- Avoid by careful placement of ligatures on the OAVC and uterine body.

Urinary Incontinence

- Urinary incontinence after ovariohysterectomy can occur in susceptible individuals (approximately 20% of canine patients) due to a combination of low systemic estrogen levels and increase production and secretion of follicle-stimulating hormone and luteinizing hormone.
- Additional structural causes of urinary incontinence may include adhesions or granulomas of the uterine stump that interfere with urinary bladder sphincter function and, rarely, vaginoureteral fistula from common ligation of the vagina and ureter.
- Prudent administration of exogenous estrogens or alpha-adrenergic drugs may be indicated for estrogen-responsive urinary incontinence (see Chapter 83).

Fistulous Tracts and Granulomas

- Sublumbar draining sinus tracts in spayed female dogs may develop when non-absorbable multifilament suture material, such as polymerized caprolactam (Braunamid, B. Braun Melsungen) used for ligating the OAVC or uterine body becomes contaminated.
- Treatment is exploratory celiotomy and removal of suture material.

▼ ***Key Point*** Do not use non-absorbable multifilament suture material for ligation of the OAVC or uterine body.

Body Weight Gain

Weight gain may occur after ovariohysterectomy; the cause is poorly understood.

Eunuchoid Syndrome

This is a rare complication identified in working dogs after ovariohysterectomy. Clinical signs include decreased aggression, loss of interest in work, and decreased stamina.

Complications Related to Celiotomy

The most common complications associated with celiotomy are the following:

- Self-mutilation of the abdominal wound
- Seroma formation
- Dehiscence
- Failure to remove gauze sponges from the abdominal cavity
- Laceration of the spleen or urinary bladder

CESAREAN SECTION

Preoperative Considerations

Indications for Cesarean Section

- Dystocia from primary uterine inertia
- Protracted dystocia resulting in secondary uterine inertia

- Obstructive dystocia (oversized fetus or narrow pelvic canal)
- Prolonged gestation
- Dystocia from fetal malpositioning
- Fetal death with putrefaction

Certain breeds (Chihuahuas, English bulldogs) frequently require cesarean section because of a high incidence of dystocia. (See Chapter 90 for further discussion of dystocia.)

Anesthesia

- Animals that require cesarean section may have fluid and metabolic disturbances that place them at greater risk for general anesthesia.
- Correction of fluid and metabolic abnormalities should be well under way prior to induction of anesthesia. Administer intravenous fluid therapy and a prophylactic broad-spectrum antibiotic such as cefazolin, 22 mg/kg IV.
- Various regimens for induction and maintenance of anesthesia (see Chapter 2 for general principles of anesthesia) have been recommended. The objective is to administer an appropriate level of anesthesia and analgesia to the dog or cat without causing excessive depression of the puppies or kittens.
- Epidural anesthesia using a local anesthetic with or without an opioid can be attempted in dogs.
- Intravenous narcotics or propofol combined with local anesthesia may be used in dogs.
- Ketamine and local anesthesia may be used in cats.
- Administer standard inhalation anesthesia after the puppies or kittens are removed.

▼ ***Key Point*** Minimize time from induction to delivery by fully preparing the surgical site prior to anesthesia.

- Induce anesthesia and intubate the animal on the surgery table, preferably after the initial skin preparation.

▼ ***Key Point*** Inform the owner prior to surgery that ovariohysterectomy may be necessary if the uterus is not viable.

Surgical Procedure

Objective

- To remove all fetuses from the gravid uterus as quickly and safely as possible

Equipment

- Standard general surgery instrument pack and suture
- Laparotomy sponges
- Clean towels
- Doxapram (Dopram, Robins) and naloxone (Narcan, Elkins-Sinn) (if narcotics are used for induction)
- Incubator or heat lamp

Technique

1. Position the animal in standard dorsal recumbency.
2. Perform the final skin preparation and place surgical drapes.
3. Incise skin, subcutaneous tissue, and linea alba on the ventral midline beginning cranial to the umbilicus and extending as far caudally as necessary to exteriorize the uterus.

▼ ***Key Point*** Avoid incising mammary tissue when making the initial skin incision. Enter the abdominal cavity cautiously to avoid lacerating the gravid uterus.

4. Exteriorize the uterus.
5. Isolate the uterus from the abdominal viscera with moist laparotomy sponges.
6. Identify an avascular area on the dorsal or ventral midline of the uterine body. Make a small incision in the uterine body with a scalpel by tenting the tissue of the uterine wall to avoid inadvertently lacerating a fetus with the scalpel.
   a. Extend the incision with Metzenbaum scissors to a sufficient length to accommodate the largest fetus. The uterus may tear during extraction of a fetus if the length of the incision is not adequate.
7. Move a fetus to the incision by gently squeezing the uterine horn (Fig. 91-3*A*).
8. Grasp the fetus and gently remove it from the uterus.
9. Open the amniotic sac as the fetus is removed (Fig. 91-3*B*). Direct fetal fluids away from the operative field to minimize contamination.
10. Clamp and transect the umbilical vessels approximately 2 cm from the fetal abdominal wall (Fig. 91-3*C*).
11. Place the neonate on a sterile towel and pass it to an assistant. Alternatively, the neonate can be passed to the assistant before the umbilical vessels are transected, leaving this responsibility to nonsterile operating room assistants.
12. Remove the placenta by separating the placental attachment from the endometrium using gentle traction. To decrease the potential for severe postoperative uterine hemorrhage, do not remove the placenta if placental separation is difficult.
13. Extract the remaining fetuses by gently manipulating them toward the site of the uterine incision.
14. Palpate the uterus from the pelvic canal to the ovaries to make certain that no fetuses remain.
15. The uterus will contract rapidly after all fetuses have been removed and occasionally during extraction of the last few fetuses. Administration of oxytocin rarely is necessary to initiate uterine involution.
16. Close the uterus with 2-0 or 3-0 absorbable suture material in a one- or two-layer inverting suture pattern (e.g., Cushing and Lembert).

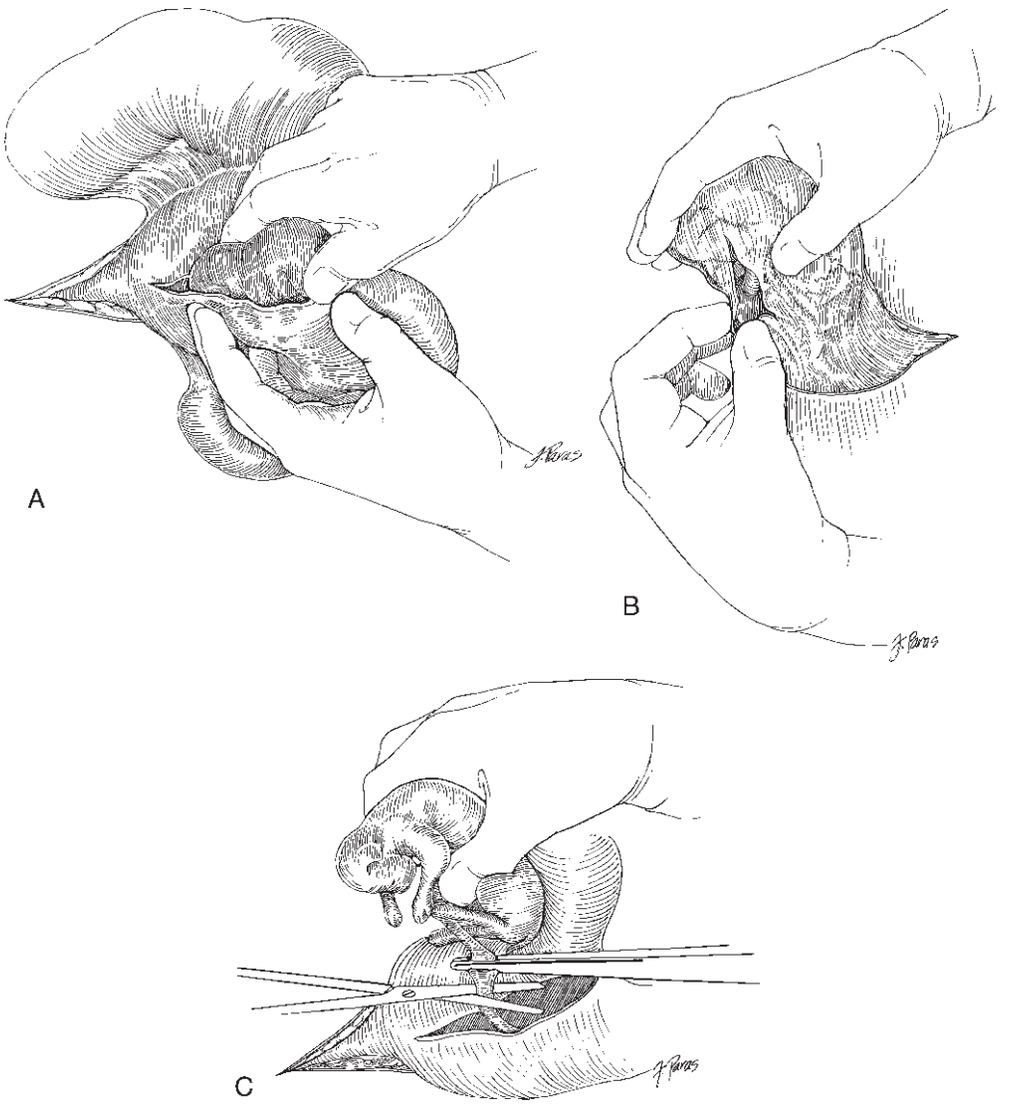

Figure 91-3. Cesarean section. *A,* Move the fetus toward the incision. *B,* Break the amniotic sac as the fetus is removed. *C,* Clamp and transect the umbilical vessels.

17. Locally lavage the uterus with warm physiologic saline solution prior to returning it to the abdominal cavity.
18. Lavage the abdominal cavity with warm physiologic saline solution and aspirate all lavage fluid if contamination or spillage of uterine contents occurred.

