur with either form of the disease.

Diagnosis

Histopathology of affected tissues provides the only definitive antemortem diagnosis. The classic FIP lesion is **pyogranulomatous infiltration around venules**.

The following are **typical abnormalities associated with FIP**. All asterisked items must be present for a high likelihood of FIP; if any one parameter is not present, FIP is unlikely. A negative coronavirus (“FIP”) titer suggests FIP is not the cause of the fever, although a few cats with the effusive form of the disease are titer negative.

Lymphopenia ($< 1.5 \times 10^3$ cells/ μ l).* Occurs in many cats with FIP, and many cats without FIP.

Hyperglobulinemia > 51 g/L [> 5.1 g/dl].* Present in 50% of cats with effusive FIP and 70% with non-effusive FIP.

High coronavirus/FIP titers ($\geq 1:160$).* Present in most cats with FIP and many healthy cats without FIP.

The effusive or wet form of FIP has pleural and/or abdominal effusion with:

- Protein 35 g/L [> 3.5 g/dl].
- Albumin:globulin ratio < 0.8 .
- Protein electrophoresis should demonstrate a polyclonal gammopathy with gamma globulins representing $> 32\%$.
- Cell count varies from low to moderate (1500 to more than 25 000 cells/ μ l) and mainly non-lytic neutrophils, lymphocytes and macrophages.

“FIP titers” reported by laboratories are either **coronavirus titers** or **titers to the 7B protein in coronavirus**. **Neither are specific for the mutated FIP-coronavirus**. Although it had been claimed that 7B protein was specific for FIP strains, subsequent studies have shown that it is not present in some FIP strains, and that non-FIP coronavirus may have an active 7B component. Currently there is no serological test that is specific for FIP-coronavirus.

- **30% of household pet cats and 80–90% of cattery cats carry coronavirus and have positive coronavirus titers.**
- Although a few cats with effusive FIP have a negative coronavirus titer, cats with a negative coronavirus titer are unlikely to have FIP.

Reverse transcriptase, polymerase chain reaction (PCR) is available for detection of viral RNA. Positive results correlate with a diagnosis of FIP when fluid

from an effusion is used for analysis. Note that when whole blood is used for analysis, positive results do not correlate to FIP.

- To date, **no nucleoprotein sequences specific for FIP-coronavirus have been identified**. Some non-pathogenic coronaviruses have systemic spread, therefore finding coronavirus nucleoprotein by PCR in the systemic circulation or tissue is not indicative of FIP-coronavirus infection.

Except where the classical effusive fluid is present, **definitive diagnosis of FIP requires organ biopsy** and demonstration of classical histopathological lesions.

Various non-specific abnormalities may be evident on laboratory tests, including increased total white cell count, mild to moderate anemia, and increased concentrations of bilirubin, liver enzymes, BUN, creatinine, fibrinogen, globulin and mild proteinuria.

Disseminated intravascular coagulopathy (DIC) is evident in some cats.

CSF typically has **increased protein (> 2 g/L) and cell counts (> 100 cells/ μ l)** which are predominantly non-lytic neutrophils.

Differential diagnosis

Ocular signs: toxoplasmosis, fungal agents.

Neurologic signs: toxoplasmosis, neoplasia (e.g., lymphoma), trauma, congenital abnormalities in young cats.

Other clinical signs: rule out other diseases associated with the apparent organ dysfunction.

Lymphocytic, plasmocytic cholangiohepatitis occasionally produces a high protein abdominal fluid similar to that of effusive FIP.

Treatment

FIP is a **fatal disease with no known treatments**. The therapies listed below have been used in an attempt to slow progression and/or to improve quality of life.

Glucocorticoids at immunosuppressive doses (prednisolone 4 mg/kg/day).

Cyclophosphamide (200–300 mg/m² q 2–3 weeks or 2.2 mg/kg daily for 4 days each week) or chlorambucil (20 mg/m² q 2–3 weeks).

+/- **Broad-spectrum antibiotics** to control secondary bacterial infections while the cat is immunosuppressed.

+/- **Interferon-alpha** (see FeLV/FIV section for recommended dosages).

Prognosis

Prognosis is poor. The mortality is > 95%.

Transmission

Fecal-oral transmission is most likely; transplacental transmission is rare.

Fomites, e.g., **food bowls and litter trays**, may be an important mode of transmission, as some strains of FCoV survive in dried secretions for **several weeks**.

About 1/3 of cats seropositive for coronavirus shed virus for up to 10 months; 40–75% of cats with FIP shed virus.

A **seronegative cat** introduced into a household where coronavirus is endemic has a **1 in 6 chance of developing FIP**; a seropositive cat under the same conditions has a 1 in 12 chance.

Both young and old animals seem to be most susceptible due to vulnerable immune systems.

Maternal antibodies that protect kittens wane at approximately 5–6 weeks of age.

Prevention

Reduce fecal-oral contamination by providing one litterbox for every 1–2 cats, cleaning litterboxes daily, and placing litterboxes away from feeding areas.

Minimize stress, especially crowding in catteries.

Do not introduce FCoV-positive cats into a multi-cat household.

Wean kittens at 5 weeks and remove from the queen's environment if she is seropositive.

An **intranasal vaccine** is available for use in seronegative cats. However, efficacy has not yet been demonstrated against wild strains.

FELINE LEUKEMIA VIRUS (FeLV)*-***

Classical signs

- **Opportunistic infections.**
- **Weight loss/cachexia.**
- **Chronic fever.**
- **Neoplasia.**

See main reference on page 540 for details (The Anemic Cat).

Clinical signs

Onset of illnesses occurs over an extended period of time (months to years), although young kittens can become acutely ill.

Chronic, opportunistic infections occur that **do not respond to appropriate antibiotic therapy** and are primarily due to immunosuppression.

Fever may occur in any age cat but is primarily seen **initially in the viremic stage** or later in response to neoplastic, inflammatory or immunosuppressive effects. **Chronic fever** occurs in later stages of disease.

Weight-loss/cachexia.

Non-regenerative anemia.

Thrombocytopenia.

Lymphoma is associated with FeLV-positive cats, especially thymic and multicentric forms.

Diagnosis

History and clinical signs may be suggestive.

Complete blood count showing anemia, thrombocytopenia, leukemias, increased MCV and leukopenia are supportive.

Bone marrow aspirate may show myeloproliferation and arrested erythroid differentiation.

A **positive FeLV antigen test** (viral core antigen p27) on whole blood using an IFA (can also be done on bone marrow sample) or an ELISA test (also on serum, plasma, saliva, tears). See page 543 for interpretation.

Polymerase chain reaction is available from some laboratories.

MYCOPLASMA HAEMOFELIS AND CANDIDATUS 'M. HAEMOMINUTUM' (HAEMOBARTONELLA FELIS)**

Classical signs

- Pale mucous membranes.
- Depression.
- Anorexia.
- Icterus.
- Splenomegaly.
- Fever.

See main reference on page 530 for details (The Anemic Cat).

Clinical signs

Classical signs are **pale mucous membranes and/or icterus** primarily from **extravascular hemolysis** due to complement binding of infected erythrocytes.

Severe, regenerative hemolytic anemia may ensue.

Anorexia and depression are typical.

Fever occurs in **50% of cats** in the acute phase, and may occur intermittently in chronic infections.

Diagnosis

History and clinical signs are suggestive, especially if an immunosuppressive disorder is present concurrently.

Diagnosis is via **demonstration** of the **organism on the surface of erythrocytes**. Use a margined blood sample for diagnosis, e.g., ear vein. Multiple blood smears over a number of days may be required as most of the organisms are removed from circulation by the time clinical signs are apparent.

Infected cats may be Coomb's positive.

A **polymerase chain reaction** test is available in some laboratories for diagnosis.

TOXOPLASMA GONDII**

Classical signs

- Fever.
- Anorexia/weight loss.

Classical signs—Cont'd

- Anterior uveitis, retinochoroiditis.
- Seizures, ataxia.
- Dyspnea/polypnea.
- Icterus.
- Abdominal discomfort.
- Small bowel diarrhea.

Pathogenesis

Gastrointestinal signs, primarily abdominal discomfort and small bowel diarrhea, are due most likely to replication of the organism (tachyzoites) in enteroepithelial cells resulting in necrosis.

Clinical signs in the acute, fatal form of **extraintestinal disease** are caused primarily by tissue damage from the rapidly dividing tachyzoites.

Tachyzoites begin to disappear from tissues approximately 3 weeks after infection. The organism may persist in tissues as **tissue cysts containing bradyzoites**.

Chronic disease may be a result of delayed hypersensitivity reactions and tissue reaction to antibody—antigen complex deposition.

Concomitant illness, such as FeLV, FIV and immunosuppression with glucocorticoids, has been reported in some cases.

Clinical signs

Gastrointestinal disease.

- **Mild, self-limiting small bowel diarrhea** may occur in the definitive host (cats), but only after ingestion of tissue cysts, oocysts or sporulated oocysts.
- **Young kittens** are more likely to have gastrointestinal signs, although mild clinical disease has been reported in adult cats as well. All newborn kittens experimentally infected developed severe diarrhea 5–6 days later.

Fatal extraintestinal disease (acute course).

- Fatal extraintestinal disease is most likely to occur in **transplacentally infected kittens**.
- Kittens may be **stillborn** or **exhibit signs that are severe and rapidly progressive** and reflect involvement of the **lungs, liver** and **CNS tissues**.

These signs may also be observed in **postnatally infected kittens** and include:

- A **distended abdomen** from an enlarged liver and/or ascites.
- **Icterus** from hepatitis or cholangiohepatitis.
- **Dyspnea** is present in most kittens and cats with signs of acute infection.
- **Neurologic deficits; continuous vocalization; excessive sleeping.**
- **Fever, anorexia, depression** often accompanies the tissue-specific signs.

Non-fatal extraintestinal disease (chronic, intermittent course).

- Cats may have a **moderate fever, lethargy and depression** that waxes and wanes.
- **Hyperesthesia and stiff painful joints or shifting lameness** may be evident, presumably due to an immune-mediated process.
- Unilateral or bilateral **anterior or posterior uveitis** may occur with possible sequelae of lens luxation, glaucoma or retinal detachment.
- **Seizures and ataxia** may be present if CNS tissues are involved.
- Rarely, a **toxoplasma granuloma (tissue cyst)** forms in the **gastrointestinal tract or pancreas** causing chronic vomiting.

Diagnosis

Clinical signs consistent with toxoplasmosis are **suggestive**, especially when other causes of the signs have been ruled out.

IgM titers > 1:64 and a **four-fold increase in IgG:IgM titers** within 2 weeks correlate best with clinical toxoplasmosis. However, some cats do not develop detectable IgM titers, and in other cats, positive IgM titers can persist for months to years after infection.

Elevated ocular and CSF titers relative to serum titers in cats with ocular or neurologic signs, respectively, are very suggestive. Coefficient values > 1.0 are highly suspect and > 8.0 strongly suggest local production of *T. gondii* antibodies.

Response to therapy for toxoplasmosis is a useful indicator of infection.

Definitive diagnosis requires demonstration of the organism in inflamed tissues by histology, immunohistochemistry or polymerase chain reaction assay.

Differential diagnosis

Rule out diseases associated with affected organs, e.g., FIP for neurologic and ocular signs.

Treatment

Clindamycin at 10–12 mg/kg orally q 12 hours for 4 weeks is usually effective.

- Cats should respond within several days of treatment.
- If no response is evident after 3 weeks of antibiotic therapy, reconsider the diagnosis.
- The chronic form may recur even after successful treatment, as drugs tend to suppress replication rather than kill the parasite.

Other systemic drugs with potential efficacy include the trimethoprim sulfas combination, doxycycline, minocycline, azithromycin and clarythromycin.

Cats with **ocular lesions** should also be treated with **corticosteroids**, either topically (e.g. topical 0.5% Prednisolone acetate drops applied q 6–12 h) or systemically to control inflammation and its sequelae (glaucoma, lens luxation).

Prognosis

Gastrointestinal disease has a good prognosis, although it may lead to inflammatory bowel disease in rare cases.

Acute extraintestinal disease has a guarded to poor prognosis.

Chronic extraintestinal disease has a fair to good.

Transmission

Infection in cats can occur via:

- The placenta or milk with tachyzoites.
- Ingestion of meat infected with tissue bradyzoites, e.g., rodents.
- Ingestion of sporulated oocysts in food or water.

***T. gondii* has a zoonotic potential.** Infection of humans can occur via:

- Ingestion of **undercooked meat** containing tissue bradyzoites (most common mode of transmission).
- Ingestion of sporulated oocysts from the environment.

- Transplacentally, if first-time exposure to the organism occurs during pregnancy.

Only cats host the sexual replication that results in oocysts in the feces.

- Oocysts are shed for 1–2 weeks.
- Most seropositive cats do not shed oocysts on repeat exposure.

Oocysts must sporulate to be infectious:

- Sporulation occurs 1–5 days after environmental exposure, thus handling individual cats rarely results in infection of humans.

Transplacental transmission occurs in cats and people after primary exposure.

Prevention

Discourage cats from going outdoors and hunting behavior.

Do not feed cats undercooked meat.

To prevent human infection:

- **Cook meat** at 80°C (176°F) for 15 minutes.
- Use **gloves when gardening** or changing the litterbox, and wash hands well.
- **Change litterboxes daily.** Use litterbox liners or clean with scalding water.

PANCREATITIS**

Classical signs

- Lethargy and anorexia.
- Fever.
- Vomiting.
- Dehydration.
- Tachycardia.
- Hypothermia.
- Abdominal pain.

See main reference on page 272 for details (The Cat With Depression, Anorexia or Dehydration).

Clinical signs

The **classical signs** are **not as well-defined for cats** as for dogs for the following reasons:

- Cats tend to have intermittent bouts of **chronic pancreatitis**.
- Diagnostic tests for pancreatitis are not as reliable in cats.
- There is poor correlation of biochemical parameters with pancreatitis in the cat.

Lethargy and anorexia is variable depending on chronicity.

Vomiting only occurred in **35%** of cases in one study.

Dehydration occurred in **50%** of cases in the same study.

Abdominal pain is quite **variable**.

Fever is variably present, and generally mild. In severe acute pancreatitis it may progress to hypothermia, which is a poor prognostic sign.

Diagnosis

Diagnosis is unreliable based on a biochemistry panel. Lipase may be increased or normal in pancreatitis.

- **Hyperbilirubinemia** and **elevated liver enzymes** may be present.
- **Hypocalcemia** occurs in 40% (total serum calcium) or 60% (plasma ionized calcium concentration) of cats due to saponification of fat. Cats with a plasma ionized calcium concentration < 1.00 mmol/L (< 4.00 mg/dl) have a grave prognosis (77% mortality) and aggressive medical treatment is indicated.

Pancreatic lipase immunoreactivity is probably a **more sensitive diagnostic tool** for confirming pancreatitis in cats than measurement of plasma lipase concentration or trypsin like immunoreactivity. A feline-specific assay must be used.

Abdominal ultrasound to visualize an enlarged pancreas or heterogeneous echogenicity in the area of the pancreas is considered by many to be most sensitive.

Demonstration of higher lipase levels in abdominal fluid compared to those of the serum is suggestive. Diagnostic peritoneal lavage may be necessary to obtain a fluid sample.

CHOLANGIOHEPATITIS**

Classical signs

- Anorexia.
- Vomiting.
- Icterus.
- Dehydration.
- Fever.
- Weight loss.

See main reference on page 427 for details (The Yellow Cat or Cat With Elevated Liver Enzymes).

Clinical signs

Clinical signs may be acute, chronic or intermittent.

Typically, there is **anorexia and depression** together with **icterus** or increased bilirubin and **liver enzymes on a biochemistry panel**.

Vomiting and dehydration may be present.

Fever, especially in the suppurative form occurs in approximately 38% of the cases.

Chronic cholangiohepatitis may lead to **end-stage liver disease** and the cat may present with **ascites and hepatic encephalopathy**.

Multiple causes include bacterial, protozoal (*T. gondii*) and immune-mediated disease.

Diagnosis

Complete blood count may show neutrophilia with a left shift, and mild non-regenerative anemia.

Biochemistry panel shows **hyperbilirubinemia, elevated liver enzyme activities** (ALP, ALT, GGT), +/- **elevated serum bile acids**.

- Signs of late-stage liver disease are occasionally present, such as decreased BUN, glucose and albumin concentrations.

Abdominal ultrasound should be performed to evaluate the gall bladder and bile duct for cholelithiasis, bile sludging and cholecystitis.

Liver aspirates/biopsy allows for differentiation of suppurative from non-suppurative forms of cholangiohepatitis.

Culture and sensitivity of the **liver biopsy** should be performed if suppurative cholangiohepatitis suspected.

Lymphocytic, plasmocytic cholangiohepatitis occasionally produces a **high protein abdominal fluid** similar to that of **effusive FIP**.

FELINE IMMUNODEFICIENCY VIRUS (FIV)**

Classical signs

- Opportunistic infections.
- Gingivitis.
- Weight-loss/cachexia.
- Diarrhea.
- Chronic fever.

See main reference on page 339 for details (The Thin, Inappetent Cat).

Clinical signs

Clinical signs are primarily due to **immunosuppression**, i.e., chronic recurring infections that do not respond to appropriate therapy.

Gingivitis, stomatitis and peridontitis are more common findings in FIV infections than in FeLV, although one study suggests that these signs may be to an effect of age, rather than a consequence of FIV infection.

Fever is chronic and is related to production of tumor necrosis factor and/or IL-1 in infected cats.

Weight loss/cachexia are common in the late stages of FIV, as in human HIV infections.

Diarrhea resembles a panleukopenia-type syndrome that may be due to actual enterocyte infection by the virus or secondary to inflammation.

Cats are often thin and scruffy with an **unkempt hair-coat**, and may have miliary dermatitis.

Diagnosis

Diagnosis may be suspected based on history and clinical signs, but requires antibody or antigen tests for confirmation.

Diagnosis of FIV infection is by demonstration of **FIV-specific antibody titers via ELISA, IFA or Western blot.**

Virus isolation and polymerase chain reaction for virus detection is available at some research facilities.

Cats infected with FIV can be co-infected with FeLV.

CRYPTOCOCCUS NEOFORMANS* (CRYPTOCOCCOSIS)*

Classical signs

- Sneezing.
- Stertorous breathing.
- Chronic nasal discharge.
- Facial deformity.
- Low-grade fever.
- Regional lymphadenopathy.
- Neurologic signs: ataxia, seizures, blindness.
- Skin form: ulcerated lesions.

See main reference on page 25 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Chronic nasal discharge can be unilateral or bilateral and is generally serosanguineous. Sneezing and stertorous breathing is often present.

Facial deformity may occur due to invasion of the surrounding bone.

Chronic low-grade fever may be present.

Depression, anorexia and weight-loss are signs of disseminated disease.

Neurologic signs occur via hematogenous spread or invasion into the CNS through the cribiform plate but are uncommon. Signs include seizures, blindness, depression and ataxia.

The skin form typically produces nodules which often ulcerate.

Diagnosis

Diagnosis is by **demonstration of narrow-based budding yeast** with a **very thick capsule** from affected tissue or by culture of affected tissue or CSF.

Demonstration of *Cryptococcus* antigen in serum, urine or CSF is also diagnostic.

NON-SUPPURATIVE MENINGOENCEPHALITIS**

Classical signs

- Seizures.
- Focal or multifocal neurologic signs.
- Fever.
- Lethargy.
- Inappetence.

See main reference on page 803 for details (The Cat With Seizures, Circling and/or Changed Behavior).

Clinical signs

Occurs in cats of all ages, with and without outdoor access.

Progressive clinical signs occur over a period of 1–4 weeks.

Recurrent seizures may be the only clinical sign, while other cats exhibit multifocal neurologic abnormalities including:

- Progressive spinal cord signs.
- Vestibular signs.
- Cerebellar signs.
- Cranial nerve signs.

According to one study, non-supportive meningo-encephalitis may be the most common cause of seizures in cats.

Systemic signs, which are not present in all cats, include **fever, anorexia, lethargy, vomiting, diarrhea and lymphadenopathy.**

Viral or immune-mediated etiology is suspected.

The condition, however, does not appear to be contagious to other cats.

Diagnosis

CSF tap can be very useful to **rule out other causes of CNS signs**, specifically toxoplasmosis and FIP; CSF analysis reveals a normal or mild protein elevation (typically < 1 g/L) and/or an increased white cell count (< 50 cells/μl).

Complete blood count findings are non-specific and may include leukopenia or leuko-cytosis, eosinophilia and anemia.

MYOCARDITIS/DIAPHRAGMITIS**

Classical signs

- Uniphasic or biphasic fever.
- Depression.
- Lethargy.
- Mild generalized lymphadenopathy.
- +/- Signs of cardiac failure.

Pathogenesis

Several different **infectious agents have been implicated** in cats:

- Viral, e.g., FIP has been shown to cause cardiac infection.
- *Trypanosoma cruzi*, which causes Chagas' disease in humans.
- *Streptococcus* and *Borrelia* (Lyme's disease) in certain geographic areas.

No single agent has been identified, and the disease may be **multifactorial**.

Clinical signs

Fever is biphasic in 50% of the cats; if biphasic:

- **First fever** occurs approximately 10 days after exposure, lasts 1–3 days and peaks at 39.3–40.7°C (102.7–105.2°F).
- **Second fever** occurs 1–2 weeks after the first fever (at 3–4 weeks post-exposure), lasts 5 days and peaks at 39.9–40.9°C (103.8–105.6°F).

Depression and lethargy lasts 5–10 days.

Appetite is mildly decreased in some cats, but most continue to eat and drink.

Some animals exhibit **mild generalized lymphadenopathy**.

Irritable disposition and **hyperesthesia** may occur, and are most likely due to fever and malaise.

In a few case reports, cats have died from **peracute cardiac failure**, but this outcome is not common.

Diagnosis

Myocarditis/diaphragmitis is a **diagnosis of exclusion**.

Biochemistry and complete blood counts are unremarkable, except for a mild to moderate increase in CK in less than 50% of experimentally infected cats.

Definitive diagnosis can only be made at **necropsy**.

Histopathology shows a neutrophilic infiltrate with a foci of myonecrosis in myocardium and diaphragm.

Differential diagnosis

Any **other causes of fever should be ruled out** including infectious, inflammatory, immune-mediated, drugs, neoplasia and metabolic.

Other causes of cardiac failure that should be ruled out include congenital deformities, hypertrophic cardiomyopathy, restrictive cardiomyopathy and dilatative cardiomyopathy.

Treatment

Supportive therapy is indicated if dehydration or cardiac disease are present.

Broad-spectrum antibiotics are indicated if complete blood count supports an infectious cause.

Prognosis

Fever and depression **resolve spontaneously in the majority of cats**.

Prognosis is poor if peracute cardiac failure is present with systemic signs of fever and depression.

Prevention

Although an infectious agent is suspected, no single etiologic agent has been identified, making recommendations for prevention difficult.

TRAUMA**

Classical signs

- Cardiovascular or respiratory compromise.
- External signs of injury.

Classical signs—Cont'd

- Pain on palpation.
- Moderate fever approx. 39.2°C–40.0°C (102.5–104.0°F).

See main reference on page 52 for details (The Dyspneic or Tachypneic Cat).

Clinical signs

Cardiovascular compromise may result in **tachycardia**, **hypovolemia** or **hypotension**.

Respiratory compromise may produce **dyspnea/tachypnea** due to pneumothorax, hemothorax or pyothorax.

External injuries including abrasions/bruising, degloving injuries, bite wounds and open fractures may be evident.

Internal injuries may result in abdominal pain from organ rupture, bone/joint pain or focal swelling.

Fever from inflammation may occur but often lags behind acute injury by 10–14 hours.

Diagnosis

Diagnosis is based on **clinical signs and history**.

Radiographs of the chest, abdomen and/or limbs may be required to characterize the injury.

Complete blood count and biochemistry panel is indicated to rule out specific organ injury and primary infection.

DRUG-INDUCED FEVER***Classical signs**

- Alert, febrile cat being treated with antibiotics or antifungal agents.

Clinical signs

History of treatment with **antibiotics** or **antifungal agents**.

Fever does not correspond to clinical appearance of animal. Cats are bright, alert and responsive, despite a temperature in the range of 39.4–40°C (103–104°F).

Onset of **fever** is **idiosyncratic** and variable, but the fever is generally present for the duration of the drug treatment.

Tetracycline is the most common antibiotic cause of drug-induced fever in cats.

Amphotericin B can cause fever by disrupting cell membranes and releasing pyrogens into circulation.

Be aware that other drugs (griseofulvin, chloramphenicol and chemotherapeutic drugs) can cause bone marrow suppression leading to a cat with fever, neutropenia and secondary bacterial infection. These cats are obviously sick, whereas the drug-induced fever animals are bright and alert in comparison.

Diagnosis

Diagnosis is based on history and clinical signs.

- History is of treatment with fever-inducing drugs, especially tetracycline and amphotericin B.
- Clinical signs are inappropriate, that is, the cat appears bright and alert although febrile.

Temperature normalizes after drug is discontinued.

CHLAMYDOPHILA FELIS***Classical signs**

- Sneezing.
- Conjunctivitis and ocular discharge.
- Nasal discharge.
- Fever.

See main reference on page 13 for details (The Cat With Acute Sneezing or Nasal Discharge).

Clinical signs

Marked conjunctivitis is the predominant sign, which often starts unilaterally, but usually progresses to both eyes.

Classic triad of upper respiratory infection signs including oculonasal discharge and sneezing.

Serous ocular discharge accompanied by blepharospasm, chemosis and conjunctival hyperemia are initial signs. Discharge becomes mucopurulent over the course of the disease.

Mild to moderate **fever can be seen in the acute phase**.

Pneumonia is rarely associated with this infection.

Diagnosis

History and clinical signs are highly suggestive.

Cytology of conjunctival scrapings reveal dark blue inclusion bodies (Giemsa stain).

Immunofluorescent antibody staining or polymerase chain reaction assay to demonstrate the organism in conjunctival scrapings is available from some laboratories.

PANLEUKOPENIA*

Classical signs

- Acute onset of depression.
- Acute onset of vomiting.
- Diarrhea usually 1–2 days later.
- Dehydration.
- Fever or hypothermia.
- In utero infection can result in cerebellar signs.

See main reference on page 722 for details (The Cat With Signs of Acute Small Bowel Diarrhea).

Clinical signs

Rapid onset of depression, anorexia, and vomiting especially in peracute and acute disease. Fetid diarrhea (may be hemorrhagic) typically follows 1–2 days after initial onset of signs.

Severe dehydration and electrolyte abnormalities.

Initial fever followed by hypothermia as the disease progresses.

High mortality rate when signs are severe.

Diagnosis

The disease should be suspected in cats less than one year of age with no history of vaccination and a rapid clinical course.

Panleukopenia evident on hematology.

Parvoviral antigen can be detected in feces using the canine parvoviral antigen tests or electron microscopy.

Histopathologic changes include denuded intestinal crypts and blunted villi (often a post-mortem diagnosis).

FRANCISELLA TULARENSIS (TULAREMIA)*

Classical signs

- Fever.
- Anorexia.
- Lethargy.
- Lymphadenopathy.
- Oral ulcers.
- Icterus.

Pathogenesis

Francisella tularensis is a Gram-negative coccobacillus. Clinical signs are associated with **Gram-negative endotoxins** and **bacteremia**.

There are two main strains of the organism, both of which have been isolated from cats.

Type A strain is:

- Associated with **tick–rabbit cycle**.
- Found only in North America.
- Highly virulent for laboratory rabbits.
- Associated with more severe disease in humans.

Type B strain is:

- Associated with a more complex cycle involving rodents, ticks, mosquitoes, mud and water.
- Found throughout the northern hemisphere.
- Avirulent for laboratory rabbits.

Clinical signs

History of **contact with rabbits**, especially if the cat is a hunter.

Any age of cat can be infected, but younger cats are more susceptible to developing septicemia.

The spectrum of **illness varies** from severely affected to asymptomatic.

Fever is generally $> 40^{\circ}\text{C}$ (104°F).

Marked depression, anorexia and lethargy, with or without vomiting are typical.

On physical examination, **peripheral lymphadenopathy, icterus and palpable splenomegaly and hepatomegaly** are reported.

Oral, lingual or pharyngeal ulcers may be present.

Diagnosis

Clinical signs together with a history of exposure to wild rabbits is highly suggestive.

Hematologic and serum biochemical abnormalities may include **panleukopenia**, with **severe toxic changes in neutrophils**, high band neutrophil count, thrombocytopenia and hyperbilirubinemia.

Definitive diagnosis is via identification of the bacterial agent by **IFA or bacterial culture**, but should only be performed in a qualified laboratory.

- Samples can be obtained from affected **lymph nodes, bone marrow, urine or blood**.

Serum antibody titers > 1:120 or a four-fold increase in serum antibodies in samples collected during acute and convalescent phases (10–14 days) are considered diagnostic.

Differential diagnosis

FIP, FIV, panleukopenia.

Plague (*Yersinia pestis*).

Toxoplasmosis.

Cytauxzoon felis.

Multicentric lymphoma.

Treatment

Antimicrobial efficacy studies have not been done in the cat, therefore therapy is derived from case reports and/or human therapy regimens.

Enrofloxacin (5 mg/kg q 12 hours IV or PO).

Tetracycline and chloramphenicol may be effective, but because they are bacteriostatic for *F. tularensis*, relapses can occur.

In humans, the drugs of choice are streptomycin and gentamycin.

Prognosis

Prognosis is poor to fair as mortality rate varies across case reports.

Transmission

F. tularensis has a **serious zoonotic potential** if there is **contact with infected animal tissue**.

Bites from infected ticks, deer flies or mosquitoes are the most common method of transmission.

Infection can also occur via ingestion of infected meat.

Transmission may occur via a **bite or scratch from an infected mammal**.

- This is the most common method of transmission to humans in cat-associated cases.
- The infected cat may have no obvious signs of illness, but have a history of hunting wild animals, especially rabbits.

Inhalation of aerosolized organisms may also transmit the disease. **Care should be taken by veterinary and laboratory personnel handling suspected animals** or samples being prepared for IFA or culture.

Prevention

Discourage hunting behavior in cats.

Ectoparasite control, especially tick control.

YERSINIA PESTIS (FELINE PLAGUE)*

Classical signs

- Acute onset of signs.
- Moderate to high fever (39.4–41.2°C; 103–106°F).
- Submandibular lymphadenopathy.
- Depression.
- Anorexia.

Pathogenesis

Onset of **illness occurs 24–72 hours after exposure** to the organism.

Transmission to cats is either **via ingestion of infected rodents** or a **fleabite** from infected fleas.

Rapid multiplication of organism causes tissue damage and necrosis. The host immune response contributes to pathology.

Three forms of the plague exist: **bubonic (local infection)**, **bacteremic/septicemic** and **pneumonic**.

Bacteremia occurs in many cases, resulting in the **septicemic** or **pneumonic form** of plague.

Endemic regions of the world include the western USA, South America, Africa, Asia, eastern Europe.

Clinical signs

History of hunting rodents, especially in known endemic areas.

Current **flea infestation** is evident.

Acute onset of fever, anorexia, depression over a period of 2–6 days. The clinical course may last 6–20 days.

Submandibular or cervical swelling associated with lymph nodes (can be unilateral or bilateral). The inflamed, swollen lymph node is referred to as a **bubo**.

Subcutaneous abscessation may occur and appear similar to a cat bite abscess.

In the **pneumonic form** (~10% of cases), upper and lower respiratory signs may be present, including **sneezing, nasal discharge, coughing**, dyspnea/tachypnea.

Diagnosis

Initially, **microscopic examination of a lymph node aspirate**, especially a markedly swollen lymph node (bubo) should reveal a homogeneous population of **bipolar-staining coccobacilli**.

- Blood should be examined in cats with the bacteremic/septicemic form.

Fluorescent antibody testing of sample provides a definitive diagnosis.

Culture of organism should be performed by a qualified laboratory only.

A **four-fold rise in antibody titers** (taken 10–14 days apart) is suggestive of plague. These results must be

interpreted carefully, as high titers can persist for up to one year after infection.

Chest radiographs may reveal patchy, nodular lesions if the pneumonic form is present.

Be aware that the **risk of exposing other staff members to the disease** should be weighed against the benefit of the diagnostic test.

Differential diagnosis

Reactive lymph nodes from a percutaneous abscess or tooth-root abscess.

- Aspirates of cat bite abscesses contain a mixed bacterial population compared to *Y. pestis*, which is homogeneous.

Neoplasia, although it is less common in the US for cats with lymphoma to have peripheral lymphadenopathy.

Respiratory signs may be due to other upper respiratory infections (**calicivirus, herpesvirus, Chlamydomphila**) or lower respiratory disease (parenchymal lung disease, pleural disease).

Other diseases which cause high fever (**tularemia, toxoplasmosis, FIP**, etc.).

Treatment

Absolute caution must be practiced in all suspect plague cases. Cautionary measures include gloves, mask, isolation of animal and limited exposure to other staff members.

Doxycycline/tetracycline: (1) Doxycycline at 5 mg/kg q 12 hours PO for 14–21 days or (2) tetracycline 25 mg/kg q 8 hours PO.

- Begin treatment immediately after samples for diagnosis have been collected.
- Doxycycline is preferred as tetracycline has been associated with relapse.

Consider aminoglycosides or enrofloxacin (5 mg/kg IM q 8 hours) **for the first 3 days** to avoid placing hands into the cat's mouth (see Transmission section below).

Prognosis

Prognosis for **bubonic plague** is fair to good.

Prognosis for the **pneumonic form** is guarded to fair.

Prognosis for **septicemic form** is guarded.

Persistent fever > 40°C (104°F) despite treatment is associated with a poor prognosis.

Transmission

Y. pestis has a serious zoonotic potential, and great care should be taken in suspect cats to prevent transmission to humans and other cats.

- Infected cats are no longer a zoonotic risk after 3 days of antibiotic therapy.

Transmission occurs via **rodent flea bites or ingestion of infected animals**.

Infection can also occur via **inhalation of aerosolized organism**, either from **aspirates** of infected tissue or **nasal discharge/sneezing** of cats with pneumonic form.

Prevention

Confine cats indoors in endemic areas.

Discourage hunting behavior especially during the peak flea season (April to October).

Provide effective flea control to prevent flea bites.

EHRLICHIA SPP. AND ANAPLASMA PHAGOCYTOPHILUM*

Classical signs

- Anorexia and weight loss.
- Fever.
- Lymphadenopathy.
- Lameness.
- Non-specific hyperesthesia.

See main reference on page 547 for details (The Anemic Cat).

Clinical signs

This disease is **uncommonly reported in cats** and is difficult to diagnose because of its vague and variable clinical signs.

Age range of cats with documented disease was **2–10 years of age**, with no breed or sex predilection reported.

Infection has a variable effect on appetite, from **mild inappetence to anorexia** and mild to moderate weight loss.

Chronic intermittent fever in the moderate range is common.

Lymphadenopathy was reported in three of 23 cats.

Hyperesthesia, joint pain or irritable disposition is common.

Complete blood counts may show a **non-regenerative anemia** with a leukopenia or a leukocytosis; **thrombocytopenia** is present in about **25%** of the cats.

Biochemistry abnormalities are uncommon, except for **hyperglobulinemia** in about **33%** of documented cases.

Diagnosis

A complete blood count and biochemistry panel consistent with chronic *Ehrlichia* spp. infection is suggestive.

Diagnosis is by demonstrating *E. canis* and/or *Anaplasma phagocytophilum* serum **antibody titers** or a positive IFA test.

Demonstration of **morulae in mononuclear cells, neutrophils** or eosinophils (rare) is diagnostic.

PCR assays can be positive.

NEOPLASIA

Classical signs

- Anorexia, lethargy, weight loss.
- ± Fever.
- Signs depend on tumor type and organ system involved.

Clinical signs

Anorexia, lethargy and weight loss.

Poorly groomed coat.

Some cats have a fever associated with neoplasia, which is generally a secondary neoplastic syndrome. **Tumors which destroy the bone marrow** and result in

neutro-penia are classically associated with fever. Fever may occur with other tumors via other mechanisms, including antibody stimulation from tumor antigens, and tissue necrosis which activates leukocytes to release pyrogenic factors.

Signs are specific to the organ system involved.

Lymphoma (mediastinal, GI, renal), **mammary adenocarcinoma**, **squamous cell carcinoma** (nasal, oral) and **mast cell tumor** are the most common tumors in cats.

Diagnosis

Hematology, biochemistry panel, radiology, ultrasound and/or bone marrow aspirates may be necessary to **provide evidence that a tumor is present**, especially if it involves the hematopoietic system (leukemia) or is located internally (splenic mast cell tumor).

Identification of the tumor type is via fine-needle aspirates and/or biopsies.

Differential diagnosis

Organ dysfunction due to infectious or degenerative disease process.

FeLV/FIV or other immunosuppressive illness.

Benign masses (granulomas, abscesses, reactive lymph nodes, benign tumors).

Treatment

Treatment involves **surgical excision of identifiable masses** +/- regional lymph nodes, especially for mammary adenocarcinoma, nasal squamous cell carcinoma, splenic mast cell tumor, etc.

Chemotherapy may be effective and needs to be based on tumor type, e.g., COP (cyclophosphamide, vincristine, prednisolone) protocol in lymphoma cases.

Radiation therapy is used for local disease only, and response to radiation therapy is tumor dependent (e.g., squamous cell carcinoma).

- Radiation therapy is most effective after surgical debulking of the primary mass. The effectiveness of radiation therapy may be enhanced with concurrent chemotherapy.

SALMONELLA SPP. (SONGBIRD FEVER)

Classical signs

- Vomiting/diarrhea.
- Fever (40.0–40.6 °C [104.0–105.0 °F]).
- Depression.
- Anorexia.

See main reference on page 719 for details (The Cat With Signs of Acute Small Bowel Diarrhea).

Clinical signs

Acute onset of fever and malaise are initial clinical signs.

Vomiting, diarrhea and abdominal pain may occur, however, approximately 50% do not have gastrointestinal signs.

Dehydration.

Shock may occur if **septicemia/bacteremia** develops.

Mortality rate approaches 10% and may be higher if the cat is concurrently immunosuppressed.

Diagnosis

Typically, the cat is an **outdoor cat with a history of hunting behavior**, especially of birds.

Complete blood count and biochemistry panel supports infectious diarrhea or septicemia, e.g., neutropenia with a left shift, bacterial rods in blood leukocytes if overwhelming sepsis present, hypoglycemia, hypoproteinemia, pre-renal azotemia.

Blood cultures provide the **best definitive diagnosis if positive**. Three separate samples over a 4–6 hour period should be taken during febrile episodes using aseptic techniques.

Fecal cultures may isolate *Salmonella* organisms, but because **many animals are subclinical carriers**, positive culture does not prove that the organism is the cause of the clinical signs.

COCCIDIOIDES IMMITIS

Classical signs

- Skin lesions.
- Respiratory signs.
- Ocular lesions.
- Fever, anorexia, depression.

Pathogenesis

The geographical distribution includes **south-west USA, Central America** and **South America** in areas that have **sandy soil with low rainfall** and high temperatures.

Soil is the **reservoir for infection**, and the highest frequency of cases occur when the soil is dry and dusty, and organisms are disseminated in the wind.

Most humans and animals in endemic areas become infected, but the **majority of infections are subclinical** or cause only mild, transient clinical signs.

Cats are more resistant to infection and signs are less common than in dogs.

Infection is contracted via inhalation, and only a few organisms are required to produce signs, which occur after 1–3 weeks.

Initial infection is confined to the respiratory tract, but **dissemination may occur** resulting in chronic disease over months or years with signs referable to bones, eyes, central nervous system and abdominal organs.

Localized infection following a penetrating skin wound appears to be rare.

Clinical signs

Cats appear to be resistant to clinical disease.

Skin lesions are the most frequent types of infection in cats and were reported in 56% of cats in one study.

- Lesions begin as small bumps and progress to abscesses, ulcers or draining tracts.
- In cats, underlying bone involvement is uncommon.

Systemic signs such as **fever, anorexia and depression** are commonly reported (44% of cats) and can be seen with skin lesions.

Respiratory signs such as coughing and wheezing are less common in cats and occur in approximately 25% of cases.

Musculoskeletal signs such as lameness, with or without painful bone swelling, were reported in 19% of cats.

Ocular lesions are seen infrequently and include chorioretinitis and anterior uveitis. **Ocular or CNS signs** were reported in 19% of cats.

Most cats have clinical signs for less than 4 weeks prior to diagnosis.

Diagnosis

Hyperproteinemia is present in approximately 50% of cats.

Definitive diagnosis is by identification of the organism via biopsy of lesions.

Antibody detection is available using latex agglutination (IgM), AGID (IgM) or ELISA (IgM or IgG).

Tube precipitin (TP) for IgM and complement fixation (CP) for IgG were previously thought to be less reliable in cats, but have been subsequently demonstrated to detect feline infections.

Treatment

Itraconazole (10 mg/kg PO if possible, q 24 h or 5 mg/kg q 12 h) is the treatment of choice. Treatment is required for **4–6 months** and must be continued for at least 2 months after all signs have resolved.

- Some cats develop anorexia, and less commonly vomiting or diarrhea. Stop the drug for a few days until the cat is eating, and then restart at 1/2 the dose for 7–10 days, before increasing back to the full dose, which is usually then tolerated.

Amphotericin B is also effective (0.25 mg/kg in 30 ml dextrose 5% IV over 15 minutes q 48 h or given subcutaneously) – see page 26, for Cyptococcosis in The Cat With Signs of Chronic Nasal Disease. Continue amphotericin B therapy until a cumulative dose of 4 mg/kg is given or until BUN > 17.9 mmol/L (50 mg/dl). Amphotericin has the disadvantage of requiring frequent parenteral or subcutaneous administration and causes significant nephrotoxicity.

- Because of its quick onset of action, **amphotericin B in combination with itraconazole is useful in cats with severe pulmonary signs** that are rapidly deteriorating. If the cat survives, after a few weeks treatment can be continued with itraconazole alone.
- **Lipid-complexed amphotericin** formulations allow **higher dosages with less toxicity**, and should be used in cats with severe pulmonary signs, although the cost is higher. Dose at 2–3 mg/kg IV 3 days per week for a total of 9–12 treatments (cumulative dose of 24–27 mg). Dilute to a concentration of 1 mg/ml in dextrose 5% and infuse over 1–2 hours.

If the **titer has decreased four-fold** and there is a similar **improvement in physical and radiographic signs**, treatment can be stopped after 4–6 months. Antibodies may persist for long periods and obtaining a zero titer is not a useful treatment goal.

BLASTOMYCES DERMATIDITIS (BLASTOMYCOSIS)

Classical signs

- Fever.
- Respiratory signs.
- Ocular signs.
- Lymphadenopathy.

Pathogenesis

The geographical distribution includes **North America, Central America and Africa**.

Soil is believed to be the **reservoir for infection**, and living near a lake or river increases the risk of infection in dogs.

Signs are more common in dogs than in the cats.

Disseminated disease is primarily contracted via **inhalation**.

Clinical signs

Respiratory signs include coughing, dyspnea and harsh lung sounds.

Ocular disease, such as uveitis, glaucoma and retinal detachment, is a frequent finding.

Fever, anorexia, depression, weight loss and lymphadenopathy are systemic signs associated with disseminated disease.

Draining skin lesions may occur and are usually a manifestation of systemic disease rather than local disease.

Neurological signs are associated with CNS involvement of the brain or spine and include circling, disorientation, anisocoria, paresis, decreased conscious proprioception, or upper motor neuron signs, hyperesthesia and extensor rigidity.

Diagnosis

Definitive diagnosis is by demonstration of an **extra-cellular, broad-based budding yeast** in aspirates or biopsies from lymph nodes, draining tracts, bone lesions or vitreous humor.

An **antibody detection** test is available, but may be negative.

Treatment

Itraconazole (10 mg/kg PO if possible, q 24 h or 5 mg/kg q 12 h) is the treatment of choice. Treatment is required for **4–6 months** and must be continued for at least 2 months after all signs have resolved.

- Some cats develop anorexia, and less commonly vomiting or diarrhea. Stop the drug for a few days until the cat is eating, and then restart at 1/2 the dose for 7–10 days, before increasing back to the full dose, which is usually then tolerated.

Amphotericin B is also effective (0.25 mg/kg in 30 ml dextrose 5% IV over 15 minutes q 48 h or given subcutaneously) – see page 26, for Cyptococcosis in The Cat With Signs of Chronic Nasal Disease. Continue amphotericin B therapy until a cumulative dose of 4 mg/kg is given or until BUN > 17.9 mmol/L (50 mg/dl). Amphotericin has the disadvantages of requiring frequent parenteral or subcutaneous administration and causing significant nephrotoxicity.

- Because of its quick onset of action, **Amphotericin B in combination with itraconazole is useful in cats with severe pulmonary signs** that are rapidly deteriorating. If the cat survives, after a few weeks treatment can be continued with itraconazole alone.
- **Lipid-complexed amphotericin** formulations allow **higher dosages with less toxicity**, and should be

used in cats with severe pulmonary signs, although the cost is higher. Dose at 2–3 mg/kg IV 3 days per week for a total of 9–12 treatments (cumulative dose of 24–27 mg). Dilute to a concentration of 1 mg/ml in dextrose 5% and infuse over 1–2 hours.

CYTAUXZOOM FELIS

Classical signs

- Fever.
- Anorexia.
- Dyspnea.
- Pale mucous membranes.
- Icterus.
- Collapse.

See main reference on page 534 for details (The Anemic Cat).

Clinical signs

Primarily found in the south-central and southeast United States. The North American **bobcat** is the natural host.

There is usually a history of **exposure to ticks** in the previous 5–20 days (incubation period is 5–20 days).

The clinical course of disease is approximately 1 week and **often ends in death**.

Clinical signs are the result of an overwhelming **hemolytic crisis**.

Rapid onset of fever, dyspnea, anorexia, pale mucous membranes, icterus and dark-colored urine are typical.

Collapse and **death occur 2–3 days after the fever peak**. Hypothermia occurs in the terminal stages.

There appear to be non-pathogenic strains as well.

Diagnosis

A **complete blood count** reveals **regenerative anemia**, hemoglobinemia and neutrophilia or neutropenia.

The biochemistry panel commonly has **hyperbilirubinemia**.

Urinalysis may show evidence of **hemoglobin and bilirubin**.

Demonstration of the **organism in erythrocytes (merozoite stage)** is possible only **relatively late in the disease**, approximately 1–3 days before death. Parasitemic cats usually have only 1–2% of RBCs affected, and up to 50% of cats have parasitemias that are very low or undetectable.

Demonstration of the organism in macrophages from **bone marrow, spleen, liver or lymph node aspirates** may be possible even when organisms are not evident in blood.

Serum antibody levels and **direct FA test** for detection of tissue phase are available through some labs.

HYPERTHYROIDISM

Classical signs

- Weight loss.
- Polyphagia.
- Polyuria/polydipsia.
- Behavioral changes.
- Unkempt appearance.
- Mild elevations in temperature.

See main reference on page 304 for details (The Cat With Weight Loss and a Good Appetite).

Clinical signs

Weight loss in spite of normal to increased appetite.

Polyuria/polydipsia.

Behavioral changes which often include hyperactivity and aggression.

Unkempt, rough hair coat and sometimes overgrown nails.

Tachycardia accompanied by a “gallop” rhythm and/or a systolic murmur.

Mild fever which may be intermittent in nature and reflect the increased metabolic rate in this disease. These cats are easily stressed and may present dyspneic and tachycardic with a mildly elevated temperature, usually not greater than 39.4°C (103.0°F).

Enlarged thyroid glands are often evident on palpation of the neck.

Diagnosis

Diagnosis is based on clinical signs and history and confirmed by demonstrating increased thyroid hormone concentrations (**total T4, free T4**).

Thyroid glands can be palpated in approximately 80% of cats with hyperthyroidism, and are unilaterally or bilaterally enlarged.

- Enlarged thyroid glands may not be palpable if the abnormal thyroid tissue is within the thoracic inlet.

Complete blood count and a biochemistry panel are required to rule out diseases such as diabetes mellitus, renal disease, etc.

A **TRH stimulation test** may be necessary when clinical signs are highly suggestive and total and free T4 are in the upper region of the reference range for normal cats.

Thyroid radionuclide uptake and imaging with pertechnetate (^{99m}Tc) is also available at some institutions.

Response to therapy with anti-rickettsial drugs (tetracycline or doxycycline) is highly suggestive.

BARTONELLA HENSELLA (CAT-SCRATCH FEVER)

Classical signs

- Subclinical or mild fever and occasional ocular signs.

Pathogenesis

Bartonella henselae is an intracellular bacterium within erythrocytes.

Bacteremia is present in many healthy cats in the population, and cats are reservoirs for infection.

B. henselae is an important pathogen because of its **zoonotic potential in immunocompromised humans**.

- **Humans** may develop **fever, malaise, lymphadenopathy and skin eruptions following cat scratches or bites**.
- *B. henselae* causes bacillary angiomatosis, bacillary peliosis and encephalitis in human AIDS patients.

Clinical signs

Naturally infected cats usually only develop **subclinical infection**.

Mild, **self-limiting fever** lasting 48–72 hours has been documented in some experimentally infected cats.

Anterior uveitis and fever were documented in naturally exposed cats.

Lymphadenopathy.

Stomatitis and gingivitis have been proposed as **clinical manifestations**.

Atypical seizures occur in some cats.

Diagnosis

Antibody titers are prevalent in healthy cats, but there is a **poor correlation with blood culture and PCR assay results**.

Intermittent bacteremia may occur for longer than one year following infection, with 25–41% of healthy cats bacteremic for up to 22 months.

The organism is present within erythrocytes, therefore, **hemolyzing red blood cells** increases the sensitivity of the culture.

Differential diagnosis

Other causes of mild transient fever need to be considered, such as mild cellulitis following a cat fight.

Other infectious causes of anterior uveitis need to be ruled out, such as toxoplasmosis, fungal diseases, FeLV, FIV, Cuterebra or dirofilaria.

Treatment

Antimicrobial efficacy has not been clearly demonstrated.

Clinical signs of disease have resolved when the cats are administered **doxycycline** at 25–50 mg PO q 12 h for 28 days.

Azithromycin is used in humans and is a safe alternative in cats when administered at 10 mg/kg PO q 24 h for 28 days

Fluoroquinolones also may be effective.

While clinical signs resolve, bacteremia is usually only temporarily suppressed.

Prognosis

B. henselae has very low pathogenicity in cats.

Once cleared of infection, cats are resistant to re-infection by inoculation, but are still susceptible if transmitted via blood transfusion.

Transmission

Transmission is via **arthropod vectors**. In endemic areas, cats infested with **fleas and/or ear mites** are more likely to be seropositive.

The organism survives in flea feces for at least 9 days.

Because of the frequency of bacteremia in healthy cats, blood transfusions are a likely route of infection.

IMMUNE-MEDIATED DISEASE

Classical signs

- Fever.
- Anemia or thrombocytopenia.
- Cutaneous lesions.
- Polyarthrititis.

Clinical signs

Primary immune-mediated disease is **extremely rare in cats**.

Stimulation from primary infectious disease antigens is the most common cause of immune-mediated disease in cats, and is most often associated with **hemobartonella** (mycoplasma) and **calicivirus**.

Systemic lupus erythematosus is rare in cats. A multitude of signs may occur including fever, weight loss and cutaneous lesions.

Immune-mediated hemolytic anemia is most commonly associated with hemobartonellosis. Signs include anemia, icterus, fever and anorexia. Cats with immunosuppressive disorders such as FeLV may be more susceptible.

Immune-mediated thrombocytopenia is rarely reported in cats. FeLV-positive cats, however, may have thrombocytopenia that is thought to be the result of an immune-mediated response.

Immune-mediated polyarthrititis is uncommon in cats, but has been documented in kittens and adult cats with post-calicivirus vaccination.

20. The cat with enlarged lymph nodes

Anthony Abrams-Ogg

KEY SIGNS

- Hyperplasia, neoplasia, lymphadenitis most common.
- Edema, vascularization, infarction less common.
- Biopsy and culture lymph node.

MECHANISM?

- Reactive lymphoid **hyperplasia, neoplasia or lymphadenitis** are the most common causes of lymphadenopathy.

WHERE?

- Peripheral (superficial) lymph nodes – enlargement may be confined to a solitary/local node, or be regional or generalized.
There may be accompanying internal (deep) lymphadenopathy.

WHAT?

- The most common causes of **generalized lymphadenopathy** are generalized skin diseases, retroviral infections and lymphoma. The most common causes of **local and regional lymphadenopathy** are bacterial and fungal infections in the area drained by the node(s). All causes may result in mild to marked lymphadenopathy.

QUICK REFERENCE SUMMARY

Diseases causing enlarged lymph nodes

MECHANICAL

- **Obstructive edema*** (p 411)

Local or regional lymphadenopathy occurs due to nodal edema and/or hyperplasia, secondary to obstructive edema from a tumor or other mass involving the head, neck or a limb.

NEOPLASTIC

- **Nodal lymphoma*** (p 403)

Regional (head and neck) or generalized (multicentric) lymphadenopathy occurs with predominance of lymphoblasts on biopsy. Average age of cats with multicentric lymphoma is 4 years. Age

continued

continued

of most cats with Hodgkin's-like lymphoma is > 6 years. Cats may be presented for nodal enlargement without concurrent signs, with non-specific signs of illness (lethargy, inappetence and weight loss), and with specific signs due to internal organ involvement (e.g. icterus with hepatic involvement).

- **Metastatic neoplastic lymphadenopathy: mast cell tumor, other tumors (carcinomas, sarcomas, plasma cell tumors, myeloid leukemias, malignant histiocytosis, melanoma)* (p 409)**

Local to generalized lymphadenopathy occurs with malignant cells and hyperplasia found on biopsy. Most metastatic neoplasia occurs in older cats. Cats usually have localizing signs of the primary tumor or non-specific signs of illness.

NUTRITIONAL

- **Steatitis (p 412)**

Regional to generalized lymphadenopathy results from hyperplasia. Other clinical signs include fever, anorexia, depression, reluctance to move, pain on handling, ascites and firm subcutaneous and abdominal fat.

IDIOPATHIC

- **Plexiform vascularization of lymph nodes (p 414)**

Solitary or regional lymphadenopathy in neck or inguinal area occur due to capillary vasoproliferation. Tracheal compression may occur causing dyspnea. No other signs are present.

INFLAMMATION

- **Parasitic, immunologic and miscellaneous skin disorders** (p 400)**

Regional or generalized lymphadenopathy results from hyperplasia. Signs of skin disease are present, such as erythema, pruritus, alopecia, excoriations, scales, crusts, papules, nodules, plaques, vesicles, pustules, erosions and ulcers.

- **Idiopathic atypical hyperplasia (p 412)**

Generalized lymphadenopathy occurs due to atypical hyperplasia. Cats are ~ 4 years of age. Cats are usually presented for nodal enlargement without other signs, but variable non-specific and specific signs may be present.

- **Non-cutaneous immunologic/inflammatory disorders (p 416)**

Regional or generalized lymphadenopathy results from hyperplasia associated with polyarthritis (lameness), systemic lupus erythematosus (cutaneous signs) or certain forms of lymphocytic cholangitis (icterus and ascites).

- **Hypereosinophilic syndrome (p 416)**

Generalized lymphadenopathy results from eosinophilic lymphadenitis. Other clinical signs are usually present, including lethargy, inappetence, weight loss, vomiting and diarrhea.

- **Post-vaccinal lymphadenopathy (p 416)**

Local or generalized lymphadenopathy results from hyperplasia, associated with a history of vaccination in the preceding few weeks.

- **Cutaneous/subcutaneous foreign body reaction* (p 406)**

Local lymphadenopathy occurs due to hyperplasia or lymphadenitis, secondary to aseptic or septic inflammation around the foreign body. Other localizing clinical signs include erythema, warmth and pain on palpation, swelling or thickening of tissue, and wounds.

- **Oral cavity diseases* (p 406)**

Mandibular lymphadenopathy results from hyperplasia or lymphadenitis. Signs of oral cavity disease are present, including halitosis, gingivitis, ulceration and masses.

INFECTIOUS

Viral:

- **Feline leukemia virus (FeLV) infection** (p 398)**

Generalized lymphadenopathy occurs due to hyperplasia during acute and persistent viremia. Lymphadenopathy may also result from lymphoma or secondary infection. Cats may otherwise be normal, or have lethargy, inappetence and fever. Localizing signs of infection or neoplasia may also be present.

- **Feline immunodeficiency virus (FIV) infection** (p 398)**

Generalized lymphadenopathy occurs due to hyperplasia during acute and chronic clinical stages of infection. Lymphadenopathy may also result from lymphoma or secondary infection. Cats may otherwise be normal, or have lethargy, inappetence and fever. Localizing signs of infection or neoplasia may also be present.

Bacterial:

- **Acute cat-bite wound cellulitis/abscess** (p 401)**

Local to regional lymphadenopathy occurs due to hyperplasia. Other localizing clinical signs include erythema, warmth and pain on palpation, swelling or thickening of tissue, and wounds. Systemic signs may be present including lethargy, inappetence and fever.

- **Juvenile streptococcal lymphadenitis (p 415)**

Cervical lymphadenopathy occurs due to lymph node abscessation in kittens. Kittens are depressed, inappetent and febrile.

- **Mycobacterial infections* (p 407)**

Generalized lymphadenopathy results from granulomatous lymphadenitis in tuberculosis, and accompanies chronic vomiting, diarrhea and weight loss. Regional lymphadenopathy due to hyperplasia may accompany cutaneous nodules in leprosy, and occur with chronic ulcerated subcutaneous lesions in atypical mycobacteriosis.

- **(Pyo)granulomatous bacterial infections*, mycoplasma and L-form infections, miscellaneous bacterial infections* (p 408)**

Local to generalized lymphadenopathy results from hyperplasia or lymphadenitis and often accompanies an acute or chronic wound. Systemic signs may be present including lethargy, inappetence and fever.

- **Plague* (p 404)**

Fulminant disease with head and neck lymphadenopathy resulting from abscessation and/or necrosis. Cats are highly susceptible to plague. Cats typically have acute onset of high fever, depression and anorexia.

continued

continued

- **Tularemia* (p 410)**

Fulminant disease with peripheral and internal lymphadenopathy. Cats are moderately susceptible to tularemia. Cats typically have acute onset of high fever, depression and anorexia.

- **Anthrax (p 418)**

Fulminant disease sometimes presenting as acute death with no promontory signs. Rare in cats because they are resistant to anthrax. Cervical lymphadenopathy and edema of the tongue and pharynx.

- **Ehrlichiosis and bartonellosis (p 417)**

Regional to generalized lymphadenopathy occur due to hyperplasia. Cats with ehrlichiosis usually have non-specific signs of illness, while cats with bartonellosis are asymptomatic.

- **Bacteremia (p 416)**

Variable lymphadenopathy due to hyperplasia may occur in chronic bacteremia, accompanied by chronic signs of fever, lethargy and inappetence.

Fungal and algal:

- **Dimorphic fungal infections**, protothecosis (p 418)**

Local to generalized lymphadenopathy occurs due to hyperplasia or lymphadenitis. Concurrent localizing signs include nasal discharge, dyspnea, lameness, cutaneous nodules and ulcers, seizures and uveitis. Concurrent systemic signs include fever, weight loss and inappetence.

- **Miscellaneous fungal infections* (p 411)**

Local to generalized lymphadenopathy results from hyperplasia or lymphadenitis. Cats typically have chronic ulcerating cutaneous or subcutaneous lesions.

Protozoal:

- **Cytauxzoonosis, American and African trypanosomiasis (p 418, 419)**

Fulminant diseases where generalized lymphadenopathy may be present. Cats with cytauxzoonosis and African trypanosomiasis are febrile. Cats with American trypanosomiasis have signs of acute heart failure.

- **Toxoplasmosis (p 419)**

Acute toxoplasmosis may cause reactive peripheral lymphadenopathy and mesenteric lymph node necrosis.

INTRODUCTION

MECHANISM?

Lymphadenopathy refers to **enlarged lymph nodes**. Lymphadenopathy may accompany a number of common and uncommon diseases, but it is uncommonly the chief complaint.

Reactive lymphoid hyperplasia, neoplasia and lymphadenitis are the usual causes of lymphadenopathy. Lymphadenopathy is infrequently due to vascularization, edema or infarction.

- Lymph node biopsy (fine needle, incisional or excisional) for cytology, histology and culture is required to identify these mechanisms.

Hyperplasia is the most common cause of lymphadenopathy. It represents the immune response of normal lymphoid cells to antigenic stimulation.

- It is characterized **cytologically** by a predominance of **small mature lymphocytes** with or without increased numbers of immature lymphocytes, plasma cells and macrophages.
- Some distinguish between **lymph node hyperplasia** and **reactive lymphadenopathy**. The former is

characterized by a clinically enlarged node but normal cellular composition on biopsy; the latter is characterized by a mild to marked increase of plasma cells, with or without a mild increase of immature lymphocytes and/or macrophages. These two patterns have the same etiologies, will not be distinguished here, and will be referred to as “hyperplasia”.

- Based on lymph node **histology**, patterns of lymph node hyperplasia may vary, e.g. as follicular center expansion (B-cells), paracortical expansion (T-cells), combined B- and T-cell hyperplasia, and sinusoidal cell hyperplasia (macrophages). In most disorders lymph node architecture is preserved.
- **Hyperplasia is generally a non-specific finding.**
- Some tendencies for specific cytologic and histologic patterns occur with certain diseases, e.g. increased numbers of **eosinophils in parasitic skin diseases**. Communicating with the pathologist may assist the clinician in determining etiology.
- Hyperplasia may be the initial finding before the development of detectable neoplasia or lymphadenitis.
- Hyperplastic nodes without a diagnosis should be **cultured for bacteria and fungi**.

Neoplastic lymphadenopathy is characterized by **proliferation or invasion of malignant cells**.

- Lymphoma and lymphoid leukemia are due to proliferation and invasion of malignant lymphocytes.
- On histology, lymphoid neoplasia typically **disrupts lymph node architecture and demonstrates a uniform cell-type and chromatin pattern**.
- Other **hematopoietic tumors and solid tumors may metastasize** to local, regional or distant nodes.

Lymphadenitis is characterized by a **cellular infiltrate of neutrophils** (suppurative) macrophages (pyogranulomatous), or **eosinophils** (eosinophilic), focal necrosis or abscessation. It usually results from an **extension of an inflammatory process into the node**.

- Severe, peracute infectious lymphadenitis may cause hemorrhage and necrosis with destruction of architecture, minimal inflammatory infiltrate, and nodal and perinodal edema.

Lymphadenopathy may be mild to marked with any cause.

- Lymphadenopathy tends to be more prominent in younger animals compared to older animals.

Lymph nodes may be **painful, warm and soft with bacterial and fungal lymphadenitis**. Lymph nodes are painless, firm and at body temperature with most other diseases.

Lymph nodes may be fixed (instead of mobile) with lymphadenitis, metastatic neoplasia and lymphoma with extracapsular invasion.

Lethargy, inappetence, weight loss and fever may be present, especially with generalized lymphadenopathy.

Local or regional enlargement is usually due to a disorder in the area drained by the node(s).

WHERE?

The focus of this chapter is **peripheral lymphadenopathy** (e.g. mandibular, prescapular, axillary, inguinal and popliteal nodes). There may be accompanying internal lymphadenopathy (e.g. hilar and mesenteric nodes).

- **Inguinal fat should not be mistaken** for enlarged inguinal nodes and contracted muscles of the caudal aspects of the hindlimb should not be mistaken for popliteal nodes.

Diseases causing primarily internal lymphadenopathy are discussed in The Dyspneic or Tachypneic Cat, The Cat With Chronic Diarrhea and The Thin Inappetent Cat.

WHAT?

The most common causes of **generalized lymphadenopathy** are chronic generalized skin diseases (dermatopathic lymphadenopathy), FeLV/FIV infections and lymphoma.

- The most common causes of **marked generalized lymphadenopathy** are chronic flea allergy dermatitis, lymphoma, idiopathic atypical hyperplasia and acute FIV infection.

The most common causes of **local and regional lymphadenopathy** are bacterial and fungal infections in the area drained by the node(s).

- The most common cause of **marked solitary lymphadenopathy** is abscessation.

DISEASES CAUSING PERIPHERAL LYMPHADENOPATHY

FELINE LEUKEMIA VIRUS (FeLV) INFECTION**

Classical signs

- Lethargy, inappetence, weight loss, unkempt haircoat.
- Fever, gingivitis, recurrent upper respiratory infections, opportunistic infections.
- Anemia.
- Generalized lymphadenopathy may occur in viremic cats.

See main reference, page 540 (The Anemic Cat).

Pathogenesis

FeLV infection may cause **solitary, regional and generalized lymphadenopathy** by several mechanisms. These include:

- Lymphoid hyperplasia during primary viremia (initial infection).
- Lymphoid hyperplasia during persistent viremia.
- Atypical hyperplasia.
- Lymphoma.
- Metastatic neoplasia.
- Immunosuppression causing bacterial infections (e.g. gingivitis/stomatitis, pyoderma) and fungal infections (e.g. cryptococcosis), and reactive hyperplasia or lymphadenitis.
- Immune-complex diseases (e.g. polyarthritis) and reactive hyperplasia.

Clinical signs

Mild to moderate generalized lymphadenopathy may occur during **primary viremia**.

- Cats may otherwise be normal or have **variable lethargy, inappetence and fever**.

Mild to moderate generalized lymphadenopathy may occur during **persistent viremia**.

- Mandibular nodes may be more affected.
- Cats may otherwise be normal or have variable lethargy, inappetence and fever.

Mild to marked lymphadenopathy and various associated signs may occur with other **FeLV-associated disorders** (e.g. neoplasia and fungal infection).

Diagnosis

FeLV tests.

- **ELISA, FA and rapid immunomigration (RIM) tests detect p27 protein** produced by the virus.
 - ELISA test may be weakly positive during primary viremia; FA test is negative. Because primary viremia may be terminated by an effective immune response, the ELISA test should be repeated in 4–6 weeks.
 - ELISA and FA tests are usually both positive during persistent viremia.
 - RIM test results correlate closely to ELISA test results.
- Some PCR tests are available to detect viral DNA. PCR may be positive during primary viremia. PCR is positive during persistent viremia, and is more sensitive than either ELISA or FA. **It should be noted that PCR testing has not been standardized and is more likely to give false-positive results than ELISA and FA if the laboratory does not maintain the highest standards of quality control.**
- If FeLV tests on peripheral blood are negative and another cause of lymphadenopathy has not been determined, obtain a **FA or PCR test on a bone marrow or lymph node aspirate, or immunohistochemistry test on a bone marrow core or lymph node biopsy**.

Lymph node biopsy reveals follicular or paracortical lymphoid hyperplasia.

Differential diagnosis

Lymphoma, metastatic lymphadenopathy, atypical hyperplasia, and possibly hyperplasia from other causes may be distinguished from FeLV-induced hyperplasia by **lymph node histology**.

Lymphoma may be present at other sites – e.g. bone marrow, liver, spleen.

A primary tumor should be identifiable with metastatic lymphadenopathy.

Signs of infections, skin diseases or immune-mediated disorders should be present if lymphadenopathy

is due to hyperplasia from a cause other than retroviral infection.

An FIV antibody test or PCR test for FIV DNA may be used to rule out FIV infection.

Treatment

Treat neoplasia, infection, skin disease or immune-mediated disease as discussed elsewhere.

There is no specific treatment for lymphadenopathy that is not due to these conditions.

Supportive care as needed.

Immunomodulation with agents such as *Staphylococcus protein A* or *interferon- α* may improve subjective impression of the cat's well-being, but will not accelerate resolution of lymphadenopathy.

Prognosis

Lymphadenopathy of primary viremia will resolve with resolution of viremia.

- Lymphadenopathy usually resolves within 4 months.
- Cats with more pronounced signs during primary viremia are more likely to become persistently viremic.

In most cases, **lymphadenopathy of persistent viremia** not due to neoplasia, infection, skin disease, or immune-mediated disease **will resolve spontaneously**.

- Some cases will progress to lymphoma.

Long-term prognosis is determined by other FeLV-associated disorders.

FELINE IMMUNODEFICIENCY VIRUS (FIV) INFECTION**

Classical signs

- Lethargy, inappetence, weight loss, unkempt haircoat.
- Fever, gingivitis, diarrhea, dermatitis, recurrent upper respiratory infections.
- Opportunistic infections.
- Neurologic signs, uveitis.
- Generalized lymphadenopathy usually occurs during symptomatic phases.

See main reference, page 378 (The Pyrexia Cat).

Pathogenesis

FIV infection can cause solitary, regional and generalized lymphadenopathy by several mechanisms. These include:

- Hyperplasia during the acute phase (initial infection).
- Hyperplasia during the chronic symptomatic phase of infection (encompassing the phases of progressive generalized lymphadenopathy, AIDS [acquired immunodeficiency syndrome]-related complex and terminal AIDS). Some of the hyperplastic changes may be reactions to secondary infections.
- Increased risk for lymphoma, which may cause lymphadenopathy.
- Increased risk for non-lymphomatous neoplasia, which may cause metastatic lymphadenopathy.
- Immunosuppression causing bacterial infections (e.g. gingivitis/stomatitis, pyoderma) and fungal infections (e.g. dermatophytosis), and subsequent reactive lymph node hyperplasia or lymphadenitis.
- **Immune-mediated disorders** (which may have associated lymphadenopathy) have been described in FIV-positive cats, but the role of FIV in pathogenesis is not known.

Clinical signs

Mild to moderate generalized lymphadenopathy is common during the **acute phase**.

- Concurrent signs include variable lethargy, inappetence, fever and signs of gingivitis/stomatitis, enteritis, conjunctivitis, respiratory tract infections, dermatitis and neurologic disorders.
- Although other clinical signs are usually only present for several days to weeks, **lymphadenopathy may persist for over a year**.
- **Internal lymphadenopathy occurs concurrently**.

Mild to moderate generalized lymphadenopathy is common during the **chronic symptomatic phase**.

- Concurrent signs include variable lethargy, inappetence, fever, and signs of gingivitis/stomatitis, enteritis, conjunctivitis, uveitis, respiratory tract infections, dermatitis, neurologic disorders and other signs due to secondary infections.
- Internal lymphadenopathy occurs concurrently.
- **In the terminal phase** of infection, lymphadenopathy may disappear and **lymph nodes may become small** due to marked follicular involution.

Mild to marked lymphadenopathy and various associated signs may occur with **other FIV-associated disorders** (e.g. neoplasia and fungal infection).

- In the **terminal phase of FIV infection**, appropriate lymphadenopathy due to hyperplasia may not occur in response to secondary infection because of **marked follicular involution**.

Diagnosis

FIV antibody test (ELISA, RIM, FA, western blot).

- Antibody is usually detectable within 2 months of infection, but may take up to 6 months, therefore a negative test should be repeated.

PCR test for FIV DNA. The sensitivity of PCR for viral DNA compared to antibody tests is not known. **It should be noted that PCR testing has not been standardized and is more likely to give false-positive results than antibody tests if the laboratory does not maintain the highest standards of quality control.**

During the **acute phase**, lymph node biopsy reveals **marked follicular hyperplasia** with or without dysplasia, and less intense parafollicular hyperplasia.

During the **chronic symptomatic phase**, lymph node biopsy reveals **follicular hyperplasia** with or without follicular involution, **follicular plasmacytosis**, and variable erythrophagocytosis by macrophages. These changes are not specific for FIV infection. **Lymph node histology progresses** from **follicular hyperplasia**, through mixed **hyperplasia/involution**, to follicular involution, corresponding to generalized lymphadenopathy, AIDS-related complex and terminal AIDS.

Neutropenia and lymphopenia are common hematologic abnormalities in symptomatic cats.

Differential diagnosis

Lymphoma, metastatic lymphadenopathy, atypical hyperplasia and possibly hyperplasia from other causes may be distinguished from FIV-induced hyperplasia by **lymph node histology**.

Lymphoma may be present at other sites – e.g. bone marrow, liver or spleen.

A **primary tumor** should be identifiable with metastatic lymphadenopathy.

Signs of infections, skin diseases or immune-mediated disorders should be present if lymphadenopathy is due

to hyperplasia from a cause other than retroviral infection.

A **FeLV antigen test** may be used to rule-out FeLV infection.

Generalized lymphadenopathy is a more prominent feature of FIV, compared to FeLV, infection.

Treatment

Treat neoplasia, infection, skin disease or immune-mediated disease as discussed elsewhere.

There is no specific treatment for lymphadenopathy that is not due to these conditions.

Supportive care as needed.

Prognosis

Lymphadenopathy is not a distinct disorder in FIV-positive cats, but rather a **marker of the symptomatic phases of infection**. There is no specific prognosis attached to lymphadenopathy, except that **disappearance** during the chronic symptomatic phase **correlates with progression to terminal illness**.

Prognosis is determined by other FIV-associated disorders.

PARASITIC, IMMUNOLOGIC AND MISCELLANEOUS SKIN DISORDERS**

Classical signs

- Skin lesions typical of the primary disease (e.g. miliary dermatitis).
- ± Mild to marked lymphadenopathy.

See The Cat With Miliary Dermatitis (page 1022), The Cat With Skin Lumps and Bumps (page 1067) and The Cat With Non-healing Wounds (page 1081).

Clinical signs

Mild to marked lymphadenopathy may be present with disorders of the skin and subcutis, especially chronic ones, but it is not the salient feature.

Mandibular lymphadenopathy may be present with acne, mosquito bite hypersensitivity, notoedric mange,

poxvirus infection, discoid lupus erythematosus and auricular chondritis.

Regional and generalized lymphadenopathy may be present with flea allergy dermatitis, eosinophilic granuloma complex, food hypersensitivity, neoplasia (including cutaneous lymphoma), dermatophytosis, demodicosis, pemphigus complex, panniculitis, vasculitis, systemic lupus erythematosus, drug eruption, erythema multiforme/toxic epidermal necrolysis, mechanobullous skin disease and steatitis.

Diagnosis

Work-up of the primary disease will usually identify the reason for the lymphadenopathy. Skin biopsy is often required for a definitive diagnosis.

Lymph node biopsy will reveal **hyperplasia** with or without metastasis with neoplastic disorders.

Differential diagnosis

Chronic bacterial and other fungal infections. Differentiation is on the basis of biopsy and culture.

Treatment

Treat the primary disease.

ACUTE CAT BITE WOUND CELLULITIS/ABSCESS**

Classical signs

- Acute onset fever, lethargy, inappetence.
- Puncture wounds or abscess(es) from bite.
- ± Mild local lymphadenopathy.

See main reference on page 368 (The Pyrexia Cat).

Clinical signs

Acute-onset fever, lethargy and inappetence.

The wound area is usually swollen and/or painful; bites to limbs cause acute lameness.

Gentle passage of a finger back and forth through the fur over a painful area will reveal puncture wounds.

Abscesses may spontaneously rupture, at which time systemic signs usually improve.

Mild local non-painful lymphadenopathy may occur.

Diagnosis

Diagnosis is based on **physical examination findings**.

Culture is not routinely performed, but numerous common organisms have been isolated.

Lymph node biopsy is rarely warranted but reveals hyperplasia.

Wound and lymph node should be examined cytologically and cultured if there is painful local lymphadenopathy.

Differential diagnosis

Foreign body cellulitis and abscessation.

Lymph node abscessation due to juvenile streptococcosis or bubonic plague.

Infection with atypical organism that may progress to a chronic condition.

Differentiation is on the basis of clinical progression, cytology and culture.

Treatment

Treat the primary disease. See The Pyrexia Cat (page 369).

DIMORPHIC FUNGAL INFECTIONS**

Classical signs

- Fever, weight loss, inappetence and localizing signs of infection.

See main references on page 25 for details of cryptococcosis (The Cat With Signs of Chronic Nasal Disease), page 1095 for sporothricosis (The Cat With Non-Healing Wounds), and page 62 for histoplasmosis and blastomycosis (The Cat With Dyspnea or Tachypnea).

Clinical signs

Non-specific signs are common.

Common localizing signs of infection include:

- **Respiratory signs**, including nasal discharge (cryptococcosis), and dyspnea due to fungal pneumonia; hilar lymphadenitis. More than 50% of cats with histoplasmosis are dyspneic.
- **Lameness** from bone or joint infection, especially with coccidioidomycosis.
- **Skin lesions**: nodules, ulcers and abscesses that have not resolved with typical wound treatment, i.e. drainage, irrigation and antibiotic therapy. Skin lesions are the salient feature of sporotrichosis.
- **Neurologic signs**, including seizures.
- **Ocular signs**, including uveitis and chorioretinitis.

Solitary, regional, generalized peripheral and internal lymphadenopathy may be present. Peripheral lymphadenopathy is common with sporotrichosis.

Diagnosis

Exposure history is important for diagnosis. Endemic areas include: eastern North America (blastomycosis); southwest North America, northern and south central South America (coccidioidomycosis). Others are world-wide.

Blastomycosis is uncommon in cats compared to dogs.

Lymph node biopsy reveals hyperplasia or less commonly lymphadenitis.

Definitive diagnosis is by identification of the organisms in biopsy specimens of affected tissues by cytology or histology. **Cytologically**:

- ***Cryptococcus neoformans*** appears as large, encapsulated, narrow-based budding yeasts. With the capsule most organisms are the same size or larger than surrounding inflammatory and epithelial cells. India ink stain helps identify the capsule.
- ***Sporothrix schenckii*** appears as a cigar-shaped yeast inside macrophages.
- ***Blastomyces dermatitidis*** appears as broad-based budding yeasts, slightly larger than surrounding neutrophils. With new methylene blue stain the organism has an obvious double wall and green tinge.
- ***Coccidioides immitis*** appears as solitary large non-budding yeasts three times the size of surrounding neutrophils, but it is present in low numbers and hard to find.

- ***Histoplasma capsulatum*** appears as numerous small round yeasts with a dark center and surrounding halo inside macrophages.

Serology is useful for identifying cryptococcosis, coccidioidomycosis, blastomycosis and sporotrichosis.

Organisms can be cultured, but this requires special media and biohazard containment.

Differential diagnosis

Neoplasia – signs of neoplasia and systemic mycoses are similar because both are due to invasion and proliferation of eukaryotic cells.

Tuberculosis, nocardiosis and other chronic bacterial infections.

Differentiation is based on cytology, histology and culture.

Treatment

Itraconazole 5 mg/kg q 12 h for weeks to months is effective against most dimorphic fungi. Treat a minimum of 30 days beyond clinical resolution. Amphotericin B and liposomal-encapsulated amphotericin B are alternate treatments. Ketoconazole may be substituted for itraconazole in some cases to reduce cost of therapy, but is often less effective.

Fluconazole is the drug of choice for **central nervous system infections**.

Iodides are the older standard treatments for sporotrichosis. Supersaturated solution of **potassium iodide** or **20% sodium iodide** may be used at a dose of 20 mg/kg PO once or twice daily, with food.

Zoonotic potential:

- ***Sporothrix schenckii*** is highly contagious from lesions.
- ***Coccidioides immitis*** may revert from tissue yeast phase to mycelial phase on bandage surfaces and release highly contagious arthrospores. Avoid bandaging wounds or change dressings frequently.

Other dimorphic fungi are not contagious.

NODAL LYMPHOMA*

Classical signs

- Painless lymphadenopathy.

Pathogenesis

Based on the histological classification in humans, lymphoma in cats may be classified as **non-Hodgkin's lymphoma** and **Hodgkin's-like lymphoma**. The latter has been recently recognized.

- **Non-Hodgkin's lymphoma** includes the most commonly recognized forms of lymphoma in cats, including **mediastinal, alimentary, multicentric, other extra-nodal lymphomas and lymphocytic leukemia**.
- Primary **multicentric nodal lymphoma** (initial site of disease is a lymph node) causes generalized peripheral lymphadenopathy from malignant lymphoid cell proliferation.
- The disease may metastasize to the bone marrow (leukemic lymphoma) and liver and spleen.
- Primary **lymphocytic leukemia** (initial site of disease is the bone marrow) may metastasize to peripheral nodes and cause lymphadenopathy.
- Non-Hodgkin's nodal lymphoma **less commonly involves solitary or regional nodes**, and occasionally solitary to generalized nodal involvement accompanies other forms (e.g. mediastinal lymphoma).
- Historically, **multicentric nodal lymphoma and lymphocytic leukemia** in most cats has been **associated with FeLV infection**. However, as the prevalence of FeLV declines in some regions, the incidence of FeLV-negative nodal lymphoma is increasing.
- FIV infection increases the risk of non-Hodgkin's lymphoma.

Hodgkin's-like lymphoma histologically resembles "lymphocyte-predominance Hodgkin's disease" in humans.

- Most cases involve a **solitary mandibular or cervical node**. Solitary inguinal, regional cervical and generalized lymphadenopathy have also been recognized.
- Most cats tested are **FeLV and FIV negative**.

Clinical signs

Solitary, regional (especially mandibular or cervical) or **generalized**, moderate to marked painless peripheral lymphadenopathy.

- Non-Hodgkin's lymphoma may occur at any age. The **average age** for cats with multicentric lymphoma is **4 years**.
- Most cats with **Hodgkin's-like lymphoma** are **> 6 years of age** (range 1–14 years).

Cats may not have other historical signs, or may have lethargy, inappetence and weight loss.

Hepatosplenomegaly may be present.

Mediastinal lymphoma and alimentary lymphoma are not typically associated with peripheral lymphadenopathy, although nodal involvement occasionally occurs.

Diagnosis

Diagnosis requires finding lymph node cytology consistent with lymphoma, and biopsy-confirmed lymphoma (cytology or histology) at another site, e.g. bone marrow, liver, spleen.

If lymphoma cannot be confirmed at another site, **excisional lymph node biopsy and histology are mandatory** to distinguish from atypical hyperplasia and to characterize the lymphoma.

FeLV and FIV tests should be obtained.

Differential diagnosis

Differential diagnoses for generalized lymphadenopathy include atypical hyperplasia, hyperplasia in response to generalized skin diseases, immunologic disorders and systemic infections, widely metastatic neoplasia, and generalized bacterial or fungal lymphadenitis.

Differential diagnoses for solitary or regional lymphadenopathy include plexiform vascularization of lymph nodes, atypical hyperplasia, hyperplasia in response to local tumors, oral cavity and skin diseases, and infections, metastatic lymphadenopathy, and bacterial or fungal lymphadenitis.

These are distinguished on the basis of lymph node cytology, histology and culture and work-up for an underlying disease.

Treatment

Multicentric lymphoma should be treated with **chemotherapy** as described in Chapter 31.

Some cats with **solitary nodal lymphomas** have been cured by **surgical excision** alone.

- Because of the tendency for lymphoma to be a systemic disease, chemotherapy is usually recommended following excision.
- If work-up fails to identify lymphoma at another site, then surgery (or radiation therapy) without subsequent chemotherapy may be considered, especially for Hodgkin's-like lymphoma.

Prognosis

Reported response rates to therapy provide general information, but it is difficult to give a prognosis for an individual cat.

Providing a prognosis is even more difficult for a cat with multicentric nodal lymphoma.

- In some studies "multicentric" included extra-nodal lymphomas involving multiple sites.
- Some cats with only peripheral lymph node disease and long-term remissions may have had atypical hyperplasia or Hodgkin's-like lymphoma.

Providing a prognosis for leukemic cats may be complicated by difficulty in distinguishing nodal leukemic lymphoma and primary leukemia, which carries a worse prognosis.

The best predictor of response is response itself, i.e. the longer a cat is in remission, the more likely it is to remain in remission.

FeLV and FIV status does not affect initial response to therapy. It does negatively affect long-term survival, mostly because of the occurrence of other FeLV- and FIV-related disorders.

Cats with a small tumor burden have a better prognosis.

With these caveats, using combination chemotherapy protocols for the treatment of non-Hodgkin's nodal lymphoma:

- **For multicentric nodal lymphoma:** rate of **complete remission is 60–80%**, 1-year survival is 10%, and 2 and 3 year survival 5%. These figures are based on older studies where the majority of cats were FeLV positive. In a more recent study

where the majority of cats were **FeLV-negative**, **rate of remission was 86% and 1-year survival was 57%**.

- **For solitary or regional nodal lymphoma:** **rate of complete remission is > 80%**, 1-year survival is 35%, and 2 and 3 year survival is 20–30%.
- **For primary lymphocytic leukemia:** rate of complete remission is 25%, 1-year survival is 10%, and 2 and 3 year survival 5%. Cats with acute pancytopenia have a worse prognosis.

It appears that many cats with solitary Hodgkin's-like lymphoma may be cured with surgical excision alone.

PLAGUE*

Classical signs

- Acute high fever.
- Cranial body regional lymphadenopathy.

See main reference page 383 (The Pyrexia Cat).

Pathogenesis

Infection with *Yersinia pestis*. Cats are uniquely sensitive among carnivores.

Most cats appear to be infected by ingestion of an infected rodent. The organism spreads rapidly to the regional nodes (mandibular and cervical nodes). Cats may also be infected by a **bite from an infected flea**, where the organism spreads rapidly to the local lymph node.

- The **organism replicates in the local/regional nodes** and from there may progress to other nodes, **bacteremia and pneumonia**.

Clinical signs

Signs appear within **1–7 days of infection**.

High fever (> 40°C), lethargy, inappetence, dehydration.

Minimal reaction at site of inoculation.

Bubonic plague is characterized by **marked solitary or regional painful mandibular, retropharyngeal and cervical lymphadenopathy** due to **severe lymphadenitis**.

The lymphadenitis is characterized by hemorrhage, necrosis and perinodal edema, and later by lymph node abscessation. **Abscesses may rupture** and drain thick, creamy pus. The severely swollen, inflamed nodes are referred to as “bubos”.

- This distribution of lymphadenopathy results from oral exposure during hunting.
- Flea bites may occur elsewhere resulting in a different distribution, e.g. solitary inguinal bubo formation.

Other possible signs include **oral ulcers, tonsillar enlargement, ocular and nasal discharges and abdominal distention**. Cats may initially present with less severe signs.

Septicemic plague, characterized by fever and septic shock may occur with or without bubo formation.

Pneumonic plague in cats, characterized by **fever, dyspnea**, oral or nasal discharges, and coughing or sneezing occurs occasionally and is usually a sequel to bubonic or septicemic plague.

Diagnosis

History of exposure to **infected rodents**.

Cytology of lymph node biopsy/exudate reveals neutrophils and a **monomorphic population of Gram-negative, bipolar staining, coccobacilli**.

FA test of air-dried smears of tissues or exudate.

Culture of organism from lymph nodes or other affected tissues (e.g. tonsils).

Acute (as early as possible once illness is detected) and convalescent (14 days later) **antibody titers demonstrating a four-fold rise in titer** are diagnostic for plague. Titers are useful to confirm a zoonotic disease when treatment is based on a tentative diagnosis.

All plague suspects should have **thoracic radiographs** taken to **rule-out pneumonia**.

Differential diagnosis

Cat bite abscess.

- Most **cat bite wounds** result in **cellulitis and subcutaneous abscessation rather than lymph node abscessation**. However, subcutaneous/muscle

abscesses have been reported in plague, with lymphadenopathy due to hyperplasia.

- *Pasteurella multocida*, a frequent organism found in bite wounds, resembles *Y. pestis* cytologically. However, **bite wounds usually contain a mixed bacterial population** while bubos usually contain a monomorphic population of bacteria.

Anthrax.

- Rare.
- Lymph node abscessation probably does not occur as with plague.
- Lingual, pharyngeal and cervical edema may be more pronounced than with plague.

Tularemia.

- A papule may be present at the site of inoculation.
- Lymphadenopathy is not as prominent, and abscessation does not occur.

Other causes of bacterial lymphadenitis.

- Unlike most other causes of bacterial lymphadenitis, there is usually minimal reaction at the site of inoculation with plague organisms.
- Culture of organism is required to definitively differentiate.

Acute infection with FeLV or FIV and regional lymphadenopathy.

- Retroviral infections have clinically a more subacute to chronic course.
- Lymph node biopsy with retroviral infections will reveal hyperplasia.

Treatment

Treat early on the basis of tentative diagnosis.

Antibiotics (optimal treatment is not known).

- Recommended antibiotics include **tetracycline, doxycycline, chloramphenicol, trimethoprim-sulfonamide, streptomycin, gentamicin, and kanamycin** at standard recommended doses. Fluoroquinolones have been effective experimentally.
- Recommended duration of therapy is 10–21 days.
- Use **parenteral treatment initially** to minimize contact of nursing personnel with oral cavity. Use follow-up treatment with oral antibiotics to minimize hospitalization and aminoglycoside toxicoses.

Treat animal and environment for fleas.

Strict isolation and barrier nursing procedures must be followed.

- Treat in an isolation area using isolation gowns, high-density filter masks and gloves.
- Clean and decontaminate all surfaces with usual hospital disinfectants.
- Lance and irrigate abscessed lymph nodes.
- Place all contaminated material in double-layer biohazard bags and incinerate.

Notify public health officials; veterinary personnel should contact a physician.

Prognosis

Mortality of plague is **50% in untreated cats**.

There are a number of reports of successful treatment of cats with bubonic plague.

Cats with septicemic and pneumonic plague have the worst prognosis.

Transmission

Cats become infected by ingesting, or being bitten by fleas from infected rodents or other wild animals.

The disease is highly zoonotic.

- **Humans may be infected by flea-bites and contact with infected animals or their tissues.**
- There is a high risk for developing **primary pneumonic plague** following inhalation of *Y. pestis*-infected droplets expelled from cats with secondary pneumonic plague.

Prevention

Minimize cat contact with rodents and fleas in endemic areas.

- Eliminate rodents indoors; control rodent habitats near domestic dwellings (e.g. garbage piles).
- Keep cats indoors; neuter outdoor cats to reduce roaming and hunting.
- Flea control.

Use post-exposure prophylaxis for other cats: tetracycline or doxycycline at standard doses for 7 days.

ORAL CAVITY DISEASES*

Classical signs

- Oral lesions typical of the primary disease.
- \pm Mild to moderate mandibular lymphadenopathy.

See The Cat With Bad Breath or Oral Lesions. (page 602)

Clinical signs

Mild to moderate mandibular lymphadenopathy may be present with lymphocytic-plasmacytic stomatitis/gingivitis, periodontal disease, and oral neoplasia, but it is not the salient feature of the disorders.

Diagnosis

Work-up of the primary disease will usually identify the reason for the lymphadenopathy. Biopsy of lesions may be necessary.

Lymph node biopsy is recommended if lymphadenopathy is present, and bilateral lymph node biopsy should always be performed in the staging of oral cancer.

Biopsy reveals hyperplasia with or without metastasis with neoplastic disorders.

Differential diagnosis

Differential diagnoses for mandibular lymphadenopathy include hyperplasia due to regional skin disorders, FeLV/FIV infection, lymphoma, metastatic lymphadenopathy and atypical hyperplasia.

Treatment

Treat the primary disease.

CUTANEOUS/SUBCUTANEOUS FOREIGN BODY REACTION*

Classical signs

- Lymphadenopathy in local node draining from foreign body region.

See main reference on page 1073 (The Cat With Skin Lumps and Bumps).

Clinical signs

Signs of aseptic or septic inflammation are present at the foreign body site (cutaneous, subcutaneous or deeper) and local lymphadenopathy may or may not be present.

Diagnosis

Exploration of area reveals foreign body.

Lymph node biopsy reveals **hyperplasia** or uncommonly lymphadenitis.

Differential diagnoses

Bite wound cellulitis, chronic bacterial and fungal infections, neoplasia and eosinophilic granuloma complex.

Differentiation is based on cytology, histology and culture.

Treatment

See The Cat With Skin Lumps and Bumps (page 1074).

MYCOBACTERIAL INFECTIONS*

Classical signs

- Chronic vomiting, diarrhea, mesenteric lymphadenopathy (tuberculosis).
- Multiple chronic ulcerated fleshy cutaneous nodules on head and limbs (leprosy) and regional lymphadenopathy.
- Chronic ulcerated subcutaneous lesions on caudal abdomen, inguinal and groin regions (atypical mycobacteriosis) ± local or regional lymphadenopathy.

See main reference, page 1085 (The Cat With Non-Healing Wounds).

Clinical signs

There are three categories of *Mycobacterium* sp. infection in cats: tuberculosis, leprosy and atypical.

Tuberculosis is caused by *M. tuberculosis*, *M. bovis*, *M. tuberculosis-bovis* variant, and *M. microti*. It may

be subclinical or cause chronic weight loss, vomiting, diarrhea and mesenteric lymphadenopathy.

- The infection **occasionally disseminates** to virtually all organs with corresponding systemic and local signs.
- **Peripheral lymphadenopathy** occurs with disseminated disease.

Leprosy is caused by *M. lepraemurium* and is characterized by chronic single to multiple, freely moveable, non-painful intact or ulcerated and abscessed **fleshy cutaneous nodules**, with or without subcutaneous lesions. Systemic signs are rare.

- **Painless regional lymphadenopathy** is typical.

Atypical mycobacteriosis is caused by several non-tubercular, non-lepromatous *Mycobacterium* sp., and is usually characterized by **chronic, local or regional subcutaneous lesions** with multiple draining tracts. Lesions are most often found on the caudal abdomen, inguinal region or lumbar region, but also on the thorax. Systemic signs are uncommon but may occur.