▼ ***Key Point*** En bloc ovariohysterectomy (rapid removal of the uterus and ovaries before hysterotomy and removal of the neonates) is associated with a neonatal survival rate that is similar to other techniques for medical and surgical management of dystocia.

Postoperative Care and Complications

Care of Neonates

▼ ***Key Point*** Remove the fetal membranes from the neonate's mouth and nose immediately after delivery.

- Clamp the umbilical vessels and remove the fetal membranes if this was not done by the surgeon.
- Clear mucus from the mouth and nares with gentle suction or cotton swabs.
- Assess the viability of the neonate. Neonates often are bradycardic and apneic.

- Dry the neonate briskly with a soft towel because skin stimulation reflexly stimulates respiration.
- Mucus can be cleared from the upper airway by grasping the neonate firmly and slowly swinging it downward.
- Administer a respiratory stimulant such as doxapram (Dopram, Robins), 0.5 to 2.0 mg/kg PO or IM, if the neonate does not respond to mechanical stimulation.
- Poor neonatal viability can be due to anesthetic agents administered to the dam for induction of anesthesia. Administer a narcotic antagonist such as naloxone (Narcan, Elkins-Sinn), 0.01 mg/kg PO or IM, if the dam was given a narcotic for induction of anesthesia.
- Alternately, medications can be given topically on the neonate's tongue to be absorbed through the mucous membranes.
- Some neonates may not breathe spontaneously for 30 to 60 minutes after delivery. Be persistent with resuscitation efforts. Neonates that do not breathe spontaneously can be intubated with a sterile puppy feeding tube for assisted ventilation.
- Place neonates in an environmental temperature of approximately 32°C.
- Examine neonates for congenital abnormalities such as cleft palate, imperforate anus, hernias, and limb deformities.

Care of the Dam

- Clean residual antiseptic solution, blood, and fetal fluids from the dam's mammary glands prior to allowing the neonates to nurse.
- Place the dam with neonates after anesthetic recovery so that neonates receive colostrum as soon as possible after birth.
- Make certain that the dam has adequate milk and that each neonate nurses.
  - Oxytocin (0.5 U/kg IM or SC) can be administered to stimulate milk letdown.

▼ ***Key Point*** Ovariohysterectomy performed in conjunction with cesarean section should not interfere with the dam's mothering instincts or ability to produce milk. Ovarian hormones are not important for maintenance of lactation.

- Consider discharging the dam and neonates as soon as the dam has recovered from anesthesia and has demonstrated appropriate behavior toward the neonates.

Complications

Short Term

- These include hemorrhage, hypovolemia, and hypothermia.
- Place the dam in a warm, quiet environment and administer intravenous crystalloid or colloid fluids as needed.

Long Term

- Potential long-term complications include peritonitis, wound dehiscence, agalactia, and uterine hemorrhage.
- Prolonged severe endometrial hemorrhage may require administration of oxytocin or, in nonresponsive cases, emergency ovariohysterectomy.
- Monitor serum calcium levels if hypocalcemia is suspected. See Chapter 32 for diagnosis and treatment of eclampsia.
- Although multiple cesarean sections can be performed on a dam, uterine scarring may prevent future placentation, and peritoneal adhesions may complicate subsequent celiotomies.

UTERINE PROLAPSE

Preoperative Considerations

- Uterine prolapse is a rare condition that can occur anytime during or up to several days after parturition.
- Animals presented with uterine prolapse may be clinically stable or may have mild to severe metabolic imbalances. Treat disturbances in fluid, electrolyte, or acid-base balance before managing the uterine prolapse.
- Assess the viability of the prolapsed uterus.
- Treatment options include manual reduction, manual reduction with immediate ovariohysterectomy, internal reduction via celiotomy, and amputation of the uterus externally.
- Manual reduction of the prolapsed uterus is the treatment of choice, although an episiotomy may be required.
- Ovariohysterectomy may be necessary after manual reduction if the uterus is devitalized.
- Consider external amputation only if the uterus cannot be reduced. Then remove ovaries through a celiotomy incision.

Manual Reduction

Technique

1. Epidural anesthesia is preferred, but standard general anesthesia can be used.
2. Clean the uterus and wrap it with sterile gauze sponges soaked in physiologic saline. Soaking the sponges with a hypertonic dextrose solution may help reduce swelling.
3. Apply sterile water-soluble lubricating jelly to the uterus and attempt gentle reduction with a gloved finger or with a sterile, smooth syringe case.
4. If manual reduction is unsuccessful, prepare the perineum and the prolapsed uterus for aseptic surgery and perform an episiotomy (see Chapter 93 for technique). Reduction is facilitated by episiotomy. If manual reduction still is not possible,

consider internal reduction via celiotomy or external amputation.

Surgical Procedure for External Amputation of Prolapsed Uterus

Objectives

- To resect the prolapsed uterine horns and, if possible, the ovaries
- To avoid contamination of the abdominal cavity
- To minimize uterine hemorrhage

Equipment

- Standard general surgical instrument pack

Technique

1. Administer epidural or general anesthesia.
2. Position the animal in dorsal recumbency with the rear limbs tied forward.
3. Prepare the ventral abdominal and perineal areas for aseptic surgery. Place a purse-string suture in the anus.
4. Incise the uterine body near the vulva. Place stay sutures in the incised proximal wall of the uterine body to prevent retraction into the vagina. Be careful not to damage the urethra if the vagina has prolapsed with the uterus.
5. Identify the uterine horns.
6. Apply gentle caudal traction on the uterine horns to expose the ovaries. Ligate the right and left OAVC.
7. If the ovaries cannot be exposed, place two circumferential ligatures around each uterine horn as far cranial as possible. Transect the uterine horns between the two ligatures.
8. Double-ligate and transect the uterine vessels.
9. Close the proximal stump of the uterine body with synthetic absorbable suture material in a simple interrupted pattern and reduce the remaining tissue into the abdomen.
10. If the ovaries remain, perform a ventral midline celiotomy and bilateral ovariectomy.

Postoperative Care and Complications

- Recurrence after successful manual reduction of a uterine prolapse is rare. However, warn owners that recurrence is possible with subsequent whelping, particularly if dystocia occurs.
- Complications seldom occur after manual reduction or external amputation of the uterus. Life-threatening hemorrhage can occur rarely after external amputation.

UTERINE BIOPSY

Uterine biopsy and culture is most commonly indicated in female patients of breeding age with a clinical history of reproductive failure or persistent vaginal discharge arising from the uterus. Uterine biopsy is performed for the purposes of diagnosis and prognosis.

Surgical Procedure for Uterine Biopsy

Objectives

- To obtain a full thickness tissue sample and culture sample from the uterus
- To minimize contamination of the peritoneal cavity

Equipment

- Standard general surgical instrument pack

Technique

1. Follow the surgical technique described under "Cesarean Section," steps 1 to 5, to expose the uterus.
2. Palpate the uterus for abnormalities such as mass lesions, cystic areas, or fluid accumulation.
3. Use a 4- to 6-mm skin biopsy punch to obtain a full thickness biopsy sample of either one of the uterine horns or the uterine body.
4. Insert a small sterile swab into the uterine lumen to obtain a sterile culture sample.
5. Close the biopsy site using 4-0 or 5-0 synthetic absorbable monofilament suture (Monocryl, PDS) in an interrupted or cruciate pattern.

▼ ***Key Point*** The submucosa is the holding layer of the uterus. Avoid placing suture material within the lumen of the uterus.

Chapter 92

Diseases of the Vagina and Vulva

Mary A. McLoughlin

Small animals with diseases of the vulva and vagina can present with clinical signs of lower urinary tract disease (urgency, pollakiuria, stranguria, and hematuria), intermittent or continuous urinary incontinence, vaginal discharge, perivulvar dermatitis, excessive licking, and foul odor. Because the vulva and the vestibule form a common orifice for the lower urinary and reproductive systems, careful examination of associated diseases is warranted. See Chapter 93 for discussion of the anatomy of the vagina and vulva.

DISEASES OF THE VULVA

Congenital Abnormalities

Congenital abnormalities of the vulva are uncommon and are often detected because of the secondary problems they cause. Abnormalities of the anatomic structure, size, or positioning of the vulva have been shown to be contributing factors to the development several disorders, including chronic or recurrent urinary tract infections, cystitis, vaginitis, vestibulitis, urine pooling or urinary incontinence, perivulvar dermatitis, and difficulty with natural mating. Diagnosis of vulvar disorders is made by physical examination of the vulva and perivulvar region, as well as digital palpation and vaginoscopy.

Vulvar Hypoplasia or "Juvenile" Vulva

Etiology

- Vulvar hypoplasia has been described as a small or infantile vulva, which is frequently retracted and obscured by the perivulvar skin folds. The patient's weight or body condition score should not bias the diagnosis of vulvar hypoplasia.
- The vulva should not be covered or obscured by regional skin folds dorsally or laterally. It should not be necessary to pull upward on the perineal skin between the anus and the vulva to expose the complete extent of the vulva.
- Tremendous variation in size, structure, and position of the vulva exists among various breeds of dogs, as well as within specific breed standards. The vulva should be located on the perineal midline directly ventral to the anus. Although the size of the vulva varies among dogs, it should be readily visible in the standing dog when viewed from behind. The vulva should not be positioned ventrally between the rear legs so that it is no longer visible.
- Perivulvar skin folds may obscure both hypoplastic and normal-sized vulvas. There are a number of breeds of dogs that appear to be conformationally predisposed to perivulvar skin folds as young dogs without being overweight, including Newfoundland, Labrador retriever, mastiff, German shepherd, Akita, basset hound, Staffordshire terrier, and bull terrier.
- It is well recognized that the anatomic characteristics of the vulva are altered due to the hormonal influence of the estrus cycle in unspayed females. The vulva becomes swollen and enlarged during proestrus and estrus. As the vulva enlarges, it is generally assumes a more dorsal position in the perineal region to facilitate mating.
- The size of the vulva generally does not change in spayed female dogs. It has been theorized that vulvar hypoplasia results from ovariohysterectomy at an early age prior to development of secondary sex characteristics. However, there is no scientific literature to support this statement.

Clinical Signs

- A small or hypoplastic vulva is common and frequently not associated with any clinical abnormalities. However if the vulva is small and recessed by the surrounding perivulvar skin folds, body heat and moisture from vaginal secretions or urine can accumulate between local skin folds, creating an environment conducive to skin maceration, inflammation, and bacterial overgrowth. Microtrauma to the skin surfaces from friction between the opposing skin folds, combined with tissue maceration and inflammation, causes normal skin defense mechanisms to be overwhelmed, allowing secondary bacterial infections to occur.

- Superficial dermatitis in the perivulvar region can result in a foul odor and discharge.
- Secondary clinical signs of chronic vestibulitis, vaginitis, cystitis, and ascending urinary tract infection have also been reported.

Treatment

- Medical management of perivulvar dermatitis with systemic antibiotics or topical therapies such as antimicrobials, antiseptic, cleansing, or drying agents can be performed (see Chapter 38). However, this approach is typically only palliative and often unrewarding for long-term resolution.
- Episioplasty, the surgical excision of the excessive perivulvar skin folds to expose and reposition a small or recessed vulva, is the treatment of choice for perivulvar dermatitis, chronic or recurrent urinary tract infections, or vestibulitis secondary to ascending infection or chronic local inflammation (see Chapter 54).

Vulvar Stenosis

Etiology

- Abnormal fusion of the genital folds and genital swellings can result in narrowing or stenosis of the vulva, vestibule, or vestibulovaginal junction.
- Vulvar stenosis has been most frequently reported in the collie and Shetland sheepdog breeds.

Clinical Signs

- There are frequently no clinical signs if the affected animal has been spayed.
- This abnormality may be overlooked unless the affected female is intended for breeding or a digital examination of the vulva, vestibule, and vestibulovaginal junction is indicated.
- Affected females may experience pain when mating is attempted, requiring the deposition of semen by artificial insemination.
- If pregnancy does occur, vulvar stenosis can result in dystocia. A planned cesarean section can be performed to avoid this complication, or an episiotomy can be performed at the time of delivery of the first fetus.

Treatment

- Enlargement of the vulvar orifice, rima vulvae, by permanent episiotomy (episiostomy) can be performed (see Chapter 93).
- Increasing the size of the vulvar orifice may result in an increased exposure of the vestibule, vagina, and lower urinary tract to ascending environmental contaminants, resulting in secondary vestibulitis, vaginitis, and urinary tract infection.

Clitoral Hypertrophy

The clitoris is located on the ventral floor of the vulva, normally recessed within the clitoral fossa. The clitoral fossa demarcates the cranial edge of the vulva at the transition of the vulva to the vestibule. The clitoris is described as the female homologue to the penis and may contain an os clitidoris.

Etiology

- Clitoral enlargement is typically associated with any one of a number of developmental or acquired etiologies, including disorders of sexual differentiation (see Chapter 90), exposure to anabolic steroids, or hyperadrenocorticism (see Chapter 33).
- Enlargement of the clitoris may result in exposure of the clitoris by its protrusion through the vulvar cleft.
- Clitoral enlargement has been documented in normal female dogs.

Clinical Signs

- The clinical signs associated with clitoral hypertrophy are variable. Animals may be presented for purely cosmetic reasons rather than specific health concerns.
- Enlargement of the clitoris and exposure through the vulvar cleft can result in clitoritis from environmental exposure, drying, and mechanical irritation.
- Inflammation of the clitoris can also result in secondary urinary tract infection, vestibulitis, or vaginitis with discharge due to drainage around the enlarged clitoris.

Treatment

- Symptomatic therapy with systemic antimicrobials, anti-inflammatory drugs, or local treatment with topical therapies is typically unrewarding for long-term resolution of clinical signs.
- Determination of an underlying etiology is essential to direct treatment at an inciting cause. Withdrawal of all anabolic steroids or treatment of hyperadrenocorticism may result in regression of the clitoral enlargement.

▼ ***Key Point*** Surgical treatment of clitoral hypertrophy is not indicated if a patient does not have any associated clinical signs.

- Perform clitoral resection for patients with persistent clinical signs associated with clitoral enlargement.

Surgical Procedure: Clitoral Resection

Technique

1. Perform an episiotomy to expose the clitoris and clitoral fossa. The external urethral orifice is identified and catheterized (see Chapter 93).

2. Dissect the base of the clitoris, which may include an os, from the fossa and surrounding vulvar and vestibular mucosa using sharp dissection.
3. Control hemorrhage with electrocautery or a laser. Larger "phalluses" present in dogs with intersex disorders may bleed profusely. Control of local hemorrhage is essential.
4. Close the incised edges of the vulvar and vestibular mucosa with a monofilament absorbable suture, eliminating the clitoral fossa.
5. Close the episiotomy in a routine manner (see Chapter 93).

Postoperative Care

- Place an Elizabethan collar to prevent self-trauma.
- Consider administration of nonsteroidal anti-inflammatory drugs after surgery for swelling, pain, and discomfort (see Chapter 6).

Vulvar Enlargement

Etiology

- Edema or swelling of the vulva is a normal response to estrogenic stimulation during the follicular stages of the estrus cycle in intact dogs and cats. Typically, vulvar swelling resolves on its own as the female enters diestrus.
- Persistent or prolonged swelling of the vulva in cycling females may represent prolonged estrogenic stimulation from cystic ovaries or an estrogen-producing ovarian neoplasm, such as a granulosa cell tumor (see Chapter 90).
- Vulvar swelling in a spayed female dog is also associated with estrogenic stimulation and may be a result from the presence of functional ovarian tissue after ovariohysterectomy (ovarian remnant syndrome; see Chapter 90).
  - Ovarian remnants are reported more frequently in cats than in dogs, with remnant ovarian tissue more frequently retained at the site of the right ovarian pedicle.

Clinical Signs

The vulvar lips appear edematous and turgid on physical examination. A serosanguineous discharge may be noted.

Diagnosis

- *Vaginal cytology:* Evidence of estrogenic stimulation. Smears should contain mostly superficial and anuclear squamous cells.
- *Hormonal evaluation:* Evaluation of serum concentrations of estradiol and progesterone may be warranted (see Chapter 90).
- *Abdominal ultrasound examination:* Cystic ovarian tissue, ovarian remnants, and ovarian neoplasia may be evident in the region of the ovaries at the caudal pole of either kidney.

Treatment

Exploratory laparotomy and biopsy: Direct identification, excision, and biopsy of a mass lesion in the region of either or both ovarian pedicles will definitively diagnose the presence of estrogen-secreting ovarian tissue and distinguish among ovarian remnant syndrome, neoplasia, and cystic ovaries (see Chapter 91). Surgical identification of ovarian remnants is easier if the exploratory is performed while the animal is in estrus.

Vulvar Trauma

Etiology. Injury to the vulva is relatively uncommon but can occur as a result of blunt or penetrating trauma, dog fights, injury during breeding, attempts to disrupt a mating, or difficulty whelping.

Diagnosis

- Evaluation of the injury requires a complete physical examination, digital vulvar and vestibular examination, episiotomy, or vaginoscopy.
- Complete examination of the vulva to determine the extent of the injury may require sedation or general anesthesia when the patient is stable.
- Placement of a urethral catheter and closed urinary collection system may be necessary with severe trauma or swelling of the vulvar or perivulvar region.

Treatment

- Standard care and treatment of local wounds is indicated. Flushing of the wounds and surgical debridement may be necessary (see Chapter 56).
- Primary closure or reconstruction of the vulva may be necessary to prevent narrowing or stenosis as a result of second-intention healing.
- Placement of a urinary catheter attached to a closed collection system will aid management of wounds in this location.

DISEASES OF THE VESTIBULE AND VAGINA

Congenital Abnormalities

Abnormalities in the embryologic development of the urogenital sinus may result in structural malformations affecting the vagina and vestibule, including vaginal septum, persistent hymen, septal remnants, or persistent paramesonephric remnant and vestibulovaginal stenosis. Any of these conditions may prohibit or prevent natural mating or may contribute to the susceptibility of the local environment to chronic or recur-

rent ascending infections of the urinary or reproductive tracts.

Persistent Hymen, Septal Remnants, Paramesonephric Remnants, and Vestibulovaginal Stenosis

Many names are currently being used to describe the persistent vertical bands of tissue located at the opening of the vestibulovaginal junction, including persistent hymen, septal remnants, paramesonephric remnants, and vaginal septum.

Etiology

- If the paramesonephric ducts fail to unite with each other or fail to fuse or cannulate with the urogenital sinus, it can result in a vertical septum or annular fibrous stricture at the vestibulovaginal opening.
- Incomplete fusion of the caudal paramesonephric ducts with retention of a medial partition results in an elongated vertical vaginal band, a vaginal septum, or rarely a bifid vagina.
- Vertical bands of tissue of varying width are commonly identified at the cingulum, which is the circular opening at the vestibulovaginal junction. These bands can be found in normal female dogs and those with developmental abnormalities of the lower urinary and reproductive tracts.
- Vertical bands of tissue at the cingulum of the vestibulovaginal junction are seen in almost all patients diagnosed with ureteral ectopia.
- Vertical or annular bands that narrow or partition the vestibulovaginal junction result in clinical signs associated with mating difficulties.

Clinical Signs

Clinical signs of chronic vaginitis, vestibulitis, vaginal discharge, urine pooling, chronic cystitis, or urinary tract infection have been attributed to narrowing of the vestibulovaginal junction in dogs. However, no cause and effect has been clearly identified.