- **Disseminated infection** (systemic non-tuberculous mycobacteriosis), which is clinically similar to tuberculosis, **is most likely with organisms from the *M. avium* complex**,
- Local, regional or generalized lymphadenopathy may occur.

Diagnosis

Cytology and histology of affected tissues reveal **granulomatous to pyogranulomatous inflammation**.

Lymph node biopsy reveals hyperplasia (all clinical forms) or granulomatous lymphadenitis (tuberculosis, systemic non-tuberculous mycobacteriosis).

Acid-fast bacteria are **usually detectable** in affected tissues with tuberculosis and leprosy, but may be difficult to find with atypical mycobacteriosis.

Culture is possible at selected laboratories, and particularly **useful for identifying fast-growing mycobacteria**, the most common causes of atypical mycobacteriosis.

Tuberculin testing is not reliable in cats.

Immunoassays may be available for some organisms.

Differential diagnosis

Differential diagnoses for disseminated mycobacterial infections include multicentric lymphoma, widely metastatic tumors, other pyogranulomatous bacterial infections and systemic fungal infections.

Differential diagnoses for leprosy include neoplasia, eosinophilic granuloma complex, other chronic bacterial infections and fungal infections.

Differential diagnoses for local or regional atypical mycobacteriosis include neoplasia, foreign body reaction, eosinophilic granuloma complex, panniculitis, pansteatitis, other chronic bacterial infections and fungal infections.

Differentiation is based on cytology, histology and culture.

Treatment

Tuberculosis.

- **Notify public health officials.** Euthanasia is often advised because of the zoonotic risk. If treatment is attempted, drug doses are provided in the reference at the end of the chapter.

Treatment of leprosy and atypical mycobacteriosis are discussed in The Cat With Non-Healing Wounds (page 1086).

(PYO)GRANULOMATOUS BACTERIAL INFECTIONS*

Classical signs

- Chronic ulcerating cutaneous/subcutaneous lesions.
- ± Local, regional or generalized lymphadenopathy.

See main reference, page 1086 (The Cat With Non-Healing Wounds).

Clinical signs

Chronic ulcerating lesions occur with a number of bacteria, including *Rhodococcus equi*, *Actinomyces* sp., *Nocardia* sp., and *Dermatophilus congolensis*.

These organisms typically produce chronic ulcerating lesions or masses (abscesses and mycetomas) that are cutaneous or subcutaneous. The lesions have usually developed at sites of penetrating wounds and have **not resolved with typical wound treatment**. Localized infections in other organs and disseminated infections may also occur. Accompanying signs vary with organ involvement.

Local, regional, generalized peripheral and internal lymphadenopathy may occur.

Systemic signs may be absent or mild with local cutaneous and subcutaneous infections. Mild to severe signs occur with internal or disseminated infections.

Diagnosis

Pyogranulomatous-granulomatous inflammation is evident on cytology and histology of exudates and biopsy specimens.

Cytology may reveal Gram-positive bacteria in macrophages (*Rhodococcus equi*), mats of Gram-positive filamentous organisms (*Actinomyces* sp.), Gram-positive, weakly acid-fast beaded filamentous organisms (*Nocardia* sp.), or Gram-positive branching filamentous organisms with transverse longitudinal divisions resulting in paired rows of coccoid spores (*Dermatophilus congolensis*).

Lymph node biopsy reveals hyperplasia or lymphadenitis.

Definitive diagnosis is by culture of the organism from lesions.

There may be a history of exposure to horses with rhodococcosis.

Differential diagnosis

Eosinophilic granuloma complex, mycobacterial infections, fungal infections, neoplasia, panniculitis and steatitis.

Differentiation is based on cytology, histology and culture.

Treatment

Treat the primary disease. See page 1087 (The Cat With Non-Healing Wounds).

METASTATIC NEOPLASTIC LYMPHADENOPATHY: MAST CELL TUMOR*

Classical signs

- Firm cutaneous nodule (cutaneous form).
- Marked splenomegaly (lymphoreticular form).

See main reference, page 1074 (The Cat With Skin Lumps and Bumps).

Clinical signs

Most primary cutaneous mast cell tumors present as single, or less commonly, multiple dermal **nodules** without other clinical signs.

- Histologically they may be classified as compact mastocytic, diffuse mastocytic and histiocytic. The **average age of cats** with mastocytic tumors is **10 years**, while the average age with histiocytic tumors is 2.4 years.

Cutaneous mast cell tumors may **infrequently metastasize** to local, regional and distant peripheral lymph nodes causing lymphadenopathy. **This is most likely with diffuse mastocytic tumors and tumors with > four mitoses/ten high-power fields.**

Cutaneous and lymphoreticular (splenic) mast cell tumors may occur together with variable involvement of internal and peripheral lymph nodes. The average age of cats with lymphoreticular tumors is 10 years.

Diagnosis

Biopsy of the cutaneous mass and/or spleen reveals numerous normal or atypical mast cells.

Lymph node biopsy reveals hyperplasia and increased numbers of mast cells.

Differential diagnosis

Other neoplasia, eosinophilic granuloma complex, chronic bacterial infections, fungal infections, and protothecosis.

Differentiation is based on cytology, histology and culture.

Treatment

See page 1075 (The Cat With Skin Lumps and Bumps).

METASTATIC NEOPLASTIC LYMPHADENOPATHY: OTHER TUMORS*

Classical signs

- Signs of primary tumor.
- \pm Local, regional or generalized lymphadenopathy.

See main reference, page 1067 (The Cat With Skin Lumps and Bumps).

Clinical signs

The cat is usually presented for signs of the primary tumor.

Occasionally the cat is presented because of local, regional or rarely generalized lymphadenopathy.

Most metastatic neoplasia occurs in older cats.

Diagnosis

Lymph node biopsy reveals hyperplasia and infiltration by carcinoma, uncommonly sarcoma, and rarely non-lymphoid, non-mast cell round cell tumors.

- **Carcinomas include** squamous cell carcinoma, bronchogenic carcinoma, mammary carcinoma and others.
- **Sarcomas include** fibrosarcoma, osteosarcoma and others.
- **Round cell tumors include** plasma cell tumors, myeloid leukemia, malignant histiocytosis and melanoma.

If the cat is presented for lymphadenopathy, reviewing the history and physical examination, and performing routine laboratory evaluation, and **thoracic and abdominal radiographs** and **ultrasound** examinations, will help **identify and stage the primary tumor.**

Normal and enlarged regional lymph nodes should be biopsied as part of clinical staging of the cat with cancer.

Differential diagnosis

For a cat presented for lymphadenopathy, differential diagnoses include lymphoma and most chronic causes of hyperplasia.

Differentiation is based on cytology, histology and culture.

Treatment

See page 1067 (The Cat With Skin Lumps and Bumps).

TULAREMIA*

Classical signs

- Acute high fever.
- Peripheral and internal lymphadenopathy

See main reference, page 382 (The Pyrexia Cat).

Clinical signs

Signs appear within 2–7 days of infection with *Francisella tularensis* subsp. *tularensis* or *palaeartica*.

High fever (> 40°C), lethargy, inappetence, dehydration.

Moderate to marked painful lymphadenopathy due to lymphadenitis is common; site of infection affects distribution:

- Cats exposed by **mouth** or **ingesting a rabbit or rabbit tick** will have initial mandibular, cervical or mesenteric lymphadenopathy.
- Cats exposed by **a mosquito, tick bite or inoculation** will have initial lymphadenopathy in the **node draining the region**.

Other variable signs include multifocal white oral ulcers, abdominal pain, hepatosplenomegaly, vomiting and diarrhea.

- Localized tularemia causing a chronically draining subcutaneous mass has also been reported.

Diagnosis

History of exposure to wild rabbits (North America, *F. tularensis tularensis*).

History of exposure to infected rodents, ticks and mosquitoes, or contaminated soil and water (Northern hemisphere, *F. tularensis palaeartica*).

Lymph node cytology reveals hyperplasia; histology reveals multifocal necrosis.

The organism, a **small Gram-negative coccobacilli**, is difficult to see on routine cytology and Gram-stain.

- **FA test** of air-dried smears of tissues or exudate helps identify the organism.

The organism may be **cultured from an aspirate of lymph node**, bone marrow (not blood), or other tissue.

- Not all laboratories will attempt culture and special media is required – check before submitting.

A single titer ~ 1:80 gives a presumptive diagnosis, while acute (as early as possible once illness is detected) and convalescent (14 days later) antibody titers demonstrating a four-fold rise give a confirmatory diagnosis. Titers are useful to confirm a zoonotic disease when treatment is based on a tentative diagnosis.

Differential diagnosis

Other acute viral, bacterial, fungal and parasitic (e.g. toxoplasmosis) infectious processes.

- These are distinguished on the basis of exposure risk, serologic testing and organism identification.
- Acute Gram-negative bacteremia, e.g. secondary to myelosuppression, is not usually associated with lymphadenopathy.

Treatment

Treat early on the basis of tentative diagnosis.

Antibiotics (optimal treatment is not known).

- **Recommended antibiotics include** tetracycline, doxycycline, chloramphenicol, streptomycin and gentamicin at standard recommended doses. Fluoroquinolones have been effective experimentally.
- Recommended duration of therapy is 7–14 days.
- **Use parenteral treatment** initially to minimize contact of nursing personnel with oral cavity. **Use follow-up treatment with oral antibiotics** to minimize hospitalization and aminoglycoside toxicoses.

Treat animal for ticks.

Highly zoonotic from tissues and ticks – strict isolation and barrier nursing procedures must be followed.

- Treat in an isolation area using isolation gowns, high-density filter masks and gloves.
- Clean and decontaminate all surfaces with usual hospital disinfectants.
- Place all contaminated material in double-layer biohazard bags and incinerate.

Notify public health officials; veterinary personnel should contact a physician.

OBSTRUCTIVE EDEMA*

Classical signs

- Localized edema.
- \pm Local or regional lymphadenopathy.

Clinical signs

Lymphatic obstruction due to a tumor or other mass causes edema (e.g. head and neck, limb).

Local or regional nodes may be enlarged.

Diagnosis

Biopsy of the primary lesion.

Lymph node biopsy reveals edema with or without hyperplasia, metastasis or infection.

MISCELLANEOUS BACTERIAL INFECTIONS*

Classical signs

- Localizing signs of inflammation.
- Local, regional or generalized lymphadenopathy.

Clinical signs

Solitary to generalized lymphadenopathy.

Oral or skin wounds may be present indicating the site of entry. Infection may also be via the intestinal tract and cause mesenteric lymphadenopathy.

Systemic signs are usually present, and more severe with more generalized infections.

Diagnosis

Lymph node biopsy reveals **hyperplasia** or **lymphadenitis**.

Culture of bacteria from lymph node or other lesions. Bacteria include *Pseudomonas mallei* (glanders), *Burkholderia pseudomallei* (melioidosis), *Yersinia enterocolitica*, *Yersinia pseudotuberculosis*, *Serratia marscecens*, *Listeria monocytogenes*, and *Chriseomonas luteola*.

With glanders there is a history of exposure to diseased horses or other solipeds, or contaminated meat, and there may be respiratory tract nodules similar to tuberculosis.

MISCELLANEOUS FUNGAL INFECTIONS*

Classical signs

- Chronic ulcerating cutaneous/subcutaneous lesions.
- \pm Local, regional or generalized lymphadenopathy.

Clinical signs

Chronic ulcerating lesions or masses that are cutaneous or subcutaneous. Usually they have developed at sites of penetrating wounds and have **not resolved with typical wound treatment**.

Infections of mucosal surfaces, localized infections in other organs and disseminated infections may also occur with accompanying signs varying with organ involvement. Internal infections are more common with certain organisms.

Local, regional or generalized lymphadenopathy may occur.

Systemic signs may be absent or mild with local cutaneous and subcutaneous infections, and mild to severe with internal or disseminated infections.

Diagnosis

Culture of the organism and histologic demonstration of tissue invasion in biopsy specimens. **Organisms include** *Pythium insidiosum* (oomycete), *Trichosporon*

sp. (yeastlike fungus), *Candida* sp. (dimorphic fungus), dermatophytes (pseudomycetoma) and numerous hyphae-producing organisms. The latter infections are termed zygomycosis, hyalohyphomycosis and phaeohyphomycosis based on characteristics of fungal hyphae, and eumycotic mycetoma if pyogranulomatous nodules containing tissue grains are formed.

Lymph node biopsy reveals hyperplasia or lymphadenitis.

Rule out immunosuppression (diabetes mellitus, hyperadrenocorticism, lymphoma, FeLV/FIV infection, immunosuppressive therapy) and neutropenia, especially if internal or disseminated mycosis is present.

STEATITIS

Classical signs

- Depression, anorexia, reluctance to move and pain on landing.
- \pm Lymphadenopathy.

Clinical signs

Depression, anorexia, reluctance to move because of pain, and pain upon handling.

Firm and lumpy subcutaneous fat with or without accompanying lymphadenopathy.

Other clinical signs include **fever** and **abdominal distention** from fluid and firm abdominal fat.

Diagnosis

History of a diet high in oxidized unsaturated fats (e.g. rancid tuna) and/or deficient in vitamin E. Rare in cats fed commercial foods.

Biopsy of fat confirms steatitis – the fat may be grossly yellow to brown.

Lymph node biopsy reveals hyperplasia.

IDIOPATHIC ATYPICAL HYPERPLASIA

Classical signs

- Moderate to marked generalized lymphadenopathy in young cats.

Pathogenesis

Two forms have been described.

- In cats \sim 2 years of age, lymphadenopathy was due to a **distinctive hyperplasia resembling that seen in experimental FeLV infection**.
 - Some cats were FeLV positive.
 - It was postulated that lymphadenopathy was due to FeLV infection.
- In cats \sim 4 years of age, marked lymphadenopathy was due to **hyperplasia resembling lymphoma**.
 - Tested cats were FeLV negative.
 - Cats were recovering from urinary tract, upper respiratory, and FeLV infections.
 - It was postulated that lymphadenopathy was due to an immune response to infection.
- A follow-up report used **silver staining** to identify tiny bacteria in the nodes of some cats from both studies. These bacteria may have been *Bartonella henselae*, the causative agent of cat-scratch disease in humans. Cats harboring *B. henselae* are usually young and recent studies show that *Bartonella henselae* may induce lymph node hyperplasia in cats.
 - Could the acute phase of FIV infection have been responsible for some of the cases?
 - FIV status was not known – reports antedated routine testing for FIV infection.
 - A recent study shows that co-infection with *Bartonella henselae* and FIV increases the risk for lymphadenopathy.
 - Unusual infections in some of the cases suggest immunodeficiency.
 - However, no cases of atypical hyperplasia have been reported in FIV-infected cats.

Clinical signs

Moderate to marked, regional to generalized **non-painful peripheral lymphadenopathy** in a cat \sim 4 years of age.

- **Lymphadenopathy is usually the chief complaint**; most cats are otherwise normal.

Other signs variably present include lethargy, inappetence, weight loss, fever, pale mucous membranes, hepatosplenomegaly (first case series) and signs due to concurrent infections (e.g. sneezing, hematuria).

Diagnosis

Lymph node cytology consistent with **hyperplasia, lymphoma, or suspicious for lymphoma.**

Lymph node histology reveals marked hyperplasia with disruption of lymph node architecture.

- Characteristic findings in the first case series were paracortical hyperplasia with histiocytes, lymphocytes, plasma cells, and immunoblasts, and post-capillary venular proliferation.
- Characteristic findings in the second case series were paracortical, follicular or diffuse lymphoid expansion, but other findings typical of lymphoid malignancy were variably absent.

Idiopathic lymphadenopathy is not a diagnosis in itself. Lymph node hyperplasia is an immune reaction to a cause. Atypical hyperplasia represents either an unusual cause or an atypical response to a usual cause. Aggressive diagnostic evaluation should be performed to reveal infection or neoplasia, especially since multi-system immune-mediated diseases such as systemic lupus erythematosus are rare in cats. **Work-up includes:**

- **FeLV test.**
- If an ELISA (enzyme-linked immunosorbent assay) test on blood is negative, and another cause of lymphadenopathy has not been found, obtain a FA (fluorescent antibody) or PCR (polymerase chain reaction) test on blood. If negative, obtain a FA or PCR test on a bone marrow or lymph node aspirate, or immunohistochemistry test on a bone marrow core or lymph node biopsy. It should be noted that PCR testing has not been standardized and is more likely to give false-positive results than ELISA and FA if the laboratory does not maintain the highest standards of quality control.
- **FIV test.**
- Search for other infections and neoplasia.
 - Detailed review of history of physical examination for subtle signs, including ophthalmologic examination.
 - Further work-up will depend on clinical signs, exposure risks for infectious agents and financial considerations.
 - Diagnostic evaluation may include complete blood count, serum chemistry profile, urinalysis, blood culture, urine culture, abdominal and thoracic radiographs, cardiac and abdominal ultra-

sound examinations, bone marrow biopsy, lymph node bacterial/fungal culture, biopsies of other abnormal organs (submit for cytology/histology and culture), tests for *Bartonella henselae* and *Ehrlichia* sp. infection (see page 417), serologic tests for fungal agents, and antinuclear antibody and lupus erythematosus cell tests.

- Although FIP may cause mesenteric lymphadenopathy, peripheral lymphadenopathy has not been reported.

Differential diagnosis

Lymphadenopathy is a problem and not a diagnosis, and as such this discussion of idiopathic generalized lymphadenopathy is an extension of the Introduction.

The most common causes of generalized lymphadenopathy are generalized skin diseases, FeLV/FIV infections and lymphoma.

- Skin lesions are usually obvious if lymphadenopathy is due to a skin disease.
- If a cat is FeLV- and/or FIV-positive, the possibility of concurrent neoplasia or infection contributing to lymphadenopathy should be considered.
- **Nodal lymphoma** is one of the **less common forms of lymphoma.**
 - It may be solitary, regional or generalized, similar to cats with atypical hyperplasia.
 - Cats may have no historical signs other than lymphadenopathy, similar to cats with atypical hyperplasia.
 - **Excisional biopsy is mandatory** and communication with the pathologist essential to rule in or rule out lymphoma.
 - There may be evidence of lymphoma at another site, e.g. bone marrow, liver, spleen or the disease will progress to involve these sites. Hepatosplenomegaly was not reported in the case series where lymph node histology resembled lymphoma.

Treatment

Treatment should be supportive if needed pending a diagnosis.

If the owner refuses a work-up, and the cat is otherwise normal, encourage observation rather than euthanasia.

Pending a diagnosis, or if owner refuses a work-up, if the cat is febrile or has localizing signs of infection, consider **empirical antibiotic treatment**. Acceptable choices include amoxicillin 10–20 mg/kg PO bid, amoxicillin-clavulanate 62.5 mg (combined dose) PO bid, doxycycline 5 mg/kg PO bid, enrofloxacin 5 mg/kg PO once daily, orbifloxacin 2.5–7.5 mg/kg once daily, and marbofloxacin 2.5–5.0 mg/kg once daily, for 2 weeks. Cats receiving fluoroquinolones should be monitored for visual disturbances.

Do not treat for lymphoma unless lymph node histology is unequivocal or there is evidence of lymphoma at another site.

- Waiting to treat is probably not harmful.
- An indolent lymphoma is unlikely to respond to aggressive chemotherapy.

Do not treat with corticosteroids.

- Corticosteroids may allow an infectious process to worsen that may otherwise resolve spontaneously.
- Corticosteroids may induce lymphoma cell resistance to other anticancer drugs.

Prognosis

Dependent on cause of lymphadenopathy.

In the two case series, **lymphadenopathy resolved within 4 months in 60% of cats** with follow-up in the first study, and all cats with follow-up in the second study.

PLEXIFORM VASCULARIZATION OF LYMPH NODES

Classical signs

- Unilateral cervical mass.
- Unilateral or bilateral inguinal mass(es).

Pathogenesis

A single case series and individual cases have been reported.

Pathogenesis is not known.

- An **ischemic pathogenesis has been postulated**, but cats have not been evaluated with respect to thromboembolic disease nor have other thromboembolic events been identified.

FeLV/FIV status has not been reported in most cases, but cats have not had signs of such infections.

Clinical signs

Unilateral cervical, or unilateral and bilateral inguinal masses.

Mass has been painless on palpation in 2/3 of cases.

No sex predilection; the majority of cases have been reported in **cats 3–8 years of age**.

Cervical mass may cause **dyspnea from tracheal compression**.

No other clinical signs.

Diagnosis

Histology of excised lymph node reveals **capillary vasoproliferation, lymphoid atrophy** and preservation of architecture.

Differential diagnosis

Differential diagnoses for superficial masses include benign and malignant solid tumors of skin, subcutaneous tissue, and muscle; epidermal cyst, granuloma, abscess, hematoma, and scar tissue; typical and atypical lymph node hyperplasia, lymphoma, metastatic lymphadenopathy, and lymphadenitis.

Additional diagnoses for cervical masses include enlarged thyroid or parathyroid gland, and salivary mucocele.

Additional diagnoses for inguinal masses include prominent inguinal fat pads.

Differentiation is based on biopsy for cytology, histology and culture.

Presence of other clinical signs, laboratory findings, radiographs and ultrasound examination of the mass may help narrow the list of differential diagnoses prior to biopsy, and in some cases exclude biopsy (e.g. hyperthyroidism).

Treatment

Surgical excision of the affected node(s).

Prognosis

Complete resolution reported for all cats.

Local edema for several weeks may occur post-operatively.

JUVENILE STREPTOCOCCAL LYMPHADENITIS

Classical signs

- Kittens.
- Fever.
- Cervical lymphadenopathy.

Pathogenesis

Streptococcus canis (Group G β -hemolytic streptococci) may cause a variety of infections in cats including bacteremia, wound sepsis, pyoderma/cellulitis, pyothorax, pneumonia, urogenital infections, arthritis, discospondylitis, acute neonatal death, and fading kittens.

In 3–7-month-old kittens, streptococcal lymphadenitis may occur.

- The organism colonizes the tonsils (pharyngeal trauma is not necessary) and then disseminates along lymphatics to the lymph nodes of the head and neck.

In mature cats **necrotizing fasciitis** has been reported. The pathogenesis of increased streptococcal virulence is not known.

In dogs, the use of fluoroquinolones has been incriminated as a risk factor for streptococcal infections.

Clinical signs

Juvenile lymphadenitis is characterized by **acute fever, lethargy and inappetence**.

- **Marked unilateral or bilateral cervical lymphadenopathy** with or without generalized lymphadenopathy occurs.
- **Single to multiple kittens** in a litter may be affected; they are usually litters from a young queen.

Necrotizing fasciitis in mature cats is characterized by **multifocal ulcerative purulent skin lesions and lymph-**

adenopathy. Unlike in other species, **minimal systemic signs** have been noted.

Diagnosis

Lymph node biopsy reveals lymphadenitis with or without abscessation; chains of cocci are seen.

Biopsy of distant nodes reveals hyperplasia.

Culture of organism from lymph nodes, or skin (fasciitis) and tonsil (cervical lymphadenitis).

Differential diagnosis

In the initial febrile phase, **other infections** could mimic juvenile streptococcosis, and lymphadenitis from other organisms could rarely occur. **Acute FeLV/FIV infection** can also cause fever and lymphadenopathy, although cats are not usually as ill and nor is lymphadenopathy as prominent. Differentiation is on the basis of lymph node culture and FeLV/FIV tests.

Differential diagnoses for necrotizing fasciitis include eosinophilic granuloma complex, other chronic bacterial (e.g. nocardiosis) and fungal infections, panniculitis and steatitis. Differentiation is based on cytology, histology and culture.

Treatment

Reported treatments include procaine penicillin 50 000 IU SC once daily, or **procaine and benzathine penicillin** 75 000–100 000 IU (combined dose) q 48–72 hours, or penicillin V 20 mg/kg PO q 8 h, for 5 days. Penicillin G, ampicillin, amoxicillin and amoxicillin-clavulanate should also be effective.

Lance and irrigate abscesses.

Prognosis

Prognosis is excellent with early treatment.

Untreated cases of juvenile lymphadenitis may progress to **pyothorax, pneumonia and acute death**, likely due to streptococcal toxic shock syndrome.

Transmission

Streptococci do not live in the environment; the **source of infection is other cats** harboring streptococci in a carrier state.

Juvenile streptococcal lymphadenitis is **usually a cattery problem**, with concurrent neonatal infections.

- **Vaginal colonization in young nulliparous queens** is the **main source of neonatal infection**; older queens eliminate the infection and pass colostral antibodies to their young.
- Epidemics may occur following introduction of an **infected queen or tom** (preputial colonization) into a naïve cattery.

Transmission with juvenile lymphadenitis is presumably from **oral to oral contact** (e.g. grooming) with carrier cats with pharyngeal/tonsillar colonization.

Prevention

The **carrier state cannot be eliminated by antibiotic therapy**. While short-term penicillin treatment of queens at parturition will reduce neonatal mortality, chronic treatment in a cattery as prophylaxis against juvenile infections is not recommended as this will promote resistant organisms. As herd immunity increases, epidemics will resolve.

POST-VACCINAL LYMPHADENOPATHY

Classical signs

- Mild incidental lymphadenopathy.
- History of recent vaccination.

Clinical signs

Mild generalized lymphadenopathy or local lymphadenopathy draining the vaccination site may be noted for **several weeks post-vaccination**.

Diagnosis

History of vaccination and no other clinical signs.

Lymph node biopsy reveals hyperplasia.

NON-CUTANEOUS IMMUNOLOGIC/INFLAMMATORY DISORDERS

Classical signs

- Signs of polyarthritis.
- Signs of systemic lupus erythematosus.
- Signs of lymphocytic cholangitis.

Clinical signs

Lymphadenopathy may be present but is not the salient feature of **chronic progressive polyarthritis**.

Lymphadenopathy is one of the “minor signs” of **systemic lupus erythematosus**.

Lymphadenopathy was present in a series of cats with progressive **lymphocytic cholangitis**.

Diagnosis

- Work-up of the primary disease.
- Lymph node biopsy reveals hyperplasia.

HYPEREOSINOPHILIC SYNDROME

Classical signs

- Lethargy, inappetence, weight loss, vomiting, diarrhea.

See main reference page 758.

Clinical signs

Most cats are presented for chronic lethargy, inappetence, weight loss, vomiting and diarrhea.

Other clinical signs include fever, pruritus and seizures.

Abdominal palpation may reveal thickened intestines, mesenteric lymphadenopathy and hepatosplenomegaly.

Peripheral lymphadenopathy is present infrequently.

Diagnosis

Marked mature eosinophilia, increased synchronous eosinopoiesis on bone marrow biopsy, and exclusion of other causes of eosinophilia.

Lymph node biopsy reveals hyperplasia with or without eosinophilic infiltration.

BACTEREMIA

Classical signs

- Fever, lethargy, inappetence.

Clinical signs

Lymphadenopathy is not usually present in acute bacteremia or endotoxemia due to conventional Gram-negative (e.g. *Escherichia coli*), Gram-positive (e.g. *Staphylococcus* sp.) and anaerobic (e.g. *Clostridium perfringens*) organisms unless lymphadenitis occurs.

Mild–moderate generalized lymphadenopathy may be present with **chronic bacteremia** regardless of origin.

Diagnosis

Documenting infection and identifying the site may require routine laboratory tests, imaging, and blood, urine and lymph node cultures.

Lymph node biopsy reveals hyperplasia or lymphadenitis.

MYCOPLASMA AND L-FORM INFECTIONS

Classical signs

- Chronic limb wound and lameness.
- \pm Local or regional lymphadenopathy.

Clinical signs

Non-healing bite wound (cellulitis) and **lameness** due to (poly)arthritis/synovitis.

Local or regional lymphadenopathy may be present.

Diagnosis

Cytology of skin lesions or joint fluid lesions reveals **suppurative inflammation but no organisms**.

Lymph node biopsy reveals hyperplasia or lymphadenitis.

Culture of organism is necessary for a definitive diagnosis. Culture requires special transport and culture media – contact the laboratory prior to submitting specimen.

Response to a tetracycline or a fluoroquinolone gives a presumptive diagnosis. Failure to respond does not rule-out the diagnosis.

EHRlichiosis

Classical signs

- Lethargy, inappetence, weight loss.
- \pm Lymphadenopathy.

Clinical signs

Most cats have lethargy, inappetence and weight loss.

Other signs variably present include fever, anemia, hyperesthesia, arthralgia, irritable disposition, lymphadenopathy and splenomegaly.

Diagnosis

Variable laboratory findings include **non-regenerative anemia**, neutropenia, neutrophilia, lymphopenia, lymphocytosis, monocytosis, thrombocytopenia and hyperproteinemia due to polyclonal gammopathy.

Lymph node biopsy reveals hyperplasia.

A positive FA test for antibodies against *Ehrlichia canis* and *Ehrlichia risticii* or positive PCR test for ehrlichial DNA is diagnostic of infection. Preliminary evidence suggests that cats may be PCR positive but FA negative.

Resolution of clinical signs with treatment with tetracyclines.

BARTONELLOSIS

Classical signs

- Asymptomatic cats.
- \pm Lymphadenopathy.

See main reference page 530 (The Anemic Cat).

Clinical signs

Cats usually harbor *Bartonella henselae*, the main causative agent of human cat-scratch disease, without clinical signs.

Mild popliteal lymphadenopathy occurs during acute experimental infection.

Lymph nodes are normal during chronic experimental infection.

Bacteria resembling *B. henselae* have been seen in some clinical cases with moderate to marked lymphadenopathy due to **atypical hyperplasia**.

Diagnosis

Lymph node biopsy reveals **follicular hyperplasia** in grossly normal lymph nodes during chronic experimental infection.

Silver staining of lymph nodes of cats with lymphadenopathy may reveal bacteria. In such cases blood culture and/or serologic testing and/or PCR testing for *B. henselae* should be performed.

PROTOTHECOSIS

Classical signs

- Firm cutaneous nodule on foot.

Clinical signs

Large firm **cutaneous nodule(s)**, which may be ulcerated, on foot, limb, head or base of tail. Nodules are not painful on palpation, but may cause discomfort and other signs from local mass effect.

Local lymph node is usually normal.

No systemic signs.

Diagnosis

Cytology and histology of biopsy specimens reveal granulomatous inflammation.

Lymph node biopsy may reveal hyperplasia or lymphadenitis.

Identification of *Prototheca* sp. (algae), in specimens by cytology, histology or culture.

- Mature organisms are round, have a hyaline cell wall, small central nucleus, may show internal cleavage into endospores, and vary from smaller to larger than neutrophils.

CYTAUXZOOONOSIS

Classical signs

- Fulminant disease with fever and hemolytic anemia.

See main reference page 389 (The Pyrexia Cat).

Clinical signs

Acute onset of fever, lethargy, inappetence, dyspnea, **anemia** and **jaundice**.

Lymphadenopathy is usually identified at necropsy.

Diagnosis

Exposure history (tick exposure in south-central or south-eastern North America).

Identification of the protozoan, *Cytauxzoon felis*, on red cells, as tiny dot, tetrad, safety-pin or signet ring forms.

Lymph node histology reveals hemorrhage and edema.

ANTHRAX

Classical signs

- Edema of the head and neck.
- Acute death with no promontory signs.

Clinical signs

Rare – cats are resistant to anthrax.

Lingual and pharyngeal edema cause oral serosanguineous discharge and dyspnea.

Cervical regional lymphadenopathy due to edema, hemorrhage and necrosis may occur.

In one case acute death occurred with no promontory signs and there were no significant necropsy findings other than congested lungs and unclotted blood.

Diagnosis

History of **ingesting potentially contaminated raw meat or animal by-products**.

Do not perform necropsy if anthrax suspected.

Identification of a large bacillus on stained blood smear from marginal ear vein or other peripheral vein, or on stained smear from aspiration biopsy of tissue.

Culture of *Bacillus anthracis* from aspirated material.

AMERICAN TRYPANOSOMIASIS

Classical signs

- Acute and chronic right-sided heart failure.

Clinical signs

The cat is susceptible to infection in South America and may act as a reservoir host.

Clinical disease has not been formally described but is stated to be similar to dogs.

Generalized lymphadenopathy is present during acute infection in dogs, in addition to signs due to **myocarditis** (acute death, collapse, hypothermia, pale mucous membranes, weak pulses, arrhythmias, dyspnea).

Diagnosis

Diagnosis is based on exposure history (*Triatoma* [kissing bugs] vectors), clinical signs, serologic testing for antibodies to *Trypanosoma cruzi*, and identification of trypomastigotes in buffy coat smears.

AFRICAN TRYPANOSOMIASIS

Classical signs

- Fulminant disease resembling overwhelming sepsis.

Clinical signs

Fever, generalized edema, purulent nasal and ocular discharges, signs of disseminated intravascular coagulation, lymphadenopathy, splenomegaly and neurologic signs.

Diagnosis

Exposure history (*Glossina* spp. [tsetse flies] vectors), clinical signs, serologic testing for antibodies to *Trypanasoma* sp.

The cat is highly susceptible to experimental infection with certain African *Trypanasoma* sp., but natural infection is rarely encountered clinically.

TOXOPLASMOSIS

Classical signs

- Anorexia, fever, dyspnea and signs of ocular inflammation in mature cats.
- Fading neonate.

See main reference on page 432 for details (The Yellow Cat or Cat With Elevated Liver Enzymes), page 375 (The Pyrexia Cat).

Clinical signs

Common signs include **fever, uveitis, dyspnea** (pneumonia), **vomiting, diarrhea, icterus** (hepatitis and hepatic necrosis), **mesenteric lymphadenopathy, muscle pain** and **neurologic signs**.

Generalized peripheral lymphadenopathy may be present, which is due to reactive lymphoid hyperplasia and not *Toxoplasma*-induced lymphadenitis.

Diagnosis

Acute systemic toxoplasmosis typically affects kittens, or immunosuppressed cats, which usually have a history of chronic disease.

Confirmation is **by measuring serum IgM antibodies or demonstrating rising serum IgG antibodies**.

The organism occasionally may be seen in airway wash cytology of cats with pneumonia.

Peripheral lymph node biopsy may reveal hyperplasia. Mesenteric lymph node biopsy may reveal necrosis.

21. The yellow cat or cat with elevated liver enzymes

Albert E Jergens

KEY SIGNS

- Jaundiced cat.

MECHANISM?

- Jaundice occurs when serum bilirubin values exceed 2.0 mg/dl. Jaundice results from either increased erythrocyte hemolysis or hepatobiliary disease.

WHERE?

- **Pre-hepatic** (hemolytic processes), **hepatic** (parenchymal disease), or **post-hepatic** (extra-hepatic biliary obstruction).

WHAT?

- Most cats with jaundice have hepatic lipidosis, cholangiohepatitis syndrome (CHS), or extrahepatic biliary obstruction (EHBO). Non-jaundiced cats with elevated liver enzymes may or may not have liver disease. The degree of dysfunction is assessed by bile acid analysis and the cause determined by liver cytology and/or biopsy if indicated.

QUICK REFERENCE SUMMARY

Diseases causing a yellow cat or cat with elevated liver enzymes

PRE-HEPATIC

- Hemolytic processes causing clinical signs are usually associated with PCV < 18%.

INFLAMMATION

INFECTION

- ***Mycoplasma haemofelis* * (*Hemobartonella felis*) * (p 424)**

Bacterial (Mycoplasma) parasite which infects red blood cells and causes RBC destruction. Jaundice, lethargy, inappetance and occasional vomiting.

continued

continued

IMMUNE

- Immune-mediated anemia (p 424)

Jaundice, lethargy, inappetance, occasional vomiting, and respiratory distress with severe anemia.

HEPATIC

- Jaundice caused by primary hepatic parenchymal diseases.

DEGENERATIVE

- Cirrhosis (p 435)

Rare and usually follows severe chronic hepatopathy. Jaundice, anorexia, weight loss and/or hepatomegaly.

METABOLIC

- Diabetes mellitus (p 436)

Polyuria, polydipsia, increased appetite, weight loss, plantigrade stance with neuropathy.

- Hyperthyroidism (p 437)

Generally seen in cats greater than 8 years old. Often have an increased appetite, weight loss, poor hair coat, vomiting.

- **Hepatic lipidosis*** (p 425)**

Often previous history of obesity and/or anorexia. Jaundice, weight loss, and anorexia are common.

NEOPLASTIC

- **Lymphosarcoma* (p 431)**

Usually a manifestation of multicentric lymphosarcoma. Jaundice, anorexia, weight loss, vomiting and/or diarrhea.

- Non-hematopoietic liver tumors (biliary cyst adenoma, hepatocellular carcinoma) (p 436)

Vast majority are benign tumors seen in old cats. Anorexia, lethargy, and weight loss predominate.

INFLAMMATION

- **Feline cholangitis (cholangitis/cholangiohepatitis syndrome)*** (p 427)**

The neutrophilic form is seen most commonly in male cats. It may be associated with other inflammatory disorders (IBD, pancreatitis) concurrently affecting the gastrointestinal tract. It occurs as an acute phase associated with signs of systemic illness such as fever, anorexia, lethargy, vomiting and jaundice. Signs in the chronic phase are milder and weight loss predominates. The lymphocytic form is associated with jaundice, hepatomegaly, vomiting, diarrhea and/or ascites.

INFECTIOUS

Mycotic:

- Histoplasmosis (p 438)

Of regional significance in the central US. Seen primarily in young cats with depression, weight loss, fever and anorexia. Dyspnea, tachypnea and abnormal lung sounds seen in 50% of cats.

Viral:

- **Feline infectious peritonitis (FIP)* (p 430)**

Progressive anorexia, weight loss, jaundice, fever and/or ascites with effusive forms of disease.

- **Feline leukemia virus* (p 437)**

May cause pre-hepatic jaundice, immunosuppression and/or lymphosarcoma. Salient signs include mucus membrane pallor, anorexia, weight loss, lymphadenopathy and/or jaundice.

Protozoan:

- **Toxoplasmosis* (p 432)**

Jaundice, cyclical fever, and anterior uveitis are commonly observed. Dyspnea and central nervous system signs may or may not occur concurrently.

Toxic:

- Acetaminophen (paracetamol) toxicity (p 433)

Acetaminophen toxicity causes cyanosis, dyspnea and facial edema.

- Diazepam toxicity (p 434)

Diazepam toxicity causes anorexia, depression and jaundice.

POST-HEPATIC

Jaundice caused by decreased or impaired biliary excretion.

Mechanical:

- **Extrahepatic biliary obstruction (EHBO)** (p 439)**

May be caused by pancreatic diseases, neoplasia or extrinsic compression. Jaundice, anorexia, weight loss, vomiting and abdominal pain seen with pancreatitis.

Inflammation:

- **Pancreatitis** (p 439)**

Anorexia, lethargy and abdominal pain predominate. Jaundice may occur several days after mild signs.

- **Cholecystitis (p 440)**

Uncommonly recognized, but may cause abdominal pain, fever, vomiting and jaundice.

Trauma:

- Ruptured bile duct (p 441)

Low-grade abdominal pain, malaise, weight loss and/or effusion.

INTRODUCTION

MECHANISM?

Jaundice results when serum bilirubin is increased above 2 mg/ml.

Most bilirubin originates from senescent erythrocytes and is processed in the liver for excretion in the bile.

Jaundice results from either increased erythrocyte hemolysis, which exceeds the processing capacity of the liver, or hepatobiliary disease.

WHERE?

Pre-hepatic jaundice is due to hemolytic processes. Erythrocyte hemolysis causes release of increased heme pigments, which overwhelm hepatic processing/excretion of bilirubin.

Hepatic jaundice is seen with severe diffuse hepatic cholestasis (via inflammation) or major bile duct obstruction. Inflammation in portal or periportal areas causes jaundice early in the disease course; whereas, parenchymal injury away from periportal areas results in jaundice development late in the disease course.

Post-hepatic jaundice is caused by intraluminal or extraluminal disorders that mechanically occlude the biliary tree (e.g., gall bladder and common bile duct).

Post-hepatic (extrahepatic biliary obstruction).

WHAT?

Pre-hepatic causes for jaundice are primarily attributable to erythrocyte parasitemia (hemobartellosis), infectious disease (FeLV), and immune-mediated hemolysis (rare).

Hepatic causes for jaundice may be caused by hepatic lipidosis, cholangiohepatitis syndrome and hepatic lymphosarcoma.

Post-hepatic causes for jaundice are caused by pancreatitis and neoplasms involving the gallbladder and biliary tree (less common).

Non-jaundiced cats with elevated liver enzymes may or may not have significant hepatic disease. An underlying defect in bilirubin metabolism affecting conjugation reactions or cytosolic pigment transport

or storage is suspected. This phenomena is observed with a variety of non-hepatic primary disorders (e.g., renal and gastrointestinal diseases) which may cause these cats to later develop primary liver disease. Bile acid analysis determines hepatic function and the need to obtain cytologic/biopsy specimens for definitive diagnosis.

INCREASED BILIRUBIN PRODUCTION (PRE-HEPATIC CAUSES OF JAUNDICE OR INCREASED LIVER ENZYMES)

MYCOPLASMA HAEMOFELIS (HEMOBARTONELLA FELIS)* IMMUNE-MEDIATED ANEMIA

Classical signs

- Pale mucus membranes, PCV usually < 18%; hemoglobin < 10 g/dl.
- Lethargy, in appetite, and anorexia may be observed.
- +/- fever.
- Occasional vomiting.

See main reference on page 530 for details (The Anemic Cat).

Pathogenesis

Rapid destruction of red cells exceeds the liver's capacity to metabolize increased hemoglobin breakdown products (bilirubin).

Most commonly associated with *Mycoplasma haemofelis* infection and less commonly with immune-mediated anemia. Hemolysis may also be caused by feline leukemia viral (FeLV) infection.

Pre-hepatic causes for jaundice in the cat are uncommon.

Clinical signs

Pale mucus membranes, PCV < 18% and often 12–15%; hemoglobin < 10 g/dl.

Lethargy, inappetence, anorexia.

+/- fever and vomiting.

Lymphadenopathy, or skin, respiratory, and gastrointestinal infections secondary to immunosuppression are seen with FeLV infection.

Diagnosis

Typically anemia is moderate to severe (PCV 12–17%) with a reduced hemoglobin < 10 g/dl.

Examine blood smears closely with a reduced PCV for presence of red cell parasites (hemobartonellosis).

Saline agglutination and direct Coomb's tests confirm immune-mediated anemia but the Coomb's test requires feline specific antibody to be meaningful.

Liver enzymes (ALT, ALP) are often normal or insignificantly elevated.

Serologic testing (ELISA or fluorescent antibody) for FeLV infection.

Polymerase chain reaction assays may be of great benefit in documenting infection if available.

Differential diagnosis

Hepatic and post-hepatic disorders are often chronic diseases and are associated with some anemia. In these instances, the anemia is mild (PCV of 18–27%), non-regenerative and is attributable to anemia of chronic disease.

Hemolytic anemia is usually regenerative unless it is detected early (< 4 days) or if stem cells are involved; as may occur with *Mycoplasma haemofelis* infection or immune-mediated red cell destruction.

Hemolytic anemia associated with FeLV infection may or may not be regenerative.

Treatment

Supportive care and antibiotics (doxycycline 5 mg/kg PO q 12 h for 21 days or enrofloxacin 5 mg/kg PO q 12 h for 7–14 days) for cats with hemobartonellosis.

Whole blood/packed red cell transfusions, corticosteroids (prednisone 1–2 mg/kg PO q 12 h as needed), and supportive care for immune-mediated anemia. Clinical parameters which suggest the need for transfu-

sion include increased heart and respiratory rates which usually occur when the PCV < 15–18% for acute loss and < 12% for more chronic loss. See page 531 (The Anemic Cat).

Antivirals and immunotherapy for FeLV infection.

HEPATOCELLULAR DISEASES (JAUNDICE OR INCREASED LIVER ENZYMES CAUSED BY HEPATIC PARENCHYMAL DISEASES)

HEPATIC LIPIDOSIS***

Classical signs

- Obese anorectic female cats are predisposed.
- Progressive anorexia, vomiting, and diarrhea are common.
- Severe jaundice and hepatomegaly are present.

Pathogenesis

The etiopathogenesis is poorly understood and ill-defined.

Triglycerides accumulate in the liver as a consequence of imbalanced fat metabolism which is likely multifactorial in origin. These imbalances may include uptake of fatty acids, use of fatty acids for energy (e.g., ketone production and fatty acid oxidation), production and dispersal of lipoproteins throughout the body, and de novo synthesis of triglycerides. Many metabolic conditions, nutritional factors, drugs and toxins can cause excessive hepatic fat accumulation (see below). Approximately 50% of cats have idiopathic (primary) hepatic lipodosis in which no underlying medical condition is detected.

- History of previous obesity is observed in nearly all cats.
- Anorexia or rapid weight reduction contributes to hepatic fat accumulation. Anorexia may be preceded by a stressful event such as a move to a new house.
- Imbalanced nutrition using caloric- or protein-restricted diets, especially if unpalatable, can trigger marked weight loss. Experimentally, dietary

energy must be restricted 50–75% for at least 2 weeks to induce hepatic lipidosis.

- Hepatic lipidosis occurs either as a primary idiopathic event or secondary to another disease process. Frequently it occurs secondary to underlying diseases, most commonly cholangiohepatitis, inflammatory bowel disease, and acute or chronic pancreatitis. A recent study for 30% of cats had acute pancreatitis.
- Acquired carnitine deficiency may be related to the development of hepatic lipidosis. Carnitine is primarily synthesized in the liver and is essential for enzyme-mediated uptake of fatty acids into mitochondria. In health, it also facilitates fatty acid product transport and the oxidation of long-chain fatty acids. Starved cats have diminished capacity for fatty acid beta-oxidation or export of VLDL, leading to hepatic triglyceride sequestration.
- Less commonly observed in association with diabetes mellitus and toxicity (e.g., aflatoxins, bacterial toxins).

Fat accumulation in hepatocytes results in cholestasis and hepatic jaundice.

Progressive liver dysfunction causes anorexia, vomiting and dehydration.

Signs of overt hepatic encephalopathy (ptyalism, seizures) are uncommon.

Clinical signs

Most commonly seen in middle-aged to older cats of either sex. There is no breed predisposition.

The most common early signs are progressive anorexia and depression with intermittent vomiting over several weeks.

Common presenting complaints include, weight loss, prolonged (> 2 weeks) anorexia, vomiting and lethargy.

Jaundice, hepatomegaly and dehydration are detected on physical examination.

Ascites, fever and ptyalism are uncommon.

Diagnosis

Cytologic examination of hepatic parenchyma obtained via fine-needle aspirate, or histologic examination of a liver biopsy specimen is usually diagnostic for

hepatic lipidosis. Histologic confirmation is the preferred modality, as recent reports have noted poor correlation between cytologic interpretation and histologic findings in cats with liver disease.

Histopathologic confirmation requires specialized processing to assess.

- Both hematoxylin/eosin and specific staining for fat should be performed.
- Greater than 50% of hepatocytes contain lipid vacuolation.

Abdominal ultrasonography may suggest hepatic lipidosis versus extrahepatic biliary obstruction, cholangiohepatitis and neoplasia.

- Cats with hepatic lipidosis have diffuse hyperechogenicity, hepatomegaly, and an absence of biliary tract abnormalities.

Non-regenerative anemia is seen in 30% of cats.

Biochemical liver parameters are often suggestive of hepatic lipidosis.

- Marked but discrepant increases of serum ALP in comparison to ALT and AST.
- Total bilirubin values exceed 2 mg/dl as most cats are severely jaundiced.

Approximately 30% of cats are hypokalemic.

Abnormal coagulation tests are observed in > 50% of cats. Approximately 20% have clinical evidence of excessive bleeding. Vitamin K deficiency is the most common coagulation abnormality.

- Carefully appraise coagulation status prior to liver aspirate or biopsy.

Differential diagnosis

Cats with inflammatory liver disease (cholangiohepatitis) are often febrile and may have ascites. Increased ALT +/- AST and hyperglobulinemia are prominent features in these cats and are not observed in cats with hepatic lipidosis.

Sonographic abnormalities to the biliary excretory pathway or hepatic parenchyma are evident in most cats with extrahepatic biliary obstruction and neoplasia, respectively.

Treatment

Cats must be fed 65–90 kcal/kg/day until eating.

- Gastrostomy or jejunostomy tube alimentation with high-energy commercial enteral diets is necessary if vomiting is frequent.
- Esophagostomy tubes can be used when vomiting is not frequent, and may be simpler and safer to place than gastrostomy tubes.
- Nasoesophageal tubes are indicated in cats too ill for a gastrostomy tube.
- They are often used for short-term support until placement of gastrostomy tube.
- Nasoesophageal and some esophageal tubes require liquified commercial diets (Iams Nutritional Recovery Formula, Clinicare, or Hill's A/d mixed with water).
- It takes several days before the caloric requirements can be fed in 3–4 meals per day without inducing vomiting. Initially small volumes, e.g., 5 ml, should be fed every 2 hours, and the volume is increased while reducing the frequency over several days. Alternatively, feeding can begin with a constant rate infusion over 24 hours using a syringe infusion pump with the volume increased gradually until the daily caloric requirements are met. Cats can then be transitioned to bolus feeding four times daily. Tubes should be left in place until the cat is voluntarily eating its full caloric requirements for 2 weeks and has a stable and increasing weight.

Avoid benzodiazepines as they are inadequate to stimulate appetite and may aggravate CNS signs.

Vomiting is controlled with metoclopramide (0.2–0.5 mg/kg q 8 h or using a constant rate infusion 1–2 mg/cat/24 h). Two periods of exercise totaling 45–60 min/day help reduce vomiting and high gastric residual volumes. This can be accomplished by letting the cat free in a consulting room, preferably with a window.

Correct dehydration and electrolyte imbalances with fluid therapy.

- Monitor serum potassium and phosphorous and supplement with KCl and potassium dihydrophosphate as needed to combat hypokalemia and hypophosphatemia.

Ursodeoxycholic acid (10–15 mg PO q 24 h) for intrahepatic cholestasis.

Vitamin K₁ is often given (3–5 mg per cat q 12 h initially) due to the frequency of coagulation disturbances.

Thiamine supplementation (100 mg of thiamine hydrochloride, q 12 h by oral, subcutaneous or IM routes) is generally advised.

The potential value of carnitine (1250 mg L-carnitine/cat q 24 h) and taurine (250–500 mg q 24 h) supplementation has not been critically assessed but is unlikely to be harmful.

Prognosis

Survival rates are up to 60% with aggressive therapy.

Evaluate closely for concomitant diseases (pancreatitis) as they warrant a more guarded prognosis.

Prevention

It is important to use sensible restriction diets for obese cats. Feed 60–75% of maintenance requirements (60 kcal/kg) to promote slow but steady weight loss. Food intake should be adjusted monthly for the individual cat to produce a weight loss of 1–2% per week.

- A variety of commercial, nutritionally balanced but reduced caloric rations are available.

FELINE CHOLANGITIS (CHOLANGITIS/CHOLANGIOHEPATITIS SYNDROME)***

Classical signs

- Anorexia, weight loss, and vomiting.
- Jaundice, +/- fever, +/- ascites.
- Often palpable hepatomegaly.

Pathogenesis

Cholangitis is the cause of jaundice in 30% of cats.

Etiology is unknown but may involve causative factors such as bacterial infection. The different forms of cholangitis **may** represent different stages of the same disease process. One hypothesis suggests that the unique anatomic relationship in which the bile duct and major pancreatic duct form a short common duct entering the duodenum may predispose cats to inflammatory hepatic disease. This connection might favor the ascension of luminal bacteria or the entrance of pancreatic enzymes into the biliary tract. Supporting this theory is

the observation that inflammatory disease of other alimentary organs, such as pancreatitis and inflammatory bowel disease, are associated with cholangitis.

A new classification scheme by the World Small Animal Veterinary Association Liver Diseases and Pathology Standardisation Research Group recognizes three distinct forms of cholangitis in cats.

In the traditional classification scheme, cholangitis denoted inflammation of the biliary tree and cholangiohepatitis referred to inflammation around bile ducts and peribiliary hepatocytes.

However, with the new classification scheme, the term cholangitis is used in preference to cholangiohepatitis, because inflammatory disruption of the limiting plate to involve hepatic parenchyma is not always a feature and, when present, is an extension of a primary cholangitis, and inflammation is centered on intrahepatic bile ducts.

Three separate syndromes occur as defined by clinical and histologic criteria: **neutrophilic cholangitis, lymphocytic cholangitis and chronic cholangitis.**

Cirrhosis may occur as an end-stage of cholangitis but is rare.

- The lymphocytic form is more common than the neutrophilic form of cholangitis in the UK and Australia, but the neutrophilic form appears to be the most common form in some other locations.

Neutrophilic cholangitis.

- This is usually referable to ascending bacterial infection but is also rarely reported in protozoal infections. *E. coli* is sometimes cultured from the bile, and occasionally Gram-positive anaerobes are cultured.
- **Two phases of neutrophilic cholangitis** are recognized; an acute phase and a chronic phase.

Neutrophilic cholangitis – Acute phase.

- Neutrophils are within walls and lumina of intrahepatic bile ducts and within portal areas. Bile duct epithelial degeneration and necrosis is present. There is variable extension of inflammation through the limiting plate to involve periportal parenchyma. Bacteria may be visible. There is usually minimal biliary hyperplasia or periductal fibrosis.
- Generally, there is an acute onset of signs with marked systemic illness (fever, anorexia, lethargy, vomiting).

Neutrophilic cholangitis – Chronic phase.

- Mild to severe infiltration of portal areas by plasma cells, lymphocytes and neutrophils, without or without macrophages is present. Leukocytes are within walls and/or lumina of bile ducts, and are associated with biliary epithelial degeneration or necrosis. Lymphoid aggregates may be present in portal areas. Biliary hyperplasia, periductal fibrosis or bridging portal fibrosis may be present.
- It is usually associated with partial or complete biliary obstructive lesions resulting in cholestasis.
- Signs and liver enzyme elevations tend to be milder than with the acute neutrophilic phase, and reflect a smoldering inflammatory hepatic disease. Weight loss is a dominant sign. Signs may wax and wane. Jaundice may or may not be present. Ascites is not a feature of the acute or chronic phase. In general, the chronic phase appears less common than the acute phase.

Lymphocytic cholangitis.

- Lymphocytic cholangitis is postulated to be immune-mediated in origin.
- Histologically there is moderate to marked infiltration of portal areas by small lymphocytes. With chronicity, the intensity of portal infiltration tends to abate. Lymphocytic infiltrates may also be present that are centered on and infiltrating walls of bile ducts, but this is an inconsistent feature, especially in the chronic phase. Inflammation may or may not extend into the periportal parenchyma. Histologic evidence of intrahepatic cholestasis may be present.
- It occurs primarily in middle-aged cats with chronic (> 3 weeks) signs. Recurrent episodes of clinical signs are often interspersed with weeks or months of normalcy, with a normal or even increased appetite.
- Cats are often less ill than with the acute neutrophilic form, and may have ascites.

Chronic cholangitis associated with liver fluke infestation.

- Lesions result from infection by liver flukes such as *Amphimerus pseudofelineus*, (*Opisthorchis pseudofelineus*), *Opisthorchis tenuicollis*, *Metorchis albidus*, *M. conjunctus* (*M. complexus*), *Platynosomum concinnum* (*page fastosum*).

Clinical signs

Often observed in middle-aged cats.

Intermittent episodes of inappetance or anorexia and lethargy.

Weight loss.

Fever occurs with neutrophilic cholangitis.

Ascites is sometimes observed with lymphocytic cholangitis. Ascitic fluid had a high total protein content attributable primarily to globulins.

Jaundice +/- hepatomegaly occur with both types.

Diagnosis

Definitive diagnosis requires histologic evaluation of liver biopsy specimens.

- Tissues may be obtained via ultrasound-guided percutaneous biopsy, laparoscopically or by laparotomy. However, 18-gauge needle biopsies are less reliable than wedge biopsies. In one study, less than 60% of cats with cholangitis had needle biopsy results that were in accordance with the diagnoses based on the wedge biopsy.
- Perform coagulation tests (ACT or APTT/OSPT or PIVKA) prior to hepatic biopsy. Initiate vitamin K₁ therapy if abnormal (see dosage below).

Bile and liver culture are recommended in cats with suspected neutrophilic cholangitis.

Survey abdominal radiographs are usually normal but are useful to confirm hepatomegaly and the presence of peritoneal effusion. Abdominal sonography shows biliary tract thickening and distention (neutrophilic cholangitis) or increased parenchymal echogenicity (lymphocytic cholangitis).

Biochemical liver parameters show high ALT, ALP and total bilirubin concentrations. Total bilirubin concentrations may increase 2–10 times normal values, with ALT concentration increased to a greater extent relative to ALP.

Increased plasma globulin and decreased albumin are often present in the lymphocytic form.

Leukocytosis may be present in suppurative form.

Biliary obstruction should be suspected in cats with lethargy, intermittent fever and progressive jaundice. These cats will require surgical correction for obstructive jaundice.

Differential diagnosis

Cholangitis produces greater increases of serum ALT as compared to HL.

- Cats with lymphocytic cholangitis may have concurrent inflammation involving pancreatic, intestinal and renal tissues.

Fever and ascites are common with cholangitis but are not observed with HL.

Cats with HL have higher ALP activity as compared to cholangitis-affected cats.

Feline infectious peritonitis (FIP) may appear similar to the lymphocytic form, particularly if there is ascitic fluid with a high protein content. The syndromes clinically look similar, although fever is more common with FIP. Liver biopsy, especially a wedge section, is usually diagnostic.

Treatment

Specific treatment is dictated by results of hepatic biopsy.

Neutrophilic cholangitis.

- Empiric antibiotic choices are amoxicillin (22 mg/kg PO q 12 h) and metronidazole (10 mg/kg PO q 12 h) or enrofloxacin (2.2 mg/kg bid PO) until bile culture results are known.
- Continue antibiotic therapy for 6–8 weeks.
- Ursodeoxycholic acid (10–15 mg/kg PO q 24 h) may be useful for cholestasis following correction of biliary obstruction.
- S-adenosylmethionine (20 mg/kg PO q 24 h) is recommended to replenish glutathione stores and scavenge free radicals.
- Surgical correction (biliary diversion) is indicated in cats with clinical signs or imaging features (e.g., distended and tortuous common bile duct, large gall bladder and/or prominent intrahepatic bile ducts) indicative of obstructive biliary tract lesions.

Lymphocytic cholangitis.

- Use immunosuppressive doses of steroids (prednisone 2 mg/kg PO q 24 h) for 4–6 weeks to reduce hepatic inflammation. If a favorable response is observed, then steroids may be tapered at 25% of the dose q 2 weeks as determined by clinical signs, liver enzymes and/or bile acid tests.

- Administer ursodeoxycholic acid for cholestasis and modulation of “noxious” bile acids.
- Long-term immunosuppressive therapy (steroids +/- metronidazole) is often required in cats with persistent clinical signs or abnormal laboratory values. Some cats that fail to respond to prednisone may respond to chlorambucil (0.2 mg/kg PO q 48 h).

Supportive care as dictated by the animal’s needs.

- Vitamin K₁ for coagulopathy (3–5 mg per cat PO q 24 hours as needed).
- Fluid therapy to combat dehydration and electrolyte disturbances.
- Nutritional therapy is important to reduce the hepatic workload and augment recovery.
 - Jejunostomy or gastrostomy tubes and feeding a pureed commercial or esophagostomy tubes and feeding a commercial liquified diet are best tolerated.
 - Feed a protein-modified diet as dictated by the status of renal function and signs of hepatic encephalopathy (rare).
 - Control vomiting with famotidine (0.2 mg/kg SID PO) or metoclopramide (0.2–0.5 mg/kg q 8 h) or constant rate infusion at 1–2 mg/cat/24 h.

Prognosis

Long-term follow-up on a large number of cats with cholangitis has not been performed.

The prognosis with neutrophilic cholangitis is less favorable than for cats with lymphocytic cholangitis.

Cats with the neutrophilic form that survive the initial treatment period of several months have a reasonable chance for long-term survival.

Cats with lymphocytic cholangitis may survive comfortably for months to years with appropriate therapy.

Prevention

Medical/surgical correction of biliary obstructive lesions when recognized.

Treatment of inflammatory (lymphocytic-plasmacytic) lesions involving the intestinal mucosa (i.e., inflammatory bowel disease).

FELINE INFECTIOUS PERITONITIS (FIP)*

Classical signs

- 50% of cats are < 2 years of age.
- Weight loss, anorexia, vomiting and lethargy.
- Jaundice +/- cyclical fever.
- Protein-rich ascites in “effusive” form.

See main reference, page 372 (The Pyrexia Cat).

Clinical signs

Young cats (< 2 years old) and from a multicat environment are most susceptible.

Signs are referable to chronic inflammation of the kidneys, liver, visceral lymph nodes, intestines, lungs, eyes and brain.

Chronic, progressive inappetence, weight loss, fever and depression.

Signs may be cyclical at first.

Jaundice and ascites may occur in cats with chronic liver involvement.

Dyspnea from pleural effusion occurs in about one in five cats.

CNS signs include seizures, personality changes, nystagmus, head tremor and hyperesthesia.

Vomiting may occur with granuloma formation in the intestines, or inflammation in other organs such as the liver.

Ocular signs include bilateral uveitis, perivascular exudates, retinal hemorrhage or detachment.

Diagnosis

Diagnosis is based on history, clinical signs and characteristic histologic lesions on tissue biopsy.

- Parenchymal lesions are characterized by multifocal hepatic necrosis with pyogranulomatous inflammation.
- Pyogranulomas may be grossly evident on the capsule of the liver.

Increased activities of ALT and ALP are common. Total bilirubin values may be increased above 2–3 mg/dl (jaundice).

Diagnostic sampling of effusions is useful as they are generally high protein but low to moderate cellularity (modified transudate) with non-lytic neutrophils.

Serologic testing for FIP antibodies may give confounding results. Coronaviral antibodies are widespread in the general cat population and the new 7B FIP antibody test appears to have problems with false negatives and false positives in the field.

- Reverse transcriptase-PCR detection of coronaviral antigens in effusion fluid or tissues presently lacks high diagnostic accuracy. False positives occur because enteric coronavirus may be present systemically, and false-negative results also occur.
- Immunocytochemistry demonstrating coronavirus antigen within circulating monocytes or tissue macrophages appears to be specific, but low numbers of infected cells in tissue samples limit the sensitivity for use in biopsy samples. The technique is only available at some laboratories.

Differential diagnosis

Abdominocentesis in FIP-infected cats may yield a protein-rich exudate which is dissimilar from other inflammatory/degenerative hepatopathies except lymphocytic cholangiohepatitis. Histopathology of the liver is diagnostic. Also, differentiate FIP from cardiomyopathy and neoplasia which may cause chronic illness similar to FIP or cavity effusion.

Cats with FIP will often have involvement of multiple organ systems (eyes, lungs, CNS).

Treatment

There is no definitive therapy for FIP and the disease is almost uniformly fatal in cats with signs.

- Supportive care is palliative at best.
 - Immunosuppressive doses of steroids (2–4 mg/kg PO q 24 h) +/- other cytotoxic drugs (e.g., cyclophosphamide 2.2 mg/kg/day on four consecutive days each week or chlorambucil 20 mg/m² every 2–3 weeks) are recommended for vasculitis.
 - Administer broad-spectrum antimicrobials for secondary bacterial infections.

- Give human interferon- β 30 IU/day for 7 days at alternate weeks to boost immunity.
- Nutritional support via force feedings, esophagostomy or gastrostomy tube, or naso-esophageal catheter.
- Because of the extremely poor prognosis, euthanasia is recommended if there is no response to palliative therapy.

LYMPHOSARCOMA*

Classical signs

- Most cats > 10 years of age.
- Lethargy, anorexia, weight loss.
- Jaundice may be present.
- Hepatomegaly +/- effusion (ascites or hemoperitoneum).

Pathogenesis

Generally presents as a manifestation of multicentric lymphosarcoma. Lesions may occur in conjunction with neoplastic infiltrates involving other lymphoid organs, such as peripheral lymph nodes, or the alimentary mucosa.

Neoplastic lymphocytes gradually replace normal hepatocytes causing organ enlargement and hepatic failure.

- Cholestasis and jaundice result from involvement of intrahepatic biliary structures.

Clinical signs

Mostly seen in middle-aged and older cats.

Lethargy, anorexia, and weight loss predominate.

Hepatomegaly +/- jaundice are common.

Diagnosis

Suspicion of hepatic neoplasia is raised by older age, history of chronic illness and suggestive clinical signs.

Increased serum ALT and ALP activities are common. In general, relatively greater increases in ALT versus ALP are observed.

Radiographic imaging may aid diagnosis.

- Symmetrical hepatomegaly is often observed on survey radiographs.
- Hepatic sonography shows generalized hyperechogenicity or multifocal hypoechogenicity to the liver parenchyma.

Definitive diagnosis requires cytologic or histologic evaluation of liver specimens.

Differential diagnosis

Rule out benign conditions, such as hepatic cysts, hepatocellular/bile duct adenomas, and regenerative nodules which may mimic hepatic lymphosarcoma. These other diseases may be definitively ruled out by performance of liver biopsy with histologic interpretation.

Treatment

Combination chemotherapy using cyclophosphamide (300 mg/m² PO q 3 weeks), vincristine (0.75 mg/m² IV weekly for 4 weeks), and prednisone (2 mg/kg/day) is recommended. See page 676 for treatment details.

Provide supportive therapy (including provision of enteral feeding if needed) as needed.

Prognosis

The prognosis is guarded. Approximately 50% of cats with hepatic lymphosarcoma will respond to multi-drug chemotherapy.

Concurrent FeLV infection shortens survival times but does not influence response to chemotherapy.

TOXOPLASMOSIS*

Classical signs

- Anorexia, lethargy, neurologic signs and dyspnea.
- Cyclical fever.
- +/- icterus, vomiting and diarrhea.
- Anterior or posterior uveitis.

See main reference, page 375 (The Pyrexia Cat).

Clinical signs

Infection with the obligate intracellular coccidia causes inflammation and cell necrosis in affected tissues. Lung, brain, gut, liver and eye are most affected.

Diverse but are generally referable to respiratory, neuromuscular or gastrointestinal systems.

Anorexia, cyclical fever, dyspnea and lethargy are common.

Uveitis may involve one or both eyes.

Cystic involvement of the CNS may cause pronounced neurologic deficits (with the type of observed CNS deficit dependent upon involvement of the brain, brain stem and/or spinal cord), or may be rapidly fatal with advanced disease.

Cysts located within skeletal muscles are painful, and often cause hyperesthesia on muscle palpation, stiffness of gait and shifting leg lameness.

Hepatic involvement may follow dissemination causing jaundice due to hepatitis or cholangiohepatitis. Cystic involvement of the intestinal mucosa may cause lymphocytic-plasmacytic enteritis.

Diagnosis

Non-regenerative anemia and leukopenia.

Marked increases in serum ALT and AST activities occur with hepatic infection.

Hyperproteinemia occurs in some cats with chronic toxoplasmosis.

Thoracic radiographs may demonstrate diffuse interstitial to alveolar opacities.

Serologic testing provides useful diagnostic information.

- IgM and IgG titers are assessed by ELISA techniques.
 - A high (> 256) IgM titer is suggestive of active infection.
 - A 4 × rise in IgG titer over 2–3 weeks is suggestive of active infection.

Demonstration of the organism (cysts) in affected biopsy/necropsy tissues is helpful in making a diagnosis.

Differential diagnosis

Toxoplasmosis should be differentiated from other feline systemic infections including feline leukemia and immunodeficiency viral infections and feline infectious peritonitis.

Treatment

Available drugs suppress replication of *T. gondii* but do not completely kill the parasite.

- Use clindamycin (12.5 mg/kg PO q 12 h) for 3 weeks.
- Cats with ocular inflammation should be judiciously treated with topical glucocorticoids (topical 0.5 % prednisolone acetate drops q 6–12 h).

ACETAMINOPHEN (PARACETAMOL) INTOXICATION

Classical signs

- Often history of recent drug exposure.
- Acute onset of cyanosis, dyspnea and facial edema.
- +/- jaundice occurs several days post-ingestion.

Pathogenesis

Cats have impaired ability to readily metabolize acetaminophen. Ingestion of 50–60 mg/kg may be fatal for cats. This is equivalent to one child tablet or half an adult tablet.

Large doses of acetaminophen produce toxic intermediates which cause oxidative damage in cells, especially erythrocytes and hepatocytes.

- Oxidative damage to hemoglobin leads to methemoglobinemia and reduced oxygen-carrying capacity.
- Tissue hypoxia and vascular injury occur.

Hepatic injury is characterized by hepatocellular necrosis.

Clinical signs

Pale mucous membranes or acute cyanosis with blue-tinged mucous membranes, dyspnea, facial edema, salivation and depression are typical signs of poisoning.

Increasing depression, weakness and panting occur. Increasing harsh lung sounds are secondary to worsening pulmonary edema.

Vomiting and generalized weakness are less common.

Jaundice may occur 3–6 days post-ingestion.

Hemoglobinuria occurs in some cats or a dark brown urine containing increased amounts of hemoglobin, bilirubin and protein may be seen.

Death occurs within 18–36 hours of ingestion of a toxic dose.

Diagnosis

Diagnosis is based on a history of recent drug exposure and the presence of “unique” clinical signs.

Anemia is typically non-regenerative within 4–6 days of intoxication.

- Heinz-bodies may be visualized with new methylene blue stain.
- Increased numbers of nucleated red cells reflecting hypoxemia may be evident.

Neutrophilic leukocytosis reflects stress.

Unexplained and rapid increase in liver biochemical parameters are observed.

- ALT, AST, ALP and total bilirubin concentrations may be elevated.

Histologic examination of hepatic biopsy specimens reveals hepatocellular necrosis, lipid accumulation and/or biliary duct proliferation.

Differential diagnosis

The features of acetaminophen toxicosis (drug exposure classic signs, clinico-pathologic findings and acute hepatic injury) make most other diseases unlikely.

Treatment

Attempt to minimize drug absorption in acute (< 4 hours) intoxications.

- Perform orogastric lavages (several cycles each at 5–10 ml/kg of tepid water) to mechanically remove gastric contents.
- Give activated charcoal (2 g/kg body weight) to bind residual luminal toxicants via orogastric tube.

Fluid therapy may be required to correct dehydration, acid–base imbalances and electrolyte abnormalities occurring from vomiting.

Specific antidotal therapy.

- N-acetylcysteine (Mucomyst, Mead Johnson & Co.) helps to neutralize toxic intermediates.
 - Administer a loading dose of 140 mg/kg orally, followed by doses of 70 mg/kg every 4–6 hours for upto 3 days.
- Ascorbic acid is used in combination with N-acetylcysteine.
 - Its use is controversial. It works slowly and is used as adjunctive therapy.
 - Give 30 mg/kg q 6 h PO for seven or more treatments.
- Cimetidine inhibits hepatic production of toxic intermediates.
 - Give 5 mg/kg q 8 h PO or parenterally for 3 days minimum.

Blood transfusions and oxygen therapy should be given as needed.

Prognosis

The prognosis is guarded and is highly dependent on severity of intoxication and time lapse prior to treatment.

Prevention

Avoid drug overdosage.

Store medication safely away from pets.

DIAZEPAM INTOXICATION

Classical signs

- Lethargy, ataxia and anorexia < 3–4 days post-ingestion.
- Jaundice commonly observed.

Pathogenesis

Idiosyncratic hepatotoxicity is suspected. The dosage causing toxicity may range from 1 mg once daily to 2.5 mg twice daily.

Prior sensitization to diazepam is **not** required.

Clinical signs

Most cats become lethargic, ataxic and anorectic within 96 hours following ingestion.

Jaundice is common and occurs during the first 11 days of illness.

Diagnosis

History of recent drug exposure.

Unexplained and rapid increase in liver biochemical parameters.

- Profound increases in ALT, AST and total bilirubin are present.
- Hypoglycemia/hypocholesterolemia indicates severe hepatic insufficiency.
- Abnormal coagulation tests (OSPT, APTT) suggest disseminated intravascular coagulation.

Death occurs from acute hepatic failure.

- Histologic review of tissue specimens reveals profound hepatocellular necrosis.

Differential diagnosis

A history of diazepam administration associated with fulminate hepatic failure make most other diseases unlikely.

Treatment

Supportive care as dictated by the patient.

Fluid therapy for hydration maintenance.

- Add dextrose to combat hypoglycemia.

Meet nutritional needs to facilitated hepatic regeneration.

- Total parenteral nutrition or nasoesophageal catheter feeding.

Plasma transfusions to replace consumed coagulation factors.

Prognosis

Poor: cats presented in an obtunded condition warrant a grave prognosis.

Prevention

Evaluate baseline ALT and AST activities in cats prior to initiating daily oral treatment with diazepam.

- Retest again 1 week after initiating therapy.
- Discontinue diazepam therapy in cats with unexplained increases in liver enzyme activities.

Peractin is a more effective appetite stimulant, and has not been reported to have serious idiosyncratic reactions.

CIRRHOSIS

Classical signs

- Anorexia, weight loss, lethargy and jaundice.
- Hepatomegaly or a normal-sized liver may be palpated.

Pathogenesis

Cirrhosis is a relatively uncommon disease in the cat but may occur as a progression of specific feline hepatopathies (e.g. cholangiohepatitis, chronic biliary obstruction), systemic disorders (e.g., pancreatitis, inflammatory bowel disease, chronic renal disease), and possibly vascular and immune-mediated diseases.

Cirrhosis would appear to occur most frequently with diseases affecting the portal areas, specifically the bile ducts.

Cirrhosis is characterized by both fibrosis and the conversion of normal hepatic architecture into structurally abnormal (regenerative) nodules.

Clinical signs

Anorexia, weight loss and lethargy predominate.

Hepatomegaly and intermittent diarrhea may also be observed.

Ascites is uncommon.

Jaundice is often present.

Diagnosis

Cats usually have a previous diagnosis of chronic hepatopathy, such as cholangitis (cholangitis/cholangiohepatitis).

Liver enzyme activities are variably increased depending upon the relative magnitude of cholestasis or hepatocellular inflammation.

Ultrasound may reveal diffuse parenchymal nodules and an irregular liver margin.

Histologic evaluation of liver biopsy specimens is required for definitive diagnosis.

- Microscopic lesions show both fibrosis and abnormal regenerative nodules.
- Tissues may be obtained by ultrasound-guided biopsy, laparoscopy or via laparotomy.
- Cirrhosis may be difficult to confirm by needle biopsy unless multiple sites are sampled. In practice, a small laparotomy incision and wedge biopsy of the liver gives a better diagnostic sample and is quick and simple. In cats with chronic hepatitis/cirrhosis, less than 40% of paired needle biopsy results may be in accordance with the wedge biopsy diagnosis.
- Patients with cirrhosis may have occult bleeding tendencies. Screen for the presence of coagulopathy prior to liver biopsy by performing evaluation of a PIVKA assay or APTT/OSPT.

Differential diagnosis

Cirrhosis is the end result of many **different chronic** liver disorders. Therefore, differentiation of the primary parenchymal disease leading to cirrhosis is generally not clinically relevant.

Treatment

Strategies for therapeutic support in cats with cirrhosis are first prioritized as to severity, and approached in a logical step-wise fashion. The presence of jaundice or ascites does not indicate a hopeless situation for medical treatment.

Feed adequate calories (1.25–1.50 MER) to prevent further malnourishment. Use of enteral nutrition is strongly recommended in anorectic cats. Reduce dietary protein intake in cats with overt signs of hepatic encephalopathy (HE).

Supplement water-soluble vitamins as needed at twice the normal dose. Use vitamin K in cats with biliary occlusion and elevated PIVKA or APTT/OSPT assays.

Control signs of HE with antimicrobials, reduced protein diets and mucosal protectants (e.g., sucralfate). Vitamin K therapy may reduce GI bleeding which also contributes to HE.

Correct hydration deficits with intravenous fluids. Fluid choices are based on the presence of ascites and electrolyte status.

Use low-salt diets, cage rest and diuretics for control of ascites.

Antibiotics are indicated in patients with suppurative inflammation, fever and/or leukocytosis.

Use anti-inflammatory (e.g., prednisone, azathioprine) drugs to reduce mononuclear cellular infiltrates.

Anti-fibrotic agents, such as colchicine, D-penicillamine, may reduce hepatic fibrosis.

Actigal may cause choleresis and promote a more beneficial bile acid milieu.

Reduce free radical damage to hepatocytes by administration of S-adenosyl.

Prognosis

The prognosis in most animals with cirrhosis is poor.

DIABETES MELLITUS

Classical signs

- Polyuria and polydipsia.
- Increased appetite.
- Weight loss with palpable hepatomegaly.

Clinical signs

Polyuria/polydipsia (PU/PD) are common.

Increased to ravenous appetite, although terminally it may be decreased.

Weight loss with or without hepatomegaly.

Jaundice is an uncommon complication of diabetes. It is more commonly associated with sulfonylurea (e.g., glipizide) therapy. Approximately 20% of cats on sulfonylurea therapy develop increased liver enzymes and a small percentage become jaundiced.

Diagnosis

Suggested by salient clinical signs (PU/PD, alterations in appetite, weight loss).

Persistent hyperglycemia observed on 2–3 occasions at least 3 hours apart over 24 hours.

Urinalysis shows glucosuria, +/- ketonuria, +/- proteinuria and +/- bacteriuria.

Liver biochemical parameters (ALT, ALP) are mildly to moderately increased.

NON-HEMATOPOIETIC LIVER TUMORS (BILIARY CYST ADENOMA, HEPATOCELLULAR CARCINOMA)

Classical signs

- Most cats are > 10 years old.
- More common in DSH.
- Hepatomegaly +/- mass lesion is often palpable.

Pathogenesis

Most (60%) of cats have benign tumors.

Bile duct tumors may progress from benign to malignant lesions.

- Benign lesions are usually focal and cystic; malignant tumors often involve multiple lobes.

Hepatomegaly is associated with extensive infiltrative disease.

Metastasis is common with bile duct carcinomas.

Clinical signs

Generally seen in geriatric cats (> 10 years old).

More common in DSH than in Siamese.

Anorexia, lethargy and weakness are seen.

Hepatomegaly +/- mass lesion is often palpable.

Diagnosis

Variable elevation in hepatic biochemical parameters. In general, relative increases in ALP versus ALT activity are observed. However, dramatic increases in either liver enzyme may not be present even with moderately sized tumors.

Abdominal imaging (survey radiographs, sonography) confirms hepatomegaly or mass.

- Ultrasonography is useful in detecting involvement of multiple hepatic lobes and in obtaining a guided core biopsy of lesions.

Definitive diagnosis requires histologic evaluation of liver biopsy specimens.

Differential diagnosis

It is important to distinguish benign from malignant hepatic tumors, as treatment and prognosis are widely divergent. Differentiation may only be made by histologic interpretation of hepatic biopsy specimens.

Treatment

Surgical resection (lobectomy) of benign hepatocellular or biliary tumors is recommended.

Chemotherapy is not useful for treatment of malignant neoplasia.

Prognosis

The prognosis for cats with benign tumors after resection is good. Most cats are disease free at least 1 year later.

The prognosis for malignant neoplasia is poor.

HYPERTHYROIDISM

Classical signs

- Rarely seen in cats < 8 years of age.
- Weight loss, polyphagia and unthrifty appearance predominate.
- Polyuria/polydipsia +/- vomiting/diarrhea may be seen.

See main reference, page 304 (The Cat With Weight Loss and a Good Appetite).

Clinical signs

Clinical signs result from overproduction/secretion of thyroid hormones. Malignant thyroid tumors are rare.

More than 70% of hyperthyroid cats have bilateral thyroid adenomas or adenomatous hyperplasia.

Weight loss, polyphagia and unkempt haircoat are common.

Vomiting and small bowel diarrhea may be observed.

A reduced appetite is seen in about one in ten cats with hyperthyroidism.

Panting and respiratory distress are observed with concomitant cardiac disease.

Seen primarily in middle-aged and older cats.

Physical examination is suggestive.

- Palpable thyroid gland enlargement is evident in 90% of cats if the examiner is experienced.
- Patchy alopecia/unkempt haircoat, overgrown toe nails are often present.
- Reduced muscle mass; most cats are thin.

Cardiac auscultation may reveal cardiac disturbances.

- Tachycardia (>240 bpm), murmurs and/or a gallop rhythm suggest cardiac manifestations of thyrotoxicosis.

Diagnosis

Increased liver enzyme (ALT, ALP) activities are seen in > 75% of hyperthyroid cats.

Closely assess renal parameters (BUN, creatinine, urinalysis) as concomitant renal disease may be present.

Demonstration of elevated basal serum thyroxine (T_4) concentration provides definitive diagnosis.

- Suspicious cats with a “borderline” T_4 value should be retested.
- Increased free T_4 may be observed in some cats with high normal total T_4 concentrations.
- Alternatively, performance of a T_3 suppression test may discriminate between normal and mildly hyperthyroid cats.

Perform thoracic radiography, electrocardiography (ECG), +/- echocardiography to rule out cardiac disease.

FELINE LEUKEMIA VIRUS

See page 424 under pre-hepatic causes for jaundice and page 432 for hepatic causes for jaundice (e.g. lymphosarcoma).

HISTOPLASMOSIS

Classical signs

- Young, outdoor cats (< 4 years old).
- Lethargy, anorexia and weight loss.
- Pale mucous membranes.
- Mild to moderate respiratory signs (fever, dyspnea, tachypnea).
- Occurs in central United States.

Pathogenesis

The etiologic agent is a soil-borne dimorphic fungus, *Histoplasma capsulatum*. The organism is likely inhaled and disseminates from the respiratory tract to multiple other sites in the body (e.g. liver).

Granulomatous inflammation occurs in response to fungal infection.

The disease is of regional significance in the central United States, especially the Mississippi and Ohio River Valleys and Texas.

Clinical signs

Primarily disease of young (< 4 years of age) outdoor cats.

Cats present with a vague history of an insidious chronic illness.

Lethargy, anorexia, weight loss and pale mucous membrane color are common.

Respiratory distress (dyspnea/tachypnea) is seen in 50% of infected cats and occasionally coughing.

Lymphadenopathy, splenomegaly and hepatomegaly are common.

Mild to moderate fever is usually present, but the temperature may be normal.

Intestinal involvement may result in diarrhea and weight loss. On palpation thickened intestinal loops, mesenteric lymphadenopathy and/or hepato/splenomegaly may be evident.

Ocular involvement may cause granulomatous chorioretinitis, retinal detachment with blindness and optic neuritis.

Diagnosis

Non-regenerative anemia is typically present and neutrophilic leukocytosis. Severe pancytopenia is occasionally observed when there is bone marrow involvement.

Hyperproteinemia, hyperglobulinemia, +/- mild elevations of ALT may be observed.

Radiographic imaging may aid diagnosis.

- Survey thoracic radiographs show a diffuse pulmonary interstitial pattern suggesting fungal pneumonia.
- Symmetrical hepatomegaly is observed on survey abdominal radiographs/ultrasonography.

Definitive diagnosis requires demonstration of organisms in infected tissues.

- Potential diagnostic modalities include bronchoalveolar lavage, fine-needle aspiration and exfoliative cytology, and tissue biopsy.

Serologic tests for antibodies directed against *Histoplasma* antigens are not recommended, as false-negative results are common in cats with naturally occurring disease.

Differential diagnosis

Neoplasia and other systemic mycoses may produce similar signs to histoplasmosis.

- Cats with histoplasmosis (and other mycoses) tend to be younger than cats with neoplasia.
- Serologic testing may be useful in detecting cats with cryptococcosis.

Treatment

Combination chemotherapy with amphotericin B and itraconazole (5 mg/kg PO q 12 h), or high loading doses (10 mg/kg PO q 12–24 h) of itraconazole.

Generally treat for 4–6 months but dependent on remission of signs.

See page 26 for details of amphotericin treatment in cats (Cryptococcus in The Cat With Signs of Chronic Nasal Disease).

Prognosis

Fair to good with disseminated disease depending on the severity of fungal involvement and the chronicity.

Emaciated cats with advanced disseminated disease have a poor prognosis and they may not live long enough for the treatment to take effect.

POST-HEPATIC CAUSES OF JAUNDICE OR INCREASED LIVER ENZYMES

EXTRAHEPATIC BILIARY OBSTRUCTION (EHBO)** PANCREATITIS**

Classical signs

- Progressive anorexia, lethargy and marked jaundice.
- Vomiting and fever may be episodic.
- Hepatomegaly.
- +/- acholic feces.

Pathogenesis

Obstruction of the extrahepatic biliary system has diverse causes, including pancreatic disease, neoplasia, cholelithiasis and extrinsic compression (masses). Consequences of biliary obstruction include cell membrane and organelle injury due to stagnation of bile acids and other injurious substances. Pancreatitis and neoplasia are the most common causes.

- Pancreatitis may cause obstructive jaundice through direct cholangiohepatic injury via refluxed pancreatic secretions, pancreatic fibrosis and/or obstruction of the common bile duct within a few weeks following pancreatic injury.
- Neoplasia (e.g., pancreatic adenocarcinoma) may cause slowly progressive external compression of the major bile ducts, resulting in obstructed biliary flow and jaundice.

Complete occlusion leads to cholestasis, hepatomegaly and dilatation of intrahepatic biliary structures.

Obstruction of bile flow incites biliary tract/hepatocellular inflammation and injury.

- Permanent biliary tract dilatation and hepatic fibrosis may be seen with chronic extrahepatic biliary obstruction.

Clinical signs

Anorexia, lethargy and marked jaundice which are progressive.

Cyclical vomiting and fever.

Hepatomegaly may be palpable.

Acholic feces are occasionally seen with complete obstruction.

Acute pancreatitis may cause anorexia, lethargy, abdominal pain and jaundice as a consequence of extrahepatic biliary obstruction.

Pancreatic abscesses, cysts and neoplasia may cause signs of extrahepatic biliary obstruction.

Diagnosis

Non-regenerative anemia and possibly a neutrophilic leukocytosis are seen.

Increased liver biochemical parameters are commonly observed.

- Dramatic elevations in serum total bilirubin concentration. Elevations may occur as rapidly as 4 hours following complete biliary obstruction.
- Increased ALP and GGT activities occur secondary to cholestasis. A 3–5-fold increase in GGT and 2–10-fold rise in ALP are often present.
- Increased ALT (up to 10-fold) and 3–10-fold increased AST activities reflect hepatocellular injury.

An antemortem diagnosis of pancreatitis causing obstructive jaundice is elusive.

- Variable leukocytosis with elevation of liver biochemical parameters (total bilirubin, ALP, ALT) are present.
- Recent studies show that elevation in feline pancreatic-like immunoreactivity assay (fPLI) may provide presumptive serologic evidence of pancreatitis. Serum fPLI appears to be more sensitive and more specific than serum feline trypsin-like immunoreactivity assay (fTLI) or abdominal ultrasonography.
- Ultrasonography demonstrates a generalized loss of pancreatic echogenicity with pancreatitis in most cases.

Ultrasonography may confirm the presence of a pancreatic mass and/or extrahepatic biliary obstruction causing extrahepatic biliary obstruction.

- Diagnosis of extrahepatic biliary obstruction is confirmed on ultrasonographic evaluation or exploratory surgery.

- Sonography shows a distended/tortuous common bile duct, large gall bladder and distended intrahepatic biliary ducts. These findings may be observed as early as 5–7 days post-obstruction when viewed by an experienced sonographer.

Differential diagnosis

The historical, clinical and laboratory features of extrahepatic biliary obstruction may be indistinguishable from other severe cholestatic hepatopathies.

Abdominal ultrasonography is the quickest and least invasive means to confirm extrahepatic biliary obstruction.

Treatment

First stabilize the patient with fluid and electrolyte therapy.

Perform a laparotomy for inspection/correction of the biliary tract obstructive lesion.

- Prompt correction of complete obstruction via performance of cholecystoduodenostomy or cholecystojejunostomy is recommended.
- Broad-spectrum antibiotics are indicated if biliary-enteric anastomosis is performed.

Extrahepatic biliary obstruction caused by pancreatitis may be amenable to medical therapy (dietary modification, IV fluids, antiemetics, etc.).

- Biliary decompression is recommended in pancreatitis patients with rising hyperebilirubinemia or sonographic evidence of worsening gall bladder distention.

Specific therapy for hepatocellular inflammation (confirmed by biopsy) and intrahepatic cholestasis may be required.

- Use ursodeoxycholic acid (10 mg/kg PO q 12 h) for 5–7 days post-operatively to reduce cholestatic injury.

Prognosis

Guarded to good depending upon the underlying cause.

Biochemical abnormalities associated with extrahepatic biliary obstruction subside quickly following successful surgery.

CHOLECYSTITIS

Classical signs

- Abdominal pain, fever, vomiting.
- +/- jaundice.
- Palpable right cranial abdominal mass.

Clinical signs

Abdominal pain, fever, vomiting and jaundice.

A mass lesion may be palpable in the cranial abdomen.

Animals may present in endotoxic shock with gall bladder rupture.

Pathogenesis

Inflammation of the gall bladder is uncommon.

Inflammation may occur from occlusion of the cystic duct, with resultant gall bladder inflammation resulting from bile stasis. Occlusion may occur due to extraluminal compression (e.g., mass, adhesion) or intraluminal obstruction as seen with cholelithiasis.

Emphysematous cholecystitis is most commonly observed in association with diabetes mellitus, acute cholecystitis with/without cholelithiasis, and traumatic ischemia of the gall bladder.

E. coli bacteria are most commonly cultured from the biliary tree of affected cats.

Diagnosis

Most animals have a variable leukocytosis.

Hepatic biochemical parameters (total bilirubin, ALT and ALP) are modestly increased.

Ultrasonography or laparotomy is usually necessary for a diagnosis.

- Gas accumulation within the biliary tree/gall bladder indicates cholecystitis.
- Choleliths may be an uncommonly recognized incidental finding.
- Cranial abdominal fluid accumulation indicates biliary rupture and peritoneal inflammation. Analysis of peritoneal effusion reveals the presence of inflammatory cells (e.g., neutrophils, macrophages) and bilirubin crystals in a turbid golden-brown or green fluid.

Laparotomy allows for cholecystectomy and treatment of peritonitis.

Treatment

Surgically remove calculi causing clinical signs of hepatobiliary disease.

Assess patency of biliary tree during surgery. If the gallbladder appears inflamed, consider cholecystectomy.

- Administer vitamin K 12–24 hours prior to surgical intervention.
- Perform concurrent liver biopsy to assess the extent of hepatic inflammation.

Culture bile fluid for the presence of aerobic/anaerobic bacterial pathogens.

- Use broad-spectrum antibiotic therapy effective against enteric pathogens. Good first-choice drugs which reach therapeutic biliary concentrations include cephalosporins, penicillins, doxycycline, metronidazole, clindamycin and the quinolones. Base antimicrobial therapy on the results obtained from biliary culture and susceptibility testing.

Fluid therapy is administered to hypovolemic cats or those requiring correction of electrolyte derangements.

Prognosis

The prognosis in most cases is guarded. Those cats which are not extremely debilitated or that have necrotizing cholecystitis have a more favorable prognosis.

RUPTURED BILE DUCT

Classical signs

- Malaise, weight loss.
- Low-grade abdominal pain.
- Abdominal effusion +/- jaundice.

Clinical signs

There is often a history of trauma.

General malaise, weight loss and abdominal pain predominate.

Abdominal effusion +/- jaundice may be present. Intervals ranging from 3 days to 3 weeks before the presentation may be observed.

Pathogenesis

Rupture of the extrahepatic biliary tree may occur with blunt or penetrating abdominal trauma, necrotizing cholecystitis and cholelithiasis (rare). Leakage of significant volumes of bile into the peritoneal cavity induces tissue inflammation. Unconjugated bile acids are most irritating, as they alter the permeability of vascular structures within the peritoneal membranes.

Altered membrane permeability promotes transmural bacterial migration into the peritoneal cavity, septic inflammation and septicemia.

Non-septic inflammation causes intra-abdominal fluid sequestration, contraction of circulating blood volume and dehydration which may induce hypovolemic shock.

Diagnosis

Suggestive history with other evidence of trauma.

Liver enzymes (ALP, ALT) are mildly to moderately increased. Moderate-to-severe hyperbilirubinemia is often present.

Cytologic examination of abdominal effusion confirms the diagnosis.

- The effusion is turbid and golden brown-to-green in appearance. Inflammatory cells (macrophages and neutrophils) and bilirubin crystals are generally seen.

Treatment

Immediate surgical correction of bile leakage.

- Perform cholecystectomy if concurrent necrotizing cholecystitis is present.
- Provide adequate post-operative drainage.

Correct fluid and electrolyte derangements intravenously using a balanced electrolyte solution with electrolyte supplements as needed. Colloids may be needed for correction of hypoalbuminemia if present.

Broad-spectrum antibiotic therapy, as per cholecystitis, if septicemia is present.

Prognosis

A guarded prognosis is warranted in most cats. Cats having pronounced effusion, chronic debilitation, or clinical evidence of sepsis at the time of diagnosis have a poor prognosis.

22. The cat with abdominal distention or abdominal fluid

Anthony Abrams-Ogg

KEY SIGNS

- Abdominal distention or pendulous abdomen.
- Fluid wave on ballotment.
- Abdominal mass.

MECHANISM?

- In the “8F” classification scheme the causes of abdominal distention are **fluid, fat, food, feces, flatus, fetus, formidable** organomegaly and **feeble** abdominal musculature.

WHERE?