Diagnosis

- A number of diagnostic techniques can be used to evaluate the vestibulovaginal anatomy, including digital vaginal examination, urogenital endoscopy, and positive-contrast retrograde vaginourethrography.
- *Digital examination* can be performed with the patient awake or sedated.
  - Diagnosis of a hymen or persistent septal remnant is made when two small openings are identified on either side of a centrally oriented band.
  - For female dogs with an annular or stenotic opening at the vestibulovaginal junction, digital penetration of the cranial vaginal vault is not possible. If vestibular or vaginal stenosis is of concern, the bitch should be evaluated under the effects of sedation during estrus, when this opening should be at it widest.
- *Rigid or flexible endoscopy* allows examination of the vestibule, vestibulovaginal junction, and cranial vaginal vault region. Fluid insufflation will provide an optically clear environment and provide distension of the local tissues to improve visualization.
  - Definitive diagnosis of a septum, septal remnant, or annular narrowing at the vestibulovaginal junction is made by endoscopic examination.
- *Positive-contrast retrograde vaginourethrography* has recently been advocated as a method to diagnosis vestibulovaginal stenosis in dogs. Controversy exists regarding the specific radiographic measurements necessary to accurately make this diagnosis. No effort has been made to correlate clinical signs and endoscopic and radiographic findings in female dogs with suspected vestibulovaginal stenosis.

Treatment

Persistent Hymen or Septal Remnant. Surgical correction of persistent vertical bands of tissue located at the vestibulovaginal junction is indicated in bitches with persistent clinical signs or failure to successfully breed or whelp.

▼ ***Key Point*** Surgical excision of the vertical band of tissue at the vestibulovaginal junction is not indicated in asymptomatic patients.

Surgical Procedure: Removal of Persistent Hymen or Septal Remnant

1. Thin and moderately thick bands of tissue can be easily removed using cupped biopsy forceps while examining the area through a rigid or flexible endoscope.
2. Grasp the band with the forceps at its base and separate it from its attachment along the vestibulovaginal junction.
3. Separate the tissue remnant from the opposite base of attachment and remove.
4. Remove thick or broad-based septa via a direct surgical approach using an episiotomy (see Chapter 93) or using a surgical laser.

Annular Bands or Vestibulovaginal Stenosis

Complete resection of an annular stricture at the vestibulovaginal junction and anastomosis of the remaining vagina and vestibule is an extremely difficult and time-consuming surgery. A short (<1.5 cm) narrowed region of the vagina or vestibulovaginal junction can be opened or widened using a vestibulovaginoplasty procedure (see Chapter 93).

Vaginal Edema (Vaginal Hyperplasia)

Etiology

An edematous thickening of the vaginal and vestibular mucosa occurs during the follicular phase of the estrous cycle. This broad-based mucosal proliferation originates cranial to the external urethral orifice.

Clinical Signs

- The proliferative vaginal tissues may protrude through the vulvar orifice as a smooth, fleshy mass. Exposure of the vaginal mucosa to the environment quickly results in drying, inflammation, congestion, edema, ulceration, and potential necrosis.
- Vaginal edema is most commonly recognized in young female dogs during their first estrus cycle. It is reported with an increased frequency in several breeds, including bulldogs, boxers, and Labrador retrievers.
- The edematous tissue will spontaneously regress during diestrus. Affected females may experience recurrence of the condition with each successive estrus cycle.

Diagnosis

- Determine recent history and physical examination findings of estrus.
- Digital examination of the vulva and vestibule and vaginoscopy reveals a broad-based mass arising from the cranial vaginal vault. The external urethral orifice is caudal to the base of the protruding mass.
- Differentiate vaginal edema from benign or malignant neoplasia of the vestibule or vagina. If vaginal neoplasia is suspected, obtain tissue samples for histopathology.

Treatment

- Ovariohysterectomy is the surgical treatment of choice and appropriate for females that were not intended for breeding purposes (see Chapter 91).
- Attempts can be made to reduce the edema of the exposed tissues by applying gentle manual compression and topical application of a hyperosmotic solution such as 50% dextrose. As the edema subsides, attempts can be made to reduce the exposed tissues through the vulvar orifice into the vestibule.
- If the proliferative vaginal tissue cannot be reduced, it must be kept moist and well lubricated until it regresses following the spay procedure. It is essential that the patient be fitted with an Elizabethan collar or cage muzzle to prevent self-trauma.
- Vaginal edema in dogs intended for breeding poses a number of issues to consider.
  - The heritable nature of this disorder is unknown.
  - Although breeding can be accomplished via artificial insemination, the protruding mucosa must be managed until it regresses during diestrus.
  - As the concentration of progesterone decreases at the end of diestrus, with impending whelping, recurrence of the vaginal edema can occur.
  - If the redundant vaginal tissue remains regressed, ability to whelp should not be affected. It is unknown whether affected bitches may be predisposed to vaginal prolapse.
- Surgical treatment of vaginal edema should only be considered in patients with devitalized or necrotic tissues. Surgical treatment involves resection of the redundant mucosa (see Chapter 93).

▼ ***Key Point*** Surgical resection of redundant vaginal mucosa does not prevent reoccurrence of vaginal edema at the next estrus cycle.

Vaginal Prolapse

Etiology

- Vaginal prolapse is relatively uncommon in small animals and should not be confused with vaginal edema. Like vaginal edema, vaginal prolapse is also recognized during the estrus phase of the reproductive cycle or periods of hyperestrogenism.
- Complete or partial vaginal prolapses can occur. If the cervix protrudes from the vulva, a complete vaginal prolapse has occurred.
- The underlying etiology remains unknown in most cases.
- Brachycephalic breeds including Boston terrier and boxer appear to have an increased predisposition compared with other breeds of dogs for the development of vaginal prolapse.
- Vaginal prolapse can result from dystocia.

Clinical Signs

- The animal presents with a protrusion of the complete vaginal circumference including the external urethral orifice, which is positioned ventrally.
- Swelling and protrusion of the vaginal mucosa rapidly results in venous congestion and discoloration of the tissues with a “doughnut” appearance. These tissues are friable and ulcerate readily.

Diagnosis

- Physical examination reveals a tubular or doughnut-shaped structure protruding from the vulva.
- Differential diagnoses are vaginal edema or vaginal neoplasia.
  - Differentiate vaginal prolapse from these other lesions by passing a sterile probe between the mass and the vaginal wall. Whereas with a tumor or edema the probe will travel well into the vagina without obstruction, with vaginal prolapse the probe will hit a blind “pouch” and not be able to penetrate further.

Treatment

- A mild or partial prolapse may resolve during diestrus.
- Keep exposed tissues clean, moist, and lubricated.
- If possible, manually reduce the exposed tissues to a more normal anatomic position.
- If necessary, apply a hyperosmotic solution such as 50% dextrose to the exposed tissue after cleaning to assist in reducing some of the edema.
- Episiotomy may also aid the manual reduction of the displaced vaginal tissues.
- If manual reduction is successful, a sterile, balloon-tipped catheter should be placed through the urethra into the bladder and attached to a closed urinary collection system.
- The labia of the vulva can be sutured closed using a non-absorbable monofilament suture until the swelling resolves.
- Perform ovariohysterectomy in females that are not intended for breeding purposes (see Chapter 91). Owners wanting to salvage a potential breeding female should be counseled that the heritable nature of this trait is unknown and that reoccurrence is possible.
- Surgical pexy of the uterine body or horns to the dorsolateral body wall can be performed to help prevent future prolapse in a breeding female. Objective evaluation of uterine pexy on future reproduction status is unknown.
- Severe or devitalized vaginal prolapse may present as an acute or chronic condition with congestion, ulceration, infection, and necrosis of the affected tissues.
  - Attempts at reduction and replacement of the devitalized tissues are contraindicated. Evaluate the patient for systemic infection.
  - Surgical resection of devitalized tissue may be necessary on an emergency basis (see Chapter 93).
  - Reevaluate the surgical site via digital vaginal examination at 2 weeks and again before the next estrus cycle to evaluate continuity of healing and to be sure that a stricture has not occurred.

Neoplasia of Vagina, Vestibule, and Vulva

The most common neoplasms of the vulva, vestibule, and vagina are benign and include leiomyoma, fibromas, and lipoma. The most common malignant neoplasms of this region include leiomyosarcoma, squamous cell carcinoma, adenocarcinoma, mast cell tumor, and transmissible venereal tumor (TVT).

Benign Neoplasia

Etiology

Leiomyoma

- Leiomyoma is the most frequently reported neoplasm affecting the cervix, vagina, or vestibule arising from the smooth muscle of these structures.
- Leiomyomas can be intraluminal or extraluminal.
  - Intraluminal leiomyomas appear as a smooth fleshy mass pedunculated on a stalk arising from the vestibular wall.
- When the initial mass is small, it may go unnoticed for an extended period of time as it is contained within the vestibule. The tumor may remain unnoticed until it is large enough to protrude through the vulvar cleft.
  - Extraluminal leiomyomas arise from the wall of the vestibule or vagina and may expand into the perineal space. Extraluminal leiomyomas may present because of perineal swelling or impingement on surrounding structures such as the rectum. Complete surgical resection is typically curative. Local recurrence can be a problem if surgical resection is incomplete.

Lipoma

Benign fatty masses located in the perineal region, vagina, or vestibule can occur but are less common than leiomyoma.

Clinical Signs

- Clinical signs are extremely variable and are dependent on the location and size of the mass.
- Signs may range from none to perineal swelling, vaginal discharge, mass protrusion through the vulvar cleft, bloody vaginal discharge or hematuria, excessive licking, foul odor, constipation, dysuria, or dystocia.