- Abdomen. The primary disease process may be intra-abdominal, extra-abdominal or systemic.

WHAT?

- The most common causes of moderate to marked abdominal distention in cats are physiologic – pregnancy and obesity. The most common pathologic cause is abdominal fluid.

QUICK REFERENCE SUMMARY

Diseases causing abdominal distention or abdominal fluid

ANOMALY

- Intrahepatic arteriovenous fistula (p 474)

The pressure differential between the artery and portal vein leads to ascites (transudate) secondary to portal hypertension.

- Portal vein atresia or hypoplasia (p 475)

Congenital underdevelopment of the portal vein leads to ascites (transudate) secondary to portal hypertension.

- Inherited coagulation defects (p 473)

Inherited coagulation factor deficiencies or deficiencies in vitamin K metabolism may cause spontaneous abdominal bleeding and re-bleeding after trauma.

continued

continued

- **Umbilical or inguinal hernia* (p 478)**

Owners may misinterpret a change in abdominal contour due to herniation of abdominal fat or organs as abdominal distention.

METABOLIC

- **Obesity*** (p 452)**

A round abdominal contour results from excessive intra-abdominal and abdominal subcutaneous fat.

- **Pregnancy*** (p 455)**

Abdominal distention is usually apparent by the last 2 weeks of gestation.

- **Hepatic lipidosis* (p 472)**

Ascites (usually transudate or modified transudate) occasionally occurs with hepatic lipidosis. Abdominal bleeding may occur secondary to coagulopathy.

- **Juvenile abdominal fluid** (p 465)**

A mild increase in normal peritoneal fluid compared to a mature animal may be encountered during laparotomy of an immature animal. Fluid is a transudate.

- **Hyperadrenocorticism* (p 470)**

A pendulous abdomen results from feeble abdominal musculature and increased abdominal fat.

NEOPLASTIC

- **Abdominal lymphoma*** (p 458)**

Alimentary lymphoma may cause abdominal distention due to marked intestinal thickening, mesenteric lymphadenopathy or obstructive effusion. Splenic or hepatic lymphoma may spontaneously bleed.

- **Visceral mast cell tumor** (p 461)**

Marked splenic enlargement with a mast cell tumor may cause abdominal distention. Abdominal mast cell tumors may spontaneously bleed or cause obstructive ascites. Abdominal fluid often contains mast cells.

- **Solid tumors*** (p 460)**

Hepatic or splenic hemangiosarcoma and other solid tumors may spontaneously bleed. A tumor may cause portal hypertension. Carcinomatosis may cause obstructive effusion.

- **Neoplasia obstructing or compressing lower urinary tract (p 474)**

Tumors obstructing or compressing the trigone region of the bladder or the urethra and causing paradoxical incontinence may cause abdominal distention secondary to marked enlargement of the bladder.

NUTRITIONAL

- **Overeating* (p 471)**

An unusually large meal may cause transient abdominal distention.

PHYSICAL

- **Aerophagia* (p 471)**

Dyspneic or tachypneic cats may swallow sufficient air to cause mild abdominal distention.

IDIOPATHIC

- **Megacolon** (p 465)**

Obstipation results in marked colonic enlargement that may cause abdominal distention.

- **Peliosis hepatis (p 476)**

Hepatomegaly and/or spontaneous abdominal hemorrhage may cause abdominal distention.

- **Hepatic amyloidosis (p 475)**

Hepatomegaly, splenomegaly, intestinal dilation and/or spontaneous intra-abdominal hemorrhage may cause abdominal distention.

- **Hepatic necrosis (p 475)**

Ascites or spontaneous abdominal hemorrhage may occur secondary to hepatic necrosis due to various causes.

- **Hepatic cirrhosis (p 472)**

Ascites may occur with hepatic cirrhosis. The fluid may be transudate, modified transudate or exudate.

- **Gastric-dilation volvulus (p 478)**

Gastric dilation with air results in tympanic abdominal distention.

- **Perirenal pseudocysts (p 476)**

Fluid-filled sacs surrounding the kidneys cause abdominal distention. Chronic renal failure is commonly present.

- **Right heart failure** (p 462)**

Ascites may occur in cats with right heart failure. The fluid is a modified transudate.

- **Extra-uterine fetuses (p 477)**

Ascites occasionally occurs with “ectopic pregnancy”.

- **Budd–Chiari-like syndrome (p 477)**

Obstruction of the cranial vena cava or venous vasculature of the liver causes ascites. Ascitic fluid is a modified transudate.

- **Idiopathic chylous ascites (p 479)**

Chylous ascites is usually due to neoplasia. Idiopathic chylous ascites is rare.

INFLAMMATION

- **Gastroenteritis* (p 468)**

Flatus formation and intestinal thickening in cats with diarrhea may cause mild abdominal distention.

- **Non-suppurative cholangiohepatitis* (p 472)**

Ascites occasionally occurs with cholangiohepatitis. The fluid may be a transudate, modified transudate or exudate.

- **Pancreatitis** (p 466)**

Cats with pancreatitis may have abdominal effusion, which is occasionally detectable on physical examination. Fluid may be a modified transudate or exudate.

- **Pneumoperitoneum (p 477)**

Acute pneumoperitoneum is usually due to gastric perforation or gastrointestinal rupture.

continued

continued

- **Steatitis (p 472)**

Inflammation of abdominal fat may cause peritoneal effusion with high protein content and mature neutrophils (exudate).

- **Granulomatous urethritis and urethral stricture (p 474)**

Chronic narrowing of the urethra leads to massive enlargement of the bladder and urine dribbling from paradoxical incontinence.

- **Glomerulonephritis (p 473)**

Glomerulonephritis may cause nephrotic syndrome and ascites, which is a transudate.

- **Sclerosing encapsulating peritonitis (p 479)**

The abdominal mesothelial lining becomes replaced by fibrous tissue. Ascites may occur.

INFECTIOUS:

Viral:

- **Feline infectious peritonitis (FIP)*** (p 456)**

Immune-complex vasculitis results in a marked peritoneal exudate. Fluid is typically straw-colored, viscous like egg white and highly proteinaceous (exudate) with mature neutrophils. Hepatic infection may also cause ascites due to portal hypertension.

Bacterial:

- **Septic peritonitis* (p 467)**

Bacterial infection results in a septic suppurative exudate.

- **Intestinal tuberculosis* (p 469)**

Effusion may occur secondary to mesenteric lymphadenopathy. The fluid may be a transudate, modified transudate, exudate or chylous effusion and may contain macrophages containing acid-fast bacteria.

- **Leptospirosis (p 478)**

Leptospirosis has been associated with liver disease and ascites in cats.

- **Hepatic abscess (p 476)**

Hepatic abscesses may be associated with septic and non-septic effusions.

Protozoal:

- **Toxoplasmosis* (p 469)**

Toxoplasmosis may cause peritoneal effusion secondary to liver and mesenteric lymph node infection. Fluid is a transudate or modified transudate and may contain tachyzoites.

Parasitic:

- **Abdominal fluke infection (p 479)**

Metorchis spp. are bile duct parasites that may cause hepatic cysts and ascites.

Iatrogenic:

- **Fluid overload* (p 471)**

Excessive fluid therapy tends to cause pulmonary edema leading to dyspnea or subcutaneous edema.

- Ligation of portosystemic shunt (p 475)

Ligation of a portosystemic shunt may lead to ascites secondary to portal hypertension.

Toxic:

- **Anticoagulant rodenticide poisoning (and other acquired coagulopathies)* (p 473)**

Acquired coagulopathy may cause abdominal hemorrhage.

Trauma:

- **Traumatic hemorrhage*(p 471)**

Abdominal hemorrhage may occur with blunt trauma (e.g. motor vehicle accident, falling from heights), penetrating trauma (e.g. abdominal bite wound), or post-operatively.

- **Traumatic rupture of the urinary bladder or urethra* (p 463)**

The urinary bladder may rupture from motor vehicle trauma, falling from heights, bladder expression, cystocentesis, penetrating trauma and as a complication of urethral obstruction. Abdominal fluid is urine \pm blood.

- Umbilical, inguinal and traumatic abdominal wall hernia (p 478)

Owners may misinterpret change in abdominal contour due to herniation of abdominal fat or organs as abdominal distention.

- Ruptured gall bladder or bile duct (p 478)

Motor vehicle trauma, falling from heights, gunshot wounds and cholelithiasis may cause rupture of the gall bladder or a major bile duct. Fluid is dark bile-stained and a modified transudate to exudate.

- **Traumatic abdominal wall hernia* (p 478)**

Owners may misinterpret a change in abdominal contour due to herniation of abdominal fat or organs as abdominal distention.

INTRODUCTION

MECHANISM?

Abdominal distention has several causes. These causes may be present alone or in combination. A mnemonic classifies the causes using an “8F scheme”: **fluid, fat, food, feces, flatus, fetus, formidable** organomegaly and **feeble** abdominal musculature.

Fluid accumulation in the peritoneal cavity is the most common cause of pathologic abdominal distention and of marked abdominal distention, but it is not as common in cats as in dogs.

- In broad definitions (used here), fluid in the peritoneal cavity is referred to as **peritoneal effusion** or **ascites**. In terms of clinical pathology, the type of fluid may be a **transudate**, **modified transudate**, **septic exudate**, **non-septic exudate**, **chyle**, **blood**,

bile or **urine**. In narrow definitions, peritoneal effusion and ascites refer to transudates and modified transudates. Characteristics of the various types of fluids vary somewhat with laboratories, but the following definitions are typical.

- **Transudate** – clear and colorless, specific gravity (SG) \leq 1.013–1.018, total protein <25 g/L (2.5 g/dl), low cellularity (total nucleated cell count $< 1.0\text{--}1.5 \times 10^9/\text{L}$ [1000–1500/ μL]).
- **Modified transudate** – clear to slightly cloudy, straw-colored to pink-white, SG $> 1.013\text{--}1.018$, total protein between 25 and 50 g/L (2.5–5.0 g/dl), and total nucleated cell count $< 5.0\text{--}7.0 \times 10^9/\text{L}$ ($< 5000\text{--}7000/\mu\text{L}$). Nucleated cells consist of mesothelial cells, non-degenerate neutrophils, macrophages and lymphocytes.
- **Exudate** – turbid to opaque white to yellow or red, SG > 1.018 , high protein (> 25 g/L [2.5 g/dl]), highly cellular (total nucleated cell count $> 5.0 \times 10^9/\text{L}$ [5000/ μL]).

- Cell types in a non-septic exudate are similar to a modified transudate, except for feline infectious peritonitis, where the predominant cells are non-degenerate neutrophils, and in some neoplastic effusions, where malignant cells predominate.
- Cells in a septic exudate are predominantly neutrophils. The fluid is further characterized by the presence of intracellular bacteria, degenerate changes in the neutrophils and a foul odor.
- **Degenerate and non-degenerate neutrophils are distinguished on the appearance of their nuclei.** Non-degenerate neutrophils appear similar to peripheral blood neutrophils and have tightly clumped, basophilic nuclear chromatin. As the neutrophils age, the nuclei become hypersegmented, and then pyknotic (tightly clumped sphere), and then eventually break up into several smaller tightly clumped spheres (karyorrhexis). This aging change should not be confused with degenerative change. Degenerate neutrophils have swollen pale eosinophilic nuclei resulting from increased membrane permeability to water. Toxic changes in the cytoplasm (basophilia, vacuolation and Dohle bodies) may also be present.
- In a recent report, a nucleated cell count $> 13 \times 10^9/L$ ($13\,000/\mu l$) was highly sensitive and specific for septic peritonitis, although cats with FIP were not included.
- Protein content characteristic of an exudate may be confirmed by Rivalta's test (see Feline infectious peritonitis).
- **Chyle** – opaque and white to pink (slightly cloudy and straw-colored in fasting animals), SG variable, protein 2.0–7.0 g/L (20–70 g/dl), and total nucleated cell count $< 10 \times 10^9/L$ ($10\,000/\mu l$) containing a large number of small lymphocytes (chyle is comprised of lymph and chylomicrons). The fluid in the tube separates into a cream-like layer when refrigerated. Chylous effusions are also characterized by fluid triglyceride level greater than serum triglyceride level, fluid cholesterol level lower than serum cholesterol level, and a fluid cholesterol:triglyceride ratio < 1 (with the values measured in mg/dl).
- **Blood** – cloudy and red (centrifugation results in a clear supernatant above red sediment), SG, protein and total nucleated cell count consistent with peripheral blood. Effusion may contain clots but

does not clot further after withdrawal. Platelets disappear within several hours, and erythrophagocytosis by macrophages begins within 1 day, and this can be used to help age the effusion.

- **Bile** – clear to cloudy and dark yellow with a green or orange tinge, SG > 1.018 , protein > 25 g/L (2.5 g/dl), total nucleated cells $> 5 \times 10^9/L$ ($5000/\mu l$) with cell composition similar to modified transudate, but may become a highly cellular septic exudate. Bilirubin may be confirmed using a urine dipstick or by seeing bilirubin crystals free in the fluid or in macrophages.
- **Urine** – clear to slightly cloudy and pale yellow, variable SG and protein content. It may be a transudate, but total nucleated cells are often $> 3 \times 10^9/L$ ($3000/\mu l$) with cell composition similar to modified transudate, and it may become a highly cellular septic exudate.
- While in theory a specific disease process causes a specific type of fluid, in reality the type of fluid may vary somewhat. In particular, the disorders that generally cause pure transudates are occasionally associated with modified transudates, and vice versa. This may be due to modification of fluid production by concurrent disorders as well as variable criteria for characterizing the fluids. The implication of this fact is that **a specific differential diagnosis should not be ruled out strictly on the grounds that the type of fluid is not the classic type for that disorder.**
 - Although protein content is one of the classic clinicopathologic values by which to categorize fluids, protein levels were recently reported to be similar in septic and non-septic peritoneal fluids.
- The peritoneal cavity is lined by a serous membrane (serosa) and normally contains a small amount of fluid that serves as a lubricant for the abdominal organs. **Normal peritoneal fluid** is a transudate (ultrafiltrate) that comes from interstitial fluid produced by local capillary beds, which diffuses across the serosa into the peritoneal cavity. The serosa is equally permeable to diffusion of the fluid back into the interstitium, but most is reabsorbed from the abdomen by uptake by lymphatics, especially of the diaphragm. The ultrafiltrate contains protein that is in equilibrium with plasma protein. The mechanisms that promote formation of subcutaneous edema will thus promote formation of peritoneal fluid. These mechanisms are:

- **Reduced plasma colloidal osmotic (oncotic) pressure** due to **hypoalbuminemia**. Hypoalbuminemia occurs by the same mechanisms as in dogs, i.e. reduced hepatic production, or renal, gastrointestinal or cutaneous loss. **Hypoalbuminemia** severe enough to cause spontaneous effusions or edema (typically $\leq 10\text{--}15$ g/L [$1\text{--}1.5$ g/dl]) is **rare in cats**. As albumin levels drop there is a progressive risk for exacerbation of ascites formed by other mechanisms, for example, increased hydrostatic pressure. When spontaneous fluid accumulation occurs, subcutaneous edema may develop preferentially to pleural and peritoneal effusions. Peritoneal fluid is a transudate.
- **Increased capillary hydrostatic pressure**. This may occur from **fluid overload**, decreased arteriolar resistance, and **increased venous pressure**. Cats with fluid overload usually develop pulmonary or subcutaneous edema preferentially to pleural and peritoneal effusions. Fluid overload causes a transudate.
- **Portal venous hypertension** is an increase in venous pressure unique to the abdomen. It is classified anatomically as pre-hepatic (which is also pre-sinusoidal), hepatic (pre-sinusoidal, sinusoidal, or post-sinusoidal), or post-hepatic (which is also post-sinusoidal) in origin. Anatomic location affects protein content of the ascitic fluid and is relevant to differential diagnoses. Pre-sinusoidal disorders usually cause a pure transudate. Sinusoidal and post-sinusoidal disorders increase hepatic sinusoidal pressure, which, in addition to portal hypertension, causes effusion of hepatic lymph from the hepatic lymphatics through the surface of the liver. Hepatic lymph is high in protein. The resulting fluid is a modified transudate, i.e. a transudate modified by increased levels of protein. The fluid may also have a mild increase in red blood cells, resulting in a serosanguineous fluid.
- **Pre-hepatic** portal hypertension results from **obstruction of the portal vein**, usually by a tumor. The fluid is a transudate, but may contain neoplastic cells. Other potential causes include **surgical ligation of a portosystemic shunt** or of the portal vein, portal vein atresia or hypoplasia (anecdotal reports in the cat), and portal vein thrombosis (not reported in the cat). The fluid is usually a transudate.
- **Pre-sinusoidal hepatic** portal hypertension may be caused by an **arterioportal fistula** and **surgical ligation of a portosystemic shunt**. The fluid is usually a transudate.
- **Sinusoidal hepatic** portal hypertension results from **liver disease**. The most common cause is cirrhosis, which is uncommon in cats. Severe hepatocyte swelling in hepatic lipidosis, and chronic cholangiohepatitis and hepatic neoplasia may also cause sinusoidal hypertension. Other mechanisms contribute to ascites in liver disease, including hypoalbuminemia, water and salt retention (see below) and non-septic peritonitis. The fluid may thus be a transudate, modified transudate or exudate. Although liver diseases are common in cats, ascites sufficient to cause abdominal distention is not.
- **Post-sinusoidal hepatic** portal hypertension is caused by veno-occlusive disease. The fluid is a modified transudate.
- **Post-hepatic (post-sinusoidal)** portal hypertension results from **obstruction of the hepatic veins or caudal vena cava** and **right heart failure**. Increase in vena caval pressure increases hepatic vein pressure, which increases sinusoidal and portal pressures. The fluid is a modified transudate.
- **Obstruction** of the venous outflow of the liver, from the hepatic venules to the right atrium, is referred to as **Budd–Chiari-like syndrome**. It is rare in cats.
- **Reduced lymphatic uptake**. This usually occurs with **tumors** obstructing a substantial portion of the serosal surface or mesenteric lymph nodes (\pm venous obstruction). The fluid is a transudate to modified transudate, but may contain neoplastic cells. Lymphatic obstruction occurs occasionally with inflammation, in which case the fluid is a modified transudate to exudate.
- **Increased permeability of the capillary endothelium and blood vessels**. This occurs secondary to inflammation.
 - In **feline infectious peritonitis** a type III hypersensitivity reaction leads to leukocytoclastic (neutrophil-mediated) vasculitis. The fluid is a non-septic exudate, containing increased levels

of inflammatory proteins and neutrophils from the vasculitis.

- In **septic peritonitis** the fluid is a septic exudate containing bacteria and increased levels of protein, neutrophils and bacteria.
- In **pancreatitis** the fluid is a modified transudate to non-septic exudate, depending on the increase in protein and cells.
- Ascites may be associated with a **decreased effective plasma volume**, which **promotes salt and water retention** by the renin-angiotensin-aldosterone system, antidiuretic hormone, and the sympathetic nervous system, thereby helping to maintain the ascitic state. (Water retention may result in hyponatremia. Hyperkalemia may also result from a decreased effective plasma volume and other mechanisms in cats with ascites. The combination of hyponatremia and hyperkalemia mimics hypoadrenocorticism.)

Chyle in the peritoneal cavity is an uncommon **non-specific finding** indicating that lymphatic rupture has occurred. Chylous effusion may occur with any of the basic mechanisms that promote peritoneal fluid production except for hypoalbuminemia. Most cases are caused by **neoplasia**, and fewer are caused by **inflammation, right heart failure and liver disease**. Other causes are rare in cats, including **primary abdominal lymphangiectasia and traumatic rupture of a major lymphatic vessel**.

Blood in the peritoneal cavity results from injury to blood vessels, spontaneous or traumatic rupture of abnormal blood-filled spaces, or a coagulopathy. Hemoperitoneum is not as common in cats as dogs, because abdominal trauma does not commonly cause severe abdominal hemorrhage in cats, and hemangiosarcoma is rare. Other causes of hemoperitoneum in the dog such as anticoagulant rodenticide poisoning, perforated gastrointestinal ulcers, and splenic torsions, are also uncommon in cats. Clinical signs due to acute anemia and local effects of hemorrhage vary with the severity of bleeding. Signs of acute hypovolemia, e.g. weakness, lethargy, hypothermia, pale mucus membranes, tachycardia and weak pulses, occur with a smaller volume of blood loss than do abdominal distention. In most cases of hemoperitoneum in cats, abdominal distention is not noted. In converse, cats with abdominal distention due to acute blood loss will have signs of hypovolemia.

Bile in the peritoneal cavity results from traumatic injury to the gall bladder or bile ducts. It is rare in cats. The presence of bile may be associated with septic or non-septic peritonitis, with increases in bacteria and/or protein and neutrophils accordingly.

Urine in the peritoneal cavity usually results from traumatic injury to the urinary bladder. It is uncommon in cats. Rarely direct effusion of urine may occur with severe cystitis. The presence of urine may be associated with septic or non-septic peritonitis, with increases in bacteria and/or protein and neutrophils accordingly. Rupture of the bladder may also cause abdominal hemorrhage.

Fat accumulates because of overeating and underactivity. Fat accumulates within the abdomen as well as within the abdominal subcutaneous tissue, especially of the caudal ventral abdomen.

Food may cause increased distention of the stomach and small intestine after a large meal. This is a physiologic cause of organomegaly.

Feces may cause increased distention of the large intestine after a large meal. This is a physiologic cause of organomegaly. More often, increased accumulation of feces in the large intestine is a sign of constipation. Severe constipation (obstipation, megacolon) may result in marked abdominal distention.

Flatus (gastrointestinal air) is not physiologically common in cats. Flatus may develop secondary to aerophagia in dyspneic cats and as a sign of primary intestinal disorders. Gastric dilation-volvulus is rare. Abdominal distention may also develop from pneumoperitoneum. Sources of air include gastric perforation, gastrointestinal rupture, extension of air from the thoracic cavity, penetrating abdominal wounds and intra-abdominal gas-forming bacteria.

Fetuses are a cause of physiologic organomegaly.

Formidable organomegaly usually results from markedly distended hollow organs (bladder, intestinal tract, uterus) or neoplasia. Granulomatous inflammation, cyst and pseudocyst formation is less common. Rare causes include heterotopic ossification. Acute inflammation of an organ usually causes minimal to moderate organomegaly and does not cause abdominal distention.

Feeble abdominal musculature is caused by hyperadrenocorticism.

WHERE?

Abdominal distention and/or fluid may be signs of:

- A **primary abdominal disorder** or physiologic change. Any abdominal organ may be involved.
- An **extra-abdominal disorder**.
- A **systemic disorder**.

Peritoneal fluid may be accompanied by pleural fluid, pericardial fluid or subcutaneous edema.

A large volume of abdominal fluid, in addition to causing abdominal distention, may cause dyspnea (diaphragmatic compression), anorexia (compression of the stomach), increased frequency of urination (compression of the bladder), abdominal discomfort, and difficulty walking. A large volume of fluid can also compress the caudal vena cava and decrease venous return to the heart.

WHAT?

The chief complaint may be abdominal distention, perceived weight gain, signs due to abdominal distention, or signs of an underlying or associated disease.

Most causes of abdominal distention may result in minimal to marked distention, but most commonly result in minimal to mild distention. The most common causes of abdominal distention in cats are physiologic – pregnancy and obesity. The most common pathologic cause of moderate to marked abdominal distention is abdominal effusion. The most common causes of marked abdominal effusion are right heart failure, feline infectious peritonitis and neoplasia.

DIAGNOSIS

Fat is easily confused with fluid, both peripherally and in the abdomen, and the two cannot always be distinguished by palpation alone. However, cats with severe abdominal distention due to fluid will have a more taught abdomen than severely obese cats, and body contour will change more with position when distention is due to fluid. Fluid is confirmed on physical examination only if a fluid thrill or abdominal organ is noted with ballottement, which requires a large volume of fluid. Smaller amounts of fluid may cause the abdominal organs, especially the loops of intestine, to feel more slippery than usual, or to be less distinct than usual, on palpation.

Organomegaly is easily detected on abdominal palpation, with the exception of hepatomegaly where falciform fat may preclude palpation of the liver.

- Mild distention of the intestines with air may make them less distinct than usual on palpation.
- Free-living toms may have firm abdominal musculature and be more difficult to palpate.

Abdominal pain may be signaled by contraction of abdominal musculature, vocalization on abdominal palpation, attempting to escape, and defensive aggression. Some clinicians believe that cats with abdominal pain may not react, and that inactivity and remaining hunched-up also signify abdominal pain. Abdominal pain may be caused by trauma, inflammation of a specific organ, peritonitis, acute over-distention of the bladder or gastrointestinal tract, and over-exuberant palpation. Abdominal pain may be mimicked by back pain (uncommon in cats), or the cat objecting to veterinary examination. Fluid distention due to transudates and modified transudates is not painful.

Abdominal **radiography**, abdominal **ultrasound** examination, and **abdominocentesis** will reveal the cause of abdominal distention if clinical findings are inconclusive.

- If imaging is planned it should be performed prior to abdominocentesis (1) to identify organomegaly, and (2) because a small amount of air may enter the abdomen during abdominocentesis, which may create imaging artifacts.
 - **Radiography** will not detect small volumes of fluid. There is progressive loss of abdominal detail with increasing amounts of fluid, and large-volume ascites creates a homogeneous soft-tissue density. Radiography is not very useful to distinguish the type of fluid, except that exudates tend to produce a “ground-glass appearance” because the presence of flocculent material produces variation in radiographic density.
 - **Ultrasonography** will detect small volumes of fluid, and may identify flocculent densities in exudates and debris on the serosa.
- **Abdominocentesis** will usually be positive if there is > 4–5 ml/kg of fluid.
 - If fluid is detected during an ultrasound examination, ultrasound-guided aspiration of the fluid is recommended.
 - For blind abdominocentesis, the cat is best supported in the standing position or held in the restrainer’s arms with the ventrum parallel to the ground. Ideally the bladder should be empty.

- If a large volume of fluid is known to be present, a regular needle, butterfly needle, intravenous catheter or peritoneal lavage catheter attached to a syringe \pm three-way stopcock may be used to remove the desired volume. Following surgical preparation of the skin, the needle or catheter is inserted along the ventral midline caudal to the umbilicus.
- If the procedure is being used to diagnose the presence of a small volume of fluid, a 1-inch, 22-G needle should be inserted along the ventral midline caudal to the umbilicus, and the fluid allowed to drip out by gravity. Samples should be collected into an EDTA (purple top) tube and into a clot tube (red top). If no fluid appears, the needle should be gently twisted, and, if this is unsuccessful, a syringe may be attached and gentle suction applied. If midline abdominocentesis is negative, the abdomen may be “divided” into four quadrants with the umbilicus as the center point, and the procedure repeated in each quadrant, stopping when a sample is obtained.
- Minimal analysis of the fluid consists of visual inspection, specific gravity, packed cell volume and total protein (measured by refractometer or urine dipstick), and cytologic examination using a routine hematology stain. Fluids with high cellularity may be examined using a smear similar to a blood smear or using a squash smear. Fluids with low cellularity should be centrifuged prior to examination and/or examined using a line-smear technique, a technique similar to a blood smear, but where the spreader slide is rapidly drawn back several millimeters before the end of the sample slide, thus concentrating the cells in a line. More extensive evaluation may include cell counts, bilirubin, urea, creatinine, potassium, glucose, bicarbonate, lactate, pH, albumin, globulin, cholesterol, triglyceride, amylase and lipase levels, RT-PCR for feline coronavirus, Gram-stain and microbial culture.
- If abdominocentesis is unsuccessful, **diagnostic peritoneal lavage** may be performed.
 - The bladder is emptied and the cat is restrained in dorsal or left lateral recumbency.
 - The skin is surgically prepared. An intravenous catheter (which may be fenestrated with a scalpel blade, although this may make

the catheter more difficult to advance and more prone to kinking or breakage) or peritoneal dialysis/lavage catheter (preferred) is inserted caudally, or right laterally, to the umbilicus (dissection may be used), and directed caudally and towards the right.

- 20 ml/kg warm saline is infused by gravity or injected over 2–5 minutes. The cat is gently rolled from side-to-side (catheter in place), and then after 2–5 minutes a diagnostic sample is retrieved by gravity or by aspiration (it is neither necessary nor possible to retrieve all the infused fluid). The catheter is removed and the skin incision sutured.
- Complications from presence of a large volume of ascites may necessitate large-volume abdominocentesis. This is normally a safe procedure, however:
 - The fluid may rapidly re-accumulate, especially if intra-abdominal pressure from the fluid (tamponade) was in equilibrium with the forces promoting fluid accumulation. Very rapid re-accumulation could lead to acute hypovolemia. This is most likely to occur with hypoproteinemia and right-sided heart failure.
 - Repetitive large-volume abdominocentesis will promote hypoproteinemia because of repetitive loss of protein in the ascitic fluid.
 - For these reasons it is recommended to remove enough fluid to resolve secondary problems, but not to try to empty the abdomen.

The prognosis for cats with peritoneal effusion is generally poor, especially if accompanied by pleural effusion.

DISEASES CAUSING ABDOMINAL DISTENTION OR ABDOMINAL FLUID

OBESITY***

Classical signs

- Disproportionately large abdomen compared to head, thorax and distal limbs.

Pathogenesis

Obesity results from **caloric intake in excess of that required for basal metabolism and physical activity**.

Overfeeding prior to maturity may cause adipocyte proliferation predisposing to obesity in maturity.

Adipocyte numbers gradually increase with aging and basal metabolic rate decreases.

Some cats are probably more likely to become obese by genetic predisposition.

Neutering promotes obesity in part because sex hormones affect appetite and protein and fat metabolism. Neutered cats have lower basal energy requirements and are also less likely to roam.

- Neutered male cats are more prone to obesity than neutered female cats.
- Obesity in neutered male cats is primarily due to increased food intake.

Physical activity is reduced in many housecats and with aging. Reduced physical activity reduces caloric needs, and also results in reduced muscle mass, which in turn lowers basal metabolic rate.

Offering **highly palatable foods** and boredom may increase calorie intake.

Appetite stimulation is a **side effect of certain drugs**. This effect is most pronounced with megestrol acetate and benzodiazepines, but may occur occasionally with glucocorticoids and phenobarbital. Various drugs may also reduce physical activity.

Endocrine disorders causing obesity are rare in cats.

- Hypothyroidism is usually caused by treatment of hyperthyroidism. Naturally occurring hypothyroidism in mature cats is rare, but may be idiopathic or immune-mediated as in the dog.
- Acromegaly may cause initial obesity by appetite stimulation and weight gain by stimulation of bone and muscle growth. Cats with acromegaly ultimately develop diabetes mellitus, which causes weight loss.
- Hyperadrenocorticism may cause initial obesity by appetite stimulation. Many cats with hyperadrenocorticism develop diabetes mellitus, which causes weight loss.
- Insulinoma could theoretically promote obesity because of the anabolic effects of insulin, but this has not been reported.

Obesity causes or increases the risk for insulin resistance, impaired glucose tolerance, diabetes mellitus, hepatic lipidosis, feline lower urinary tract disease, musculoskeletal problems, bacterial skin infections, increased risk of surgical and anesthetic complications and impaired immune function. Obesity as a risk factor for cardiovascular disease and neoplasia in cats has not been reported.

Clinical signs

Obesity is typically **most pronounced in the abdominal region**, although the thorax, neck and upper limbs will also have increased subcutaneous fat.

- If abdominal distention is due to intra-abdominal fat, it will be **accompanied by deposition of subcutaneous fat**. Large subcutaneous fat depots may accumulate in the inguinal area.

Signs of adult-onset **hypothyroidism** include lethargy, inappetence, mild hypothermia and heat-seeking behavior, skin changes (dry lusterless hair, scale formation, alopecia, myxedema), bradycardia and reproductive problems. Obesity may be severe.

Signs of **acromegaly** include signs of diabetes mellitus, facial and carpedal dysmorphism, and cardiomegaly. Signs of **hyperadrenocorticism** include signs of diabetes mellitus, abdominal distention, alopecia and fragile skin. The signs of **insulinoma** are those of hypoglycemia.

Diagnosis

Diagnosis of obesity is usually made on the basis of physical examination. Abdominal radiography or ultrasound examination can be used to confirm obesity as a cause of abdominal distention if necessary.

There is usually a **history of a highly palatable, high-calorie diet** being consumed and **physical inactivity**.

There is absence of other clinical signs of other causes of abdominal distention.

If there are signs of endocrinopathy, it should be confirmed by appropriate testing. Endocrinopathies are rare causes of obesity.

- Hypothyroidism may be suspected on the basis of clinical signs, a low T4 and/or free T4 (measured by equilibrium dialysis validated for cats), and absence

of evidence for a concurrent disorder causing euthyroid sick syndrome.

- If there is a history of treatment for hyperthyroidism, the above findings plus response to therapy are sufficient for a diagnosis.
- If naturally occurring hypothyroidism is suspected, additional testing is recommended. Similar to testing for hypothyroidism in dogs, interpretation of tests is controversial.
- TSH response tests using animal-origin TSH have been used in the past, but such TSH is no longer widely available. Recombinant human TSH is now available, and protocols using this preparation should be defined in the future.
- TRH response test may be used: Obtain baseline serum sample, give 0.1 mg/kg IV, obtain post serum sample at 4 hours. A normal response is a > 50% increase from baseline.
- The assay for canine TSH has been used anecdotally but has not been validated for the cat.
- Thyroid biopsy may be obtained, demonstrating atrophy or thyroiditis.
- If there is a response to therapy, thyroid supplement can then be withdrawn to observe for recurrence of signs.

Differential diagnosis

The principal cause of abdominal distention that may be confused with fat is **fluid**. However, **many cats with ascites are chronically ill and have muscle wasting**.

Pregnancy – in pregnant cats the degree of abdominal distention may be disproportionate to the amount of subcutaneous fat.

Obesity is a common disorder and may make diagnosis of other concurrent causes of abdominal distention difficult by interfering with palpation.

Treatment

For successful management of obesity, it is **essential that the owner is committed to the goal** that their cat achieves a healthy body weight. The owner needs to understand and believe that appropriate management of obesity leads to a more active and healthier pet, and a longer life of their pet. The evidence that only **53% of obese cats were alive after 4 years** compared to 83% of cats with optimum body weight may help to convince some owners of the importance of weight loss.

Primary obesity is best treated by offering a **hypocaloric diet** designed for weight loss in cats. These diets generally have reduced fat and higher carbohydrate than maintenance diets, and a higher concentration of essential nutrients. Some are also high in fiber. Newer weight-loss diets for cats have restricted carbohydrate (<25% ME) and are high in protein.

A satiety effect of insoluble fiber (e.g. cellulose) used as a bulking agent has not been proven in cats, and foods rich in such fiber increase the risk of constipation. Fermentable fiber may promote satiety.

Because some obese cats have very low metabolic rates, it is best to calculate the amount of energy being consumed by the cat, and then **reduce energy fed to 80% of current consumption**. Using current energy consumption as a basis for restricting calories, makes it more likely that successful weight loss will be achieved in the first month of the program, which makes it more likely the owner will continue the program.

- If current energy consumption cannot be determined, a guideline is to offer 60–75% of energy theoretically required for maintenance of ideal body weight (i.e. **60–75% of 60 kcal/kg ideal body weight/day**) and **adjust every 2–4 weeks** to achieve a loss of about 1% of body weight per week.

At 1% weight loss per week, about 90% of weight will be lost from fat and <10% from lean body tissue. More severe calorie restriction decreases the proportion lost from fat and increases the proportion of weight lost from lean body tissue. Losses of body weight greater than 2% per week are dangerous as hepatic lipidosis may develop. During a weight loss program it is important to verify that the cat is eating regularly. Fasting will increase the risk for developing **hepatic lipidosis**.

It is important not to restrict calories by restricting protein.

Dietary additives may help promote weight loss and/or ameliorate secondary glucose intolerance, and are being added to commercial diets for cats.

- **L-carnitine** increases fatty acid oxidation and promotes fat loss, while preserving muscle mass. It also appears beneficial in treating cats with hepatic lipidosis. Supplemental L-carnitine can be dosed orally (250 mg/cat q 24 h of pharmacological grade product added to food or formulated as aqueous suspension).
- **Vitamin A** promotes weight loss by stimulating uncoupling protein formation, which increases

energy loss as heat. Vitamin A also decreases leptin (a hormone involved in fat metabolism) concentrations, which may improve insulin sensitivity.

- **Chromium, fermentable fiber and low glycemic index starch sources** (corn, sorghum) may improve glucose tolerance status by improving insulin sensitivity, increasing insulin secretion and decreasing post-prandial glucose concentrations, respectively.
- **Increasing physical activity is also beneficial**, but is not as easy to achieve in cats as in dogs. The most practical approach is to encourage the owner to engage in regular active play with the cat, such as having the cat chase an object on a string or a light spot, although it is not known what constitutes a proper “feline exercise program”. Other alternatives for indoor cats are to provide an outdoor enclosure or leash-controlled outdoor activity sessions.
 - Cats given **environmental enrichments** such as additional food dishes, water bowls and litter boxes, plus climbing towers, window perches, scratching posts, cat spas, grooming supplies and toys, had **increased activity levels and greater weight loss** compared to cats that did not have an enriched environment

Surgical debulking of fat or liposuction has not been reported in cats and is not recommended.

The **use of drugs is currently not recommended**. Dehydroepiandrosterone may cause severe adverse reactions in cats. Thyroid hormone should only be used in cases of proven hypothyroidism. The initial dose is 0.05–1.0 mg once a day, with a goal of maintaining serum T4 between 20–40 nmol/L 4–6 hours after dosing.

Prognosis

The prognosis for weight reduction is dependent upon compliance.

The prognosis for complications of obesity depends upon the severity of obesity and other factors affecting the complicating disorder.

The prognosis for hypothyroidism is excellent.

Prevention

The ration should be restricted or a hypocaloric diet offered as soon as the propensity for obesity is noticed. Physical activity should be encouraged.

PREGNANCY***

Classical signs

- Mild to marked abdominal distention in breeding cats.

Pathogenesis

Intentional or unintentional breeding.

Clinical signs

Previous signs of estrus.

Abdominal distention usually does not become apparent until the **last 1–2 weeks of gestation**. It is easiest to detect in queens that are thin, have a short haircoat, have had previous pregnancies, and have large litters.

Mammary gland development (“milk bar”) usually **does not become apparent until the last week of gestation**, although pinking of the nipples may be noted sooner. Abdominal distention is usually noted before development of a milk bar.

Nesting behavior does not begin until **1–2 days before delivery**.

Diagnosis

History of estrus, indoor/outdoor lifestyle, escape from indoors, or intentional breeding.

Fetal membranes can usually be **palpated from day 17–25 of gestation**, and occasionally up to day 35. The fetuses palpate as distinct water-filled spheres (“tiny bladders”). An enlarged uterus is palpable as a tubular organ between the colon and bladder from day 25 of gestation and on.

Fetuses can be seen by **ultrasound examination** beginning day **11–14 of gestation**; **fetal heartbeats** can be **seen by day 22–24**.

Fetal mineralization is first detectable by radiography beginning day 38 of gestation, but is most reliable for identifying **fetal skeletons after day 45 of gestation**. This corresponds to the period that abdominal distention becomes apparent.

- The above times are based on breeding dates and are not as reliable as times based on days prior to parturition. In a recent report, fetal mineralization

was first detectable 25–29 days prior to parturition, and the vertebral column detectable by day 22–27 prior to parturition. The pattern of progressive mineralization was used to accurately predict day of parturition.

Differential diagnosis

Cats with uncomplicated pregnancies are healthy, and as such the **main differential diagnosis is obesity**. However, obese cats are more often neutered, and obese cats also have evidence of increased subcutaneous inguinal fat. Palpation of an enlarged uterus is usually possible in pregnant cats, and palpation findings can be confirmed by imaging.

If a **sick cat with abdominal distention with an unknown pregnancy** is presented for examination, all other causes for abdominal distention should be considered. If the only cause of abdominal distention found during work-up appears to be an enlarged uterus, then **acute metritis or spontaneous abortion should be considered**, as well as an unrelated disorder complicating pregnancy.

Treatment

Ovariohysterectomy if the pregnancy is unwanted.

Prognosis

Good – dystocia is uncommon in cats.

Prevention

Ovariohysterectomy; isolate from toms during heat.

FELINE INFECTIOUS PERITONITIS (FIP)***

Classical signs

- Depression, anorexia, weight loss, fever, pleural or peritoneal effusion.

Pathogenesis

FIP is caused by strains of **feline coronavirus (FCoV)**. These virulent strains have the **ability to replicate in macrophages as well as in epithelial cells**. The viru-

lent FIP strains arise from mutations in the avirulent (enteric) strains during replication of the latter. Both type I (genuine) FCoV and type II FCoV (which result from recombination between FCoV and canine coronavirus) can give rise to FIP strains.

The virus initially replicates in epithelial cells of the pharynx, respiratory system and intestinal tract.

Antibodies are produced, which fail to eliminate the virus and facilitate its uptake by macrophages, where the virus further replicates.

Macrophages migrate in the blood to venules of various tissues, e.g. the serosa of the abdomen. The macrophages exit the venules, and virus replication continues. **Antigen–antibody complexes form around the venules, attracting neutrophils**. The result is a **pyo-granulomatous vasculitis, resulting in effusion**.

FIP is **more common in cats infected with feline leukemia virus (FeLV)** in areas where FeLV is frequent.

Clinical signs

Most common in cats **3 months to 3 years old**. There may also be an **increased prevalence in geriatric cats**.

FIP occurs in **two main forms: wet (effusive) and dry**. **Non-specific signs (depression, anorexia, weight loss, fever)** are common in both forms.

In **wet FIP**, **pericardial, pleural and/or peritoneal effusions** occur.

- Initially abdominal organs, especially the **intestines, may not feel as distinct as usual**.
- Later, as fluid accumulates, **marked painless distention of the abdomen** occurs.

In **dry FIP**, signs are referable to the organ involved.

- FIP may cause **chronic hepatitis**, which could result in abdominal distention from hepatomegaly and ascites from portal hypertension.
- Massive mesenteric lymphadenopathy has also been reported.

Diagnosis

No routinely performed test has 100% sensitivity or specificity, and diagnosis always relies on a combination of clinical signs and laboratory test results.

A complete blood count may reveal a mature **neutrophilia** (chronic inflammation), lymphopenia (stress), and **high plasma total protein** (increased globulins and fibrinogen).

A serum chemistry profile may reveal hyperglobulinemia and a decreased albumin to globulin ratio. (Total serum protein is less than plasma protein because of the absence of fibrinogen.) Liver enzymes \pm bilirubin will be elevated if there is hepatic involvement.

“FIP tests”, which include various **serum antibody tests and RT-PCR assays for FCoV viral antigens, are often non-contributory**. Positive tests indicate exposure or presence of FCoV and not necessarily the FIP strains. Tests are likely to be positive with classic effusive FIP, but a negative test result does not rule out the disease if the clinical, laboratory and pathologic findings are typical of the disease. Cats with very high titers are likely to have FIP. Furthermore, because the negative predictive value of the antibody test is high overall, cats with abdominal effusion and a negative antibody test result are unlikely to have FIP (although serum antibody titers may be low because of binding by the large viral load in the effusion).

Abdominal radiography or ultrasonography will demonstrate peritoneal fluid, typically containing echogenic debris.

Abdominocentesis. Cytologic, biochemical and immunologic **tests on the abdominal fluid are more useful than blood tests**. These tests include:

- **Cytology.** Peritoneal fluid from a cat with wet FIP will typically reveal a non-septic exudate. The **fluid is pale to straw-colored**, may contain white flecks (fibrin) and may clot upon standing. Cytology reveals a **high-protein** background (stippling, crescent formation) and **mature neutrophils**. Chylous effusion may also occur.
- **Total protein, albumin and globulin levels.** As in serum, but of more diagnostic value: the higher the total protein and globulin level, and lower the albumin to globulin ratio, the more likely the cat has FIP. Total protein ≥ 120 g/L (12 g/dl) had a specificity of 99% and positive predictive value of 89% in one study, while gamma-globulins ≥ 30 g/L (3.0 g/dl) and gamma-globulin content $>32\%$ in the fluid as demonstrated by protein electrophoresis have been reported to have 100% specificity and positive predictive values for FIP. An albumin to globulin ratio

of 1 was reported to have a negative predictive value of 91% (and a higher ratio would presumably have a higher negative predictive value.)

- Rivalta’s test is useful to confirm that the fluid is an exudate, by testing for coagulation of protein in an acetic acid solution. Five ml of distilled water and one drop of 98% (glacial) acetic acid are mixed in a test tube. Vinegar should be a practical alternative to use as a point-of-care test. One drop of the effusion is carefully layered on the surface of the solution. If the drop disappears and the solution remains clear, the test is negative and the fluid is a transudate. If the drop retains its shape, remains on the surface, or slowly floats down, the test is positive and the fluid is an exudate. Rivalta’s test may also be positive in septic peritonitis and lymphoma (i.e. other causes of exudates), but these disorders can usually be ruled in or out with other tests.
- Glucose may be detected with a urine dipstick but the diagnostic value of glucose level is not known.
- **Direct immunofluorescence of FCoV antigen** in the peritoneal fluid macrophages. This has been reported to have a specificity and positive predictive value of 100%, and negative predictive value of 57–89%.
- **Utility of measuring FCoV antibody in the effusion varies**, but it is at least as good as, and probably better, than a serum test.
- Preliminary results indicate that RT-PCR for FCoV in the effusion is of high sensitivity and specificity.
- Adenosine deaminase activity. The level in the fluid is usually higher than with other causes, but the test is not routinely available.

An FeLV test should be performed.

Exploratory surgery or laparoscopy with reveal multifocal small (e.g. 1–5 mm) white serosal plaques. Biopsies of abdominal lesions seen at surgery or laparoscopy reveal **pyogranulomatous to granulomatous inflammation**. Immunohistochemistry may be used to demonstrate FCoV antigen within tissues. Viral culture may be available through research facilities.

Differential diagnosis

Differential diagnoses for cats with non-specific signs and peritoneal fluid include **neoplasia, pancreatitis and right heart failure**.

The main differential diagnoses for abdominal distention due to a **non-septic exudate** are **steatitis** and **cholangiohepatitis**. With **steatitis**, the abdomen is usually painful on palpation and abdominal fat is yellow to brown.

Differential diagnoses for liver disease include **cholangiohepatitis**, **lipidosis** and **neoplasia**.

Treatment

Supportive care.

Large-volume abdominocentesis.

Corticosteroids and immunosuppressive agents at standard doses have been used with limited success.

Antiviral drugs have been used with limited success.

Recombinant human and recombinant feline interferons appear to prolong survival in some cats. Recombinant feline interferon has been used at a dose of 1 million U/kg SC every other day until remission of clinical signs, followed by 1 million U/kg SC once a week. Prednisolone has been given concurrently at an initial dose of 2 mg/kg once a day and then tapered to 0.5 mg/kg every other day. A common recommendation is to use low-dose human recombinant interferon-alpha at 30 U/cat/day PO for 7 days on alternate weeks, although there are little firm data documenting benefit.

The **thromboxane synthetase inhibitor ozagrel hydrochloride**, 5–10 mg/kg, **combined with prednisolone**, 2 mg/kg, dramatically improved clinical signs in two cases, but ozagrel is not readily available.

Dapsone is effective in the treatment of vasculitis but has not been evaluated for FIP.

Prognosis

Effusive FIP is **almost always fatal within a few days to months** of onset of signs.

Transmission

FIP is most **common in multiple cat households** where cats are exposed to FCoV.

FCoV transmission occurs by **inhalation** of virus shed from oronasal secretions or **ingestion** of virus shed in feces.

An important time of transmission is from asymptomatic queens to kittens at 5–7 weeks of age.

In utero infection may occur, but this usually leads to abortion or neonatal loss.

Prevention

Routine disinfection is important because the virus is readily inactivated.

Do not introduce FCoV test-positive cats into a household. Identifying FCoV carriers prior to introduction in a multi-cat facility is the main value of FIP tests.

For catteries with a history of FCoV infections, isolate queens 2–3 weeks before parturition, quarantine queen and kittens after parturition, and then wean kittens at 4–5 weeks of age and isolate.

Modified-live intranasal vaccine is recommended for open multiple-cat households.

FeLV vaccination is recommended for open, multiple-cat households.

ABDOMINAL LYMPHOMA***

Classical signs

- Painless lymphadenopathy (multicentric lymphoma).
- Anorexia, weight loss, vomiting, diarrhea (alimentary lymphoma).

Pathogenesis

Multicentric nodal lymphoma, characterized by **peripheral lymphadenopathy**, **frequently involves the liver and/or spleen**. This form is often associated with **FeLV infection** and is occasionally associated with **FIV infection**.

Alimentary lymphoma may affect various sites in the **gastrointestinal tract and mesenteric lymph nodes**, and may extend into the **liver, spleen or kidneys**. Extra-abdominal sites (e.g. lung, bone marrow) may also be involved. Alimentary lymphoma is infrequently associated with FeLV infection, and is occasionally associated with FIV infection.

- It has long been believed that chronic inflammatory bowel disease may progress to lymphoma.

Alternatively, severe inflammatory bowel disease may actually represent an indolent lymphoma. A progressive course of disease is more consistent with lymphoma while a waxing and waning course is more consistent with inflammatory bowel disease.

- Alimentary lymphoma has historically been considered to be primarily of B-cell origin. There is increasing evidence of T-cell alimentary lymphoma, especially with low-grade lymphomas.

Solitary hepatic, splenic or renal lymphoma may also occur.

Abdominal lymphoma may cause abdominal distention by hepatomegaly, splenomegaly, gastrointestinal thickening or dilation, or fluid.

- Abdominal lymphoma may cause ascites by portal vein compression, lymphatic obstruction, septic peritonitis secondary to intestinal perforation and spontaneous hemorrhage.

Clinical signs

Multicentric nodal lymphoma:

- Variable lethargy, inappetence and weight loss. Some cats have no systemic signs.
- Generalized moderate to marked painless **peripheral lymphadenopathy**.
- Variable hepatomegaly and icterus, splenomegaly, abdominal distention (uncommon).

Alimentary lymphoma:

- Anorexia, inappetence and weight loss.
- **Variable vomiting and diarrhea**, but absence of these signs does not rule out alimentary lymphoma.
- Variable intestinal mass or thickening, organomegaly, icterus and abdominal distention.
- Peripheral lymphadenopathy is uncommon.

Other abdominal extra-nodal lymphoma:

- Signs of specific organ failure, e.g. icterus with hepatic lymphoma.
- Variable organomegaly and abdominal distention.

Diagnosis

Abdominal radiography or ultrasonography may demonstrate an intestinal mass or intestinal thickening, splenomegaly, hepatomegaly, lymphadenopathy or peritoneal fluid.

Biopsy of gastrointestinal tract or other abdominal organ.

- In addition to making a diagnosis, the biopsy should be used to grade the lymphoma with respect to its aggressiveness. High-grade lymphomas are poorly differentiated and may be further characterized as immunoblastic or lymphoblastic. Low-grade lymphomas are well differentiated and may also be referred to as lymphocytic. Intermediate forms also occur. The percentage of cell types varies between studies, but overall low-grade lymphomas are less common than intermediate and high-grade lymphomas.
- Lymphocytic gastrointestinal lymphoma may have a tendency to be epitheliotropic (to involve the mucosa) and to be of T-cell origin.

FeLV and FIV tests should be obtained.

Iron-deficiency anemia from chronic gastrointestinal hemorrhage may occur with alimentary lymphoma.

Peritoneal fluid may be a **transudate, modified transudate, septic exudate, chylous or hemorrhagic effusion**, and may contain neoplastic cells.

Differential diagnosis

Differential diagnoses for generalized lymphadenopathy include atypical hyperplasia, hyperplasia in response to generalized skin diseases, immunologic disorders and systemic infections, widely metastatic neoplasia, and generalized bacterial or fungal lymphadenitis.

Differential diagnoses for lethargy, anorexia, weight loss, vomiting and diarrhea include inflammatory bowel disease, other gastrointestinal neoplasia, pancreatitis, systemic mycoses and cholangiohepatitis. Other than inflammatory bowel disease, these disorders may also cause lethargy, anorexia and weight loss without vomiting and diarrhea.

Differential diagnoses for marked splenomegaly include mast cell tumor and other tumors.

Treatment

Chemotherapy as described in Chapter 31 Aggressive lymphomas should be treated aggressively and indolent lymphomas should be treated more conservatively.

Cats with **high-grade lymphoma** should be treated with a **multi-agent protocol**.

Cats with **low-grade lymphoma** (usually alimentary) may be treated with less aggressive protocols such as **prednisone and chlorambucil**.

Splenectomy may be considered for splenic lymphoma if there is no evidence of lymphoma at another site. Because there is always the possibility of undetected microscopic lymphoma at another site, surgery should be reserved **for cats where there is poor response to, or unacceptable side effects with, chemotherapy**.

Surgical removal of a gastrointestinal lymphomatous mass should be reserved for cats where the tumor is causing gastrointestinal obstruction or perforation. **Surgical removal in addition to chemotherapy in other cases does not appear to be of added benefit.**

Prognosis

Response to chemotherapy in several case series provides general information, but it is difficult to give a prognosis for an individual cat. Ultimately the only way to determine prognosis is to treat the cat and observe response.

The prognosis for multicentric lymphoma is discussed in The Cat With Enlarged Lymph Nodes.

In recent reports, about **one-third to two-thirds of cats with alimentary lymphoma achieved a complete remission** with chemotherapy, many of the other cats achieved a partial remission (with overall response rates up to 90%), and **1-year survival about 20–40%**. Some of these cats will become long-term survivors and are considered to be cured.

Regardless of anatomic location, usually only cats that achieve a complete remission with induction chemotherapy have the possibility of being cured.

FeLV status, FIV status, sex, tumor burden and location, histologic grade and immunophenotype do not independently consistently predict achievement of remission, duration of remission or survival. Some of the weakness of prognostic factors may reflect different criteria for anatomic location and histologic grade as well as the poor statistical power of relatively small case series. Certain combination of factors may affect prognosis. For example, cats with well-differentiated

intestinal epitheliotropic lymphoma have a better prognosis than with other forms of abdominal lymphoma. In one report, 69% achieved complete remission with a median survival of 22.8 months.

Most cats tolerate chemotherapy for lymphoma and fatal complications of chemotherapy are rare.

Solid tumors***

Classical signs

- Chronic anorexia, lethargy, weight loss.

Clinical signs

Anorexia, lethargy and weight loss.

Variable fever, vomiting, diarrhea, icterus, palpable mass, depending upon the location of the tumor.

- Absence of vomiting or diarrhea does not rule out a gastrointestinal tumor.

Abdominal fluid ± abdominal distention may be present because of **pre-hepatic or hepatic portal hypertension, lymphatic obstruction or hemorrhage**. A **large abdominal mass** may contribute to abdominal distention.

- **Splenic or hepatic hemangiosarcoma** is the most common neoplastic cause of **hemoperitoneum**, but it is much less common than in the dog. Other tumors may also spontaneously bleed.
- **Abdominal fluid** has been recognized with **many solid tumors**, including those of the **liver, pancreas, kidney, intestinal tract and peritoneum** (mesothelioma).

Iron-deficiency anemia from chronic gastrointestinal hemorrhage may occur with gastrointestinal adenocarcinomas.

Diagnosis

Abdominal radiography or ultrasonography may demonstrate an abdominal mass, organomegaly or peritoneal fluid.

Biopsy of suspected neoplastic tissue.

Abdominal fluid may be a transudate, modified transudate, chylous or hemorrhagic effusion, and may contain neoplastic cells.

Differential diagnosis

Differential diagnoses for a cat with subacute to chronic non-specific signs and peritoneal fluid include cholangiohepatitis, pancreatitis, tuberculosis, pyogranulomatous bacterial infections, systemic mycoses and toxoplasmosis.

Differential diagnoses for an abdominal mass include cyst, focal necrosis, abscess, granulomatous inflammation, intussusception and heterotopic ossification of the liver. Most of these will not commonly cause abdominal distention or fluid.

Differential diagnosis for a thickened peritoneum or peritoneum covered with multiple plaques or nodules other than mesothelioma or metastatic neoplasia include FIP, tuberculosis and sclerosing encapsulating peritonitis.

Treatment

Most solid tumors are best treated by surgical excision, but they are often unresectable by the time ascites develops.

Benefit of chemotherapy for most abdominal solid tumors is not known, but effect is likely to be poor in most cases, and anorexia is common with aggressive combination protocols. Use of **carboplatin** or **lomustine** as single agents may be considered in that side effects in most cats are minimal.

Radiation therapy may be considered, but in many cases will not be feasible.

Abdominocentesis may be used to reduce signs attributable to marked abdominal distention.

Rutin, 50 mg/kg PO tid, may be considered to reduce effusion if it is chylous. (It may also be used to help alleviate chylous effusions due to other causes.)

Intracavitary chemotherapy with carboplatin or thiotepa may be considered in an effort to alleviate effusion due to widespread metastasis or mesothelioma.

Diuretics may reduce malignant ascites in some cases. Furosemide, 1 mg/kg PO/SC/IV once to twice daily, or spironolactone, 1–2 mg/kg PO, bid may be tried.

VISCERAL MAST CELL TUMOR**

Classical signs

- Depression, anorexia, weight loss, marked splenomegaly (splenic mast cell tumor).
- Depression, anorexia, weight loss, vomiting, diarrhea (intestinal mast cell tumor).

Pathogenesis

Mast cell tumor is a spontaneously arising neoplasm and is not related to FeLV or FIV infection.

Splenic mast cell tumor **frequently metastasizes**; organs involved, in decreasing order of frequency, are **liver, abdominal or thoracic lymph nodes, bone marrow** and peripheral blood, lung and intestine.

Intestinal mast cell tumor most commonly involves the **small intestine**, and may involve multiple sites. Metastasis to liver and mesenteric lymph nodes is common; metastasis to spleen, lung and bone marrow may also occur.

Visceral mast cell tumor may cause abdominal distention by **splenomegaly**, effusion or spontaneous hemorrhage.

Clinical signs

Splenic mast cell tumor:

- Variable depression, anorexia, weight loss, intermittent vomiting, dyspnea.
- Marked splenomegaly.
- Abdominal fluid may be detectable on physical examination.

Intestinal mast cell tumor:

- Variable depression, anorexia, weight loss, fever, dyspnea, intermittent vomiting, diarrhea. Melena or hematochezia may be present.
- Intestinal mass(es) or thickened intestines may be palpable.
- Peritoneal fluid may be detectable on physical examination.

Diagnosis

Abdominal radiography or ultrasonography may demonstrate splenomegaly, hepatomegaly, intestinal mass, lymphadenopathy or peritoneal fluid.

- Sonographic abnormalities of the spleen include splenomegaly, irregular contour, mottled appearance, and hyperechoic and hypoechoic nodules. Lymph nodes may be hypoechoic. Intestinal masses are hypoechoic and there is loss of normal wall layering. Effusion is anechoic.

Fine-needle biopsy of spleen, gastrointestinal mass or other organ based on clinical signs will often reveal neoplastic mast cells. Surgical biopsy of intestinal masses may be required for diagnosis. Intraoperative cytology is recommended, so that wide surgical excision of the tumor(s) may follow.

- **Abdominal fluid usually contains mast cells with or without eosinophils.** Occasionally no mast cells are present.

Fifty percent of cats with splenic mast cell tumor will have **mast cells in the peripheral blood** on cytologic examination of direct smear or buffy coat smears. Other laboratory findings include **hyperglobulinemia** and coagulation abnormalities.

Iron-deficiency anemia from chronic intestinal hemorrhage may occur with intestinal mast cell tumor.

Eosinophilia may occur with visceral mast cell tumors.

Differential diagnosis

The main **differential diagnosis for marked splenomegaly** is **lymphoma**, but it does not typically cause the massive splenomegaly seen in cats with mast cell tumor.

The main differential diagnoses for an **intestinal mass and abdominal distention** are **adenocarcinoma** and **lymphoma**. Chronic intussusceptions are rare, and would not typically be associated with abdominal distention or fluid.

The **presence of eosinophils in peritoneal fluid** is not specific for mast cell tumor, and has also been seen with **lymphoma**, **septic peritonitis** and **pneumothorax**. However, the presence of mast cells is highly specific for visceral mast cell tumor.

Treatment

Splenectomy or excision with 5–10 cm margins of intestinal masses.

The benefit or detriment of chemotherapy in addition to surgery is not known. Prednisone alone or protocols used to treat lymphoma may be considered.

Prognosis

The prognosis for **splenic mast cell tumor** is good, even with evidence of widespread dissemination. **Median survival post-splenectomy is 12–19 months**, and peripheral mastocytosis declines.

The **prognosis for intestinal mast cell tumor is poor**, with most cats being euthanized soon after diagnosis or treatment.

RIGHT HEART FAILURE**

Classical signs

- **Dyspnea due to pleural effusion.**

Pathogenesis

Cats with right heart failure usually develop pleural effusion. Peritoneal effusion is a less common occurrence.

- Peritoneal effusion has been observed with **congenital tricuspid valve dysplasia**, **patent ductus arteriosus** and **intrapercardial heterotopic liver**.
- Peritoneal effusion has been observed with **acquired pericardial effusion** (which in-itself may be a sign of right heart failure), **persistent atrial standstill**, traumatic tricuspid valvular insufficiency, tricuspid valvular endocarditis, myocarditis, **heartworm disease**, severe chronic anemia, and **dilated, hypertrophic and restrictive cardiomyopathy**. Of these various disorders, dilated cardiomyopathy is most likely to cause peritoneal effusion.

Pulmonary edema may also be present due to left heart failure.

Clinical signs

Peritoneal effusion is usually accompanied by pleural effusion. Pleural effusion \pm pulmonary edema will cause dyspnea.

- Most peritoneal effusion due to right heart failure causes undetected to minimal abdominal distention.

- Marked abdominal distention is occasionally the predominant clinical sign.

Other signs of heart disease variably present include jugular distention, murmur, gallop rhythm, tachycardia, bradycardia and irregular rhythm.

Diagnosis

Radiography is useful to demonstrate pleural effusion and large-volume peritoneal effusion.

Echocardiography will assess myocardial function, and valvular competency, and may demonstrate transdiaphragmatic peritoneal effusion. If echocardiography is not available, non-selective angiocardiology is useful to diagnose dilated and hypertrophic cardiomyopathy.

Electrocardiography will characterize arrhythmias.

Abdominal ultrasonography will demonstrate peritoneal fluid.

Abdominocentesis usually reveals a **modified transudate**.

Differential diagnosis

The **main differential diagnosis** for a cat presented in **acute heart failure** characterized by cardiogenic shock, dyspnea and abdominal fluid is **acute abdominal hemorrhage**. Pulmonary crackles will usually be present in heart failure.

The main differential diagnosis for a cat with **chronic heart failure** characterized by **pleural and peritoneal effusions is neoplasia**. Other differential diagnoses include iatrogenic volume overload, hypoalbuminemia, feline infectious peritonitis and systemic bacterial and mycotic infections.

Treatment

The treatment of heart failure is discussed in The Cat With an Enlarged Heart or Abnormal Heart Sounds.

Specific treatment of peritoneal effusion is usually not required.

Diuretic therapy (e.g. furosemide, initial dose 1–2 mg/kg bid) will help reduce abdominal fluid.

Large-volume abdominocentesis should be considered for ascites not responsive to diuretic treatment that is causing diaphragmatic compression, stomach compression or abdominal discomfort.

Prognosis

The prognosis for cats with ascites due to right heart failure is poor, because of the poor prognosis of most of the underlying heart diseases.

For a specific heart disease, it is not known if the presence of peritoneal effusion in addition to pleural effusion changes prognosis.

TRAUMATIC RUPTURE OF THE URINARY BLADDER OR URETHRA**

Classical signs

- Acute depression, anorexia, dehydration, vomiting, anuria.

Pathogenesis

Causes are listed in approximate decreasing order of frequency. These causes include:

- **Blunt abdominal trauma.**
 - **Motor vehicle trauma** is the most common cause, followed by **falling from heights**, although a ruptured urinary bladder is not a common injury, especially compared to other traumatic injuries (e.g. pelvic fractures, facial injuries). **Trauma usually causes rupture at the apex of the bladder.**
- **Urethral catheterization.**
 - This is most likely to occur when treating urethral obstruction. Rupture usually occurs in the **urethra or neck of the bladder**. Urethral obstruction may also spontaneously lead to urethral rupture without catheterization.
- **Expression of the urinary bladder.**
 - This is most likely to occur when trying to express the bladder in an unsedated cat with urethral spasm following relief of urethral obstruction, or following cystocentesis.
- **Cystocentesis.**
 - This rarely causes rupture of the bladder, but has occurred when performing cystocentesis on cats

with a severely distended bladder following urethral obstruction.

- **Penetrating abdominal trauma.**

- Bite wounds, staking injuries and bullet wounds are uncommon causes of urinary tract trauma.

Acute bladder rupture occasionally causes marked hemorrhage into the abdomen or into the bladder (with massive clot formation).

Clinical signs

Clinical signs are due to **post-renal uremia** and associated disorders.

Non-specific signs of uroperitoneum include variable **depression, lethargy, anorexia and dehydration**. Body temperature and heart rate may be elevated, normal or low. Vomiting is common. Abdominal pain may be present.

Many cats are not urinating, but **presence of urination does not rule out urinary tract rupture**. (If urination is present, there may be hematuria.)

Similarly, a **palpable bladder does not rule out rupture of either the bladder or urethra**.

Abdominal distention and a fluid wave are occasionally evident. Urethral rupture may also cause inguinal subcutaneous edema (there may also be signs of inflammation due to cellulitis).

Diagnosis

A serum chemistry profile will reveal mild to **marked elevations in urea and creatinine levels** unless the animal is tested shortly after injury. Hyperkalemia may also be present.

Abdominal ultrasonography will demonstrate peritoneal fluid.

Peritoneal fluid is initially a pale yellow to serosanguineous transudate, and cytology will be unremarkable, unless the cat is a tom, where sperm may be present. Cell counts may increase with time ($> 3 \times 10^9/L$, $3000/\mu l$) resulting in a modified transudate. Secondary septic peritonitis will result in an exudate with degenerate neutrophils and bacteria.

- **Creatinine or potassium levels** in the abdominal fluid **greater than that of the serum** are strongly suggestive of uroperitoneum. (It is not sufficient to simply measure those parameters in the peritoneal fluid because azotemic animals with ascites will also have creatinine and potassium in the ascitic fluid.) The higher the abdominal fluid:serum creatinine and potassium ratios, the more likely the cat has uroperitoneum. In one study of cats with uroperitoneum, the abdominal fluid:serum creatinine ratio ranged from 1.1:1 to 4:1, with a mean of 2:1, and the abdominal fluid:serum potassium ratio ranged from 1.2:1 to 2.4:1, with a mean of 1.9:1. Abdominal fluid:serum urea ratios are not as reliable because of more rapid equilibration of urea.

Contrast radiography will demonstrate a rupture of the bladder or urethra. To demonstrate a rupture of the bladder, the **radiograph should be obtained just as the final amount of contrast material is injected**. If only a small amount of contrast material leaks out of the bladder, it may be rapidly diluted in the peritoneal fluid resulting in a false-negative study.

Differential diagnosis

Differential diagnoses for a cat presented for **no urination** include **ethylene glycol** or **lily poisoning**, or **urethral obstruction**.

Differential diagnoses for a cat presented with **acute depression and peritoneal fluid** include **right heart failure, acute pancreatitis, liver disease** with ascites and hepatic encephalopathy, and **acute abdominal hemorrhage** (mucous membranes will be pale).

Other rare causes of **uroperitoneum** include spontaneous leakage at the site of a bladder tumor, traumatic avulsion of a ureter, transudation of urine through a severely inflamed bladder wall and leakage post-nephrotomy. Radiographic contrast studies will facilitate diagnosis. An excretory urogram may be required to demonstrate an avulsed ureter.

Treatment

Fluid therapy to correct dehydration and reduce uremia.

Antibiotics if there is secondary septic peritonitis, e.g. ampicillin, cefoxitin at standard doses.

Large-volume abdominocentesis to reduce uremia. Peritoneal dialysis will further reduce uremia but is not usually required.

Ruptured urinary bladders are usually surgically repaired.

Non-surgical management (catheterization to keep the bladder empty) has been described in other species. It may be considered if the cat is too unstable for surgery, but will not usually reduce costs because of the longer hospitalization period.

Ruptured urethras may be treated by **surgical repair** or by **placement of an ante-pubic urinary catheter**, or less optimally by chronic urethral catheterization.

Prognosis

Uroperitoneum in-itself carries a good prognosis. Uremia will rapidly resolve once the urinary tract is repaired. Chemical peritonitis from urine also usually rapidly resolves. Prognosis is largely determined by associated injuries.

MEGACOLON**

Classical signs

- Chronic straining to defecate.

See main reference on page 783 for details (The Constipated or Straining Cat).

Clinical signs

Variable anorexia, lethargy, weight loss, unkempt hair-coat and vomiting.

Straining to defecate, with the resultant minimal passage of feces that may be dry or mucoid.

Large volume of firm feces in the colon on abdominal palpation. Digital rectal examination may reveal **narrowing of pelvic canal** secondary to fractures or tumor. Neurologic examination may reveal **sacral nerve injury**.

Marked colonic dilation may occur causing abdominal distention.

Diagnosis

Abdominal radiography will demonstrate marked accumulation of feces in the colon.

Differential diagnosis

The main differential diagnosis for a cat with chronic dyschezia, tenesmus and abdominal distention is colonic neoplasia with metastases resulting in obstructive ascites.

Treatment

For the cat with megacolon sufficiently severe to cause abdominal distention, subtotal colectomy is recommended.

If medical therapy is desired, correct dehydration, administer parenteral antibiotics (e.g. ampicillin) to protect against bacterial translocation, and administer multiple small volume enemas with lactulose prior to anesthetizing the cat for manual disimpaction. Use of enema soap will facilitate the latter (do not use chlorhexidine soaps). If disimpaction is successful, chronic therapy consists of a low-residue diet, lactulose and prokinetic agents (e.g. cisapride).

JUVENILE ABDOMINAL FLUID**

Classical signs

- Mild excess in abdominal fluid encountered during pediatric ovariohysterectomy.

Clinical signs

More peritoneal fluid may be encountered when spaying a cat at an early age (e.g. 3 months) than at a traditional age (e.g. 6 months).

Diagnosis

The fluid is a **transudate**.

Differential diagnosis

FIP, where the fluid is a non-septic exudate.

Treatment

None required.

PANCREATITIS**

Classical signs

- Acute depression and anorexia.
- Ascites may develop.

See main reference on page 272 (The Cat With Depression, Anorexia or Dehydration).

Clinical signs

Cat may be of **any age, with no sex or breed predilection**, except perhaps for Siamese cats.

Duration of clinical signs prior to presentation varies from **several days to more than 3 weeks**.

Depression and/or anorexia are the most common historical signs and may be the only signs present. The **most common physical abnormalities are dehydration and hypothermia**. Fever is uncommon.

Other inconsistent signs include weight loss, vomiting, diarrhea, cranial abdominal pain, cranial abdominal mass, dyspnea, ataxia and disorientation, and shock. Polydipsia may be present, but is usually due to concurrent diabetes mellitus.

- **Peritoneal effusion** may occur, and in some cases may be of sufficient quantity to cause abdominal distention. Peritoneal effusion may be more likely to occur when there is concurrent liver disease. Pleural effusion may also occur.

Diagnosis

Because clinical and laboratory findings are non-specific, diagnosis requires a high index of suspicion.

Pancreatitis should be considered in any cat with unexplained acute depression. Pancreatitis should also be considered in any critically ill cat developing ascites, pleural effusion or hypothermia.

Laboratory findings are variable and are most valuable in ruling out other causes of depression and anorexia. The most sensitive and specific tests are elevations in feline trypsin-like immunoreactivity and

feline pancreatic lipase immunoreactivity. No laboratory abnormality appears to be correlated with the development or severity of effusion.

- Peritoneal effusion is usually a modified transudate, but may be a non-septic exudate.

Diagnostic imaging findings are also variable.

- On abdominal radiographs, **decreased contrast** may be present due to effusion. This may be restricted to the cranial abdomen or be more generalized.
- Other radiographic findings supportive of pancreatitis include a mass effect in the right cranial quadrant (displacement of organs), and localized dilation of loops of intestine (ileus). Normal findings do not rule out pancreatitis.
- On abdominal ultrasonography, accumulation of **peritoneal fluid around the pancreas** is a highly specific finding for pancreatitis. Generalized peritoneal effusion is a less specific finding.
- Other ultrasonographic findings with a high specificity for pancreatitis include pancreatic regular or irregular enlargement, pancreatic hypoechogenicity, hyperechogenicity of peripancreatic fat (may be difficult to appreciate), and dilation of the pancreatic duct in the left lobe. Normal findings do not rule out pancreatitis.
- Definitive ante-mortem diagnosis requires **biopsy** obtained by exploratory laparotomy or laparoscopy.

Differential diagnosis

Differential diagnoses for cats with **pancreatitis causing acute depression and abdominal fluid** include septic peritonitis, acute abdominal hemorrhage, right heart failure, ruptured urinary bladder, ruptured gall bladder, steatitis, toxoplasmosis, ligation of a portosystemic shunt and, uncommonly, hepatic encephalopathy where liver disease is also causing ascites.

For cats with **pancreatitis causing subacute depression and abdominal fluid**, the primary differential diagnoses are neoplasia, feline infectious peritonitis and right heart failure.

Treatment

Address the inciting cause if one is identified.

The remainder of therapy is largely **supportive**.

Antiemetics and analgesics.

Surgical debridement of grossly necrotic tissue and therapeutic abdominal lavage, or closed therapeutic abdominal lavage using a technique similar to diagnostic peritoneal lavage, should be considered if peritoneal fluid is an exudate.

If there is a large volume of ascites that is a modified transudate, therapeutic abdominocentesis should be considered, and it should definitely be performed if there is a problem secondary to a volume effect (e.g. dyspnea from diaphragmatic compression), but the benefit of the procedure on the course of the disease is not known.

SEPTIC PERITONITIS*

Classical signs

- Acute depression, anorexia, fever, abdominal pain.

Clinical signs

Acute onset of depression and anorexia; the cat may be moribund.

Variable vomiting and diarrhea. These are most likely if the cause is a perforating intestinal foreign body.

Initial fever, tachycardia ± dark pink mucous membranes, but these signs may **progress rapidly to normothermia or hypothermia, bradycardia and pale mucous membranes with severe sepsis or septic shock** (see The Cat With Acute Depression, Anorexia and Dehydration).

Pain is present on abdominal palpation in about 2/3 of cases. The cat is probably less likely to react if it is moribund. Mild abdominal distention may be present.

Polypnea and icterus may be present.

Diagnosis

History or signs of **abdominal surgery**, sharp or blunt **trauma to abdomen**, linear or sharp gastrointestinal **foreign body**, pre-existing **infection of abdominal organ** (e.g. hepatic abscess, pyometra), pre-existing abdominal neoplasia, pre-existing disorder with ascites, pre-existing infection outside of abdomen causing peritonitis by extension or hematogenous spread, ingestion

of raw meat (source of *Salmonella* spp.), or inappropriate use of NSAIDs. In some cases no cause can be found. Septic peritonitis is less common in cats than dogs.

A complete blood count usually reveals **hemoconcentration and a left shift and toxic neutrophils**. The total neutrophil count may be elevated, normal or low, depending upon the severity and acuteness of inflammation. Mild anemia may be present.

A serum chemistry profile may reveal **hyperalbuminemia (dehydration)**, **hypoalbuminemia (abdominal exudation)**, **hyperglycemia (stress)** or **hypoglycemia (severe sepsis)**.

Abdominal radiography may demonstrate loss of detail and **“ground-glass” appearance and/or free gas** in the abdomen. Abdominal ultrasonography may demonstrate peritoneal fluid and ileus. Imaging may also reveal evidence of pleural fluid.

Abdominocentesis may yield fluid. The **fluid is a septic exudate**, although intra-cellular bacteria may not be seen. Sensitivity of cytology is reported as approximately 60–90%, although in a recent case series peritoneal fluid cytology and a nucleated cell count $> 13 \times 10^9/L$ ($13\,000/\mu l$) had a diagnostic accuracy of 100% in cats. Abdominal fluid should be Gram-stained and cultured for aerobic and anaerobic bacteria. The most frequently isolated organisms are *Escherichia coli*, *Enterococcus* spp and *Clostridium* spp.

- In a recent report, glucose levels in septic peritoneal fluid were usually lower than blood glucose levels, and a difference of > 1.1 mmol/L (20 mg/dl) was highly specific for septic peritonitis. In contrast, glucose levels in non-septic effusions were equal or higher than blood levels. (This study did not include cats with FIP.) In addition, septic effusions tended to have a lower pH and higher lactate levels than non-septic effusions.
- Food particles may be seen with gastrointestinal perforation.
- If abdominocentesis is unsuccessful, and pre-surgical confirmation of septic peritonitis is desired, diagnostic peritoneal lavage should be performed.

Differential diagnosis

Differential diagnoses for an **acutely depressed cat** with abdominal distention and/or pain include **trauma**,

urethral obstruction, panleukopenia and other causes of **acute enteritis, acute pancreatitis** and **acute pyelonephritis**.

Differential diagnoses for a **moribund cat with abdominal distention** include **urethral obstruction, hepatic encephalopathy, feline infectious peritonitis**, advanced neoplasia, **heart failure** and **hemoperitoneum**.

Treatment

Supportive care and treatment for hypotension or shock, including intravenous fluids, is required.

Broad-spectrum intravenous antibiotics, e.g. **ampicillin** and **gentamicin**; **cefoxitin** (second-generation cephalosporin); cefazolin (first-generation cephalosporin) combined with enrofloxacin and metronidazole or clindamycin; or imipenem-cilastatin as a single agent. It should be remembered that enrofloxacin is not licensed for parenteral use in the cat, and there are anecdotal reports of blindness following a single injection. If “sulfur granules” are seen suggestive of *Actinomyces* spp. or *Nocardia* spp., then initial empirical therapy should consist of penicillin G or ampicillin and trimethoprim-sulfa, or imipenem-cilastatin.

Exploratory laparotomy to address underlying cause of peritonitis and to lavage abdomen. Post-operative open-abdomen management or closed-suction drainage systems are often required to treat severe generalized peritonitis. With such management, the prognosis for cats appears to be similar to dogs, with average survival rates of 60–80%.

GASTROENTERITIS*

Classical signs

- Vomiting and/or diarrhea.

Clinical signs

Cats with acute or chronic gastroenteritis will have vomiting and/or diarrhea of variable frequency and severity.

Other variable clinical signs include depression, anorexia, dehydration, weight loss, reduced growth rate in kittens, abdominal pain, melena and hematochezia.

Abdominal distention may occur because of **ileus**, with **intestinal fluid retention, flatus** (especially in acute gastroenteritis), **thickening of the intestinal wall** (especially in chronic gastroenteritis, e.g. inflammatory bowel disease), or **rarely because of ascites due to protein-losing enteropathy**. **Enlarged intestines** contribute to the prominent abdominal contour characteristic of **malnourished kittens** with a heavy roundworm burden.

- **Abdominal distention is usually mild** except in neonatal kittens where it may be severe.
- Distended loops of intestine may feel more or less distinct than usual. **Palpation may yield a “squishy” or spongy sensation and create borborygmus.**
- Thickened loops of intestine will feel more prominent on abdominal palpation.

Diagnosis

Abdominal radiographs will always demonstrate **dilation of the intestines with air**, and may demonstrate dilation of the intestines with **fluid**. Neither plain nor contrast radiographs are very useful to evaluate thickness of the intestinal walls.

Abdominal ultrasonography is very useful to rule out peritoneal fluid, **to demonstrate intestinal wall thickening** and to evaluate intestinal motility.

Differential diagnosis

Differential diagnoses for cats with vomiting, diarrhea and abdominal distention include acute pancreatitis, cholangiohepatitis, hepatic lipidosis, gastrointestinal neoplasia and acute renal failure with volume overload.

Treatment

Treatment of the primary disease.

Severe **gastrointestinal distention by flatus in neonates should be relieved by intubation** (stomach air) or **trans-abdominal enterocentesis** (intestinal air).

Simethicone is not of proven value to reduce flatus formation in humans, and is likely of no benefit in cats.

TOXOPLASMOSIS*

Classical signs

- Anorexia, fever, dyspnea and signs of ocular inflammation in mature cats.
- Fading neonate.

See main references on page 375 for details (The Pyrexia Cat).

Clinical signs

Non-specific signs of **depression, anorexia, weight loss and fever** are common.

Specific clinical signs vary with the various organs involved.

- Common signs include **uveitis, dyspnea** (pneumonia) and **muscle pain**.
- All abdominal organs may be infected by *Toxoplasma gondii*. Specific clinical signs of abdominal infection are usually due to **hepatitis** and **hepatic necrosis** (icterus), and **mesenteric lymphadenopathy** (palpable nodes). Vomiting, diarrhea and pain on abdominal palpation may be present. Peritoneal fluid may also be present, but is unlikely to cause abdominal distention.

Specific signs may also be due to concurrent disorders causing immunosuppression.

Diagnosis

Routine laboratory results are variable. **Neutrophilia** is common with systemic infection. Hepatitis is common, causing **elevations in liver enzymes and bilirubin**.

Abdominal imaging may reveal hepatomegaly, changes consistent with pancreatitis (see The Cat With Acute Anorexia, Depression or Dehydration), mesenteric lymphadenopathy and peritoneal fluid.

Peritoneal fluid is presumably a **transudate or modified transudate, which may contain tachyzoites**.

Abnormalities at exploratory laparotomy include hepatomegaly, reticular pattern to the surface of the liver

with **multiple 1–3 mm spots, thickened pancreas** with **saponification of peripancreatic fat, lymphadenopathy** and focal thickening of the intestines.

Biopsies of abdominal organs may reveal **mixed inflammation, tachyzoites**, and **occasionally cysts**. Histology will also reveal multifocal necrosis.

Elevated IgM titer; **four-fold rise in IgG titers 3 weeks apart**. Serology gives the most interpretable information if both acute and convalescent IgM and IgG titers are obtained.

Differential diagnosis

Differential diagnoses for cats with hepatopathy, mesenteric lymphadenopathy and peritoneal fluid include concurrent inflammatory bowel disease and pancreatitis, alimentary lymphoma, FIP, tuberculosis and systemic fungal infections. Of these, only the infectious diseases are likely to also cause pleural fluid, pneumonia (except for FIP), or uveitis.

Treatment

Clindamycin 10–25 mg/kg PO, IM, IV bid continuing at least 2 weeks beyond resolution of clinical signs.

Sulfadiazine (30 mg/kg PO bid) and **pyrimethamine** (0.5 mg/kg PO bid) may be used if clindamycin is not available or not tolerated. **Folinic acid** (5 mg/day) or **brewer's yeast** (100 mg/kg/day) may be required to correct myelosuppression resulting from folinic acid deficiency caused by therapy.

Trimethoprim-sulfonamide 30 mg/kg bid may be considered if these are the only drugs available.

Supportive care.

INTESTINAL TUBERCULOSIS*

Classical signs

- Chronic weight loss, vomiting, diarrhea, mesenteric lymphadenopathy.

Clinical signs

Cats with the intestinal form of tuberculosis (caused by *Mycobacteria tuberculosis*, *M. bovis*, *M. tuberculosis-bovis* variant, and *M. microti*) and intestinal involvement with non-tubercular mycobacteria (*M. avium* complex) may show signs varying from **subclinical infection to chronic enteritis** characterized by **weight loss, fever, vomiting, diarrhea and mesenteric lymphadenopathy**.

Cats with advanced disease may develop obstructive ascites.

Diagnosis

Laboratory results are variable, but **non-regenerative anemia** is common.

Abdominal radiographs may reveal **mesenteric lymphadenopathy** and **peritoneal fluid**. Abdominal ultrasonography may reveal **intestinal thickening, mesenteric lymphadenopathy**, and peritoneal fluid. Lymph nodes may be calcified.

Peritoneal fluid may presumably be a **transudate, modified transudate, chylous or exudate**. **Macrophages containing acid-fast bacteria** may be seen.

Cytology and histology of a biopsy of the intestinal tract and mesenteric lymph nodes reveal **granulomatous to pyogranulomatous inflammation**. Acid-fast bacteria are usually detectable in biopsies.

Culture is possible at selected laboratories, but may take weeks for a positive result.

Differential diagnosis

Differential diagnoses for **intestinal tuberculosis** include **alimentary lymphoma**, widely metastatic tumors, other pyogranulomatous bacterial infections and systemic fungal infections.

Treatment

Notify public health officials. Euthanasia is often advised with true tuberculosis because of the zoonotic risk. If treatment of a mycobacterial infection is attempted, drug doses are provided in references in The Cat With Non-Healing Wounds and The Cat With Enlarged Lymph Nodes.

HYPERADRENOCORTICISM*

Classical signs

- Polyuria, polydipsia, polyphagia.
- Abdominal distention, alopecia, fragile skin.

See main reference on page 251 for details (The Cat With Polyuria and Polydipsia).

Clinical signs

Many cats with hyperadrenocorticism have diabetes mellitus, which causes the polyuria and polydipsia. **Polyphagia** may be due to both diabetes and hyperadrenocorticism, and may be severe.

Muscle wasting is due to both disorders. This contributes to **abdominal distention**, which is manifested as a “**pot-bellied**” appearance, similar to the dog.

Dermatologic signs include **unkempt haircoat, patchy alopecia, and skin that tears and bruises easily**.

Diagnosis

Confirmatory testing and distinguishing a pituitary tumor from an adrenal tumor is similar to the dog, involving urine cortisol:creatinine ratio, ACTH stimulation test, dexamethasone suppression tests, plasma ACTH level, abdominal ultrasonography and CT-scanning or magnetic resonance imaging.

Differential diagnosis

Other causes of insulin-resistant diabetes mellitus.

Muscle wasting from another chronic disease plus marked obesity or peritoneal fluid can mimic the pot-bellied appearance of hyperadrenocorticism.

Treatment

Hypophysectomy and adrenalectomy have historically provided the most consistent results.

Trilostane has alleviated clinical signs of pituitary-dependent hyperadrenocorticism in all reported cases.

Mitotane and ketoconazole have inconsistent results.

Pituitary irradiation has inconsistent results.

FLUID OVERLOAD*

Classical signs

- Dyspnea due to pulmonary edema, and/or subcutaneous edema.

Clinical signs

Excessive fluid therapy **tends to cause pulmonary or subcutaneous edema** more than pleural or peritoneal effusions.

Fluid therapy may exacerbate pre-existing ascites by causing increased hydrostatic pressure or exacerbating hypoalbuminemia. The presence of a mechanism for ascites formation may divert fluid away from the lungs or subcutaneous tissue into the peritoneal space.

Diagnosis

History of fluid therapy and improvement of ascites with decreasing fluid rates or diuretic therapy.

OVEREATING*

Classical signs

- Abdominal distention following a large meal.

Clinical signs

Mild abdominal distention is commonly noted in **kittens following nursing or drinking**.

Occasionally a mature cat may eat an unusually large quantity of food sufficient to cause noticeable abdominal distention. This is most likely to happen when offering a new, highly palatable food, in cats that have fasted, and in cats with polyphagia.

Diagnosis

History of consuming a large meal.

Palpable distention of gastrointestinal tract.

Radiography will demonstrate a large quantity of ingesta.

AEROPHAGIA*

Classical signs

- Mild abdominal distention in a dyspneic cat.

Clinical signs

Dyspnea.

Mildly distended stomach or loops of intestine on abdominal palpation. Loops of intestine may feel more or less distinct than usual. **Palpation may yield a “squishy” or spongy sensation and create borborygmus.**

Diagnosis

History of dyspnea.

Palpable distention of gastrointestinal tract by air.

Radiography will confirm air in the gastrointestinal tract and rule out dyspnea due to diaphragmatic compression by a large volume of fluid causing abdominal distention.

TRAUMATIC HEMORRHAGE*

Classical signs

- Pale mucous membranes, weak pulses, tachycardia.
- External signs of trauma.

Clinical signs

With blunt trauma in cats (e.g. motor vehicle accidents, falling from heights), thoracic injuries and resulting dyspnea are more common or clinically important than abdominal injuries. Abdominal hemorrhage may occur but is rarely life threatening.

- Signs of blunt trauma may be present, including shorn nails, excoriations of the skin, fractured teeth and mandible, epistaxis and pelvic fractures.

Penetrating trauma is less common than blunt trauma, and includes bite wounds, staking injuries and bullet wounds. Bacterial peritonitis is more common or clinically important than acute abdominal hemorrhage.

- The wound may be difficult to visualize or palpate, but palpation of the abdominal wall at the wound site will usually incite a painful response. The severity of bleeding varies with the organs and blood vessels that are injured.

Abdominal hemorrhage may occur following surgery or external biopsy procedures (e.g. percutaneous liver biopsy).

Regardless of the type of trauma, the signs of abdominal hemorrhage are those of acute hypovolemia. Abdominal distention is unlikely.

Diagnosis

Abdominal ultrasonography will usually demonstrate peritoneal fluid. Abdominocentesis may yield blood.

- Following percutaneous biopsy of an abdominal organ, tachycardia is the first sign of hemorrhage and this finding is more sensitive than ultrasound or abdominocentesis to detect active bleeding.

HEPATIC LIPIDOSIS, NON-SUPPURATIVE CHOLANGIOHEPATITIS AND HEPATIC CIRRHOSIS*

Classical signs

- Anorexia, lethargy, weight loss, icterus.

See main reference on page 425 for details (The Yellow Cat or Cat With Elevated Liver Enzymes).

Clinical signs

Anorexia, lethargy and weight loss.

Variable icterus, vomiting, diarrhea.

Ascites is uncommon, especially ascites sufficient to cause abdominal distention.

- Ascites is reported more frequently in some case series, which may represent distinct sub-types of chronic liver diseases.

Hepatomegaly is common with lipidosis, but is usually not sufficient to cause abdominal distention.

Diagnosis

These liver diseases may be **suspected on the basis of clinical signs and variably elevated liver enzymes.**

Abdominal ultrasonography may reveal a normal or enlarged liver, altered hepatic echogenicity and peritoneal fluid.

Peritoneal fluid is **usually a transudate or modified transudate**. Occasionally, high protein fluid typical of an exudate occurs with non-suppurative cholangiohepatitis.

Definitive diagnosis requires liver biopsy.

Differential diagnosis

Differential diagnoses for a cat with signs of liver abnormalities and peritoneal fluid include hepatic neoplasia and other chronic liver diseases, acute pancreatitis, right heart failure, feline infectious peritonitis and toxoplasmosis.

Treatment

Nutritional support.

Corticosteroids for cholangiohepatitis.

Therapeutic abdominocentesis is not required.

STEATITIS

Classical signs

- Depression, anorexia and reluctance to move.

Clinical signs

Depression, anorexia, fever and reluctance to move because of pain.

Abdominal distention may occur from fluid and firm abdominal fat, and the abdomen may be tense because of pain.

Other clinical signs include fever and firm and lumpy subcutaneous fat with or without accompanying lymphadenopathy.

Diagnosis

History of a **diet high in oxidized unsaturated fats** (e.g. **rancid tuna**) and/or **deficient in vitamin E**. Rare in cats fed commercial foods.

Biopsy of fat – may be grossly yellow to brown.

Abdominal ultrasound examination may reveal peritoneal fluid. Abdominocentesis may reveal a **sterile exudate high in protein and mature neutrophils, similar** to that seen with **feline infectious peritonitis**, or a **chylous effusion**. Associated sclerosing encapsulating peritonitis has also been reported.

INHERITED AND ACQUIRED (ANTICOAGULANT RODENTICIDE POISONING) COAGULATION DEFECTS

Classical signs

- Spontaneous bleeding and re-bleeding after trauma.

Clinical signs

Spontaneous bleeding and re-bleeding may occur at various sites, including within the abdomen, although thoracic hemorrhage tends to be more common.

Signs due to acute anemia and abdominal distention vary with the severity of blood loss.

Diagnosis

Abdominal ultrasonography will demonstrate peritoneal fluid. Abdominocentesis will confirm that the fluid is blood.

Cats bleeding from **hemophilia A or hemophilia B** will have **prolonged activated partial thromboplastin time**. Definitive diagnosis is by quantification of factor VIII or factor IX, respectively.

Devon Rex cats bleeding from **inherited vitamin K responsive coagulopathy** will have **prolonged prothrombin time and activated partial thromboplastin time**, which resolve with vitamin K therapy.

Cats bleeding from **coagulopathy due to vitamin K antagonist rodenticide poisoning** will have **prolonged prothrombin time, activated partial thromboplastin time, and PIVKA clotting time**, which resolve with vitamin K therapy.

Cats bleeding from **coagulopathy due to liver disease** (e.g. hepatic lipidosis or cholangiohepatitis) will have **prolonged prothrombin time and/or activated**

partial thromboplastin time. If the **prothrombin time** is elevated, it may **normalize with vitamin K therapy**.

Differential diagnosis

Hemorrhage due to abdominal neoplasia, trauma, or hepatic necrosis, amyloidosis, or peliosis.

Treatment

Transfusion.

Vitamin K for Devon Rex cats, vitamin K antagonist rodenticide poisoning, and cats with liver disease with prolonged prothrombin times (see main references on page 509 for details, The Bleeding Cat).