Diagnosis

- Most vestibular or vaginal masses are diagnosed by examination of the vulva, digital examination of the vagina and rectum, or vaginoscopy.
- Although vaginal cytology is not typically helpful to obtain a specific diagnosis of the mass lesion, fine-needle aspiration of the mass itself may provide cytologic information for diagnosis.
- Incisional biopsy samples may be obtained surgically using a local anesthetic if the mass is assessable.
- Biopsy samples may be obtained from a mass that cannot be exteriorized (within the vestibule or vagina) using a biopsy instrument with a rigid or flexible endoscope.

Treatment

- Complete surgical resection is the treatment of choice for benign masses located within the vestibule and vagina (see Chapter 93).
- Extremely large masses may require complete vulvovaginectomy and urinary diversion for complete excision. Refer these patients to a surgical specialist.
- Consider ovariohysterectomy as an adjunct surgical treatment for all vestibular and vaginal tumors (see Chapter 91).

Malignant Neoplasia

Etiology

Leiomyosarcoma

- Leiomyosarcoma is the most common malignant tumor affecting the vestibule and vagina. Other malignant tumors that have been reported affecting the vulva, vestibule, or vagina include squamous cell carcinoma, adenocarcinoma, mast cell tumor, hemangiosarcoma, and hemangiopericytoma.
- It may be difficult to distinguish between benign and malignant neoplasia in this region without biopsy results.

Transmissible Venereal Tumor

- Canine TVT is a proliferative tumor of the vulva, vestibule, or vagina that is transmitted by sexual or social contact between animals. Cells of this tumor directly transplant, resulting in proliferative or cauliflower-like lesions (see Chapters 30 and 88).
- TVT is noted in younger sexually active male and female dogs, often in crowded urban areas.
- Metastasis is rare but can occur in the regional lymph node.

Clinical Signs

- TVT may present as a solitary lesion or as multiple friable, hemorrhagic, or cauliflower-like lesions.
- Extragenital sites include oral and nasal mucosa, skin, and perineum.

Diagnosis

See the previous discussion under "Benign Neoplasia" of the vagina.

Treatment

- Staging of the patient prior to surgery is essential.
- Complete surgical resection of malignant tumors with adequate margins is the treatment of choice.
- Complete resection of malignant masses in this region may require vulvovaginectomy and urinary diversion. Refer the animal to a surgical specialist.
- Small, isolated lesions can be removed surgically. Large or multiple lesions can be treated with radiation therapy or chemotherapy.
  - Chemotherapy is the treatment of choice for multiple or metastatic TVT. Either a single-agent or a combination protocol is effective in controlling this tumor (see Chapters 30 and 88).

▼ ***Key Point*** Vincristine is highly effective for the treatment of TVT.

Vaginitis

Etiology

Juvenile Vaginitis

Inflammation of the vestibule and vagina can occur in female dogs prior to their first estrus cycle (generally less than 1 year of age). The cause of the inflammation is nonspecific and usually resolves without treatment after the first estrus cycle. This type of vaginitis is not a result of bacterial overgrowth.

Bacterial Vaginitis

Bacterial infection of the vagina or vestibule is uncommon as a primary disorder in small animals. The vagina contains a mixed population of bacteria considered normal flora, including *Staphylococcus aureus, Streptococcus, Escherichia coli, Pasteurella, Klebsiella, Mycoplasma,* and *Ureaplasma.* Bacterial vaginitis typically occurs secondary to diseases of the lower urinary system, reproductive system, neoplasia, clitoral hypertrophy, and trauma.

Viral Vaginitis

- In addition to causing fatal infections in newborn puppies, canine herpesvirus infection causes vesicular mucosal lesions in the vagina and vestibule of affected females (see Chapter 16).
- These vesicular lesions are usually transient but often recur during proestrus.
- The raised mucosal lesions identified with canine herpesvirus can look similar to the more commonly diagnosed lymphoid hyperplasia in the vestibule, which occurs secondary to inflammation or bacterial infections associated with either the genital or the urinary system.
- Canine herpesvirus infection can result in infertility, abortion, and neonatal death.

Diagnosis

- *Physical examination:* Perform a complete examination of the external genitalia and surrounding perivulvar region. Determine vulvar size, position, and degree of recession by surrounding skin folds. Carefully examine the perivulvar region for ulceration, maceration, or hyperpigmentation commonly seen with perivulvar skin fold dermatitis.
- *Digital examination of the vulva and vestibule:* Examine for any underlying anatomic abnormalities such as vulvar or vestibular stenosis, presence of a vaginal septum, or septal remnant. Digital examination may reveal mass lesions within the vagina or vestibule that are not visible.
- *Vaginal cytology:* Microscopic examination of exfoliated cells from the vaginal vault will aid in differen-

tiating vaginitis from a vaginal discharge associated with any one of the stages of the estrus cycle. Examination of the vaginal cytology will also determine the general type and number of bacteria and the characterization of neutrophils and other cell types.

- *Urinalysis:* Obtain a urine sample by cystocentesis for urinalysis and aerobic bacteriologic culture of the urine to rule out urinary pathogens as a predisposing or secondary cause of the vaginitis.
- *Endoscopic examination of the vestibule, vagina, and lower urinary tract:* Rigid or flexible endoscopy will confirm the presence of suspected anatomic abnormalities or mass lesions and will permit biopsy.
- *Bacteriologic culture and susceptibility testing*
- *Abdominal ultrasound:* Completely evaluate the urinary and reproductive organs within the abdominal cavity.

Treatment

Juvenile Vaginitis

- This disorder is self-limiting and will resolve after the first estrus; therefore, no treatment is indicated.
- Systemic or local symptomatic treatment typically does not cause resolution of the clinical signs.
- Be sure to examine the external anatomy of the vulva to rule out perivulvar skin folds as a possible underlying cause, even in a young female.
- If the vaginitis persists after the first estrus, further diagnostic evaluation as described above is warranted.

Bacterial Vaginitis

- Identify and treat the underlying primary genital or urinary abnormality, including correction of developmental abnormalities and excision of mass lesions within the vagina, vestibule, clitoral fossa, and vulva.
- Secondary bacterial vaginitis commonly resolves with no therapy or medical treatment once the underlying cause is resolved or eliminated.
- Medical treatment consists of appropriate antibiotics based on results of culture and sensitivity testing.
- In dogs, trimethoprim-sulfonamide, erythromycin, norfloxacin, and ciprofloxacin have been shown to achieve concentrations in the urethra and vaginal secretions several times higher than the minimal inhibitory concentration against common urinary pathogens.

Viral Vaginitis

- No specific therapy is currently available to treat canine herpesvirus infections in affected bitches.
- Symptoms can be transient and commonly recurrent.
- Isolate affected females and counsel breeders not to use affected individuals in the breeding program.
- See Chapter 16 for more information on prevention of transmission of canine herpesvirus.

Chapter 93

Surgery of the Vagina and Vulva

Gretchen K. Sicard / Roger B. Fingland

The surgical procedures performed most commonly on the vagina and vulva are episiotomy, episioplasty, and excision of devitalized hyperplastic vaginal tissue. Episiotomy is performed to increase exposure for excision of vaginal or vestibular masses. Vaginal neoplasia is uncommon, and the majority of vaginal tumors are benign. Vaginal edema (previously referred to as vaginal hyperplasia) and vaginal prolapse occur only in intact females during estrus. Diseases of the external genitalia that require surgical intervention are rare in neutered females. See Chapter 92 for discussion of diseases of the vagina and vulva.

ANATOMY

Vagina

- The vagina is a musculomembranous distensible canal that extends from the uterus to the vulva.
- The caudal boundary of the vagina is located cranial to the urethral opening, a point demarcated from the vestibule by a transverse mucosal ridge. A hymen normally is not present at the vestibulovaginal junction in the adult, although a vestige is retained in some females.
- The vagina is quite long in dogs, necessitating episiotomy for adequate surgical exposure. Caudal abdominal celiotomy may be necessary to gain surgical exposure to the cranial aspect of the vagina.
- The longitudinal folds (rugae) of the vaginal mucosa allow significant expansion in diameter during pregnancy and whelping.
- The dorsal median postcervical fold extends from the cervix and terminates caudally by blending with longitudinal folds of vaginal mucosa. This fold can be mistaken for the cervical os during vaginoscopy.
- Blood supply to the vagina is via the vaginal artery, a branch of the urogenital artery.

Vulva

The vulva (external genitalia) consists of three parts:

- The *vestibule* is the space between the vagina and the labia.
  - The urethral tubercle (papilla), a ridgelike projection on the ventral floor of the vestibule caudal to the vestibulovaginal junction, contains the external urethral orifice.
  - The vestibulovaginal junction is readily identified because the vestibular mucosa is smooth, unlike the vaginal mucosa, which is thrown into distinct ridges.
- The *labia* form the external boundary of the vulva.
  - The right and left labia join dorsally and ventrally at the commissures.
  - The labia open to form the vulvar cleft.
- The *clitoris* is the homologue of the penis.
  - The clitoris normally does not contain structures comparable to the os penis or the urethra of the male.
  - An os clitoris may develop in response to altered hormone balance.
- The vulva is surrounded by two striated circular muscles.
- The constrictor vestibule muscle fuses along its caudal surface to the external anal sphincter.
- The thinner constrictor vulvae muscle lies immediately caudal to the constrictor vestibule muscle.
- Blood supply to the vestibule, labia, and clitoris is via branches of the urogenital arteries and the internal and external pudendal arteries.

EPISIOTOMY

Indications

- Resect benign or malignant vaginal masses.
- Reduce a vaginal prolapse.
- Resect or revise vaginal strictures.
- Manage dystocia resulting from vulvar or vestibular stenosis.
- Suture vaginal lacerations.
- Expose the urethral papilla for catheterization or surgery.

Surgical Procedure

Objective

- Temporarily enlarge the vulvar cleft to enhance exposure of the vestibule and vagina.

Equipment

- Standard general surgery instrument pack and suture
- Gelpi or Weitlaner retractor
- Sterile Foley catheter

Technique

1. Episiotomy can be performed under general, epidural, or local anesthesia.
2. Position the dog in ventral recumbency, preferably in a perineal stand or an end of the surgical table that is elevated to raise the hindquarters.