Environment that minimizes trauma.

GLOMERULONEPHRITIS

Classical signs

- Chronic depression, anorexia, weight loss.
- Polyuria/polydipsia if chronic renal failure.
- Subcutaneous edema and/or ascites if nephrotic syndrome.

Clinical signs

Signs are those of **chronic renal failure and/or nephrotic syndrome**. Concurrent signs may be present from an underlying disease (FeLV infection, FIP, *Mycoplasma* arthritis and other chronic infections, systemic lupus erythematosus and other immune-mediated disorders, mercury intoxication). Dyspnea may occur due to pleural effusion or pulmonary thromboembolism.

Diagnosis

A serum chemistry profile will reveal **azotemia with chronic renal failure, and severe hypoalbuminemia with nephrotic syndrome**.

Urinalysis will reveal **inappropriately low urine specific gravity with chronic renal failure, and marked proteinuria with nephrotic syndrome** (note that proteinuria will raise specific gravity).

Abdominal imaging may reveal small kidneys, altered renal echogenicity or peritoneal fluid.

Peritoneal fluid is a transudate.

Kidney biopsy will reveal glomerulonephritis.

Potential underlying diseases should be investigated. Littermates should be evaluated for familial disease.

Differential diagnosis

Other causes of chronic weight loss and ascites include FIP, neoplasia, pancreatitis, liver diseases, right heart failure, steatitis and tuberculosis. If the peritoneal fluid is a transudate, the main differential diagnosis is neoplasia.

Treatment

Treat the underlying disorder if possible.

Prednisone (initial dose 2–4 mg/kg/day) has been recommended but is of questionable value.

Treatments that are ineffective in most dogs include cytotoxic drugs and cyclosporine.

Treatments of potential benefit in dogs include **ACE-inhibitors** (e.g. enalapril, benazepril) to **reduce hypoproteinemia**, **n-3 fatty acids to reduce inflammation and inhibit platelets**, and **low-dose aspirin (0.5 mg/kg PO every other day) to inhibit platelets**.

Plasma transfusions will temporarily ameliorate hypoalbuminemia.

NEOPLASIA OBSTRUCTING OR COMPRESSING THE LOWER URINARY TRACT, GRANULOMATOUS URETHRITIS AND URETHRAL STRICTURE

Classical signs

- Chronic straining to urinate and incontinence.

Clinical signs

Dysuria characterized by increased time in litter box, straining, and dribbling urine from paradoxical incontinence.

Tumors affecting mucosa may cause hematuria.

Urinary bladder may be markedly enlarged (\pm atonic), **sufficient to cause abdominal distention**.

Diagnosis

Difficulty in passing urinary catheter.

Abdominal radiography will confirm enlargement of the bladder. Contrast urethrogram or excretory urogram may identify **narrowing of urethra or a mass at the trigone**.

Abdominal ultrasonography will confirm enlargement of the bladder and may identify a mass at the trigone.

Definitive diagnosis requires biopsy, which may require surgery.

INTRAHEPATIC ARTERIOVENOUS FISTULA

Classical signs

- Ascites.

Clinical signs

A fistula between the hepatic arterial system and portal venous system causes **ascites from pre-sinusoidal portal hypertension**. Other signs could include **poor weight gain**, reduced appetite, and **dyspnea secondary to ascites**. Congestive heart failure and hepatic encephalopathy from secondary porto-systemic shunting are theoretical sequelae.

Usually a congenital lesion, therefore seen in **young animal**, but could occur secondary to trauma or surgery.

Diagnosis

Rare.

Abdominal **ultrasound** examination will confirm peritoneal fluid and may detect a **cavernous lesion**. Doppler ultrasound may detect high-velocity turbulent blood flow through the fistula.

Abdominocentesis reveals a **transudate**.

Angiography may be used to confirm the diagnosis.

Exploratory laparotomy may reveal prominent subcapsular hepatic blood vessels.

PORTAL VEIN ATRESIA OR HYPOPLASIA

Classical signs

- Ascites.
- Hepatic encephalopathy.

Clinical signs

An underdeveloped portal venous system causes **ascites from pre-sinusoidal portal hypertension** in a young animal. Other signs could include **hepatic encephalopathy, poor weight gain**, reduced appetite and **dyspnea** secondary to ascites.

Diagnosis

Rare.

Elevated serum bile acids.

Abdominal **ultrasound** examination will confirm peritoneal fluid and a small liver.

Abdominocentesis reveals a **transudate**.

Angiography or exploratory laparotomy may be used to confirm the diagnosis.

LIGATION OF PORTOSYSTEMIC SHUNT

Classical signs

- Ascites.

Clinical signs

Ligation of a portosystemic shunt may cause ascites from pre-sinusoidal portal hypertension.

Diagnosis

Common for 2 days following surgical ligation of a portosystemic shunt. Ascites is less likely to occur with an ameroid constrictor or cellophane banding.

Abdominal **ultrasound** examination will confirm peritoneal fluid.

Abdominocentesis reveals a **transudate** to **modified transudate**.

HEPATIC AMYLOIDOSIS

Classical signs

- Lethargy, anorexia, weight loss, anemia, hepatomegaly.

Clinical signs

Amyloidosis is a systemic disease with deposition of amyloid protein AA in numerous tissues including the liver.

- In most cases, including familial amyloidosis in Abyssinian cats, **renal failure from renal amyloidosis dominates the clinical presentation**. Nephrotic syndrome causing ascites is rare because **amyloid affects primarily the renal medulla**.
- In some cases, including as a familial disease in some lines of **Siamese cats and Oriental short-hair cats**, **amyloid deposition in the liver is clinically most important**.
 - Signs are mostly due to **chronic liver disease** (lethargy, anorexia, weight loss), or **acute hemorrhage** (anemia, hemoperitoneum) resulting from spontaneous hepatic rupture. Signs of liver failure (icterus, hepatic encephalopathy) are not common.
 - **Abdominal distention** may occur due to **hepatomegaly, splenomegaly, intestinal dilation** and **hemoperitoneum**.

Diagnosis

Liver enzymes are normal to variably elevated.

Liver biopsy will demonstrate amyloid. If amyloidosis is suspected, biopsy of the intestinal tract may be considered to demonstrate amyloid deposition because there is an increased risk of hemorrhage from liver biopsy.

HEPATIC NECROSIS

Classical signs

- Acute depression and anorexia.

Clinical signs

Hepatic necrosis may result from a wide variety of mechanisms (e.g. tissue hypoxia, free radical forma-

tion) and specific etiologies (e.g. **feline infectious peritonitis**, virulent systemic feline calicivirus infection, toxoplasmosis, **acetaminophen** and **diazepam toxicosis**).

Clinical signs are due to the specific cause and to acute liver injury, which may range from subclinical to fulminant hepatic failure with hepatic encephalopathy.

Necrotic liver tissue may spontaneously hemorrhage resulting in peritoneal fluid and acute anemia.

Diagnosis

Liver biopsy will demonstrate necrosis.

Abdominal ultrasonography will confirm the presence of peritoneal fluid. Abdominocentesis will confirm that the fluid is blood.

PELIOSIS HEPATIS

Classical signs

- Spontaneous abdominal hemorrhage.

Clinical signs

Variable clinical signs include:

- **Spontaneous abdominal hemorrhage from irregular blood-filled cystic spaces**, which may result in pale mucous membranes, collapse or abdominal distention.
- Signs of liver disease, including hepatomegaly or jaundice. Telangiectasia is often present.
- Weight loss, dyspnea.

Diagnosis

Abdominal radiographs may reveal hepatomegaly or loss of abdominal detail.

Abdominal ultrasound examination will reveal hypoechoic regions in liver \pm peritoneal fluid.

Fine-needle aspiration of liver lesions should yield blood. Abdominocentesis may yield blood.

Histology of liver biopsy will confirm the diagnosis.

Peliosis hepatis may be caused by *Bartonella henselae* infection in humans, and the two have been associated

in a dog, so testing for this organism should be considered.

HEPATIC ABSCESS

Classical signs

- Lethargy, anorexia, and weight loss.

Clinical signs

Non-specific signs are most common.

In a case series about a quarter of cats had a fever and about a third were hypothermic. One third of cats had abdominal pain.

Diagnosis

Rare disorder.

Variable neutrophilia, anemia, hypoalbuminemia, hyperbilirubinemia and elevation in liver enzymes.

Ultrasound may demonstrate hypoechoic or mixed hypoechoic/hyperechoic lesions in the liver and abdominal effusion.

Abdominal fluid cytology usually reveals degenerate neutrophils and bacteria. Degenerate neutrophils without bacteria and hemorrhagic effusion have also been seen.

Culture of hepatic lesions.

PERI-RENAL PSEUDOCYSTS

Classical signs

- Abdominal distention.
- Polyuria and polydipsia.
- Inappetence and weight loss.

Clinical signs

Abdominal distention occurs due to the formation of unilateral or bilateral fluid-filled sacs. The sacs lack an epithelial lining and contain either a transudate of serum, urine, or uncommonly, blood.

About 75% of cats have concurrent chronic renal failure, but cause and effect are not known.

Cats are presented for abdominal distention and/or clinical signs of chronic renal failure such as polyuria, polydipsia, inappetence and weight loss.

Diagnosis

Abdominal radiography will demonstrate large kidneys. Ultrasonography will demonstrate small kidneys within fluid-filled structures.

Presence of fluid may be confirmed by abdominocentesis. Analysis of fluid will reveal a transudate, urine or blood.

Routine hematology and serum biochemistry may reveal changes consistent with chronic renal failure.

EXTRA-UTERINE FETUSES

Classical signs

- None.

Clinical signs

Most “ectopic pregnancies” are not associated with clinical signs, and are an incidental finding during ovariohysterectomy.

Because **extra-uterine fetuses usually occur secondary to uterine rupture**, marked hemorrhage at the time of rupture or septic peritonitis may occur, which may result in peritoneal fluid.

Ascites without systemic signs of illness may also occur.

Diagnosis

Abdominal radiography or ultrasonography will demonstrate a mummified fetus \pm peritoneal fluid.

BUDD-CHIARI-LIKE SYNDROME

Classical signs

- Marked abdominal distention due to ascites.

Clinical signs

Budd-Chiari-like syndrome is congenital or acquired **obstruction of the venous outflow of the liver**, including the hepatic venules, hepatic veins and caudal vena cava, causing **post-sinusoidal portal hypertension**. It is rare in cats. Cases have included veno-occlusive disease and fibrous webs in the caudal vena cava.

The predominant clinical sign is **progressive abdominal distention due to fluid**.

Diagnosis

Angiography will demonstrate caudal vena caval obstruction.

Liver biopsy will demonstrate veno-occlusive disease.

Abdominocentesis will reveal a modified transudate.

PNEUMOPERITONEUM

Classical signs

- Marked abdominal distention.

Clinical signs

Mild pneumoperitoneum usually occurs following laparotomy and intentional marked pneumoperitoneum occurs during laparoscopy.

Marked spontaneous pneumoperitoneum usually results from a **perforating gastric ulcer or neoplasm, rupture of the stomach or large intestine**, or less often as an **extension from pneumothorax or pneumomediastinum**. Small intestinal rupture usually does not cause marked pneumoperitoneum unless it is a complication of endoscopy, which uses insufflation. Gas may also enter from penetrating abdominal wounds or perforation of the bladder during traumatic urinary tract catheterization, or may be produced by intra-abdominal bacteria, but such gas does not usually cause abdominal distention.

The predominant clinical sign of marked pneumoperitoneum is marked **abdominal distention due to air**, and acute onset of depression if associated with gastrointestinal tract rupture.

- Perforating gastric ulcers may result in marked pneumoperitoneum without generalized peritonitis and may be associated with minimal systemic signs.
- Gastrointestinal perforation may occur with minimal-to-absent pneumoperitoneum.

Diagnosis

Radiography will demonstrate free air in the abdomen. This is best seen along **the peritoneal surface of the diaphragm and the fundus of the stomach**. **Lateral views obtained in dorsal or sternal recumbency** will demonstrate the air if standard views are inconclusive.

With marked pneumoperitoneum, abdominocentesis will reveal air. Abdominocentesis may also reveal abdominal fluid, the characteristics of which will vary with the cause.

UMBILICAL, INGUINAL, TRAUMATIC ABDOMINAL WALL HERNIA*

Classical signs

- Localized swelling of the abdomen.

Clinical signs

Congenital or acquired hernias are usually evident as localized changes in abdominal contour.

- Owners may misinterpret marked **displacement of abdominal fat or organs into the hernia as abdominal distention**.

With acquired traumatic abdominal hernias there are usually also internal or external signs of motor vehicle trauma or fight wounds.

- Ventral abdominal herniation may be associated with rupture of the cranial pubic ligament.

Diagnosis

The focal nature of the lesion is usually evident on abdominal palpation, especially if the hernia is reducible.

Abdominal imaging or surgical exploration may be necessary to confirm the hernia.

LEPTOSPIROSIS

Classical signs

- Undefined.

Clinical signs

Positive titers and seroconversion to *Leptospira* spp. have been documented in various sick cats.

Clinical signs are variable and many are attributable to concurrent diseases.

- **Abdominal distention due to ascites has been reported.**

Diagnosis

The **disease in cats is rare compared to dogs**.

Most cats with positive titers have had some **evidence of liver disease**, e.g. increased liver enzymes, bilirubin or ascites.

Currently diagnosis in dogs relies on demonstrating a **four-fold rise in acute and convalescent titers**, and arguably the same criteria should be applied to cats.

GASTRIC DILATION-VOLVULUS

Classical signs

- Tympanic cranial abdomen, shock.

Clinical signs

Gastric dilation-volvulus is rare in cats. Clinical signs are similar to dogs.

Abdominal distention occurs because of dilation of the stomach with air.

Diagnosis

Abdominal radiography will demonstrate marked gastric distention with air.

RUPTURED GALL BLADDER OR BILE DUCT

Classical signs

- Progressive icterus and abdominal distention.

Clinical signs

Rupture of the gall bladder or biliary tract is rare in cats. Causes include motor vehicle trauma, falling from heights, penetrating trauma (e.g. bullet wound) or cholelithiasis.

Bile peritonitis causes **mild systemic signs** in dogs unless secondary infection occurs.

Diagnosis

Abdominal ultrasonography will demonstrate **peritoneal fluid**. **The gall bladder is small with gall bladder rupture and small-to-large with bile duct rupture.**

Abdominocentesis will reveal a **dark bile-stained modified transudate to (usually septic) exudate** containing high levels of bilirubin pigment with or without crystals. It should be noted that ascites in an animal that is icteric from pre-hepatic or hepatic causes also contains some bilirubin, because of diffusion of bilirubin from the blood into the ascitic fluid. If there is question as to whether the source of bile is the blood or the biliary tract, **the bilirubin level in the abdominal fluid may be compared to serum, with a higher level in the fluid indicating biliary tract rupture.** (In one case series of dogs and cats, bilirubin level in the fluid was consistently at least two times the serum level.)

ABDOMINAL FLUKE INFECTION

Classical signs

- Chronic weight loss, anorexia, vomiting, diarrhea, jaundice.

Clinical signs

Platynosomum spp., *Metorchis* spp., *Opisthorchis* spp., *Clonorchis* spp. and *Amphimerus* spp. are **bile duct parasites** in numerous mammals, including cats.

Infections may be subclinical or may cause chronic weight loss, anorexia, vomiting, diarrhea and jaundice. Some infections may cause hepatic neoplasia or hepatic cysts.

Fluke infection of the peritoneal cavity causing ascites has been reported rarely.

Diagnosis

Infection is usually diagnosed by finding characteristic operculated eggs on fecal floatation.

Abdominal ultrasonography may demonstrate **hepatic tumors or cysts and peritoneal fluid**.

Abdominocentesis may rarely reveal **peritoneal fluid containing single-end operculated eggs**.

SCLEROSING ENCAPSULATING PERITONITIS

Classical signs

- Variable (rare disorder).

Clinical signs

The abdominal mesothelial lining becomes replaced by fibrous tissue resulting in encasement of abdominal organs. Clinical signs reported in dogs and cats due to the peritonitis or underlying disorders include anorexia, vomiting, abdominal pain, abdominal mass and ascites.

Diagnosis

Biopsy of peritoneum reveals fibrous tissue.

IDIOPATHIC CHYLOUS ASCITES

Classical signs

- Ascites.

Clinical signs

Idiopathic chylous ascites is rare compared to idiopathic chylothorax.

Peritoneal effusion with or without concurrent pleural effusion.

Diagnosis

Abdominocentesis reveals chylous effusion.

Neoplasia or other underlying causes of effusion are not identified.

23. The bleeding cat

Anthony Abrams-Ogg

KEY SIGNS

- Rule out a local lesion.
- Confirm a bleeding tendency.
- Identify a vascular, platelet or clotting disorder.

MECHANISM?

- Bleeding is caused by vascular injury or a disturbance of one or more stages of normal hemostasis.
- The stages of normal hemostasis are: vasoconstriction and formation of a platelet plug (primary hemostasis), formation of a fibrin clot (secondary hemostasis) and clot dissolution (fibrinolysis).

WHERE?

- Bleeding caused by a vascular injury may occur at any site.
- Bleeding caused by a non-traumatic vascular disorder varies with the specific disorder.
- Bleeding due to a platelet disorder tends to be cutaneous and mucosal.
- Bleeding due to a coagulopathy tends to be subcutaneous and internal.

WHAT?

- The **most common causes of bleeding** are **local lesions**. These result from trauma, inflammation or neoplasia.
- The most common causes of **bleeding tendencies** are liver diseases, neoplasia, and infectious diseases. Most of this is subclinical.
- The most common causes of abnormal clinical bleeding are hepatic lipidosis, retroviral-induced megakaryocytic hypoplasia and vitamin K antagonist poisoning.

QUICK REFERENCE SUMMARY

Diseases causing a bleeding cat

VASCULAR DISORDERS

ANOMALY

- Cutaneous asthenia (Ehlers–Danlos syndrome) (p 519)
Inherited fragile skin and/or fragile vessels may lead to vascular trauma.

continued

continued

METABOLIC

- **Renal failure*** (p 494)**

Uremia causes alimentary tract ulceration, systemic hypertension causes retinal hemorrhages, a platelet function defect may be present, coagulation defects may be present, and hemolytic-uremic syndrome is an uncommon complication of renal transplantation.

- **Hyperadrenocorticism (p 520)**

Acquired fragile skin may lead to vascular trauma.

- **Systemic hypertension** (p 495)**

Systemic hypertension may cause retinal hemorrhages and, less often, epistaxis. The most common cause of hypertension is chronic renal failure. Other causes include hyperthyroidism, diabetes mellitus, hyperadrenocorticism and polycythemia vera. Rare disorders that may cause hypertension include multiple myeloma, pheochromocytoma and hyperaldosteronism.

NEOPLASTIC, INFLAMMATION, TRAUMA

- **Local lesions causing localized hemorrhage *** (p 492)**

Tumors (e.g. cutaneous squamous cell carcinoma), local inflammation (e.g. cat bite abscesses, idiopathic cystitis), and trauma (e.g. lacerations) may cause local bleeding at the site.

- **Motor vehicle and other major blunt trauma*** (p 493)**

Major trauma can cause mild to severe local bleeding at numerous sites.

- **Strangulation (p 519)**

External choking injury may cause scleral hemorrhage.

TOXIC

- **Snake bite envenomation (p 503)**

Snake venom toxins may cause edema and bleeding around the bite.

PLATELET DISORDERS

ANOMALY

- **Chediak-Higashi syndrome (p 520)**

An inherited platelet function defect causes prolonged bleeding after trauma.

- **Idiopathic thrombocytopathia (p 520)**

An inherited platelet function defect causes spontaneous mucosal bleeding.

- **Von Willebrand's disease (p 521)**

An inherited von Willebrand's factor (a platelet adhesion protein) deficiency causes prolonged bleeding after trauma.

METABOLIC

- **Megakaryocytic hypoplasia** (p 495)**

Reduced platelet production may be due to hematopoietic neoplasms in the bone marrow, retroviral infections, histoplasmosis infecting the bone marrow, idiopathic causes (which are probably immune-mediated) and toxicoses. Severe thrombocytopenia causes spontaneous mucosal bleeding and prolonged bleeding after injury.

- **Disseminated intravascular coagulation* (p 501)**

Acute and chronic DIC are characterized by variable thrombocytopenia, although clinical bleeding is uncommon.

- **Splenomegaly (p 521)**

Splenic sequestration may contribute to thrombocytopenia when there is marked splenomegaly.

INFLAMMATION (INFECTIOUS)

- **Feline leukemia virus (FeLV) infection** (p 499)**

Bleeding tendencies may be caused by megakaryocytic hypoplasia, immune-mediated platelet destruction, and DIC secondary to infections and neoplasia. Clinical bleeding is uncommon except with severe thrombocytopenia.

- **Feline immunodeficiency virus (FIV) infection** (p 500)**

Bleeding tendencies may be caused by megakaryocytic hypoplasia, prolongation of clotting times due to unknown mechanisms, and DIC secondary to infections and neoplasia. Clinical bleeding is uncommon except with severe thrombocytopenia.

INFLAMMATION (IMMUNE)

- **Immune-mediated thrombocytopenia (ITP) (p 506)**

ITP may be primary or secondary to neoplasia, infectious diseases or drugs. Transient thrombocytopenia may occur following vaccination in dogs, but has not been documented in cats. Severe thrombocytopenia causes spontaneous mucosal bleeding and prolonged bleeding after injury.

IDIOPATHIC

- **Miscellaneous diseases (p 505)**

Thrombocytopenias due to unknown mechanisms have been seen with a variety of diseases not typically associated with abnormal bleeding. Clinical bleeding with these abnormalities is uncommon.

TOXIC

- **Antibiotics (p 523)**

Antibiotics may have various effects on hemostasis including idiosyncratic megakaryocytic hypoplasia, impaired platelet function, and exacerbating vitamin K deficiency and antagonism.

- **Antiplatelet cardiac drugs (p 520)**

Aspirin and n-3 fatty acids are given to impair platelet function in an attempt to prevent thromboembolism in cardiomyopathy. Effect, if any, is subclinical. Risk for spontaneous bleeding with newer drugs that block specific platelet receptors is probably low.

- **Non-steroidal anti-inflammatory drugs (p 524)**

Non-steroidal anti-inflammatory drugs given for analgesia may impair platelet function. Effect on risk for bleeding is probably minimal.

- **Miscellaneous drugs (p 524)**

Sedatives, anesthetic agents and anti-histamines may impair platelet function. Effect on risk for bleeding is probably minimal.

continued

continued

COAGULOPATHIES

ANOMALY

- **Hemophilia A (classical hemophilia) (p 510)**
Inherited factor VIII deficiency causes spontaneous internal bleeding and re-bleeding after trauma.
- **Hemophilia B (Christmas disease) (p 513)**
Inherited factor IX deficiency causes spontaneous internal bleeding and re-bleeding after trauma.
- **Hageman trait* (p 504)**
Inherited factor XII deficiency causes markedly prolonged activated clotting time and activated partial thromboplastin time without clinical signs.
- **Vitamin K responsive coagulopathy in the Devon Rex (p 515)**
An inherited defect in vitamin K metabolism causes spontaneous internal bleeding and re-bleeding after trauma.
- **Factor X deficiency (p 522)**
Inherited factor X deficiency causes spontaneous internal bleeding and re-bleeding after trauma.
- **Hemophilia C (p 514)**
Inherited factor XI deficiency causes excessive bleeding after trauma.

METABOLIC

- **Liver disease** (p 498)**
Vitamin K deficiency (several causes), failure of coagulation factor synthesis, and chronic DIC may cause excessive bleeding after venepuncture and liver biopsy. The liver may be friable.
- **Pancreatitis (p 518)**
Hemostatic abnormalities are usually subclinical. Clinical bleeding is unlikely unless there is severe DIC or concurrent liver disease.
- **Exocrine pancreatic insufficiency (EPI) (p 516)**
Vitamin K malabsorption may cause spontaneous or excessive bleeding.
- **Inflammatory bowel disease (IBD) (p 517)**
Vitamin K malabsorption may cause spontaneous or excessive bleeding.
- **Disseminated intravascular coagulation* (p 501)**
Acute and chronic DIC are characterized by variable prolongation of clotting times, although clinical bleeding is uncommon. DIC may be caused by hematopoietic and solid neoplasms, viral infections (panleukopenia, feline infectious peritonitis), bacterial and fungal sepsis, systemic protozoal infections and hyperthermia. Clinical bleeding is uncommon.

NUTRITIONAL

- **Vitamin K deficient diet (p 523)**
A diet severely deficient in vitamin K1 or containing a vitamin K antagonist may cause spontaneous internal bleeding and re-bleeding after trauma. Anorexia may contribute to vitamin K deficiency in liver disease.

INFLAMMATION (IMMUNE)

- Circulating anti-coagulant (p 522)

Circulating anti-coagulants may be acquired in immune-mediated diseases and cause spontaneous or excessive bleeding.

IDIOPATHIC

- **Miscellaneous diseases* (p 505)**

Prolongation of clotting times due to unknown mechanisms have been seen with a variety of diseases not typically associated with abnormal bleeding. Clinical bleeding with these abnormalities is uncommon.

TOXIC

- Antibiotics (p 523)

Some antibiotics may exacerbate vitamin K deficiency and antagonism.

- Vitamin K antagonist rodenticides and drugs (p 507)

Poisoning with these compounds may cause severe spontaneous internal bleeding and excessive bleeding following trauma.

- Anti-convulsants (p 523)

Phenobarbital may cause a subclinical vitamin K antagonism.

- Anti-thyroid drugs (p 524)

Anti-thyroid drugs may cause a subclinical vitamin K antagonism.

- Anti-coagulants (p 522)

Anti-coagulant drug overdose may cause spontaneous bleeding.

- **Snake bite envenomation* (p 503)**

Snake venom hematoxins may cause subclinical and clinical bleeding tendencies.

INTRODUCTION

MECHANISM?

Hemostasis following injury to a blood vessel is classically divided into primary hemostasis, secondary hemostasis and fibrinolysis, although there is extensive interaction between these parts.

- **Primary hemostasis** consists of:
 - Vasoconstriction.
 - Formation of the initial platelet plug.
- **Secondary hemostasis** consists of a cascade of coagulation proteins that converts the platelet plug

into a stable fibrin clot. Calcium (factor IV) is needed for most steps in the cascade.

- Secondary hemostasis is classically divided into the extrinsic, intrinsic, and common system, although there is extensive interaction between these pathways.
- The **extrinsic system** (tissue factor pathway) is initiated when tissue factor (factor III) is expressed on the surface of activated subendothelial fibroblasts and monocytes at sites of vascular injury or inflammation. In a simplified view, tissue factor interacts with factor VII to form a tissue factor–activated factor VII complex that amplifies itself and directly activates

factor X (the start of the common system). The extrinsic system is the main pathway for the **initiation** of coagulation in vivo, but it cannot sustain coagulation.

- The **intrinsic system** (contact activation pathway) is activated by exposure to subendothelial tissue following vascular injury. Activation of contact activating factors (factors XII [Hageman], high-molecular-weight kininogen, prekallikrein), XI, IX and VIII occurs. Contact activation by factor XII is probably of minimal importance in initiating normal coagulation in vivo. However, while the extrinsic system is most important for initiating coagulation, the intrinsic system is important in **sustaining** coagulation. In a simplified view, thrombin resulting from extrinsic system activation ultimately results in factors IX and VIII (together with calcium and platelet phospholipid) forming a “tenase complex” on the surface of activated platelets, which activates factor X. The contact activation factors are important in inflammation and fibrinolysis.
- The **common system** is activated by the end-products of the extrinsic and intrinsic systems (i.e. the tissue-factor-activated factor VII and tenase complexes, respectively). In a simplified view, the initial step is activation of factor X, which then activates factor V. Activated factors X and V (together with calcium and platelet phospholipid) form a “prothrombinase complex” on the surface of activated platelets, which activates thrombin (factor II), which in turn converts fibrinogen (factor I) to fibrin. Factor XIII then stabilizes the fibrin clot, converting the fibrin monomer to a fibrin polymer.

- **Fibrinolysis** refers to clot dissolution by the plasminogen-plasmin system.

Bleeding is most often caused by local vascular injury. Normal hemostasis ensues and the degree of bleeding is **appropriate** for the injury. Causes of vascular injury include:

- **Sharp and blunt trauma.** This includes clinical procedures (e.g. venepuncture, dentistry, surgery).
- **Tissue inflammation.** Inflammation disrupts blood vessels and causes vasodilation. The latter increases blood flow to the area and promotes extravasation of red blood cells.

- **Neoplasia.** Neoplasia may disrupt blood vessels, promote inflammation, promote angiogenesis and promote fragile vasculature (e.g. endothelium without a vessel wall).

Bleeding is less often caused by a disorder of primary or secondary hemostasis. Such disorders may cause **subclinical abnormalities** in test results or **abnormal clinical bleeding**.

Abnormal bleeding is spontaneous or excessive.

- **Spontaneous bleeding** occurs as a result of the minor trauma of daily activity.
- Similar to other organ systems, **hemostasis has a large reserve capacity** – a severe deficiency is required for spontaneous bleeding to occur, for example, a platelet count $< 10\text{--}20 \times 10^9/\text{L}$ (10 000–20 000/ μL), or a factor VIII level $< 10\%$ normal is required for spontaneous bleeding to occur.
 - Bleeding diatheses are less common in cats than in dogs.
- **Excessive bleeding** occurs following trauma or development of other local lesions. The degree of bleeding is **inappropriate** for the severity of the lesion.

Bleeding disorders may be **inherited** or **acquired**.

- Inherited disorders are as common in mixed-breed cats as in purebreds.

Multiple mechanisms may contribute to bleeding in an individual patient.

Acute blood loss causes acute anemia and hypovolemia. Signs include lethargy, anorexia, hypothermia, pallor, tachycardia, weak pulses and dyspnea.

Chronic blood loss causes iron-deficiency anemia.

Regardless of cause, acute substantial bleeding may cause signs due to a **space-occupying effect** and/or inflammation incited by the presence of blood. Signs include mucosal and cutaneous swellings (hematomas); neurologic signs from bleeding into or around the central nervous system; lameness, muscle pain, muscle stiffness, joint swelling and joint pain (hemorrhage into muscles and joints); uveitis; dyspnea from pulmonary or pleural hemorrhage, or tracheal compression by a jugular hematoma; acute cardiac tamponade from pericardial hemorrhage (causing tachycardia and hypotension similar to hypovolemia), abdominal **distention** and abdominal pain (presumably due to hemorrhage

within organs), dysuria due to a clot within the bladder, and possibly vomiting due to a clot within the stomach.

WHERE?

Bleeding may be the result of a local lesion or a disturbance in primary or secondary hemostasis.

Bleeding from a **local lesion** may occur into or from any tissue and is **appropriate for the severity of the lesion**.

- Bleeding varies with the severity, type and location of lesion. Hemostasis may be insufficient to stop bleeding, and manipulation of the lesion may reactivate bleeding.
- Presence of blood clots in shed blood rules out a typical coagulopathy, but not a platelet disorder, as the cause of bleeding.

Absence of blood clots in shed blood does not rule in a coagulopathy.

- Initial bloodshed may be too rapid to immediately activate coagulation (e.g. laceration of a large vessel).
- Clots may have been removed (e.g. swallowed) and only red blood cells not incorporated into the clot remain.
- Clot lysis may have occurred.
- Blood in body cavities and the intestinal tract may not clot because of defibrination on epithelial surfaces and clots may be digested.

Vascular disorders may result in either spontaneous or excessive bleeding at the site of the disorder.

- Vascular disease secondary to systemic hypertension commonly causes retinal hemorrhages and less commonly epistaxis.
- Other vascular disorders are not common causes of bleeding in cats.

Platelet disorders may result in either spontaneous or excessive bleeding.

- **Spontaneous bleeding** occurs because blood vessel walls are continuously sustaining minute injuries and being plugged by platelets. A platelet disorder permits bleeding at sites of minute injury in small vessels resulting in the following signs:
 - Bleeding at multiple sites.
 - Petechiation and ecchymoses, especially in dependent areas and areas subject to normally high wear and tear (e.g. gums).

- Bleeding from mucosal surfaces – epistaxis, melena and hematuria.
- Intraocular hemorrhage.

– **Risk of spontaneous bleeding is related to the platelet count**, but quantification of the risk is imprecise, in part because of imprecision in platelet counting, especially in cats (see discussion below). The following values are derived from humans and dogs; cats are at less risk of bleeding for a given platelet count. Indeed, signs of clinical bleeding in cats are usually absent or mild until almost no platelets are evident on a blood smear. Bleeding is worse at a given platelet count if there is concurrent vasculopathy, platelet function defect, coagulopathy, fever, or, possibly, anemia.

- Platelets $< 80 \times 10^9/L$ ($< 80\,000/\mu l$) – increased bleeding at surgery.
- Platelets $< 50 \times 10^9/L$ ($< 50\,000/\mu l$) – microscopic spontaneous bleeding.
- Platelets $< 20 \times 10^9/L$ ($< 20\,000/\mu l$) – mild risk of spontaneous clinical bleeding.
- Platelets $< 10 \times 10^9/L$ ($< 10\,000/\mu l$) – moderate risk of spontaneous clinical bleeding.
- Platelets $< 5 \times 10^9/L$ ($< 5\,000/\mu l$) – severe risk of spontaneous clinical bleeding.

- **Excessive bleeding** may be characterized by:

- Occurrence immediately following injury, because the initial platelet plug does not form.
- Increased rate of bleeding.
- Prolonged bleeding.
- **Prolonged bleeding after venepuncture is one of the most common initial signs of thrombocytopenia.** It should not be dismissed and attributed to the venepuncture technique in a cat at risk for a bleeding disorder.

Coagulopathies may result in either spontaneous or excessive bleeding.

- **Spontaneous bleeding** occurs because vasoconstriction and platelet plugs are insufficient to stop bleeding from larger vessels. Coagulation is necessary, and a coagulopathy permits bleeding from larger vessels into tissues and body cavities resulting in the following signs:
 - More localized bleeding (although widespread hemorrhage may occur).
 - Subcutaneous hematomas and intramuscular hemorrhages.

- Bleeding into body cavities (pleural space, peritoneal cavity, joints).
- Scleral hemorrhage.
- **Excessive bleeding** may be characterized by:
 - Delayed bleeding and rebleeding because the initial platelet plug is not stabilized by a fibrin clot.
 - **Detection of a bruise following venepuncture is one of the most common initial signs of coagulopathy.** It should not be dismissed as a result of venepuncture technique in a cat at risk for a bleeding disorder.
 - Increased rate of bleeding if a larger vessel is injured.

Differences are not absolute between bleeding due to platelet disorders and coagulopathy, and clinical signs overlap. Bleeding patterns seen with both include cutaneous and subcutaneous bleeding at venepuncture sites, gingival bleeding, retinal hemorrhages, cerebral hemorrhages, pulmonary hemorrhages and widespread bleeding.

WHAT?

To diagnose the cause of bleeding:

- Rule out a local lesion.
- Confirm abnormal bleeding with tests of hemostasis.
- Characterize abnormal bleeding as a defect in primary and/or secondary hemostasis based on clinical signs and tests of hemostasis.
- Determine if the hemostatic defect is inherited or acquired.
- Determine the mode of inheritance if inherited.
- Determine an underlying cause if defect is acquired.

The most common causes of bleeding are local lesions – trauma, inflammation and neoplasia.

The most common causes of impaired hemostasis are liver diseases, neoplasia and infectious diseases. Most of the alterations in hemostasis are subclinical.

The most common causes of abnormal clinical bleeding are hepatic lipidosis, retroviral-induced megakaryocytic hypoplasia and vitamin K antagonist poisoning.

TESTS OF HEMOSTASIS

Tests of hemostatic function are necessary to determine what stage of the hemostatic process is abnormal.

If the blood sample is being collected by using a winged-infusion set (“butterfly”), jugular catheter, or vacuum tube draw, then the first 2–5 ml should be discarded or used for serum chemistry determinations. This may reduce platelet clumping and premature activation of coagulation. In most cases a blood sample is obtained by venepuncture using a syringe and needle, in which case the EDTA (platelet count) and citrate tubes (coagulation tests) should be filled first, and the remaining blood used for serum chemistry determinations.

Routine tests of hemostasis include:

- **Platelet count.**
 - Used for detecting **thrombocytopenia**.
 - Platelet counts may be obtained by estimation from a blood smear, manual counting, or with automated cell counters.
 - To **estimate platelet count**, prepare a routinely stained blood smear. Examine the blood smear monolayer where red cells are close together and 50% are touching. Normally there are about 10–30 platelets/oil immersion field (magnification = $\times 1000$); each platelet $\approx 20 \times 10^9/L$ ($20\,000/\mu l$). This requires a properly prepared blood smear. An alternative method that avoids a blood smear uses a disposable counting chamber and supravital stain (ZynoStain, Zynocyte, MA, USA) (Tasker et al, 2001).
 - **Manual counting** may be performed using a Unopette microcollection system (Becton Dickinson) and a hemocytometer.
 - **Automated cell counters** use impedance (Coulter principle), quantitative buffy coat (QBC) or light scattering properties (flow cytometry).
 - Platelet counting in cats has historically been problematic because cats are prone to **artificial thrombocytopenia** due to **platelet clumping**. Platelet clumping results from difficulties in obtaining blood samples and increased aggregability of platelets.
 - Citrate samples are superior to EDTA samples, although platelet clumping may still occur.
 - If a citrated blood sample has been obtained for coagulation testing (see below), consider using this sample for platelet counting.
 - A solution containing citrate, theophylline, adenosine and dipyradamole (CTAD) con-

tains platelet inhibitors and reduces platelet clumping. It is commercially available in a vacuum tube (CTAD tube [formerly Diatube-H], Becton Dickinson).

- Manual agitation and vortex mixing of blood samples does not reliably break up platelet clumps.
- The effect of delay in processing the sample on the platelet count is controversial, but the general recommendation is to perform the platelet count as soon after collection as possible.
- Automated cell counters that use light-scattering technology may detect platelet clumps.
- Some clumping may occur without dropping the platelet count below normal range.
- **Examination of a blood smear is always recommended.** This can be used to verify a platelet count obtained by manual or automated methods. This is especially important when platelet counts are obtained in-house using quantitative buffy coat technology.
 - Closely examine the feather edge of the blood smear to identify platelet clumps. Also examine the blood sample to identify a blood clot in the tube.
 - Evaluation of a blood smear in a bleeding cat will rapidly determine whether or not the cat is bleeding due to thrombocytopenia.
 - If there are ≥ 1 –2 platelets per oil field, it is unlikely the cat is suffering from spontaneous hemorrhage. If there are ≥ 3 –4 platelets per oil field, it is unlikely that the cat will bleed excessively.
 - If platelet clumps are present, the platelet count is probably adequate and bleeding is not due to thrombocytopenia.
- The most reliable results are obtained with manual counting, estimation from a well-prepared blood smear, and automated cell counters using flow cytometry.
- **Reference ranges** vary with the method of counting – a typical range is 200 – $600 \times 10^9/L$ ($200\,000$ – $600\,000/\mu l$).
- **Buccal mucosal bleeding time (BMBT).**
 - BMBT is typically used for detecting disorders of platelet function when platelet numbers are normal.
 - The test is used most often for screening cats with uremia prior to kidney biopsy.
 - Do not routinely perform if cat has thrombocytopenia. **BMBT is usually prolonged when the platelet count is $< 50 \times 10^9/L$ ($50\,000/\mu l$),** and progressive prolongation is expected with worsening thrombocytopenia. A platelet count of 10 – $15 \times 10^9/L$ ($10\,000$ – $15\,000/\mu l$) is likely to result in a BMBT of 5–6 minutes. BMBT may be performed in a cat with thrombocytopenia to detect a concurrent platelet function defect, if bleeding is considered to be excessive for the platelet count and clotting tests are normal.
 - Ketamine-acepromazine sedation is normally used, but BMBT with other sedatives or anesthetics is similar.
 - Place cat in lateral recumbency and fold up the upper lip. Secure the lip with a tightly tied gauze strip passed through the mouth, around the head rostral to the ipsilateral ear, and caudal to the contralateral ear.
 - Avoiding obvious blood vessels, make a 5–6 mm long by 1 mm deep incision in the buccal mucosa of the everted lip above the molars or premolars; this is best done using a spring-loaded device (e.g. Triplett Bleeding Time Device, Helena Laboratories). Blot the blood with a filter paper 1–2 mm from the incision. The incision should not be stretched or touched during the test. However, if a fibrin film forms over the incision it should be teased away using the filter paper to touch the blood as it wells up.
 - **Normal BMBT is 1–3.25 min.**
 - **Prolonged BMBT in an animal with a normal platelet count indicates a vascular defect, platelet function defect or von Willebrand's disease.** Anemia will prolong bleeding time in humans, rabbits, and dogs, but this effect has not been evaluated in cats. A coagulopathy will not immediately affect BMBT, but rebleeding may occur. If the incision is made in an inflamed area, bleeding time will be prolonged.
 - In general, the longer the BMBT value, the more likely the risk of bleeding, but there are no precise values defining the risk.
- **Activated clotting (coagulation) time (ACT).**
 - The intrinsic system is initiated by contact activation. In the ACT siliceous (diatomaceous) earth or glass particles are used to provide a very

large surface for contact activation. Blood clots via the intrinsic and common pathways.

- Add 2 ml fresh blood to an ACT tube pre-warmed to 37°C using a heating block or human axilla. Invert the tube rapidly five times and incubate at 37°C for 60 s. Quickly tip the tube gently to observe for clot formation. If no clot is observed, quickly re-incubate for another 10 seconds, and then re-examine for clot formation. Repeat observations every 10 seconds until the very first signs of a clot appear. **Time to first clot formation is the activated clotting time.** After clot formation is first noted, re-incubate and re-examine every 10 seconds. A complete solid clot, which is detected by tipping the tube upside down, normally forms within another 10 s. The formation of an incomplete “soft” clot is indicative of the presence of heparin (in low concentration) or low fibrinogen levels.
- Earlier **reported ranges for ACT in cats** vary from < 65–75 s to 60–125 s. In the author’s practice the accepted range is 60–90 s. In a recent study (Bay et al, 2000), normal range was 55–165 s.
 - In that study, blood was collected by direct draw into ACT vacuum tubes. The most common practice is to collect blood with a syringe, and then inject the blood into the ACT tube. It is possible that syringe collection and injection shortens ACT by increasing platelet activation (although this is not important in humans), and by initiating coagulation before the blood enters the ACT tube.
 - Traumatic venepuncture inconsistently prolongs ACT.
- **Prolonged ACT indicates a defect in the intrinsic or common system of coagulation.**
 - The clotting process requires phospholipid from the platelets in the blood, so it has been suggested that **severe thrombocytopenia** ($<10 \times 10^9/\text{L}$ [$<10\,000/\mu\text{L}$]) may also prolong ACT. This has not been proven in the cat, and probably a virtual absence of platelets would be necessary.
- ACT is not affected by sedation with ketamine and acepromazine.
- Although ACT depends to some extent on the operator, a defect in the intrinsic or common pathway causing clinical bleeding will usually result in an ACT > 1.5–2 min.

- There is **no direct correlation between the degree of prolongation of ACT and the risk for bleeding.** The risk for bleeding at a given ACT value will vary with the underlying disorder causing the coagulation abnormality. In general, for a given disorder, the longer the ACT value the more likely the risk of bleeding, but there are no precise values defining the risk.

● **Activated partial thromboplastin time (aPTT).**

- In this test, calcium, a contact activator and a platelet phospholipid substitute are added to plasma, and the time to clot formation is measured. Normal blood clotting via the intrinsic system requires contact activation and the thromboplastin effect of platelet phospholipid. (A thromboplastin is a substance having procoagulant activity.) The various platelet phospholipid substitutes used in the test have only partial thromboplastin activity, hence the name of the test.
- Most laboratories perform this assay with a fibrometer or photo-optical device, which detects the formation of fibrin strands. The assay should only be performed in a laboratory that has validated its assay for use in cats.
- Blood is collected into 3.2% citrate anti-coagulant (9 parts blood:1 part citrate). Underfilling, overfilling or a clot in the citrate tube invalidates the results. The margin for error in the blood:citrate ratio in cats is not known. Citrate vacuum tubes are designed to draw the correct amount of blood.
- The sample should be centrifuged promptly and kept refrigerated or frozen until assayed. If the sample cannot be centrifuged promptly, it should be refrigerated until assayed.
- Prolonged aPTT > 20–25% of a control sample (prepared from a pool of donors) and/or outside the normal range indicates a defect in the intrinsic or common system of coagulation.
 - It may also be beneficial to submit an additional control sample from a clinically normal cat collected and handled in exactly the same manner as the patient sample in order to detect artifactual prolongation of the aPTT.
- When comparing serial test results, results from one laboratory cannot be directly compared against results from another laboratory because of differences in methodology, including use of different thromboplastins.

- As with ACT, there is no direct correlation between the degree of prolongation of aPTT and the risk for bleeding. The risk for bleeding at a given aPTT value will vary with the underlying disorder causing the coagulation abnormality. In general, for a given disorder, the longer the aPTT value the more likely the risk of bleeding, but there are no precise values defining the risk.

- **Prothrombin time (PT).**

- This test is similar to the aPTT, except that a thromboplastin with tissue factor-like activity is added in excess to the test system, thus mimicking the extrinsic system. The assay should only be performed in a laboratory that has validated its assay for use in cats.
- Collect sample as for aPTT.
- Prolonged PT > 20–25% of control sample and/or outside the normal range indicates a defect in the extrinsic or common system of coagulation.
- It may also be beneficial to submit an additional control sample from a clinically normal cat collected and handled in exactly the same manner as the patient sample in order to detect artifactual prolongation of the PT.

When comparing serial test results, results from one laboratory cannot be directly compared against results from another laboratory because of differences in methodology, including use of different thromboplastins. To facilitate comparison in humans an international normalized ratio (INR) may be calculated as $INR = (\text{patient PT} / \text{mean normal PT})^{ISI}$, where ISI represents the international sensitivity index of the thromboplastin. The validity of using INR in cats has not been extensively evaluated.

- PT results are typically shorter than aPTT results.
- As with ACT and aPTT, there is no direct correlation between the degree of prolongation of PT and the risk for bleeding. The risk for bleeding at a given PT value will vary with the underlying disorder causing the coagulation abnormality. In general, for a given disorder, the longer the PT value the more likely the risk of bleeding, but there are no precise values defining the risk.
- **Proteins induced by vitamin K antagonism or absence (PIVKA).**

- PIVKA clotting time is similar to PT, but a **different thromboplastin is used** to activate coagulation, and the **plasma is diluted, resulting in longer clotting times**. The test was introduced as a **more sensitive assay than the standard PT** for monitoring warfarin therapy in humans. The assay is more sensitive both because the thromboplastin is more sensitive to factor X deficiency, and because the longer clotting times facilitate detection of subtle changes. It is also believed, but not proven, that the test is more sensitive than the PT to detect vitamin K deficiency or antagonism because the PIVKAs (uncarboxylated clotting factors, see Vitamin K antagonist poisoning, below) inhibit the thromboplastin and the factor X conversion of prothrombin to thrombin.

- **PIVKA time is a modified PT, and does not actually measure concentration of PIVKAs.**

- The test was first introduced as the Thrombotest™, and this name is used interchangeably with PIVKA. The former is recommended to avoid the confusion that arises from the term PIVKA.
- PIVKA time is more sensitive than PT to detect subclinical and clinical coagulopathies in cats due to vitamin K deficiency.
 - Most cats (> 95%) with a bleeding tendency due to vitamin K deficiency will have a prolonged PIVKA time.
 - It is controversial whether or not PIVKA time is more sensitive than the PT for the detection of vitamin K antagonism in dogs. This has not been evaluated in cats. Certainly any cat with clinical hemorrhage due to vitamin K antagonist poisoning will have a prolonged PT. PIVKA time may be more useful than PT for the monitoring of warfarin therapy for prophylaxis of thromboembolism in cats with cardiomyopathy.
- PIVKA time is not specific for vitamin K deficiency or antagonism. Similar to the PT, **it will be prolonged in any disorder affecting factors II, VII, IX and X**, including congenital factor VII deficiency and some cases of DIC.
- Collect sample as for PT and aPTT.
- Although the Thrombotest is a simple test for a reference laboratory to perform, it is not as

widely offered by such laboratories as are PT and aPTT. Point-of-care instruments are available.

- **Thrombin time (TT) and fibrinogen (factor I) level.**

- Thrombin measures the time required for thrombin to convert fibrinogen to fibrin. The test is performed by adding thrombin to diluted citrated plasma.
- Collect sample as for aPTT and PT.
- Prolonged TT is due primarily to hypofibrinogenemia and thus **TT is a precise method to assay fibrinogen level.** Thrombin time is also **prolonged by inhibitors such as heparin and fibrin degradation products.**

- **Fibrinogen level** can also be measured in a clinic or laboratory by heat precipitation as follows (this method is best for measuring increased levels of fibrinogen and may not be sufficiently sensitive to measure decreased levels):

- Fill two microhematocrit tubes with EDTA (or citrated) blood.
- Immerse one of the tubes in a 56–58°C (133–136°F) water bath for 3 minutes to precipitate fibrinogen.
- Centrifuge both tubes at standard rate and time, and measure microhematocrit and total protein (using a refractometer).
- [Total Protein in the room temperature sample (albumin + globulin + fibrinogen)] – [Total Protein in the heated sample (albumin + globulin)] = fibrinogen.
- An alternative, less precise, method is to obtain serum from a separate clot tube and subtract total protein in the serum sample from total protein in the plasma sample.

- Several other methods for measuring fibrinogen level, including immunologic assays, are in use in reference laboratories.

- **Fibrin-degradation products (FDPs).**

- FDPs are the breakdown products of fibrinogen and fibrin monomers by plasmin.
- The latex agglutination test is most commonly used.
- This was originally exclusively a serum test, where blood is collected in a special tube containing a soybean trypsin inhibitor and fer-de-lance (*Bothrops atrox*) venom to promote rapid and complete clotting of the sample. The rapid clotting facilitates emergency testing, while the complete clotting circumvents

inhibition of clotting in samples from patients treated with heparin. The venom typically causes hemolysis of the sample.

- Assays that use citrated plasma are now available. This facilitates measurement of FDPs as part of a coagulation screen.

- **Increased FDPs suggest accelerated fibrinolysis by the plasmin system.**

- **The test is infrequently positive in cats.**

- D-dimers, measured by immunologic assays, are another marker of fibrinolysis, and represent breakdown products of cross-linked fibrin. Little is currently known of the utility of d-dimer measurement in cats.

- **Schistocytes and other poikilocytes.**

- Fragmented and other abnormal red cells may appear with disseminated intravascular coagulation (DIC).

- **Specialized tests of hemostasis.**

Other tests of hemostasis are used in research laboratories and may be required to investigate a novel bleeding disorder.

- **Platelet aggregation** is the test most often used to further investigate a defect of primary hemostasis. In the most widely used method, various aggregating agents are added to platelet-rich plasma, and a **change in plasma turbidity** is detected by a spectrophotometer as the platelets aggregate. Whole blood aggregometry is an alternative, but less widely used, technique. Platelet aggregation is very sensitive, and in vitro defects may not result in clinically relevant effects.

DISEASES CAUSING BLEEDING

LOCAL LESIONS CAUSING LOCALIZED HEMORRHAGE***

Classical signs

- Clinically evident localized bleeding.
- Local signs of trauma, inflammation or neoplasia.

Clinical signs

Diseases where clinical bleeding may be the chief complaint or a clinical problem include:

- **Bleeding into or from skin, underlying tissues, ears and footpads** with lacerations, puncture wounds, blunt trauma, ruptured cat bite abscesses and bleeding tumors (see The Cat With Skin Lumps and Bumps, page 1067 and The Cat With Non-Healing Wounds, page 1081). Vasculitis usually results in edema, but may rarely cause local bleeding.
- **Bleeding from oral cavity** due to lacerations and puncture wounds, periodontal disease, and oral neoplasms (see The Cat With Bad Breath or Oral Lesions, page 602).
- **Epistaxis** from nasal trauma, rhinitis and neoplasms (see The Cat With Upper Respiratory Tract Signs of Chronic Nasal Disease, page 19).
- **Ocular hemorrhage** from corneoscleral lacerations, severe uveitis, and ocular neoplasms (see The Cat With Eye Problems, page 1165).
- **Hematuria** from major trauma to the kidney or bladder, idiopathic lower urinary tract disease, neoplasms of the kidney or bladder (see The Cat With Urinary Tract Signs, page 173). Clot formation in the bladder may cause or exacerbate signs of lower urinary tract disease.
- **Vaginal bleeding** from pyometra, spontaneous abortion or lochia (see The Infertile Queen, page 1145).
- **Melena** from intestinal neoplasia, which may cause iron-deficiency anemia (see The Cat With Signs of Gastrointestinal Tract Disease, page 578).
- **Hematochezia** from colitis (and rarely acute enteritis), and colonic and anorectal neoplasms (see The Cat With Signs of Gastrointestinal Tract Disease, page 578).
- **Hemoptysis** from major blunt trauma, acute heart failure and less commonly lung lobe torsion and primary lung neoplasms (see The Dyspneic or Tachypneic Cat, page 47).
- **Hemothorax** from major blunt trauma, penetrating trauma and spontaneous bleeding from the thymus (see The Dyspneic or Tachypneic Cat, page 47).
- **Hemopericardium** from major blunt trauma, penetrating trauma or neoplasia (rare) (see The Dyspneic or Tachypneic Cat, page 47).
- **Hemoperitoneum** from major blunt trauma, penetrating trauma, liver disorders (especially hepatic amyloidosis and peliosis hepatis), and bleeding neoplasms (see The Cat With Abdominal Distention or Abdominal Fluid, page 443).

Diagnosis

See the appropriate chapters listed above.

Tests of hemostasis (platelet count, BMBT, ACT, aPTT, PT) are either normal or not sufficiently abnormal to account for the hemorrhage.

Differential diagnosis

If a local lesion is not apparent, a hemostatic defect is likely.

Local lesions and hemostatic defects may be concurrent.

Systemic hypertension may cause retinal hemorrhages and epistaxis.

Treatment

Treat the local lesion – see the appropriate chapters listed above.

Use fluid therapy and/or whole blood transfusion (10–20 ml/kg) to correct acute hypovolemia and anemia.

MOTOR VEHICLE AND OTHER MAJOR BLUNT TRAUMA***

Classical signs

- Shorn nails, fractured mandible, fractured pelvis, dyspnea.

Clinical signs

External signs of trauma include shorn nails, and bleeding from skin and oral cavity lacerations.

Internal signs of trauma include palpable fractures, non-palpable bladder, hemoperitoneum and dyspnea from pneumothorax, hemothorax, diaphragmatic hernia, pulmonary contusions, neurogenic pulmonary edema, shock and pain.

The cat may be in **shock** with pale mucous membranes and weak pulses.

Diagnosis

Diagnosis is facilitated if the event is witnessed, e.g. hit by motor vehicle, fall from a height, kicked by a horse.

Physical examination findings consistent with trauma are supportive evidence.

Radiographic findings often reveal fractures and thoracic abnormalities. Intra-abdominal bleeding may cause loss of detail on abdominal radiographs, but ultrasound, abdominocentesis and diagnostic peritoneal lavage are superior for its detection.

- Thoracic injuries and resulting dyspnea are more common and clinically important than abdominal injuries following blunt trauma in cats. Abdominal hemorrhage may occur, but is rarely life threatening.

Hemostatic testing is usually normal in traumatized cats, although mild thrombocytopenia may occur secondary to massive bleeding. Trauma does not appear to be an important trigger for DIC in cats.

Differential diagnosis

Differential diagnoses for hemoperitoneum include anti-coagulant rodenticide poisoning, inherited coagulopathy (e.g. hemophilia A and B), ruptured neoplasm (e.g. hemangiosarcoma) and spontaneous bleeding from a diseased liver (e.g. amyloidosis, peliosis hepatis).

Differential diagnoses for hemothorax include anti-coagulant rodenticide poisoning, inherited coagulopathy (e.g. hemophilia A and B), and spontaneous bleeding from the thymus.

Treatment

See the appropriate chapters for treatment of specific traumatic disorders.

RENAL FAILURE***

Classical signs

- Lethargy, inappetence, weight loss, polyuria, polydipsia.
- Pale mucous membranes (anemia).

See main reference, page 235 (The Cat With Polyuria and Polydipsia).

Clinical signs

Cats with chronic renal failure show varying **lethargy, inappetence, weight loss, polyuria, polydipsia**, intermittent vomiting and anemia.

Uremic stomatitis and uremic gastroenteritis may cause bleeding in acute and chronic renal failure, contributing to anemia in the latter.

Hypertension may cause retinal hemorrhages and/or retinal detachment.

Hemolytic-uremic syndrome is an uncommon complication of renal transplantation.

Diagnosis

Hemostatic testing is usually normal.

- Mildly prolonged aPTT and mild thrombocytopenia (mechanisms not known) have been seen in chronic renal failure.
- Uremic thrombocytopathia has not been documented in cats, but probably occurs. Determining BMBT prior to renal biopsy is recommended.
- Hemolytic-uremic syndrome results in thrombocytopenia.

Differential diagnosis

If a cat with chronic renal failure is showing signs of acute bleeding other than retinal hemorrhages, a concurrent local or hemostatic disorder should be pursued.

Treatment

The use of **H2-blockers and/or sulcralfate** may reduce **gastrointestinal bleeding**.

Dental prophylaxis may reduce oral cavity bleeding.

Amlodipine, enalapril or benazapril is recommended for treatment of **hypertension** (see The Blind Cat or Cat With Retinal Disease, page 1171).

No specific treatment is recommended for the hemostatic disorders. If BMBT is prolonged and requires correction prior to an invasive procedure, treatments useful in humans and/or dogs include:

- **Whole blood or packed red cell transfusion, or recombinant human erythropoietin therapy** to improve anemia, because uremic bleeding is worse at a lower hematocrit.
- **Fresh-frozen plasma or cryoprecipitate transfusion**, or desmopressin to improve von Willebrand's factor level and/or function, because defects in von

Willebrand's factor may contribute to the thrombocytopathia (in humans) and augmenting von Willebrand's factor may compensate for non-von Willebrand's factor-dependent defects. Fresh-frozen plasma and cryoprecipitate may also contain functional platelet microparticles. Recombinant factor VIIa is beneficial in humans.

- Peritoneal or hemodialysis, to reduce uremic toxins that contribute to bleeding.

SYSTEMIC HYPERTENSION**

Classical signs

- Retinal hemorrhages.
- Epistaxis.
- Signs of the underlying disease.

Clinical signs

Sustained systemic blood pressure leads to vascular damage manifested clinically most often as **retinal hemorrhages** and less frequently as **epistaxis**.

Cats with **chronic renal failure** (the most common cause of hypertension) will have varying lethargy, inappetence, weight loss, polyuria, polydipsia and intermittent vomiting.

Cats with **hyperthyroidism**, **diabetes mellitus** and **hyperadrenocorticism** may have systemic hypertension but bleeding and other signs of organ damage do not commonly occur without concurrent renal failure.

Cats with **multiple myeloma** show non-specific signs of lethargy, inappetence and weight loss.

Cats with **polycythemia vera** have dark mucous membranes and may seizure.

Hyperaldosteronism (may cause weakness and polyuria/polydipsia due to hypokalemia) and **pheochromocytoma** (may cause polyuria/polydipsia) can cause hypertension, but the risk for abnormal bleeding is not known. These disorders are both rare in the cat.

Diagnosis

Routine work-up is required to identify the primary disease.

Hemostatic testing is normal or may identify abnormalities secondary to underlying (e.g. myeloma) or concurrent (e.g. FIV infection) diseases.

Differential diagnosis

Differential diagnoses for retinal hemorrhages include a platelet disorder or coagulopathy.

Differential diagnoses for epistaxis include trauma, rhinitis, neoplasia, a platelet disorder or coagulopathy.

Treatment

Amlodipine, enalapril or benazapril are used most often to treat renovascular hypertension (see The Blind Cat or Cat With Retinal Disease, page 1171).

For other conditions, treatment of the primary disease may be sufficient to resolve hypertension.

MEGAKARYOCYTIC HYPOPLASIA**

Classical signs

- Signs of the primary disease such as leukemia, lymphoma, FeLV/FIV infection, histoplasmosis (e.g. fever, inappetence, weight loss, gingivitis, lymphadenopathy, hepatosplenomegaly, dyspnea, diarrhea).
- Signs of concurrent cytopenias (e.g. pale mucous membranes from anemia, fever secondary to neutropenic sepsis).
- History of drug use known to cause myelosuppression.
- Platelet disorder bleeding (e.g. prolonged bleeding after venepuncture, melena, epistaxis, petechiation).

Pathogenesis

Megakaryocytic hypoplasia reduces platelet production (hypoproliferative thrombocytopenia).

Megakaryocytic hypoplasia occurs most commonly as part of generalized bone marrow failure or dyshematopoiesis resulting in pancytopenia. Causes of bone marrow failure include:

- **Hematopoietic neoplasia** causing myelophthisis. Neoplasms include lymphoid leukemia, myeloid

leukemia, myelodysplastic syndrome, multiple myeloma, malignant histiocytosis and mast cell tumor.

- **Infections** causing generalized bone marrow failure or dyshematopoiesis. Infectious agents include feline leukemia virus, feline immunodeficiency virus, *Histoplasma capsulatum*, and, possibly, *Ehrlichia* spp.
 - Feline panleukopenia virus infection causes transient myelosuppression, but acute thrombocytopenia is due to disseminated intravascular coagulation.
- **Cytotoxic anticancer drugs** and large-field radiation therapy produce predictable dose-dependent effects.
 - Cats are more sensitive to azathioprine toxicosis than dogs, probably because of decreased levels of thiopurine methyltransferase, the enzyme responsible for the drug's metabolism.
- **Idiosyncratic, immune-mediated, and toxic drug reactions** have been reported with chloramphenicol, griseofulvin (especially in FIV-infected cats), cephalosporins, ribavirin, albendazole, anti-thyroid drugs (propylthiouracil, methimazole, carbimazole), and phenobarbital.

Occasionally no cause is found and/or megakaryocytic hypoplasia is the only bone marrow abnormality. Some of the idiopathic cases are due to immune-mediated mechanisms. A diagnosis of immune-mediated hypoplasia is usually based on ruling out other causes of megakaryocytic hypoplasia, presence of other disorders that are typically immune-mediated, and response to immunosuppressive therapy.

Clinical signs

In most cases thrombocytopenia is noted during work-up of the primary disease or work-up of other signs, e.g. fever.

Clinical bleeding is occasionally the chief complaint or noted during examination or work-up.

Spontaneous bleeding includes petechiation, ecchymoses, epistaxis, ocular hemorrhages, hematuria and melena.

Excessive bleeding is usually first noted as **bleeding from venepuncture sites**. Biopsy sites, suture lines and other local lesions may also bleed excessively.

Signs due to anemia (e.g. pale mucous membranes, tachycardia) and local effects of hemorrhage (e.g. hematoma formation) vary with severity and acuteness of blood loss.

Signs of underlying hematopoietic neoplasia, FeLV or FIV infection, or histoplasmosis include fever, inappetence, weight loss, lymphadenopathy, hepatosplenomegaly, dyspnea and diarrhea.

- FeLV or FIV infection may cause gingivitis.

Fever may be present due to spontaneous infection secondary to concurrent neutropenia.

Diagnosis

History and physical examination findings are consistent with a primary disease (e.g. drug therapy).

A complete blood count will reveal thrombocytopenia.

- **Artifactual thrombocytopenia** is common in cats. A platelet count generated by a laboratory instrument or manual count should be verified with a blood smear, and the blood smear should be closely examined for platelet clumps.

Bone marrow biopsy will reveal **megakaryocytic hypoplasia**. Concurrent erythroid hypoplasia, myeloid hypoplasia and neoplasia may also be identified.

- If feline leukemia virus infection is suspected but peripheral blood tests are negative, then obtain a fluorescent antibody (FA) or PCR test on a bone marrow aspirate or ELISA test on a bone marrow core biopsy. **It should be noted that PCR testing has not been standardized and is more likely to give false-positive results than ELISA and FA if the laboratory does not maintain the highest standards of quality control.**

Differential diagnosis

Other causes of thrombocytopenia are usually associated with normal to increased platelet counts on bone marrow biopsy. For many of these causes the primary disease is sufficiently characterized on routine work-up to explain thrombocytopenia without the need for bone marrow biopsy. Other causes of thrombocytopenia include:

- DIC (**platelet consumption**).
- Immune-mediated thrombocytopenia (**platelet destruction**). This is a rare disorder in the cat.
- Marked splenomegaly (**platelet sequestration**). This is an uncommon cause of thrombocytopenia in the cat.
- Severe bleeding (**platelet loss**).
 - **Severe bleeding** may result in mild thrombocytopenia. In a series of cats with anticoagulant rodenticide poisoning, a platelet count as low as $58 \times 10^9/\text{L}$ (58,000/ μl) was noted (reference 9). If severe bleeding is associated with mild thrombocytopenia, it is more likely that the low platelet count is a result of, rather than the cause of, the bleeding.

Treatment

Treat the primary disease if possible.

Thrombocytopenia may be transiently improved by **transfusion of fresh whole blood, platelet-rich plasma, or fresh-frozen plasma** (which contains functional platelet particles), 10–20 ml/kg, or platelet concentrate, 1–2 units/cat.

- This is recommended before biopsy of internal organs if the platelet count is $< 50 \times 10^9/\text{L}$ (50 000/ μl).
- Platelet transfusions may be used prophylactically against spontaneous hemorrhage in humans with platelet counts $< 10\text{--}20 \times 10^9/\text{L}$ (10 000–20 000/ μl). This is not recommended in cats because spontaneous critical hemorrhage is rare in thrombocytopenic cats, and because most practices have a limited donor blood supply.

Augmenting one part of hemostasis compensates to some extent for a deficiency in another part. To this end **inhibitors of fibrinolysis** (e.g. aminocaproic acid), which augment coagulation, have been useful in treating thrombocytopenia in humans but have not been evaluated in cats.

General treatment measures for cats with a bleeding tendency include the following recommendations. These are most important in cats with moderate to marked defects in hemostasis:

- Minimize exuberant exercise and risk for trauma at home (keep indoors).

- Handle gently in the hospital and provide a well-padded cage.
- Feed soft food to minimize gingival trauma.
- Minimize invasive procedures and injections. If injection is required, use 25-G or smaller needles. The intravenous route is preferred (with the exception of vitamin K). Subcutaneous and especially intramuscular injections may cause hematomas that may impair absorption of the drug in addition to causing discomfort.
- Apply moderate manual pressure or pressure bandages to sites of active bleeding when possible.
- Do not drain hematomas unless they are causing a problem (e.g. tracheal compression).
- Avoid over-exuberant intravenous fluid therapy, which dilutes platelet and coagulation factor concentrations. Synthetic colloids may cause platelet dysfunction.
- Avoid drugs that significantly decrease platelet function (e.g. aspirin), antagonize vitamin K, or have direct anti-coagulant effects (e.g. heparin).
 - **Penicillins, some cephalosporins, tetracyclines, gentamicin and sulfa drugs** have been demonstrated to **variably impair platelet function in vitro or in vivo** in humans, rabbits or dogs. Worsening hemorrhage is likely to be seen only in severely thrombocytopenic patients. Effects of these drugs in cats are not known. However, amoxicillin, cefazolin, cephalixin, doxycycline, and enrofloxacin at standard doses do not impair platelet function in normal dogs and are unlikely to have any clinically relevant hemostatic effects in cats.
 - Acepromazine and some antihistamines impair platelet function in humans. Acepromazine does not impair platelet function in dogs and these drugs are unlikely to have any clinically relevant hemostatic effects in cats.

Prognosis

Prognosis is determined by the primary disease.

If megakaryocytic hypoplasia cannot be promptly corrected and if the cat is clinically bleeding from severe thrombocytopenia, the prognosis for long-term transfusion support is poor because of donor exhaustion and possibly platelet alloimmunization.

LIVER DISEASE**

Classical signs

- Lethargy, inappetence, weight loss, vomiting, icterus.
- Spontaneous or excessive bleeding may occur.

See main reference page 421 (The Yellow Cat or Cat With Increased Liver Enzymes).

Pathogenesis

The **most common causes of liver disease in the cat are lipidosis, cholangiohepatitis and lymphoma**. Less common causes include congenital portosystemic shunts, amyloidosis, non-lymphoid neoplasia, feline infectious peritonitis, peliosis hepatis, toxoplasmosis and toxins (e.g. diazepam).

Liver disease may cause bleeding tendencies by several mechanisms including:

- Acquired platelet function defects (not proven in cats).
- Decreased synthesis of coagulation factors.
 - Primary **hepatocellular failure affecting synthesis** of all factors.
 - **Vitamin K deficiency** (contributing to coagulopathy in about 50% of cases).
 - Intrahepatic **cholestasis** and extrahepatic bile duct obstruction prevent release of **bile acids** into the small intestine that are **needed for absorption of vitamin K1 and K2**.
 - Anorexia and antibiotic therapy contribute to vitamin K deficiency.
- Synthesis of abnormal prothrombin (not proven in cats).
- **DIC** causing consumption of platelets and coagulation factors.
- **Decreased clearance of plasminogen activators** thus promoting fibrinolysis (not proven in cats).

In general, **fever decreases the half-life of coagulation factors** and wound healing increases consumption of coagulation factors (e.g. after exploratory laparotomy). Both of these may be present with liver disease.

The **liver may be more fragile** with hepatic lipidosis, amyloidosis and peliosis hepatis increasing the risk of bleeding after liver biopsy. Spontaneous hemoperi-

toneum may occur with amyloidosis and peliosis hepatis.

Coagulation abnormalities are **more likely** to be present if there is **concurrent pancreatitis**.

Clinical signs

More than 80% of cats with liver disease may have a coagulation abnormality, but **abnormal clinical bleeding is uncommon**.

Excessive bleeding may occur following venepuncture and liver biopsy.

Severity of coagulopathy correlates to some extent to increase in alkaline phosphatase value, likely due to cholestasis.

In other species acute bleeding into the intestinal tract may precipitate hepatic encephalopathy, but this has not been documented in the cat.

Diagnosis

Combining results of several studies, coagulation abnormalities may be categorized as follows:

- **Vitamin K deficiency:** Normal platelet count, prolonged PT, \pm prolonged aPTT, normal TT.
- **Synthesis failure:** Normal platelet count, prolonged PT, prolonged aPTT, prolonged TT.
- **Indeterminate:** Normal platelet count, normal PT, prolonged aPTT, normal TT.
- **DIC:** Low platelet count, prolonged PT, prolonged aPTT, prolonged TT; or 3 of the following: low platelet count, prolonged PT or aPTT, prolonged TT or hypofibrinogenemia, decreased antithrombin III (not routinely available), presence of FDPs, red blood cell fragments.

Vitamin K deficiency may also be identified by improvement in coagulation following vitamin K1 therapy.

PIVKA time is more sensitive in identifying abnormal coagulation than are PT and aPTT. Cats may show a bleeding tendency with a prolonged PIVKA time and normal PT and aPTT.

More than one mechanism may contribute to coagulopathy.

Differential diagnosis

In most cases the cat with liver disease is presented for subacute to chronic non-specific signs and coagulopathy is identified in the work-up of liver disease.

A large number of disorders may be associated with subacute non-specific signs and subclinical coagulopathy, including neoplasia, retroviral infections, FIP, heart disease and pancreatitis. Routine work-up will help identify the primary disease.

Treatment

Vitamin K1, 2.5–5 mg/kg SC for 1–2 days, will usually **normalize PT and aPTT in 1–2 days** if vitamin K deficiency is solely responsible for coagulopathy. (**PIVKA values take 3–5 days to normalize.**) The need for further vitamin K1 therapy will depend on success of managing the primary disease.

Prognosis

Prognosis is determined by the primary liver disease.

Prognosis for resolution of a vitamin K deficient state is excellent.

FELINE LEUKEMIA VIRUS (FeLV) INFECTION**

Classical signs

- Lethargy, inappetence, weight loss, unkempt haircoat, fever, anemia, gingivitis, recurrent upper respiratory infections, opportunistic infections.
- Cats with megakaryocytic hypoplasia may have platelet disorder type bleeding.

See main reference on page 540 (The Anemic Cat).

Pathogenesis

FeLV infection can cause bleeding tendencies by several mechanisms. These include:

- **Megakaryocytic hypoplasia.**
- Immune-mediated platelet destruction.
- DIC secondary to infections and neoplasia.

Clinical signs

Clinical bleeding is uncommon except with severe thrombocytopenia, in which case bleeding is typical of platelet disorders, e.g. petechiation, epistaxis, melena, prolonged bleeding after venepuncture.

Diagnosis

FeLV antigen test.

- Bleeding tendencies are most likely to **occur during persistent viremia**, in which case ELISA and FA tests are usually both positive.
- If peripheral blood tests are negative and another cause of megakaryocytic hypoplasia has not been determined, obtain a FA or PCR test on a bone marrow aspirate or ELISA test on a bone marrow core biopsy. **It should be noted that PCR testing has not been standardized and is more likely to give false-positive results than ELISA and FA if the laboratory does not maintain the highest standards of quality control.**

Hemostatic testing may reveal thrombocytopenia, and prolonged PT, ACT, and aPTT and hypofibrinogenemia if DIC is present.

Differential diagnosis

The main cause of clinical bleeding in FeLV-infected cats is megakaryocytic hypoplasia. If a FeLV-positive cat is bleeding without severe thrombocytopenia (usually platelets $< 20 \times 10^9/L$, $< 200\,000/\mu l$), another hemostatic disorder should be investigated.

A concurrent disease may be responsible for sub-clinical hemostatic defects including liver disease, cardiomyopathy, pancreatitis, renal failure, other systemic infections, lymphoma and other neoplasms, and snakebite envenomation and other toxicoses.

Feline immunodeficiency virus (FIV) infection causes similar signs to FeLV infection and may also cause megakaryocytic hypoplasia and other hemostatic defects. An FIV test may be used to rule this out.

Most causes of megakaryocytic hypoplasia, ITP and DIC may be identified by routine work-up.

Treatment

Thrombocytopenia and other hemostatic defects may be transiently improved by transfusion of **fresh**

whole blood, platelet-rich plasma, or fresh-frozen plasma (which contains functional platelet particles), 10–20 ml/kg. Bleeding due to **thrombocytopenia** may also be treated with platelet concentrate, 1–2 units/cat.

- Transfusion is recommended **before biopsy** of internal organs **if the platelet count is** $< 50 \times 10^9/L$ (50,000/dl).

Treat infections and neoplasia.

Recombinant human **interferon- α** , 1 unit/cat PO q 24 h may ameliorate myelosuppression.

Bone marrow transplantation for megakaryocytic hypoplasia may be considered if available.

Prognosis

Prognosis for severe FeLV-induced megakaryocytic hypoplasia is poor.

Long-term prognosis with other hemostatic defects is determined by the FeLV-associated underlying disease.

FELINE IMMUNODEFICIENCY VIRUS (FIV) INFECTION**

Classical signs

- Lethargy, inappetence, weight loss, unkempt haircoat, fever, generalized lymphadenopathy, gingivitis, diarrhea, dermatitis, recurrent upper respiratory infections, opportunistic infections, neurologic signs, uveitis.
- Various hemostatic abnormalities may occur but are usually subclinical.

See main reference on page 339 (The Thin, Inappetent Cat).

Pathogenesis

The following hemostatic defects may occur with FIV infection:

- **Thrombocytopenia.** This may be due to the primary infection or secondary to other disease

processes, e.g. neoplasia, bone marrow failure with griseofulvin therapy.

- FIV infection in-itself does not commonly cause severe megakaryocytic hypoplasia.
- FIV infection in-itself does not appear to cause platelet function defects.

- **Prolongation of aPTT.** The mechanism is not known, but it is not due to specific factor deficiencies, DIC, or a circulating inhibitor.
- **Prolongation of TT.** The mechanism is not known, but it is not due to hypofibrinogenemia or dysfibrinogenemia.
- **DIC** secondary to infections and neoplasia.

Clinical signs

Clinical bleeding is uncommon.

Severe thrombocytopenia may cause bleeding typical of platelet disorders, e.g. petechiation, epistaxis, melena, prolonged bleeding after venepuncture.

Prolongation of the aPTT and TT do not result in abnormal bleeding.

Diagnosis

FIV antibody test (ELISA, FA, western blot).

- Antibody is **usually detectable within 2 months** of infection, but may take up to 6 months, therefore a negative test should be repeated if FIV is being considered in the differential diagnoses of a cat with thrombocytopenia.
- PCR test for viral DNA. **It should be noted that PCR testing has not been standardized and is more likely to give false-positive results than antibody tests if the laboratory does not maintain the highest standards of quality control.**

Neutropenia and lymphopenia are common concurrent hematologic abnormalities in symptomatic cats.

Hemostatic testing may reveal the following abnormalities due to FIV infection: low to normal platelet count, normal BMBT unless thrombocytopenic, shortened to normal PT, normal to prolonged ACT and aPTT, normal to prolonged TT and normal to increased fibrinogen. In addition, prolonged PT, ACT and aPTT and hypofibrinogenemia may occur if DIC is present.

Differential diagnosis

FeLV infection causes similar signs to FIV infection. FeLV infection causes severe megakaryocytic hypoplasia more commonly than FIV infection, and other hemostatic defects may also occur. A FeLV antigen test may be used to rule this out.

Most **other causes of megakaryocytic hypoplasia and DIC** may be identified by routine work-up.

Concurrent disease may be responsible for the hemostatic defect. Subclinical coagulation abnormalities have been identified with a number of disorders including liver disease, cardiomyopathy, pancreatitis, renal failure, other systemic infections, lymphoma and other neoplasms, and snake bite envenomation and other toxicoses.

Treatment

The **prolonged aPTT and TT** may be corrected by transfusion of **fresh or fresh-frozen plasma**, 10–20 ml/kg.

- This is recommended before biopsy of internal organs, although the need for such transfusion is not known.

Bleeding due to **thrombocytopenia** may be transiently improved by transfusion of **fresh whole blood, platelet-rich plasma or fresh-frozen plasma** (which contains functional platelet particles), 10–20 ml/kg, or platelet concentrate, 1–2 units/cat.

- This is recommended **before biopsy** of internal organs **if the platelet count is** $< 50 \times 10^9/L$ (50 000/dl).

Prognosis

Prognosis for severe FIV-induced megakaryocytic hypoplasia is poor.

Myelosuppression associated with griseofulvin or other drug therapy will usually resolve, but intensive supportive care is required.

There is no specific prognosis associated with the unique FIV-associated coagulation defects.

Long-term prognosis is usually determined by other FIV-associated diseases.

DISSEMINATED INTRAVASCULAR COAGULATION (DIC)*

Classical signs

- Signs of underlying sepsis or non-septic inflammation (e.g. anorexia, depression, fever, hypothermia, tachycardia, abdominal pain).
- Signs of underlying neoplasia (e.g. inappetence, weight loss, lymphadenopathy, hepatosplenomegaly, abdominal mass, dyspnea).
- Signs of underlying FIP (e.g. inappetence, weight loss, fever, abdominal distention, dyspnea).
- Signs of underlying liver disease (e.g. inappetence, weight loss, icterus).
- Signs of other underlying diseases, e.g. hyperthermia (temperature $\geq 42^\circ\text{C}$ [107.6°F]), shock, snake bite wound.
- Spontaneous and excessive bleeding at various sites may occur, but is uncommon.

Pathogenesis

Concurrent **intravascular activation of hemostasis and accelerated fibrinolysis** lead to **microvascular thrombosis and embolism**.

Thrombosis and embolism may lead to organ failure.

Bleeding tendencies occur secondary to consumption of platelets and coagulation factors, increased plasmin activity, and circulating anti-coagulants, including fibrin degradation products (FDPs).

Numerous disease processes may trigger DIC, including thromboembolism due to cardiomyopathy, neoplasia (e.g. hemangiosarcoma, hepatic, biliary and pulmonary carcinomas, mesothelioma, lymphoma, myeloid leukemia, malignant histiocytosis), infections (e.g. bacterial sepsis, tuberculosis, histoplasmosis, cytauxzoonosis, toxoplasmosis), non-infectious inflammation (e.g. pancreatitis, immune-mediated diseases), heat stroke, major trauma, penetrating head trauma, shock and snake bite envenomation.

DIC has wide clinical and pathological spectra and may be **acute to chronic, localized to generalized, and subclinical to fulminant**. A broad definition is used

here to include most cases of consumptive thrombocytopenia and microangiopathic disorders.

Acute DIC is not as common in cats as in dogs. The most common causes are **panleukopenia virus** infection, other **overwhelming infections** (e.g. cytauxzoonosis), and **neoplasia**.

The most common causes of **subacute to chronic DIC** are **liver diseases**, **neoplasia** and **FIP** (due to vasculitis).

Thrombocytopenia has also been noted with several other diseases (see Miscellaneous diseases, page 505), where the thrombocytopenia is likely consumptive in origin.

Clinical signs

Signs of the primary disease.

Most DIC is **subclinical**.

Superficial and deep spontaneous **bleeding may occur**, but it is uncommon.

Venepuncture and biopsy sites, suture lines, and internal and external injuries may bleed excessively.

Signs due to anemia and local effects of hemorrhage vary with severity of blood loss.

Diagnosis

Identification of a primary disease.

Diagnosis is controversial in all species and there is not a single test or combination of tests that rules in or rules out DIC.

Laboratory abnormalities consistent with DIC include:

- Low platelet count, prolonged ACT, prolonged aPTT, prolonged PT, prolonged TT, hypofibrinogenemia, decreased antithrombin III concentration, presence of FDPs, and red blood cell fragments.
- One approach uses **presence of three of the above abnormalities** (counting prolonged PT and/or aPTT as one abnormality) as criteria for diagnosing DIC.
 - Another approach uses low platelet count, prolonged PT, prolonged aPTT, and prolonged TT as diagnostic of DIC in liver disease.

- In the author's opinion, firm diagnostic criteria should not be used. Rather, the probability of DIC increases with the number of consistent laboratory abnormalities: e.g. it is possible that a cat with only thrombocytopenia has DIC, it is more likely that a cat with thrombocytopenia and prolonged ACT has DIC, while it is highly probable that a cat with thrombocytopenia, prolonged PT and aPTT, hypofibrinogenemia and increased FDPs has DIC. Scoring systems based on this approach have been used in humans.

- Measuring **antithrombin III**, which tends to be consumed in DIC, may add specificity but probably does not increase sensitivity to the diagnosis of DIC.
- Measurements of **D-Dimer** are being used with increasing frequency to support the diagnosis of DIC in dogs. Little is currently known of the utility of D-dimer assay in the diagnosis of DIC in cats. D-dimer is a more specific marker of thrombosis than are FDPs, but D-dimer is not specific for DIC. D-dimer levels will be increased in thromboembolic disorders including arterial and pulmonary thromboembolism.
- There is poor correlation between degrees of coagulation abnormalities, severity of underlying clinical disease and risk for hemorrhage.

Differential diagnosis

Differential diagnoses for the various primary diseases are discussed throughout this book. If a hemostatic defect is identified in the work-up of the primary disease, the possibility of a defect unrelated to the primary disease should be considered, e.g. Hageman trait.

Differential diagnoses for abnormal hemostasis with liver disease include vitamin K deficiency, synthesis failure and undetermined causes (which might be mild DIC).

In cats with neutropenia due to myelosuppression and secondary sepsis, thrombocytopenia may be due to concurrent megakaryocytic hypoplasia rather than DIC.

Treatment

Treat the primary disease.

- This is the most important treatment. If this is not possible, other treatments will ultimately fail.

Adequate **fluid therapy** to promote microvascular circulation, but not excessive fluid therapy, which will promote edema and bleeding.

If clinically bleeding, **transfuse** to replace platelets and/or clotting factors and anti-thrombin III with fresh whole blood, platelet-rich plasma, or fresh/fresh-frozen plasma, 10–20 ml/kg.

Heparin therapy is controversial.

- It is recommended because, although bleeding is clinically more obvious, **thrombosis causes most of the organ damage**.
- The goal is to **block microvascular thrombosis** while not aggravating bleeding.
- In cats with fulminant DIC, doses of 50–200 units/kg SC q 6–8 h have been recommended; 75–100 units SC q 8 h is used most often. The dose may be incubated for 30 minutes in the blood product prior to transfusion to activate antithrombin III, although the value of this practice is unproven. An initial **goal is prolongation of the ACT or aPTT to 1.5–2 times** the mean value of normal range or aPTT control value.
- It should not be used in cats with subclinical, subacute or chronic DIC, unless thromboembolism is present.
 - If thromboembolism is present, an initial dose of 200 units/kg SC q 6–8 h is recommended.

Prognosis

The prognosis is largely determined by the primary disease.

Acute diffuse DIC has a very poor prognosis.

SNAKE BITE ENVENOMATION*

Classical signs

- Bite wound on cranial half of body ± local swelling or bleeding (Viperidae, Crotalidae).
- Paresis/paralysis or bleeding tendency depending upon species of snake.

Clinical signs

Cats are believed to be less likely to be bitten by most snake species than dogs, and to be more resistant to hematoxins.

- Resistance to hematoxins may in part reflect cats playing with, and subsequently being bitten, by smaller snakes (thus receiving less venom), and/or only cats with mild–moderate envenomation surviving long enough to be presented to a veterinarian.

Venoms from **Elapidae** snakes (e.g. Australian tiger snake and brown snake, North American coral snakes, Indian cobras) are predominantly **neurotoxic**, although **procoagulants and myolysins** may cause significant complications.

- Signs include areflexic dilated pupils, dysphagia (salivation), dyspnea (respiratory paralysis), hindlimb ataxia and flaccid quadriplegia.
- Local reaction to the bite wound may be minimal.
- Although neurologic signs predominate, cats with tiger or brown snake bites may have significant disturbances of hemostasis.
 - **Potent procoagulants**, especially in the brown snake venom, act as **prothrombin converters, resulting in consumption of fibrinogen**.
 - 10–30% of cats show evidence of hemostatic abnormalities. Typical signs include **non-clotting blood, prolonged coagulation times** (ACT typically 180–240 s), **continuous bleeding from wounds** and venepuncture sites, hematemesis and hematuria.

Venoms from **Viperidae** (e.g. common adder in Britain and continental Europe, *Vipera palaestina* in the Middle East) are predominantly hematoxic, although some have neurotoxic properties.

- **Edema ± bleeding/bruising around the bite** is typical, but is not predictive of systemic toxicosis.
- Widespread bleeding is uncommon with bites from the common adder and *V. palaestina*, but may occur.

Venoms from **Crotalidae** (e.g. North American rattlesnakes, copperhead, cottonmouth, and South American fer-de-lance and bushmaster) are predominantly **hematoxic**, although some (e.g. Mojave rattlesnake, Asian habu snake) are potent neurotoxins.

- **Severe regional swelling** may occur surrounding the bite from massive extravasation of plasma and red cells, but local reaction is not predictive of systemic toxicosis.
- Hypotension may result from pooling of blood in lungs and thoracic vessels.
- **Widespread bleeding may occur.**

- Clinical reports of Massasauga rattlesnake bites to cats are lacking. In dogs envenomation may cause marked prolongation of clotting times but clinical bleeding is rare.

Venoms from most **Colubridae** are mild and clinical reports of bites to cats lacking.

- The boomslang of central and South Africa produces a powerful **hematoxin** that is procoagulant and causes DIC in humans and dogs.

Diagnosis

Diagnosis is based on a history of exposure to the snake (try to identify species) and/or physical examination findings.

CBC may reveal hemoconcentration, hemolysis, echinocytosis, rubricytosis or thrombocytopenia.

Serum chemistry profile may reveal hypoproteinemia, hypokalemia and elevated CK, ALT, urea and creatinine levels.

Urinalysis may reveal myoglobinuria or hemoglobinuria, and glucosuria.

Hemostatic testing may reveal variable thrombocytopenia, prolonged PT and/or ACT, aPTT, and increased FDPs (i.e. DIC).

A Snake Venom Detection Kit (CSL Limited, Australia) can be used for identification of the presence and type of Australian snake venom. Testing is also available from commercial veterinary laboratories. Urine is preferred over blood because of non-specific binding with plasma proteins. A swab of the bite site is most accurate, but is rarely identifiable in cats with bites from Australian snakes.

Differential diagnosis

See The Weak and Ataxic or Paralyzed Cat (page 952) for differential diagnosis of neurologic signs.

Differential diagnoses for the local reaction include angioedema from insect envenomation, animal bite wounds, sharp and blunt trauma.

Differential diagnoses for hemostatic abnormalities include other causes of DIC.

Treatment

Keep animal calm.

If a bite on a limb is witnessed, application of a tourniquet or cold pack by the owner for 10–20 min may be beneficial, but should not delay transport to a veterinarian.

Supportive care.

Specific **antivenom** (antivenin) therapy.

- Observe for allergic reactions.
- Premedication with an anti-histamine, e.g. diphenhydramine, 1 mg/kg IV as a slow bolus over 10–15 min is recommended. This will not potentiate the venom.

If there are signs of hemostatic abnormalities, treat as for DIC (page 502) (see Disseminated intravascular coagulation, above) with transfusions of fresh whole blood, fresh plasma or fresh-frozen plasma.

Antibiotic therapy for secondary wound infection and delayed surgical management of the wound may be necessary.

HAGEMAN TRAIT*

Classical signs

- None.

Pathogenesis

Hageman trait refers to **reduced synthesis, release or function of factor XII** (Hageman factor).

Activation of factor XII to XIIa is the first step in the intrinsic system. As previously noted, this does not appear to be an important mechanism for the initiation of coagulation in vivo.

Factor XII is involved in the **conversion of plasminogen to plasmin**, which is responsible for clot dissolution (fibrinolysis).

Factor XII is also involved in inflammation.

Clinical signs

Spontaneous bleeding does not occur.

Prolonged ACT and aPTT are usually noted incidentally, e.g. when hemostasis is evaluated prior to biopsy.

Concurrent thrombocytopenia or thrombocytopathia was believed to have triggered bleeding in a cat following modified-live virus vaccination. This would appear to be an uncommon event, and is not reported in humans with Hageman trait.

Humans with Hageman deficiency are at increased risk for thromboembolic events as a result of a deficient fibrinolytic system. It is not known if cats with Hageman trait and cardiomyopathy are at increased risk of arterial thromboembolism.

It is not known if cats with Hageman trait have blunted inflammatory responses.

Diagnosis

No signs of abnormal bleeding unless another disease process affecting hemostasis is present.

Hageman trait is the most common inherited coagulation factor deficiency in cats, but prevalence is not known. Although stated to be common, recent large retrospective reviews of hemostatic disorders in sick cats have not identified any cases.

Hemostatic testing reveals normal platelet count and BMBT, normal PT, and markedly **prolonged ACT and aPTT** (e.g. aPTT > 50 s, often > 100 s, where the upper limit of normal range is 25 s).

Definitive diagnosis is based on **quantification of factor XII activity** (FXII:C), similar to the diagnosis of hemophilia A, and ruling-out acquired factor XII deficiency (see Circulating anti-coagulant, below).

Differential diagnosis

Hemophilia A, B (and C) are the main differential diagnoses for markedly prolonged ACT and aPTT as solitary abnormalities.

If a cat is presented with bleeding and a prolonged ACT and aPTT are found, a judgment must be made as to whether the bleeding is appropriate for the injury. For example, a cat with hemothorax and prolonged ACT and aPTT could have hemophilia A or chest trauma and Hageman trait, but in the former case there would be no evidence of injury.

Hemophilia B and Hageman trait have occurred concurrently.

Vitamin K antagonist poisoning – PT is prolonged as well as aPTT.

DIC – thrombocytopenia is often present, in addition to signs of a primary disease.

Acquired factor XII deficiency has been reported in humans but not in cats.

Treatment

None required.

Prognosis

Normal life expectancy.

Transmission

Factor XII deficiency is a heritable single-gene defect that is autosomal recessive.

Prevention

Probably none is required.

MISCELLANEOUS DISEASES*

Classical signs

- Signs of the primary disease.

Clinical signs

Thrombocytopenia, increased ACT/aPTT/PIVKA time, or decreased antithrombin III levels have been noted in various diseases not typically associated with bleeding tendencies. Diseases include hypertrophic cardiomyopathy, congenital cardiac disorders, pleural effusions not due to feline infectious peritonitis, diabetes mellitus, hyperthyroidism, hypertension, chronic renal failure, urinary tract infection, urethral obstruction, rhinitis, *Mycoplasma haemofelis* infection (haemobartonellosis), primary neurologic diseases, and non-anti-coagulant toxicoses.

DIC may be the mechanism for at least some of these abnormalities. The close **interaction** between the **intrinsic system and inflammation via factor XII**

may be responsible for some alterations in ACT and aPTT.

Hemostatic abnormalities are subclinical.

Diagnosis

Clinical signs and work-up of the primary disease.

IMMUNE-MEDIATED THROMBOCYTOPENIA (ITP)

Classical signs

- Platelet disorder bleeding (e.g. prolonged bleeding after venepuncture, melena, epistaxis, petechiation).

Pathogenesis

In ITP, **platelets become antigenic** leading to **accelerated platelet destruction** by the macrophage–monocyte system, particularly in the spleen.

In **primary, or idiopathic, ITP** an underlying disease is not found and the disease is considered to be autoimmune.

In **secondary** ITP, a primary, or underlying, disease is found, e.g. FeLV infection, where there is immune-complex deposition on the surface of infected platelets.

- **Lymphoma** is another primary disease associated with ITP, and ITP may be the mechanism of thrombocytopenia associated with various other neoplasms.
- Thrombocytopenia caused by **anti-thyroid drugs** (propylthiouracil, methimazole, carbimazole) is presumed to be immune-mediated because affected cats may have antinuclear antibodies.
- **Modified live virus vaccination** has been associated with thrombocytopenia and thrombocytopathia in dogs, typically occurring within 2–4 weeks of vaccination. Thrombocytopenia varies from a subclinical, self-limiting fall within normal range to severe thrombocytopenia requiring immunosuppressive therapy. Post-vaccinal thrombocytopenia or thrombocytopathia has been suspected in cats based on post-vaccinal bleeding in cats with otherwise sub-clinical hemostatic defects (see Hageman

trait, page 504 and Vitamin K responsive coagulopathy in the Devon Rex, page 515).

ITP may be concurrent with other autoimmune diseases, e.g. hemolytic anemia, myasthenia gravis, and systemic lupus erythematosus.

Clinical signs

Primary ITP is rare. There is usually marked thrombocytopenia and signs are typical of platelet disorder bleeding, including **petechiation, epistaxis, melena and hematuria**.

Signs of an underlying disease may be present, e.g. lymphadenopathy with lymphoma.

Splenomegaly may be present due to hyperplasia, extra-medullary hematopoiesis and neoplasia.

Thrombocytopenia may be an incidental finding in a work-up.

Anemia and associated signs vary.

Diagnosis

Rule out other causes of thrombocytopenia based on clinical signs and work-up.

Hemostatic testing reveals **thrombocytopenia, normal PT and aPTT**, and normal to increased fibrinogen level. Platelet counts $< 10 \times 10^9/L$ ($10\,000/\mu l$) are stated to mildly prolong ACT, but this effect is poorly documented.

Bone marrow biopsy reveals increased numbers of megakaryocytes.

Demonstration of **platelet or megakaryocyte-associated antibody** by immunofluorescence (test may not be readily available). Platelet and megakaryocyte-associated neutrophils have also been reported.

Response to immunosuppressive therapy.

Differential diagnosis

Megakaryocytic hypoplasia is distinguished from ITP on the basis of identification of a disease that causes decreased platelet production, e.g. myeloid leukemia, on bone marrow biopsy.

- Note that idiopathic megakaryocytic hypoplasia and pancytopenia may be immune-mediated in origin. If there are any megakaryocytes present in the marrow biopsy, testing by immunofluorescence for megakaryocyte-associated antibody should be performed. ITP and immune-mediated megakaryocytic hypoplasia are both uncommon but well-documented causes of thrombocytopenia in cats. Whether or not concurrent immunologic attack on platelets and megakaryocytes is occurring in some cases is not known.
- Note that FeLV infection may cause both megakaryocytic hypoplasia and decreased platelet lifespan.

In **DIC** a primary disease can usually be identified, thrombocytopenia tends to be mild–moderate, and there may be prolongation of PT, aPTT, and TT, hypofibrinogenemia, increased FDPs, and red cell fragments.

Splenomegaly as a cause of thrombocytopenia is probably rare. If it is due to neoplasia it may be identified by splenic biopsy, but this does not rule out that thrombocytopenia is due to secondary ITP. An increase in the platelet count with prednisone treatment of a non-hematopoietic neoplasm, e.g. hemangiosarcoma, gives putative evidence that ITP is present.

Severe bleeding may result in mild thrombocytopenia. In a series of cats with anti-coagulant rodenticide poisoning, a platelet count as low as $58 \times 10^9/L$ ($58\,000/\mu L$) was noted. If severe bleeding is associated with mild thrombocytopenia, it is more likely that the low platelet count is a result of, rather than the cause of, the bleeding.

Treatment

Prednisone 2–4 mg/kg PO until platelet count is normal or stable (usually within one week). The dose is slowly tapered after 2 weeks with re-measurement of platelet count.

If there is no response, then strategies used in dogs may be tried, e.g. vincristine 0.02 mg/kg IV, cyclophosphamide 50 mg/m² PO alternate days, cyclosporine 5 mg/kg PO bid.

If the cat is acutely weak from blood loss, a **transfusion** should be given (10–20 ml/kg whole blood), especially if the PCV < 15.

Prognosis

Based on a limited number of cases, the prognosis is good.

VITAMIN K ANTAGONIST RODENTICIDES AND DRUGS

Classical signs

- Spontaneous or excessive internal or external bleeding.

Pathogenesis

Vitamin K is normally obtained from the diet and intestinal flora, and absorbed in the intestinal tract.

Vitamin K is essential for carboxylation of clotting factors II, VII, IX and X. The uncarboxylated clotting factors cannot bind calcium, a necessary step in clot formation.

Vitamin K is converted to inactive vitamin K-epoxide during the carboxylation process.

The enzyme, **epoxide reductase**, converts vitamin K-epoxide back to active vitamin K. This cycle conserves vitamin K and precludes the need for daily intake.

Anti-coagulant rodenticides inhibit epoxide reductase preventing the re-cycling of vitamin K, such that hepatic stores become rapidly depleted, leading to coagulopathy.

There are numerous products classified chemically as **hydroxycoumarins** (e.g. warfarin) and **indandiones** (e.g. diphacinone). Second-generation products are those effective against warfarin-resistant rats and are more potent. Potency is related to degree and duration of enzyme inhibition. The half-life of second-generation products is much longer than warfarin.

Most toxicity data are based on other species or limited data. As rules-of-thumb, single-dose oral LD₅₀ for warfarin is 5–50 mg/kg, for diphacinone 15 mg/kg, and for bromadiolone and brodifacoum 25 mg/kg. Ten percent of the LD₅₀ is a rule-of-thumb to determine the minimum toxic dose. The lack of information is not a big concern since ingestion is rarely observed or quantifiable with cats.

Anti-coagulant rodenticide poisoning may occur from either **ingesting the poison** (primary toxicosis) or **a poisoned rodent** (secondary toxicosis). Secondary toxicosis is unlikely with warfarin, but may occur with second-generation products, and indeed may be the most common cause of anti-coagulant rodenticide poisoning in cats. Secondary toxicosis was suspected as the cause of poisoning in a recent case series.

Cats with cardiomyopathy may be treated with vitamin K antagonists as prophylaxis for thromboembolism.

Clinical signs

Signs appear **2–5 days after exposure**.

- Severity and time to onset of signs depends on amount of poison ingested and the animal.
 - The **higher the dose of poison the earlier and more severe the signs**. For a given amount of poison, **exposure over several days is more toxic** than a single large exposure.
 - Because cats put less physical stress on their tissue compared to dogs, signs tend to appear later in cats after exposure than in dogs.
 - Signs appear earlier and are more severe in very young and old animals.
- The newer generation poisons do not necessarily cause earlier onset of signs.

Signs of **acute anemia** and **hypovolemia** are present. Other non-specific signs include **depression** (which may appear before detectable anemia), non-localizable **pain and fever**.

Localizing signs of hemorrhage include scleral hemorrhages, otic hemorrhages, epistaxis, cough, hemoptysis and dyspnea (pulmonary hemorrhage), inspiratory dyspnea or restrictive breathing (hemothorax), abdominal pain (presumably due to hemorrhage within organs), abdominal distention (hemoabdomen), lameness, muscle pain and stiffness (hemorrhage into muscles), lameness and joint swelling (hemarthrosis), neurologic signs (cerebral hemorrhage), ecchymoses, subcutaneous hematomas and excessive bleeding from wounds.

- Pleural hemorrhage, mediastinal hemorrhage, and subcutaneous hematomas appear to be most common.

- Mucosal surface bleeding (petechiation, melena, hematochezia) may also occur.

Sudden death may occur due to cerebral hemorrhage, hemopericardium, pulmonary or mediastinal hemorrhage, or exsanguination into the pleural or abdominal cavities.

Diagnosis

Anti-coagulant poisoning is less common in cats than dogs because of difference in eating habits.

Feces may be colored (e.g. green) from dye in bait with primary toxicosis.

Measuring hematocrit and total protein may help identify blood loss as a cause of lethargy, bearing in mind that in the first few hours of bleeding these parameters may not change appreciably.

Reticulocytes will appear after 4 days of the onset of hemorrhage, but this is late in the disease process and not usually useful to identify blood loss as a cause of acute anemia.

Radiographs and ultrasound examinations may detect fluid accumulation in organs and body cavities.

Maintaining a high index of suspicion when a cat at risk has appropriate signs will lead to hemostatic testing.

- **PT is the most valuable routine test.**
 - Factor VII has the shortest half-life of the vitamin K dependent factors and is in the extrinsic system. The other vitamin K dependent factors have longer half-lives and are in the intrinsic or common system.
 - PT becomes prolonged before aPTT does, but by the time a cat is presented with clinical bleeding, **both PT and aPTT are usually prolonged**.
 - If PT is not prolonged, then a prolongation of aPTT is not due to vitamin K antagonism.
- Platelet count is normal, or may be mild to moderately decreased if there is marked hemorrhage. BMBT should be normal, but rebleeding may occur.
- Response to vitamin K1 (see Treatment, below).
- **PIVKA time is increased** (see Tests of hemostasis, above). PIVKA time is more sensitive than PT to vitamin K antagonism, but is not necessary to make the diagnosis in the bleeding animal, nor, despite its

name, is it specific for a vitamin K dependent coagulationopathy.

- Analytic confirmation of the poison in the blood is possible through some diagnostic laboratories.

Differential diagnosis

Trauma, e.g. by a motor vehicle, can result in similar patterns of hemorrhage and systemic signs. This is differentiated on the basis of evidence of injury (e.g. sheared nails, lacerations, fractured pelvis) and hemostatic testing.

Differential diagnoses for bleeding at a specific site include **local lesions at that site**. These are differentiated on the basis of other signs of these processes and normal hemostatic test results.

Liver and gastrointestinal diseases may result in vitamin K deficiency, but the signs of the primary disease are present (e.g. jaundice, diarrhea) and are usually subacute to chronic.

Fulminant DIC causing overt bleeding is not common in cats, and there will be clinical or laboratory signs of an underlying disease. If in doubt, response to vitamin K therapy rules out DIC.

Hemophilia A, B and C are characterized by a normal PT and prolonged aPTT.

Acute heart failure causes dyspnea and the same systemic signs as acute hypovolemia due to hemorrhage, and nasal and oral cavity blood-tinged liquid may be present. A heart murmur and arrhythmia may be present with both. Pulmonary crackles are more likely to be caused by heart failure. Acute heart failure is more common than anti-coagulant poisoning, and, while radiographic pulmonary changes may be the same, cardiomegaly is usually present with heart failure and the heart may be smaller with hemorrhage. Echocardiography and hemostatic testing will definitively distinguish the two.

Treatment

Post-exposure treatment.

- Induce **vomiting** with xylazine, 0.44 mg/kg IM, or with hydrogen peroxide, 2 ml/kg, or syrup of ipecac, 3–6 ml/kg diluted 1:1 with water, PO or preferably by stomach tube, if ingestion of the poi-

son is witnessed or suspected within several hours prior to consultation. (See Acute poisoning in The Cat With Depression, Anorexia or Dehydration, page 285). Examine vomitus for evidence of bait (some are colored green) or a rodent; consider saving vomitus for toxicologic analysis.

- Administer an **adsorbent and cathartic** by stomach tube if the cat is sufficiently cooperative and:
 - Examination of vomitus confirms ingestion and a toxic dose is suspected.
 - Ingestion is known, induced vomiting did not adequately eliminate poison, and it is less than 12 hours post-ingestion.
 - Ingestion is suspected, it is considered to be too late to induce vomiting, and it is **less than 12 hours post-ingestion**.
 - Give a slurry of activated charcoal, 1.0–5.0 g/kg, preferably using a preparation that includes sorbitol as a cathartic. If activated charcoal without cathartic is used, follow with sodium sulfate, 1/2 level teaspoon per kg in 5–10 volumes of tepid water, by stomach tube. If sorbitol or sodium sulfate is not available, use lactulose, 3 ml/kg PO.
- **Measure PT** at 48 and 72 hours and begin vitamin K1 therapy if PT is prolonged. Obtaining a baseline PT may be helpful to facilitate detection of early changes in PT. A less desirable alternative is to measure baseline ACT and then at 72 and 96 hours, and begin vitamin K1 therapy if ACT is > baseline.
- In some cases it may be less expensive or more convenient (e.g. cat is obstreperous in hospital) to empirically treat with vitamin K1 than to monitor coagulation.

Vitamin K1. The synthetic product is phytonadione which has the same activity as natural phylloquinone.

- The purpose of therapy is to provide a **daily source of vitamin K until the toxin is eliminated** and the vitamin K–vitamin K epoxide cycle can resume. Vitamin K1 is expensive but the small size of the doses makes therapy less expensive in cats compared to most dogs and allows empirical use of higher, longer doses.
- **Improvement in the PT is expected within 8–12 hours and normalization by 24–48 hours.**
- Preferred route is PO as it has the best absorption.
 - The **injectable products may be given orally**. Feed canned food as **fat promotes absorption**.

The daily dose may be given in one or two daily treatments. Some prefer the latter to ensure that the cat ingests at least some vitamin K1 each day.

- If animal is vomiting give SC.
- **Avoid IV injection** because of the risk for anaphylactoid reactions associated with vehicles in the preparation (this risk may be less with some newer formulations). If IV injection is necessary (e.g. severe hematoma formation at injection site), pre-treat with diphenhydramine or tripelemine, or equivalent anti-histamine, 1 mg/kg IV over 20 minutes (rapid injection causes hypotension), or acepromazine, 0.05–0.1 mg/kg IV. Dilute the vitamin K1 product in 5% dextrose or other approved diluents listed in the product circular, give slowly over 60 minutes, and observe closely for anaphylactoid reactions and urticaria.
- Vitamin K1 dose:
 - **Warfarin, fuminar, pindone, valone** – 1 mg/kg for **1–2 weeks**.
 - **Bromadiolone, diphacinone, chlorophacinone, brodifacoum** – 2.5–5 mg/kg for **3–4 weeks**.
 - **If product is not known** – 2.5–5 mg/kg for **3–4 weeks** (assume secondary poisoning with a second-generation product).
 - Do not give higher doses – response is not better and there may be a risk of causing Heinz body hemolytic anemia.
 - **Measure PT 2, 3 and 5 days after discontinuing treatment**, especially if poison is not known, to ensure treatment was sufficiently long. Alternatively measure ACT at 3, 4 and 6 days.

Provide supplemental **oxygen** using an oxygen tent (do not use a nasal catheter) if the cat is dyspneic or tachypneic.

Transfusion is required for the actively bleeding cat with existing or potential hypovolemic shock or other life-threatening hemorrhage.

- **3–8 hours are required for vitamin K to raise coagulation protein levels.**
- Transfusion is preferred for volume support since fluid therapy will dilute remaining clotting factors and platelets.
 - Fresh whole blood (10–20 ml/kg) is the most practical blood product to use and will replace

lost red cells, coagulation factors, and provide volume.

- Plasma (10–20 ml/kg). The vitamin K dependent factors are stable in plasma so fresh-frozen plasma is not necessary. Packed red cells are then given for red cell replacement.
- If only stored whole blood is available, this will provide some coagulation factor activity in addition to red cells.

Thoracocentesis should be used to relieve life-threatening pleural blood, and pericardiocentesis to relieve life-threatening cardiac tamponade.

Crystalloid or synthetic colloid **fluid therapy** may be necessary for the animal in shock, but minimum required volumes should be used to minimize dilution of clotting factors and platelets.

Avoid drugs that may enhance toxicosis by altering metabolism of poison. Such drugs commonly used in cats include sulfonamides, metronidazole, fluoroquinolones and cimetidine. Ranitidine and famotidine are safe to use.

Prognosis

Prognosis is excellent with prompt treatment.

Prevention

Prevent exposure to anti-coagulant poisons by proper storage of products and confining cats when products are in use.

For weeks to months after the initial episode, animals are more sensitive to toxicosis upon re-exposure to long-acting rodenticides. This is likely because the poison is still present in the liver and stores of vitamin K have not yet fully recovered.

HEMOPHILIA A (CLASSICAL HEMOPHILIA)

Classical signs

- Excessive internal or external bleeding in young male cats.

Pathogenesis

Hemophilia A is caused by reduced synthesis, release or function of **factor VIII** (anti-hemophilic factor).

- It is a heritable single-gene defect that is X-linked recessive (see Transmission).

Factor VIII is probably synthesized in the liver.

Severity of clinical signs correlates with factor VIII level.

- Bleeding tendency is worst if levels < 1%.
- Bleeding tendency is less if levels are 5–30%.
- Carriers are clinically normal with levels \approx 50%.

The various individual cases and hemophilic families reported are probably due to new and different mutations in the large factor VIII gene and subsequent inbreeding. Hemophilic cats may thus vary in the severity of factor VIII deficiency.

Clinical signs

Clinical signs are usually noted in **cats less than a year of age**, but occasionally the diagnosis is made in an older cat.

Most cases are diagnosed as a result of investigation of **persistent or recurrent bleeding after neutering or declawing**.

History may reveal previous excessive bleeding from wounds, hematomas, lameness (hemarthrosis), and unexplained internal bleeding.

Although umbilical bleeding in neonates and bleeding at the time of teething have not been specifically reported, some family histories have reported fatal bleeding diatheses in related kittens.

Hematomas probably form at subcutaneous vaccination sites but go unnoticed. Vaccination does not trigger bleeding at other sites.

Signs due to anemia and local effects of hemorrhage vary with severity of blood loss. Signs are acute to subacute in onset.

Males are affected the most. However, because cats may have minimal signs, males may breed, resulting in affected females (see Transmission).

Diagnosis

Hemophilia A is rare.

Hemostatic testing reveals normal platelet count and BMBT (may rebleed), normal PT, and markedly pro-

longed ACT and aPTT (typically aPTT is > 1.5–2 times control value, and aPTT > 40 s where the upper limit of normal range is 25 s).

- **Prolonged aPTT is corrected by adding plasma** (which contains factor VIII), but not serum (which does not contain factor VIII), to the sample. This result allows a presumptive diagnosis of hemophilia A as inherited deficiencies of the other coagulation factors consumed during clotting are not known.

Definitive diagnosis is based on quantification of factor VIII activity (FVIII:C) and ruling out acquired factor VIII deficiency (see Circulating anti-coagulant, below). Measuring factor VIII activity quantifies the ability of the patient's plasma to correct the prolonged aPTT of factor VIII deficient plasma. In hemophiliacs FVIII:C is < 25–30% of normal.

Differential diagnosis

Differential diagnoses for bleeding at a specific site include **local lesions at that site**. These are differentiated on the basis of other signs of injury or inflammation and normal hemostatic test results.

Abnormal bleeding due to a **platelet disorder** is ruled out on the basis of a normal platelet count and BMBT.

Hemophilia B and C are characterized by a prolonged ACT and aPTT that is corrected by adding serum to sample, and by a low factor IX or XI quantification.

Cats with coagulopathy secondary to **liver failure** will have clinical and laboratory signs of liver disease, e.g. subacute to chronic inappetence, jaundice, hepatic encephalopathy, and increased liver enzymes, respectively, and may have a prolonged PT.

Cats with **vitamin K antagonist poisoning** and other vitamin K related disorders have a prolonged PT and will respond to vitamin K therapy.

Fulminant DIC causing overt bleeding is not common in cats, and there will be clinical or laboratory signs of an underlying disease.

Acquired factor VIII deficiency has been reported in humans but not in cats.

Treatment

Transfusion with 10–20 ml/kg **fresh whole blood**, **fresh plasma**, or **fresh-frozen plasma** (frozen within 8

hours of collection and stored for < 1 year), or 2 units cryoprecipitate.

- By definition, **fresh products are those used within 8 hours of collection.** Factor VIII levels begin to decline after 8 hours of refrigeration, and in humans only 50% of factor VIII activity is present after 24 hours, but in dogs 85% of activity remains. Some factor VIII activity is probably present in both up to two weeks. The stability of feline factor VIII is not known. While ideally fresh blood products should be used, blood or plasma that is more than 8 hours old is still likely be beneficial to a hemophiliac.
- If plasma products are used, 25–70 ml packed red cells may also be needed.
- Transfusion may be used during a bleeding episode or prophylactically before a procedure.
- **Collect sufficient blood samples for hemostatic testing prior to transfusion.**
- A single transfusion may stop active bleeding in a cat if there is no underlying injury or inflammatory disorder.
- Half-life of factor VIII post-transfusion is probably only 8–12 hours, so repetitive transfusions every 12–24 hours may be necessary.
- Cats with absolute factor VIII deficiency may theoretically become refractory to transfused factor VIII because of antibody formation.

Treatment with vitamin K1 is of no benefit, except as a diagnostic test to rule out vitamin K antagonist poisoning.

Treatments in dogs and/or humans not evaluated in cats include desmopressin, lyophilized factor VIII, recombinant human factor VIII, recombinant factor VIIa, inhibitors of fibrinolysis (e.g. aminocaproic acid), liver transplantation, and gene therapy.

Prognosis

In most cases **spontaneous bleeding is minimal** or mild.

Prognosis is good for **cats kept in an environment that minimizes trauma and exuberant exercise.**

Bleeding tendency appears to be less in mature cats compared to juveniles. An explanation for this may be factor VIII levels increasing with age, as has been seen in normal cats.

Transmission

Factor VIII deficiency is a heritable single-gene defect that is **X-linked recessive.**

Based on classical mendelian inheritance, where “X” and “Y” are sex-chromosomes, “H” is the normal factor VIII gene, “h” is the abnormal factor VIII gene, and approximately half the litter are males and half females:

- Breeding an unaffected male (X^H,Y) to a normal female (X^H,X^H), will result in all normal males and all normal females, i.e. none in litter are bleeders. This is, of course, the normal situation.
- Breeding an unaffected male (X^H,Y) to a carrier female (X^H,X^h), will result in 50% of the males in the litter being affected, and 50% of the females being carriers, i.e. approximately 25% of the litter (all males) are bleeders. This is the most likely natural scenario in the random appearance of hemophilia.
- Breeding an unaffected male (X^H,Y) to an affected female (X^h,X^h), will result in all males being affected and all females being carriers, i.e. approximately 50% of litter are bleeders (all males).
- Breeding an affected male (X^h,Y) to a normal female (X^H,X^H), will result in all males being normal and all females being carriers, i.e. none in litter are bleeders.
- Breeding an affected male (X^h,Y) to a carrier female (X^H,X^h), will result in 50% of the males being affected, and 50% of the females being affected females, i.e. 50% of litter are bleeders (half male, half female).
- Breeding affected male (X^h,Y) to an affected female (X^h,X^h), will result in all males being affected and 50% all females being affected, i.e. 75% in litter are bleeders (all male, half female). This is the least likely naturally occurring situation.

Prevention

Parents and littermates may be tested for factor VIII:C to identify affected cats (males and homozygous females) and carriers (heterozygous females).

- Normal cats have normal factor VIII:C levels.
- In most species, **carrier females have \approx 40–60% normal factor VIII:C**, but the upper range may overlap with the lower range of normal. One confirmed carrier had a factor VIII:C of 69%. Breeding

studies are the only way to identify carriers with low normal factor VIII:C.

- Clinically **affected cats have < 25–30% factor VIII:C**.

A breeder should be advised not to breed affected and carrier/suspected carrier cats. One strategy would be to only breed cats with factor VIII:C $\geq 100\%$.

For clients who are not breeders, or if factor VIII testing of related cats is cost-prohibitive, neuter and spay all related cats. Measure ACT first to identify affected cats that will require transfusion prior to surgery.

HEMOPHILIA B (CHRISTMAS DISEASE)

Classical signs

- Spontaneous or excessive internal or external bleeding in young male cats.

Pathogenesis

Hemophilia B is caused by reduced synthesis, release or function of **factor IX** (Christmas factor).

- It is a **heritable single-gene defect** that is **X-linked recessive**. Newly arising cases probably represent new mutations.

Factor IX is produced by vitamin K dependent synthesis in the liver.

Severity of clinical signs correlate with factor IX level similar to hemophilia A.

- Most affected cats have levels $< 10\%$.
- Carriers typically have levels $\approx 40\text{--}60\%$.
 - Carriers may have up to $\approx 80\%$ normal levels, perhaps because factor IX levels increase with stress.

Clinical signs

Clinical signs are usually noted in **cats less than a year of age**, but occasionally the diagnosis is made in an older cat.

Signs of **spontaneous bleeding** are mild to moderate. Signs include **hemothorax** and **hemoabdomen**, **shifting lameness** due to **hemarthrosis**, **subcutaneous swellings**, **bruises**, **gingival bleeding**.

Excessive bleeding following injury or procedures, e.g. neutering, declawing, venepuncture.

Family history may reveal fatal bleeding diathesis/unexplained death in related kittens.

Other than bleeding tendencies being more severe, signs are otherwise identical to hemophilia A.

Males are affected the most. Because **signs are more apparent than in hemophilia A**, males are less likely to breed and produce affected female offspring (see Transmission).

Diagnosis

Hemophilia B is rare.

Hemostatic testing reveals normal platelet count and BMBT (may rebleed), normal PT, and markedly **prolonged ACT and aPTT**.

- In contrast to hemophilia A, **prolonged aPTT in hemophilia B is corrected by adding serum** (which contains factor IX but not factor VIII) to the sample. Prolonged aPTT in both hemophilia A and B is corrected by adding plasma. This result is consistent with a deficiency of any of the non-consumable clotting factors, and its main value is to rule out hemophilia A.

Definitive diagnosis is based on quantification of factor IX activity (FIX:C), similar to hemophilia A, and ruling out acquired factor VIII deficiency (see Circulating anti-coagulant, below).

Differential diagnosis

Differential diagnoses and differentiation for bleeding for hemophilia B are similar to those for hemophilia A.

- **Acquired factor IX deficiency** has been reported in humans but not in cats.

Comparing hemophilia B to hemophilia A, with the former:

- Spontaneous bleeding is more common.
- Prolonged ACT and aPTT are corrected by adding serum to sample.

Treatment

Transfusion with 10–20 ml/kg fresh or stored whole blood, fresh, fresh-frozen, refrigerated, or frozen plasma. Factor IX is stable during normal refrigeration

time for red cell banking (up to 35 days) and in frozen plasma. If plasma products are used, 1–2 units of packed red cells may also be needed.

- **Collect sufficient blood samples for hemostatic testing prior to transfusion.**
- A single transfusion may stop active bleeding in a cat if there is no underlying injury or inflammatory disorder.
- **Half-life of factor IX post-transfusion is probably only 24 hours**, so repetitive transfusions every 24–48 hours may be necessary.
- Cats with absolute factor IX deficiency may theoretically become refractory to transfused factor IX because of antibody formation.

Treatments in dogs and/or humans not evaluated in cats include lyophilized factor IX, recombinant factor VIIa, inhibitors of fibrinolysis (e.g. aminocaproic acid), and gene therapy.

Prognosis

Prognosis is good for cats kept in an environment that minimizes trauma and exuberant exercise, but bleeding episodes requiring transfusion are likely to occur.

Transmission

Factor IX deficiency is a heritable single-gene defect that is **X-linked recessive**. See Hemophilia A for inheritance patterns.

Prevention

As for hemophilia A, but testing for factor IX.

HEMOPHILIA C

Classical signs

- Excessive bleeding in a young cat (single case).

Pathogenesis

Hemophilia C is caused by reduced synthesis, release or function of **factor XI** (plasma thromboplastin antecedent).

Congenital hemophilia C has recently been described in a young female cat.

Clinical signs

Excessive bleeding following injury or procedures, in this case neutering and declawing.

Diagnosis

Hemophilia C is rare.

Hemostatic testing reveals normal platelet count and BMBT (may rebleed), normal PT, and markedly **prolonged ACT and aPTT**.

- In contrast to hemophilia A, as with hemophilia B, **prolonged aPTT in hemophilia C is corrected by adding serum** (which contains factor XI but not factor VIII) to the sample. Prolonged aPTT in hemophilia A, B and C is corrected by adding plasma. This result is consistent with a deficiency of any of the non-consumable clotting factors, and its main value is to rule out hemophilia A.

Definitive diagnosis is based on quantification of factor IX activity (FXI:C), similar to hemophilia A, and ruling out acquired factor XI deficiency (see Circulating anti-coagulant, below).

Differential diagnosis

Differential diagnoses and differentiation for bleeding for hemophilia C are similar to those for hemophilia A.

Acquired factor XI deficiency in a cat has been reported.

Treatment

Transfusion with 10–20 ml/kg fresh or stored whole blood, fresh, fresh-frozen, refrigerated, or frozen plasma should be considered if there is critical hemorrhage. Factor XI is stable during normal refrigeration time for red cell banking (up to 35 days) and in frozen plasma. If plasma products are used, 1–2 units of packed red cells may also be needed.

- **Collect sufficient blood samples for hemostatic testing prior to transfusion.**
- In the case reported, transfusion was not necessary.

- **Half-life of factor XI post-transfusion is probably longer (2–3 days) than factor VIII or IX.**
- Cats with absolute factor XI deficiency may theoretically become refractory to transfused factor IX because of antibody formation.

Treatments in humans not evaluated in cats include lyophilized factor XI, recombinant factor VIIa, and inhibitors of fibrinolysis (e.g. aminocaproic acid).

Prognosis

Prognosis is probably good for cats kept in an environment that minimizes trauma and exuberant exercise.

Transmission

Transmission in cats is unknown. In humans, dogs and cattle transmission is autosomal recessive.

Prevention

As for hemophilia A, but testing for factor XI.

VITAMIN-K RESPONSIVE COAGULOPATHY IN THE DEVON REX

Classical signs

- Spontaneous and excessive bleeding in Devon Rex cats.

Pathogenesis

Vitamin K is essential for carboxylation of clotting factors II, VII, IX and X. The uncarboxylated clotting factors cannot bind calcium, a necessary step in clot formation (see Vitamin K antagonist rodenticides and drugs).

The enzyme responsible for carboxylation has reduced affinity for vitamin K, impairing its function.

Clinical signs

Spontaneous bleeding in Devon Rex cats including hemothorax, intrapulmonary hemorrhage, hemarthrosis and otic hemorrhages. Reported cases range from 5 months to 2 almost years.

Excessive bleeding after venepuncture, neutering and other surgical procedures.

For cases with a defect not sufficiently severe to cause spontaneous hemorrhage, the age of detection will depend on the age when a procedure is performed. Most cats are neutered at a young age, resulting in detection of the defect at that time.

Signs due to anemia and local effects of hemorrhage vary with severity of blood loss.

Some affected cats may not show spontaneous or excessive bleeding, also consistent with **variable severity of the defect**.

In one case a bleeding episode was suspected to have been triggered by concurrent decreased platelet function associated with modified-live virus vaccination.

Diagnosis

Consistent signalment (young Devon Rex cats) and signs of spontaneous or excessive bleeding are highly suggestive.

No evidence of other vitamin K related disorders.

- No history of exposure to vitamin K antagonist poisons.
- No clinical or laboratory evidence of liver disease.
- No diarrhea (exocrine pancreatic insufficiency and inflammatory bowel disease).

Hemostatic testing reveals normal platelet count and BMBT (may rebleed), and **prolonged PT, ACT and aPTT**. PIVKA time has not been reported but is presumably prolonged.

Quantification of vitamin K dependent factor activities, using techniques similar to factor VIII quantification in hemophilia A.

Normalization of PT, ACT, aPTT and factor activities with vitamin K therapy.

Differential diagnosis

Vitamin K antagonist rodenticide poisoning may be ruled out in some cases on lack of exposure history.

- **If exposure is possible**, then the cat should be confined in a rodenticide-free environment and **treated with vitamin K for 6 weeks**. After stopping

vitamin K therapy, PT \pm aPTT should be monitored. Clotting times will become abnormal again with the genetic defect but remain normal if the cat had been poisoned.

- **Toxicological analysis of blood** can be used to identify presence of a rodenticide.

Other toxins and drugs significantly impairing vitamin K function are rare and may be ruled out by history and improvement with drug withdrawal.

Cats with **coagulopathy secondary to liver failure** will have clinical and laboratory signs of liver disease, e.g. subacute to chronic inappetence, jaundice, hepatic encephalopathy, and increased liver enzymes, respectively.

Exocrine pancreatic insufficiency and inflammatory bowel disease severe enough to cause vitamin K deficiency also cause **diarrhea**.

Differential diagnoses for bleeding at a specific site include **injury or inflammation** at that site. These are differentiated on the basis of other signs of injury or inflammation and normal hemostatic test results.

Abnormal bleeding due to a **platelet disorder** is ruled out on the basis of a normal platelet count and BMBT.

Thrombocytopenia is often present in **DIC**, in addition to signs of a severe illness causing DIC.

Treatment

Vitamin K1 at an initial dose of 5 mg/day PO, and then tapered to a minimum dose required to keep PT normal.

Cats with life-threatening bleeding may require **transfusion** (see Vitamin K antagonist rodenticides and drugs).

- Caution: There is a **high-prevalence of type B blood type** in this breed. Be sure to blood-type or cross-match donor and recipient prior to transfusion.

Prognosis

Excellent with vitamin K1 therapy.

Transmission

Mode of inheritance is not known, but defect is likely to be autosomal.

Prevention

Recommendations are tentative.

Measure PT in parents and littermates to identify affected cats.

- If PT testing is cost-prohibitive, **ACT should be useful for initial screening** (prolonged test result identifying affected cats); but if ACT is normal, PT should be performed.

Do not breed affected cats. Treat with vitamin K and neuter.

Consider not breeding related unaffected cats, in case defect is autosomal recessive.

EXOCRINE PANCREATIC INSUFFICIENCY (EPI)

Classical signs

- Chronic diarrhea, weight loss, polyphagia.
- Excessive bleeding may occur.
- Rare in cats.

Pathogenesis

Dietary triglycerides are normally **digested by pancreatic lipase to monoglycerides and fatty acids**.

This process is needed for solubilization and **subsequent absorption of fat-soluble vitamins**, including vitamin K.

In EPI, **lipase deficiency** can therefore result in **vitamin K deficiency**.

Vitamin K deficiency leads to coagulopathy due to deficiencies of factors II, VII, IX and X (see Vitamin K antagonist rodenticides and drugs).

Vitamin K deficiency is usually mild since there is not complete absence of intestinal lipolysis.

Clinical signs

Chronic diarrhea, weight loss, normal to increased appetite (see The Cat With Signs of Chronic Small Bowel Diarrhea, page 751).

Greasy soiling of the haircoat (especially perianal) may occur.

Clinical bleeding is rare and is most likely to be excessive, e.g. following venepuncture, rather than spontaneous.

Prevalence of subclinical clotting factor deficiency is not known.

Diagnosis

See The Cat With Signs of Chronic Small Bowel Diarrhea (page 752) for diagnosis of EPI.

Hemostatic testing in the bleeding cat reveals **normal platelet count and BMBT** (may rebleed), and **prolonged PT, ACT and aPTT**.

Cats with EPI and clinically normal hemostasis may have high normal range values or mild prolongation of PT, ACT and aPTT. A sub-clinical effect may be better documented by measuring **elevated PIVKA** time and quantification of factor VII using a technique similar to factor VIII quantification in hemophilia A.

Differential diagnosis

Differential diagnoses for a cat with chronic diarrhea and coagulopathy include:

- **Inflammatory bowel disease.** This is differentiated from EPI by normal trypsin-like immunoreactivity and intestinal biopsy showing inflammation.
- **Primary intestinal disease** and secondary **cholangiohepatitis** or **hepatic lipidosis**. These are identified by routine laboratory work-up and biopsy. Appetite is usually reduced with liver disease.
- **Feline leukemia virus** and **feline immunodeficiency virus** infections. Both viral diseases may be associated with chronic diarrhea, but appetite is usually reduced. Coagulopathies may occur with retroviral infections, but are usually subclinical. Both viruses may cause thrombocytopenia.
- Unrelated causes of diarrhea and abnormal bleeding.

Treatment

See The Cat With Signs of Chronic Small Bowel Diarrhea (page 752) for treatment of EPI.

Cats with EPI and clinical or laboratory evidence of coagulopathy should be given **vitamin K1**, 5 mg/kg SC daily until normalization of PT. The need for further treatment will depend on response to vitamin K1 treat-

ment and improvement of diarrhea with pancreatic enzyme supplementation.

Concurrent supplementation with vitamin E (tocopherol) may increase vitamin K1 requirements.

Avoid unnecessary antibiotic therapy that may **reduce intestinal bacterial production of vitamin K2**.

- Antibiotic treatment may be necessary to treat small intestinal bacterial overgrowth.

Prognosis

The prognosis for normalization of hemostasis is excellent.

INFLAMMATORY BOWEL DISEASE (IBD)

Classical signs

- Chronic diarrhea, weight loss, variable appetite.
- Spontaneous or excessive bleeding may occur (uncommon).

See main reference, The Cat With Signs of Chronic Small Bowel Diarrhea (page 769) for treatment of IBD.

Pathogenesis

Vitamin K deficiency leads to coagulopathy due to deficiencies of factors II, VII, IX and X (see Vitamin K antagonist rodenticides and drugs).

Vitamin K1 is the main source of vitamin K for mammals.

- It is obtained from the diet (phylloquinone) and absorbed in the proximal small intestine.
- **Severe intestinal malabsorption** may result in **vitamin K1 deficiency**.
- The main causes of **malabsorption** in cats are **IBD, hyperthyroidism and intestinal lymphoma**. Vitamin K deficiency has been documented with IBD, and is probably responsible for some of the increased PIVKA times seen occasionally in hyperthyroidism, but has not been investigated in lymphoma.

Vitamin K2 (menaquinone) is also an **important source of vitamin K for mammals**.

- It is produced by **intestinal bacteria** (especially *Escherichia coli* and *Bacteroides* spp.) and absorbed in the ileum and colon.
- If IBD affects predominantly the proximal small intestine, bacterial synthesis provides sufficient vitamin K2 to prevent coagulopathy.

Clinical signs

Chronic diarrhea, chronic intermittent vomiting, weight loss, appetite varying from episodic inappetence to polyphagia (see The Cat With Signs of Chronic Small Bowel Diarrhea, page 768).

Clinical bleeding is uncommon but spontaneous bleeding diathesis has occurred.

Based on prolonged PIVKA time, prevalence of sub-clinical factor deficiency in severe IBD is approximately 30%.

Diagnosis

Hemostatic testing in a bleeding cat reveals **normal platelet count and BMBT** (may rebleed), and prolonged PT, ACT and aPTT.

Cats with IBD and clinically normal hemostasis may have high normal range values or mild prolongation of PT, ACT and aPTT. A sub-clinical effect may be better documented by measuring **elevated PIVKA time** and quantification of factor VII using a technique similar to factor VIII quantification in hemophilia A.

Differential diagnosis

As for exocrine pancreatic insufficiency.

Treatment

Cats with IBD and clinical or laboratory evidence of coagulopathy should be given **vitamin K1**, 5 mg/kg SC daily until normalization of PT. The need for further treatment will depend on response to vitamin K1 treatment and improvement of diarrhea with corticosteroid therapy and dietary manipulations.

If intestinal malabsorption is not adequately controlled and ongoing vitamin K supplementation is needed, oral supplementation with vitamin K1 may be tried.

- Concurrent use of **medium-chain triglyceride** supplementation, 1–2 ml/kg/day PO will **promote vitamin K absorption** and promote weight gain, but the product is **unpalatable**.
- If oral vitamin K1 therapy is unsuccessful, vitamin K3 therapy may be considered. Vitamin K3 is a synthetic vitamin K that is less fat-soluble and is **absorbed in the colon**. Unfortunately it causes a **dose-dependent Heinz-body hemolytic anemia** and **methemoglobinemia**, and a safe but effective dose in the cat has not been determined.

Avoid unnecessary antibiotic therapy that may reduce intestinal bacterial production of vitamin K2.

Prognosis

The prognosis for normalization of hemostasis is excellent but ongoing vitamin K1 therapy may be needed until the underlying disorder is resolved.

PANCREATITIS

Classical signs

- **Depression and anorexia.**

See main reference on page 272 (The Cat With Depression, Anorexia or Dehydration).

Clinical signs

The most common signs are non-specific.

Hypothermia, vomiting, abdominal pain and occasionally a palpable cranial abdominal mass may be present.

Icterus may be present from concurrent liver disease or extra-hepatic bile duct obstruction.

Hemostatic abnormalities may be present due to DIC of varying severity or due to concurrent liver disease.

- Hemostatic abnormalities are usually subclinical. Clinical bleeding is unlikely unless there is severe DIC or concurrent liver disease.

Cats with concurrent liver disease and pancreatitis are more likely to have hemostatic defects and clinical bleeding than with either disease on its own.

Diagnosis

See The Cat With Depression, Anorexia or Dehydration (page 273).

Hemostatic testing may reveal evidence of DIC (e.g. thrombocytopenia, prolongation of clotting times), evidence of **vitamin K deficiency** (prolonged PT and PIVKA time), and/or evidence of other hemostatic disorders associated with concurrent liver disease (see Liver disease, above).

Differential diagnosis

See The Cat With Depression, Anorexia or Dehydration (page 275). Pancreatitis is difficult to definitively diagnose without biopsy. Many diseases in the cat cause non-specific signs and sub-clinical hemostatic defects. Systematic elimination of diseases by work-up helps narrow the list of differential diagnoses.

Treatment

See The Cat With Depression, Anorexia or Dehydration (page 277).

If there is clinical bleeding, treat with vitamin K as for liver diseases and transfusions as for DIC.

STRANGULATION

Classical signs

- Scleral hemorrhage.

Clinical signs

Non-fatal strangulation may result in scleral edema and hemorrhage, and neurologic signs. Pulmonary edema has also been seen in dogs.

Diagnosis

History is diagnostic. Usually the collar or leash is caught in a tree.

Skin lesions around neck.

Hemostatic testing is normal.

CUTANEOUS ASTHENIA (EHLERS-DANLOS SYNDROME)

Classical signs

- Excessive wounding since birth.
- Subcutaneous hematomas or seromas.

Clinical signs

Signs are present from birth, but may worsen with age.

Skin is hyperextensive and wounds easily with minor trauma, and may feel softer. Scars from previous wounds may be present. Signs result from abnormal collagen synthesis, and will vary in degree with the specific genetic defect.

- The chief complaint may be **bleeding from the skin, but bleeding is appropriate for the wound**.
- Bleeding into the skin without a wound (petechiation, ecchymoses) is not characteristic of the diseases described to date in cats.
- **Subcutaneous hematomas and seromas may occur** because blood and lymphatic vessels are fragile or are injured when the skin stretches.

Concurrent signs include **joint laxity, lens luxation and cataracts**.

Reported in domestic shorthaired, domestic longhaired, Himalayan and Burmese cats.

Diagnosis

Clinical signs are highly suggestive.

Skin extensibility index (SEI) > 19%. SEI = height of fold/body length × 100, where, with the cat standing, a fold of lumbosacral skin is pulled upwards and the height from the top of the spine to the top of the fold is measured, and body length is measured from the occipital crest to the base of the tail.

Skin biopsy for histopathology and/or electron microscopy of skin to document collagen abnormalities, special biochemical analyses, and measurement of tensile strength.

Hemostatic testing is normal.

HYPERADRENOCORTICISM

Classical signs

- Polyuria, polydipsia, polyphagia.
- Abdominal distention, alopecia, fragile skin.

Clinical signs

Polyuria, polydipsia and polyphagia commonly occur because of insulin-resistant diabetes mellitus.

Abdominal distention commonly occurs because of muscle wasting and hepatomegaly.

Cutaneous signs include **patchy alopecia** (most common), symmetrical alopecia and fragile skin.

Fragile skin may bleed when it is torn, but bleeding is typically slight.

Cats, unlike dogs, do not appear to bleed more easily from venepuncture sites.

Diagnosis

See The Cat With Polyuria and Polydipsia (page 251).

Hemostatic testing is normal.

CHEDIAK-HIGASHI SYNDROME

Classical signs

- Persian cats with congenitally dilute smoke-blue hair coat.

Clinical signs

Signs are present from birth and are associated with an autosomal recessive defect.

Affected **Persian cats** have a **dilute smoke-blue hair coat** and yellow-green irises.

Ophthalmologic evaluation reveals epiphora and blepharospasm in bright light and a red fundus.

Prolonged bleeding occurs at venepuncture sites, surgical sites and following minor and major trauma,

because of a **platelet function defect**. Spontaneous bleeding and bleeding diathesis do not occur.

Diagnosis

Clinical signs.

Routine blood smear reveals large pink cytoplasmic inclusions in granulocytes and larger than normal eosinophil granules.

Hemostatic testing reveals prolonged BMBT (9.33 → 20 min) and decreased platelet aggregation.

IDIOPATHIC THROMBOCYTOPATHIA

Classical signs

- Spontaneous epistaxis and gingival bleeding.

Clinical signs

Bleeding results from an **abnormality in platelet function affecting aggregation**.

Presumed to be a congenital defect since signs are apparent at a young age.

Recurrent epistaxis and gingival bleeding have been seen.

Diagnosis

Clinical signs.

Hemostatic testing reveals normal platelet count and prolonged BMBT.

Abnormal platelet aggregation in vitro.

ANTIPLATELET CARDIAC DRUGS

Classical signs

- None.

Clinical signs

β-blockers and calcium-channel blockers inconsistently inhibit platelet aggregation in vivo.

Acetromazine, at one time extensively used in the management of arterial thromboembolism, inhibits platelet aggregation in humans, but does not in dogs and presumably has minimal effect in cats.

Aspirin, n-3 fatty acids, and cyproheptadine variably inhibit platelet aggregation in vitro but have a minimal effect on BMBT when used as single agents.

- These drugs have been given to cats in an attempt to prevent arterial thromboembolism due to cardiomyopathy.
 - Newer classes of **antithrombotic drugs** in humans **inhibit platelet aggregation** by preventing binding of fibrinogen or ADP to specific platelet receptors. These drugs have been shown to impair platelet function in normal cats. Clopidogrel currently shows the most promise for clinical use.

The effect of the older drugs on bleeding in cats with a bleeding disorder is not known, but is unlikely to be marked in most circumstances. Aspirin should probably be avoided in cats with a moderate to marked hemostatic disorder. The effect of the newer platelet receptor blocking drugs on bleeding in cats with a bleeding disorder is not known, but these drugs should likewise probably be avoided in cats with a moderate to marked hemostatic disorder.

Diagnosis

History of drug therapy.

If a cat receiving one of these drugs has abnormal bleeding, another cause of the bleeding should be ruled out.

SPLENOMEGALY

Classical signs

- Enlarged spleen on abdominal palpation.
- Signs of a primary disease.

Clinical signs

Mild to markedly **enlarged spleen on abdominal palpation**.

Other signs of a primary disease causing splenomegaly may be present. Diseases include bacterial, fungal and

protozoal infections, non-infectious inflammation and immune-stimulation, and neoplastic infiltration. Splenomegaly may also result from portal hypertension and extra-medullary hematopoiesis. Most causes of lymphadenopathy may also cause splenomegaly (see The Cat With Enlarged Lymph Nodes, page 393).

The most common cause of marked splenomegaly is **neoplasia, especially mast cell tumor and lymphoma**.

Although the spleen of the cat is non-sinusoidal, **splenic sequestration of platelets does normally occur**. Splenomegaly could potentially contribute to thrombocytopenia, but it does not appear to be an important mechanism and a bleeding tendency is unlikely.

Diagnosis

Routine work-up to identify primary disease.

Aspiration or surgical biopsy of spleen.

Hemostatic testing may reveal **thrombocytopenia** and coagulopathy (e.g. DIC) secondary to the primary disease.

VON WILLEBRAND'S DISEASE

Classical signs

- Not known (rare disease).

Clinical signs

There is a report of a 9-year-old male neutered cat with persistent oral bleeding after tooth extraction.

In dogs the most common signs are those of excessive or prolonged bleeding following injury.

Diagnosis

Hemostatic tests reveal **prolonged BMBT**, normal to slightly prolonged ACT and aPTT, and decreased von Willebrand's factor (vWf:Ag).

FACTOR X DEFICIENCY

Classical signs

- Not known (rare disease).

Clinical signs

There is a report of a cat with **mild excessive bleeding after declawing** and **seizures** attributed to intracranial hemorrhage at 3 years of age.

The defect appeared to be inherited. The mother and one sibling were subclinically affected.

Diagnosis

Hemostatic tests reveal normal platelet count and BMBT, markedly prolonged PT, ACT, and aPTT and normal TT.

Russell's viper venom time (RVVT) is prolonged.

Factor X:C is decreased.

Rule out acquired factor X deficiency (reported in humans but not cats). See Circulating anti-coagulant, below.

CIRCULATING ANTI-COAGULANT

Classical signs

- Not known (rare disease).

Clinical signs

Primary or secondary autoimmune diseases may be associated with **acquired circulating anti-coagulants (inhibitors)**, e.g. the lupus anti-coagulant in systemic lupus erythematosus. The anti-coagulant may result in spontaneous or excessive bleeding. Paradoxically, animals and humans with lupus anti-coagulants are **also at risk for thrombosis**.

Inhibitors to most coagulation factors have been reported in humans. There is a report of a 5-year-old cat with persistent **epistaxis** due to **inhibition of factor XI** (plasma thromboplastin antecedent) causing a prolonged aPTT.

Diagnosis

Hemostatic test results will vary with the coagulation factor inhibited and platelet abnormalities.

A circulating inhibitor is demonstrated by mixing equal volumes of patient and normal plasma. If the prolonged coagulation time in the patient plasma is normalized, then it was due to a factor deficiency. (This test works because PT and aPTT do not become prolonged until there is < 25% function, so the normal plasma adds sufficient factors to the deficient plasma to normalize the test). If the **prolonged coagulation time** in the patient plasma is **not normalized** (i.e. the patient plasma prolongs coagulation time in normal plasma), then an inhibitor is present.

- If an inhibitor is demonstrated, more specific mixing studies may be performed using specific factor C assays to identify the specific factor inhibitor.

ANTI-COAGULANTS

Classical signs

- Spontaneous bleeding with excessive anticoagulation.

Clinical signs

Heparin, low-molecular-weight heparin and warfarin may be used as prophylaxis against thromboembolism in cats with cardiomyopathy (see The Cat With Signs of Heart Disease, page 130).

Heparin may be used in the treatment of pulmonary thromboembolism and DIC (see above).

There is a **narrow therapeutic margin** between effective and excessive anti-coagulant therapy. Excessive therapy will result in spontaneous hemorrhage.

Diagnosis

History of anti-coagulant therapy.

Prolongation of ACT, aPTT, PT, PIVKA time and TT with heparin and warfarin therapy. The ACT, aPTT and TT are usually used to monitor heparin therapy, while PIVKA time and PT are used to monitor warfarin therapy. Routine coagulation tests are not affected by low-

molecular-weight heparin, where plasma anti-factor Xa activity is used to monitor therapy.

VITAMIN K DEFICIENT DIET

Classical signs

- Spontaneous bleeding with certain fish diets.

Clinical signs

The cat has a **relatively low dietary vitamin K requirement** and it is difficult to experimentally induce vitamin K deficiency.

Some commercial fish-based diets caused a vitamin K responsive bleeding diathesis during feeding trials, possibly due to an anti-vitamin K factor in the diet.

Diagnosis

The main cause of vitamin K deficiency is anorexia.

If no other explanation exists to account for a vitamin K responsive coagulopathy, diet should be investigated.

ANTI-CONVULSANTS

Classical signs

- None (with respect to bleeding).

Clinical signs

Phenobarbital and diphenylhydantoin (rarely used in cats) cause **mild reduction in hepatic synthesis of vitamin K dependent clotting factors**. This is only a problem in a cat with another vitamin K related disorder.

Diagnosis

Sub-clinical effect may be **documented by PIVKA** time and/or quantification of vitamin K dependent factor activities using techniques similar to factor VIII quantification in hemophilia A. If a clinical effect

occurs, hemostatic tests reveal prolonged PT ± prolonged ACT and aPTT.

ANTIBIOTICS

Classical signs

- Abnormal bleeding associated with antibiotic therapy.

Clinical signs

Penicillins and some cephalosporins variably impair platelet function in humans, rabbits and dogs, and may exacerbate thrombocytopenic bleeding. This is most important in humans with penicillins, when the platelet count is $< 20 \times 10^9/L$ (200,000/ μl) or in the presence of other hemostatic defects. Amoxicillin, cefalexin, and cefazolin at standard doses do not impair platelet function in normal dogs and are unlikely to have any clinically relevant hemostatic effects in cats.

Other antibiotics that alter platelet aggregation *in vitro* in humans, rabbits or dogs include **tetracyclines, gentamicin and sulfonamides**. The clinical effect, if any, is less important than with the penicillins. Fluoroquinolones do not appear to impair platelet function. Doxycycline and enrofloxacin at standard doses do not impair platelet function. Doxycycline and enrofloxacin at standard doses do not impair platelet function in normal dogs. These antibiotics are unlikely to have any clinically relevant hemostatic effects in cats.

An idiosyncratic drug reaction may result in thrombocytopenia and platelet-type bleeding.

Antibiotic therapy may reduce bacterial synthesis of **vitamin K2** (menaquinone) by killing intestinal bacteria (especially *Escherichia coli* and *Bacteroides* spp.). Numerous antibiotics have been implicated in humans. This is not usually a concern in the animal with otherwise normal hemostasis, but may promote coagulopathy in animals at risk for vitamin K deficiency.

Moxalactam, cefamandole and cefoperazone may directly **impair vitamin K dependent factor** synthesis. These antibiotics are infrequently used in cats.

Sulfonamides, metronidazole and possibly fluoroquinolones may **exacerbate vitamin K antagonist rodenticide poisoning**.

Actinomycin D, an anti-tumor antibiotic, may be a vitamin K antagonist, but the clinical relevance of this in cats is not known.

Diagnosis

Abnormal bleeding associated with antibiotic therapy and improvement upon withdrawing therapy.

If vitamin K deficiency or antagonism is causing bleeding, hemostatic testing reveals prolonged PT \pm prolonged ACT and aPTT, and improvement in coagulopathy with vitamin K1 injection (assuming normal liver function).

- Sub-clinical effect may be documented by PIVKA time and quantification of vitamin K dependent factor activities using techniques similar to factor VIII quantification in hemophilia A.

ANTI-THYROID DRUGS

Classical signs

- Epistaxis, oral hemorrhages.
- Prolonged bleeding following procedures.

Clinical signs

Spontaneous bleeding (e.g. epistaxis, oral hemorrhages, melena) and excessive bleeding (e.g. following venepuncture or surgery) due to **anti-thyroid drugs** (propylthiouracil, methimazole, carbimazole) is usually due to **thrombocytopenia** caused by **peripheral destruction or megakaryocytic hypoplasia**.

Methimazole and carbimazole may interfere with **activation of the vitamin K-dependent clotting factors II, VII, IX and X**. This effect in cats is minimal – PIVKA time may be increased, but an increase in PT is unlikely.

Diagnosis

Increased PIVKA time compared to baseline in a hyperthyroid cat being treated with an anti-thyroid drug.

Presumably quantification of vitamin K dependent factor activities could also demonstrate a deficiency.

NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

Classical signs

- None (with respect to bleeding).

Clinical signs

Non-steroidal anti-inflammatory drugs (NSAIDs) are being prescribed with increasing frequency for analgesia in cats.

Similar to aspirin, non-selective NSAIDs impair platelet function by inhibition of cyclooxygenase-1. This may result in prolonged bleeding times and increased surgical hemorrhage in humans and dogs. The effect on bleeding time in cats has not been well investigated, but, given that aspirin has minimal effects on BMBT in the cat, NSAIDs are also **likely to have minimal effects**.

Diagnosis

History of drug therapy.

If a cat receiving one of these drugs has abnormal bleeding, another cause of the bleeding should be ruled out.

MISCELLANEOUS DRUGS

Classical signs

- None (with respect to bleeding).

Clinical signs

Numerous drugs inhibit platelet aggregation in various species in vitro. These include:

- Anesthetic and sedative agents: acepromazine, diazepam, ketamine, propofol and halothane, but not barbiturates or isoflurane. Acepromazine and propofol do not inhibit platelet function in normal dogs.

- Anti-histamines: H1 and H2 blockers. H2 blockers are frequently given to thrombocytopenic animals with gastrointestinal hemorrhage because ulceration cannot be ruled out. Famotidine has less of an effect on platelets than either cimetidine or ranitidine. Sucralfate will provide local gastrointestinal protection without any effect on platelets.
- The effect of these drugs on platelet function in cats is not known, but they are unlikely to have any clinically relevant hemostatic effects.

- Disturbances of platelet aggregation in vitro may not have any clinical relevance in vivo.

Diagnosis

History of drug therapy.

If a cat receiving one of these drugs has abnormal bleeding, another cause of the bleeding should be ruled out.

PART 8

Cat with abnormal laboratory data

24 The anemic cat

Michael R. Lappin

KEY SIGNS

- Pale mucous membranes.
- Weakness, depression, lethargy.
- Increased heart and respiratory rates.
- ± Splenomegaly.
- ± Melena or hematochezia.

MECHANISM?

- Blood loss or red blood cell destruction (hemolysis) produces a regenerative anemia.
Failure of the bone marrow to produce adequate red blood cells produces a non-regenerative anemia.

WHERE?

- Hemolytic anemia is intravascular or extravascular (liver, spleen), whereas blood loss anemia can be into body spaces (abdomen, thorax) or out of the body (usually GIT).
- Non-regenerative anemia indicates a **bone marrow** problem.

WHAT?

- Hemoplasmosis (previously *Hemobartonella felis*) are the most common cause of regenerative anemia.
- Non-regenerative anemia is most commonly the result of **chronic disease, especially infectious disease**.

QUICK REFERENCE SUMMARY

Diseases causing an anemic cat

REGENERATIVE ANEMIA (> 60 000 RETICULOCYTES/ML) – HEMOLYSIS

ANOMALY

- Hereditary hemolytic anemia (pyruvate kinase deficiency, osmotic fragility, porphyria)
Rarely, diseases like pyruvate kinase deficiency in Abyssinian cats result in hemolysis. Hereditary hemolytic anemias usually result in mild, intermittent regenerative anemia and weight loss. Porphyria produces severe macrocytic, hypochromic anemia and brown discoloration of the teeth.

METABOLIC

- **Hypophosphatemia* (p 534)**

Extreme hypophosphatemia during treatment of ketoacidotic diabetic cats can result in increased red blood cell fragility. Onset of anemia, muscle weakness or ataxia after intensive treatment of a diabetic cat is suspicious.

- **Microangiopathic hemolytic anemia* (p 534)**

Red blood cells can be damaged when passing through abnormal vessels resulting in schistocytes. Disseminated intravascular coagulation (fibrin strands), dirofilariasis, and splenic tumors or hematomas can damage red blood cells. Lethargy, anorexia and depression may be present in addition to the signs of the underlying disease. Schistocytes are evident on thin blood smears but are hard to detect in cats.

INFECTIOUS

- **Hemoplasmosis*** (p 530)**

In most parts of the world, the most common causes of hemolytic anemia are infectious, especially from *Mycoplasma haemofelis*, and *Candidatus M. haemominutum* infection. Typically cats present with pale mucous membranes, anorexia, mild to marked depression and sometimes fever.

- **Cytauxzoonosis**

Typically cats present with pale mucous membranes, anorexia, depression and fever. Dyspnea, collapse and death occur commonly.

IMMUNE

- **Immune-mediated hemolytic anemia** (p 532)**

Primary immune-mediated hemolytic anemia in cats is unusual when compared to dogs but secondary immune-mediated red cell destruction can occur secondary to drugs, vaccines and infectious agents. Anemia is usually regenerative but may be non-regenerative. Depression, and variable fever, splenomegaly and icterus occur. Agglutination or a positive Coomb's test are indicative of an immune-mediated process.

TOXINS

- **Drugs and toxins** (p 533)**

Some drugs like acetaminophen and benzocaines and other toxins result in Heinz body anemia in cats which is usually regenerative. Other drugs and toxins induce non-regenerative anemia (see below). Lethargy, anorexia, weakness, pale mucous membranes and elevated heart and respiratory rates are often present.

continued

continued

BLOOD LOSS

- **Local diseases of blood vessels** (p 536)**

Blood loss anemia can occur when blood vessels are damaged by trauma, erosive diseases like tumors or fungal infections, and vasculitis-like systemic lupus erythematosus. Signs include anemia, and evidence of internal or external bleeding such as melena, hematochezia, hematuria, dyspnea, hemothorax or hemoabdomen.

- **Platelet abnormalities (primary hemostatic defects)** (p 537)**

Diseases of platelets including those resulting in thrombocytopenia or those resulting in decreased platelet function. Anemia together with petechiae and ecchymoses at more than one site are typical signs. Hemorrhage may involve the fundus of the eye, mucous membranes of the mouth, vulva, and penis, and skin including ears.

- **Factor abnormalities (secondary hemostatic defects)** (p 538)**

Decreased amounts or function of coagulation factors. Typically there is anemia together with evidence of hemorrhage at more than one site involving fundus of the eye, mucous membranes of the mouth, vulva, and penis, and skin including ears. Dyspnea, coughing, hemothorax or hemoabdomen may also be evident.

- **Hypertension* (p 539)**

Systemic arterial hypertension rarely results in significant blood loss and anemia, except if epistaxis is involved. Retinal hemorrhage and epistaxis are most common sites of visible hemorrhage.

NON-REGENERATIVE ANEMIA (< 60 000 RETICULOCYTES/ μ L)

DEGENERATIVE

- **Renal failure** (p 540)**

Anemia occurs in many cats with chronic renal failure, but presenting complaints are usually those of renal disease not anemia. Polyuria, polydipsia, inappetance and weight loss are typical.

METABOLIC

- **Hypoadrenocorticism**

While rare in cats, hypoadrenocorticism does occur and results in anemia. Depression, lethargy, vomiting, diarrhea, anorexia and weakness occur.

- **Hypothyroidism**

Rarely, anemia may result from hypothyroidism following treatment of hyperthyroidism. Lethargy, weight gain, seborrhea and delayed hair regrowth are typical.

- **Iron deficiency**

While rare in cats, chronic blood loss can result in microcytic anemia. Lethargy, anorexia, weight loss and signs of chronic gastrointestinal disease resulting in chronic blood loss may be present. Severe flea infestation in young kittens may result in anemia.

- **Folic acid antagonism/deficiency**

Chronic administration of pyrimethamine or sulfa drugs can result in macrocytic anemia. Dietary insufficiency (tuna diet), malabsorption, and congenital defects may also cause folic acid deficiency.

- **Anemia of chronic disease*** (p 539)**

Diseases associated with chronic inflammation, usually infectious or neoplastic, can result in anemia of chronic disease. Chronic anorexia, lethargy and weight loss, with or without fever, are typically present.

NEOPLASTIC

- **Myelophthitic diseases* (p 546)**

Neoplasms of the bone marrow can crowd out red blood cell precursors. Lethargy, anorexia, weight loss and pale mucous membranes are often present.

INFECTIOUS

- **Feline leukemia virus** (p 540)**

Lethargy, anorexia and weight loss are typical. Anemia may be a main presenting sign. Signs may be referable to secondary infections or neoplasia.

- **Feline infectious peritonitis (FIP), feline immunodeficiency virus (FIV)** (p 545)**

Other classic viral diseases associated with non-regenerative anemia in cats include feline infectious peritonitis and feline immunodeficiency virus. Lethargy, anorexia, weight loss and fever are typical. Signs are referable to secondary infections (FIV) or effusion into body cavities and pyogranulomatous inflammation of the liver, kidney, eye or CNS (FIP).

- **Ehrlichiosis and anaplasmosis**

Uncommon diseases in cats compared to dogs. Lethargy, anorexia, depression and fever are the most common signs. Other signs reported include hyperesthesia, lameness or joint pain, pale mucous membranes, splenomegaly, dyspnea, diarrhea and uveitis.

IMMUNE

- **Immune-mediated (pure red cell aplasia)**

Immune-mediated reactions can be directed at precursor cells resulting in non-regenerative anemia. Lethargy, anorexia, weight loss and pale mucous membranes are often present. Heart and respiratory rates may be elevated once anemia is severe.

TOXINS

- **Drugs/toxins* (p 546)**

Usually a history of exposure to substances like chloramphenicol, which damage the bone marrow. Typically there is lethargy, anorexia and depression together with a history of administration of drugs known to cause bone marrow damage. Vomiting and diarrhea may be evident.

INTRODUCTION

MECHANISM?

Anemia is defined as a packed cell volume of less than 27%.

Anemia is either **regenerative or non-regenerative**.

- **Regenerative anemia** is characterized by reticulocyte counts greater than 60 000/ μ l; **non-regenerative anemia** has less than 60 000/ μ l.
- By definition, it takes from 3–5 days after acute development of anemia to have maximal reticulocytosis, and so acute anemia may initially appear as non-regenerative.

- If the anemia has been present for 3–5 days and the reticulocyte count is < 60 000 the anemia is non-regenerative.

The two primary differential diagnoses for **regenerative anemia** are **hemolysis** (destruction of red blood cells) and **blood loss**.

Loss can occur out of the body through wounds, the gastrointestinal tract, or the nose. Bleeding into body cavities and parenchymal organs also occurs.

- If the **blood loss is out of the body**, **total protein** concentrations are usually **decreased**, whereas blood loss into a body cavity and hemolytic anemias usually has normal total protein concentrations.

Blood loss can result from local diseases of vessels like **trauma or erosion of the vessel** due to diseases like neoplasia. **Vasculitis, hypertension, factor abnormalities and platelet** abnormalities also can result in blood loss anemia.

There are multiple mechanisms for **hemolytic anemia** including **infectious diseases, primary immune-mediated diseases, microangiopathic diseases, toxins, congenital diseases and metabolic diseases**.

Non-regenerative anemias generally imply **bone marrow dysfunction**, which can be caused by many things including infectious diseases, toxicities, neoplasia, chronic inflammation and metabolic diseases.

WHERE?

Hemolytic anemia is intravascular or extravascular, but is usually extravascular (**liver, spleen**) in cats.

Blood loss in regenerative anemia can be into body spaces (**abdomen, thorax**) or out of the body (**usually GIT**) as a result of **local vascular damage**, or **systemic coagulation or platelet problems**.

Non-regenerative anemia indicates a **bone marrow** problem.

WHAT?

Hemotropic mycoplasmas (previously hemobartonellosis) are the most common causes of regenerative anemia. Less common causes are immune-mediated, drug- or toxin-associated, vascular damage from

trauma, tumors or fungal infection, coagulopathies and thrombocytopenia.

Non-regenerative anemia is most commonly the result of **chronic disease** (infectious, neoplastic or renal failure). Infectious diseases include **feline leukemia virus, feline infectious peritonitis, feline immunodeficiency virus and ehrlichiosis**.

DISEASES CAUSING ANEMIA: REGENERATIVE ANEMIA DUE TO HEMOLYSIS

HEMOPLASMOSIS***

Classical signs

- Previous history or presence of fleas.
- Pale mucous membranes.
- +/- splenomegaly or icterus.
- Lethargy, anorexia, depression.
- +/- fever.

Transmission

Mycoplasma haemofelis and *Candidatus M. haemominutum* and the causes of feline infectious anemia (previously hemobartonellosis).

Experimentally the organisms can be transmitted by intramuscular, intraperitoneal or intravenous administration of infected blood and transplacentally.

Transmission by the cat flea *Ctenocephalides felis* has been shown for *M. haemofelis*, but not *Candidatus Mycoplasma haemominutum*.

Cats with hemobartonellosis may have a history of fighting.

Pathogenesis

The organisms are epicellular parasites of red blood cells (RBC).

M. haemofelis (previously known as the large form) is **most pathogenic**.

Anemia is from immune-mediated reactions that are organism specific or directed at RBC membrane proteins that have been modified by the parasitism.

Antibody-coated red blood cells are removed by the reticuloendothelial system, and intravascular lysis is unusual; Coomb's positive test results are common.

Level of parasitemia fluctuates rapidly making diagnosis difficult based on cytology.

The **acute phase** of disease usually **develops within 3 weeks**; spontaneous recovery followed by recurrence from the chronic carrier state can occur.

Anemia associated with *Candidatus Mycoplasma haemomintum* is often detected in cats with current feline leukemia virus infection.

In locations where feline leukemia virus is common, approximately 50% of infected cats are co-infected with the virus; co-infection with feline immunodeficiency virus is rare.

Clinical signs

Infection is most common in **male cats** less than 3 years of age, and occurs most often in the spring.

Cats are usually presented for **depression, lethargy and anorexia**.

Pale mucous membranes are a common physical examination abnormality. **Fever and icterus** are also common.

Splenomegaly occurs in some from extramedullary hematopoiesis and immune stimulation.

Fleas or flea dirt may or may not be noted.

Chronic infection may lead to recurrent hemolytic anemia or intermittent fever, depression and anorexia without hemolytic anemia.

Diagnosis

Diagnosis is based on cytological demonstration of the organism on the surface of RBC. However, the organism may be difficult to find even though clinical signs are present, and at least 50% of cats are falsely negative on cytological examination.

The organism may dislodge from the surface of RBCs placed in EDTA in cytologically negative suspect cats. In suspect cats, repeat cytological assessment using smears made from blood without anti-coagulants.

Polymerase chain reaction (PCR) is available commercially. PCR is positive in some cytologically nega-

tive cats suggesting it is more sensitive. Some healthy cats are PCR positive and so the predictive value for presence of disease is not 100%.

Macroscopic or microscopic agglutination, spherocytosis, or Coomb's positive test results are suggestive.

Differential diagnosis

Any infectious, immune-mediated, or neoplastic cause of hemolytic anemia can look similar as a result of signs associated with fever and anemia. Demonstration of the organism by cytological assessment or PCR differentiates mycoplasma-associated hemolytic anemia from other causes.

Treatment

Doxycycline at 10 mg/kg, PO, q 24 hours for the first week and then continued q 24 hours for 2 weeks. If the cat will tolerate treatment, a total of 4 weeks of treatment may result in more cats becoming PCR negative.

While tetracycline at 22 mg/kg, PO q 8 hours can be effective it is no longer recommended since doxycycline is superior.

Enrofloxacin at 5–10 mg/kg, PO, q 12–24 hours for 2–3 weeks may be effective in cats that are intolerant of tetracyclines. Doses over 5.5 mg/kg may be associated with retinal toxicity and blindness in a small percentage of cats.

For cats that do not tolerate or are resistant to tetracyclines and enrofloxacin, **imidocarb dipropionate** at 5 mg/kg, IM or SQ, q 2 weeks, for 2–4 injections can be used.

Chloramphenicol at 15 mg/kg, PO, q 12 hours for 3 weeks has been used but not studied experimentally; this drug also has been associated with bone marrow suppression.

Prednisolone at 1–2 mg/kg, PO, q 12 hours should be used for at least the first week of therapy because of the immune-mediated pathogenesis.

Treatment lessens clinical signs of disease but does not resolve infection in many cats.

While there is no PCV that alone indicates when to transfuse, **whole blood transfusions** are generally indicated if the PCV is dropping rapidly and heart and respiration rates are elevated at rest.

Blood typing should be performed if possible in breeds prone to the B type (British short hair, Devon Rex, Cornish Rex, Japanese bobtail, Scottish fold, Sphinx, Somali).

Cross-match results may be hard to interpret due to spontaneous agglutination.

Since *M. haemofelis* is the most common cause of hemolytic anemia in cats, **treatment should be considered for all suspect cats**, even if the organism cannot be found.

Prognosis

Most treated cats survive. The prognosis is worse for those with concurrent immunodeficiency-inducing diseases.

Because treated cats are usually not cured, exacerbations are common.

Prevention

Flea control and housing cats indoors lessen potential for exposure.

Cats used as **blood donors should be tested** for both *Mycoplasma haemofelis* and *Candidatus Mycoplasma haemomintum* using PCR techniques. Donor cats exposed to fleas should be regularly retested.

IMMUNE-MEDIATED HEMOLYTIC ANEMIA**

Classical signs

- Lethargy, anorexia, depression, +/- fever.
- Pale mucous membranes.
- +/- splenomegaly or icterus.

Pathogenesis

Primary immune-mediated hemolytic anemia (IMHA) is rare and the cause unknown.

Secondary IMHA occurs from hypersensitivity reactions against drugs (like beta-lactam antibiotics), modified-live vaccines, neoplasms, and infectious agents like *M. haemofelis* and feline leukemia virus.

RBC can be lysed in the bloodstream (**intravascular**) or removed by the reticuloendothelial system (**extravascular**), with the latter being most common.

Large concentrations of anti-RBC antibodies result in cross-linking and macroscopic or **microscopic agglutination**.

Spherocytes are formed when fixed reticuloendothelial cells remove part of the antibody or complement-coated RBC membrane.

The immune reaction can be directed at RBC precursors resulting in non-regenerative anemia.

Clinical signs

Depression, lethargy and anorexia are common presenting complaints.

History of recent vaccination (within 1 month) or antibiotic administration may be present.

History of fleas is common in cats with hemotropic mycoplasmosis.

Fading kitten syndrome occurs in kittens with a history of a type B queen mated to a type A tom (neonatal isoerythrolysis; see page 1134).

Pale mucous membranes, tachycardia and tachypnea are common.

Splenomegaly and lymphadenopathy occur in some cats.

Icterus is dependent on rapidity of anemia development. White blood cells are activated commonly resulting in fever.

Diagnosis

Presence of spherocytes is classic but difficult to document in cats compared to dogs since normal RBC of cats is relatively small, and they do not have central pallor.

Macroscopic or microscopic agglutination. If agglutinating cells are noted, mix 1 drop of blood in EDTA with 1 drop 0.9% NaCl and repeat the thin blood smear. If cells are no longer clumped, massive roulette formation was occurring and not agglutination.

Direct Coomb's testing can be used in cases without spherocytes or autoagglutination to confirm presence of IgG, IgM or complement on the surface of RBC. EDTA blood is submitted to the laboratory for reaction with Coomb's reagent (anti-IgG, anti-IgM, anti-complement). Optimally, the laboratory should provide a titer, not the result of a single dilution. Feline-specific Coomb's reagent must be used.

Antinuclear antibody testing can be performed. Some cats with systemic lupus erythematosus will be positive and have primary immune-mediated hemolytic anemia.

Erythrophagocytosis can be noted on **bone marrow examination**; maturation arrest of RBC development may be detected if immune response is directed at precursor cells.

Differential diagnosis

Any infectious or neoplastic cause of hemolytic or blood loss anemia can look similar because the signs of fever and anemia are not specific, and immune destruction of RBC may be partly involved in the pathogenesis of the anemia. Diagnosis is often based on exclusion of infectious and neoplastic causes, and demonstration of agglutination or a positive Coomb's test.

Treatment

Dexamethasone at 1 mg/kg, IV, once on day 1.

Prednisolone at 2–4 mg/kg, PO, q 12 hours initially followed by decreasing doses every other week provided anemia is resolving. If maintenance treatment is required, the target dose is approximately 0.5 mg/kg, PO, q 48 h.

Doxycycline at 5–10 mg/kg, PO, q 12 hours for at least 14 days in all cats with hemolytic anemia due to possible hemobartonellosis.

Dexamethasone administered at 0.1–0.2 mg/kg, PO, q 12 hours in cats resistant to prednisolone.

Cyclosporine at 1–5 mg/kg, PO, q 12–24 hours, for 7–14 days is indicated for acute treatment of **cats that are autoagglutinating** or undergoing **intravascular hemolysis**.

Cyclophosphamide at 6.25–12 mg/cat, PO, 4 days weekly for 1–2 weeks has been used in some cats acutely but is not currently used by the author.

Chlorambucil at 0.2 mg/kg, PO, q 24 hours may be needed in some cats with glucocorticoid-induced side effects or incomplete control, and should be used in place of cyclophosphamide for long-term management.

Azathioprine at 0.3 mg/kg, PO, q 72 hours may be needed in some cats with glucocorticoid-induced side effects or incomplete control, but extreme bone marrow suppression can occur and chlorambucil is preferred.

Whole blood transfusion may be indicated if the **PCV is dropping rapidly**, the cat is depressed, and if heart and respiration rates are elevated at rest.

Prognosis

Prognosis with primary IMHA is unknown since it is rare.

Theoretically, secondary IMHA should have a good prognosis since the initiating antigen (*M. haemofelis*, vaccines, antibiotics) can be removed.

Prevention

Avoid over-stimulating cat immune systems with antibiotics and vaccines.

Cats with primary or secondary IMHA should be housed indoors and no longer vaccinated.

Lessen exposure to fleas to potentially avoid infection by *M. haemofelis*.

DRUGS/TOXINS**

Classical signs

- Lethargy, anorexia, depression.
- Pale mucous membranes and elevated heart and respiratory rate.
- History of exposure to oxidative toxin.

Pathogenesis

Oxidation of the globin in hemoglobin leads to formation of **Heinz bodies** (precipitated hemoglobin).

Anemia results from cell lysis or fragmentation in capillaries because of fragility, **or removal** by the fixed reticuloendothelial system of the spleen and liver.

Clinical signs

Lethargy, anorexia, weakness, pale mucous membranes and elevated heart and respiratory rates occur.

History of exposure to oxidative toxins like acetaminophen (iatrogenic), onions (foodstuffs like babyfood), zinc (United States pennies, airline carrier hardware), propothiouracil (iatrogenic), methylene blue (iatrogenic), phenazopyridine (iatrogenic), vitamin K1 (iatrogenic), propylene glycol (food stuffs; carrier in some medications), and benzocaine derivatives (iatrogenic).

Diagnosis

Heinz bodies (intracytoplasmic irregular retractile granules) are seen cytologically on thin blood smears.

Methemoglobin levels can be elevated; blood has a brown color.

Treatment

Remove the source of the oxidant injury.

N-acetylcysteine at 140 mg/kg, PO, once followed by 70 mg/kg, PO every 4–6 hours if severe methemoglobinemia is present.

Supportive care including whole blood transfusion if needed.

HYPOPHOSPHATEMIA*

Classical signs

- Anemia, muscle weakness in diabetic cat.
- Ataxia, seizures.

Clinical signs

Extreme hypophosphatemia may occur during **initial treatment of ketoacidotic diabetes mellitus**, and result in muscle weakness, ataxia, seizures and **pale mucous membranes**.

Liver disease may result in red blood cell fragility.

Diagnosis

Measurement of serum phosphorus concentrations.

Treatment

Administer potassium phosphates at 0.03–0.12 mmol/kg/h until normophosphatemic.

Alternately, prevent hypophosphatemia (and hypokalemia) by giving calculated potassium requirements as 30% potassium chloride and 50% potassium dihydrophosphate.

Phosphate concentrations are usually maintained within normal concentrations by diet alone after resolution of the ketoacidotic crisis.

MICROANGIOPATHIC HEMOLYTIC ANEMIA*

Classical signs

- Lethargy, anorexia, depression.
- Clinical signs of the primary disease.

Clinical signs

Diseases that involve small vessels like **disseminated intravascular coagulation** (fibrin strands), **dirofilariasis**, and **splenic tumors or hematomas damage RBC** resulting in formation of schistocytes or fragments.

History, physical examination, and laboratory assessment support the primary disease.

Lethargy, depression, weakness and pale mucous membranes may result if anemia is severe.

Diagnosis

Schistocytes are seen cytologically on thin blood smears.

Diagnostic work-up for the suspected primary cause should be performed.

CYTAUXZONOSIS

Classical signs

- Fever, depression, shock and death.
- Indoor/outdoor cats in the Gulf Coast states.
- History of tick exposure.

Transmission

Bobcats are subclinically infected by *Cytauxzoon felis* and so are probably the natural host.

Transmission occurs from infected bobcats to domestic cats by *Dermacentor variabilis*.

Pathogenesis

Transmission of the organism results in clinical illness in 5–20 days.

Schizonts and macroschizonts form in **mononuclear phagocytes**, line the lumen of veins, and **obstruct blood flow through tissues** (tissue phase).

Merozoites released from infected macrophages **infect erythrocytes causing hemolytic anemia** (erythrocyte phase).

Clinical signs

Most infected cats are presented for **depression**.

Physical examination usually reveals **fever, anorexia, dyspnea, depression, collapse, icterus, and pale mucous membranes**.

Hypothermia develops in some cats preceeding death.

Death is a common sequel, but strains of *C. felis* that spontaneously resolve have now been recognized.

Most cases of cytauxzoonosis are in **outdoor cats**, but ticks are generally not identified

The **course of disease is generally 1 week or less** in cats infected with pathogenic strains.

Cats infected with non-pathogenic strains may live for years.

Diagnosis

Regenerative anemia, neutrophilic leukocytosis or leukopenia, thrombocytopenia or thrombocytosis, **hemoglobinemia, hemoglobinuria**, bilirubinemia and bilirubinuria are the most common laboratory abnormalities, but vary between patients.

Antemortem diagnosis is based on demonstrating the **ring-shaped erythrocytic phase on thin blood smears** which occurs in most cats with acute illness.

The organism can be detected in infected macrophages in bone marrow, spleen, liver, or lymph node aspirates stained with Wright's or Giemsa stains.

Serologic testing can be used to confirm exposure, but is usually not needed clinically

PCR assay has been studied experimentally and may be available in the future.

Differential diagnosis

Any infectious, immune-mediated, or neoplastic cause of hemolytic anemia can look similar due to the signs associated with fever and anemia. Identification of the organism is diagnostic.

Treatment

Fluid therapy and blood transfusion should be administered as indicated (see hemobartonellosis).

Imidocarb administered at 5.0 mg/kg, IM, every 14 days for two doses or **diminazene** at 2.0 mg/kg, IM, every 7 days for two doses are the drugs of choice but no treatment is known to be effective.

Parvaquone, buparvaquone, thiacetarsamide and tetracycline therapy have also been attempted.

Zoonotic potential and prevention

Cytauxzoon felis is not known to infect people.

Tick control should be maintained, and cats in endemic areas should be housed indoors.

HEREDITARY HEMOLYTIC ANEMIA (PYRUVATE KINASE DEFICIENCY, OSMOTIC FRAGILITY, PORPHYRIA)

Classical signs

- Lethargy, anorexia, weight loss.
- Pale mucous membranes.
- Young Abyssinian, Somalis, Siamese or DSH cat.

Clinical signs

Congenital diseases resulting in hemolysis are **rare in cats**.

Pyruvate kinase deficiency has been described in Abyssinian cats, Somalis and DSH with **intermittent, regenerative anemias**.

Increased osmotic fragility of erythrocytes causing **hemolytic crises** with macrocytic regenerative anemia and splenomegaly has also been documented in Abyssinians and Somalis.

Cats with hereditary hemolytic anemias exhibit **intermittent anemia and weight loss**, and the clinical signs appear to be **ameliorated by splenectomy**.

Porphyria in a family of Siamese cats was associated with **severe macrocytic, hypochromic anemia** with poikilocytosis, Howell–Jolly bodies, and nucleated red blood cells.

Porphyria in domestic shorthair cats is inherited as an autosomal dominant trait, and is characterized by only a **mild anemia**.

Porphyrins produce a **brownish discoloration of teeth**, bones (at necropsy), and urine, all of which fluoresce bright pink-red with ultraviolet light.

Diagnosis

Measure pyruvate kinase activities.

Measure blood porphyria concentrations. Demonstrate fluorescence of porphyrins in teeth or urine.

Treatment

Supportive care including transfusion if indicated.

Splenectomy for anemias caused by pyruvate kinase deficiency and increased osmotic fragility.

REGENERATIVE ANEMIA DUE TO BLOOD LOSS

LOCAL DISEASES OF BLOOD VESSELS**

Classical signs

- Anemia.
- Bleeding internally or externally.

Classical signs—Cont'd

- Evidence of trauma, neoplasia, inflammatory or erosive disease.
- Melena, hematochezia, hematuria, dyspnea, hemothorax or hemoabdomen.

Pathogenesis

Blood vessels are damaged by trauma (blunt trauma, foreign bodies, etc.), erosive diseases resulting from tumors, chronic infections (fungal in particular), toxicities (mainly gastrointestinal), or vasculitis like systemic lupus erythematosus.

Clinical signs

Weakness and lethargy are common presenting complaints.

Blood usually is lost into tissues, spaces like the **pleural space and peritoneal cavity**, the **gastrointestinal tract** (including palate of the cat), or any external damaged tissue like the nose.

Bleeding may or may not be evident, depending on where the blood is lost.

Melena or hematochezia may be present in cases with gastrointestinal blood loss; exceptions include small volume, chronic bleeding and acute loss.

Acute dyspnea or weakness associated with pale mucous membranes and evidence of **hemothorax or hemoabdomen** on centesis are typical findings.

In contrast to blood loss from coagulopathies or hypertension, local diseases usually do not result in evidence of bleeding at distant sites. The exception is vasculitis.

Fungal and neoplastic diseases of the nose that result in epistaxis usually have mucopurulent discharge prior to development of epistaxis.

Other clinical signs are associated with the primary disease.

Diagnosis

Diagnostic work-up and findings are dependent on the individual primary disease and site of bleeding.

PLATELET ABNORMALITIES (PRIMARY HEMOSTATIC DEFECTS)**

Classical signs

- Anemia.
- Petechiae and ecchymoses at more than one site.
- Hemorrhage involving fundus of the eye, mucous membranes of the mouth, vulva, and penis, and skin including ears.

Pathogenesis

Platelet diseases can be divided into those inducing **thrombocytopenia** and those inducing **platelet dysfunction**.

The differential categories for thrombocytopenia include consumption, destruction, decreased production and sequestration.

The most common causes of platelet consumption are **disseminated intravascular coagulation** and consumption at sites of inflammation.

The most common cause of platelet destruction is **immune-mediated** which can be either primary or secondary to drugs and vaccines.

Platelets are produced by the bone marrow and so any bone marrow disease can potentially result in thrombocytopenia. **Neoplasia and feline leukemia virus** are common examples.

Sequestration of platelets usually occurs in the spleen or liver but is not a primary disease.

Platelet function abnormalities can be iatrogenic (aspirin), congenital (rare in cats), or acquired (hyperglobulinemia).

Clinical signs

Diseases of platelets usually result in **petechiae and ecchymoses**.

Ingestion of aspirin may be known.

Clinical signs are usually consistent with where the primary bleeding is occurring and the primary disease resulting in hemorrhage.

Most bleeding disorders will have evidence of **hemorrhage in more than one site**. The fundus of the **eye, mucous membranes of the mouth, vulva, and penis**, and the skin especially ear and ventral abdomen are good places to evaluate for evidence of hemorrhage.

Diagnosis

Platelet count should be made; **spontaneous hemorrhage** generally occurs with **platelet counts of < 50 000 platelets/ μ l**.

Platelet estimates can be made; under oil immersion (1000 \times), every **one platelet per field** equates to approximately **20 000 platelets/ μ l**.

When thrombocytopenia is suspected, scan the blood smear evaluating for clumps which may falsely lower the count.

If giant platelets are present, decreased production of platelets is unlikely.

If persistent thrombocytopenia is present, a **bone marrow** examination is indicated to evaluate for **myelophthitic disease** and **latent feline leukemia virus infection** (IFA or PCR; see FeLV section).

Platelet function deficits in cats are rare, however **von Willebrand's disease** does occur.

Bleeding time assesses platelet function and should be less than 5 minutes.

Bleeding time should only be performed in cats with normal platelet counts and factor tests (ACT, etc.).

Treatment

Treatment varies with the primary disease (see appropriate section) but frequently includes administration of **fresh whole blood transfusion** if life-threatening hemorrhage is occurring.

Fresh plasma can be used if red blood cells are not needed.

For suspected secondary immune-mediated thrombocytopenia, remove the potential source if possible (antibiotic or vaccine).

Primary immune-mediated thrombocytopenia is rare in cats, but treatment is as discussed for hemolytic anemia (see appropriate section).

FACTOR ABNORMALITIES (SECONDARY HEMOSTATIC DEFECTS)**

Classical signs

- Anemia.
- Evidence of hemorrhage at more than one site involving fundus of the eye, mucous membranes of the mouth, vulva, and penis, and skin including ears.
- Dyspnea, coughing, hemothorax or hemoabdomen.

Pathogenesis

Factor abnormalities can be divided into **decreased amounts** (liver disease, DIC, hemophilia, cholestasis, warfarin toxicity) or **decreased function of coagulation factors** (circulating anti-coagulants like heparin).

Hepatic insufficiency leads to **decreased production** of procoagulants.

Hepatic cholestasis results in **absence of vitamin K** and **failure to convert factors II, VII, IX and X** to active coagulants.

DIC results in factor consumption

Hemophilia is the congenital lack of a factor or factors.

Warfarin toxicity results in vitamin K antagonism and the resultant failure to convert factors II, VII, IX and X to active coagulants.

Increased amounts of **circulating anticoagulants** are most common with **mast cell tumors (heparin)** or **DIC (fibrinogen degradation products)**.

Clinical signs

Most bleeding disorders will have evidence of **hemorrhage in more than one site**.

Decreased amounts or function of coagulation factors usually results in **bleeding into body cavities** like the chest and peritoneal cavity.

The **fundus of the eye** and **mucous membranes of the mouth, vulva and penis** are good places to evaluate for evidence of hemorrhage.

Clinical signs are usually consistent with where the primary bleeding is occurring and the primary disease resulting in hemorrhage.

Ingestion of vitamin K antagonistic rodenticides may be known.

Cats with **hepatic insufficiency** usually have other clinical signs like weight loss, anorexia, polyuria/polydipsia.

Cats with **cholestasis** commonly have other clinical findings like weight loss, anorexia and icterus.

DIC is a syndrome induced by other diseases; clinical findings are consistent with the primary disease.

If severe enough to cause spontaneous hemorrhage, **hemophilia** usually presents in **younger cats**.

Diagnosis

Activated clotting time (ACT; normal < 65 seconds) can be used in clinical settings to assess the intrinsic and common coagulation pathways. Factor VII is the only factor deficiency not screened by the activated clotting time (extrinsic pathway), but factor VII hemophilia is rare and so the **ACT is an excellent clinical screening test for factor deficiencies**. **Thrombocytopenia < 50 000 platelets/ul** can **prolong the ACT by up to 10–15 seconds** due to **lack of platelet phospholipid**.

The **activated partial thromoplastin time** and **prothrombin time** as well as specific assessment of different factors or **proteins induced by vitamin K** absence or antagonism are performed on **citrated plasma**; samples should be collected and stored prior to starting treatment.

Treatment

Treatment varies with the disease, but frequently includes administration of **fresh whole blood** transfusion if life-threatening hemorrhage is occurring.

Frozen plasma can be used to supply coagulation factors if red blood cells or platelets are not needed.

If vitamin K antagonists are the cause of the hemorrhage, **vitamin K1** should be given **subcutaneously at 1–5 mg/kg, q 12 hour for 24 hours**. Dose is dependent on the type of anti-coagulant ingested. Warfarin can be treated with 1–3 mg/kg and long-acting products should be treated with 3–5 mg/kg. Oral administration of vitamin K1 is initiated on day 2 at 1–5 mg/kg, q 12 hours for 2 weeks (warfarin) to 6 weeks (long-acting anti-coagulant) depending on the type of anti-coagulant ingested.

Vitamin K1 given intravenously can result in an anaphylactoid reaction.

When vitamin K1 therapy is discontinued, the cat should be **returned in 72 hours for assessment** of an ACT or prothrombin time. If increased at that time, two more weeks of therapy should be prescribed prior to the next evaluation.

HYPERTENSION*

Classical signs

- Sudden onset of blindness with dilated pupils from retinal hemorrhage.
- Epistaxis.
- Evidence of diseases causing hypertension, especially renal disease or hyperthyroidism.

Pathogenesis

Systemic arterial hypertension in cats is usually from **renal disease, hyperthyroidism, hyperadrenocorticism** and **idiopathic** (essential).

Clinical signs

Systemic arterial hypertension can result in hemorrhage; **retinal hemorrhage and epistaxis** are most common.

With the exception of epistaxis, volume of blood loss is usually small and so anemia is rare.

Diagnosis

Systolic blood pressure > 175 mmHg using a Doppler system is abnormal.

- Some normal cats will appear hypertensive due to epinephrine release from the stress of measuring the blood pressure.

Renal and endocrine causes of hypertension should be excluded by bloodwork and urinalysis.

Treatment

ACE-inhibitors, calcium channel blockers, beta-blockers, and sodium restriction are used to manage systemic arterial hypertension in cats.

See appropriate sections for specific treatment recommendations (page 134).

NON-REGENERATIVE ANEMIA (< 60 000 RETICULOCYTES/ μ L)

ANEMIA OF CHRONIC DISEASE***

Classical signs

- Chronic lethargy, anorexia and depression.

Pathogenesis

Activation of leukocytes by the primary disease results in the **production of cytokines like interleukin 1**.

In the face of inflammatory cytokines, **macrophages fail to release iron** to be used for red blood cell production.

Red blood cell life span is slightly shortened.

Response of the bone marrow to erythropoietin may be blunted.

Clinical signs

Diseases associated with chronic inflammation, usually infectious or neoplastic, can result in anemia of chronic disease.

Clinical signs are those usually related to the primary disease with minimal clinical findings associated with the anemia.