▼ ***Key Point*** To avoid femoral nerve palsy, make certain the edge of the table is well padded when placing animals in the perineal position.

3. Place a purse-string suture in the anus and fix the tail in an upright and forward position.
4. Prepare the perineal region for aseptic surgery.
5. Flush the vestibule and vagina with dilute antiseptic solution (e.g., chlorhexidine).
6. Place a Foley catheter in the urinary bladder using sterile technique.
7. Place surgical drapes so that the vulvar cleft and dorsal commissure are exposed. Exclude the anus from the surgical field.
8. Insert a finger in the vestibule and identify the caudodorsal aspect of the vaginal canal. This point represents the dorsal extent of the episiotomy incision (Fig. 93-1*A*).
9. Make a median skin incision, beginning at the point described above and extending ventrally to include the dorsal commissure of the vulvar cleft (Fig. 93-1*B*).
10. Using Metzenbaum scissors, complete the episiotomy by incising the muscular layer and the mucosa in the same plane as the skin incision (Fig. 93-1*C*).
11. Complete the procedure for which the episiotomy was performed (Fig. 93-1*D*).
12. Close the incision in three layers (Fig. 93-1*E*).
    a. Appose the mucosal edges with 3-0 absorbable suture material in a simple continuous pattern with knots exposed to the lumen.
    b. Appose the muscular layer and subcutaneous tissue together with 3-0 absorbable suture material in a simple continuous pattern.
    c. Appose the skin edges with 4-0 absorbable suture material, using a continuous intradermal suture pattern.
13. Remove the purse-string suture from the anus.

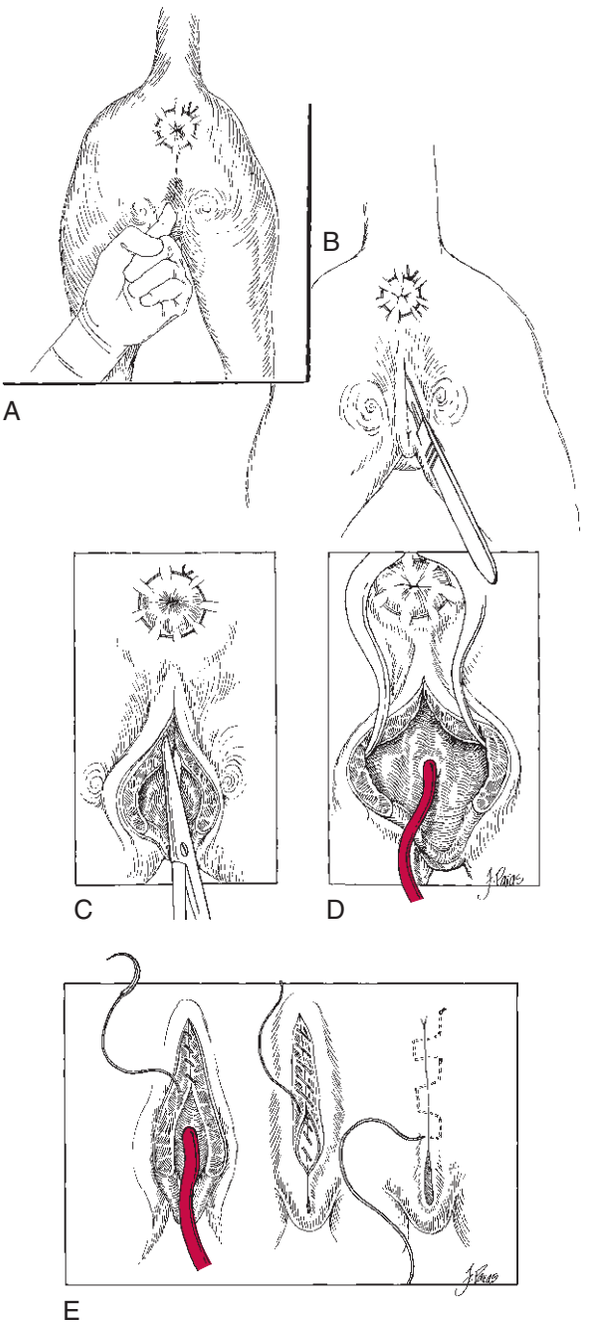

Figure 93-1. Episiotomy. *A,* After purse-string suture is placed around the anus, insert a finger in the vestibule to identify the caudodorsal aspect of the vaginal canal. *B,* Incise from the caudodorsal aspect of the vaginal canal to the dorsal commissure of the vulvar cleft. *C,* Extend the depth of the incision with Metzenbaum scissors. *D,* Complete the procedure for which episiotomy is needed (in this case, bladder catheterization). *E,* Close in three layers.

Postoperative Care and Complications

- Administer postoperative analgesics (see Chapter 6).
- An Elizabethan collar may be necessary to prevent self-trauma.
- Clean the incision if it becomes soiled.
- Postoperative complications are uncommon and usually are related to poor surgical technique (e.g., carrying the incision too far dorsally or improper suture placement).

EPISIOPLASTY

Preoperative Considerations

- Episioplasty is indicated for dogs with chronic perivulvar pyoderma resulting from redundant perivulvar skin and a recessed vulva.
- Episioplasty may also decrease the incidence chronic or recurrent urinary tract infections and urinary incontinence in dogs with a recessed vulva.

▼ ***Key Point*** Redundant perivulvar skin and recessed vulva may be associated with recurrent urinary tract infection in dogs. Episioplasty has been shown to decrease the recurrence rate of urinary infection in these dogs.

- Manage severe perivulvar pyoderma medically before performing episioplasty (see Chapter 38). Administer systemic antibiotics based on culture and susceptibility testing.

Surgical Procedure

See Chapter 54.

VAGINAL SEPTUM, SEPTAL REMNANTS, AND VESTIBULOVAGINAL STENOSIS EXCISION

Preoperative Considerations

- A number of congenital abnormalities that obstruct or constrict the vestibulovaginal opening occur in animals. Incomplete perforation of the hymen in dogs usually is observed as a vertical band of tissue of varying width or an annular fibrous narrowing at the vestibulovaginal junction.

▼ ***Key Point*** Most animals with these persistent bands of tissue are asymptomatic, requiring no treatment.

- Symptomatic animals usually present for breeding or whelping problems. Vaginal septa or septal remnants may be associated with chronic vaginitis, recurrent urinary tract infections, and urinary incontinence resulting from inadequate drainage of vaginal or uterine secretions or urine pooling. Positional incontinence occasionally is observed in animals that pool urine.
- Diagnosis of a vaginal septum, septal remnants, or vestibulovaginal stenosis can be made based on digital vaginal examination and confirmed with vaginoscopy.
- Perform endoscopic examination of the vestibule, vagina, and lower urinary system in patients with chronic vaginitis, recurrent urinary tract infections, or urinary incontinence to rule out other congenital or anatomic abnormalities.
- Vaginal septa or septal remnants are palpated as firm central bands with small stoma on either side.
- If the ostium or opening between the vestibule and the cranial vaginal vault does not allow penetration of the finger on digital examination, consider a diagnosis of annular constriction or vestibulovaginal stenosis. Evaluate patients with suspected vestibulovaginal stenosis under sedation or general anesthesia during estrus when the diameter of the ostium should be at its greatest.
- Retrograde contrast radiography of the vestibule and vagina can be helpful in diagnosing some of the congenital vestibular and vaginal abnormalities. However, it may not provide an accurate method to measure the relative size of the vestibulovaginal junction.

Surgical Procedure

Objective

- Excise the septal remnant or annular constriction.

Equipment

- Standard general surgery instrument pack and suture
- Gelpi or Weitlaner retractor
- Sterile Foley catheter

Technique

1. Perform an episiotomy, as described previously.
2. Expose the vestibulovaginal junction and place a self-retaining retractor.
3. Place a Foley catheter in the urethra to avoid inadvertent damage to the urethral papilla.
4. Identify and excise the vertical band of tissue.
   a. *Vertical band:* Place a curved instrument cranial to the band and retract the band caudally. Superficially transect the band at the dorsal and ventral attachments. Close the mucosal defects with 4-0 absorbable suture material in a simple continuous pattern.
   b. *Annular constriction:* Circumferentially excise thin membranes at the mucosal attachment. When submucosal fibrous tissue exists, make a circumferential incision in the mucosa adjacent to the membrane and submucosally dissect and excise the fibrous tissue band. Close the mucosal defect with 4-0 absorbable suture material in a simple interrupted pattern. Alternatively, suture the mucosal defect with short runs of a simple continuous pattern.

▼ ***Key Point*** Rarely, dogs have both a vertical band and annular constriction. Evaluate the diameter of the vaginal opening after a vertical band resection. Resection of an annular constriction is unlikely to be necessary.

▼ ***Key Point*** Diagnosis of vestibulovaginal stenosis is uncommon. Manual or mechanical dilation of the narrowed ostium is typically unsuccessful.

5. Close the episiotomy incision, as described previously.
6. Remove the purse-string suture from the anus.

Postoperative Care and Complications

- An Elizabethan collar may be necessary to prevent self-trauma.
- Excision of persistent hymen often is curative.
- Rarely, dogs may require intermittent digital dilation to prevent fibrous narrowing after excision of annular constrictions. Permanent stenosis is possible in animals with this complication.

VAGINAL EDEMA (VAGINAL HYPERPLASIA) EXCISION

Preoperative Considerations

- Refer to Chapter 92 for additional information on this condition.
- Application of a petroleum-based ointment or temporary labial closure with horizontal mattress sutures may provide temporary relief of the hyperplasia. Exposed vaginal mucosa is susceptible to trauma, desiccation, ulceration, and inflammation. Resection of the redundant mucosa may be necessary in severe cases if the mucosal tissues become devitalized. Warn owners of breeding bitches that recurrence may occur during subsequent heat cycles in spite of resection.
- Resection of redundant vaginal mucosa should be reserved for patients with traumatized or devitalized tissue.