The **anemia is generally mild** compared to those associated with FeLV or immune-mediated diseases.

Diagnosis

Diagnosis is usually based on exclusion of other causes of non-regenerative anemia combined with documentation of a chronic neoplastic or inflammatory disease.

Mild normocytic-normochromic, non-regenerative anemia (**PCV is generally 18–27%**).

Platelet counts are generally normal.

Neutrophilia and monocytosis may be present due to chronic inflammation induced by the primary disease.

Bone marrow cytology shows **increased iron stores in bone marrow macrophages**.

Differential diagnosis

FeLV, myelophthtic disease, ehrlichiosis, anemia of renal failure, hypoadrenocorticism.

Treatment

Remove the source of the chronic disease.

Whole blood transfusion if indicated.

Erythropoietin and other bone marrow stimulants are unlikely to be effective.

RENAL FAILURE**

Classical signs

- Weight loss, inappetence.
- Polyuria, polydipsia.
- \pm Intermittent vomiting.
- Pale mucous membranes.

Clinical signs

Polydipsia, polyuria, inappetence, weight loss, intermittent vomiting, “rubber jaw”, small kidneys, and other findings consistent with chronic renal failure (see page 234).

The **non-regenerative anemia** is generally **mild to moderate (PCV \geq 18) from erythropoietin lack**, unless accompanied by blood loss anemia from gastrointestinal hemorrhage or hemolysis from hypophosphatemia. Other factors contributing to anemia in renal

failure include shortened red cell survival, and the effects of uremic toxins such as parathyroid hormone on erythropoiesis.

Diagnosis

Documentation of **azotemia with suboptimal urine-concentrating ability** (see page 645).

Exclude other causes of non-regenerative anemia.

Mild to moderate **normocytic, normochromic, non-regenerative anemia** (PCV = 15–27%).

Neutrophil and platelet numbers are generally normal.

Differential diagnosis

Any cause of non-regenerative anemia.

Treatment

Human recombinant erythropoietin.

- 100 U/kg, SC, 3 days weekly for induction.
- Adjust dose and frequency to maintain PCV > 20 for maintenance.
- Antibodies may be generated against the human recombinant product inactivating it, which occurs in 20–30% of treated cats.
- Severe immune-mediated reactions rarely occur.
- Some clinicians use erythropoietin to induce remission of anemia and attempt to use anabolic steroids to maintain remission.
- If iron deficiency is present, response to erythropoietin can be blunted.

If clinically indicated, administer a blood transfusion while waiting for an erythropoietin response. Indication is inappetence, and increased heart and respiratory rates at rest.

Anabolic steroids (see page 1339).

FELINE LEUKEMIA VIRUS**

Classical signs

- Lethargy, anorexia, weight loss; usually in cats < 6 years.
- \pm clinical findings consistent with lymphoma; masses, etc.
- \pm secondary infections of any organ system.

Pathogenesis

Feline leukemia virus (FeLV) is a single-stranded **RNA virus** that produces reverse transcriptase enzyme.

The envelope protein **p15e** is associated with the development of **immunosuppression**.

The core protein **p27** is present in the cytoplasm of infected cells as well as in the peripheral blood, saliva and tears of infected cats; detection of p27 is the **basis of the immunofluorescence and ELISA tests** for FeLV.

The envelope **glycoprotein 70 (gp70)** contains **subgroup antigens** A, B or C; these subgroups are associated with the infectivity, virulence and disease caused by individual strains of the virus.

All cats carry subgroup A either alone or in combination with B or C.

Subgroup A may cause malignancy by itself, but coinfection with B or C may have a synergistic effect on oncogenicity.

Exposure to gp70 results in the production of neutralizing antibodies in some cats.

Feline coronavirus-associated cell membrane antigen is a FeLV-induced antigen expressed on the surface of cells with virus-induced **malignant transformation**. Antibodies formed against this antigen can be detected in some cats.

Stages of infection after oral exposure and resultant immunofluorescent antibody (IFA) and enzyme-linked immunosorbent assay (ELISA) test results:

- Stage I. **Replication in local lymphoid tissues**; 2–12 days post-inoculation (PI); IFA negative; ELISA negative.
- Stage II. **Dissemination in circulating lymphocytes and monocytes**; 2–12 days PI; IFA negative; ELISA positive.
- Stage III. **Replication in the spleen, distant lymph nodes and gut** associated lymphoid tissue; 2–12 days PI, IFA negative, ELISA positive.
- Stage IV. **Replication in bone marrow cells and intestinal epithelial crypts**; 2–6 weeks PI; IFA negative; ELISA positive.
- Stage V. **Peripheral viremia**, dissemination via infected bone marrow derived neutrophils and platelets; 4–6 weeks PI; IFA positive; ELISA positive.

- Stage VI. **Disseminated epithelial cell infection** with virus secretion in saliva and tears; 4–6 weeks PI; IFA positive; ELISA positive.

Following exposure, cats either become persistently infected, develop latent or sequestered infection, **become immune carriers** or **have self-limiting infection**.

Whether or not infection occurs following natural exposure to FeLV is determined by the virus subtype or strain, the virus dose, the age of the cat when exposed, and the cat's immune responses.

Approximately **30% of the cats with self-limiting infection** will have **provirus present (latent infection)** which can be **associated with p27-negative lymphoma** and possible reactivation to persistent viremia.

Some cats with latent infection also have evidence of immunosuppression.

Latent infection can be activated by the administration of glucocorticoids or other immunosuppressive drugs or pregnancy.

Atypical or sequestered (localized) infection occurs in up to 26% of cats exposed to FeLV; the **bone marrow, spleen, lymph node** and small intestine are the tissues most commonly involved. It is unknown what percentage of these cats develops clinical disease but some cats will transmit the virus to offspring.

In experimental studies, 100% of neonatal kittens, 70–85% of weanling kittens, and **15–30% of cats > 4 months old were infected** when exposed; adults may be more difficult to infect than kittens due to the maturation of macrophage function.

Subgroup C induces aplastic anemia from tropism for macrophages resulting in increased secretion of tumor necrosis factor- α .

Immunodeficiency syndromes are likely to occur secondary to **T lymphocyte depletion** (both CD4+ and CD8+ lymphocytes) or **dysfunction**, and either neutropenia or neutrophil function deficits.

Myeloproliferative diseases likely develop from viral induction of **bone marrow growth-promoting substances**.

Transmission

The **principal route of infection** is **prolonged contact with infected cat saliva and nasal secretions**; biting is not required but can transmit infection.

Fomite transmission and aerosol transmission are unlikely due to **poor survival of the organism in the environment**.

Transplacental infection and transmission by milk occur but more kittens are probably infected when **licked and groomed by the infected queen**.

FeLV has been detected in semen and vaginal epithelium and so venereal transmission is possible.

The role of blood-sucking arthropods in the transmission of FeLV is largely unknown but considered of minimal importance.

Clinical signs

Any age, gender or breed of cat can develop signs of FeLV infection but the **majority are male** and **between 1–6 years of age**.

Most FeLV-infected cats are evaluated for **non-specific signs** such as **anorexia, weight loss and depression** or for evaluation of abnormalities associated with specific organ systems.

Of FeLV-infected cats evaluated at necropsy, **23% have evidence of neoplasia** (96% – lymphoma/leukemia complex) and the remainder die from non-neoplastic diseases including those from **secondary infections due to immunosuppression**.

Gastrointestinal abnormalities.

- **Stomatitis and halitosis** may be secondary to **overgrowth of normal bacterial flora** or **persistent calicivirus** infection from immunosuppression.
- **Vomiting and diarrhea** occur in some FeLV-infected cats and may be due to opportunistic infections such as **salmonellosis, giardiasis or cryptosporidiosis or lymphoma**.
- A form of enteritis clinically and histopathologically resembling panleukopenia but apparently related to FeLV infection has been described, and is possibly secondary to enteric coronavirus infection.

Icterus.

- **Pre-hepatic icterus** is related to immune-mediated destruction of red blood cells induced by FeLV or secondary infection by *M. haemofelis* or *Candidatus Mycoplasma haemomintum* (*Haemobartonella felis*).
- **Hepatic icterus** is related to **hepatic lymphoma**, hepatic lipidosis and focal liver necrosis.
- **Post-hepatic icterus** may occur due to **alimenteric lymphoma**.

Respiratory abnormalities.

- Sneezing, nasal discharge, pneumonia, bronchitis and pyothorax occur in some FeLV-infected cats from immunosuppression and secondary infections.
- Dyspnea and restrictive breathing pattern with muffled heart or lung sounds are common in cats with **thymic lymphoma**; these **cats are generally < 3 years** of age and may have decreased cranial chest compliance on palpation.

Lymphadenopathy due to lymphoma or hyperplasia of lymphoid tissues occurs in FeLV-infected cats.

Neoplasia.

- **Mediastinal (thymic), multicentric and alimenteric lymphoma** are common neoplasms associated with FeLV.
- Fibrosarcomas occasionally develop in young cats co-infected with FeLV and feline sarcoma virus.
- Lymphocytic, myelogenous, erythroid and megakaryocytic leukemia all are reported secondary to FeLV infection; **myelodysplasia and myelofibrosis** also occur.

Urinary tract abnormalities.

- Urinary tract problems most frequently associated with FeLV-infected cats are urinary incontinence and renal failure.
- **Renal failure** is generally secondary to renal lymphoma or glomerulonephritis.
- **Urinary incontinence** has been predominantly a small bladder, nocturnal incontinence that appears to be caused by either sphincter incompetence or detrusor hyperactivity.

Ocular abnormalities.

- Intraocular lymphoma induces uveitis and glaucoma in some cats; cats are generally presented for miosis, blepharospasm or cloudy eyes.

- Aqueous flare, mass lesions, keratic precipitates, lens luxations and glaucoma are often found on ocular examination.
- If anterior uveitis is present, the abnormality is usually because of co-infection with FIP, *T. gondii*, *C. neoformans* or FIV.

Reproductive abnormalities.

- FeLV-infected queens may be presented for abortion, stillbirth or infertility.
- Kittens that are infected in utero but survive to parturition generally develop accelerated FeLV syndromes or die as a part of the kitten mortality complex.

Neurologic abnormalities.

- Nervous system disease is likely to develop due to **polyneuropathy** or **lymphoma**.
- Neurologic abnormalities are occasionally secondary to other infectious agents like FIP or *T. gondii*.
- Anisocoria, ataxia, weakness, behavioral change and urinary incontinence are the most common neurologic signs.
- Neurologic examination commonly reveals **tetraparesis** or **paraparesis** and **decreased conscious proprioception**.
- Leukemic cells were detected in the bone marrow of 69% of a group of cats with spinal lymphoma.

Secondary infections.

- **Concurrent infections by viral, bacterial, fungal, rickettsial and parasitic agents** are commonly detected in FeLV seropositive cats; it is difficult clinically to determine which are primary and which are secondary to FeLV-induced immunosuppression.
- A strong association exists between FeLV and infections with **feline infectious peritonitis virus** and hemotropic mycoplasmas (previously *Haemobartonella felis*).
- Secondary infections may be more difficult to treat in FeLV-infected cats that are immunosuppressed.

Musculoskeletal abnormalities.

- **Multiple cartilaginous exostosis** occur in some cats.
- **Polyarthritis with resultant stiffness** and lameness with or without swollen, hot and painful joints occurs in some cats and has been attributed to immune complex deposition.

Laboratory abnormalities.

- **Anemia is common; non-regenerative** anemia occurs alone or in combination with decreases in lymphocytes, neutrophils and platelets.
- Evidence of abnormal red blood cell release from the bone marrow characterized by **increased numbers of circulating nucleated red blood cells without an appropriate reticulocytosis** is common.
- Examination of bone marrow often documents a **maturation arrest in the erythroid line**.
- **Regenerative anemia** is detected in some cats with immune-mediated destruction of erythrocytes induced by FeLV or in some cats co-infected with *M. haemofelis*.
- Microagglutination of erythrocytes or positive direct Coomb's testing occurs in some cats.
- **Neutropenia** occurs in some due to bone marrow suppression or immune-mediated destruction.
- **Renal azotemia** occurs in cats with renal lymphoma.
- **Hyperbilirubinemia** occurs due to pre-hepatic hemolytic anemia or hepatic disease associated with lymphosarcoma.
- Increased activities of liver enzymes develop secondary to hepatic lipidosis or hepatic lymphosarcoma.
- **Proteinuria** occurs in some FeLV-infected cats secondary to glomerulonephritis.
- **Malignant lymphocytes** characteristic of FeLV-induced lymphosarcoma are easily identified cytologically, and occasionally are identified in peripheral blood smears and in cerebrospinal fluid.
- Leukemias can be detected in peripheral blood smears and on bone marrow aspirates.

Diagnosis

Detection of FeLV antigens in neutrophils and platelets by IFA or in whole blood, plasma, serum, saliva or tears by ELISA are most commonly used clinically to document infection by FeLV.

Antibody titers to FeLV envelope antigens (neutralizing antibody) and against virus-transformed tumor cells (FOCMA antibody) are available in some research laboratories but clinical use is limited due to poor prognostic value.

Results of IFA and ELISA testing during the dissemination of FeLV are listed under Pathogenesis.

- The **ELISA can detect p27 antigen prior to infection of bone marrow** and release of infected neutrophils and platelets and so can be positive in some cats during early stages of infection or during self-limiting infection even though IFA results are negative.
- **Positive serum test results** occur anywhere between **2 and 30 weeks** (generally 2–8 weeks) after infection.
- Systemic epithelial tissue (including salivary glands and tear glands) infection occurs after bone marrow infection.
- There is generally a delay of 1–2 weeks after the onset of viremia before ELISA tear and saliva tests become positive.
- Since p27 can be detected by ELISA in cats that are developing self-limiting infection, **all cats positive by serum ELISA should have the results confirmed immediately by IFA or should be isolated and retested by ELISA in 4–6 weeks.**
- Some ELISA-positive cats that revert to negative have become latently infected; the majority of latently infected cats are negative by ELISA and IFA but the virus can be isolated from the bone marrow.
- **False-positive ELISA** results can develop secondary to poor laboratory technique and are more common with whole blood, tears or saliva than with serum or plasma.
- **False-negative ELISA** using tears or saliva occur during early stages of infection.
- Results of the IFA test are accurate 98% of the time.
- **False-negative IFA** results may occur when leukopenia or thrombocytopenia prevents evaluation of an adequate number of cells.
- **False-positive IFA** results can occur if the blood smears submitted for evaluation are too thick.
- A positive IFA indicates that the cat is viremic and contagious; **viremia will be sustained for life in 90–97% of cats with positive IFA results.**
- Virtually all IFA-positive cats will also be ELISA positive.
- The rare combination of IFA-positive and ELISA-negative results suggests technique-related artifact.
- Negative ELISA results correlate well with negative IFA results and an inability to isolate FeLV.
- Cats that are ELISA-positive and IFA-negative are termed discordant; discordant results are usually

due to false-positive ELISA results, false-negative IFA results, or self-limiting infection.

- **Cats that are ELISA-positive and IFA-negative** are probably not contagious at that time, but should be **isolated until retested 4–6 weeks later** since progression to persistent viremia and epithelial cell infection may be occurring.
- There is no reliable means of **identifying local or latent FeLV infections** other than **virus isolation and polymerase chain reaction on bone marrow cells.**
- Positive ELISA or IFA results do not document immunodeficiency or disease induced by FeLV; many seropositive cats have disease manifestations induced by secondary invaders.

Treatment

Antiviral drugs.

- Use of antiviral drugs is controversial.
- Numbers of reported cats is minimal and so definitive statements cannot be made for predicted response. The **primary goal of treatment is to improve quality of life** evidenced by attitude, appetite and physical appearance.
- If used, **zidovudine (AZT)** should be administered at 5 mg/kg bid. Cats should be monitored for development of anemia.
- 9-(2-phosphonoyl-methoxyethyl) adenine (**PMEA**) treated cats have greater therapeutic responses but more adverse effects than AZT-treated cats.

While nothing has been able to consistently clear viremia, immunotherapy may benefit some clinically ill, persistently viremic cats. The practitioner should realize that controlled studies for most are lacking and the following should be considered primarily anecdotal.

- **Interferon-alpha.** Prevents release of budding virions. 30 units (1 ml) PO, once daily or once daily, every other week. 10 000 units/kg, SQ daily for several weeks if life threatened.
- **Staphylococcus A.** B lymphocyte and T lymphocyte activation, immune-complex binding, interferon induction, and immunoglobulin Fc binding. 1 ml/kg intraperitoneally, twice weekly for 10 weeks followed by 1 ml/kg intraperitoneally, twice weekly every fourth week for life.

- ***Propionibacterium acnes***. Activation of macrophages and natural killer cells. Increased production of interferon, tumor necrosis factor, and interleukin 1. 0.5 ml IV, twice weekly for 2 weeks followed by 0.5 ml IV, weekly for 20 weeks.
- **Acemannan**. Enhanced release of tumor necrosis factor, prostaglandin E₂, and interleukin 1-alpha by macrophages. 2 mg/kg, IP, once weekly for 6 weeks.
- **Pind-orf**. Inactivated parapox ovis virus.

Antibiotics are often indicated **for secondary infections** and should be used at the high end of the dose range for an extended duration.

Supportive care including fluid therapy, appetite stimulants and enteral nutrition supplied via force feeding or nasogastric, pharyngostomy, gastrostomy or jejunostomy tube placement may be indicated.

Blood transfusions, erythropoietin, hematinic agents, vitamin B12, folic acid and anabolic steroids generally have been unsuccessful in the management of the non-regenerative anemia.

Immunosuppressive therapy may be required in the management of hemolytic anemia but has the potential for virus activation.

Prognosis

The **majority of cats (> 80%)** with persistent viremia will **die** of an FeLV-related illness **within 2–3 years**.

Most cats with self-limiting infection will be subclinically affected.

Prevention

Avoid exposure; house cats indoors.

Test and removal of seropositive cats can result in virus-free catteries and multiple-cat households.

Multiple FeLV vaccines have been developed and licensed in the last several years.

- Due to variation in challenge study methodology and the difficulty of assessing preventable fraction of a disease with a relatively low infection rate, long sub-clinical phase, and multiple field strains, efficacy of individual vaccines continues to be in question.

- Vaccination of cats not previously exposed to FeLV should be considered in cats at high risk (i.e. particularly kittens less than 1 year old in contact with potentially infected cats).
- Owners should be warned of the potential efficacy of less than 100%.
- Cats should be tested for FeLV prior to vaccination.
- Vaccination is not indicated in seropositive cats.
- Vaccination does not induce seropositivity.
- Soft tissue sarcomas develop at the vaccination site in 1:1000 to 1:10 000 cats given adjuvanted vaccines.

Zoonotic aspects

While FeLV will grow in some human cell cultures (with the exception of subgroup A), antigens of FeLV have never been documented in the serum of humans suggesting that this virus is species specific.

Human complement lyses FeLV.

FELINE INFECTIOUS PERITONITIS VIRUS (FIP), FELINE IMMUNODEFICIENCY VIRUS (FIV)**

Classical signs

- Lethargy, anorexia, weight loss.
- +/- fever, pleural or abdominal effusion (FIP).
- +/- CNS, hepatic, renal disease (FIP).
- +/- secondary infections of any organ system (FIV).

See main references page 339, The Thin, Inappetent Cat (FIV), and page 372, The Pyrexia Cat (FIP).

Clinical signs

Anemia is not usually a main presenting sign, and occurs as a consequence of chronic disease. Signs of the agent predominate.

Typically FIP presents as fever, weight loss, anorexia and lethargy. Highly proteinaceous pleural or abdominal effusions may be present, or there may be evidence of hepatic, renal, ocular or CNS disease.

Cats with signs from FIV often have lethargy, anorexia and weight loss associated with secondary

infections of the skin, and gastrointestinal or respiratory tracts.

Diagnosis

Diagnosis of FIV is based on the appropriate antibody test, whereas pre-mortem diagnosis of FIP is usually presumptive, unless biopsy samples are available for histological examination.

DRUGS/TOXINS*

Classical signs

- Lethargy, anorexia and depression.
- Other specific signs of the toxin.
- Vomiting and diarrhea are common.

Clinical signs

Usually there is a **history of exposure to the drug or toxin**; grizeofulvin, azathioprine, estrogens, chloramphenicol, some chemotherapeutic agents and non-steroidal anti-inflammatory agents are most common.

Mechanism varies with the toxin. **Bone marrow suppression** (azathioprine, estrogens, chloramphenicol, chemotherapeutic agents) is the mechanism for non-regenerative anemia. Any drug can be protein bound and serve as a hapten for **secondary immune-mediated hemolytic anemia** (see Regenerative anemia). Other drugs and toxins result in bleeding (see Regenerative anemia). **Idiosyncratic reactions** can occur with most drugs or toxins, but each one listed here also is an intrinsic toxin damaging the bone marrow if the toxic dose is exceeded.

Weakness, lethargy, pale mucous membranes, tachycardia and tachypnea may be present due to anemia.

Other clinical findings from the toxin inducing non-regenerative anemia may be present.

Hemorrhage (thrombocytopenia) or evidence of infections (neutropenia) may be evident.

Non-steroidal anti-inflammatory agents can cause clinical findings consistent with gastrointestinal bleeding or renal disease.

Diagnosis

Severe normocytic-normochromic, non-regenerative anemia.

Most drugs and toxins damage the bone marrow and so **have concurrent thrombocytopenia and neutropenia**.

Since bone marrow damage is present, anemia may be severe.

Bone marrow hypoplasia can be documented by cytologic examination of bone marrow aspirates or histology of core biopsies but these techniques do not prove the cause of damage.

Historical evidence of exposure to a drug or toxin is the best way to determine cause of anemia.

Differential diagnosis

FeLV, myelophthitic disease, ehrlichiosis.

Treatment

Whole blood transfusions are given as needed.

Recombinant erythropoietin can be administered as described for renal failure-associated non-regenerative anemia, but is unlikely to be effective since maximal erythropoietin responses are likely occurring.

Antibiotics may be indicated if fever due to neutropenia is occurring.

MYELOPHTHITIC DISEASES*

Classical signs

- Lethargy, anorexia and depression.

Clinical signs

Abnormalities result from neoplastic infiltration (lymphoma and myeloproliferative neoplasms most common) into the bone marrow inducing loss of normal bone marrow cells.

Findings may be consistent with the primary neoplasia; i.e. masses.

Weakness, tachycardia and pale mucous membranes result from anemia.

Fever or other evidence of secondary infections develop if neutropenia is present

Bleeding results from thrombocytopenia.

Diagnosis

Pancytopenia (aplastic anemia) is most common; pure red cell aplasia is unusual.

Lymphoma, myeloproliferative disease or multiple myeloma are often detected on bone marrow cytology or biopsy.

Circulating malignant cells may be detected.

Differential diagnosis

FeLV, drugs or toxins, ehrlichiosis.

Treatment

Treat the neoplasm primarily.

Supportive care.

EHRlichiosis AND ANAPLASMOSIS

Classical signs

- Lethargy, anorexia, depression and fever.
- Lameness from polyarthritis.
- Pale mucous membranes.

Transmission

It is unknown how clinically ill, naturally exposed cats are infected with an *Ehrlichia canis*-like organism.

Ixodes spp. ticks have been associated with several cases with *Anaplasma phagocytophilum* (previously *E. equi*) infection.

Exposure to arthropods has been reported in about 30% of the cases in the literature.

Pathogenesis

Pathogenesis is unknown, but it is likely similar to dogs based on clinical and laboratory findings.

In dogs, infection may result in either a regenerative or non-regenerative anemia.

Early in infection, acute aplastic anemia occurs because of destruction of progenitor and proliferative cells in the bone marrow. The resulting anemia is usually mild or absent because of the long erythrocyte lifespan.

Secondary immune-mediated anemia may occur.

In the chronic phase of the disease, hemopoietic stem cell injury results in moderate to severe non-regenerative anemia.

Cats experimentally infected with *Neorickettsia risticii* develop **morulae in mononuclear cells** and occasionally develop **fever, depression, lymphadenopathy, anorexia and diarrhea**.

Cats experimentally infected with *A. phagocytophilum* develop **morulae in neutrophils and eosinophils**.

Cases proven by genetic sequencing were *E. canis* (North America and France) or *A. phagocytophilum* (Sweden, Ireland, Denmark and North America).

Ehrlichia-like morula have been detected in mononuclear cells or neutrophils of naturally exposed cats in the United States, Kenya, France, Sweden, Brazil and Thailand.

Other cases have been diagnosed based on the combination of positive *E. canis* or *A. phagocytophilum* serology, clinical or laboratory findings consistent with ehrlichial infection, exclusion of other causes, and response to an anti-rickettsial drug. However, it is unknown whether these cats were ill from the *Ehrlichia* spp. infection.

Clinical signs

Cats are usually **young** and both males and females have been affected.

Cats infected by *A. phagocytophilum* have only been diagnosed in areas with *Ixodes* ticks.

Fever, inappetence, lethargy, weight loss, hyperesthesia or joint pain, and pale mucous membranes are the most common abnormalities. **Splenomegaly, dyspnea, uveitis, diarrhea and lymphadenomegaly** are also detected in some.

Concurrent diseases are rarely reported but included hemotropic *Mycoplasma* infection and lymphosarcoma.

Anemia was reported for some cats; most are non-regenerative and both cats with known regenerative anemia were infected with a hemotropic *Mycoplasma* spp.

Leukopenia, leukocytosis characterized neutrophilia, lymphocytosis, monocytosis, and intermittent thrombocytopenia can occur.

Thrombocytopenia is the most common abnormality in cats infected by *A. phagocytophilum*.

Hyperglobulinemia was reported for some cats; protein electrophoresis documented polyclonal gammopathy in the cat assayed.

Epidemiologic associations have been made with ocular discharge, **monoclonal gammopathy** or **polyarthritis** in *E. canis* seropositive cats and with outdoor exposure and vomiting in *N. risticii* seropositive cats.

Diagnosis

Morulae appear as clusters of short rods in the cytoplasm of leukocytes.

Determination of species by PCR or culture and electron microscopy.

Presumptive diagnosis based on the combination of positive serologic test results, clinical signs of disease consistent with *Ehrlichia* infection, exclusion of other causes of the disease syndrome, and response to anti-rickettsial drugs.

Some cats with suspected clinical ehrlichiosis had antibodies against *E. canis* and *N. risticii* and some had antibodies against *E. risticii* alone or *E. canis* alone.

Positive serologic test results occur in healthy cats as well as clinically ill cats, and so a diagnosis of clinical ehrlichiosis should not be based on serologic test results alone.

Some cats proven by PCR assay to be infected by an *E. canis* like organism were negative for *E. canis* antibodies.

All cats proven by PCR assay to be infected by *A. phagocytophilum* have also been seropositive.

Differential diagnosis

Infectious, neoplastic, or immune-mediated diseases resulting in fever, polyarthritis and anemia.

Treatment

Clinical improvement after therapy with tetracycline, doxycycline, or imidocarb dipropionate was reported for most cats.

Doxycycline at 10 mg/kg, PO, q 24 h, for a minimum of 4 weeks.

Imidocarb at 5 mg/kg, IM, q 14 days for 2 doses.

Prognosis

Good.

Prevention and zoonotic aspects

Avoid exposure, house cats indoors.

Ehrlichia canis and *A. phagocytophilum* infect people as well as cats. However, transmission is from tick exposure not contact with cats.

If indicated, use tick control on high-risk cats.

IMMUNE-MEDIATED (PURE RED CELL APLASIA)

Classical signs

- Lethargy, anorexia and depression.

Clinical signs

Most cases of pure red cell aplasia are thought to be due to **primary or secondary immune-mediated destruction of red blood cell precursors**.

Lethargy or weakness, pale mucous membranes, and elevated heart and respiration rates occur at rest.

Clinical course may be protracted due to the slow development of anemia.

Diagnosis

Feline leukemia virus infection, drugs and toxins should be excluded.

CBC generally reveals **severe normocytic-normochromic, non-regenerative anemia** with normal neutrophil and platelet numbers.

Bone marrow examination reveals either **maturation arrest or lack of erythroblasts**.

IFA or polymerase chain reaction for FeLV should be performed on bone marrow cells.

Spherocytes, positive direct Coomb's test results and autoagglutination might be present in some affected animals.

Differential diagnosis

FeLV, myelophthitic disease, ehrlichiosis, anemia of chronic disease.

Treatment

Immunosuppressive therapy as described for regenerative hemolytic anemia (see page 533) should be prescribed.

Several blood transfusions may be required; since the bone marrow is involved, response to therapy is more delayed.

Recombinant erythropoietin can be administered as described for renal failure-associated non-regenerative anemia (see page 540), but is unlikely to be effective since maximal erythropoietin responses are likely occurring.

FOLIC ACID ANTAGONISM/DEFICIENCY

Classical signs

- Lethargy, anorexia and depression.

Clinical signs

Folic acid is required for DNA synthesis, which is important in red blood cell production; **insufficient folic acid** results in **macrocytic anemia as a maturation**

defect. Mechanisms include folic acid antagonist administration, dietary insufficiency, malabsorption and congenital defect.

History of chronic (> 2 weeks) **administration of folic acid antagonists** including **pyrimethamine** and **sulfa drugs**.

Clinical signs are associated with anemia and those of the disease the antibiotic was being used to treat.

Diarrhea and weight loss may be associated with **malabsorption syndromes**.

The cat may have been fed a **folic acid deficient diet** like **tuna**.

Diagnosis

Macrocytic-hypochromic, or macrocytic-normochromic non-regenerative anemia with nuclear remnants.

Mean corpuscular volume >55 fl.

Neutropenia with hypersegmented neutrophils may be present

History of drug administration.

Bone marrow cytology shows **erythroid hyperplasia** and **megaloblastic changes**.

Serum folate concentrations decreased (normal = 13–38 µg/L) with normal cobalamin concentrations.

Treatment

Stop drug treatment.

Folic acid supplementation at 0.004–0.01 mg/kg/day, PO.

Signs resolve within 3 weeks of supplementation.

IRON DEFICIENCY

Classical signs

- Lethargy, anorexia and depression.

Clinical signs

Most commonly develops from **chronic loss of blood from the body**.

The most common site of loss is the **gastrointestinal tract**.

Iron is required for the production of hemoglobin; lack of iron leads to **microcytic, hypochromic anemia**.

Melena or hematochezia may or may not be present.

Clinical signs including **vomiting, diarrhea and weight loss** that are associated with gastrointestinal diseases resulting in chronic blood loss.

Gastrointestinal parasites (hookworms) and fleas can result in iron deficiency anemia in **kittens**.

Clinical signs of end-stage liver disease or portosystemic shunts including failure to thrive and central nervous system disease.

Melena or hematochezia may or may not be present.

The primary disease generally is chronic and low grade; acute blood loss usually does not result in iron deficiency and thus is usually regenerative.

Diagnosis

Mild to severe microcytic-hypochromic, non-regenerative anemia.

Mean corpuscular volume is generally **< 39 fl**.

Bone marrow iron stores subjectively are decreased.

Decreased serum iron concentrations and increased total iron binding capacity.

Thrombocytosis and occasionally neutrophilia are present from non-specific bone marrow stimulation.

Serum bile acids, ultrasound, contrast studies, scintigraphy and hepatic biopsy can be used to document portosystemic shunts or end-stage liver disease.

Differential diagnosis

Any cause of non-regenerative anemia.

Treatment

Control underlying disease.

Ferrous sulfate 50–100 mg/cat, PO, q 24 hours.

It requires weeks to months to correct iron deficiency since the gastrointestinal transferrin system can only absorb small concentrations of iron daily.

HYPOADRENOCORTICISM

Classical signs

- Weakness, lethargy, anorexia.
- Vomiting or diarrhea.

Clinical signs

Very rare in cats.

Cats are usually presented for evaluation of **depression, lethargy, vomiting, diarrhea and anorexia** (see page 253).

Bradycardia in the face of shock may be present due to hyperkalemia.

Clinical signs of anemia are unusual, because the anemia is mild.

Diagnosis

Normocytic-normochromic, non-regenerative anemia usually with a PCV of 15–27.

ACTH stimulation to document hypoadrenocorticism.

Treatment

Treatment of shock and hyperkalemia acutely.

Glucocorticoid and mineralocorticoid supplementation (see page 254).

HYPOTHYROIDISM

Classical signs

- Lethargy, weight gain.
- Poor coat, seborrhea sicca, slow hair regrowth after clipping.

Clinical signs

Extremely rare cause of anemia post-thyroidectomy or I^{131} treatment.

Most cats maintain enough thyroid function and never become anemic.

Obesity, lethargy and pale mucous membranes.

Poor coat, seborrhea sicca, slow hair regrowth after clipping and thick skin.

Diagnosis

Normocytic-normochromic, non-regenerative anemia usually with a PCV of 15–27.

Decreased total and free T4 concentrations after treatment for hyperthyroidism.

Treatment

Levothyroxine supplementation (see page 1354).

25. The cat with polycythemia

Jacquie Rand and Annette Litster

KEY SIGNS

- Increased red cell concentration in peripheral blood.
- Injected mucous membranes.

MECHANISM?

- Dehydration resulting from disease of many organs may produce relative polycythemia. Polycythemia may be an appropriate physiological response to hypoxia caused by pulmonary or cardiac disease. Alternatively, inappropriate polycythemia may be associated with renal space-occupying masses or other visceral tumors. Inappropriate primary polycythemia results from a rare myeloproliferative disorder, polycythemia vera.

WHERE?

- Gastrointestinal tract, renal or skin (burns) disease causing excessive fluid loss.
 - Cardiac or respiratory disease causing chronic hypoxia.
 - Renal (space-occupying masses) or visceral (neoplastic conditions) conditions associated with inappropriate erythropoietin secretion.
- Bone marrow associated with myeloproliferative disease.

WHAT?

- The most common cause of polycythemia is dehydration. Hyperthyroidism produces mild polycythemia in many cats. Appropriate polycythemia associated with hypoxia from chronic respiratory or cardiac disease is less common. Primary or secondary inappropriate polycythemia is very rare.

QUICK REFERENCE SUMMARY

Diseases causing polycythemia

DEGENERATIVE

- **Cardiac disease* (p 561)**

Cardiac conditions such as cardiomyopathy which result in tissue hypoxia or cyanosis from cardiac failure may stimulate increased erythropoietin production, resulting in increased red

blood cell mass. Clinical signs may include dyspnea, lethargy, weakness, a gallop rhythm, heart murmur and arrhythmia. Mucous membranes may be pale or cyanotic with prolonged capillary refill time.

ANOMALY

● Congenital heart disease* (p 561)

Congenital cardiac anomalies associated with right to left shunting, e.g. tetralogy of Fallot, reverse patent ductus arteriosus, and atrial or ventricular septal defects may cause secondary polycythemia in young cats. There may be a history of lethargy and stunted growth, and on clinical examination, dyspnea, cyanosis and a heart murmur may be noted. PCV is often markedly elevated (> 60%).

● Renal space-occupying mass

Renal conditions such as renal cysts and hydronephrosis have been associated with inappropriate erythrocytosis secondary to increased erythropoietin production, but these are very rare. Kidneys are unilaterally or bilaterally enlarged on abdominal palpation, and there may be associated clinical signs of renal disease such as polyuria and polydipsia.

NEOPLASTIC

● Polycythemia vera*(p 563)

Primary polycythemia is caused by a myeloproliferative disorder, similar to polycythemia vera in humans. There may be a history of bleeding, seizures, polydipsia and polyuria, and physical examination reveals dark pink mucosa with a PCV often exceeding 60%. Circulating erythropoietin levels are normal or low. This condition is very rare in cats.

● Neoplasia (p 565)

Neoplasia of a wide variety of organs including the kidneys, liver, adrenal gland, female reproductive tract and central nervous system have been associated with inappropriate polycythemia. The condition is characterized by increased circulating erythropoietin levels without a hypoxic stimulus. Impaired renal blood flow secondary to a space-occupying mass, or tumor secretion of erythropoietin or erythropoietin-like substances have been hypothesized as possible causes of erythrocytosis. Clinical signs relate to the type of tumor involved and its anatomical location.

METABOLIC

● Dehydration*** (p 557)

Derangement of fluid balance from a variety of causes is the most common cause of polycythemia in cats. Polycythemia occurs most commonly when **excessive fluid loss** through the gastrointestinal tract (**vomiting or diarrhea**) or kidney (**diabetes mellitus or renal failure**) is coupled with **inadequate fluid intake**. Typically there is depression and anorexia, and signs that relate to the underlying condition such as polyuria, polydipsia, vomiting or diarrhea. Skin tents on pinching, mucous membranes are dry, and may have delayed refill. Accompanying laboratory abnormalities include increased total protein, increased urine specific gravity and pre-renal azotemia.

continued

continued

- **Hyperthyroidism** (p 560)**

Hyperthyroidism may be associated with a mild increase in PCV, possibly from a direct effect of thyroxine on erythrocyte precursors. Affected cats are usually older (> 8 years), with a history of weight loss despite a robust appetite. Associated clinical signs include irritable behavior, tachycardia, sometimes with a gallop rhythm, polyuria, polydipsia and often chronic vomiting.

- **Severe obesity (Pickwickian syndrome) (p 568)**

Morbid obesity may predispose to tissue hypoxia from inadequate alveolar ventilation because of fat accumulation in the thorax and compression of upper airways. Blood O₂ saturation levels are low (<92%) and there are slightly to markedly increased circulating levels of erythropoietin.

PHYSICAL

- **High altitude (p 568)**

Decreased O₂ levels in the atmosphere at high altitudes may stimulate increased renal erythropoietin production in response to tissue hypoxia. The cat is otherwise clinically normal, although there may be mild dyspnea with a fast, shallow respiratory pattern. Circulating erythropoietin levels are elevated.

PSYCHOLOGIC

- **Stress-induced splenic contraction (p 567)**

The stress response in cats may include splenic contraction, with a resultant infusion of stored splenic erythrocytes into the circulation. Affected cats usually have an appropriate history and may have other accompanying signs such as dilated pupils and behavioral changes. Hemoconcentration caused by stress is usually mild and transient.

IATROGENIC

- **Excessive blood transfusion or overdose of exogenous erythropoietin (p 564)**

This is a potential, although previously unreported, cause of polycythemia. The diagnosis is made with an appropriate history and clinical signs of erythrocytosis such as weakness, injected mucous membranes and neurological signs.

IMMUNE

- **Acute systemic anaphylaxis (p 566)**

Acute systemic anaphylaxis results from an extremely rapid and overwhelming immune reaction to a foreign antigen. It may cause hemoconcentration, most likely from a combination of fluid loss caused by increased vascular permeability, and splenic contraction in response to acute shock. There should be a history of exposure to a foreign antigen, usually protein. Anaphylaxis may occur on the first exposure to the inciting antigen. Clinical signs include acute dyspnea, collapse, pale mucus membranes and other signs of hypotensive shock.

INFLAMMATION

- **Chronic pulmonary disease* (p 562)**

Chronic pulmonary disease such as feline asthma/bronchitis complex may cause tissue hypoxia, resulting in increased erythropoietin production and erythrocytosis. There is usually a history of chronic coughing, with dyspnea and lethargy in more severe cases. Clinical signs include crackles and wheezes on thoracic auscultation.

INTRODUCTION

MECHANISM?

Increased red cell concentration may result from a **relative or absolute** increase in erythrocytes.

A **relative increase in red blood cells** is caused by **dehydration**. In dehydration, a reduction in plasma volume causes hemoconcentration, resulting in erythrocytosis and increased total plasma protein concentration. Blood oxygen saturation levels are normal.

Transient absolute polycythemia may occur with excitement when **splenic contraction** releases red cells into circulation.

Absolute polycythemia may be an appropriate physiological response to **chronic hypoxia** from cardiac or pulmonary disease, and is mediated by increased serum erythropoietin levels.

- Signs relate to the **underlying cardiac cause** and include a cardiac murmur and cyanosis consistent with right to left shunting of blood causing hypoxia, e.g. tetralogy of Fallot, atrial or ventricular septal defect (ASD or VSD).
- Clinical signs of **chronic primary lung pathology** include coughing, dyspnea, wheezes and crackles, which accompany generalized hypoxia in more severe cases.

Alternatively, **absolute polycythemia** may be caused by **increased, but physiologically inappropriate, erythropoietin secretion**, associated with a variety of **neoplastic conditions or space-occupying renal masses**. In these cases, blood oxygen saturation levels are normal.

- **Secondary causes of inappropriate polycythemia** include **visceral tumors** involving the kidneys, liver, adrenal gland, female reproductive tract and central nervous system. These occasionally secrete erythropoietin or an erythropoietin-like substance **without a hypoxic stimulus**. While these tumors have been reported to cause polycythemia in humans and dogs, they are yet to be reported as a cause of polycythemia in the cat.
 - Clinical signs are expected to relate to the type of tumor involved, its anatomical location, and the polycythemia.

- **Space-occupying renal masses** including neoplasia, cysts or hydronephrosis may impair renal blood flow and stimulate secretion of inappropriate concentrations of erythropoietin.
 - Polycythemia from a **renal space-occupying mass** is sometimes accompanied by signs of renal failure, such as polydipsia/polyuria, reduced urine specific gravity and azotemia.

Primary inappropriate polycythemia is called polycythemia vera, and is a neoplastic proliferation of erythroid cells, associated with low or **undetectable erythropoietin concentrations**. Typically **PCV is greater than 60–65%**.

Once the PCV exceeds 65%, the ensuing **hyperviscosity increases peripheral resistance, decreases cardiac output and decreases oxygen transport to the tissues**. Increased blood volume distends vessels and together with sluggish flow, **predisposes to thrombosis and vessel rupture**. It is hypothesized that erythrocytosis impairs renal tubular concentrating mechanisms, resulting in polyuria and polydipsia.

Clinically, polycythemia causes **injected mucous membranes, torturous retinal blood vessels**, and there may be a history of **intermittent bleeding diatheses**.

Insufficient vascular perfusion of the central nervous system may result in **neurological signs such as seizures, ataxia, abnormal behavior and/or blindness**.

WHERE?

Relative polycythemia may result from **gastrointestinal or renal disease**, and rarely from extensive **skin burns** which cause excessive fluid loss, or **severe disease of any organ** sufficient to cause marked lethargy and inadequate fluid intake.

Absolute polycythemia from a physiological increase in erythropoietin concentration may result from **cardiac or pulmonary disease**.

Absolute polycythemia from a pathological increase in erythropoietin concentration may result from space-occupying **renal disease or neoplasia of a wide variety of organs**.

Primary absolute polycythemia is the result of a myelodysplastic condition of the **bone marrow**.

WHAT?

The **most common cause** of polycythemia is **dehydration**. **Hyperthyroidism**, acquired cardiac disease such as **cardiomyopathy**, and respiratory disease including **feline asthma/bronchitis complex** are less common causes of polycythemia. Renal cysts and hydronephrosis are rare causes of polycythemia in cats. All other causes of polycythemia are uncommon, with **congenital cardiac disease** the most common cause of severe polycythemia. **Polycythemia vera** and neoplasia secreting erythropoietin-like products are very rare causes of severe polycythemia in cats.

DIAGNOSIS

Relative polycythemia from dehydration should be suspected if **plasma protein is elevated** and there is **clinical evidence of dehydration**.

- **PCV is usually $\leq 60\%$.**
- Treatment with fluids normalizes PCV and plasma protein concentration.

Cats that are very stressed at the time blood is collected may have **transient polycythemia**.

- **PCV is usually ≤ 60 and polycythemia is mild and transient.**

Absolute polycythemia should be suspected if **plasma protein is normal** and there is **no evidence of dehydration**, in an **unstressed** cat.

Appropriate polycythemia (in response to hypoxia) is differentiated from inappropriate polycythemia by measurement of **oxygen saturation** of arterial blood.

- **Appropriate polycythemia is likely if arterial oxygen saturation is less than 92% (normal $\geq 97\%$).**
- **Cardiac and pulmonary systems should be examined** initially using auscultation and thoracic radiographs, and if indicated, by echocardiography and electrocardiography.

Inappropriate polycythemia should be suspected if **arterial oxygen saturation is normal**.

Secondary causes of inappropriate polycythemia include visceral tumors or a space-occupying renal mass such as neoplasia, cyst or hydronephrosis. These should be investigated using renal palpation, abdominal radiographs, abdominal ultrasonography and/or intravenous pyelogram.

Serum erythropoietin assay helps differentiate secondary from primary inappropriate polycythemia. However, accurate measurement of feline erythropoietin is compromised by the **lack of an assay technique validated for use in cats**. A human ELISA assay technique has been successfully used to detect erythropoietin in cat serum and is available through Dr Urs Giger at the University of Pennsylvania.

Serum erythropoietin concentrations are normal or increased in most cases of **secondary inappropriate polycythemia**.

Primary polycythemia (polycythemia vera) is likely if **PCV > 60 – 65%** and there is **no evidence of dehydration, hypoxia, cardiac or pulmonary disease, neoplasia or a space-occupying renal lesion**.

- **Erythropoietin is low or undetectable in primary polycythemia.**
- Primary polycythemia may be accompanied by **leukocytosis and thrombocytosis**.
- Bone marrow typically has increased cellularity, with erythroid hyperplasia or panhyperplasia, normal maturation within the erythroid line, and **normal morphology of cells**.

TREATMENT

In relative polycythemia, intravenous or subcutaneous balanced electrolyte solutions should be administered to correct dehydration.

Primary polycythemia vera can be treated by a combination of regular, intermittent phlebotomy and fluid therapy. More severe cases may require adjunct chemotherapy with hydroxyurea.

In secondary polycythemia (appropriate or inappropriate), the underlying disease must be diagnosed and treated, and symptomatic therapy with phlebotomy and fluid therapy should be provided to manage the erythrocytosis.

DISEASES CAUSING POLYCYTHEMIA

DEHYDRATION***

Classical signs

- Skin tenting.
- Tacky mucus membranes.
- Combination of increased PCV and plasma protein concentration.
- Signs attributable to underlying disease.

Pathogenesis

A **relative increase** in red cells occurs as a result of **dehydration**. The increase in red cell concentration is secondary to decreased plasma volume from dehydration. **Total red cell mass is normal**, although red cell mass can only be determined using radio-isotope-tagged autologous red blood cells, a technique not generally available in practice.

Relative polycythemia occurs most commonly when **excessive fluid loss** through the gastrointestinal tract (**vomiting or diarrhoea**) or kidney (**diabetes mellitus or renal failure**) is coupled with **inadequate fluid intake**.

Clinical signs

Clinical signs of dehydration include **skin tenting, tacky mucus membranes and high plasma protein levels**.

- Dehydration is assessed initially by examining **skin turgor**, usually by drawing the skin at the back of the neck upward.
 - It is not until there is **5% dehydration** that there is **subtle loss of skin elasticity**.
 - At **6–8% dehydration**, there is a **delay in return of the skin to its normal position**, the capillary refill time may be slightly prolonged, and mucous membranes may be dry to touch.
 - At **10–12% dehydration**, tented skin stands in place; mucus membranes are dry; the eyes are sunken in the orbits; there is prolonged capillary refill time; and there may be signs of shock.
 - By **12–15% dehydration**, signs of shock are present and death is imminent.

Accompanying clinical signs are attributable to the **cause of the dehydration**. **Renal and gastrointestinal tract fluid losses** are common causes of dehydration, and present with **polyuria and polydipsia**, or **vomiting and diarrhea**, respectively, coupled with inadequate fluid intake.

Massive fluid deficits can occur after **burns** because of fluid losses from the skin.

Acute viral respiratory disease can cause dehydration because of losses from **ocular and nasal discharges and hypersalivation**.

Diagnosis

Characteristic clinical signs of dehydration are accompanied by **hemoconcentration, normal blood oxygen saturation and increased total plasma protein concentration**.

Differential diagnosis

Since clinical signs of dehydration are characteristic, **differential diagnoses mainly refer to the condition causing the dehydration**, rather than to dehydration itself.

Treatment

Fluid and electrolyte therapy is initially required to **restore intravascular volume** because this is most critical for survival, and then to **replace fluid and electrolytes in the extravascular compartments** including both intracellular and interstitial fluid. Many patients that are dehydrated have adequate circulating blood volume to maintain tissue perfusion, and do not need rapid volume expansion.

Of total body water, **2/3 is intracellular and 1/3 is extracellular**. Only about **1/6 of body water is intravascular**.

- **Sodium and chloride** are the major electrolytes in the **extracellular fluid**.
- **Potassium and phosphates** are the major electrolytes in **intracellular fluid**.

Type of fluid selected should be based on the **electrolyte and acid–base status** of the cat, and whether it is being used for replacement or maintenance.

Crystalloids are the most common types of fluids used, and have sodium as their major osmotically active par-

ticle. Sodium and water rapidly traverse semipermeable membranes such as the endothelium, and **only 20–33% remains in the vascular space 30 min after administration.**

- **Crystalloids** may be **balanced** and have a similar electrolyte composition and osmolality to normal plasma (e.g. lactated Ringer's solution, Plasma-lyte A or Normisol-R), or **unbalanced**. Unbalanced fluids (eg. 0.9% NaCl, 5% dextrose in water) are used to correct specific deficits in plasma electrolyte concentrations or water, and should be chosen only after serum electrolyte concentrations have been determined.
- Fluids may also be classified as **replacement fluids**, provided to correct electrolyte or pH imbalances, or **maintenance fluids**, which are restricted in sodium, contain additional potassium and are **hypotonic** when administered or after metabolism of dextrose, e.g. Plasma-Lyte 56, Normosol M, 0.45% NaCl with added potassium, or 0.45% NaCl with 2.5% dextrose and added potassium, Plasma-Lyte 56 with 5% dextrose, and Normisol-M with 5% dextrose.

Metabolic acidosis is the most common acid–base disorder, and is usually corrected with volume expansion, correcting the underlying disease, and using fluids with an alkalizing effect. Where there is **severe metabolic acidosis or hepatic failure**, NaHCO_3 may need to be added to the IV fluid infusion.

- **Fluids containing lactate or buffers metabolized to lactate** (acetate and gluconate) are alkalizing, because lactate is metabolized to bicarbonate by the liver, which makes it suitable for the treatment of metabolic acidosis.
 - **Lactated Ringer's solution** is buffered by lactate.
 - **Plasma-Lyte and Normosol** are buffered by acetate and gluconate.

Metabolic alkalosis is usually corrected once chloride deficits are corrected. Metabolic alkalosis occurs as a result of **chloride depletion and dehydration**, because to maintain intravascular volume, the renal tubules reabsorb bicarbonate along with sodium instead of the depleted chloride.

- **Normal saline** is unbuffered and has an acidifying effect.

Hypotonic fluids should be used when there are free water deficits or when serum sodium is elevated.

- **Hypotonic fluids** include 5% dextrose in water and 0.45% sodium chloride with 2.5% dextrose. These fluids have similar osmolalities to plasma prior to administration, but once administered the dextrose is metabolized and the remaining fluid becomes hypotonic.
- Five percent dextrose in water is useful as a carrier fluid for administration of drugs and does not add extra electrolytes to the cat. For example, it can be used as a constant rate infusion (CRI). Drugs such as metoclopramide or morphine may be administered as a constant rate infusion (CRI) in 5% dextrose in water.

Hypertonic fluids result in rapid volume expansion because the high sodium concentration (e.g. 7.5% NaCl) or dextrose (**10% dextrose**) attracts water from the extravascular compartments, and small volumes (3–5 ml/kg) can be administered. However, the effect is short term (~30 min), and they should be administered with additional crystalloids, with or without colloids. Administer the dose slowly IV over 5–10 minutes. Hypertonic saline is most useful in cats that require small volume resuscitation, for example after head trauma or pulmonary contusions. It can be combined with colloids such as Hetastarch.

- **Hypertonic saline** causes volume expansion equivalent to colloids, but at 1/4 the volume administered.
- **Dose** is 3–5 ml/kg of 7.5% NaCl administered slowly IV over 5–10 minutes.

Colloids contain osmotically active particles that are too large to cross vessel walls, and most of the infused volume remains in circulation. **Colloids** are indicated for **rapid restoration of circulating fluid volume** and to **slow loss of fluid from the intravascular space**.

- The addition of **colloids** to the fluid therapy regimen may also be appropriate where losses are ongoing from the intravascular space, such as with burns, acute shock, systemic inflammatory response syndrome (SIRS), sepsis or acute systemic anaphylaxis. Commercially available hetastarch solution may be used for up to 30% of the maintenance IV fluid requirements in severe cases while losses are ongoing.
- In general, when administering **colloids**, **divide the dose into four aliquots and administer slowly IV over 10–15 minutes. Recheck the cat after each aliquot, carefully evaluating the lungs for signs of**

pulmonary edema. Use a **syringe pump or infusion pump** because cats are very sensitive to the volume expansion effects of colloids, and manual administration increases the risk of adverse effects such as pulmonary edema. Hypothermic cats are particularly sensitive to colloids, and administering hypertonic saline or colloids to cats with undiagnosed and asymptomatic hypertrophic cardiomyopathy may precipitate pulmonary edema.

Colloid solutions include **dextran**, **hydroxyethyl starch** (HES) and hemoglobin-based oxygen-carrying solutions such as **Oxyglobin®**. They are contraindicated for use in very dehydrated, oligouric patients because the possibility of renal damage is increased. The fluid attracted intravascularly comes from within cells, exacerbating intracellular dehydration.

- **Colloid osmotic pressure** (COP) and volume-expanding capacity varies with the colloid as follows:
 - 6% hetastarch has a COP of 30 mmHg, and expands the volume by 1–1.3 ml per ml of colloid infused, and stays in the vascular space for 12–48 h.
 - 10% dextran 40 has a COP of 40 and expands the volume by 1–1.5 ml per ml of colloid infused, and stays in the vascular space for 4–8 h.
 - 6% dextran 70 has a COP of 40 and expands the volume by 0.8 ml per ml of colloid infused, and stays in the vascular space for 4–8 h.
- **Dextran** is made from high-molecular-weight linear glucose polymers produced by bacteria, and is available as Dextran 40 and 70, but Dextran 40 is rarely used in veterinary medicine because of its association with acute renal failure. The dose rate is 5–10 ml/kg, beginning with the lower dose.
- **Hydroxyethyl starch** is composed primarily of amylopectin, and is a branched polysaccharide closely resembling glycogen. It is available as Hetastarch and Pentastarch. The standard dose rate is 10–15 ml/kg/day, but administer 2–5 ml/kg initially and re-evaluate the cat.
- **Oxyglobin®** is used primarily for its oxygen-carrying capacity, but can be used for its colloidal effect. However it is expensive to use solely for volume expansion. The COP of Oxyglobin is 37 mmHg, thus, it has slightly more colloidal pull than Hetastarch, and retains oxygen-carrying capacity for up to 40 h. The dose rate in cats is 1–2 ml/kg/h with a total dose of 15 ml/kg.

- **Haemacel®** is a colloid solution available in Europe and Australasia that is comprised of 3.5% polygeline, a gelatin-based colloid.

To achieve a very rapid increase in intravascular volume using low volumes of infused fluids, **colloids and hypertonic saline** can be combined. Replacement or maintenance crystalloids are administered concurrently to maintain or replenish interstitial and intracellular fluid levels, and are administered at 50% of the volume that would be required if they were used alone. Examples of combinations used are:

- Combine 1.3 ml/kg of 23.4% NaCl with 2.7 ml/kg of 6% hetastarch, and administer slowly over 10–15 minutes. Mixing the solutions together results in a 7.5% NaCl solution.
- 20% NaCl at 1.5 ml/kg combined with Dextran 70 at 3 ml/kg and administer slowly over 10–15 minutes. Mixing results in approximately 7% NaCl.

Plasma can be used as a colloid, but it is best used when there is a specific indication such as pancreatitis or a coagulation disturbance. It is not the preferred method of replacing albumin or improving the oncotic pressure, because the volume of plasma required to measurably increase serum albumin concentration is very large. However, it can be used as a component of fluid therapy to help increase plasma oncotic pressure in a hypoproteinemic cat, and to decrease the tendency for loss of intravascular fluid. Plasma can be administered at 20 ml/kg over 4 h in place of 1/3 of the calculated crystalloid fluid volume to be administered.

The **intravenous route of fluid administration** is preferred for correction of severe dehydration, major electrolyte and acid–base imbalances, and shock. While the jugular, cephalic, femoral and saphenous veins are available for IV catheter placement, the cephalic vein is the site of choice as the catheter is most readily secured at that site and less commonly soiled with urine and feces than in caudal limb sites.

Fluid rates administered depend on the requirement of the animal.

If the cat has insufficient plasma volume to maintain tissue perfusion, intravascular volume must be restored rapidly.

- **Inadequate tissue perfusion is indicated by:**
 - Tachycardia and tachypnea, and sometimes bradycardia.

- Pale mucus membranes and increased capillary refill time (> 2 s).
- Cold extremities.
- Anuria or oliguria (< 1 ml/kg/h urine produced).
- Decreased central venous pressure (< 5 cmH₂O).

- **Inadequate interstitial hydration** is evident as tacky mucus membranes, skin tenting and sunken eyes.

Crystalloids can be used alone, but colloids and hypertonic saline result in much more rapid restoration of normal perfusion, because only small volumes need to be administered (3–5 ml/kg), and they act immediately to attract water into the vascular space.

- When **tissue perfusion is inadequate**, for example from **severe dehydration or shock**, crystalloids administered alone can be infused at **40–55 ml/kg/h** for a total dose of 45–60 ml/kg to **restore circulating intravascular volume**. This volume should be reduced by 40–60% if colloids are administered together with crystalloids.
- In general, the patient should be reassessed after 1/4 to 1/3 is administered or after 15 min, because IV fluids administered too rapidly can cause pulmonary edema. Intravascular volume is usually restored over the first 2 hours.
- If the electrolyte status of the patient is unknown, use a crystalloid most like plasma in sodium and potassium content, pH and osmolality, such as **lactated Ringer's, Normosol-R or Plasma-Lyte A**. These have an alkalizing effect which is useful because patients with reduced circulating blood volume are usually acidotic. 0.9% NaCl can also be used.

For hemodynamically stable patients with dehydration, fluid deficits are corrected over the first 12–24 hours, followed by maintenance fluid rates. Maintenance rates of **70 ml/kg/day (3 ml/kg/h)** are calculated, and the dehydration fluid deficit is added to the maintenance figure. Dehydration fluid deficit is calculated by the following formula: % dehydration \times body weight (kg) = fluid deficit (liters).

- For example, a 5 kg cat that is 10% dehydrated requires 500 ml (0.1×5 L) to correct the fluid deficit and 350 ml (70×5 ml) for maintenance, which is 850 ml in the first 24 h, or 35 ml/h or 0.59 ml/min. Using a microdrip set with 60 drops per ml, the infusion rate is 35 drops per minute (0.59 ml \times 60 drops/ml), or just over one every 2 seconds. This rate may be increased in the first 4–6 h to correct the fluid deficit more rapidly.

- Replacement fluids include **lactated Ringer's, Normosol-R or Plasma-Lyte A**.

If ongoing maintenance fluids are required over several days because fluid intake is inadequate or there are continuing fluid losses, change to a **maintenance fluid** that resembles the amount of free water and electrolytes that would be consumed daily and are being lost. Maintenance solutions are hypotonic crystalloids that are lower in sodium and chloride but higher in potassium concentration than plasma, such as Plasma-Lyte 56, Normosol M, 0.45% NaCl with added potassium, or 0.45% NaCl with 2.5% dextrose and added potassium.

- Maintenance fluid rates are **70 ml/kg/day**, but if there are **ongoing fluid losses from polyuria, diarrhea or vomiting**, then calculate an additional **5%/kg requirement** (or 50 ml/kg/day), which is nearly equivalent to doubling the daily maintenance rate. **Fever** can increase fluid requirements by 15–20 ml/kg/day.

Potassium is usually added to fluids at the following rates, and the infusion rate of the fluid is adjusted so the rate does not exceed 0.5 mmol (mEq)/kg/h.

Serum potassium concentration (mmol or mEq/L)	Potassium supplementation to 1 L of IV fluids
> 3.5	20 mEq
30 mEq	3.0–3.5
40 mEq	2.5–3.0
60 mEq	2.0–2.5
80 mEq	< 2.0

Prognosis

The prognosis ultimately depends on the **inciting condition**, but acute dehydration treated with prompt and vigorous fluid therapy has an excellent prognosis.

HYPERTHYROIDISM**

Classical signs

- Weight loss despite polyphagia.
- Polyuria/polydipsia.
- Tachycardia, sometimes with a gallop rhythm.
- Mild erythrocytosis in some cases.

See main reference The thin cat (or cat with weight loss) and a good appetite on page 304 for details.

Pathogenesis

Many hyperthyroid cats have **mild increases in PCV**, which are thought to be a **direct effect of thyroid hormone stimulating red cell precursors**. **Erythropoietin production** may also be increased in hyperthyroidism, because of the increased metabolic rate.

Clinical signs

There is usually a history of **weight loss despite polyphagia**.

Cats are often **hyperexcitable** and the **coat is often unkempt** from poor grooming.

Vomiting and polyuria/polydipsia occur in about one third of cats.

On physical examination, there may be **palpable thyroid nodules, and tachycardia or a heart murmur** on cardiac auscultation.

Diagnosis

Serum total thyroxine (T_4) is usually increased, unless there is an accompanying medical condition that may suppress total T_4 to the upper half of the reference range (“**sick euthyroid syndrome**”). In these cases, a diagnosis of hyperthyroidism can be made by detection of **increased serum free T_4** or by a triiodothyroxine (T_3) suppression test.

Differential diagnosis

Other causes of **mild absolute erythrocytosis with normal blood O_2 saturation**, such as **stress-induced splenic contraction**, must be differentiated from erythrocytosis associated with hyperthyroidism.

- Demonstration of increased thyroxine is diagnostic for hyperthyroidism, although stress-induced splenic contraction could occur concurrently and compound the mild polycythemia.

Treatment

The treatment of choice for hyperthyroidism is **radioactive I^{131} therapy** where available.

Hyperthyroidism is commonly treated with oral daily **methimazole**, which is generally continued for the life of the cat.

Surgical treatment by unilateral or bilateral thyroidectomy may be recommended if the cat has acceptable anesthetic risk factors. Careful surgical technique is necessary to avoid **post-operative hypoparathyroidism** and life threatening hypocalcemia.

Adjunctive treatment with beta-blockers or other hypotensive agents may be necessary to manage the **cardiovascular complications** of hyperthyroidism.

Prognosis

The prognosis for successful management of hyperthyroidism is generally **very good provided associated complicating factors such as thyrotoxic heart disease are well controlled**.

CARDIAC DISEASE INCLUDING CONGENITAL DISEASE*

Classical signs

- Abnormal cardiac rhythm or rate, often accompanied by a cardiac murmur.
- Blood O_2 saturation is reduced (<92%).
- Advanced cases may present with acute dyspnea.
- Usually cardiomegaly on thoracic radiography.

See main references The Cat With Abnormal Heart Sounds and/or an Enlarged Heart and The Cat With Tachycardia, Bradycardia, or an Irregular Rhythm on pages 140, 157 for details.

Pathogenesis

Cardiac failure causes **chronic hypoxia, stimulating increased secretion of erythropoietin, resulting in polycythemia**.

The most dramatic increases in PCV occur in young cats with **congenital heart disease with right to left shunting** (e.g. tetralogy of Fallot, reverse patent ductus

arteriosus, atrial or ventricular septal defects), but appropriate secondary polycythemia may also occur with **left-sided or biventricular congestive heart failure**, as occurs with cardiomyopathy.

Clinical signs

Feline cardiac disease **usually presents at an advanced stage**, with dyspnea and hypoxia (oxygen saturation <92%).

There may be **open-mouth breathing and cyanosis**.

Mucosae are dark pink, or purple if the polycythemia is caused by hypoxia from right to left shunting of blood in the heart or lungs.

Tachycardia and arrhythmia may be detected on cardiac auscultation, with accompanying **crackles and wheezes** on thoracic auscultation from pleural effusion and/or pulmonary edema.

Congenital cardiac disease often causes **stunted growth** in comparison with littermates.

Diagnosis

Initial diagnosis may be made on **auscultatory abnormalities**, together with other signs of cardiac failure such as **dyspnea and hypertension**.

Thoracic radiology reveals **cardiomegaly** with or without **pulmonary edema** and/or **pleural effusion**.

Cardiac chamber abnormalities, abnormal wall thicknesses and/or pressure or flow irregularities may be detected using **echocardiology**.

ECG abnormalities may be detected, although this is not as common in cats as in dogs.

Differential diagnosis

Other causes of chronic hypoxia, such as **pulmonary disease**, should be differentiated from hypoxia from congenital or degenerative cardiac disease.

Treatment

Treatment of cardiac conditions is dependent on **correct diagnosis of the cause of cardiac failure**.

Medical therapy is instituted to treat the **physiological effects of cardiac failure**. This may include treatment for hypertension, cardiac rate disturbances, arrhythmia, pulmonary edema and/or pleural effusion. See The Cat With Abnormal Heart Sounds and/or an Enlarged Heart and The Cat With Tachycardia, Bradycardia, or an Irregular Rhythm on pages 124, 157 for treatment details.

Hypoxia in tetralogy of Fallot is decreased when the condition is treated by **aortic banding**, which reduces right-to-left blood flow.

Hematocrit should be reduced to 45% before surgery is performed to treat any underlying conditions, to decrease the risk of thromboembolism during surgery. This is achieved by performing phlebotomy and administering intravenous fluids.

Prognosis

The prognosis for feline cardiac disease is guarded and may be poor if the disease is initially diagnosed at an advanced stage.

CHRONIC PULMONARY DISEASE*

Classical signs

- \pm History of chronic coughing.
- Dyspnea may be acute, chronic or intermittent.
- Cyanosis and open-mouth breathing in severe cases.
- Crackles, wheezes and sometimes muffled cardiac sounds.

See main references The Cat With Stridor (page 32), The Dyspneic or Tachypneic Cat (page 47), The Cat With Hydrothorax (page 71) and The Coughing Cat (page 90) for details.

Pathogenesis

Respiratory disease causes **chronic hypoxia**, stimulating increased **secretion of erythropoietin** and resulting in **polycythemia**.

The most common cause of chronic pulmonary disease in cats is feline asthma/feline bronchitis complex,

which is an idiopathic inflammatory condition causing a combination of bronchoconstriction, chronic airway inflammation and excessive mucus production. Parasitic pulmonary disease such as lungworm or heartworm may also cause chronic respiratory signs with intermittent hypoxia.

Clinical signs

Coughing, intermittent dyspnea and hypoxia (oxygen saturation <92%) are the most common clinical signs of chronic feline respiratory disease. Dyspnea may be acute, chronic or intermittent.

There may be **open-mouth breathing and cyanosis** in severely affected cats.

Crackles and wheezes from **bronchial disease and/or pleural effusion** may be heard on thoracic auscultation.

Diagnosis

Chronic pulmonary disease presents with **auscultatory abnormalities**, together with a **history of intermittent or continuous dyspnea and often chronic coughing**.

Thoracic radiology reveals **characteristic lung patterns** associated with **bronchial, pleural or pulmonary disease**.

Bronchoalveolar lavage cytology and microbiology is useful in the diagnosis of inflammatory or bacterial (e.g. *Mycoplasma felis*) lung disease.

Fecal flotation and examination should be performed to check for **parasites such as lungworm** (*Aelurostrongylus abstrusus*).

Serology should also be performed to detect **heartworm** (*Dirofilaria immitis*) infection in endemic areas, as clinical signs of feline heartworm disease are generally respiratory in nature.

Toxoplasma serology may be performed as the lungs are a common site for the extra-intestinal (tissue) phase of the disease.

Differential diagnosis

Other causes of chronic hypoxia, such as congenital or degenerative cardiac disease, should be differentiated from hypoxia caused by chronic pulmonary disease.

Treatment

Treatment of respiratory conditions is dependent on the **correct diagnosis of the cause of the respiratory condition**, using a **thorough diagnostic work-up procedure**.

Specific therapies are needed to treat **respiratory infections**.

Symptomatic medical therapy is recommended for **chronic inflammatory pulmonary disease** such as **feline asthma/bronchitis complex**. **Oral corticosteroid therapy** at anti-inflammatory dose rates and bronchodilators such as terbutaline or aminophylline may reduce the severity and frequency of dyspneic episodes. **Inhaled corticosteroid and/or bronchodilator therapy** can be administered using pediatric asthma inhalers.

Prognosis

The prognosis for feline respiratory disease is **good for most respiratory infections**, although **chronic infections may result in chronic inflammatory disease** even after successful treatment of the infection.

POLYCYTHEMIA VERA*

Classical signs

- Injected dark pink mucous membranes.
- ± History of intermittent bleeding diatheses.
- ± Systolic ejection (hemic) murmur.
- ± Central nervous system signs, such as seizures.
- PCV > 60% with low serum erythropoietin concentration and normal blood O₂ saturation.

Pathogenesis

Polycythemia vera results from an **absolute increase** in red cell mass because of a **clonal proliferation of neoplastic erythroid stem cells** in the bone marrow associated with myeloproliferative disease.

- Erythroid precursors proliferate independent of erythropoietin in a normal orderly pattern of maturation.

Because normal feedback inhibition of erythrocytosis does not occur, **circulating erythropoietin levels are usually very low.**

Polycythemia vera is **very rare in cats.**

There is often **leukocytosis and thrombocytopenia.**

The erythrocytes produced in polycythemia vera are **morphologically normal.**

Clinical signs

Mucosae are dark pink.

Bleeding may occur from numerous sites, e.g. nose, gums, skin, gastrointestinal tract, urinary tract or in the eye.

Central nervous system signs such as seizures, abnormal behavior, ataxia and blindness often occur because of reduced vascular perfusion of the central nervous system.

There may be a history of **polydipsia and polyuria.**

Dilated tortuous retinal vessels and retinal hemorrhage may be observed on ophthalmic examination.

A **systolic ejection murmur** (hemic murmur) may be present over the base of the heart secondary to abnormal viscosity.

Diagnosis

Polycythemia vera is diagnosed when there is a **combination of marked erythrocytosis (PCV > 60), low or undetectable serum erythropoietin levels, normal plasma protein concentration and normal blood O₂ saturation levels.**

The **bone marrow** has **increased cellularity with erythroid hyperplasia or panhyperplasia.** There is relatively normal maturation of erythroid precursors and cells have **normal morphology**, with no evidence of neoplastic features. Myeloid to erythroid ratio may be normal, or reflect erythroid hyperplasia.

Differential diagnosis

Polycythemia vera needs to be differentiated from other more common causes of erythrocytosis, such as **dehydration, hyperthyroidism and chronic hypoxic cardiac or pulmonary disease.**

Treatment

Primary polycythemia should be treated with **phlebotomy and intravenous fluids** to reduce PCV to below 60%.

Ten ml/kg/day of blood should be removed, and replaced with an equivalent volume of fluid (0.9% NaCl or balanced electrolyte solution) or the cat's own plasma.

- Regular phlebotomies may be adequate to maintain PCV. If phlebotomies are required more than once a month to maintain PCV < 60%, hydroxyurea therapy should be tried.

Bone marrow can be suppressed using **hydroxyurea** indefinitely (15–30 mg/kg q 24 h with food, reduce dose to 15 mg/kg q 24–48 h after 7–14 days).

- Complete blood counts should be performed every 7–14 days until PCV is normal, then every 3–4 months.
- When using hydroxyurea, serious bone marrow depression resulting in anemia, thrombocytopenia and leukopenia may occur, so cats receiving the drug need to be monitored carefully. If leukopenia, thrombocytopenia or anemia develops, stop the drug until blood counts are normal, and then resume at a lower dose.

Prognosis

The prognosis for polycythemia vera is **guarded**, depending on the response to treatment and the incidence of side effects of the therapies used.

EXCESSIVE BLOOD TRANSFUSION OR OVERDOSE OF EXOGENOUS ERYTHROPOIETIN

Classical signs

- Injected mucus membranes.
- Weakness.
- CNS signs including seizures.

Clinical signs

This is a potential, although previously unreported, cause of polycythemia.

Expected clinical signs are those of erythrocytosis, i.e. weakness, injected mucus membranes and neurological signs.

Diagnosis

The diagnosis is made using a combination of an appropriate history and clinical signs.

NEOPLASIA

Classical signs

- Signs are referable to the causative space-occupying mass.
- Mucosae may be dark pink.
- Signs of hyperviscosity, e.g. tortuous retinal vessels, seizures, bleeding diatheses, polyuria, polydipsia.

Pathogenesis

It is hypothesized that **renal** and other **visceral tumors** may **secrete erythropoietin or an erythropoietin-like substance**, resulting in erythrocytosis. While these tumors have been reported to cause polycythemia in humans and dogs, they are yet to be reported as a cause of polycythemia in the cat.

This kind of polycythemia is **secondary to another pathological condition and inappropriate**, since blood O₂ saturation levels are normal.

Clinical signs

Clinical signs are **referable** to the underlying neoplasia and polycythemia.

Mucus membranes are dark pink.

Signs of hyperviscosity include tortuous retinal vessels, seizures and other CNS signs, and intermittent bleeding diathesis.

Diagnosis

Erythrocytosis associated with neoplasia is diagnosed when there is a **combination of marked erythrocytosis (PCV > 60)**, normal or **increased serum erythropoietin levels**, **normal plasma protein** concentration, and normal **blood O₂ saturation levels**.

Visceral tumors are diagnosed ideally by **abdominal ultrasound**, although **intravenous pyelography** may also be a valuable imaging technique for renal masses.

Serum erythropoietin levels are normal or elevated, and blood O₂ saturation levels are normal.

Differential diagnosis

Secondary inappropriate polycythemia **must be differentiated from relative polycythemia** in dehydration, **secondary polycythemia** due to hypoxia, and from **primary polycythemia**.

- In neoplastic conditions, there is a **normal plasma protein** concentration, normal **blood O₂ saturation** and **normal or increased serum erythropoietin** concentration. This differentiates secondary inappropriate polycythemia associated with neoplasia from other conditions causing polycythemia.

Treatment

Treatment should be directed at the tumor, which is the **underlying cause of the polycythemia**.

Polycythemia may reoccur if metastatic foci secrete erythropoietin or an erythropoietin-like substance.

Prognosis

The prognosis **depends on the underlying cause of the polycythemia**. The prognosis with neoplasia varies according to the tumor type.

RENAL SPACE-OCCUPYING MASS

Classical signs

- Signs are referable to the causative space-occupying mass.
- Dark pink mucosae.
- Signs of hyperviscosity, e.g. tortuous retinal vessels, seizures, bleeding diatheses, polyuria, polydipsia.
- ±Signs of renal insufficiency, such as azotemia, reduced urine specific gravity, polydipsia and polyuria.

Pathogenesis

A **space-occupying renal mass** such as a cyst, **hydro-nephrotic disease** or **tumor** may induce local tissue **hypoxia**, **stimulating renal oxygen sensors**, resulting in

increased erythropoietin production. These sensors are thought to be located in the juxtaglomerular complex.

Some renal tumors may secrete erythropoietin or an erythropoietin-like substance, resulting in erythrocytosis.

This kind of polycythemia is **secondary to another pathological condition and inappropriate**, since blood O₂ saturation levels are normal.

Clinical signs

Clinical signs are **referable to the inciting condition**, whether renal or neoplastic. Lethargy, weight loss and inappetence are common.

Mucus membranes are dark pink.

Signs of hyperviscosity may be present including tortuous retinal vessels, seizures and other CNS signs, and intermittent bleeding diathesis.

Signs of renal insufficiency, such as azotemia, reduced urine specific gravity, polydipsia and polyuria may be present. However, not all cases of polycythemia from renal space-occupying masses will be accompanied by signs of renal insufficiency, due to the relatively large functional reserve of the kidneys.

Diagnosis

Renal space-occupying masses are best visualized using **abdominal ultrasound**, although **intravenous pyelography** may also be a valuable imaging technique.

Serum erythropoietin levels are normal or elevated, and blood O₂ saturation levels are normal.

Differential diagnosis

Secondary inappropriate polycythemia **must be differentiated from relative polycythemia** caused by dehydration, **secondary polycythemia** from hypoxia and **primary polycythemia**.

- When a renal space-occupying mass is causing polycythemia, **plasma protein concentration and blood O₂ saturation levels should be normal, while serum erythropoietin concentration is often inappropriately high**. These factors differentiate secondary inappropriate polycythemia due to a renal space-occupying mass from other conditions causing polycythemia.

Treatment

Treatment should be directed at the space-occupying mass, which is the **underlying cause of the polycythemia**.

Nephrectomy may be considered in cases of secondary inappropriate polycythemia from a renal space-occupying mass, but nephrectomy is considered a last-resort treatment as the resultant reduction in functional renal mass may precipitate renal insufficiency or failure. Also, polycythemia may reoccur if metastatic foci secrete erythropoietin or a functionally similar substance.

Prognosis

The prognosis **depends on the underlying cause of the polycythemia**. **Polycystic renal disease is a degenerative condition with a poor prognosis**, and most **renal tumors have a guarded prognosis**, at best. The prognosis with other kinds of neoplasia varies according to the tumor type.

ACUTE SYSTEMIC ANAPHYLAXIS

Classical signs

- Acute dyspnea.
- Hypotensive shock.
- Collapse.
- Pale mucous membranes.

Pathogenesis

Acute systemic anaphylaxis is caused by **exposure to a foreign antigen**, usually protein, and generally by the intravenous route.

While prior exposure to the antigen is usually necessary for sensitization to occur, **anaphylaxis may occur on first exposure to the antigen**. This is termed an anaphylactoid reaction.

Anaphylaxis causes **increased vascular permeability**, allowing potentially large amounts of plasma to escape from the intravascular space, resulting in hemoconcentration.

It is also hypothesized that epinephrine is released during acute shock, causing splenic contraction and the infusion of large numbers of stored erythrocytes into the circulation.

Clinical signs

Clinical signs of acute systemic anaphylaxis vary between species, as **the major organs affected in the reaction are species-specific**.

Since **the “shock organ” in the cat is the lung**, pulmonary signs such as severe acute dyspnea predominate.

Signs of **hypotensive shock**, such as pallor and collapse, accompany the pulmonary signs.

The onset of clinical signs occurs in seconds to minutes after exposure to the inciting antigen.

Occasionally, **cutaneous swelling** may be noted around the face and paws.

Diagnosis

Polycythemia may be evident on hematological examination. Typically, mucus membranes are pale and signs are peracute. This is in contrast to other causes of polycythemia where mucous membranes are dark pink and there are often signs suggesting chronic disease such as weight loss. Diagnosis is made by a **combination of appropriate history and characteristic clinical signs**.

No laboratory tests are currently available to make a definitive diagnosis of acute systemic anaphylaxis.

Blood O₂ saturation is acutely and severely reduced.

Differential diagnosis

Polycythemia associated with anaphylaxis is usually readily distinguishable from all other causes of polycythemia due to its peracute onset. Accompanying clinical signs differentiate it from dehydration, which is associated with more chronic signs including anorexia and depression.

Acute systemic anaphylaxis must be differentiated from **other causes of acute shock** such as major trauma.

Treatment

Acute shock caused by anaphylaxis should be treated by a combination of **intravenous fluid therapy at shock dose rates** (perhaps including colloids in the

protocol), **supplemental O₂** and intravenous high-dose **prednisolone sodium succinate** (100 mg/cat IV). The rate of fluid administration should be as rapid as possible to restore circulating blood volume. In cats, 150 ml can be given rapidly in the first hour but additional fluids should be administered more slowly to prevent pulmonary edema. Fluid therapy may be evaluated by monitoring blood pressure, packed cell volume and urine output.

Adjunctive therapy with bronchodilating agents (epinephrine 0.2 ml/cat of a 1:1000 dilution IV; terbutaline 0.1 mg/kg SC or IV) and **antihistamines** (chlorpheniramine maleate 1 mg/kg SC) may also be used.

Prognosis

Since acute systemic anaphylaxis is such an acute, overwhelming and life-threatening condition, the prognosis is guarded to poor, depending on how promptly and aggressively therapy is initiated, and perhaps on the amount of inciting antigen to which the cat was exposed and the rapidity of exposure.

STRESS-INDUCED SPLENIC CONTRACTION

Classical signs

- The stress response in cats may include splenic contraction, with a resultant infusion of stored splenic erythrocytes into the circulation.
- Hemoconcentration caused by stress is usually mild and transient.

Diagnosis

Affected cats often have an appropriate history of acute stress. This may be stress associated with surgery or other treatment, as well as the flight-or-fight response to acute stress.

There may be associated signs of acute stress such as dilated pupils and behavioral changes.

Erythrocytosis should resolve promptly after the inciting incident.

SEVERE OBESITY (PICKWICKIAN SYNDROME)

Classical signs

- Cats are morbidly obese (body condition score 9/9), have chronic dyspnea and difficulty with normal ambulation.

Diagnosis

While the Pickwickian syndrome causing chronic hypoxia and resultant erythrocytosis has not been reported in cats, it is logical to assume that this may occur.

Morbid obesity may predispose to tissue hypoxia from inadequate alveolar ventilation because of fat accumulation in the thorax and compression of upper airways.

Blood O₂ saturation levels are expected to be low (<92%), and there should be slightly to markedly increased circulating levels of erythropoietin.

HIGH ALTITUDE

Classical signs

- Mild polycythemia in an otherwise healthy cat living at altitude.
- Decreased O₂ levels in the atmosphere at high altitudes stimulate increased renal erythropoietin production in response to tissue hypoxia.

Diagnosis

Expected signs include mild polycythemia in an otherwise healthy cat.

A presumptive diagnosis is based on finding mild polycythemia in a cat living at high altitude (e.g. > 5000 feet/1500 m).

26. The cat with hyperlipidemia

Boyd Robert Jones

KEY SIGNS

- Lipemia (lactescent appearance of plasma).
- Lipemia retinalis (lipemic appearance of retinal vessels with a pink or salmon color).
- Cloudy cornea or anterior chamber.
- Cutaneous xanthomata (yellowish subcutaneous nodules or plaques).

MECHANISM?

- Hyperlipidemia is an increase in the **plasma triglyceride and/or cholesterol** concentrations.
- Hyperlipidemia may result from a **primary defect** in triglyceride or cholesterol metabolism.
- Hyperlipidemia may also occur when lipoprotein metabolism is altered by **systemic disease**.

WHERE?

- Abnormalities occur in blood/plasma, eye, skin, peripheral nerves, spleen, kidney and liver.
- Hyperlipidemia should be suspected when there is a persistent fasting hyperlipidemia (> 12 hours after feeding) or when a cat has any of the following signs:
- Lipemia retinalis.
- Cloudy cornea or anterior chamber.
- Cutaneous xanthomata.
- Peripheral neuropathy.
- Splenomegaly.

WHAT?

- The most common causes of hyperlipidemia are **idiopathic** and **secondary systemic diseases**, such as **diabetes mellitus**.

QUICK REFERENCE SUMMARY

Diseases causing hyperlipidemia

ANOMALY

- **Inherited hyperchylomicronemia (p 575)**

Domestic shorthair cats. May have no clinical signs, or signs of hyperlipidemia such as lipemia retinalis, xanthomata or peripheral neuropathy. Caused by a breed-related defect in lipoprotein lipase (LPL) activation due to a point mutation in the gene for LPL.

- **Cholesterol ester storage disease (p 576)**

Siamese < 1 year old, corneal clouding, intermittent diarrhea and vomiting, hepatomegaly. Lysosomal acid lipase (cholesterol ester hydrolase) deficiency results in accumulation of cholesterol esters in lysosomes.

METABOLIC

- **Nephrotic syndrome (p 576)**

Hypercholesterolemia occurs in the nephrotic syndrome as a sequel to protein-losing nephropathy. Proteinuria with hypoalbuminemia are classical findings.

- **Diabetes mellitus** (p 574)**

Hypertriglyceridemia occurs in some cats with diabetes. LPL activity is reduced, but the cause of the hypertriglyceridemia is likely multifactorial. Hypercholesterolemia may also occur and results from increased hepatic synthesis of cholesterol.

- **Idiopathic hyperlipidemia*** (p 573)**

May have no clinical signs, or have signs of hyperlipidemia. Any breed may be affected but Burmese kittens are over-represented and may present with severe anemia, lethargy and dyspnea. The cause of many cases of hyperlipidemia will be unconfirmed. The cause in most of these cases is due to a so far unidentified defect in lipid metabolism.

INTRODUCTION

MECHANISM

Definition of terms

Hyperlipidemia is an **increase** in the **plasma triglyceride and/or cholesterol concentrations**.

Hyperlipidemia may result from a primary defect in lipoprotein metabolism or from lipoprotein metabolism being altered by systemic disease.

Lipemia is the **lactescent appearance of plasma** and indicates an increase in the plasma triglyceride concentration in chylomicrons and/or low-density lipoproteins.

Lipid metabolism

Medium- and short-chain fatty acids are bound to albumin and transferred from the intestine directly to the liver via the portal vein.

Cholesterol and triglycerides are insoluble in plasma and their transport through the bloodstream relies upon their incorporation into specialized lipid-protein complexes called lipoproteins.

There are **four classes of lipoproteins (chylomicrons, VLDL, LDL and HDL)**, each with separate physical and chemical characteristics.

Each of the four lipoprotein classes have discrete roles in plasma lipid transport.

- Chylomicrons and VLDL are the primary transporters of triglycerides.
- LDL and HDL are the cholesterol transporters (LDL are the cholesterol suppliers; HDL are the cholesterol scavengers).

All lipoproteins share a **common structure**.

- The hydrophobic components (triglycerides and cholesteryl esters) are carried in the core of the particle.
- These are surrounded by a polar coat of phospholipids, special proteins called **apolipoproteins**, and a small amount of free cholesterol.

Chylomicrons are formed in the intestinal mucosa. They transport dietary triglycerides from the small intestine to adipose tissue for storage, to skeletal muscle for use as energy substrate, and to lactating mammary tissue for milk fat synthesis.

- Chylomicrons are the largest and lightest of the lipoproteins, and remain at the **origin on gel** electrophoresis.
- Triglycerides are removed from chylomicrons through the action of the enzyme **lipoprotein lipase**.
 - **Lipoprotein lipase** is located on the luminal surface of **capillary endothelium** in adipose tissue, skeletal and cardiac muscle, and lactating mammary tissue.
 - Lipoprotein lipase is **activated by apolipoprotein C-II** (apoC-II) on the surface of the chylomicron, and releases the triglycerides as fatty acids.
 - Chylomicrons are **cleared** from the blood **within 12 hours after eating**, and therefore, are not normally present in the fasted cat.
 - Removal of triglycerides from the chylomicron leaves a smaller remnant particle that is rich in cholesterol.
 - The remnant particle is removed from the circulation by specific cell surface receptors in the liver that recognize apolipoprotein E (apoE) present on the surface of these particles.

Very-low-density lipoproteins (VLDL) export triglycerides and cholesterol from the major site of endogenous synthesis in the liver, and deliver triglycerides to peripheral tissues.

- VLDL are also known as **pre- β lipoprotein** because of the electrophoretic mobility.

- Triglycerides are released to adipose tissue, skeletal and cardiac muscle, and lactating mammary tissue by lipoprotein lipase.
- The cholesterol-rich remnant particles are processed by a second lipase, called **hepatic lipase**, to form LDL.

Low-density lipoproteins (LDL) are formed from VLDL and deliver cholesterol to peripheral tissues such as the adrenal and reproductive glands.

- These lipoproteins migrate in the **β -position** on electrophoresis.
- Cholesterol delivery is facilitated by the interaction of the structural protein of LDL (apolipoprotein B-100) with specific receptors, called the LDL receptors.
- LDL receptors are also found in high concentrations in the liver where they remove excess LDL.

High-density lipoproteins (HDL) scavenge cholesterol that is excess to tissue needs and transport it to the liver. The HDL are the major carriers of cholesterol.

- HDL are the smallest and most dense lipoproteins and migrate in the **α -position** on electrophoresis.
- In the liver, cholesterol is excreted as bile salts, stored, or redistributed to other body tissues as VLDL and LDL.
- HDL are secreted into the circulation **from the liver and intestine** as small immature discoidal particles.
- The free cholesterol picked up from peripheral tissues is esterified by the enzyme lecithin:cholesterol acyl transferase (**LCAT**) to form cholesteryl esters, which enter the core of the particles.
 - In humans, the cholesteryl esters are transferred from HDL to chylomicrons, VLDL and LDL and hence back to the liver.
 - Cats lack the enzyme responsible for this, cholesteryl ester transfer protein (**CETP**), so that the HDL continue to pick up free cholesterol and expand under the action of LCAT.
 - These large HDL particles then acquire apoE and are subsequently removed from the circulation by the remnant and LDL receptors in the liver.

Hyperlipidemia

Diagnosis of hyperlipidemia is based on history, physical examination, examination of plasma and special laboratory tests.

Understanding the metabolic origins of hyperlipidemia provides the basis for the investigation of patients and for therapeutic management.

Fasting hypertriglyceridemia results from defects in **metabolism of chylomicrons and/or VLDL**.

Hypercholesterolaemia results from defects in the metabolism of **LDL and HDL**.

Compositional changes in certain lipoproteins, for example cholesterol-enrichment of VLDL or triglyceride-enrichment of LDL, may also occur in certain disorders.

Hypertriglyceridemia

Plasma concentrations of triglycerides are raised when the amounts of chylomicrons and/or VLDL increase in the circulation.

- **Chylomicrons and VLDL** are both catabolized by the enzyme **lipoprotein lipase**, which removes the triglycerides from these particles.
- Defects in the activity of lipoprotein lipase, either genetic or acquired, result in reduced clearance of chylomicrons and VLDL and hypertriglyceridemia.

Persistence of chylomicrons in the circulation for > 12 hours after ingestion of a fat-containing meal and in fasting plasma are abnormal and suggest **impaired lipoprotein lipase activity**.

Chylomicrons rise to the surface and form a **creamy layer** when plasma is **refrigerated** for 12–14 hours. VLDL remain in suspension and produce a turbid or lactescent sample.

Hypercholesterolemia

Raised plasma cholesterol concentrations generally result from **deranged metabolism of LDL and HDL**.

Raised HDL concentrations have been found in certain types of **secondary hyperlipidemia** in cats, but the precise metabolic origins of this change is unclear.

Hypercholesterolemia does not produce visible lipemia (opalescence) as HDL and LDL are too small to refract light.

WHERE?

Signs of hyperlipidemia cause problems in the following organs: blood/plasma, eye, skin, peripheral nerves, spleen, kidney, liver.

The most common signs include:

- **Lipemia retinalis** (lipemic appearance of retinal vessels with a pink or salmon-colored appearance rather than red).
- **Cloudy cornea or lipemic aqueous** (cloudy anterior chamber of eye).
- **Cutaneous xanthomata** (well-circumscribed soft, smooth, alopecic subcutaneous nodules or plaques, which may have a yellowish appearance and may ulcerate in locations prone to trauma, often multiple over the trunk and head, less frequently involve the limbs).
- **Peripheral neuropathy** resulting in paresis or paralysis of cranial or spinal nerves (e.g. 3rd sympathetic producing Horner's syndrome, trigeminal, tibial or radial nerves).
- **Splenomegaly**.

WHAT?

The **most common cause of hyperlipidemia is idiopathic**. The abnormality in lipid metabolism is unidentified.

The most common metabolic cause is **diabetes mellitus**.

The inherited diseases are uncommon but occur most frequently in **young kittens** (weaning to 6 months age).

Diagnosis is based on history and physical examination, blood examination, special diagnostic tests and histopathology.

LABORATORY REFERENCE RANGES

Reference values (adult cats):

- Cholesterol 1–4.5 mmol/L (40–170 mg/dl)
- Triglyceride 0.2–1.1 mmol/L (20–100 mg/dl)

Clinical pathology laboratories have their own reference ranges for both cholesterol and triglycerides. Always compare your results with your own laboratory's reference ranges.

There are no significant breed or gender differences which affect plasma lipid values in cats.

Pregnancy is not a cause of secondary hyperlipidemia.

During **lactation**, the concentration of cholesterol decreases owing to a reduction in VLDL cholesterol and LDL cholesterol concentrations and suppression of HDL cholesterol production.

The plasma cholesterol concentration in suckling kittens up to 8–12 weeks of age is significantly higher than the adult reference range reflecting the fat content of the queen's milk.

The cat with hyperlipidemia – what to do

Is the hyperlipidemia from a recent meal?

- Fast overnight and resample. Plasma should be cleared of lipid in 7–8 hours in a healthy cat.
- The presence of hypercholesterolemia in the absence of triglyceridemia does not give visibly lipemic plasma.
- If hyperlipidemic, measure the **plasma cholesterol and triglyceride**. If **triglyceride** is elevated there is a defect in **chylomicron or VLDL** metabolism. If the **cholesterol** is elevated there is more likely a defect in **LDL and/or HDL** metabolism.
- Is the hyperlipidemia **secondary to other diseases**? Eliminate other diseases including:
 - Diabetes mellitus (polyuria, polydipsia, weight loss, persistent hyperglycemia, glycosuria).
 - Nephrotic syndrome (proteinuria, hypoalbuminemia, hypercholesterolemia).

If no secondary disease is identified, the problem is probably a primary disorder of lipid metabolism.

Specialized tests are available and can be applied in the investigation. They are useful in lipidemic cats to determine the metabolic basis for the hyperlipidemia, which helps determine therapy.

These tests include:

- **Chylomicron refrigeration test:** Harvest serum or plasma and refrigerate at -4°C overnight. Chylomicrons, if present will rise to form a “cream” layer (the supernatant). If the infranatant is lactescent this indicates elevated triglyceride in VLDL.
- **Tests of chylomicron clearance:** Fast for 24 hours. Collect a basal blood sample. Feed a small meal of a high-fat tinned cat food (4–5 g per cat). Collect

blood at 7, 12 and 24 hours post-prandially. Measure triglyceride in each sample. Triglyceride values should return to baseline by 7 hours and remain stable for 24 hours. Cats with altered triglyceride metabolism will show elevated triglyceride values which fail to return to baseline by 24 hours.

- **Quantification of the individual lipoprotein classes** by qualitative methods (gel electrophoresis). Electrophoresis confirms the relative abundance of a lipoprotein class: chylomicrons (origin), VLDL (pre-Beta), LDL (beta) and HDL (alpha 1).
- **Lipoprotein separation** and quantification[#].
- **Assay of lipoprotein lipase activity.** The Heparin response test. Collect a basal blood sample. Administer 100 IU heparin intravenously and collect a second blood sample after 10 minutes. Measure triglyceride in each sample. A reduction in triglyceride indicates LPL activity. Special lipid laboratories can complete more specialized LPL assays[#] on each sample. This procedure is advised.
- **Assay of LCAT activity[#].**
- **PCR analysis** for a specific genetic disease[#].
 - The tests marked [#] are available in a small number of research laboratories and are not available to most veterinarians.

DISEASES CAUSING HYPERLIPIDEMIA

IDIOPATHIC HYPERLIPIDEMIA***

Classical signs

- None.
- Lipemia retinalis.
- Cutaneous xanthomata.
- Anemia.
- Lipemic aqueous or cornea.
- Hypertriglyceridemia and/or hypercholesterolemia.

Pathogenesis

Idiopathic hyperlipidemia includes all cats with hypertriglyceridemia and/or hypercholesterolemia for which the defect in lipid metabolism is unidentified. Currently most cats with hyperlipidemia are classified as idiopathic.

Burmese kittens are over-represented, but any breed may be involved.

Pathogenesis is unknown, but it is probably due to a primary defect of lipid metabolism, if secondary causes (diabetes nephrotic syndrome) have been eliminated.

There is probably one phenotypic expression for **many different genetic mutations**, which may involve the enzyme lipoprotein lipase or other essential molecules in lipoprotein metabolism, e.g. apolipoproteins.

The pathogenesis of the concurrent clinical signs and anemia is unknown.

Clinical signs

There may be no clinical signs, just hyperlipidemia.

Alternatively, a variety of clinical signs may occur including:

- **Lipemia retinalis.**
- **Cutaneous xanthomata.**
- **Lipemic aqueous.**
- Frequently associated with severe anemia (PCV < 11%) in kittens around the time of weaning. Kittens may present with acute lethargy, dyspnea and death within 48 h. Usually the entire litter has severe fasting hypertriglyceridemia. Reported in purebred (including Siamese, Persian, Burmese, Oriental) and domestic shorthair breeds.

Diagnosis

Confirmation of hypertriglyceridemia and/or hypercholesterolemia.

Other diagnostic tests may indicate where the abnormality of lipid metabolism is located by the relative distribution of the lipoproteins.

Treatment

Severely anemic kittens need emergency treatment with **supplemental oxygen and a blood transfusion** to survive.

The plasma **triglyceride** should be **reduced to less than 5.5 mmol/L** (500 mg/dl), which minimizes the risk of hyperlipidemia-associated signs.

Feed either a homemade or commercial **diet low in saturated fats**, calorie restricted, and high in fiber to reduce lipid values. Wean kittens onto a low-fat diet.

Once hypertriglyceridemia resolves, many kittens can tolerate normal cat food.

Gemfibrozil (Lopid, Parke Davis, 7.5–10 mg/kg daily) may help reduce triglyceride values if dietary therapy alone fails.

Marine (fish) oils which are rich in n-3 fatty acids may reduce plasma triglycerides by decreasing the synthesis of VLDL. Dose at 10–30 mg/kg PO daily for cats that are unresponsive to dietary fat restriction.

Always check body weight at regular intervals if cats are on a calorie-restricted or reducing diet to ensure normal weight is maintained.

DIABETES MELLITUS**

Classical signs

- Polyuria, polydipsia.
- Polyphagia or inappetence.
- Weight loss.
- Persistent hyperglycemia, glycosuria.

See main references on page 236 for details (The Cat With Polyuria and Polydipsia).

Pathogenesis

Hyperlipidemia occurs in **some cats with diabetes mellitus**.

Rarely, cats with diabetes have concurrent hyperadrenocorticism or acromegaly, conditions which result in insulin-resistant diabetes mellitus.

The hypertriglyceridemia results from a combination of **reduced lipoprotein lipase activity** as insulin is required for normal activity of this enzyme, **increased synthesis of VLDL** due to poor regulation of hormone-sensitive lipase, **increased flux of non-esterified fatty acids** to the liver and **increased triglyceride synthesis**.

The raised cholesterol concentrations reflect **increased hepatic synthesis**, which leads to down-regulation of LDL receptor activity and increased LDL.

Clinical signs

Signs of diabetes mellitus (polyuria, polydipsia, weight loss).

Lipemic plasma.

Lipemia retinalis.

Cutaneous xanthomata (very rare finding in diabetic cats).

Diagnosis

Increased plasma or serum glucose and glycosuria, together with signs of diabetes (see Diabetes mellitus in The Cat With Polyuria and Polydipsia, page 237).

Treatment

Insulin or oral hypoglycemic drugs. See Diabetes mellitus for treatment details, page 237.

Feeding a low-fat diet is essential.

INHERITED HYPERCHYLOMICRONEMIA

Classical signs

- Domestic short-haired cats.
- Hyperchylomicronemia and hypertriglyceridemia.
- Lipemia retinalis (if triglyceride > 15 mmol/L).
- Cutaneous xanthomata.
- Peripheral neuropathies.
- Reduced appetite and lethargy.
- or NO CLINICAL SIGNS other than hyperlipidemia.

Pathogenesis

Absent lipoprotein lipase (LPL) activity.

Inherited as an **autosomal recessive** mode of inheritance.

Heterozygotes have intermediate LPL activity consistent with an autosomal recessive trait.

Molecular basis for the LPL deficiency is a single base-pair change in the lipoprotein lipase gene. An arginine for glycine transposition is present at amino acid residue 412 in exon 8.

This mutation results in the expression of **catalytically inactive enzyme**, which fails to be activated or to bind appropriately.

Clinical signs

No clinical signs other than hyperlipidemia may be evident.

Alternatively, a variety of clinical signs may occur including:

- Lipemia retinalis.
- **Cutaneous xanthomata.**
- **Peripheral nerve paralysis involving:**
 - 3rd sympathetic cranial nerve (Horner's syndrome with protrusion of 3rd eyelid, miosis, narrowed palpebral fissure).
 - Tibial nerve.
 - Radial nerve.
 - Trigeminal nerve.
- Splenomegaly.
- Xanthomata in other organs including:
 - Intestine.
 - Heart.
 - Liver.

In kittens there is increased still-birth rate, reduced body mass and reduced growth rates.

Diagnosis

Gross lipemia of fasting blood samples. Blood looks like “cream of tomato soup”.

Massive **hyperchylomicronemia** and **elevated VLDL**. Cream layer and lactescent serum or plasma are present after refrigeration.

Raised triglycerides (15–150 mmol/L, 1300–13 000 mg/dl).

Raised triglyceride and cholesterol in chylomicrons and VLDL.

Lowered LDL cholesterol.

Reduced fat tolerance. Post-prandial plasma lipid values are significantly elevated for > 48 hours after fat ingestion in homozygous cats.

There is no difference in lipoprotein composition between normal and affected genotypes except for an increase in the ratio of apoC to apoE in chylomicrons and VLDL.

Pre- and post-heparin plasma contains increased LPL mass, but no enzymic activity, that is, triglyceride does not decrease after heparin.

PCR mismatch analysis can detect normal cats, homozygotes and heterozygotes for this genetic defect.

Treatment

A **low-fat diet** either homemade or commercial will reduce blood lipid values and clinical signs will regress after 4–12 weeks.

Siblings and parents should be tested, and affected homozygotes and heterozygotes neutered and not bred.

The prevalence of this mutation in cat populations is very low.

CHOLESTEROL ESTER STORAGE DISEASE

Classical signs

- Siamese cats.
- Corneal clouding.
- Hepatomegaly.
- Intermittent vomiting and diarrhea.

Pathogenesis

Lysosomal lipase (cholesterol ester hydrolase) hydrolyzes cholesterol esters in various lipoproteins as they are removed from plasma and enter the cellular compartment.

Deficiency of this enzyme results in **cholesterol ester accumulation within lysosomes** which may result in organ failure and death.

The condition is transmitted as an **autosomal recessive** mode of inheritance in the **Siamese**.

Homozygous recessive cats are more severely affected than the heterozygotes.

Clinical signs

Siamese breed.

Onset of signs **before 1 year of age**.

Corneal clouding.

Intermittent vomiting and diarrhea.

Hepatomegaly.

Diagnosis

History of **vomiting and diarrhea with corneal clouding**.

Plasma cholesterol values are in the reference ranges.

Plasma triglyceride and low-density lipoprotein are **increased**.

Plasma and serum are grossly normal.

Heparin response test indicates normal lipoprotein lipase activity.

Cytoplasmic vacuolation containing cholesterol esters is present in a proportion of neutrophils (16%), **lymphocytes (56%), and monocytes (60%)**, stained by Wright-Giemsa.

Acid lipase activity in cultivated fibroblasts and hepatocytes is markedly decreased compared with controls.

Differential diagnosis

Other inherited metabolic and lysosomal storage diseases.

Treatment

In theory, a **reduced-fat diet** and treatment with one of the **HMG CoA-reductase inhibitors** (statins) should reduce cholesterol synthesis, and up-regulate LDL-receptor activity thus reducing plasma cholesterol, triglyceride and the LDL cholesterol concentrations. This treatment was not attempted in the reported cases.

NEPHROTIC SYNDROME

Classical signs

- Proteinuria.
- Hypoalbuminemia.
- Peripheral edema.
- Ascites.
- \pm polydipsia, polyuria.

Pathogenesis

Rare disease in cats.

Hypercholesterolemia is a common **sequel to protein-losing glomerulopathy**.

LDL and HDL cholesterol concentrations are both increased.

The exact **pathogenesis** of the cholesterol elevation is **unknown**.

Clinical signs

Peripheral edema.

Ascites.

± polydipsia and polyuria.

Diagnosis

Proteinuria.

Hypoalbuminemia.

Concurrent hypercholesterolemia.

RECOMMENDED READING

Ginzinger DE, Lewis MES, Yuanhong MA, et al. A mutation in the lipoprotein lipase gene is the molecular basis of Chylomicronemia in a colony of domestic cats. *J Clin Invest* 1997; 97: 1257–1266.

PART 9

Cat with signs of gastrointestinal tract disease

27. The cat with salivation

Victor Hans Menrath

KEY SIGNS

- Drooling.
- Excessive salivation.

MECHANISM?

- Ptyalism (**drooling**) occurs as a result of either: **excessive saliva production** or **normal production of saliva** but inability to swallow or retain saliva in the mouth.

WHERE?

- Oral causes – mouth (including pharynx) and tongue.
- Extra-oral causes – includes **central nervous system** and **gastrointestinal tract** causes.

WHAT?

- **Fear** or **stress** is the most common cause of **non-pathological** ptyalism in the clinic situation. Careful **examination of the oral cavity** is essential to distinguish **oral** from **extra-oral causes**.
- Recurrent, **intermittent**, non-stress-induced ptyalism in **young** cats (usually less than 1 year) is likely to be caused by **portosystemic shunt**.
- Other causes of recurrent, **intermittent** ptyalism (usually in cats more than 1 year old) include **hiatal hernia**, **gastroesophageal intussusception** and **diaphragmatic hernia**.
- Most other causes of ptyalism are likely to be **acute in onset** and produce **continuous drooling**. **Pain** is a major cause of ptyalism in cats.

QUICK REFERENCE SUMMARY

Diseases causing salivation

ANOMALY

- **Portosystemic shunt (PSS)* (p 588)**

Congenital liver abnormality causing intermittent central nervous system (CNS) signs with ptyalism. Usually in young cats (< 1 year). Often associated with eating. Affected cats are often very stunted in size.

MECHANICAL

- **Esophageal foreign body* (p 590)**

Repeated swallowing attempts with neck outstretched/retching, regurgitating white or blood stained foam.

- **Oral foreign body** (p 586)**

Acute onset of salivation, gagging and pawing at the mouth. Dysphagia, halitosis and inappetence may be evident. Most commonly associated with a bone lodged laterally between the 4th upper premolars.

NEOPLASTIC

- **Oral neoplasia* (p 587)**

Squamous cell carcinoma most common. Often under tongue or associated with a canine tooth or in tonsillar region. Ulcerated and/or proliferative.

PSYCHOLOGICAL

- **Psychogenic causes*** (p 582)**

Ptyalism can be caused by stress, fear, pleasure and pain.

INFECTIOUS

- **Rabies (p 599)**

Progressive central nervous system signs of muscle fasciculation, weakness, ataxia combined with behavioral changes, low-grade fever and ptyalism in unvaccinated cats. Serious zoonosis.

- **Feline herpes virus** (p 583)**

Pronounced ptyalism can occur in the very early stage of the disease. Invariably followed by the normal classical signs of viral upper respiratory disease – i.e. sneezing, naso-ocular discharge, etc.

- **Feline calicivirus** (p 582)**

Ptyalism as a result of tongue laceration due to virus, usually in young kittens. Often associated with other upper respiratory signs – e.g. chemosis, sneezing, coughing.

- **Feline spongiform encephalopathy (FSE) (p 600)**

Progressive central nervous signs including hindlimb ataxia, behavioral changes, hyperesthesia, head tremor and muscle fasciculation. Ptyalism.

continued

continued

- **Feline panleukopenia (parvo virus) (p 600)**

Continuous ptyalism has been recorded in a 3-month-old kitten suffering from feline panleukopenia caused by feline parvovirus.

INFLAMMATORY

- **Esophagitis* (p 591)**

Characterized by repeated attempts at swallowing, ptyalism, “neck stretching” and regurgitation of ingested food, often with mucoid foam. Early treatment essential to prevent secondary esophageal stricture.

- **Periodontal disease/periodontitis*** (p 582)**

Saliva-stained perilabial fur, often reluctance to pick up food, quidding and pawing at mouth.

IMMUNE

- **Feline oral inflammatory disease (plasmacytic-lymphocytic stomatitis)** (p 585)**

Mild to severe granulomatous inflammation in fauces. Often extremely painful and refractory to treatment. Cats resent mouth examination.

- **Eosinophilic granuloma complex (EGC)** (p 586)**

Orange-white lesions on tongue surface, soft and hard palate. Usually associated excessive grooming due to skin allergy. Lesions often painful.

TOXIC

- **Household cleaners and disinfectants* (p 587)**

Common cause of chemical burns on tongue. Especially shower recess cleaners.

- **Acetaminophen (paracetamol) toxicity (p 595)**

Facial edema, cyanosis and chocolate urine. Prompt treatment is essential.

- **Organophosphate and carbamate toxicity (p 594)**

Carbamate toxicity is most common. Miosis, muscular twitching and hypersalivation.

- **Pyrethrin and pyrethroid toxicity (p 595)**

Salivation, tremors, seizures. No definitive test for diagnosis.

- **Spider envenomation (p 597)**

Severe pain, vocalization, hyperexcitability and ataxia early, progressing to muscular weakness and collapse. Severe, prolonged ptyalism, possibly due to pain.

- **Dieffenbachia (dumb cane) poisoning (p 598)**

Sudden onset of salivation immediately after chewing plant. Tongue paralysis is characteristic.

- **D-limonene, linalool and crude citrus oil extracts (p 598)**

Used in insecticidal sprays and shampoos. Ptyalism may be the only clinical sign. Muscular tremors and ataxia can occur in more severely affected cases.

- **Lead poisoning (p 596)**

Gastrointestinal signs (inappetance, diarrhea) and/or CNS signs (behavioral changes, seizures, blindness).

- **Oral medication** (p 584)**

Can be unpleasant tasting or irritant to the oral mucous membranes. Some drugs can cause a delayed hypersalivation (e.g. trimethoprim-sulfa combinations).

TRAUMA

- **Tongue laceration** (p 584)**

Sudden onset, inability to eat, rapid secondary bacterial infection.

- **Jaw fracture/dislocation** (p 584)**

Inability to chew, slack jaw, asymmetry of jaw.

- **Hiatal hernia/gastroesophageal intussusception (p 592)**

Uncommon, intermittent salivation, age of cats. Intussusception can be rapidly fatal.

- **Diaphragmatic hernia with incarcerated stomach (p 598)**

Very uncommon, intermittent salivation, often associated with feeding and dyspnea.

INTRODUCTION

MECHANISM?

Ptyalism (hypersalivation, drooling, hypersialosis) occurs as a result of

Either: excessive saliva production due to stimulation of the salivary nuclei located in the brainstem via **local receptors** (taste and tactile) in **the mouth** and on **the tongue**, or via **higher centers** in the central nervous system (CNS).

Or: **normal** or **increased** saliva production but with an inability to swallow or retain the excessive saliva in the mouth due to an **anatomical** problem.

WHERE?

Oral causes mouth (including pharynx) and tongue.

Extra-oral causes including CNS and gastrointestinal tract (especially esophagus and stomach).

WHAT?

The most common non-pathological cause of ptyalism in **the clinic situation** is **fear** or **stress** and occurs especially in very nervous cats. These cats do not have ptyalism at home.

Medication or attempted medication with **unpleasant-tasting oral medication**.

Pleasure is a common **non-pathological** cause of ptyalism **at home**. This often occurs in older cats and is usually associated with other signs of pleasure, e.g. purring and kneading of paws.

Ptyalism **at home** unassociated with pleasure and ptyalism **in the clinic**, unassociated with fear or stress **suggests a pathological cause**.

Careful history-taking will help differentiate **pathological** from **non-pathological** causes of ptyalism.

Careful examination of the oral cavity will help differentiate **oral** from **extra-oral** causes of ptyalism.

Recurrent, intermittent (non-stress-induced) ptyalism **in young cats** (<1 year old) is likely to be caused by **portosystemic shunt**.

Other causes of recurrent, intermittent ptyalism include **hiatal hernia**, **gastroesophageal intussusception** and **diaphragmatic hernia**.

Most other causes are likely to be **acute in onset** and produce **continuous drooling**.

Pain is a major cause of ptyalism in the cat – usually combined with **dilated pupils**.

DISEASES CAUSING SALIVATION

PSYCHOGENIC CAUSES***

Classical signs

- Ptyalism.
- Dilated pupils.

Pathogenesis

Fear, anxiety, pleasure, nausea.

May be exacerbated by underlying or concomitant **hyperthyroidism**.

Anticipation of unpleasant experience (e.g. tableting or painful injection).

Especially in “**highly-strung**” cats, e.g. Siamese.

Makes oral medication virtually impossible.

Probably the most common cause of ptyalism in the cat in the clinic situation.

Clinical signs

Drooling, ptyalism.

Usually **during traveling** or **at veterinary clinic**.

Often triggered by cat **recognizing unpleasant event to come**.

Pupils dilated when due to stress or fear.

Repeated lip smacking and swallowing

Treatment

0.01 mg/kg PO or SC **atropine** 1/2 hour **before traveling/-event**.

Diazepam 0.5 mg/kg PO or SC 1/2 hour **before traveling/-event**.

Above drugs can be **combined**.

PERIDONTAL DISEASE/PERIODONTITIS***

Classical signs

- Dysphagia.
- Pawing at mouth.
- Halitosis.
- Ptyalism.

See main reference on page 604 for details (The Cat With Bad Breath or Oral Lesions).

Clinical signs

Severe periodontal disease will result in tooth loss, deep pockets with heavy anaerobic infections and strong halitosis.

Cat may show signs of attempting to pick up food, dropping it and pawing at mouth.

Peri-labial fur may be saliva stained.

Feline odontoclastic resorptive lesions (“neck lesions”) can also be very painful and show similar signs.

Diagnosis

Probing to identify periodontal pockets. Tapping affected teeth will cause jaw “chattering”.

FELINE CALICIVIRUS**

Classical signs

- Sneezing, coughing, oculonasal discharge.
- Oral ulceration, especially tongue.
- Ptyalism.

See main reference on page 11 for details.

Clinical signs

Sudden onset of **acute conjunctivitis (usually one eye first)**.

Rapidly followed by sneezing, coughing, pyrexia.

Tongue ulceration is common – ulcer is usually large, in the **central tongue** it is often butterfly-shaped. Ulceration of the nose philtrum, dorsal surface hard palate, footpads can also occur.

Most commonly in **kittens 8–12 weeks of age**.

Salivation due to **ulceration** and **pain in the tongue**.

Occasional **viral pneumonia, lameness (“limping kitten syndrome”)**.

Growth rate of kittens is often temporarily delayed.

Diarrhea can occur and be protracted.

Diagnosis

Clinical signs.

Response to antibiotics.

PCR, viral isolation.

Treatment

Supportive nursing and broad-spectrum antibiotics, e.g. doxycycline (2.5 mg/kg PO q 24 h), cephalexin (30 mg/kg PO q 12 h).

Maintain hydration.

FELINE HERPES VIRUS**

Classical signs

- Sudden onset of severe ptialism.
- Depression, inanition, dehydration.
- Pyrexia followed by sneezing, coughing naso-ocular discharge.

See main reference on page 7 for details (The Cat With Acute Sneezing or Nasal Discharge).

Pathogenesis

Caused by **feline herpes virus I**.

Viral replication in oral mucosa and/or perhaps salivary glands causes massive production of saliva in the **very early stages of the course of the disease**. Viral parotitis could be involved in the cause of salivation.

Severe clinical signs are usually associated with a **very short incubation period** (1–4 days) (i.e. severity of signs is **virus dose-responsive**).

Salivation is followed by varying degrees of **pharyngitis, laryngitis, tracheitis and esophagitis** and classical signs of viral upper respiratory tract infection, i.e. coughing, sneezing, runny eyes and nose.

May have concurrent FeLV, FIV, calicivirus, bordetella or mycoplasma infection.

Clinical signs

Hypersalivation syndrome usually occurs in adult unvaccinated or poorly vaccinated cats, with **novel exposure**.

Severe **drooling salivation** with **depression** and **rapid dehydration** precedes classical signs of viral upper respiratory tract disease.

Pyrexia usually lasts for period of hypersalivation (24–48 h).

Often followed by severe pharyngitis, laryngitis, tracheitis, esophagitis (retching, choking cough, vomiting) and requires long periods of intensive care if signs are severe.

Diagnosis

PCR, viral isolation.

Classical signs of viral upper respiratory tract infection (i.e. sneezing, coughing etc.) follow salivation within 24–48 h.

Treatment

Rapid **dehydration** can occur – IV fluid support, steam inhalation therapy.

Place **feeding tube** (esophagostomy, gastrostomy).

Be prepared for **2–4 weeks intensive nursing** if signs are severe.

Prevent secondary bacterial rhinitis and sinusitis with **broad-spectrum antibiotics**, e.g. cephalexin (30 mg/kg PO; 15 mg/kg q 12 h) or amoxycillin/clavulanic acid (12.5 mg/kg PO q 12 h) which should be continued for **4 weeks minimum**.

Prognosis

Good with good intensive care.

Cat will almost always become a **herpes virus carrier**.

ORAL MEDICATION**

Classical signs

- Ptyalism, excessive salivation.
- Usually immediately following oral medication.
- Sometimes ptyalism delayed.

Clinical signs

Acute ptyalism following attempted or successful oral medication.

Often associated with rapid tongue movements in an attempt to remove drug or taste from mouth.

Ptyalism is often delayed for 5–10 minutes after the successful administration of trimethoprim-sulfa tablets.

Ptyalism is self-limiting and usually short duration (e.g. 5–10 minutes).

Treatment

Treatment is not necessary.

Reassure owner that it is self-limiting.

TONGUE LACERATION**

Classical signs

- Ptyalism.
- Dysphagia.
- Halitosis.

Pathogenesis

Trauma from cat's **own teeth biting on tongue** (e.g. car accident, falling from height).

Trauma from cat fight – claw slicing tongue.

Clinical signs

Hemorrhage may be significant if acute.

Reluctance to groom.

Paws and chest are sticky with foul-smelling saliva.

Rapid secondary bacterial infection.

Diagnosis

Obviously lacerated tongue.

Treatment

Surgical debridement and repair with absorbable sutures (e.g. 4/0 plain gut).

Antibiotics. Parenteral or paste-form best, e.g. cephalexin (15 mg/kg IM q 12 h), amoxycillin/clavulanic acid (8.5 mg/kg SC or IM q 24 h).

JAW FRACTURE/DISLOCATION**

Classical signs

- Ptyalism.
- Mouth held open (“slack-jawed”).
- Jaw asymmetry.

Clinical signs

Excessive salivation.

Unable to close jaw.

Jaw dislocation without fracture is uncommon – temporo-mandibular dislocation can be **rostradorsal (most common)** or **caudo-ventral**. **Dislocation** is almost invariably **bilateral**.

Mandibular symphyseal separation is most common and is often associated with temporo-mandibular dislocation and/or fracture of the mandible, causing jaw asymmetry.

Diagnosis

Symphyseal separation is usually obvious on examination.

Careful palpation of both horizontal and vertical sections of mandibles from inside mouth under anesthesia will help to identify fractures.

Careful radiography.

Treatment

Rostral temporo-mandibular joint (TMJ) dislocation can be reduced by placing a ballpoint pen or pencil horizontally across the mouth **behind** the lower molars and forcibly closing mouth until joints relocated.

Caudal TMJ dislocations are reduced in a similar fashion but the mandible is forced rostrally.

Surgical repair of symphyseal separation by using cir-clage stainless steel wire.

FELINE ORAL INFLAMMATORY DISEASE** (PLASMACYTIC-LYMPHOCYTIC STOMATITIS/FAUCITIS) (PLASMA CELL GINGIVITIS AND PHARYNGITIS)

Classical signs

- Ptyalism.
- Difficult prehension.
- Halitosis.
- Pain, reluctance to open mouth.
- Severe faucitis, gingivitis.

Pathogenesis

Etiology unknown. Suggested causes are **viral** (especially **calicivirus**), **bacterial** and **immunological** (possibly hypersensitivity to plaque proteins).

The condition appears to be the result of a **chronic-immune-mediated process** because lymphocytes and plasma cells predominate, and lesions respond to immunosuppressive drugs.

Moderate to severe **calicivirus-induced gingivitis** occurs commonly in young (8–12 weeks) kittens with or without concomitant tongue ulceration. Gingivitis often persists as chronic **gingival hyperplasia** through adulthood, predisposing to excessive plaque, periodontal disease and early loss of teeth. A small percentage of these cats develop plasmacytic-lymphocytic faucitis later in life, usually middle age.

Clinical signs

Intense oral pain and resentment to oral examination occurs with **severe faucitis**. Bright red proliferate

granulomatous tissue **may partially occlude pharynx** in severe cases.

Dysphagia, excessive salivation and **weight loss** occur in severe cases.

Severe faucitis is often associated **with FIV or FeLV** infection.

Treatment

Thorough dental prophylaxis and **complete** extraction of all teeth showing resorptive lesions. Severe faucitis often responds to extraction of all molars and premolars and any **retained root tips**.

Antibiotic therapy using amoxycillin (10 mg/kg PO q 12 h), metronidazole (10 mg/kg PO q 12 h) or clindamycin (5.5 mg/kg PO q 12 h) often results in improvement, but rarely complete resolution of inflammation. Doxycycline (25 mg/kg PO q 24h) has anti-inflammatory effects.

In most cases, antibiotic therapy will need to be combined with **immunosuppressive therapy**. Many cases will not be able to be medicated orally and will require **parenteral therapy**, e.g. methylprednisolone acetate (2–4 mg/kg IM).

If the cat can be medicated orally, prednisolone (2 mg/kg PO q 12 h) for 10 days, then taper.

For very refractive cases, may have to use **azathioprine** (0.3 mg/kg PO q 72 h), or **cyclophosphamide** (6.25–12.5 mg/cat once daily, 4 days PO per week) or **chlorambucil** (0.1–0.2 mg/kg q 24 h PO initially, then q 48 h) or **aurothioglucose** (0.5–1 mg IM every 7 days). Cyclosporine (5 mg/kg PO q 12–24h) can be very effective.

A topical gel (Bonjela®, choline salicylate, cetalkonium chloride, Reckitt & Coleman Pharmaceuticals, UK) applied with or without sedation/anesthetic has been reported to ameliorate the faucitis and gingivitis in affected cats. The gel is rubbed into the lesions in the mouth over a period of about 2 minutes once a week until signs regress. Note that this is an off-label use of this product designed as an oral analgesic gel in humans and contains salicylate. To date there have been no reported adverse reactions with its use in cats.

Prognosis

This condition, in its severe form remains **one of the most difficult and frustrating to treat in feline practice**. Thorough oral debridement is essential.

Most cases eventually end up requiring chronic medication with immunosuppressants for the rest of their lives.

ORAL FOREIGN BODY**

Classical signs

- Ptyalism, acute onset.
- Gagging, pawing at mouth.
- Halitosis.
- Dysphagia.

Pathogenesis

Usually **sliver of bone** jammed laterally between 4th upper premolars.

Linear foreign body (string, cotton) around base of tongue.

Clinical signs

Salivating, pawing at mouth – sometimes bleeding laceration around mouth from self-trauma.

Dysphagia, halitosis.

Diagnosis

Self evident on oral examination.

Examine roof of mouth and under tongue.

Treatment

Remove foreign body.

Antibiotics if secondary infection from self-trauma or foreign body damage.

EOSINOPHILIC GRANULOMA COMPLEX (EGC)**

Classical signs

- Ptyalism.
- Dysphagia.

Pathogenesis

Immune-mediated process resulting in granuloma formation (eosinophilic granuloma) in the oral cavity, especially the **dorsum of the tongue** and **hard palate**, but can occur in other areas, e.g. soft palate.

Histopathology shows typical **granuloma formation with collagen degeneration**.

Usually associated with a concurrent pruritic **skin disease** and **excessive grooming**.

The **cause of this association is unknown**. Oral mucous membrane trauma from excessive grooming could cause the lesions, or both the oral and skin lesions may be a reaction to antigens, such as flea antigen, on the coat.

Clinical signs

Salivation and **dysphagia** usually only occurs in severe cases of eosinophilic granuloma complex with associated glossitis.

Oral exam reveals single or multiple raised, firm 1–2 mm white-yellow nodules, scattered throughout mouth, but especially on dorsum tongue surface causing the surface of the tongue to have **“cobble-stone” appearance**. Associated glossitis may occur **causing** difficulty in prehension and swallowing.

Evidence of **over-grooming** and **itchy skin disease** is usually present.

Halitosis may occur with secondary bacterial infection.

Diagnosis

Lesions have a very characteristic appearance.

Histopathology confirms diagnosis.

Differential diagnosis

Oral neoplasia. Squamous cell carcinoma usually occurs on the **ventral surface** of the tongue in the region of frenulum and has an ulcerated, red appearance.

Treatment

Treatment can be difficult and frustrating.

Treat concurrent skin allergy and ectoparasites to achieve control.

Change to a **novel protein diet**.

Regular **manual grooming and bathing**.

Prednisolone (2 mg/kg PO q 12 h for 5–10 days, then taper).

Megestrol acetate (2.5–5 mg/cat PO for 4 days, then 2.5–5 mg q 5–7 days until lesions regress).

NB This drug, although very effective, has numerous side effects **especially in the Burmese breed** (diabetes mellitus, pyometra, obesity, iatrogenic Cushing's disease).

Cyclosporine (5 mg/kg PO q 12–24h).

Doxycycline (2.5 mg/kg PO q 24h).

ORAL NEOPLASIA *

Classical signs

- Ptyalism, often blood stained.
- Halitosis.
- Dysphagia.

Pathogenesis

Squamous cell carcinoma is the most common neoplasm. Usually on the ventral surface of the tongue causing immobility of the tongue but sometimes tonsillar crypt or under the canine tooth.

Usually in older cats (> 10 years).

Other tumors include **epulis**, **fibrosarcoma** and **lymphosarcoma**.

Clinical signs

Excessive salivation, often blood stained. Signs usually present longer than 1 week.

Dysphagia, difficulty in prehension.

Facial distortion, halitosis.

Weight loss due to inability to eat or metastatic disease.

Diagnosis

Biopsy and histologic examination.

Radiography to assess extent of tumor invasion.

Differential diagnosis

Inflammatory polyps – usually have stalk.

Intra-oral abscess and granulation tissue can have a similar appearance – differentiate by **biopsy** or trial **antibiotics**.

Eosinophilic granuloma complex (linear granuloma) has characteristic white-yellow nodules – differentiate by **biopsy** or trial corticosteroids.

Treatment

Treatment of lingual squamous cell carcinoma in the cat **has not proved successful**, however some of the newer chemotherapeutic agents may be more effective combined with tumor excision.

Mandibular masses can be treated by **partial mandibulectomy**.

Prognosis

Grave for squamous cell carcinoma of the tongue.

For other tumors, the prognosis will depend on the tumor type and suitability for treatment.

HOUSEHOLD CLEANERS AND DISINFECTANTS*

Classical signs

- Ptyalism, acute onset.
- Dysphagia.
- Depression, saliva-stained front feet.

Pathogenesis

Most common household cleaning products and disinfectants are **extremely toxic to cats**.

These include **chlorine** (sodium hypochlorite), **strong alkalis**, **strong acids**, **pine oils**, **phenolic compounds**, **hydrocarbons** and **quaternary ammonium compounds**.

Most cause **contact necrosis** of **skin** and **mucous membranes** especially if undiluted or incorrectly diluted.

Most toxicities occur when the cat **licks water containing cleaner residues** (e.g. shower recess cleaners) or by licking paws after walking through the chemical.

This causes corrosive damage of the tongue surface, mucous membranes of the mouth and occasionally, esophagus.

Clinical signs

Acute onset of **hypersalivation, depression, dysphagia**.

Front legs are often wet and stained with saliva.

Rapid secondary bacterial infection occurs in the mouth causing halitosis.

Tongue slightly swollen, partially immobile, and the **dorsal surface initially appears very pale and dull (early necrosis)**.

Sloughing may occur to variable extent of the surface of the tongue leaving **raw, ulcerated surface** – usually within 36–48 hours.

There is rapid onset of **dehydration** due to saliva loss and inability to lap water.

Neurological signs (muscle weakness, fasciculations, seizures) may occur with **quaternary ammonium** and **pine oil/phenolic compound toxicities**.

Esophageal corrosion may occur with choking, gagging and retching and regurgitation of white foam.

Other areas of body may be affected, e.g. pads of feet.

Diagnosis

History of exposure.

Occasionally characteristic **smell of toxic agent**, e.g. chlorine.

Methemoglobinemia indicates toxicity involves phenolic compound.

Treatment

Wash corrosive material off cat.

Supportive fluids, nutrition, and **broad-spectrum antibiotics**, e.g. cephalexin (15 mg/kg IM q 12 h).

Corticosteroids in the early stages, especially if **esophagitis is suspected**, e.g. dexamethasone (0.1–0.2 mg/kg IV, IM q 12–24 h).

Pain control in the early stages, e.g. buprenorphine (0.005–0.01 mg/kg IV, IM q 4–8 h).

PORTOSYSTEMIC SHUNT*

Classical signs

- Ptyalism, excessive salivation.
- Repeated swallowing and lip smacking.
- Behavioral and neurological signs including seizures.
- Signs are intermittent, progressive and often associated with eating.
- Usually in young cats (< 1 year).

Pathogenesis

Portosystemic shunts (portocaval shunt, portovascular anastomosis) are **vascular communications** between portal and systemic venous systems.

Clinical signs are the result of **gut-produced neurotoxins** bypassing normal detoxification in the liver, entering the systemic circulation and affecting the CNS.

These gut-produced neurotoxins include ammonia, mercaptans, GABA agonists, benzodiazepam ligands and tryptophan.

Portosystemic shunts can be **congenital or acquired, intrahepatic or extrahepatic**.

Most **feline** portosystemic shunts are **congenital**, single and **extrahepatic**.

Reduced blood supply to the liver often results in a **small liver**.

High urinary excretion of ammonia and uric acid may result in **urate urolithasis** and/or **ammonium biurate crystals** in urine.

Clinical signs

CNS disturbances associated with hepatic encephalopathy are most frequent, occurring in 95% of cases of feline portosystemic shunting.

Neurological signs vary considerably and include mild behavioral changes (aggressive behavior, staring into space, head-pressing), **ataxia, weakness, stupor**,

blindness, dilated pupils, tremors, seizures, coma and death.

The hallmark of the CNS signs is that they are **intermittent, progressive in severity and often precipitated by a high-protein meal.**

Hypersalivation is an especially prominent clinical sign (78%).

Signs wax and wane with episodes lasting minutes to hours and may or may not be associated with feeding.

Signs related to **hepatic dysfunction** include **stunted growth, delayed anesthesia recovery, diarrhea, polydipsia/polyuria and lethargy.**

Signs of urinary tract disease as a result of **urate urolithiasis** include **hematuria, dysuria and pollakiuria.**

Signs often abate with **antibiotic administration** (i.e. reduced production of toxic metabolites by enteric bacteria).

In cats, clinical signs of hepatic encephalopathy most commonly **become apparent at about 6 months of age.**

Diagnosis

Serum bile acids – 2 hours post-prandial **always** elevated with portosystemic shunts (>100 µmol/L).

- Serum bile acids are specific indicators of hepatobiliary disease in the cat. Fasting bile acids are normally less than 5 µmol/L and 2 hour post-feeding bile acids usually less than 20 µmol/L. Cats with portosystemic shunt usually have elevated (>100 µmol/L) bile acids 2 hours after feeding. Serum bile acids concentration cannot however differentiate between hepatocellular, vascular or cholestatic liver disease.

Ammonia tolerance test: more specific than bile acids, but not practical unless in-house ammonia testing available as ammonia is very labile. Cats with portosystemic shunt may have normal fasting blood ammonia levels. Blood is taken 30 minutes after a challenge with 100 mg/kg ammonium chloride. This ammonia-loading test, although very specific, has a propensity for inducing vomiting and excessively high serum ammonia levels causing severe CNS signs.

Hematology – RBC **microcytosis** may occur (MCV < 39 fl).

Biochemistry – normal to decreased BUN, hypocholesterolemia, mild increase in ALT and AST.

Ultrasonography – can be useful to visualize shunt vessel especially with **intrahepatic shunts.**

Portography – contrast portogram via mesenteric vein provides definitive diagnosis and location of shunt vessel.

Urinalysis – may reveal ammonium biurate crystals or urate uroliths.

Liver biopsy – histology shows periportal fibrosis, bile duct hyperplasia.

Transcolonic portal scintigraphy – availability likely to be restricted.

Differential diagnosis

The combination of intermittent, **recurrent ptyalism** and **neurological signs** associated **with eating** in a **young cat** is **almost pathognomonic** for portosystemic shunt.

Viral encephalitides such as **rabies and feline spongiform encephalopathy** can present with severe CNS disturbances combined with ptyalism but these diseases are always **progressive** and signs are **continuous.**

Lead poisoning can occasionally present with clinical signs of intermittent neurological disturbances and hypersalivation in the cat. Blood lead levels will confirm or rule out diagnosis.

Pyrethrin and pyrethroid toxicity produces signs of hypersalivation and neurological signs. Signs are continuous and history of recent exposure generally confirms diagnosis.

Organochlorine (chlorinated hydrocarbon) and **organophosphate toxicity** is characterized by hypersalivation and neuromuscular disturbances including muscular disturbances such as muscular twitching, weakness and seizures. History of exposure and serum cholinesterase levels (OP) will confirm diagnosis.

Treatment

The medical management of portosystemic shunt encephalopathy plays a vital role in **both pre- and post-surgical treatment.**

Medical management on its own, however, is **palliative at best.**

Medical management consists of:

- Minimize formation and absorption of **ammonia** and other toxic substances by the administration of **oral antibiotics** (**ampicillin** (20–40 mg/kg PO q 8 h), **metronidazole** (10–25 mg/kg PO 24 h), and **oral lactulose** 2.5–5 ml q 8 h). The dose of lactulose (a palatable syrup) should be increased or reduced to produce soft stools 2–3 times daily.
- **Retention enemas** can be used to treat **hepatic coma**. The enema consists of **neomycin** (15 mg/kg) plus **lactulose** (diluted 1:2 with warm water) and is given in doses of 40–200 ml and repeated until colon is completely empty and then given every 6–8 hours as long as the coma persists.
- Determine **blood glucose, fluid, electrolyte** and **acid–base** status of patient and normalize balances using **lactated Ringers** solution supplemented with **2.5–5% dextrose** and **potassium chloride** depending on laboratory results.

Control seizures with diazepam (0.25–0.5 mg/kg IV q 6–8 h).

Dietary therapy – the ideal diet should contain the **minimum amount of high-biological-value protein**, highly available **carbohydrates** as the primary source of energy, adequate levels of **arginine** and **minerals**, and be **palatable**. Diets designed for renal-failure cats generally meet these requirements although, in severe cases, even more protein restriction may be required.

Surgery is ultimately the treatment of choice as it offers the possibility of cure.

- Surgery involves isolating the shunting vessels and **partial** (using ameroid constrictor band) or **complete ligation** depending on measured portal venous pressure.
- Rapidly fatal **portal hypertension** and gastrointestinal venous stasis may occur with complete ligation of the shunting vessel and **close observation is required for 48 hours** in case repeat surgery is required to relax the ligature.
- Clinical signs of hepatic encephalopathy may recur months after surgery, necessitating repeat surgery to re-ligate the shunting vessel.

Prognosis

Good if surgery successful.

Often difficult to manage medically without surgery.

ESOPHAGEAL FOREIGN BODY*

Classical signs

- Hypersalivation, dysphagia.
- Gagging, retching, swallowing, outstretched neck.
- Regurgitating white or blood-tinged foam.

Pathogenesis

Caudal-pointing papillary spines on the tongue and the playful nature of cats make **linear foreign body** (string, cotton thread) ingestion common. These are **often wrapped around the base of the tongue**.

Other foreign bodies include sewing needles, fish hooks, hair balls, V-shaped cooked avian bones (e.g. wish-bone) and string attached to the end of continental sausages. These usually lodge at **thoracic inlet, base of the heart** or at **diaphragm hiatus**.

Complications include secondary aspiration pneumonia, esophageal perforations, regional esophagitis with or without secondary stricture and bronchoesophageal fistula.

Clinical signs

Acute onset of gagging, retching, ptyalism, often with **neck stretched forward**.

Regurgitation of **white foam** often stained with **fresh blood**.

Signs of depression, anorexia, fever, cough and dyspnea can suggest **esophageal perforation** or **aspiration pneumonia**.

Signs are generally continuous and persistent.

Diagnosis

History of playing with or eating a **potential foreign body**.

Plain and/or contrast **radiography** to demonstrate foreign body.

Endoscopy is useful to confirm the presence of a foreign body and to assess damage to the esophagus.

Check under tongue for linear foreign body (e.g. cotton or string).

Differential diagnosis

Pharyngeal **foreign body** or **acute pharyngitis**. Examine pharynx under general anesthetic.

Acute **viral** esophagitis/pharyngitis/laryngitis. Usually other viral signs predominate (i.e. sneezing, running eyes, etc.). Both calici and herpes virus possible.

Acute **gastroesophageal intussusception** or **hiatal hernia** – usually **intermittent** signs.

Caustic chemical pharyngitis/esophagitis (rare) is always associated with chemical burning of the **dorsum of the tongue**.

Treatment

Retrieval of the foreign body by **endoscopy**.

Perforating foreign bodies require **thoracotomy** and **esophagotomy**.

Sewing needles and fish hooks on string can often be retrieved by passing a plastic tube down the string to dislodge and guard the foreign body during retrieval.

Broad-spectrum **antibiotics** (amoxicillin 20 mg/kg SC or IM q 12 h).

Withhold food and water for 24–48 hours.

Intravenous or **subcutaneous fluid** support will be required first 24–48 hours.

Some foreign bodies can be pushed into the stomach and retrieved by gastrotomy.

Prognosis

Good unless esophageal perforation has occurred.

ESOPHAGITIS*

Classical signs

- Excessive salivation.
- Repeated attempts at swallowing.
- Anorexia, dysphagia.
- Regurgitation.

Pathogenesis

Most commonly due to **gastric reflux** during and after **anesthesia**.

Pre-anesthetic and anesthetic agents suppress normal esophageal motility and can cause the lower esophageal sphincter to relax allowing **gastric reflux**.

Refluxed in **hydrochloric acid** can reduce esophageal pH to 2.0 and cause protein denaturation of the esophageal mucosa.

Once esophagitis exists, the **lower esophageal sphincter becomes incompetent, perpetuating reflux**.

Tilting of the surgery table and **poor patient preparation** (food-filled stomach) before surgery **predisposes cats to reflux esophagitis**.

Esophagitis can occur secondary to **esophageal foreign bodies** or **persistent vomiting**.

Rarely, esophagitis can result from **ingestion of caustic agents**.

Pooling of gastric fluids and resultant esophagitis characteristically occurs in the region of the **base of the heart**.

Young animals with **congenital esophageal hernia** are likely to have a higher risk for reflux esophagitis.

Occasionally, esophagitis associated with **severe feline herpes virus or calicivirus** infection occurs.

Pain and **inability to swallow** probably plays a major role in pathogenesis of ptyalism.

If untreated, esophagitis often leads to **secondary esophageal stricture**.

Clinical signs

Dysphagia, excessive salivation, repeated swallowing attempts with out-stretched neck occurs in the **early, acute phase** of the disease syndrome.

Regurgitation of white froth, often blood stained occurs in the early stages of acute, severe esophagitis.

Signs generally occur **within 24–48 hours of anesthetic** if post-anesthetic esophagitis.

Intense pain associated with swallowing attempts may cause the cat to cry out.

Concomitant oral ulceration and stomatitis may indicate caustic **chemical ingestion**.

Regurgitation of food and/or vomiting can occur in milder cases of esophagitis, hiatal hernia or healing/stricture phase of severe acute esophagitis.

Diagnosis

History of **chemical exposure**, ingestion of a **foreign body** or a **recent anesthetic**.

Survey radiographs of the esophagus are often unremarkable.

Endoscopy reveals variable hyperemia, bleeding, ulceration and pseudomembranes of the esophageal mucosa, or a foreign body.

Post-anesthetic reflux esophagitis lesions are characteristically in the region over the **base of the heart**.

Reflux **due to severe vomiting or hiatal hernia** characteristically causes esophagitis in the **distal esophagus**.

Endoscopy can differentiate a **functional** esophageal stricture due to severe mucosal and sub-mucosal inflammation and edema from a **fibrous stricture** (forming subsequent to severe esophagitis).

Differential diagnosis

Hiatal hernia usually causes **intermittent** signs of vomiting, ptyalism, regurgitation and dyspnea. Plain radiography shows a soft tissue density dorsal to the vena cava in the caudal thorax. Contrast radiography reveals the gastric fundus in the region of the terminal esophagus.

Gastroesophageal intussusception – may cause intermittent signs but often causes persistent and severe clinical signs of vomiting and salivation leading to rapid onset of vascular shock and death. Plain or contrast radiography or endoscopy to confirm.

Diaphragmatic hernia involving the stomach – rapid expansion of incarcerated stomach after eating due to accumulating gases causes rapid onset of dyspnea, salivation and attempts to vomit. Plain or contrast radiography to confirm presence of stomach in the chest. **Often history of feeding immediately prior to onset of signs.**

Treatment

Acute reflux or chemical esophagitis must be treated aggressively in the early stage in an attempt to prevent fibrous esophageal stricture.

Preferably, all medication should be given **parenterally for the first 5–6 days**.

Broad-spectrum antibiotics to control secondary bacterial infections (amoxicillin/clavulanic acid).

Corticosteroids to prevent stricture (dexamethasone 0.2 mg/kg IM or IV q 12–24 h).

Sucralfate suspension to protect mucosa per os if not vomiting (0.25 g PO q 8–12 h).

Cimetidine (10 mg/kg IV, IM PO q 6–8 h) or **ranitidine** (2.5 mg/kg IV q 12 h; 3.5 mg/kg PO q 12 h) to **reduce gastric acidity**.

Metoclopramide (0.2 mg/kg IV, IM, PO q 6–8 h) or **cisapride** (5 mg/cat q 8–12 h) to promote gastric emptying.

Narcotics for pain control e.g. methadone 0.1–0.5 mg/kg IV or IM q 4–6 h

Placement of **gastrotomy** or **esophagotomy** tube for nutrition while “resting esophagus” – leave in place 5–7 days.

Surgical repair of hiatal hernia, gastroesophageal hernia or diaphragmatic hernia.

Prognosis

Esophageal stricture due to fibrosis and scarring secondary to esophagitis is common and is characterized by repeated regurgitation after eating.

This can be treated with gradual dilatation of stricture by balloon dilation catheter or bouginage. Often requires repeated dilation over weeks or months to achieve resolution of signs.

HIATAL HERNIA/GASTROESOPHAGEAL INTUSSUSCEPTION

Classical signs

- Ptyalism.
- Vomiting/regurgitation.

Classical signs—Cont'd

- May or may not be related to eating.
- Dyspnea, hematemesis, collapse, shock, death with large intussusceptions.
- Signs often intermittent

Pathogenesis

Hiatal hernia denotes herniation of the distal esophagus and proximal stomach into the thoracic cavity.

Hiatal hernias tend to be **intermittent** in nature but can be persistent.

Gastroesophageal intussusception occurs when the stomach (and occasionally duodenum, spleen, etc.) prolapses (invaginates) into the distal esophagus with resultant compromise of blood supply to the prolapsed segment. **Gastroesophageal intussusception** is **usually acute** and **persistent** but can be chronic with intermittent signs.

Congenital or acquired laxity of the hiatus is suspected to predispose to both hiatal hernias and gastroesophageal intussusception.

Diaphragmatic hernia may predispose to post-surgical gastroesophageal intussusception.

Reflux esophagitis occurs with both gastroesophageal intussusception and hiatal hernias.

Clinical signs

Although uncommon, both gastroesophageal intussusception and hiatal hernias are a significant **rule-out in ptyalism**.

Chronic intermittent vomiting is characteristic for both **hiatal hernia** and **chronic gastroesophageal intussusception**.

Chronic, intermittent ptyalism can occur **with or without vomiting** and weight loss.

Acute bouts of **respiratory distress** may occur.

Large, acute gastroesophageal intussusception can cause rapid onset of shock associated with hematemesis, dyspnea, collapse and sudden death.

Diagnosis

Gastroesophageal intussusception:

- **Plain thoracic radiographs** show the presence of a **soft tissue mass** in the esophagus cranial to the diaphragm. The gastric gas bubble in the cranial abdomen is often missing indicating that the stomach has prolapsed into the esophagus.
- The diagnosis can be confirmed with a **barium swallow** in which the barium will not pass beyond the intussusception.
- Endoscopy will reveal.

Hiatal hernia:

- The hernial sac is formed by the stretched phreno-esophageal ligament and **sliding hernias** are frequently associated with **gastric reflux** and **esophagitis**.
- **Plain radiographs** may or may not reveal herniation of the stomach and diagnosis is usually confirmed by **barium swallow under fluoroscopy** or by **endoscopy**.
- Applying **abdominal pressure during radiography** may help induce hernia.
- **Endoscopy** is also valuable in assessing the degree of esophagitis due to gastroesophageal reflux.

Differential diagnosis

Megaesophagus is often associated with hiatal hernia and gastroesophageal intussusception. **Regurgitation** is a predominant sign. Confirm that the megaesophagus is unassociated with hiatal hernia or gastroesophageal intussusception by esophagram.

Esophageal foreign body. Signs of gagging, retching, salivation, repeated attempts at swallowing generally acute onset and continuous. History of eating or playing with **foreign body**. **LOOK UNDER TONGUE!** Confirm with plain and/or contrast radiographs or endoscopy.

Porto-systemic shunt. Severe pain associated with gastroesophageal intussusception may induce signs that may be confused with portosystemic shunt. Portosystemic shunt can be confirmed with serum bile acids.

Diaphragmatic hernia with incarcerated stomach. Confirm with X-rays/contrast.

Treatment

Medical treatment:

- Control of **esophagitis** and clinical signs with **ranitidine** (3.5 mg/kg PO q 12 h) or **cimetidine** (5–10 mg/kg PO q12 h).
- Feed **low-fat diet**. Fat delays gastric emptying time and it is therefore desirable to feed **low-fat diets**. **Elevated feedings** may help some cats and should be trialled especially if megaesophagus is present.
- If no response to medical therapy **surgical repair** is warranted.

Surgical repair involves anatomical replacement of herniated organs, reduction in size of esophageal hiatus, phrenicoesophageal plexy and left-sided fundic gastropexy.

ORGANOPHOSPHATE AND CARBAMATE TOXICITY

Classical signs

- Ptyalism, lacrimation, vomiting, diarrhea, pollakiuria.
- Miosis, muscular tremors, seizures.
- Dyspnea, respiratory failure.
- Bradycardia, depression, death.
- Rapid onset of clinical signs.

Pathogenesis

Organophosphates (OPs) and carbamates cause **inhibition of acetylcholinesterase** (AChE) and pseudo-cholinesterase, which allows **accumulation of acetylcholine** (ACh) in RBCs and the post-synaptic receptors of nervous tissue and muscle.

Accumulation of ACh results in **marked excitation of all effector organs**.

OPs are generally considered **irreversible** inhibitors of AChE activity, while **carbamates are slowly reversible** inhibitors.

OPs are **stored in fat** and slowly released into the circulation. **Lean, long-haired breeds** of cats are **more severely affected**.

Cats are more susceptible to OP toxicity than **dogs**. Poisoning often occurs following use of **canine flea products on cats**.

Most cat poison cases are due to **carbamates**.

Clinical signs

Early signs include **apprehension, increased swallowing, ptyalism, muscular twitching around the face and eyes**. **Miosis** and **bradycardia** occur.

Muscular twitching progresses to **whole-body muscle fasciculations** and **generalized tetany** causing a stiff-legged gait progressing to a **sawhorse stance** (i.e. all four legs stiff and apart).

Abdominal pain, cramping **diarrhea, vomiting** and **frequent urination** occurs commonly and eventually progresses to **muscular weakness** and **paralysis**.

Death can occur due to **respiratory failure**.

Delayed neuropathy: certain OPs (e.g. fenthion) can cause a delayed (usually 7–10 days) neuropathy causing **hindlimb weakness** and **characteristic ventroflexion of the neck**. All the other signs of acute OP poisoning are **absent** when delayed signs occur. Delayed neuropathy may occur after minimal exposure and there may be no history of acute signs in the preceding 7–10 days.

Diagnosis

History of recent application of OP or carbamate and characteristic signs.

Cholinesterase assay – whole blood, serum or plasma. Results should be interpreted in light of clinical signs and time of onset of signs.

Differential diagnosis

Pyrethrin toxicity – history of exposure.

Quaternary ammonium toxicity – history of exposure and ptyalism with **mouth ulcers** rather than generalized parasympathetic signs as occur with OPs.

Treatment

Establish **IV fluid line** and (oxygen/ventilation if needed).

Atropine IV (0.25–0.5 mg/kg) repeated to effect can be given S/C once stabilized. **Do not over-atropinize.**

Diazepam (1 mg/kg IV) repeated to effect to control seizures.

Muscle fasciculations can be controlled with **diphenhydramine** (2–4 mg/kg PO q 8 h).

2-PAM (20 mg/kg IM or IV) is effective against confirmed OP toxicity **if given in the first 24 hours. Repeat 8 hourly until stable.** Can be given with atropine. **Do not use in carbamate toxicity.**

Prevent further absorption – **wash cat with hair shampoo**, and give **activated charcoal** PO.

Diphenhydramine is used to treat delayed neuropathy (2–4 mg/kg PO q 8 h).

Prognosis

Generally good with treatment.

PYRETHRIN AND PYRETHROID TOXICITY

Classical signs

- Ptyalism.
- Tremors, ataxia, seizures.
- Depression or hyperexcitability.
- Vomiting, diarrhea.

Pathogenesis

Popular insecticide for use on cats.

Slows the closing of the sodium ion gate in nerve cells resulting in repetitive discharges or membrane depolarization.

Extremely bitter taste of topically-applied pyrethroids.

Clinical signs

Ptyalism, tremors, ataxia, seizures.

Occasionally **dyspnea** and **coma** occurs.

Hyperthermia, vomiting and **diarrhea** can occur.

Rapid onset of signs post exposure (within a few hours).

Diagnosis

History of exposure, clinical signs.

No definitive diagnostic clinical test available to date.

Differential diagnosis

Organophosphate/carbamate toxicity – blood cholinesterase level low.

Treatment

Diazepam (0.2 mg/kg IV) to effect to control tremors or seizures.

Phenobarbital IV if not controlled with phenobarbital add pentobarbital IV. NB **Phenobarbital** is an **anticonvulsant** where **pentobarbital stops muscular activity.** Pentobarbital is associated with paddling on recovery, which can be difficult to distinguish from seizure activity, and makes it less suitable for acute seizure control.

Wash cat to reduce further absorption.

Recovery usually in 1–4 days.

Small doses of **atropine** (0.01–0.02 mg/kg IV, IM, SC q 6–8 h) can be used to control salivation. (**Do not over-atropinise.**)

IV fluids, O₂, ventilation in severely affected cases.

ACETAMINOPHEN (PARACETAMOL) TOXICITY

Classical signs

- Ptyalism.
- Pale, blue-tinged mucous membranes.
- Facial edema, respiratory distress.
- Anorexia, vomiting.
- Hemoglobinuria.

Pathogenesis

Acetaminophen is widely used as an **antipyretic** and **analgesic** in human medicine.

Most common drug-induced toxicosis in the cat.

Metabolized in the liver to **glucuronide** and **sulfate conjugates**.

Cats are **deficient in glucuronyltransferase** and the glucuronidation and sulfation biotransformation routes are **rapidly saturated**, causing acute toxicity.

Hepatic necrosis and **methemoglobinemia** results.

Fatal methemoglobinemia usually occurs before signs of hepatic necrosis develops.

Cats are poisoned by as little as 50–60 mg/kg; that is, one adult tablet.

Clinical signs

Cyanosis and **tachypnea**.

Salivation and **abdominal pain**.

Facial edema and **often edema of the paws**.

Heinz body anemia.

Chocolate-colored urine (hemaglobinuria, hematuria).

Jaundice.

Rapid onset of clinical signs (within a few hours of ingestion).

Death ensues 18–36 hours after ingestion, if untreated.

Diagnosis

History of drug administration.

Characteristic combination of **facial edema** and **chocolate-colored urine**.

Heinz bodies on RBCs.

Methemoglobinemia.

Progressive rise in **liver enzymes**.

Low blood glutathione levels.

Serum acetaminophen concentration maximally elevated within 1–3 h after ingestion.

Differential diagnosis

Phenolic and **phenolic compound toxicity**.

Nitrite poisoning.

Treatment

Prompt and **early treatment** is essential.

Gastric lavage within 4–6 hours of ingestion.

Activated charcoal per os.

N-acetylcysteine (Mucomyst) 140 mg/kg as a 5% solution PO or IV as a loading dose, then 70 mg/kg PO or IV q 4 h for 3–5 additional treatments.

Ascorbic acid 125 mg PO q 6 h.

Electrolyte and fluid therapy.

Handle patient with **least stress**.

A rough estimate of the methemoglobin content of blood can be made by comparing the color of the patient's drop of blood against that of a drop of blood from a normal cat against a white background (e.g. white absorbent paper). A noticeable brown coloration compared with normal blood indicates a methemoglobin content of more than 10%. This subjective test can be used to monitor the effectiveness of treatment and should be performed every 2–3 hours.

Good nursing and **maintain body temperature**.

Whole blood transfusion if necessary to treat **hemolytic anemia**.

Recovery usually within 48 h.

Prognosis

Guarded to poor if severe methemoglobinuria (>50%) or hemolysis.

Good with very early and aggressive treatment.

LEAD POISONING

Classical signs

- **Gastrointestinal** – diarrhea, vomiting, inappetance.
- **CNS signs** – behavioral changes, depression, seizures.
- **Occasionally, intermittent ptyalism**.

Clinical signs

Usually in **young cats**.

Vague, **chronic gastrointestinal signs** most common – e.g. inanition, **inappetance**, poor growth, occasionally diarrhea and vomiting.

CNS signs can occur in more severe cases and include behavioral changes (depression, aggression, lethargy) seizures and blindness.

Occasionally, intermittent ptialism.

Diagnosis

History of access to lead, e.g. old house renovation (lead-based paint, dust from sanding).

Blood lead greater than 0.4 ppm.

Treatment

Chelation of lead with calcium disodium ethylene diamine tetra-acetate (CaEDTA) 100 mg/kg SC daily in four divided doses. Dilute CaEDTA to a concentration of about 10 mg CaEDTA/ml with 5% dextrose solution for 5 days. In severe cases, a further 5-day course can be given after a rest period of 5 days.

Relapses of clinical signs of lead poisoning are common and are treated as they arise.

SPIDER ENVENOMATION

Classical signs

- Ptialism.
- Hyperexcitability.
- Ataxia, paralysis.

Pathogenesis

Latrodectus spp. spiders include **black widow** (USA), **red back spider** (Australia) and **katipo** (New Zealand).

Venom contains **alpha-latroxin**, a **potent neuro-toxin**. The toxin opens cation-selective channels at the presynaptic nerve terminals, causing **release of large amount**

of acetylcholine and norepinephrine resulting in sustained muscle spasm.

The mechanism of **severe pain** at the bite site and regions remote from the actual bitten area is not well understood.

Clinical signs

Initially, **severe pain** characterized by **crying out**.

Hyperexcitability, ataxia, muscle rigidity and spasm, progressing to **muscle weakness** and collapse.

Prolonged, severe ptialism, possibly due to pain.

Death can occur from **respiratory failure**.

Diagnosis

Clinical signs.

History of contact with *Latrodectus* spider.

Laboratory evaluation not helpful.

Treatment

Latrodectus antivenine results in dramatic improvement of clinical signs if given in the acute phase of the disease and good results can be achieved even if given 24 hours after envenomation.

- **Premedicate** with **antihistamine** (chlorpheniramine 2.5–5 mg IM or SC) and have epinephrine (2.5–5 µg/kg IV) on hand. *Latrodectus antivenine* is prepared from the hyperimmune serum of horses.
- Dose of antivenine is 1 vial (500 units) given by **intramuscular** injection.
- In life-threatening situations the **intravenous route** can be used but the risk of **anaphylaxis** is greater.

Muscle spasm can be controlled with small doses of **intravenous diazepam** (0.2–0.5 mg/kg q 6 h), but **avoid respiratory depression**.

Supportive care includes **intravenous fluids, cortisone** and **atropine** (to control salivation).

Prognosis

Good with use of antivenine; guarded without.

DIEFFENBACHIA (“DUMB CANE”) POISONING

Classical signs

- Ptyalism.
- Tongue paralysis.
- Dysphagia.

Pathophysiology

Dieffenbachia is a popular decorative indoor plant. The leaves contain **irritant calcium oxalate crystals**, which the plant can propel into the tissues of the mouth of cats chewing on the plant by means of special contractile cells.

Plant extract also contains **proteolytic enzymes**, which trigger the release of histamines and kinins and contribute to clinical signs.

Plant is also known as “**dumb cane**” because it produces **paralysis of the tongue**.

Clinical signs

Sudden onset of signs. There is **immediate pain on chewing plant**.

Immediate **salivation**. Often **head shaking**.

Sometimes **change in voice**.

Examination of mouth reveals mild to moderate mucosal edema and **tongue paralysis** and **swelling**.

Diagnosis

History of plant chewing.

Treatment

Symptomatic – rinse mouth with water or **milk** to precipitate soluble oxalates.

Antihistamines (diphenhydramine 2–4 mg/kg IV, IM, PO q 6–8 h), and **corticosteroids** (dexamethasone 0.1–0.2 mg/kg IV, IM, PO q 12–24 h) to relieve pain and swelling.

Prognosis

Prognosis is very good as clinical signs regress after 24–48 hours.

DIAPHRAGMATIC HERNIA WITH INCARCERATED STOMACH

Classical signs

- Uncommon.
- Intermittent bouts of ptyalism often associated with dyspnea.
- Anxious expression, often after eating.

Pathogenesis

Stomach, with or without other abdominal organs, is chronically incarcerated in pleural cavity by constricting diaphragm subsequent to **traumatic diaphragmatic hernia**.

Sudden expansion of the stomach due to a large meal, with or without associated gas production causes **acute onset of hypersalivation with anxious expression**.

Rapid expansion of stomach volume after eating causes **sudden onset nausea**, which in turn, causes ptyalism.

Clinical signs

Sudden onset of salivation with **intent, anxious expression** and varying degrees of **dyspnea**.

Usually signs occur **immediately after eating**.

Differential diagnosis

Portosystemic shunt is associated with elevated postprandial bile acids and CNS signs.

Diagnosis

Plain and/or contrast radiography.

Treatment

Surgical repair of hernia.

D-LIMONENE, LINAPOL, AND CRUDE CITRUS OIL EXTRACTS

Classical signs

- Moderate to severe ptyalism.
- Muscular tremors (shivering).
- Ataxia.

Clinical signs

Used as insecticidal sprays or shampoos.

Immediate sign of toxicosis is hypersalivation which lasts 15 minutes to 1 hour.

More severely affected cats develop muscular tremors and ataxia. Hypothermia occurs.

Clinical signs generally abate within 4 hours.

Treatment

Wash cat in unmedicated shampoo.

Maintain body temperature.

DIBUTYL PHTHALATE

Classical Signs

- Profuse salivation and foaming.
- Occasional retching and/or vomiting.

Clinical Signs

Used luminescent agent in “Glo-Jewellery” and as insect repellent

Has extremely bitter taste and causes immediate hypersalivation when cat bites into toy.

Signs of hypersalivation generally self limiting once taste removed from mouth.

RABIES

Classical signs

- CNS signs, behavioral changes.
- Ptyalism, frothing.
- Fever.

Pathogenesis

Single-stranded RNA Lyssavirus.

Virus inoculation via **bite wound** from rabid animal or **via mucous membrane** contact with infected body fluids, e.g. saliva.

Viral replication occurs in myocytes and spreads to neuromuscular junctions and neurotendinal spindles.

Virus spreads to CNS via intra-axonal fluid within peripheral nerves, then to peripheral sensory and motor neurons.

Salivary glands contain **large amounts of virus which is shed in saliva.**

Infection through contact with infected reservoir animals (bats, skunks, raccoons and foxes) or **infected dogs and cats.**

Clinical signs

Initial clinical signs are present for **only 24 hours** and include **low-grade fever** and **behavioral changes** (e.g. irritability, hiding or increased affection).

The **excitatory stage** (“**furious rabies**”) may last 2–4 days and is not always exhibited.

Signs include **muscle fasciculations**, **ptyalism**, **weakness**, **ataxia** and **increased aggressiveness** and **irritability**.

The **final stage** (“**dumb**” **rabies**) lasts 1–4 days and **general paralysis and convulsions precede death.**

Diagnosis

History of **no vaccination** with approved killed vaccine.

History of **exposure to bite or scratch wounds from infected dogs or cats.**

History of exposure to reservoir animals including foxes, skunks, raccoons and bats.

Typical clinical signs with progression almost invariably to **death within 7–10 days.**

EXTREME ZOONOTIC POTENTIAL.

Immediately notify authorities when rabies is suspected. Follow official policy for handling suspected rabies cases, including tissue or fluid samples.

Minimal changes in CSF analysis and **routine blood analysis.**

Histological confirmation with finding **Negri bodies** within the CNS on post-mortem.

Immunofluorescent antibody test on CNS tissue.

Differential diagnosis

Portosystemic shunt – intermittent, often associated with eating. Lack of rapid progression of signs over 7–10 days resulting in death. Confirm with post-prandial serum bile acids.

Pyrethrin and pyrethroid toxicity – no behavior changes and history of exposure and serum cholinesterase levels (OP) will confirm diagnosis.

Feline spongiform encephalopathy also has combination of neurological signs and hypersalivation. Histopathology differentiates.

Treatment

No treatment should be attempted. Almost uniformly fatal.

Follow official guides for management of suspected rabies case.

Prognosis

Always grave.

FELINE SPONGIFORM ENCEPHALOPATHY (FSE)

Classical signs

- CNS signs, progressive.
- Hypersalivation.

Clinical signs

Progressive neurological signs including ataxia (especially pelvic limbs), behavioral changes, hyperesthesia, head tremor, muscle fasciculations.

Ptyalism.

Diagnosis

Histopathology shows discrete **vacuolation** of gray matter throughout CNS.

Treatment

Supportive only.

Prognosis

Grave.

FELINE PANLEUKOPENIA (PARVO VIRUS, FELINE ENTERITIS, FELINE DISTEMPER)

Classical signs

- Vomiting, diarrhea.
- Lethargy.
- Severe dehydration.
- High mortality.

Clinical signs

Usually in young (2–6 months) kittens.

Acute-onset vomiting, often severe diarrhea.

Fever in early stages of disease.

Rapid dehydration.

Severe depression.

Although not generally a feature of feline panleukopenia, continuous ptyalism has been recorded as the predominate clinical sign in kitten with confirmed panleukopenia at post-mortem examination.

Diagnosis

No vaccination history, recent exposure to virus.

Panleukopenia is the most consistent clinical finding. Complete blood counts show leukocyte counts between 500 and 3000 cells per microliter during the acute phase of the disease.

Canine parvovirus antigen fecal immunoassay will detect feline parvovirus antigen in feces of affected cats.

Viral isolation from feces or affected tissues.

Histopathology.

Treatment

Rehydration, intravenous fluids.

Re-establishment of electrolyte balance.

Broad-spectrum antibiotics (amoxicillin/clavulonic acid 62.5 mg/cat PO q 12 h).

Whole blood transfusion in severely affected cats.

Prognosis

Guarded to poor in young kittens.

If cat survives 5 days, prognosis improved markedly.

28. The cat with bad breath or oral lesions

Gary John Wilson

KEY SIGNS

- Bad breath.
- Oral mass, ulceration or inflammation.
- Calculus.

MECHANISM?

- Bad breath occurs from the production of volatile sulfur-containing compounds. Hydrogen sulfide and methyl mercaptan account for approximately 90% of these. Gram-negative bacteria are primarily responsible for malodor production.

WHERE?

- Oral cavity, nasal cavity, nasopharynx and respiratory tract.

WHAT?

- Most cats with bad breath have periodontal disease.

QUICK REFERENCE SUMMARY

Diseases causing bad breath or oral lesions

ORAL CAVITY

ANOMALY

- Congenital anomaly of hard palate (cleft palate) (p 610)
Cleft palate results in rhinitis and secondary bacterial infection and nasal discharge in young kittens.

MECHANICAL

- Oral foreign body* (p 609)
Foreign bodies include grass seed, bone fragments and hair. They are usually acute onset associated with sneezing, rubbing the face, pawing at the mouth, coughing or gagging.

NEOPLASTIC

- **Oral neoplasia** (p 607)**

Visible tumors often with secondary bacterial infection and periodontal disease. Signs may include rubbing face, pawing at mouth or facial distortion.

INFECTIOUS (BACTERIAL)

- **Periodontal disease*** (p 604)**

Chronic disease with halitosis, inflamed gums and calculus on teeth.

- **Oronasal fistula (p 610)**

Chronic occasional sneezing and nasal discharge associated with dental disease or trauma.

- **Bacterial infection of tongue lacerations* (p 609)**

Halitosis with purulent open wound on or under tongue.

- **Oral ulcerations associated with viral causes (herpesvirus and calicivirus)* (p 607)**

Oral lesions are more common with calicivirus infection and the vesicles rupture to form oral ulcers, which allows secondary bacterial invasion.

IMMUNE/IDIOPATHIC

- **Feline oral inflammatory disease (plasmacytic-lymphocytic gingivopharyngitis complex, plasmacytic-lymphocytic stomatitis/faucitis)** (p 606)**

Chronic severe inflammation of gingiva and fauces.

- **Eosinophilic granuloma complex (p 611)**

Lip ulcer or raised firm lesions especially on the tongue or hard palate. Oral lesions postulated to be secondary to chronic licking.

TRAUMA

- **Mandibular and maxillary fractures (p 610)**

Inability to chew, salivation and rapid secondary infection of traumatized tissue.

- **Tooth fracture with periapical abscessation (p 610)**

Fractured teeth often go unnoticed in cats and will progress to pulp death and periapical abscessation and possible external discharge.

TOXIC

- **Oral ulcerations associated with uremic or toxic causes (p 607)**

Oral ulceration may occur with uremia or associated with concentrated cleaning agents, allowing secondary bacterial invasion.

EXTRA-ORAL CAUSES OF BAD BREATH (NASAL CAVITY, ESOPHAGUS, LOWER AIRWAY)

INFECTIOUS

Bacterial:

- **Bacterial rhinitis secondary to viral upper respiratory tract disease* (p 608)**

Chronic mucopurulent or hemorrhagic nasal discharge and sneezing.

continued

continued

- Infections associated with esophageal or lower airway disease (p 609)
Infections secondary to primary disease of the esophagus or lower respiratory tract.

Fungal:

- Cryptococcosis (p 611)
Chronic mucopurulent or hemorrhagic nasal discharge, sneezing and occasional facial distortion with associated halitosis.

INTRODUCTION

MECHANISM?

Volatile sulfur-containing compounds are the major contributors to malodor (bad breath).

Hydrogen sulfide and methyl mercaptan account for approximately 90% of the total sulfur content of mouth air.

Anaerobic Gram-negative bacteria utilize sulfur-containing amino acids for the generation of volatile sulfur-containing compounds.

WHERE?

Diseases of the oral cavity, nasal cavity, nasopharynx and the respiratory tract may cause bad breath and oral lesions.

Any malodor from the oral cavity indicates disease.

History and detailed physical examination (often under anesthesia) are essential for diagnosis.

Oral lesions should be expected if the cat is reluctant to allow oral examination (or shows any other signs of oral pain).

WHAT?

The most common diseases causing bad breath and oral lesions are:

- **Periodontal disease.**
- **Feline oral inflammatory disease** (plasmacytic-lymphocytic gingivopharyngitis complex).

Diagnosis is made after examination under general anesthesia, radiography, laboratory tests or a combination of these.

DISEASES CAUSING BAD BREATH OR ORAL LESIONS

PERIODONTAL DISEASE***

Classical signs

- Halitosis (bad breath).
- Calculus on teeth.
- Inflamed gums.

Pathogenesis

Plaque is a matrix of bacteria, salivary glycoproteins, food particles, epithelial cells and leukocytes, which adheres to the tooth surface.

Plaque can only be **removed mechanically**; it cannot be rinsed off.

Supragingival plaque occurs above the gum line and subgingival plaque below.

Subgingival plaque bacteria are responsible for the pathology found in periodontal disease.

Initially **edema and inflammation** of the gum margins (gingivitis) is seen, which is followed by **loss of epithelial attachment** at the base of the gingival sulcus with subsequent periodontal pocket formation.

Destructive processes continue with eventual **loss of the periodontal ligament and alveolar bone** (periodontitis).

If allowed to progress untreated, eventually the **tooth will be lost**.

As periodontal disease progresses, the bacteria change initially from anaerobic Gram-positive bacteria to Gram negative to anaerobes, and finally to fusiforms and spirochetes.

The halitosis is due to the **production of volatile sulfur compounds by the plaque bacteria** (especially by the anaerobes).

Chronic low-grade **bacteremia** from periodontal disease can have **systemic effects** on other organs (especially kidney, myocardium and liver).

Clinical signs

Healthy gingiva is **shiny with a sharp margin**, which appears almost transparent under magnification and has a sulcus depth which is less than 0.5 mm.

With gingivitis the margins are **edematous and inflamed** (red line around edge of marginal gingiva) and may **bleed on probing**. Halitosis will be present and supragingival calculus may be present.

As disease progresses, **pocket formation begins** with associated subgingival plaque. Halitosis and **supragingival calculus** will be present and subgingival calculus may also be present.

Further deterioration leads to bone loss, deep pocket formation, furcation exposure (loss of bone between tooth roots of multi-rooted teeth) and **tooth mobility**.

Severe periodontal disease will result in tooth loss, deep pockets with heavy anaerobic infections and strong halitosis. The cat may show signs of systemic disease and refuse to eat or **attempt to swallow food without chewing**.

Diagnosis

History of halitosis and, in severe cases, there may be a reluctance to chew food and occasional pawing at mouth.

Clinical signs are diagnostic.

In the anesthetized cat, determine **the severity of disease** by a thorough oral examination. This will include palpation of loose teeth and the **use of a periodontal probe** to check for the presence of periodontal pockets.

Evaluate radiographically to assess loss of **crestal bone** (bone between teeth) and loss of bone around the tooth roots.

Differential diagnosis

Feline oral inflammatory disease (or plasmacytic-lymphocytic gingivopharyngitis complex) has similar signs in the early stages to early periodontal disease but cats rapidly **develop a severe inflammation of the whole gingiva** and often a concurrent faucitis (compared to inflammation of the gum margin only with periodontal disease). The tissues are grossly inflamed and are friable, bleed easily and are extremely painful.

Feline odontoclastic resorptive lesions may appear similar to localized areas of periodontal disease with **gingival hyperplasia** covering the resorptive lesion. **Probing under general anesthesia** will reveal the lesion. These lesions are also extremely painful and cats will often avoid using these teeth.

Treatment

Dental prophylaxis to eliminate the bacteria causing odor and to remove diseased tissue so as to allow the reattachment of the gingiva.

- This is done under general anesthesia to ensure that subgingival plaque is removed.
- The steps involved are **supragingival scaling, subgingival scaling, polishing** and flushing (**irrigation**) of the sulcus.

For the more severe cases treatment may also involve **periodontal surgery** to expose affected tissue and to allow complete subgingival cleaning and extraction.

Antibiotics are usually not required.

Prognosis

Good if secondary organ damage has not occurred.

Prevention

Daily brushing is recommended but does require owner and cat compliance.

Chewing raw meaty bones such as chicken wings will help to mechanically remove the plaque.

Calculus control diets, which are designed to remove the adhered plaque as they are chewed, due to their abrasive nature or to compete with plaque for salivary calcium ions.

Dental chews will help in mechanically removing plaque.

FELINE ORAL INFLAMMATORY DISEASE (OR PLASMACYTIC-LYMPHOCYTIC GINGIVOPHARYNGITIS COMPLEX, PLASMACYTIC-LYMPHOCYTIC STOMATITIS/FAUCITIS)**

Classical signs

- Halitosis.
- Grossly inflamed gums especially in premolar and molar areas.
- Gums bleed easily.
- Very painful and cats often bad tempered.

Pathogenesis

The etiology of this condition is **unknown**. Suggested causes have been bacterial, viral (especially calicivirus) and immunological (possible hypersensitivity to plaque proteins).

The condition may be the result of chronic immune-mediated processes.

Lymphocytes, plasma cells and neutrophils are the predominate cells found at biopsy.

Clinical signs

Intense oral pain (and often bad-tempered cats which resent oral examination).

When eating, affected cats often attempt to **swallow the food without chewing** due to the oral pain. The appetite appears reduced due to the cat's reluctance toprehend food.

Halitosis.

Dysphagia, **excess salivation** and weight loss in severe cases.

Proliferation of gingiva with extensive inflammation. The tissue is friable and bleeds readily on palpation.

Most frequently involves the **gingiva caudal to the canine teeth** and the **fauces** but can occur associated with the incisors as well.

In severe cases the **entire gingiva** (not just the gingival margin) as well as the fauces becomes grossly inflamed.

More prevalent in **purebred cats**.

Diagnosis

Clinical signs are diagnostic in severe cases.

In early cases, the severe inflammatory reaction of the gingival margin (which bleeds easily on palpation) is suggestive.

The diagnosis can be confirmed by **biopsy** if necessary.

Differential diagnosis

Periodontal disease. The inflammation is less acute, less severe and restricted to the gingival margin.

Chronic calicivirus faucitis and gingivitis. The inflammatory response is less severe with calicivirus.

Acute herpesvirus and calicivirus infections. This is associated with lingual and palatal ulcerations and other signs of respiratory tract infection such as sneezing and oculonasal discharge.

Treatment

Initially, a careful and thorough **dental prophylaxis** and appropriate antibiotic therapy (must be effective against anaerobes such as *Actinomyces* sp., *Peptostreptococcus* sp. and the black pigmented bacteroides) will give relief although only temporary in most instances.

Corticosteroid therapy will produce improvement whilst used.

Permanent resolution is common following **extraction of all teeth** caudal to the canines (but these teeth must be extracted completely including all of the roots).

In cases that suffer recurrence following extraction (less than 5%), **acupuncture** may result in resolution.

Acupuncture alone will produce short-term relief.

Prognosis

The **prognosis is guarded** for those treated **without extraction**.

With complete extraction, the prognosis is fair to good.

Prevention

Until the etiology is understood, no prevention is possible.

ORAL NEOPLASIA**

Classical signs

- Presence of oral mass.
- Dysphagia, excessive salivation, hemorrhage.
- Halitosis.

Pathogenesis

Neoplasia may involve gingiva, tongue, oral mucosa or tonsils.

Squamous cell carcinoma is the most common neoplasm in cats and is most often found on the **ventral tongue**.

Other types of oral tumor are infrequent in the cat.

Neoplasia usually occurs in older cats (> 10 years).

Clinical signs

Oral mass.

Excessive **salivation**, **dysphagia** or **oral hemorrhage**.

Facial distortion.

Halitosis.

Poor body condition due to inability to eat or metastatic disease.

Diagnosis

Biopsy and histologic examination.

Radiography to assess the extent of hard tissue tumors.

Differential diagnosis

Intra-oral abscess and granulation tissue can have a similar appearance to neoplasia but will be differentiated by biopsy.

Eosinophilic granuloma complex is often smaller and can be differentiated by biopsy.

Treatment

Treatment of lingual squamous cell carcinoma in the cat has not proved successful.

Mandibular masses can be treated by **partial mandibulectomy** (the complete hemimandible can be removed if necessary).

Prognosis

The prognosis for squamous cell carcinoma of the tongue is **grave**.

For other tumors, the prognosis will depend on the tumor type and suitability for treatment.

ORAL ULCERATIONS FROM VIRAL, UREMIC OR TOXIC CAUSES*

Classical signs

- Excessive salivation.
- Tongue and pharyngeal ulceration.
- Anorexia.

See main reference on page 578 for details (The Cat With Salivation).

Pathogenesis

Feline herpesvirus and feline calicivirus can cause an **ulcerative stomatitis** in association with upper respiratory tract disease.

- **Calicivirus infection most commonly** causes oral lesions especially on the tongue and hard palate.
- The lesions begin as vesicles, which coalesce and rupture, forming ulcers.
- Lesions caused by herpesvirus occur less frequently but are usually more severe.

Cats with uremia produce increased ammonia in the saliva. Uremia also causes damage to blood vessels resulting in vasculitis. Ulceration of the oral mucosa may be caused by the combination.

Toxic causes of oral ulceration in the cat are most frequently associated with household cleaning agents.

- These toxic agents include **sodium hypochlorite** and **sodium hydroxide** that are used for cleaning showers and bathrooms, and **quaternary ammonium compounds**.
- The cat damages the oral mucosa whilst **licking the walls or floor** or from licking it **off their feet**.
- These cats may also have lesions on their feet if exposure was from walking in the chemical.

Clinical signs

Excessive salivation and oral pain.

Oral ulceration associated with concurrent upper respiratory tract disease.

Fever is often present associated with herpesvirus and calicivirus ulceration but not with uremic or toxic ulcers.

Sudden onset of salivation, dysphagia and depression with toxic ulceration.

Loss of sense of smell, fever and oral pain results in anorexia.

Halitosis.

Diagnosis

Presence of oral ulcers.

Virus identification using PCR if ulcers are associated with upper respiratory tract disease.

Blood tests for uremia.

History of exposure to toxins liable to produce oral ulceration.

Differential diagnosis

Electrical or heat burns to the tongue and oral mucosa are rare in the cat. Lack of **fever** and history of potential for exposure help to differentiate these from infectious causes.

Treatment

Antibiotics to control secondary bacterial infections.

Fluid therapy, soft foods and adjunct therapy (for the primary disease) until lesions are healed.

Pain control.

BACTERIAL RHINITIS SECONDARY TO VIRAL UPPER RESPIRATORY TRACT DISEASE*

Classical signs

- Chronic sneezing and snuffling.
- Mucopurulent nasal discharge.
- Stertorous respiration.

See main reference on page 21 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Chronic mucopurulent nasal discharge.

Chronic sneezing and snuffling.

Stertorous respiration.

Halitosis may be present.

Diagnosis

History of clinical signs after an acute upper respiratory tract infection.

Radiography demonstrating **fluid densities in nasal cavity and sinuses** with loss of turbinates.

Cytology showing many neutrophils with intra- and extracellular bacteria and no evidence of *Cryptococcus* sp. or neoplastic cells.

Differential diagnosis

Neoplasia. Usually older cats and radiographic signs are more often unilateral. Biopsy will differentiate.

Cryptococcosis. Often has nasal distortion or visible polyp protruding through nares. Differentiate with cytology or serology.

Treatment

Long-term broad-spectrum antibiotic therapy.

Surgery (rhinotomy) to curette sinuses may be tried as a salvage procedure.

ORAL FOREIGN BODY*

Classical signs

- Gagging, pawing at mouth.
- Halitosis.
- Dysphagia.

Clinical signs

Sudden onset of gagging and pawing at the mouth.

Dysphagia. The cat will often **appear very hungry** but has **difficulty swallowing**.

Rapid jaw and tongue movements.

Diagnosis

Evidence of foreign body or trauma caused by the foreign body in the oral cavity or pharynx.

Most commonly the tongue or pharynx are involved especially with **string or cotton**.

Differential diagnosis

Oral tumors. These can be differentiated visually from a foreign body.

Traumatic lacerations. These are usually associated with hemorrhage and no foreign body will be found on examination.

Treatment

Removal of the foreign body.

BACTERIAL INFECTION OF TONGUE LACERATIONS*

Classical signs

- Hemorrhage.
- Reluctance to groom and excessive salivation.

Clinical signs

Hemorrhage may be significant if acute.

Sudden onset of reluctance to groom, excessive salivation and reluctance to eat.

Halitosis develops as tissue becomes infected.

Laceration may be on the dorsal surface or **sublingual (more often)**.

Diagnosis

Visualize the laceration.

Differential diagnosis

Foreign bodies can usually be seen.

Ulcerations secondary to trauma.

Treatment

Surgical debridement and repair.

INFECTIONS ASSOCIATED WITH ESOPHAGEAL AND LOWER AIRWAY DISEASE

Classical signs

- Dysphagia, regurgitation (esophageal disease).
- Dyspnea, coughing (lower airway disease).

Clinical signs

Halitosis.

Dysphagia, regurgitation and possible reluctance to eat with esophageal disease. **Esophageal tumors and foreign bodies** are most often associated with halitosis.

Dyspnea, coughing with lower airway disease. **Foreign bodies, airway tumors and purulent bacterial infections** are most frequently associated with halitosis.

Diagnosis

Radiography to demonstrate lesions.

Auscultation and ultrasonography.

ORONASAL FISTULA

Classical signs

- Occasional sneezing.
- Unilateral nasal discharge.
- Excessive licking of nose.

See main reference on page 27 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Most often **associated with dental disease**; occasionally occurs after **trauma**, with formation of a fistula in the hard palate.

Occasional sneezing.

Unilateral nasal discharge (usually mucopurulent but may be hemorrhagic). If associated with dental disease or unilateral traumatic fistula.

Excessive licking of nose.

Oronasal fistula visible if tooth is absent.

Advanced periodontal disease.

Halitosis.

Diagnosis

Presence of oronasal fistula on periodontal probing (vigorous movement of probe results in blood from nostril).

MANDIBULAR AND MAXILLARY FRACTURES

Classical signs

- Mouth held open (often with tongue protruding).
- Jaw asymmetry.
- Excessive salivation.

Clinical signs

Unwilling (or unable) to close mouth and tongue protruding.

Asymmetry of jaw.

Hemorrhage in acute stages.

Excessive salivation.

Halitosis associated with secondary bacterial infection of traumatized tissue.

Diagnosis

Palpation and radiographic demonstration of fracture.

TOOTH FRACTURE WITH PERIAPICAL ABSCESSATION

Classical signs

- Presence of fractured tooth.

Clinical signs

Fractured tooth.

Oral pain in acute phase (< 48 hours) then no pain until periapical abscess forms.

Calculus build-up on teeth on affected side of mouth due to reluctance to chew with affected tooth.

Halitosis may be present if the periapical abscess is draining intra-orally.

Diagnosis

Presence of **fractured crown**.

CONGENITAL ANOMALY OF THE HARD PALATE (CLEFT PALATE)

Classical signs

- Snuffling and nasal discharge.
- Visible evidence of cleft.

Clinical signs

Snuffling and nasal discharge, which is usually bilateral.

In **young kitten** with congenital cleft, milk is visible coming from the nose during feeding.

In **traumatic cleft**, dried blood around the nose and mouth and facial injuries.

Halitosis is associated with rhinitis and secondary infection from food in the nasal passages.

Diagnosis

Evidence of cleft.

CRYPTOCOCCOSIS

Classical signs

- Chronic nasal discharge.
- Facial distortion (nasal bones).

See main reference on page 25 for details (The Cat With Signs of Chronic Nasal Disease).

Clinical signs

Chronic nasal discharge and snuffling.

Distortion of bridge of nose or nasal polyp is present in most cases.

Depression and anorexia.

Other organs may be affected.

Diagnosis

Serology for cryptococcus antibody.

Cytology for identification of the organism.

EOSINOPHILIC GRANULOMA COMPLEX

Classical signs

- Ulcerated lesion near the midline of the upper lip.
- Raised firm lesions in the oral cavity (especially tongue and hard palate).

See main reference on page 1088 for details (The Cat With Non-Healing Wounds).

Clinical signs

Ulcerated lesion on the upper lip near the midline.

Raised firm lesions (with yellow-white spots throughout) **in the oral cavity** especially on the **tongue and hard palate**.

Diagnosis

Biopsy.

29. The cat with signs of regurgitation (acute or chronic)

Debra L Zoran

KEY SIGNS

- Passive elimination via the mouth of swallowed food.
- Food is typically undigested.
- Gagging or retching may occur concurrently.

MECHANISM?

- Regurgitation is a **passive** act that may involve several anatomic regions of the alimentary tract: oral cavity, oropharynx, esophagus or occasionally the stomach.
- Oral or pharyngeal disease is more often associated with dysphagia (difficulty swallowing).
- Regurgitation is a more typical presenting sign of **esophageal disease**.
- Regurgitation is **not associated with prodromal signs** (no anxiety, nausea or hypersalivation), there will be **no abdominal muscular activity**, and is often composed of recently swallowed food (undigested, whole).
- In cases of chronic megaesophagus, where food may sit undisturbed for hours in the distal esophagus, the food may have a more liquid, unformed character.
- The pH of the material may be **neutral, slightly basic (oral) or slightly acidic** (stomach), but is typically in a range of pH 4–7.

WHERE?

- Regurgitation is usually associated with **disease of the esophagus**:
 - **Megaesophagus** (acquired or congenital).
 - Associated with esophageal anomalies, e.g. diverticular structures, vascular ring anomalies.
 - **Esophagitis**, esophageal strictures or foreign bodies.
 - Associated with oropharyngeal disease, e.g. stomatitis-pharyngitis complex.
 - Parasitic diseases of the esophagus.
- Signs of **gagging or retching** are often associated with regurgitation (or vomiting) in cats and include many oral, dental and pharyngeal infectious, inflammatory, neoplastic or toxic disorders.

WHAT?

- The most common causes of regurgitation in cats are esophagitis (due to a variety of infectious or inflammatory causes), esophageal stricture, esophageal foreign bodies, and more rarely pharyngeal or esophageal neoplasia.

QUICK REFERENCE SUMMARY

Diseases causing signs of regurgitation

ANOMALY

- **Vascular ring anomalies (persistent right aortic arch – PRAA) (p 623)**
Vascular ring anomalies cause regurgitation soon after the kitten is weaned onto solid food.
- **Esophageal diverticular structures (p 624)**
These may be clinically silent or associated with regurgitation, painful swallowing, lethargy and decreased appetite, depending on the size of the diverticular structure.

MECHANICAL

- **Esophageal foreign body** (p 616)**
Foreign bodies may cause gagging, retching or regurgitation, depending on what they are, how long they have been present in the esophagus, and whether or not they are caustic.
- **Esophageal stricture* (p 618)**
This is a complication of esophagitis that results in regurgitation due to narrowing or nearly complete obstruction of the esophageal lumen.
- **Eating too fast (food gulping) (p 628)**
Regurgitation of undigested food may be caused by eating too fast or food gulping.
- **Hiatal hernia (gastroesophageal intussusception) (p 625)**
This is a rare disorder associated with intermittent regurgitation or vomiting due to herniation of the stomach through the esophageal hiatus.
- **Esophageal fistula (p 625)**
This is an abnormal communication between the esophagus and respiratory system that usually results from foreign body penetration or a ruptured diverticulum. Clinical signs will include regurgitation as well as respiratory signs (e.g. coughing, dyspnea, etc.).