▼ ***Key Point*** Ovariohysterectomy prevents recurrence and can be used as the sole means of treatment if the vaginal edema and prolapse is small and not devitalized.

Surgical Procedure

Objectives

- Excise redundant vaginal mucosa.
- Excise or biopsy vaginal tumors (e.g., fibroma, polyp, and leiomyoma).

Equipment

- See under "Episiotomy."

Technique

1. Perform an episiotomy, as described previously in this Chapter (Fig. 93-2*A* and *B*).
2. Identify the margins of the redundant mucosa on the floor of the vagina.
3. Elevate the *mucosal* mass and identify the urethral papilla on the floor of the vagina caudal to the mass (Fig. 93-2*C*).

▼ ***Key Point*** Catheterize the urethra with a Foley catheter before excising the mucosal mass.

4. Make an elliptical superficial incision around the base of the mucosal mass.
5. Excise the mucosal mass. Use electrocoagulation to control bleeding submucosal vessels. Do not extend the excision deeper than the mucosa.
6. Suture the mucosal defect with 3-0 absorbable suture material in a simple continuous pattern (Fig. 93-2*D*).
7. Close the episiotomy incision, as described previously.
8. Remove the purse-string suture from the anus.

Postoperative Care and Considerations

- Administer postoperative analgesics (see Chapter 6).
- An Elizabethan collar may be necessary to prevent self-trauma.

VAGINAL PROLAPSE EXCISION

Preoperative Considerations

- Refer to Chapter 92 for additional information on this condition.
- Vaginal prolapse may be partial or complete. Prolapse of the complete vaginal circumference through the labia results in the appearance of a doughnut-shaped mass ventral to the anus. This is in contrast to vaginal edema, in which redundant mucosa arises from the ventral aspect of the vagina. The urethral papilla may be observed on the prolapsed vaginal mucosa.
- Vaginal prolapse is significantly less common than vaginal edema. Brachycephalic breeds are more predisposed to vaginal prolapse.
- Venous congestion can result in engorgement and discoloration of the prolapsed vaginal mucosa.
- Desiccation and self-trauma lead to ulceration and infection of the mass.
- After a thorough cleaning, coat the mass with sterile lubricating jelly and gently replace the mass with a finger or appropriately sized syringe case. Place temporary non-absorbable sutures (mattress pattern) across the vulva if the vagina tends to reprolapse.
- Consider general anesthesia followed by episiotomy if the prolapse cannot be replaced digitally in the awake dog. Manual replacement still may not be possible if a large part of the vagina is prolapsed or if there is extensive mucosal edema.

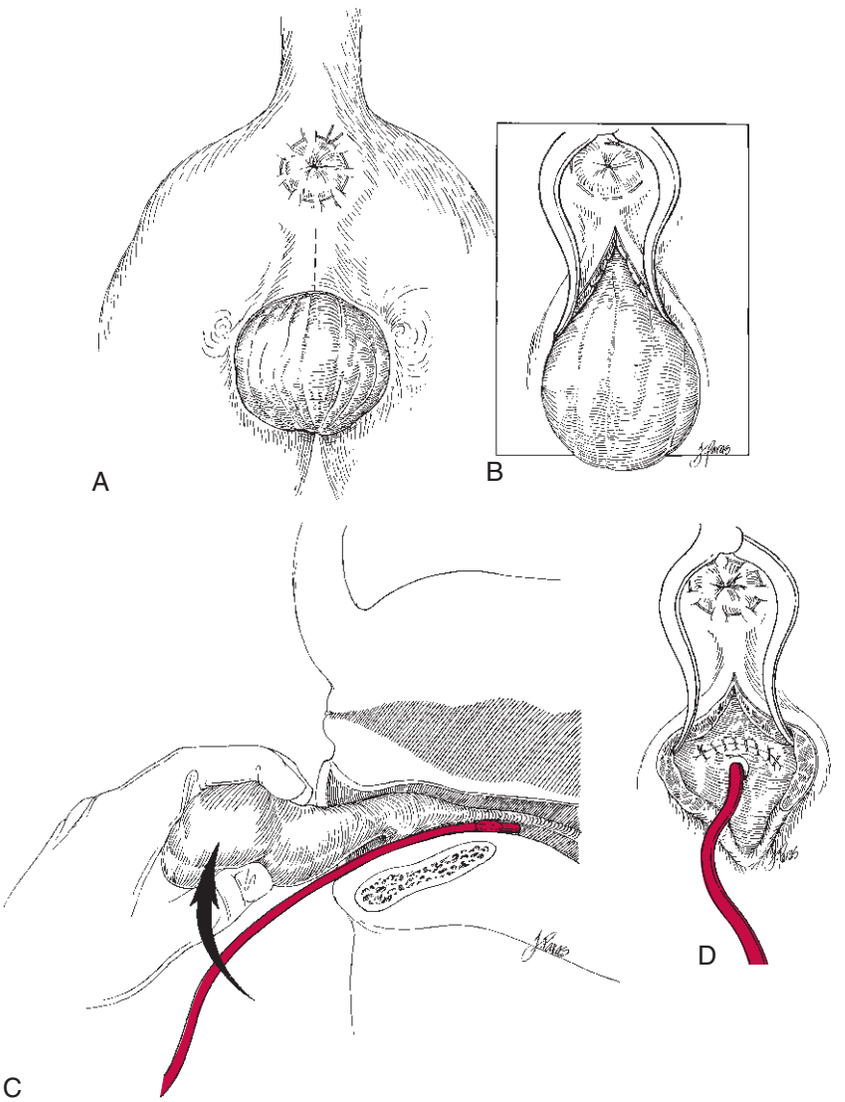

Figure 93-2. Excision of vaginal edema. *A,* Perform episiotomy as described previously. *B,* Retract the skin to expose hyperplastic tissue. *C,* Elevate the mass and identify the urethral papilla. *D,* Suture the mucosal defect in a simple continuous pattern (avoid penetrating the urethra).

- Consider repositioning by cranial traction on the uterine body through a ventral midline celiotomy when repositioning via the vulvar approach is unsuccessful and the mucosa is healthy. Perform permanent hysteropexy by suturing the uterine body or horns to the abdominal wall. Alternatively, perform ovariohysterectomy (see Chapter 91).
- Excise the prolapsed portion of the vagina when repositioning is not possible because of extensive venous engorgement or ulceration and necrosis of the vaginal mucosa.
- As in vaginal edema, ovariohysterectomy will eliminate recurrence.

Surgical Procedure

Objective

- Excise the prolapsed portion of the vagina.

Equipment

- Standard general surgery instrument pack and suture
- Sterile Foley catheter

Technique

1. Position the dog in dorsal recumbency with the rear legs tied forward (Fig. 93-3*A*).

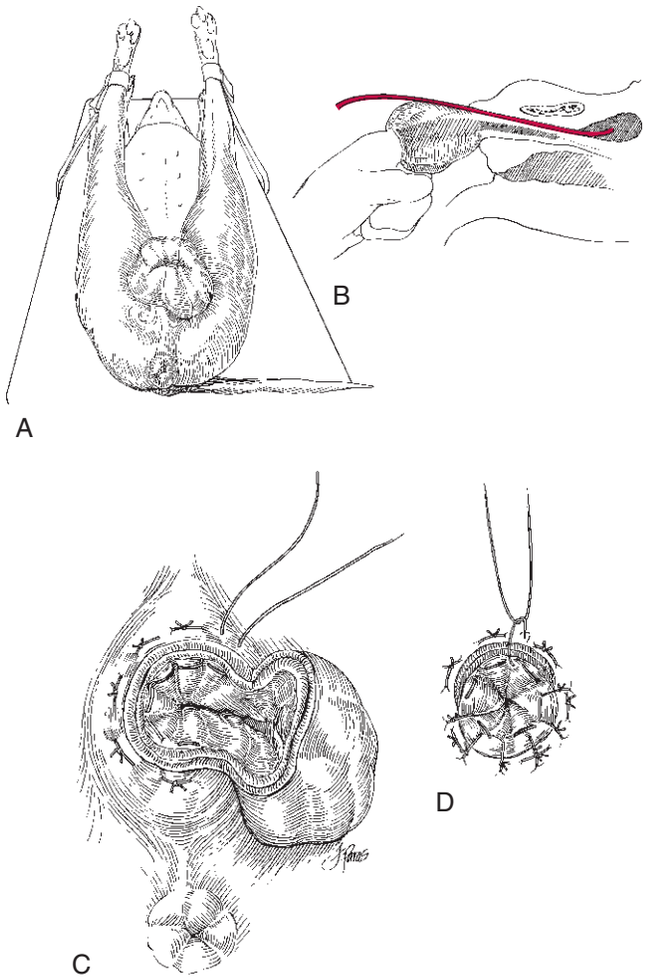

Figure 93-3. Correction of vaginal prolapse. *A,* Position the dog in dorsal recumbency. *B,* Insert an index finger or sterile syringe case into the prolapsed opening to identify the inner mucosal layer. *C,* Incise and suture the edges remaining after the prolapsed tissue is excised. *D,* Suture together the cut edges.

2. Place a purse-string suture in the anus.
3. Gently clean the prolapsed vagina. Prepare the perineal region for aseptic surgery.

▼ ***Key Point*** Perform an episiotomy only if necessary to expose the base of the prolapsed vaginal tissue.