IDIOPATHIC

- **Esophageal hypomotility/idiopathic megaesophagus (acquired or congenital)* (p 621)**
Regurgitation may or may not be associated with eating. Aspiration pneumonia is a common complication resulting from the frequent regurgitation.
- **Dysautonomia (p 627)**
Regurgitation occurs due to the development of megaesophagus secondary to abnormal functioning of the autonomic nervous system. This rare disorder is also associated with abnormal colonic and ocular muscle functions, among other things.

IMMUNOLOGIC

- **Myasthenia gravis (acquired or congenital)* (p 622)**
Myasthenia gravis can be acquired or congenital and results in megaesophagus (regurgitation) secondary to the presence of antibodies to the acetylcholine receptor in the neuro-muscular junction, with the end result being smooth muscle dysfunction.

continued

continued

INFLAMMATORY

● Esophagitis*** (p 615)

Esophagitis is an inflammatory disease of the esophagus that has multiple causes such as reflux disease, post-anesthesia, chronic vomiting, caustic or irritant ingestion and results in regurgitation and may progress to esophageal strictures if left untreated or if severe.

INHERITED

● Hereditary myopathy of Devon Rex cats (p 626)

This is an inherited myopathy in young Devon cats that presents as generalized appendicular weakness. Ventroflexion of the head and neck, dorsal protrusion of the scapulae and megaesophagus with regurgitation are the main clinical features of hereditary myopathy.

NEOPLASTIC

● Esophageal neoplasia (squamous cell carcinoma, metastatic neoplasia)* (p 619)

This is a rare tumor in cats, but is the most common tumor of the esophagus. The tumor creates an obstructive lesion that results in regurgitation, weight loss and anorexia.

● Mediastinal neoplasia* (p 628)

Thymic lymphoma and thymoma commonly result in extraesophageal obstruction and regurgitation.

TOXIC

● Lead poisoning* (p 619)

Lead poisoning is usually marked in the early phases with vomiting and GI signs. Neurologic signs develop late or with chronic exposure and may lead to the development of smooth muscle dysfunction (megaesophagus) and regurgitation.

● Plant ingestion* (p 620)

Regurgitation secondary to plant consumption is usually due to their irritant or caustic properties that result in the development of esophagitis.

INTRODUCTION

MECHANISM?

Regurgitation is the **passive removal** of ingesta, saliva, and other material from the upper GI tract (oral cavity, oropharynx and esophagus).

Regurgitation of stomach contents can occur but is much **less common than vomiting**.

Regurgitation is **not associated with abdominal muscle contraction**, has no **prodromal signs** (no anxiety, nausea or hypersalivation preceding it), and the mate-

rial is typically composed of recently swallowed food (undigested, may still be whole) with saliva.

In cases of **chronic megaesophagus**, where food may sit undisturbed for hours in the distal esophagus, the food may have a **more liquid, unformed character**.

The **pH of the material may be neutral, slightly basic (oral) or slightly acidic** (stomach), but is typically in a range of **pH 4–7**.

Diseases of the esophagus rarely cause **hematologic or biochemical abnormalities**, and their **diagnosis often requires contrast radiography, endoscopy** or other sophisticated imaging techniques.

WHERE?

Classically, regurgitation is considered to be the hallmark of esophageal disease.

Gagging or retching, painful swallowing or dysphagia can all be signs of esophageal disease, however, most of the time these signs are associated with oral or oropharyngeal disease (see page 602, The Cat With Bad Breath or Oral Lesions).

WHAT?

Esophageal diseases that may be associated with regurgitation include esophagitis, cardiac anomalies (e.g. persistent right aortic arch), mechanical problems (e.g. strictures, foreign bodies or fistula), metabolic disorders (megaesophagus – acquired, congenital or idiopathic), or toxic (plant ingestion, etc.).

Many diseases of the esophagus may be difficult, if not impossible to treat.

Megaesophagus, strictures, diverticuli, hiatal hernias, fistulae and esophageal neoplasia are all very difficult to manage or cure.

Esophagitis is the most common and potentially most treatable esophageal disease of cats other than foreign bodies and ingestion of plant material.

DISEASES CAUSING SIGNS OF REGURGITATION

ESOPHAGITIS***

Classical signs

- Regurgitation is the most common sign.
- Vomiting, gagging, retching, anorexia, weight loss and lethargy.

Pathogenesis

Esophagitis can be caused by a wide variety of insults, including **infectious** (e.g. calicivirus).

- **Gastroesophageal reflux disease** (persistent vomiting, **anesthesia**, lower esophageal sphincter abnormalities, hiatal hernias).
- **Chemical** (caustic agents) or **thermal injury**.

- **Drugs** (primarily due to direct injury if retained in the esophagus, e.g. doxycycline, potassium gluconate, propranolol).
- Secondary to **trauma from esophageal foreign bodies**.

Other than traumatically induced esophagitis, the most common cause of esophageal inflammation in cats is **reflux of acid, pepsin and stomach contents into esophagus as a result of anesthesia or chronic vomiting**.

The esophagus does not have the mucosal protection mechanisms that are present in the stomach, and thus, acid and chemical mucosal injury from reflux will set into motion a **localized inflammatory response** that, if uncorrected, can result in esophageal stricture formation or perforation.

Clinical signs

Regurgitation following eating is the predominant clinical sign in cats with esophagitis, but vomiting, anorexia, weight loss, lethargy and gagging may also be observed.

Onset of regurgitation following an anesthetic procedure or foreign body retrieval is highly suspicious of esophagitis.

Diagnosis

A history of a recent **onset of regurgitation after an anesthetic procedure** should immediately suggest esophagitis.

Concurrent oral ulceration suggests chemical, thermal, calicivirus or uremic ulceration.

History (chemical, thermal, anaesthesia, drugs, foreign bodies) usually identifies the problem.

Esophagitis in cats due to consumption of a **chemical or thermal agent** may be associated with **completely normal baseline blood work**.

Survey radiography may be helpful if the **esophageal inflammatory process is also causing motility disturbances** that can be seen as **esophageal dilatation** radiographically. Rarely, contrast radiography may be useful in identifying areas of **mucosal irregularity** suggestive of esophagitis. **Contrast radiographs** are

most helpful in identification of **esophageal stricture** formation.

Definitive diagnosis of esophagitis, and any complications associated with it, is achieved by **endoscopic examination of the esophagus and biopsy**.

Note: a normal-appearing mucosa does not rule out esophagitis. However, in most cases, **mucosal erythema, hemorrhage and increased friability** are common findings.

Differential diagnosis

Essentially any cause of regurgitation or chronic vomiting should be considered as a differential because the signs are so non-specific and many overlap with other diseases.

Treatment

Treatment of esophagitis is first aimed at **correcting the underlying cause**. If the cause cannot be identified and corrected, management of the esophagitis will be extremely difficult.

Symptomatic therapy then is used to **control the inflammatory process** that is ongoing in the esophageal mucosa. This type of approach will require both “**resting**” the esophagus and **pharmacologic therapy**.

In cats with **mild esophagitis**, simply **withdrawing food for 24–48 hours is often sufficient** to allow mucosal healing. Upon re-feeding, the diet should be a **soft, low-fat, non-abrasive food** that will not re-injure the tissue.

When **severe esophagitis** is present, **feeding should be administered via alternative feeding methods**.

Provide enteral nutrition via a gastrostomy or jejunostomy tube (pharyngostomy or nasogastric tubes will continue to irritate the esophagus and may allow continued gastroesophageal reflux) or **use total parenteral nutrition if the cat is also vomiting**.

Corticosteroids (0.5–1.0 mg/kg PO q 12 h) are **indicated if stricture formation is expected** to occur, but **will not help in cases where a stricture has already occurred** and may reduce healing in severe cases, so must be used with **caution**.

Prophylactic antibiotics that are effective against pathogens present in the oral mucosa are **only indicated** (amoxicillin, clavamox, cephalexin, clindamycin) in **severe esophagitis cases** where mucosal damage is so severe that normal mucosal defenses are compromised.

Reduction of gastric acidity with histamine-2 blockers (famotidine 0.5–1.0 mg/kg PO q 24 h) or protein pump inhibitors (omeprazole 1 mg/kg PO q 24 h) is also indicated, especially if gastroesophageal reflux disease is suspected.

Mucosal cytoprotectants, such as sucralfate (250–500 mg PO q 8–12 h made into a slurry) have also been recommended to reduce further mucosal injury, however their effectiveness is questioned.

Drugs that **increase lower esophageal sphincter tone**, metoclopramide (0.1–0.2 mg/kg PO q 12 h) and cisapride (5 mg/kg PO q 12 h), are **indicated when acid reflux is suspected** and may be required long-term to prevent disease recurrence in cats with this disease.

In all cases, the **treatment should be continued for at least 2–3 weeks beyond the resolution** of clinical signs to prevent recurrence and allow complete healing of the tissue.

Prognosis

The prognosis is **good in cats with mild esophagitis or when severe esophagitis is managed aggressively** and does not result in stricture formation.

In cases of esophagitis that develop **strictures**, the prognosis is **guarded to fair**. See section on stricture management for details.

ESOPHAGEAL FOREIGN BODY**

Classical signs

- Acute onset of regurgitation is the most common sign.
- Gagging or retching are also observed, especially when the object is in the cranial esophagus.
- Rarely, acute respiratory distress may also occur.

Pathogenesis

Esophageal foreign bodies are relatively common in cats because of their curious nature, propensity to chew on or ingest string or like objects, and their consumption of hair (or bones) from prey or grooming.

String foreign bodies will usually pass through the GI tract if they are not anchored.

Common reasons for string foreign bodies to become anchored include, attachment around the **base of the tongue** or if the string is attached to a needle that becomes lodged in the wall of the esophagus or GI tract.

The greatest dangers from esophageal foreign bodies are perforation and esophagitis.

Esophageal perforation is a life-threatening condition because it **leads to fulminant (tension) pneumothorax and pneumomediastinum**. **Extremely small perforations** (needle punctures) may not result in tension pneumothorax but instead cause **mediastinitis and pleuritis or even fistula formation**.

Esophagitis is important because it **can lead to esophageal stricture if the inflammatory response is severe or chronic**.

Clinical signs

An **acute onset of regurgitation or anorexia are the most common presenting signs**, and these may be associated with **hypersalivation, gagging, retching or anxiety**.

If the foreign body causes an **esophageal perforation**, the cat may present in **extreme respiratory distress**.

The severity of the signs observed often relate to what the object is (e.g. string, hair, bones, needles, wire), whether the object is causing a **partial or complete obstruction**, and the **duration** that it has been present (e.g. presence of esophagitis, stricture, etc.).

Diagnosis

The **acute onset of hypersalivation and regurgitation is often suggestive of an esophageal foreign body**, and the diagnosis is frequently confirmed by visualizing string entrapped around the base of the tongue.

Survey radiographs will often reveal a radio-opaque foreign object.

Endoscopy may be required in some cases **to identify small or radiolucent objects**, and is very useful in retrieving some objects.

In some cases, **contrast radiographs may be required to identify radiolucent objects or fistula**.

Because of the **acute onset of clinical signs** in cats with esophageal foreign bodies, **a routine database is usually completely normal**.

Cats that develop a **small esophageal perforation** may have an **inflammatory leukogram**.

Differential diagnosis

Primary differentials include ingestion of a caustic, irritating or noxious substance that causes acute esophagitis.

Oral ulceration is usually present **following ingestion of caustic or irritating substances**.

Other causes of regurgitation are typically associated with **clinical signs of a chronic nature** (esophageal hypomotility, gastroesophageal reflux esophagitis, neoplasia) and thus are less likely.

Treatment

The initial goal is the **immediate removal of the foreign object** from the esophagus. This must be **done carefully to minimize further esophageal damage and complications** (e.g. vagal tone induced bradyarrhythmias, further mucosal trauma or development of a perforation).

Endoscopic retrieval should be attempted first because of the difficulties associated with esophageal surgery, **unless there is radiographic evidence of a perforation**.

Use of both a rigid proctoscope and a flexible endoscope has been very successful. The flexible scope is used to manipulate the object free with grasping tools, and the proctoscope to protect the esophagus from further damage as the object is moved orad.

If the object cannot be safely removed in an oral direction, but can be propelled into the stomach, this is the next best option. The object may be allowed to pass (bony material) through the GI tract on its own or can be removed by gastrostomy.

Thoracotomy to remove an esophageal foreign body is only used as a last resort, when all other efforts have failed, **or when an esophageal perforation is eminent or has occurred**.

Following removal of the object by endoscopy, **close inspection of the esophagus to determine the extent of injury is important**.

If there is severe esophagitis or a small perforation (needle), medical management of these conditions should include **placement of a nasogastric or gastrostomy tube** for feeding and **medical management of esophagitis** (gastric acid blockers, motility modifiers, mucosal protectants, and possibly antibiotics will be required). Therapy should be continued for **2–3 weeks beyond cessation of clinical signs**.

Prognosis and prevention

Prevention is clearly aimed at **reducing the opportunity for cats to ingest these objects** by “cat-proofing” the home and preventing prey-catching and consumption. However, it is impossible to foresee all possible problems, so **early recognition is also important** to a successful outcome.

The prognosis is good to excellent if the object can be immediately retrieved and the damage to the esophagus is minimal.

In cases of a **chronic esophageal foreign body**, presence of **severe esophagitis, perforation or great difficulty in removing the object**, the prognosis is **guarded to poor**.

Cats that develop **esophageal strictures** resulting from **severe esophagitis** may require **repeated bougienage** to allow passage of ingesta.

Cats requiring thoracotomy and esophageal surgery to remove a foreign object will have a **very guarded prognosis** to survive the procedure, let alone return to normal function.

ESOPHAGEAL STRICTURE*

Classical signs

- Regurgitation is most common sign.
- Vomiting, anorexia, weight loss and lethargy.

Pathogenesis

Esophageal strictures are a complication of severe esophagitis, and are most commonly associated with **gastroesophageal reflux esophagitis** which occurs most commonly as a **complication of persistent vomiting** or can occur as a result of **reflux during general anesthesia**. There is usually a lag of 2–3 weeks between anesthesia and stricture formation.

Less frequent causes of esophageal strictures are reflux esophagitis as a result of **gastroesophageal reflux or hiatal hernia**.

Strictures form when the esophageal mucosa is severely damaged and the **inflammatory process extends down into the submucosa and muscular layers**.

Clinical signs

Regurgitation following eating is the most common presenting complaint. Liquid may be able to pass depending on the severity of the strictured area.

If the stricture is caused by **severe esophagitis secondary to chronic vomiting**, other signs may include **weight loss, lethargy and anorexia**.

Diagnosis

The diagnosis may be suspected on **survey radiography**, but can be **confirmed with contrast films or endoscopy**.

Endoscopy should be used to **evaluate esophageal strictures** and to obtain **biopsies to rule out esophageal neoplasia**, if indicated.

Routine blood work will typically be normal, unless the cat is also chronically vomiting, or the regurgitation has been present long enough to affect serum protein levels or hydration status.

Differential diagnosis

All causes of regurgitation should be considered in the initial approach, but the finding of a **narrowed lumen on contrast radiographs** narrows the primary differentials to **neoplasia, peri-esophageal masses, foreign bodies and stricture**.

Treatment

Esophageal strictures can be corrected one of two ways: by **balloon or bougie dilation or surgical removal**.

Every effort to correct the problem by stretching the strictured area with balloon catheterization or bougienage should be made, because of the difficulty of the surgical procedure and the numerous complications associated with it.

In most cases, **multiple dilation procedures are required** to slowly stretch out the stricture site to an approximately normal size.

Balloon catheters dilate the stricture site with radial forces and can be used endoscopically or fluoroscopically, thus providing better visualization of the site and better control over the force exerted.

Bougies dilate with longitudinal shearing and may require multiple procedures. Bougies are associated with a greater risk of tearing or perforation and thus balloon dilation is preferred.

Corticosteroid therapy (1.0–2.0 mg/kg/day) to prevent further fibrosis has been recommended but is controversial and **has not been proven effective in this regard**.

In many cases of stricture, the inciting cause is long resolved, but if **esophagitis is ongoing due to gastric reflux, this should be managed as well** (see section under esophagitis).

Prognosis

The prognosis is **guarded** for cats with esophageal strictures. Many cats can be helped temporarily with dilation procedures, but the stricture recurs or requires repeated procedures to maintain an open esophageal passageway.

LEAD POISONING*

Classical signs

- Inappetence, weight loss.
- Behavior changes (irritable, aggressive).
- Regurgitation secondary to megaesophagus is rare.
- Vomiting or diarrhea.
- Seizures or other central nervous system signs.

See main reference on page 596 for details.

Clinical signs

Early clinical signs include gastrointestinal tract signs such as **inappetence, salivation, vomiting and weight loss**.

Other **less common signs** of lead toxicity include **diarrhea**, and abnormalities of the hemogram are less common in cats than dogs (basophilic stippling, nucleated RBCs).

In the **late stages**, other **central nervous system signs** such as ataxia and seizures may occur.

Regurgitation secondary to megaesophagus is **very rare** in cats.

Diagnosis

Serum blood lead levels are the definitive means of diagnosis of lead poisoning.

The diagnosis is helped by a **history of exposure** to lead-containing paints usually associated with home renovation or other objects such as batteries.

Signs of **inappetence, weight loss and behavioral changes** should prompt consideration of lead poisoning as a differential.

Hematologic findings are often absent.

Survey radiographs in cats that have a history of regurgitation will reveal **esophageal dilation or megaesophagus**, and in long-standing cases, may reveal **aspiration pneumonia** as well.

ESOPHAGEAL NEOPLASIA* (SQUAMOUS CELL CARCINOMA, METASTATIC NEOPLASIA)

Classical signs

- Regurgitation secondary to obstruction, esophagitis or motility disturbances.
- Weight loss, inappetence and respiratory signs are also common.

Clinical signs

Esophageal neoplasia creates an **obstructive lesion** that is associated with regurgitation, **especially after ingestion of food**, and is typically seen in **older cats**.

Other signs may include **weight loss, anorexia and respiratory signs** if aspiration pneumonia occurs.

The most common neoplasm is squamous cell carcinoma, although esophageal tumors in general are rare in cats, and the tumor will metastasize early to regional lymph nodes and lung.

Diagnosis

The presence of **regurgitation as the predominant clinical sign** will lead the clinician to suspect esophageal disease.

Because many of these cats are older, a variety of hematological and biochemical abnormalities may be present, but **there are no typical changes associated with esophageal disease on the blood work**.

The diagnosis may be suggested by finding an **intraluminal or mass lesion obstructing the esophageal lumen on contrast radiography**.

Endoscopic evaluation and biopsy are the least invasive and most efficient means of obtaining a definitive diagnosis of esophageal neoplasia, although **surgical approaches** will also give diagnostic information as well.

Surgical resection of most esophageal neoplasms is difficult if not impossible due to the fact that most tumors are well advanced at the time of diagnosis. **Surgical excision of thymomas is often rewarding** as the mass is usually **benign and discrete**.

PLANT INGESTION*

Classical signs

- Intermittent or persistent regurgitation or vomiting of plant material.

See main reference on page 646 for details.

Clinical signs

Regurgitation or vomiting after ingestion of **plants containing materials that are irritating, caustic or abrasive**.

Signs may be intermittent or chronic in nature depending on the availability of the plants.

Other signs include **dysphagia, gagging or repeated swallowing efforts**.

Diagnosis

Plants that are associated with esophageal or gastric irritation include: Poinsettia (*Euphorbia* spp.), Mistletoe (*Phoradendron* spp.), Aloe vera, Crown of Thorns (*Euphorbia* spp.), Snow on the Mountain (*Euphorbia* spp.), Azalea (*Rhododendron*), Castor bean (*Ricinus* spp), Rosary pea (*Abrus*), English ivy (*Hedera*), Daphne (*Daphne*), Christmas rose (*Helleborus*), Holly (*Ilex*), Privet (*Ligustrum*), Iris (*Iris*), Narcissus (*Narcissus*), Philodendron (*Philodendron*), Wisteria (*Wisteria*).

Diagnosis is based upon historical exposure or evidence of exposure in the regurgitated material.

In some cats, **endoscopy should be performed to rule out esophagitis due to other causes and determine the extent of the lesions**.

Differential diagnosis

Other causes of esophagitis, especially gastroesophageal reflux disease and other causes of chronic vomiting should be considered.

Treatment

Most cases are not associated with severe esophagitis that requires alternative alimentation routes or aggressive medical therapy.

Reduction of hyperacidity with histamine-2 blockers (famotidine 0.5–1.0 mg/kg PO q 24 h), administration of **anti-emetics** (primarily for the prokinetic action of metoclopramide) as needed and feeding a **bland diet** is all that will be required in most cats.

In cats with severe esophagitis, more aggressive therapy will be required to prevent formation of strictures or fistula. See section on esophagitis.

ESOPHAGEAL HYPOMOTILITY/IDIOPATHIC MEGAESOPHAGUS (ACQUIRED OR CONGENITAL)*

Classical signs

- Regurgitation, often not associated directly with eating.
- Cats may develop aspiration pneumonia resulting in: respiratory distress, coughing, wheezing, lethargy, anorexia.

Pathogenesis

Esophageal hypomotility disorders may be **idiopathic** in origin or occur secondary to a known disease entity (**acquired or secondary megaesophagus**).

Idiopathic megaesophagus appears to be caused by a **defect in peristalsis** due to abnormal neural signal pathways and increasing evidence suggests that the disease is inherited (Siamese cats have the greatest prevalence).

The secondary causes of megaesophagus are numerous and include:

- **Neuromuscular disorders** (dysautonomia, myasthenia gravis, polymyopathies and polyneuropathies, e.g. tetanus may cause regurgitation secondary to hiatal hernia).
- **Inflammatory disorders** (e.g. esophagitis).
- **Obstructive disorders** (foreign objects, peri- or intra-esophageal masses, ring structures, hiatal hernia).
- **Stomach or pyloric dysfunction** resulting in chronic regurgitation or reflux.
- **Toxicity** (e.g. lead).

The secondary causes of megaesophagus that have major importance clinically are **discussed separately** in this chapter.

Diagnosis

The history and signalment of chronic regurgitation will be suggestive of esophageal disease.

Survey radiographs are usually all that is required to confirm the presence of megaesophagus. Survey radiographs also are important in determining the presence of **aspiration pneumonia**, the most common complication of megaesophagus.

Cats with aspiration pneumonia may have **hematologic or biochemical profile abnormalities**, but these will be **non-specific**.

- **Contrast radiographs are rarely indicated but will confirm the diagnosis** in cases with minimal dilation.

Other diagnostics are used to determine if the disease is congenital, acquired or idiopathic.

- **Fluoroscopy** (to evaluate motility).
- **Endoscopy** (for esophagitis or obstructive disorders).
- **Neuromuscular examination** (muscle or nerve biopsies, electrodiagnostics, e.g. EMG, nerve conduction testing).
- Measurement of **antibodies to acetylcholine receptors** (myasthenia gravis).
- **Blood lead levels.**
- Creatine kinase measurement is of little value as the polymyopathies in cats that cause megaesophagus, i.e. Devon Rex myopathy and myasthenia, are not associated with increased creatine kinase levels.
- **Testing of endocrine and autonomic** (e.g. dysautonomia) **function.**

Idiopathic megaesophagus is a diagnosis made by exclusion of all other possible causes.

Differential diagnosis

There are numerous differentials for regurgitation (esophageal hypomotility, inflammatory, obstructive, neoplastic, toxic or chemical irritants, or due to gastro-esophageal reflux), but once megaesophagus is found on survey radiographs, the list of differentials is reduced to the idiopathic, congenital or acquired forms of megaesophagus.

Treatment

Treatment of esophageal hypomotility disorders in cats is **symptomatic, unless a reversible cause** for the megaesophagus **is identified and corrected** before the esophagus is permanently damaged.

Other **supportive measures** include managing dehydration with **fluid therapy** as needed, **elevated feeding of multiple, small, liquid meals** (note: although **some cats will respond better to foods that are solid or semi-solid**) to facilitate gravitation of food into the stomach, and **management of aspiration pneumonia**

if it occurs (bronchodilators, antibiotics if needed, oxygen supplementation, and coupage).

If oral feeding is unsuccessful, despite trying different food types and consistencies, **gastrostomy tube feeding** may be required for long-term management. Nasogastric and esophagostomy tubes are generally not good long-term options for feeding management.

Prognosis

The **prognosis depends upon several factors but especially upon the cause**. If an underlying disorder can be identified and corrected (e.g. dilation due to PRAA), the prognosis may be favorable.

Idiopathic megaesophagus and megaesophagus due to neuromuscular function disorders (dysautonomia or myasthenia gravis) is **guarded to poor**.

MYASTHENIA GRAVIS* (CONGENITAL OR ACQUIRED)

Classical signs

- Regurgitation due to megaesophagus, and generalized muscle weakness.
- Dysphonia and cervical ventroflexion are more common in cats.

See main reference on page 896 for details.

Clinical signs

Regurgitation is reported due to megaesophagus. **Generalized muscle weakness** is seen in the generalized and acute fulminating forms of the condition, but not in focal myasthenia.

Dysphonia and cervical ventroflexion are more common in cats than in dogs.

Congenital myasthenia is more common in **Siamese and DSH cats**, while **acquired myasthenia** appears to be more common in **Somalis and Abyssinians** and occurs in slightly older kittens (4–6 months).

Acquired myasthenia has a **bimodal age distribution**, with most affected cats being young adults (2–3 years) or older (9–10 years).

Diagnosis

The definitive diagnosis is made by the demonstration of **antibodies (Ab) to the acetylcholine receptor (AChR), either in serum or neuromuscular junction biopsies**.

The **EMG** in cats with myasthenia will show the **classic decremental response** (each successive spike will have a lower magnitude, corresponding to the fatigue of the muscle).

Acquired myasthenia gravis is believed to be an **immunologic disease resulting in the destruction of AChR by immunoglobulin produced against the receptor**, but **thymoma** and other diseases are also seen in conjunction with acquired myasthenia.

Congenital myasthenia is due to **lack of AChR**, rather than immune-mediated destruction of receptors. This form of myasthenia is **rare in cats**.

An **intravenous edrophonium chloride test** may be performed on cats with generalized muscle weakness. This short-acting cholinesterase-inhibiting drug results in alleviation of weakness in about half of affected cats.

Muscle biopsy may show histopathologic signs of myositis.

Differential diagnosis

Other causes of megaesophagus, including idiopathic ME, PRAA, chronic esophagitis, metabolic or toxic causes.

Treatment

Supportive care for acquired myasthenia and associated megaesophagus includes:

Elevated feedings.

Tube (NG, gastrostomy) feeding.

Management of aspiration pneumonia as required with antibiotics and bronchodilators.

Immunosuppressive therapy (prednisolone 2–6 mg/kg/day or azathioprine).

Acetylcholinesterase antagonists (pyridostigmine bromide 0.2–2.0 mg/kg q 8–12 h PO).

If available, **plasmapheresis** may be used in some cats with acquired megaesophagus.

Thymectomy is indicated in cats with a thymoma and associated megaesophagus.

Congenital myasthenia does not respond well to immunosuppressive therapy and thus supportive care is essential.

Some cats with severe megaesophagus succumb to aspiration pneumonia.

VASCULAR RING ANOMALIES (PERSISTENT RIGHT AORTIC ARCH – PRAA)

Classical signs

- Regurgitation when kitten is weaned onto solid foods.

Pathogenesis

The vascular ring anomalies are **congenital malformations of the aortic arches** which result in a ring around the esophagus that results in an esophageal obstruction.

In cats, a **persistent right aortic arch is the most common anomaly** causing esophageal obstruction and regurgitation.

Other rare, but reported anomalies include the double aortic arch and the left aortic arch with right ligamentum arteriosum.

The obstruction of the esophagus with persistent right aortic arch anomaly is created because the esophagus is trapped by the aorta on the right, the heart base ventrally, and the ligamentum arteriosum dorsolaterally on the left.

Clinical signs

The classical sign associated with a vascular ring anomaly is the **acute onset of regurgitation in a kitten** that has just been **weaned onto solid food**.

In most kittens, regurgitation will occur immediately after eating, but later in the course of the disease, as the esophagus becomes more dilated and non-functional, **regurgitation may occur at any time** with no relationship to food intake.

Other signs include respiratory distress, coughing or lethargy associated with aspiration pneumonia that occurs secondary to regurgitation.

Diagnosis

A presumptive diagnosis is often made based on the history and signalment, however, **survey radiographs** followed by introduction of **contrast media** are required to make the definitive diagnosis and **differentiate megaesophagus due to a vascular ring structure** from other causes.

Routine hematology and serum biochemistry values will be normal unless the kitten has developed an aspiration pneumonia or secondary bacterial pneumonia as sequelae to the anomaly.

Echocardiography can be used to determine which type of vascular ring structure is involved, but is not necessary to make the diagnosis.

Differential diagnosis

The primary differential for this disease is congenital megaesophagus, but the presence of the **constricted area at the base of the heart**, along with onset of signs at the time that the kitten begins to consume solid food will help differentiate the two diseases.

Other causes of regurgitation will be readily ruled out by the survey radiographs.

Treatment

The only treatment is surgical removal of the constricting band to release the entrapped esophagus.

In kittens with long-standing esophageal dilatation due to the vascular ring, **esophageal hypomotility cranial to the stricture may be permanent** and require life-long management (see Management of megaesophagus).

Treatment of aspiration pneumonia is supportive: oxygen supplementation, fluids, antibiotics if a bacterial component is present, and respiratory therapy (bronchodilators, expectorants, coughage) as needed.

Prognosis

The prognosis is **guarded to good**. If esophageal function returns after the removal of the constricting band, the prognosis is very good, but in those kittens with residual esophageal dilatation and hypomotility, the long-term prognosis is guarded to poor.

ESOPHAGEAL DIVERTICULAR STRUCTURES

Classical signs

- Regurgitation, pain when swallowing, lethargy, and decreased appetite.

Pathogenesis

Esophageal diverticula are **sac-like dilations of the esophageal wall** that can be **congenital or acquired**.

Acquired diverticula are secondary to one of two scenarios:

Trauma or an obstruction (e.g. foreign body) that causes **increased intraluminal pressure** resulting in a dilation or diverticulum developing **cranial to the injury site**.

Esophageal fibrosis secondary to an inflammatory process (either in the esophagus or in the surrounding tissues) that causes a **contraction of esophageal tissue** and the formation of a diverticular sac.

Congenital diverticula are rare in cats.

Clinical signs

Clinical signs are usually **only observed with a large diverticula**.

Signs that may occur include:

- **Regurgitation.**
- **Inappetence and weight loss.**
- **Pain when swallowing** or thoracic pain.
- Respiratory signs.
- Fever.

Respiratory signs can be secondary to aspiration pneumonia or can be associated with an **inflammatory process in the lungs that is the cause of esophageal fibrosis** and diverticulum formation.

Diagnosis

There is no classic history or signalment that will lead to a presumptive diagnosis, however, **the signs will be suggestive of esophageal disease** in most cases.

Hematologic and serum biochemical profiles are typically **normal**.

Survey radiographs may be suggestive if there is a large diverticulum, but in most cases **contrast studies are necessary to confirm the presence of the sac-like structure**.

Endoscopic examination of the esophagus is also diagnostic and also may provide information about the cause or any associated complications. In cats that have **very small diverticula**, **endoscopy will be a more helpful diagnostic procedure than contrast radiographs** which could miss the lesion.

Differential diagnosis

Any cause of regurgitation should initially be considered a differential. But blood work and radiographs (survey and contrast) will help to rule out some of the more common causes of regurgitation, which include megaesophagus, esophageal foreign bodies, esophageal masses and peri-esophageal masses.

Endoscopic examination will be required to rule out esophagitis and other inflammatory causes of regurgitation.

Treatment

Diverticula should be managed as conservatively as possible, due to the difficulties and complications associated with esophageal surgery.

If an **underlying cause can be identified and corrected**, this greatly improves the chances for treatment success.

Conservative management of diverticula includes **preventing food accumulation in the sac**, either by **elevated feedings of gruel or liquid diets or by placement of a gastromy tube to by-pass the esophagus**.

If the conservative management fails, either due to the cause or size of the diverticulum, **surgical excision and reconstruction are options**, but **esophageal dysfunction and stricture are common sequelae to surgery**.

Prognosis

The prognosis for cats with an esophageal diverticulum depends on its cause and size.

In cats that have a small diverticulum for which the cause has been identified and removed, the prognosis is guarded to good.

If the diverticulum is large, the cause is uncorrectable, or there is no response to conservative management, the prognosis is poor.

HIATAL HERNIA/GASTROESOPHAGEAL INTUSSUSCEPTION

Classical signs

- Intermittent or persistent regurgitation or vomiting.

Pathogenesis

Hiatal hernia is the protrusion of any abdominal contents through the esophageal hiatus of the diaphragm into the thorax. With gastroesophageal intussusception, the stomach is prolapsed into the lumen of the distal esophagus.

Hiatal hernia is an uncommon problem in cats, but occurs due to enlargement of the hiatal membrane (may occur from trauma) or as a result of laxity in the phrenoesophageal membrane. Hiatal hernias have been reported in association with generalized tetanus.

Cats more commonly have sliding hiatal hernias, with cranial displacement of the abdominal esophagus and part of the stomach through the esophageal hiatus.

Gastroesophageal intussusception can cause both esophagitis and esophageal obstruction.

Clinical signs

Intermittent or persistent regurgitation or vomiting are the most common signs.

Some cats may show abdominal pain on palpation of the anterior abdomen.

Respiratory distress may be seen with large hiatal hernias or gastroesophageal intussusceptions.

Diagnosis

Survey radiographs of the thorax may reveal a soft tissue density and gas in the region of the caudal dorsal mediastinum, but contrast radiography will confirm the presence of the hernia (unless it is a sliding hernia that is in the normal position at the time of radiographs) or intussusception.

In some cases fluoroscopy will assist in identifying a sliding hernia.

Differential diagnosis

Diagnosis may be difficult if the hernia is sliding or the intussusception is intermittent and the signs are intermittent in nature. All the major esophageal disorders (esophagitis, hypomotility, stricture, etc) should be considered and ruled out by appropriate testing.

Treatment

If the cat is symptomatic, treatment is as for reflux esophagitis (histamine-2 blockers, metoclopramide and sucralfate as needed).

In cats with persistent clinical signs that do not improve with conservative medical therapy, surgical intervention is indicated.

Prognosis

Fair to good, especially since cats with hiatal hernias or gastroesophageal intussusceptions tend to have intermittent clinical signs.

ESOPHAGEAL FISTULA

Classical signs

- Regurgitation or dysphagia occurring in conjunction with coughing or respiratory distress.

Pathogenesis

Fistula development is the result of esophageal ischemia and necrosis that ultimately leads to a small perforation. The process of healing leads to develop-

ment of a **fibrous tract** and a **communication developments** between the esophagus and the respiratory system.

The most common pathway in cats is between the left caudal lung lobe or the accessory lung lobe and the esophagus.

The **most common cause** of fistula development is an **esophageal foreign body** that penetrates (e.g. needle) but other causes include **diverticular structures** and **neoplasia**.

Clinical signs

Signs are referable to **both the esophagus and lower respiratory tract**.

Signs of esophageal disease include **regurgitation, painful swallowing or repeated swallowing attempts**.

The majority of signs are **respiratory, and include dyspnea, coughing, tachypnea, anorexia, fever and weight loss**, associated with the accumulation of esophageal contents in the affected lung lobe.

The smaller the fistula, the fewer the clinical signs and the more difficult it is to diagnose.

Diagnosis

A large fistula may be visualized on survey radiographs, as well as the **pulmonary changes associated with pneumonia** (increased alveolar and interstitial pattern).

In cats with a very small fistula, contrast radiographs may be required to identify the structure. In some cases, these may be so small that endoscopy is not a means of definitive diagnosis either.

Endoscopic examination should be performed to **obtain biopsies to determine if the lesion is neoplastic** or not.

If there is significant pulmonary disease, the cat may have an **inflammatory leukogram**.

Differential diagnosis

Diverticular structures, esophageal strictures, radiolucent esophageal foreign objects, and aspiration pneumonia secondary to esophageal hypomotility, should all be considered when a differential list is being formulated.

Treatment

The only treatment is surgical closure of the fistula and correction of the underlying cause if it is still present (e.g. diverticulum, neoplasia).

In some cats, **lobectomy** may be necessary as well.

Symptomatic therapy for the pneumonia and esophageal disease includes: esophageal rest (nasogastric or gastrostomy tube), **antibiotic and bronchodilator therapy** as needed, and drugs to control esophagitis if it is present (e.g. ranitidine, metoclopramide, sucralfate, etc).

Prognosis

Guarded. Any esophageal disease that requires surgical correction must be regarded as having a guarded prognosis because of the high rate of complications that occur following surgery (e.g. stricture).

Prevention

Rapid identification and correction (removal) of esophageal foreign bodies, diverticular structures or neoplasia (if possible).

HEREDITARY MYOPATHY OF DEVON REX CATS

Classical signs

- Young Devon Rex cats.
- Appendicular weakness and fatigability.
- Passive ventroflexion of the head and neck.
- Dorsal protrusion of the scapulae.
- Megaesophagus is common, and choking and laryngospasm may occur when eating.

See main reference on page 900 (The Cat With Neck Ventroflexion) for details.

Pathogenesis

The disease is inherited in an **autosomal recessive** fashion. The pathological defect causing the **muscle weakness** has **not been determined**.

Clinical signs

Affected cats have **ventroflexion of the head and neck** because weakness of the dorsal cervical muscles leads to an inability to support the head. Ventroflexion is **accentuated during locomotion, micturition and defecation**.

A **high-stepping forelimb gait, head bobbing and progressive dorsal protrusion of the scapulae** may also be seen, particularly following exertion, stress or excitement.

Cats often have problems **prehending and swallowing food**, partly because of their abnormal head position and partly because of oropharyngeal weakness.

Acute upper airway obstruction may develop due to accumulation of ingesta in the vicinity of the larynx, and this may lead to fatal laryngospasm.

Diagnosis

Diagnosis is made on a combination of **history, breed and clinical signs**.

Routine bloodwork including serum K⁺, creatine kinase and aspartate transaminase shows **no abnormalities**.

Muscle tone, and spinal reflexes are all within normal limits.

Sparse fibrillation potentials and positive sharp waves are present on EMG.

Muscle biopsy reveals highly variable muscle fiber sizes, with increased numbers of nuclei, internal nucleation and split or degenerating fibers.

Survey or contrast radiographs may reveal megaesophagus with a U-shaped diverticulum at the thoracic inlet.

Differential diagnosis

Other myopathies such as X-linked muscular dystrophy, nemaline myopathy and hypokalaemic polymyopathy should be considered, as well as **myasthenia gravis**.

Treatment

Symptomatic treatment for reflux esophagitis may be given, including histamine-2 blockers (famotidine

0.5–1.0 mg/kg PO q 24 h), drugs that increase esophageal sphincter tone (cisapride 5 mg/kg PO q 12 h), and mucosal cytoprotectants (sucralfate 250–500 mg PO q 8–12 h).

Other supportive measures include elevated feeding of small, liquid meals, or even gastrostomy tube feeding.

Prognosis

Guarded to poor. Most of these cats suffer from chronic reflux esophagitis with megaesophagus and many die suddenly of laryngospasm after choking on food.

Prevention

Because the condition is associated with an autosomal recessive gene, the **parents of any affected kittens should no longer be used for breeding**.

DYSAUTONOMIA

Classical signs

- Regurgitation secondary to megaesophagus.
- Constipation.
- Mydriasis.
- Dry mucous membranes of mouth and eye.

See main reference on page 792 for details.

Pathogenesis

Generalized degeneration of the autonomic ganglia results in loss of GI tract motility, and loss of autonomic control to the eye and heart.

Clinical signs

Clinical signs usually develop over **48 hours** and **depression and anorexia** are present in nearly all cats.

Regurgitation occurs secondary to megaesophagus. Vomiting often occurs and regurgitation may be reported as vomiting.

Constipation is commonly reported.

Mydriasis is present with **normal vision** and third eyelids are commonly prolapsed.

Keratoconjunctivitis sicca and **dry oral mucous membranes** may be present.

Other signs include **bradycardia** (60–120 bpm) and **hypotension**

Anal areflexia has been reported.

Dysuria in association with a distended urinary bladder also occurs.

The disease is **rare in the US** (some regional areas especially in the central mid-west have more cases) but was more common in Europe in the 1980s.

It is usually seen in **young (< 3 years) cats**.

Diagnosis

The constellation of clinical signs is suggestive of **autonomic nervous system dysfunction**.

There is **no definitive diagnostic test for dysautonomia**, but the following tests of autonomic function are supportive:

- Intraocular **physostigmine** fails to provoke a response, but **pilocarpine** causes immediate miosis.
- Intradermal skin testing – There is no response to histamine (no wheal or flare).
- **Epinephrine should not be given to cats with dysautonomia because fatal arrhythmias may develop.**
- **Cats will respond to atropine** (increased heart rate), which proves that the **post-ganglionic receptors are still able to appropriately respond to stimulus.**

EATING TOO FAST (FOOD GULPING)

Classical signs

- Intermittent regurgitation of food immediately after ingestion, often in tubular form.

Clinical signs

Intermittent regurgitation of whole food, often in tubular form, immediately after it is consumed.

There are **no other abnormal clinical findings** other than the cat appears to gulp or swallow its food without chewing it.

Diagnosis

All clinical, biochemical, radiographic and endoscopic studies (if performed) **will be normal.**

This is a **diagnosis of clinical presumption** based on history, physical exam and the ability to control the signs by feeding smaller meals more frequently or reducing the competition for food that may create food gulping.

Differential diagnosis

Hiatal hernia, mild gastroesophageal reflux, mild esophageal hypomotility or lower esophageal sphincter disease.

Food intolerance and food allergy may cause vomiting very soon after eating which could be mistaken for regurgitation.

Treatment

Feed the cat **smaller meals more frequently** or change feeding location or time to **reduce competition for food** or the tendency to eat rapidly.

MEDIASTINAL NEOPLASIA

Classical signs

- Anorexia.
- Regurgitation.
- Other systemic signs if paraneoplastic disease occurs.
- Thymic lymphoma/thymoma is a mostly benign anterior mediastinal mass, usually found in older cats. Most affected cats are **FelV negative** and the tumor may be associated with **paraneoplastic syndromes**, such as myasthenia gravis, polymyositis, myocarditis or dermatitis.

See main reference on page 56 for details.

30. The cat with signs of acute vomiting

Debra L Zoran

KEY SIGNS

- Active elimination of stomach contents through the mouth.
- \pm Preceded by nausea, pacing, and salivation.
- Usually digested food or liquid with acidic or neutral pH.
- \pm 1 week's duration.

MECHANISM?

- Vomiting is an active process that must be distinguished from regurgitation.
- Vomiting in cats is associated with abdominal muscle contraction, and signs of considerable muscular effort and anxiety prior to the event.
- Vomit may consist of undigested food material (if swallowed whole), partly digested or even liquid, and may be clear, yellow (bile stained) or brown (food colored).

WHERE?

- Vomiting may result from gastrointestinal disease or extra-intestinal tract diseases.
- Vomiting is rarely associated with colonic disease, except when toxins associated with fecal retention affect the vomiting center and chemoreceptor trigger zone.

WHAT?

- The most common causes of acute vomiting are:
- Mechanical obstructions (including foreign bodies).
- Extra-intestinal tract diseases such as hepatitis.
- Renal failure or pancreatitis, dietary (indiscretion).
- Inflammatory diseases (e.g. IBD).

QUICK REFERENCE SUMMARY

Diseases causing signs of acute vomiting

DEGENERATIVE

- Dysautonomia (p 661)
Dysfunction of the autonomic nervous system resulting in dilated pupils, dry mucous membranes, regurgitation, vomiting, constipation, bradycardia and dysuria.

MECHANICAL

- **Gastrointestinal foreign bodies (obstruction)** (p 636)**

Acute onset of vomiting that may be projectile if the obstruction is at the pylorus. Vomiting may be intermittent if object is not causing a complete obstruction. Linear foreign bodies (e.g. string) may be evident wrapped around the base of the tongue.

- **Intussusception* (p 643)**

Acute onset of vomiting, anorexia and lethargy and occurs more often in kittens. The obstruction may be palpated in some cats.

- **Motility disturbances (ileus, gastroesophageal reflux)* (p 647)**

Vomiting is not associated with eating and usually is bile stained due to presence of duodenal content.

- **Antral pyloric hypertrophy/stenosis (p 660)**

Vomiting of partially or completely digested food usually several hours after eating, and may be projectile in nature. Siamese cats may be predisposed. Vomiting may appear to be acute in onset in the congenital form, as the vomiting occurs when the kitten begins to eat solid food.

METABOLIC

- **Hepatopathies (hepatic lipidosis, cholangitis, drug-induced hepatopathy)** (p 638)**

Anorexia, lethargy and vomiting are persistent. Cat may or may not be icteric.

- **Diabetes mellitus* (p 643)**

Acute onset of vomiting, lethargy, anorexia associated with uncontrolled diabetes mellitus. Cats are usually older, in poor body condition and may be severely dehydrated or in shock if owner does not recognize the condition until late.

- **Acute renal failure/pyelonephritis* (p 645)**

Acute renal failure is associated with an acute onset of vomiting and depression (may be primary, e.g. ischemic, hypovolemic, or secondary, e.g. post renal obstruction). Other signs include tachypnea, oliguria or anuria, hypothermia. Pyelonephritis causes intermittent vomiting, pain over the sublumbar region, decreased appetite, occasionally fever and polyuria.

- **Hypercalcemia (p 652)**

There are many causes of hypercalcemia, but the clinical signs most commonly seen are anorexia, vomiting, weight loss and lethargy or weakness.

NEOPLASTIC

- **Gastric or small intestinal neoplasia* (p 641)**

The most common tumor of the feline digestive system is alimentary lymphoma. Other tumors that occur in the stomach and small intestine are adenocarcinomas (second), and mast cell tumors (third), with fibrosarcomas, leiomyosarcomas and carcinoids occurring rarely. The primary site of gastric tumors is the pylorus. With the exception of lymphoma, which can occur at any age, most tumors occur in old cats. The clinical signs most often observed are anorexia, weight loss and vomiting, which may occur as acute vomiting when the tumor causes a GI obstruction.

continued

continued

NUTRITIONAL

- **Food intolerance or dietary indiscretion** (p 635)**

Indiscretion is associated with an acute vomiting due to over-eating, eating too quickly or ingesting a foreign substance (food or non-food), e.g. lizards, beetles, plants. Food intolerance causes intermittent vomiting or loose stools, with no pattern or association with eating, and resolves when food source is changed to omit offending substance from diet.

INFLAMMATORY

- **Acute pancreatitis** (p 639)**

Anorexia and lethargy are the most common signs, with abdominal pain and vomiting being observed much less frequently.

- **Gastritis/gastric ulcer disease** (p 637)**

Acute onset of vomiting, anorexia and lethargy. May be associated with hematemesis if there are deep erosions or ulcers.

- **Septicemia/bacteremia/endotoxemic shock (p 655)**

Vomiting is only one of the signs that may occur, others include hypothermia, weakness or collapse, depression, weak or thready pulses, tachypnea and pale to gray mucous membrane color.

- **Peritonitis (p 655)**

Abdominal pain, distention, fever, decreased appetite and lethargy are the most common presenting signs. Vomiting may occur, but is not a consistent problem.

- **Encephalitis/meningitis (p 659)**

Vomiting, when it occurs, is due to inflammatory effects on the CRTZ or results from systemic effects of the disease that is causing the encephalitis, e.g. histoplasmosis, toxoplasmosis, cryptococcosis, etc. Most cats with inflammatory CNS disease either have seizures, neurologic deficits, ataxia or dysmetria, or cervical pain.

- **Vestibular disease (p 656)**

Vomiting is more commonly associated with peripheral vestibular disease. In addition to vomiting, other clinical signs may include head tilt, ataxia, nystagmus and circling.

INFECTIOUS

Viral:

- **Feline panleukopenia virus* (p 650)**

Infectious viral enteritis of young cats that is often fatal in unvaccinated populations due to the severity of the clinical signs and systemic septicemia. Clinical signs include an acute onset of anorexia and depression, followed by vomiting. Diarrhea may not occur, or is delayed for 24–48 hours. The disease is a relatively rare problem in well, vaccinated cats due to the efficacy of the vaccine.

Bacterial:

- ***Helicobacter* spp.* (p 646)**

The true importance of *Helicobacter* in feline gastritis is still unknown, but increasing evidence points to them having a role in inflammatory diseases of the stomach, liver and pancreas.

- **Salmonellosis* (p 648)**

Primarily a problem in young or debilitated cats, as most cats are asymptomatic carriers. In adult cats, vomiting, diarrhea, anorexia and weight loss are more common, while in kittens, systemic signs of infection, including fever or hypothermia, weakness or collapse due to septicemia and endotoxemia.

PARASITIC

- **Physaloptera (p 653)**

Intermittent vomiting episodes in young, outdoor cats that hunt. Occasionally the small worms are observed in the vomitus.

- ***Ollulanus tricuspis* (p 654)**

Acute onset of vomiting in free-roaming or colony cats associated with infection with this gastric nematode, which has a direct life cycle.

- **Ascarids (p 654)**

Intermittent vomiting in young kittens is sometimes observed with large worm burdens due to the mass of worms obstructing normal passage of ingesta. More common signs include unthriftiness, diarrhea and pot-bellied appearance.

TOXIC

- **Plant ingestion/toxicity* (p 646)**

Many plants do not produce severe toxicity (*Philodendron*, *Diffenbachia*, *Euphorbia*, *Caladium*, etc.), but a few are nephrotoxic (*Lilium* e.g. lilies, *rheum*, e.g. rhubarb, *oxalis* e.g. sorrel) and cause vomiting in addition to signs of renal failure. Other plants that cause vomiting are *ricinus* (castor bean), *robinia* (black locust), and *solanum* (nightshade) to name a few of the more common species.

- **Pharmacologic/antibiotic induced* (p 642)**

Acute onset of vomiting after initiating antibiotic therapy. Antibiotics associated with vomiting: ampicillin, cephalosporins, tetracycline, erythromycin.

- **Ethylene glycol* (p 648)**

Vomiting occurs in two stages, one is associated with the initial ingestion of the toxin and is due to alcohol intoxication and metabolic acidosis. Other signs that occur during this time are salivation, depression, ataxia and polydipsia. The second stage occurs 2–3 days later and vomiting, depression and oral ulcers develop secondary to the acute, anuric renal failure, which is the end stage of this toxicity.

- **Pyrethrins\pyrethroids\permethrins\organophosphates* (p 644)**

Vomiting, diarrhea, hypersalivation, contact dermatitis, ataxia, excitation, seizures and dyspnea are all reported signs of toxicity to these insecticides.

- **Anesthetic agents (Xylazine) (p 658)**

Xylazine-induced emesis is a well-known side effect of its administration and is often used therapeutically.

- **Chemotherapy drug-induced vomiting (p 658)**

Those drugs associated with vomiting include: actinomycin-D, cyclophosphamide, cytosine arabinoside, dacarbazine, doxorubicin, methotrexate, mitoxantrone, vinblastine.

continued

continued

- **Non-steroidal anti-inflammatory drug (NSAID) toxicity (p 656)**

Vomiting associated with non-steroidal anti-inflammatory drugs (aspirin, ibuprofen) is usually associated with acute gastritis and erosions that occur secondary to the anti-prostaglandin effects on the stomach. Ibuprofen will also cause acute renal failure. Acetaminophen does not induce gastritis but vomiting has been observed in cats due to the hepatotoxicity. Other clinical signs that occur more frequently and are more important include facial edema, pruritus, salivation, tachypnea, depression and cyanosis (due to methemoglobinemia).

- **Arsenic poisoning (p 659)**

Arsenic is found in herbicides, insecticides, wood preservatives and blood parasiticides. Initial clinical signs include vomiting, diarrhea, anorexia and depression. This is followed by hepatic and renal failure.

INTRODUCTION

MECHANISM?

Vomiting occurs when the **vomiting center in the medulla is stimulated**, which can occur by **several mechanisms**:

- Effect of **blood-borne toxins or drugs**.
- **Afferent impulses from the cerebral cortex, chemoreceptor trigger zone (CRTZ), the vestibular apparatus, or receptors in the pharynx or abdominal viscera.**

The chemoreceptor trigger zone (CRTZ) is stimulated by:

- **Blood-borne toxins**, including uremic toxins or drugs.

Vomiting is an **active process** that must be distinguished from regurgitation.

Vomiting in cats is associated with **abdominal muscle contraction**, and signs of **considerable muscular effort and anxiety** prior to the event.

Vomit may consist of **undigested food material** (if swallowed whole), partly digested or even liquid, and may be clear, yellow (bile stained) or brown (food colored).

Vomit is **not typically tubular in form**, nor does it contain large amounts of white frothy material.

The **pH of vomitus is usually acidic** (pH < 4), but may be **neutral (pH 7) if duodenal content is present** (bile reflux).

WHERE?

Vomiting may result from **gastrointestinal disease or extra-intestinal tract diseases**.

Acute vomiting associated with **extra-intestinal diseases** may be due to:

- **CNS disease** (e.g. encephalitis or vestibular disease).
- **Pancreatitis.**
- **Hepatobiliary disease.**
- **Renal disease** causing acute or chronic renal failure.
- **Metabolic or endocrine diseases** including ketoacidotic diabetes mellitus and hypercalcemia.
- **Systemic illness or infection**, e.g. septicemia, pyometra.

Primary gastrointestinal diseases that cause acute vomiting involve the stomach or small intestine:

- **Parasites**, e.g. *Physaloptera*, *Ollulanus*, etc.
- **Infectious diseases**, e.g. *Salmonella*, *Helicobacter*.
- **Inflammatory diseases**, e.g. IBD.
- **Neoplasia.**
- **Mechanical**, e.g. foreign body obstruction, intussusception, motility disturbances.
- **Dietary disturbances**, e.g. indiscretion or food intolerance.

Vomiting is **rarely associated with colonic disease**, except when toxins associated with **fecal retention** affect the vomiting center and chemoreceptor trigger zone.

WHAT?

The **most common causes** of acute vomiting are: **mechanical obstructions** (including foreign bodies),

extra-intestinal tract diseases (such as hepatitis, renal failure or pancreatitis, dietary indiscretion), and **inflammatory diseases** (e.g. IBD).

Many cats vomit intermittently, and these episodes are attributed to **trichobezoars** (hairballs). However, some of these cats may be vomiting due to dietary indiscretion or food intolerance, gastric parasites, motility disturbances, pancreatitis or other acute inflammatory disorders.

Acute, persistent vomiting episodes that occur along with other clinical signs such as lethargy, anorexia or diarrhea, usually signal a **more serious problem** that should be investigated more thoroughly. Examples of problems fitting this category include intussusception, erosions/ulcers, acute renal failure, neoplasia or inflammatory bowel disease.

DISEASES CAUSING SIGNS OF ACUTE VOMITING

FOOD INTOLERANCE OR DIETARY INDISCRETION**

Classical signs

- Intermittent vomiting.
- Large bowel diarrhea or soft, mucoid feces.

Pathogenesis

Food intolerance is a **non-immunologic, adverse reaction to a substance(s) present in food**. This reaction may be to a food component such as the type of protein or carbohydrate, or it may be to the colorings, preservatives, flavorings, etc. that are present in pet foods. Natural chemicals in foods such as amines, salicylates and monosodium glutamate may stimulate nerve endings and have also been associated with food intolerance. Highly flavored or “rich” food has more of these chemicals. Cats may be sensitive to more than one food. Signs may require a “binge” or several days of exposure before they are evident.

The actual **mechanism** associated with vomiting or diarrhea due to food intolerance is **unknown**.

Food intolerance is usually a cause of **chronic, intermittent vomiting**, but kittens may present acutely with diarrhea when they are first introduced to new foods. Diarrhea may result when a rapid change in food overwhelms the digestive capacity. Changes in food composition require changes in digestive enzymes.

Ingesting a foreign substance (dietary indiscretion) such as lizards, beetles, moths or plants may cause acute vomiting. Over-eating or eating too quickly is poorly documented as a cause of vomiting in cats.

Clinical signs

Intermittent but persistent **vomiting or mucoid, soft feces** are common signs. Poor hair coat or failure to thrive may also be noted but this is less common.

Diagnosis

There is **no definitive diagnostic test** for this problem other than to observe a response to changing the diet.

Differential diagnosis

Intermittent but unrelenting vomiting in an otherwise healthy cat suggests possible motility disturbances, antral pyloric hypertrophy, gastric parasites or early IBD.

Treatment

Changing the diet to a diet that does not contain the offending substance. This may be as simple as changing from a grocery store brand to a premium brand food (or vice versa), but also may require changing to a hypoallergenic food product (IVD's Limited diets, Hill's d/d, Eukanuba Response formula, Waltham, etc.). Kittens often respond to being fed exactly the same food as a sole diet for at least 3 days.

Prognosis

Good if the appropriate food can be found, which is usually not a difficult problem. However, the cat may have to remain on the diet indefinitely.

GASTROINTESTINAL FOREIGN BODIES (OBSTRUCTION)**

Classical signs

- Frequent, severe vomiting episodes with upper GI obstruction.
- Intermittent vomiting with lower intestinal obstruction.
- Anorexia.
- Dehydration.
- Diarrhea is more prevalent with lower intestinal obstructions.
- Abdominal pain.

Pathogenesis

GI foreign bodies occur **more commonly in young cats**, because of their curious nature, tendency to ingest non-food substances (string, rubber bands) and prey (hair, fur, bones).

Linear foreign bodies (e.g. string, yarn, thread, etc.) are the most common foreign body in cats and create problems from the motility disturbances that are created resulting in **intestinal plication** or intussusception, and from the **intestinal perforation** due to string migration through the intestinal wall. Thread, with or without a needle, and string are the most common causes, and in some countries, the string from the end of a sausage is a common culprit.

Linear foreign bodies may first be caught under the **base of the tongue**, creating not only an oral lesion, but also preventing the possible passage of the string through the GI tract. Alternatively, they may become **trapped at the pylorus**, with the rest of the string passing into the small intestine.

Many foreign objects (especially hair, but including string) will pass through the GI tract, so if an obstruction occurs, it may be due to a **disturbance in motility, narrowing of lumen or other pathology** that prevents the normal passage of the object.

Clinical signs

The signs **depend upon the location** of the foreign object and will help in many cases to localize the lesion.

With **gastric or upper small intestinal obstructions**, **acute onset of frequent vomiting** or gagging is common.

Dehydration, lethargy and anorexia are common in these cats, and they may show evidence of abdominal discomfort (either on palpation or by posture).

In cats with a **lower intestinal obstruction**, **diarrhea will probably be more likely, vomiting less frequent and severe**, and dehydration and abdominal pain more variable.

If the foreign body is of significant size or if intestinal plication from a linear foreign body is present, these **abnormalities may be palpable**.

Cats that develop an **intestinal perforation** as a result of the foreign body deteriorate rapidly and develop **depression and fever, hypovolemia/shock**.

Diagnosis

History and physical examination findings are very important in pointing to the diagnosis (always **examine under the tongue of vomiting cats**).

Hemogram and serum biochemistry profile findings will likely be normal if the condition is acute.

Long-standing or severe linear foreign bodies or GI perforation will show an **inflammatory response**, evidence of dehydration (hemoconcentration or elevated proteins) and **electrolyte abnormalities** consistent with vomiting (hypokalemia is most common).

The diagnosis is obtained by **imaging studies**, including radiography (plain or contrast), ultrasonography or upper GI endoscopy. Radiographs may reveal evidence of intestinal plication (wash board appearance) which is the classic presentation for string foreign bodies. In some cases, endoscopy will allow retrieval of the foreign object, and is a useful means of assessing other damage (e.g. erosions, ulcers, or tears in the mucosa).

Differential diagnosis

The **acute onset, age of occurrence and history or physical examination findings** usually point to a foreign body.

However, some cats with linear foreign bodies have a **waxing/waning course of vomiting and anorexia** that may not suggest the diagnosis immediately.

Other differentials in those cases would include infectious, dietary or inflammatory gastrointestinal diseases.

Treatment

In cases where the object is still in the stomach, it is sometimes possible to safely **retrieve the object** (needle, small toy, etc.) via an **endoscopic** procedure.

Most GI foreign bodies however, will require **surgical removal**, and some may be a surgical emergency when GI perforation has occurred.

Cats that are severely dehydrated from persistent vomiting, or have suspected intestinal perforation and leakage should be stabilized as much as possible with **aggressive fluid therapy** and **broad-spectrum antibiotics** prior to surgery (e.g. combination of ampicillin/amoxicillin or cefazolin and enrofloxacin, amikacin or cefoxitin). Some cats with a protracted history of vomiting will benefit from **histamine-2 blockers** or GI protectants if gastritis or gastric erosions are suspected.

Motility-modifying agents, such as metoclopramide, should not be used until the obstruction is relieved.

Prognosis

The prognosis is good unless large portions of bowel must be resected which potentially leads to short bowel syndrome.

Prevention

The key is to prevent ingestion of string, rubber bands, needle and thread, string, etc., to not allow cats to ingest prey, and to use caution in the type of pet toys that the cat is allowed to play with.

GASTRITIS/GASTRIC ULCER DISEASE**

Classical signs

- Acute or chronic vomiting, with or without hemoptysis.
- Anorexia or reduced appetite.
- Lethargy.
- Anterior abdominal pain.

Pathogenesis

Gastritis results from hyperacidity, loss of mucosal protection (mucus, bicarbonate), reduced mucosal blood flow, or mucosal damage from direct trauma, irritation or chemical erosion.

Continued damage leads to development of a **gastric erosion** (lesion in mucosa only) or **ulcer** (lesion affecting the deeper tissue layers of the stomach wall).

Non-steroidal anti-inflammatory drugs (**NSAIDs**) **reduce the synthesis of prostaglandins** which are necessary for **gastric mucus secretion**. Gastric mucus is the primary means of surface protection against acid, irritants and trauma.

Hyperacidity can occur secondary to liver failure (hypersecretion of gastrin and reduced mucosal blood flow), renal failure (hypergastrinemia) or mastocytosis (increased release of histamine), or can result from long-term use of gastric acid-suppressing drugs (e.g. proton pump inhibitors), or a gastrinoma (gastrin-secreting tumor) which is a very rare endocrine tumor in cats.

A decrease in **bicarbonate** delivery to the gastric mucosa occurs in metabolic acidosis (e.g. renal failure) and in states of reduced blood flow (e.g. shock), thus resulting in mucosal injury.

Clinical signs

Vomiting occurs with or without hematemesis.

Vomiting may be **acute in onset with drug-induced gastritis or ulcers**, but for most other causes is **chronic** due to the development of hyperacidity from metabolic or inflammatory diseases.

Anorexia or decreased appetite and lethargy occur in cats with severe erosions or ulcers.

Anterior abdominal pain is more common with ulcer disease.

Diagnosis

History of acute onset, exposure to NSAIDs, ingestion of chemical or toxin irritating to gastric mucosa, or episode of ischemia (shock).

Radiographic findings are usually non-diagnostic, but may identify a deep erosion/ulcer with contrast.

A deep erosion or ulcer may be identified via **ultrasound**, but simple gastritis or superficial mucosal erosions will only be diagnosed by endoscopy examination or biopsy.

Endoscopy is the **definitive** way to diagnose **mucosal erosions and ulcers**, and also may help identify a cause via histopathologic examination of the tissue.

Differential diagnosis

Acute gastritis due to erosions/ulcers will mimic many causes of acute vomiting, including dietary indiscretion, **mechanical or obstructive disorders**, infectious causes, toxin-induced (especially plant ingestion), pancreatitis, and metabolic or endocrine diseases such as hepatitis, renal failure or neoplasia.

Treatment

Treatment is aimed at **identification and correction of the underlying cause** of the primary lesion, **reduction of acid secretion** and **protection of the gastric mucosa** to allow it to heal. This is accomplished by:

- Administration of **histamine-2 receptor antagonist (H₂RA)** (e.g. cimetidine 5 mg/kg PO q 8 h, ranitidine 0.5–1.0 mg/kg PO q 12 h, or famotidine 0.5–1.0 mg/kg PO q 12–24 h).
 - Famotidine is the most potent and only H₂RA to effectively reduce acid in dogs. No studies have been completed in cats.
 - **Proton pump inhibiting drugs** (omeprazole 1 mg/kg PO q 24 h) are the most effective in reducing acid secretion but can be difficult to dose.
 - **Sucralfate** (250–500 mg PO q 8–12 h) is also a useful adjunct therapy for cats with significant gastric erosions or ulcers, as it will act as a surface protectant. Sucralfate must be given in an acidic environment to be effective, so it should be administered at least 1 hour prior to giving histamine-blocking or proton pump-inhibiting drugs.
 - Feeding **nothing per os for the first 24 hours**, then feeding a highly digestible, bland, low-residue diet, either commercial or homemade (e.g. small amounts of low-fat beef, chicken or turkey), will be beneficial.

In cases where treatment of the underlying cause is not possible or where management is the only option (e.g.

chronic renal failure), long-term therapy with histamine blockade will be necessary to help reduce the development of new erosions or ulcers.

In **severe or deep ulcers**, **surgical intervention** may be necessary but this is unusual. Emergency surgical intervention will be necessary in cats that have perforating ulcers. Many deep or perforating ulcers are caused by an invasive neoplasm, or by fungal disease in geographic areas where systemic fungal infections are prevalent.

Cats with severe disease that are unable or unwilling to eat for **more than 3 days** should have **nutritional support** provided, either through placement of a feeding tube for enteral feeding, or by parenteral nutrition.

Prognosis

The majority of cats will recover completely from the insult if the cause can be identified and corrected, and in most other cases the disease can be successfully managed. In cats with ulcers due to neoplasia, the prognosis is guarded to poor.

Prevention

Reduce opportunities for ingestion of toxic or irritating substances.

Management of diseases causing **hypergastrinemia** (renal failure, hepatic disease) should **always include therapy for gastritis**.

Prevent ischemia and shock-induced gastric erosions by rapid replacement of **fluids** following shock, and maintenance of hydration during surgical procedures, etc.

HAPATOPATHIES** (HEPATIC LIPIDOSIS, CHOLANGITIS, DRUG-INDUCED HEPATOPATHY)

Classical signs

- **Weight loss, anorexia, vomiting, icterus and depression are the most common signs.**

See main reference on page 421 for details.

Clinical signs

Weight loss (often dramatic), anorexia, vomiting, icterus and depression are the most common signs. Other signs may include ascites (this is rare with hepatic lipidosis, but may occur with end-stage hepatopathies or cholangitis).

Most hepatopathies are associated with chronic vomiting, but drug-induced hepatopathies (e.g. glipizide) are associated with acute vomiting.

Diagnosis

The presence of icterus helps to narrow the differentials list to hepatic, pre-hepatic and post-hepatic diseases.

The **hemogram** in cats with hepatic disease is **often abnormal** (e.g. mild, non-regenerative anemia, with RBC morphology having schistocytes, leptocytes or target cells present), but the changes are **not specific** for liver disease. However, it does help **rule out pre-hepatic causes of icterus**.

Serum chemistry abnormalities may include **elevated liver enzyme activities** (mild to marked increases), **hyperbilirubinemia**, **hypcholesterolemia**, **hypoalbuminemia**, decreased BUN, and electrolyte alterations (consistent with vomiting or dehydration, e.g. hypokalemia, hyponatremia).

The urinalysis will have **bilirubinuria**, and occasionally may have urate crystalluria if the liver failure is severe or end-stage.

Ultrasonography is the most useful imaging modality, because it can also be used to obtain fine-needle aspirates or biopsies (note: check for a possible coagulopathy before performing a blind biopsy). In cats with hepatic lipidosis the liver is enlarged and hepatocytes are crowded out by lipid, but cats with cholangitis may have a normal, large or small liver.

Liver biopsies taken via surgical exploratory laparotomy have greater accuracy, and will also **allow placement of a gastrostomy or jejunostomy tube** (which is essential for cats with hepatic lipidosis and important for any cat that doesn't eat for longer than 3–5 days). Again, the cat should be checked for a possible coagulopathy before surgery is performed.

ACUTE PANCREATITIS**

Classical signs

- **Anorexia, lethargy and depression are the most common signs.**
- **Vomiting is seen in less than 50% of cats with pancreatitis.**

Pathogenesis

The **cause of acute pancreatitis in cats is unknown**, but it has been associated with trauma, some infectious diseases (herpes virus, toxoplasmosis, feline infectious peritonitis, etc.), hepatic lipidosis, drugs, and extension of inflammation from the small intestine. Recently pancreatitis has been **observed to occur in association with inflammatory bowel disease and cholangitis**, but whether it is due to a common inflammatory reaction or innocent bystander situation is unknown.

The destructive process in the pancreas is initiated by **activation of trypsinogen**, which leads to the activation of other proteases, lipases and inflammatory mediators such as kininogens and free radical species. Activation of these processes leads to activation of complement, induction of coagulation disorders such as DIC and hypovolemic shock.

Acute necrotizing pancreatitis is a common finding in cats with diabetes mellitus that die within the first week of diagnosis despite treatment. Histologic evidence of pancreatitis is found in approximately 50% of cats with diabetes mellitus.

In dogs, hyperlipoproteinemia, high-fat/low-protein diets, obesity, some drugs (furosemide, azathioprine, L-asparaginase, sulfonamides, tetracyclines, corticosteroids) and metabolic states (hypercalcemia, uremia) are implicated as risk factors for pancreatitis, but no such association has been reported for cats.

Clinical signs

Anorexia, lethargy and dehydration are the most common presenting signs in cats, unlike the classic signs of vomiting and abdominal pain that are exhibited in dogs.

Fewer than a third of cats with pancreatitis will present with vomiting, abdominal pain, diarrhea, tachypnea or dyspnea, or a palpable anterior abdominal mass.

Cats tend to have a **more variable clinical course** than the disease in dogs, with some cats having a course of anorexia, lethargy and weight loss that does not suggest acute illness, while other cats will present with acute deterioration, severe shock and collapse.

A critically ill diabetic cat that does not respond to appropriate therapy within the first 24–48 hours of therapy should be suspected of having acute necrotizing pancreatitis.

Diagnosis

Diagnosis of pancreatitis in cats is very difficult, primarily because of the vague clinical presentation.

Hematologic changes, if they occur, are non-specific: neutrophilia, hemoconcentration, thrombocytopenia (late), and anemia (late).

Serum **biochemical abnormalities are common, but also non-specific:** hyper- or hypoglycemia, elevated alanine aminotransferase, elevated serum alkaline phosphatase, hyperbilirubinemia, hypercholesterolemia, hypokalemia, hypophosphatemia, hypocalcemia. **Serum amylase and lipase values are unreliable and uninterpretable** (pancreatitis in cats has been associated with elevations, decreases and normal values of both enzymes).

Hypocalcemia, when present, is suggestive of acute necrotizing pancreatitis and a poorer prognosis.

Radiographic abnormalities are highly variable but those that may be observed include decreased contrast in the right, cranial abdomen; dilated and gas-filled small intestines; or a mass effect in the area of the pancreas with transposition of duodenum, stomach and transverse colon.

Ultrasonography is a very useful diagnostic tool for evaluating pancreatic pathology. Changes in pancreas size, echogenicity and the presence of masses can often be detected. **However, pancreatic abnormalities found via ultrasound may persist for months** after the condition has resolved.

An elevated serum trypsin-like immunoreactivity (TLI) assay (the feline-specific assay must be used) cannot accurately predict pancreatitis in cats, however, a value of greater than 100 µg/L has been reported to have an 80% specificity and 33% sensitivity for pancreatitis.

A feline pancreatic lipase immunoreactivity (fPLI) assay has been recently developed and validated. This assay is very specific (90%), and highly sensitive (100%), for acute pancreatitis but only 65% specific for chronic pancreatitis.

A recent study showed that the combined use of fPLI and abdominal ultrasound was nearly 100% specific and sensitive for acute pancreatitis.

Differential diagnosis

The vague and non-specific clinical signs make it impossible to rule out other causes of extra-intestinal and intestinal disease until a complete work-up has been performed.

In very ill cats, the other major differentials include peritonitis, septicemia and endotoxic shock.

Treatment

Oral alimentation should be withheld for 1–3 days if vomiting is present in cats with pancreatitis to reduce pancreatic secretions. Return to full feed gradually and feed cats a highly palatable, but highly digestible, diet (Hills feline i/d, Iam's low residue diet, etc.). In cats that are not vomiting, and especially those that have been anorectic for more than 3 days, oral alimentation should not be withheld and feeding tubes should be placed, if needed.

Eliminate, if possible, any predisposing factors that are present.

Aggressive fluid therapy is the cornerstone of treatment, not only to correct the dehydration that occurs from vomiting, but also to reduce the effects of microvascular stasis on the pancreas and other vascular beds (pulmonary, renal, hepatic). In some cases colloid therapy in addition to crystalloids is very beneficial. Attention to the need for **potassium supplementation**, phosphorus, and other electrolytes, such as magnesium, sodium and chloride are essential.

In cats with concurrent hepatic lipidosis or those that must be held off food for greater than 5 days, **enteral nutrition via a jejunostomy tube or total parenteral nutrition will be a necessary** component of the treatment plan. J-tubes must be surgically placed, which may increase the risk of complications due to pancreatitis. Total parenteral nutrition requires strict attention to sterility and close monitoring of electrolytes and is more suited to referral institutions than general practice.

Vomiting should be controlled with **antiemetic therapy**. Either **metoclopramide** (0.1–0.2 mg/kg IV q 8 h) or chlorpromazine (0.01–0.025 mg/kg IV) are effective, but it is important when using any phenothiazine antiemetics that you ensure adequate volume expansion so that hypotension is avoided. If gastritis is suspected histamine-2 blockers such as ranitidine or famotidine should also be considered.

Corticosteroids are indicated **in cats that are in shock** and may be helpful in cats with chronic pancreatitis from concurrent IBD or cholangitis.

Abdominal pain should be controlled with butorphanol (0.1–0.8 mg/kg IV q 4–6 h), buprenorphine (0.03 mg/kg q 6–8 h) or meperidine (2–4 mg/kg IM q 6–8 h).

Antibiotics should not be routinely used in pancreatitis. **Indications for use of antibiotics include evidence of toxic changes in the neutrophils, the cat is febrile, or other signs of sepsis or septicemia** are present. In cases where a pancreatic abscess is suspected or a concern, parenteral cephalosporins (cefazolin, 20–30 mg/kg IV, cephalothin 20–35 mg/kg IV) combined with fluorinated quinolones are recommended.

The **major complications** of pancreatitis include: development of pancreatic abscesses, pancreatic fibrosis resulting in obstruction of the common bile duct or development of diabetes mellitus, peritonitis, pulmonary thromboembolism, acute renal failure, and disseminated intravascular coagulation. In those cases, surgical intervention may be required (abscess, peritonitis, stricture), but in cases where respiratory, cardiovascular, renal or coagulation abnormalities develop the prognosis is guarded to poor.

Prognosis

Cats with **concurrent hepatic lipidosis or cholangitis and acute necrotizing pancreatitis have a worse**

prognosis. These cases are more difficult to manage (require TPN or jejunostomy feeding) and have more complications (coagulation abnormalities and tendency toward development of pulmonary thromboembolism).

GASTRIC OR SMALL INTESTINAL NEOPLASIA*

Classical signs

- Chronic, progressive vomiting that may include hematemesis.
- Weight loss.
- Anorexia.
- Lethargy or depression.
- Diarrhea may occur if the location of the lesion is in the small intestine.

See main reference on page 675 for details (The Cat With Chronic Vomiting).

Clinical signs

Acute vomiting may occur occasionally or the signs occur acutely, while the disease itself is chronic.

Typically chronic, progressive vomiting that may include hematemesis is observed.

Weight loss, anorexia, lethargy or depression are also common.

Diarrhea may occur if the location of the lesion is in the small intestine.

Signs occur in **older cats**, however, **lymphoma** occurs in cats of **all ages** and may be associated with FeLV infection.

Diagnosis

Palpation of the abdomen may reveal a **mass or thickened intestinal loops** in some cases.

Hematology and serum chemistry profiles are usually **non-specific**, but help to rule out other causes of vomiting. The most frequent hematologic abnormality is **anemia of chronic disease** (normocytic, normochromic), but blood loss anemia is also observed. The abnormalities found in the chemistry profile depend on the extent of the disease and severity of vomiting, and are non-specific.

The most helpful diagnostic procedures are imaging techniques: radiography, ultrasonography or possibly endoscopy. Depending on the location and size of the mass, **ultrasonography** will not only allow visualization of the lesion, but may also allow diagnosis via **fine-needle aspiration or biopsy**.

Ultimately, **histopathologic examination of the tissue is necessary for a definitive diagnosis**, and in many cases, surgical exploratory for both biopsy and resection is the best approach.

Differential diagnosis

Inflammatory bowel disease – This is usually not associated with hematemesis or severe weight loss, and occurs in young to middle-aged cats.

Metabolic diseases, e.g. hyperthyroidism, chronic renal or liver diseases.

Chronic pancreatitis.

Treatment

For **adenocarcinoma, mast cell tumors** and other tumors that tend to occur as **solitary mass lesions**, surgical removal via intestinal resection is the primary approach. **Biopsies should be obtained of liver, regional lymph nodes and mesenteric tissues** to determine if metastasis has occurred or its extent. Chemotherapy has not been proven effective for adenocarcinoma or intestinal mast cell tumors.

Lymphoma is generally an infiltrative neoplasm and **chemotherapy** using the COP protocol is the treatment of choice. See main reference on page 676 for details.

PHARMACOLOGIC (ANTIBIOTIC-INDUCED)

Classical signs

- Anorexia.
- Vomiting.
- Diarrhea.

Pathogenesis

Vomiting associated with antibiotics is a common occurrence and can occur with almost all of the popular antibiotics, including: **amoxicillin, cephalixin,**

erythromycin, lincomycin, sulfasoxazole, tetracycline, trimethoprim-sulfadiazine.

The mechanism for induction of nausea or vomiting varies for each drug. For example, erythromycin is a prokinetic and is highly acidic, causing a direct irritant effect on the gastric epithelium.

Some drugs can be given without inducing vomiting if they are given with food, while others may induce vomiting whether or not food is present because the effect is not directly on the stomach.

Clinical signs

Anorexia or a decrease in appetite is the most common sign of drug-associated discomfort, followed by **vomiting** or regurgitation.

Diarrhea may occur following antibiotic use, but is usually associated with a disruption in microflora of the colon resulting in colitis or large bowel diarrhea.

Diagnosis

The diagnosis may be straightforward if the cat was previously not vomiting and started vomiting after the drug was administered. However, if drugs are being given to treat a disease for which vomiting or diarrhea are already present, differentiating the drug effect from the disease will be quite difficult.

An especially important example of this is in **cats with cholangitis** that have **signs of vomiting due to their disease, and have to be on long-term antibiotic therapy** to treat their disease. It is sometimes very difficult to determine whether a worsening of clinical signs is due to the therapy or a worsening of the disease. In those cases, careful assessment of the physical findings and blood work changes will be necessary to separate the two problems.

Treatment

The best approach is to stop use of the antibiotic in question, and if antibiotic therapy is still required, switch to an appropriate antibiotic of another class.

Prognosis and prevention

Some antibiotics are best given with food (e.g. beta lactams), and in those cases, adverse effects are sometimes avoided by using the drug as it is recommended.

The vomiting is easily controlled by changing to another antibiotic, so the prognosis is excellent.

KETOACIDOTIC DIABETES MELLITUS*

Classical signs

- Vomiting.
- Lethargy or depression.
- Anorexia and weight loss.
- Polyuria/polydipsia.

See main reference on page 236 for details (The Cat With Polyuria and Polydipsia).

Clinical signs

At the time of diagnosis, one third of diabetic cats have a history of vomiting, and with ketoacidosis, an acute onset of vomiting may occur.

Vomiting, lethargy or depression, anorexia, polyuria/polydipsia and weight loss are the classical signs of ketoacidotic diabetes mellitus in cats.

Diabetic cats may also present without weight loss or depression, and polyphagia and polydipsia are still prominent signs.

Cats with **severe, long-standing ketoacidotic diabetes mellitus** may have **neurologic signs** such as stupor, obtundation and coma.

Diagnosis

Typical hemogram and serum chemistry abnormalities include mild non-regenerative anemia (chronic disease), leukocytosis, lymphopenia, hyperglycemia, elevated liver enzyme activities, hypokalemia, hypo-magnesemia, hypophosphatemia, and metabolic acidosis.

The **urinalysis, in conjunction with the presence of hyperglycemia, is diagnostic** and shows **glucosuria and ketonuria**. Cats may be ketonemic and have acetone breath before ketonuria is detected on the dipstick.

Many cats will also have **concurrent bacteriuria**, with elevated protein, blood or white cells.

INTUSSUSCEPTION*

Classical signs

- Acute vomiting, anorexia and lethargy, usually in kittens.
- Abdominal discomfort.
- Endotoxemia or shock may ensue if the intussusception is complete.

Pathogenesis

The exact pathophysiology of the development of intussusception is unknown.

Uncoordinated peristalsis resulting in vigorous contraction of a segment of bowel into an adjacent quiescent segment that occurs due to any variety of causes is involved, and a common predisposing cause in cats is a string foreign body.

The end result is that a segment of intestine telescopes or invaginates into the adjoining, distal segment of bowel, causing an intraluminal obstruction, vascular compromise of the affected bowel segments and ultimately the development of entoxemia and shock.

Bowel **regions that undergo changes in diameter** (gastroesophageal junction and iliocolic junction) seem to be **at the greatest risk**, but intussusceptions occur at any location, and are classified according to their location within the gastrointestinal tract.

Intussusceptions cranial to the jejunum are termed **high intussusceptions** and generally are **more severe** (signs are more acute and have more rapid clinical deterioration) than distal intussusceptions.

Siamese and Burmese cats appear to have a predilection for development of intussusceptions.

Most intussusceptions occur in **young animals** (< 1 year of age).

Intussusceptions are rare in cats compared to dogs.

Clinical signs

An acute onset of vomiting and lethargy, with diarrhea occurring occasionally, is typical in kittens.

With **high intussusceptions**, vomiting, abdominal discomfort, anorexia, lethargy, dehydration and hypovolemia leading to shock are the most common clinical signs.

Low intussusceptions (at the ileocolic junction) typically present with bloody, mucoid diarrhea, tenesmus, intermittent vomiting and weight loss. In many of these cases, the intussusception can be **palpated**.

Diagnosis

Hemogram and serum biochemistry profiles will be variable depending on the severity and location of the intussusception, however, dehydration, electrolyte abnormalities, anemia and leukocyte changes have all been observed depending on the cause of the intussusception.

Radiographs and/or ultrasound examination of the gastrointestinal tract are the best means of confirming the diagnosis. A gas- or fluid-filled, dilated loop of bowel is present immediately cranial to the intussusception, which may not be visualized without using a contrast agent. If there is not too much gas to obstruct adequate images, intestinal intussusceptions are usually readily identified using ultrasound, and are characterized by visualizing the folds of intestine layered on top of one another.

Contrast studies may be used but should not be done at the expense of delaying treatment in severely ill cases.

Endoscopic examination or colonoscopy can also be used to obtain a diagnosis, especially with low intussusceptions, but this is rarely needed and may be very difficult in kittens.

Differential diagnosis

Many **diseases that can precipitate an intussusception** (viral enteritis, foreign bodies, gastroenteritis, intestinal parasitism, etc.) also have clinical signs that **mimic it**.

A thorough physical examination, diagnostic evaluation, and close patient monitoring are essential.

Treatment

Intussusception must be considered a **surgical emergency**. Cats with signs of shock or endotoxemia should

be prepared for surgery by **correcting fluid and electrolyte imbalances**, **administration of broad-spectrum, parenteral antibiotics** (combinations such as ampicillin/amoxicillin or cefazolin and enrofloxacin, amikacin, cefoxitin or imipenam), **and use of histamine-2 blockers** (ranitidine or famotidine) or protectants (e.g. sucralfate) if gastric erosions or ulceration is suspected.

Motility-enhancing drugs, such as metoclopramide, **are contraindicated in patients with GI obstruction** and should not be used.

After surgical correction, which is most commonly surgical resection and anastomosis, **if gastric ulceration is not a complicating factor, oral alimentation should be instituted in the first 24 hours**, to enhance the return of normal motility and reduce the possibility of post-operative ileus.

Prognosis and prevention

The key point is that correction of the intussusception does not necessarily alleviate the problem unless the **underlying cause can be identified and corrected**. Otherwise **recurrences are possible** and even likely.

Surgical procedures, such as multiple enteropexy, are recommended to reduce the risk of recurrence.

Prognosis is **guarded to good if** the anesthesia and surgical procedure is **uncomplicated**.

PYRETHRINS/PYRETHROIDS/- PERMETHRINS /ORGANOPHOSPHATES*

Classical signs

- Vomiting, diarrhea.
- Hypersalivation, agitation.
- Contact dermatitis.
- Tremors, ataxia, and possibly seizures.

See main reference on page 594 for details (The Cat With Salivation).

Clinical signs

Signs associated with contact exposure or ingestion of pyrethrin/pyrethroid-containing pesticides are **generally mild**.

Vomiting, diarrhea, hypersalivation and agitation are the most common signs seen with exposure to permethrins in cats. This is currently the most commonly reported toxicity in cats in the United States due to the accidental or inadvertent exposure of cats to the over-the-counter flea products available for dogs.

Severely affected cats may develop **muscle tremors, ataxia, excitation or seizures**.

Organophosphate insecticides cause a combination of signs that include **salivation, lacrimation, increased defecation and urination due to the stimulation of the parasympathetic nervous system**. Other clinical signs that may occur are vomiting, tremors, ataxia, hyperthermia, dyspnea and seizures. Severely poisoned cats may die from the systemic effects of the toxin.

Diagnosis

History of exposure to or ingestion of products containing permethrin (most common) or pyrethroids.

There is generally no need for further diagnostic testing since signs will abate with removal of pyrethrins or permethrins from the skin or GI tract and supportive care.

With **organophosphates**, if there is no known exposure, but the toxicity is suspected based on clinical signs, measurement of **serum cholinesterase activity levels** may aid diagnosis. Levels less than 25% of normal are highly suggestive of OP toxicity.

ACUTE RENAL FAILURE/PYELONEPHRITIS*

Classical signs

- Anorexia or decreased appetite.
- Polyuria/polydipsia, and weight loss. Occasional chronic vomiting, in advanced cats.
- Cats with pyelonephritis may only have vague signs of inappetence, fever or abdominal discomfort.

See main reference on page 278 for details.

Clinical signs

Anorexia or decreased appetite, polyuria/polydipsia, and weight loss are the classic signs of renal disease.

Renal failure is a rare cause of acute vomiting in the cat.

In cats that do vomit, the signs are generally chronic and associated with the effects of increased uremic toxins causing nausea by their effects on the CRTZ and also by associated hypergastrinemia and the direct effects on the stomach.

Cats with pyelonephritis may only have vague signs of **inappetence, fever or abdominal discomfort**.

Diagnosis

Palpation of the abdomen may reveal **enlarged or painful kidneys** (acute renal disease, pyelonephritis, FIP, renal neoplasia or polycystic kidney disease), or **small, misshapen kidneys** (chronic renal disease).

Marked azotemia (elevated BUN and creatinine), hyperphosphatemia, hyperkalemia and metabolic acidosis in conjunction with isosthenuria (or impaired urine-concentrating ability, e.g. urine specific gravity < 1.030) and oliguria/anuria are classically associated with acute renal failure, while mild azotemia, hypokalemia, hyperphosphatemia, and metabolic acidosis with isosthenuria and polyuria/polydipsia are found with chronic renal diseases.

Pyelonephritis and other inflammatory diseases of the kidneys have fewer hematologic or biochemical changes. Some cats may have an inflammatory leukogram (neutrophilia with or without a left shift), but azotemia does not occur until late (renal failure develops).

Urinalysis is very helpful in distinguishing infectious, or inflammatory, renal diseases from other problems.

Pyelonephritis is difficult to diagnose definitively and is only confirmed by culture of organisms directly from the kidney, either via ultrasound-guided **pyelocentesis** or during a **surgical exploratory**.

Other tests of renal function include intravenous pyelograms or scintigraphic assessment of GFR, but these are not universally available.

Ultrasound is also a useful tool for assessing renal size and infrastructure, and is helping to assess the patency of the ureters, presence of calculi, neoplasms, cysts or other abnormalities.

Differential diagnosis

The wide range of clinical signs resulting from various renal diseases can mimic many different diseases, and so the initial history and physical examination are extremely important.

Most of the more common extra-intestinal, systemic diseases that can cause vomiting should be considered in the initial differentials, but the history, physical exam, minimum database, and urinalysis (with culture if bacteria or WBC are present) will rule out most of the diseases of concern (e.g. diabetes mellitus, hepatopathies, hyperthyroidism, etc.).

Imaging studies will help rule in or out the other major differentials: neoplasia, pancreatitis and mechanical disturbances.

Inflammatory bowel disease requires histopathologic confirmation, which can be obtained by endoscopic biopsies or via a surgical exploratory.

Treatment

The treatment of each individual renal disease is different, and the reader is referred to the primary reference for details.

HELICOBACTER SPP.*

Classical signs

- Anorexia.
- Vomiting.
- Usually associated with chronic vomiting, but may have acute onset of signs.

See main reference on page 682 for details

Clinical signs

The predominant clinical sign continues to be **chronic, intermittent vomiting**.

Diagnosis

The disease mimics so many other causes of vomiting that a thorough diagnostic evaluation is required to make the diagnosis.

Typically, the **hemogram and serum chemistry profile is completely normal**, especially since the vomiting episodes are not frequent enough to cause electrolyte imbalances or dehydration.

The most useful diagnostic test is **endoscopic examination and biopsy**. The organisms will be visualized best via histopathologic examination, but cytology or culture of the gastric contents has also yielded the organisms in some cases. However, **culture of *Helicobacter pylori* requires special media and culture conditions** to be successful, but is the best means of finding this pathogenic species.

Clo-tests, which are enzymatic tests of the presence of urease used in humans to screen for *Helicobacter* spp. organisms in gastric content, have not been adequately evaluated in cats; however, because cats have some *Helicobacter* spp. as normal flora, this test is not likely to be helpful.

PLANT INGESTION/TOXICITY*

Classical signs

- Most plants do not cause severe toxicity, but may cause drooling, vomiting or diarrhea due to their irritant effects on mucous membranes.
- Severe toxicity may result in hepatic or renal failure, with vomiting, diarrhea, depression, anorexia occurring secondary to these effects.

Pathogenesis

Most plants do not cause severe toxicity, but may cause **drooling, vomiting or diarrhea** due to their irritant effects on mucous membranes.

Severe toxicity may result in hepatic or renal failure, with vomiting, diarrhea, depression, anorexia occurring secondary to these effects.

Plants associated with an **acute onset of vomiting following ingestion** include mistletoe, azalea, black nightshade, Christmas cherry, Christmas rose, daffodil, glory lily, jessamines, lantana, larkspur, poinsettia, rhododendron, tulip, wild rosemary, youpon holly (to name a few).

The **specific cause of vomiting or other signs of toxicity is very plant-dependent** and quite variable in severity.

Clinical signs

Vomiting is the most common sign following ingestion of plant material, whether or not it is poisonous/toxic to the gastrointestinal tract or not. Other signs may include **anorexia, drooling, dysphagia or diarrhea**.

Diagnosis

History of exposure or ingestion is essential in many cases, because there is so much variability in presentation.

Plants that cause vomiting due to **irritation or direct GI upset**: *Philodendron* (sweetheart vine), *Dieffenbachia* (dumb cane), *Euphorbia* (poinsettia), *Caladium* (elephants ear), *Ricinus* (castor bean), *Robinia* (false acacia) and *Solanum* (potato, Christmas cherry) spp. to name a few of the more common plants.

Plants that cause vomiting secondary to **nephrotoxicity**: *Lilium* (lily), *Rheum* (rhubarb) and *oxalis* spp.

Differential diagnosis

Acute onset of vomiting in an otherwise healthy cat: consider dietary indiscretion, foreign body or ingestion of other toxins.

Cats ingesting plants that are **nephrotoxic** will have signs that are indistinguishable from other causes of vomiting due to systemic metabolic, infectious or inflammatory diseases.

Treatment

In most cases, the vomiting is **self-limiting** after the offending plant is removed from the GI tract.

Gastric protectants or histamine-2 antagonists may be indicated if severe gastritis develops.

Gastric lavage may be helpful if large amounts of irritant plants are consumed and will reduce further absorption of more toxic metabolites from other plants.

Other treatments that may be necessary **include fluid therapy, antiemetics and offering food that is bland or highly digestible**.

Once signs of nephrotoxicity are observed following lily plant ingestion, progression to anuric renal failure and death is unavoidable. Supportive care with fluid therapy may slow the onset of signs, but there is no effective treatment.

MOTILITY DISTURBANCES* (GASTROESOPHAGEAL REFLUX, ILEUS)

Classical signs

- Vomiting or regurgitation (esophagitis).
- Abdominal distention or abdominal pain due to accumulation of gas in the bowel.
- Anorexia.