4. Identify the urethral papilla and place a Foley catheter in the urethra.
5. Identify the proposed line of excision at the base of the prolapsed portion of the vagina. Identify the urethra by palpating the Foley catheter through the vaginal wall.
6. Incise the outer mucosal layer for approximately 4 cm along the proposed line of excision. Dissect through all layers of the vaginal wall to the inner mucosal layer. Insert an index finger or sterile syringe case into the prolapsed vaginal opening to identify the inner mucosal layer (Fig. 93-3*B*). Carefully incise the inner mucosal layer, exposing the finger or syringe case.
7. Control hemorrhage with electrocoagulation or ligation.
8. Using 2-0 absorbable suture material, place horizontal mattress sutures in the vaginal wall between the mucosal surfaces, approximately 5 mm from the cut edge.
9. Continue this incision-suture technique in approximately 4-cm increments until the prolapsed tissue is excised (Fig. 93-3*C*).
10. Appose the cut edges of the inner and outer mucosal layers with 4-0 absorbable suture material in either a simple interrupted pattern or short runs of a simple continuous pattern (Fig. 93-3*D*).
11. Remove the purse-string suture from the anus.

Postoperative Care and Complications

- An Elizabethan collar may be necessary to prevent self-trauma.
- Mild vaginal bleeding may occur for 24 to 48 hours after surgery.
- Future breeding and whelping will not be impaired by this procedure. However, breeding of females prone to vaginal prolapse is ill advised because the condition may be heritable.
- If labial sutures are placed, make certain that the animal is able to urinate spontaneously after surgery. Swelling around the urethral papilla may necessitate catheterization for several days after surgery.

Chapter

94 Infertility and Breeding Disorders

Robert V. Hutchison

FEMALE DOG

Realizing the uniqueness of the reproductive system is essential when dealing with canine infertility. Unlike other domestic species, the bitch ovulates into a progesterone environment rather than estrogen. At the time of ovulation, the canine ova are a primary oocyte. Before fertilization can occur, the ova must under go a second mitotic division and shed the associated polar body. Specific knowledge of the reproductive physiology is essential to achieve successful conception and pregnancy.

Normal Estrous Cycle

The normal estrous cycle occurs approximately every 6 months but may vary between 4 and 18 months based on the individual, breed, and family history. The normal estrous cycle of the bitch consists of four distinct phases.

Anestrus

- The time period between estrous cycles.
- Anestrus is associated with a serum progesterone level of less than 2 ng/dl with no vaginal swelling or discharge.
- Follicle-stimulating hormone (FSH) levels are elevated throughout the anestrus period.
- The anestrus period ranges between 4 and 18 months in duration. Dogs require a minimum period of 4 months to permit the uterus adequate time to repair and regenerate, permitting normal implantation on subsequent breedings.

Proestrus

- The period of bloody vaginal discharge, pheromone changes, and rising estrogen levels. This phase lasts between 3 and 14 days.
- The rising estrogen levels thicken the vaginal walls, causing the changes in epithelial cells detected on vaginal smears.
- The concentration of serum progesterone during proestrus is less than 2 ng/dl.
- Cells lining the ovarian follicles begin producing progesterone levels in the 2- to 3-ng/dl range, triggering the release of LH from the pituitary and inducing ovulation within 48 hours.
- The bitch normally begins flagging and standing at the time of the LH release.
- Swelling of the vulva is observed. Although males are attracted to the bitch, they are not permitted to breed.

Estrus

- The period of ovulation, male acceptance, and conception.
- Ovulation occurs when the serum progesterone is between 4 and 10 ng/dl.
- Estrus lasts until approximately 6 days after ovulation.
- The progesterone continues to rise steadily, reaching ranges of 15 to 50 ng/dl within 72 hours post-ovulation, and continues to be elevated during the diestrus period.
- At this time, the female “flags” her tail and is willing to stand for the male to mount and breed.
- The vulva is soft, and a blood-tinged to clear or straw-colored discharge may be evident.
- It is not uncommon for the discharge to remain slightly bloody.

Diestrus

- Begins 6 days post-ovulation and is the end of the fertile period.
- Diestral progesterone levels are not affected by pregnancy.
- Diestrus lasts until the serum progesterone levels drop below 2 ng/dl. Diestrus lasts approximately 8 weeks in the pregnant bitch and can last 2 to 4 months in non-pregnant bitches.
- The first day of diestrus is characterized by a dramatic change seen on a vaginal smear. The superficial cells seen in estrus are replaced by parabasalar and intermediate cells. WBCs also begin to appear on vaginal cytology as the bitch moves from estrus to diestrus.
- A slight mucoid vaginal discharge may be apparent.

Etiology of Conception Failure

Poor Semen Quality

Few studies have been done to determine the minimum number of normal spermatozoa necessary for conception to occur. Numbers previously thought to be required were in the 100×10^6 to 150×10^6 range. There have been successful conception and whelping from bitches inseminated with less than 30×10^6 normal spermatozoa.

See later in this chapter under "Male Dog" for more information on semen evaluation.

Ovulation Failure

- The fact that a bitch shows the physiologic signs of an estrous cycle does not guarantee that the cycle will be ovulatory.
- The only laboratory method to confirm ovulation is an increase in serum progesterone level to greater than 4 ng/dl.
- Split and non-ovulatory cycles are not uncommon in the bitch. A progesterone rise to 2 to 3 ng/dl does not guarantee that ovulation will occur.

Improper Timing of Breeding

- Historically, veterinarians and breeders have timed bitches using vaginal smears, breeding guns, and physiologic signs such as color of vaginal discharge, days of the cycle, and vulvar softness. These traditional methods of breeding timing were not only flawed but also, in many cases, irrelevant to ovulation timing.
- The average length of an estrous cycle varies from 17 to 28 days. Extremes in ovulation varying from 6 to 32 days after onset of the estrous cycle with successful breeding having been confirmed.
- Fresh semen lasts an average of 4 to 6 days in the oviducts.

Methods of Timing of Ovulation

- Serum concentration of estrogen (which is not a precise method of timing)
- Luteinizing hormone assay
- Serum concentration of progesterone—more reliable in pinpointing ovulation

Luteinizing Hormone Assay

- The release of luteinizing hormone (LH) by the pituitary triggers ovulation within 48 hours. Perform LH testing and use serum progesterone to confirm that the ovary has responded to LH release and that ovulation has indeed occurred.
- Current LH testing consists of a wicking test (Status-LH, Synbiotics, San Diego, California). The test requires 4 drops of serum. A red line occurs when the LH rises above 1 ng/dl.
- Because of the short duration of LH (12–24 hours) in the bitch's circulation, perform the test daily.
- LH in the canine is species specific and assays with non-canine reagents cannot be used.

Progesterone Assay

- LH release, the initial rise in progesterone to 2 to 3 ng/dl, followed by ovulation 48 hours later has made timing the bitch an available and easily performed procedure.
- The bitch ovulates a primary oocyte, requiring 48 hours post-ovulation for ova maturation. After the ova have reached the secondary oocyte stage, it is thought that the eggs are fertilizable for up to 36 hours.
- The timing of a breeding is based on anticipated semen survival time.
- A serum progesterone level of 5 ng/dl indicates that ovulation has occurred.
- Canine progesterone is not species specific and can be tested for using a number of testing methods. Enzyme-linked immunosorbent assay (ELISA), chemiluminescence, 3-Immulite, and radioimmune assay (RIA) using conjugated and non-conjugated serum are all testing methods available to the practitioner. The preciseness needed, the type semen most frequently used, and the frequency of result reporting will dictate which method best fits a practice's needs.

▼ ***Key Point*** Frozen canine semen lasts in the bitch 12 to 24 hours. It is important that frozen semen not be inseminated until ova have reached the secondary oocyte stage due to the frozen semen's short life span.

Improper Breeding Methods

The canine breeding system is one that involves intromission into the vaginal tract of a semi-flaccid penis containing an os penis then engorgement of the penis and bulbus glandis. Ejaculation enters the vaginal tract at the external os of the cervix. The engorged bulbus glandis causes the "tie" that stimulates hormonal release, causing the semen to be "pumped" through the cervix and into the uterus. The spermatozoa then move cranially up the uterus and enter the oviducts, where conception occurs.

- The cervix in the bitch is located within the abdominal cavity, dorsal to the bladder.
- The length or distance from the vulva to the external os varies by breed size.
- It is essential that the semen be deposited at the external os of the cervix.
- Natural breeding resulting in outside ties or incomplete penetration into the bitch and poorly positioned rods for vaginal artificial insemination significantly decrease conception rates.

▼ ***Key Point*** Artificial insemination methods such as transcervical insemination (TCI) and surgical or laparoscopic intrauterine deposition of semen permit breeding that bypasses the vaginal cavity and cervix. These methods of depositing the semen into the uterus have contributed greatly to the current success of canine frozen semen.

Implantation Failure

After spending 6 to 10 days in the oviducts, the fertilized ova are released into the uterus. Implantation occurs in the bitch 17 to 18 days post-ovulation. Inflammation of the endometrium, cystic endometrial hyperplasia (CEH), and uterine fibrosis can contribute to implantation failure.

Refusal to Accept the Male

Refusal of the bitch to accept the male can be a significant problem in breeding. Use the following methods to address this problem:

- Confirm the anticipated ovulation timing. Vaginal cytology will confirm if ovulation has previously occurred.
- Change the environment (indoors versus outdoors, male's home versus female's home, etc.).
- If necessary, it is better to perform an artificial insemination than to risk injury to canine or human components.

Inability to Achieve a "Tie"

- Examine the vulva, vestibule, and vagina of the female for strictures, bands, size, etc.
- Check the male for penile abnormalities such as a persistent penile frenulum or adhesions to the prepuce (see Chapter 88).
- Check the prepuce and fornix for mass lesions, ulceration, or foreign bodies (see Chapter 88).
- Evaluate both the male and the female for nonreproductive health issues.

Resorption and Abortion

- Total resorption of fetuses can occur up to 38 days after ovulation. Numerous conditions can cause fetal death, including genetic or chromosomal anomalies, hormonal imbalance, chemicals and drugs, infectious agents, and toxins.
- Pedigree analysis, histopathology of the aborted placenta and fetuses, uterine biopsy, and microbiologic testing may help determine the cause of the problem. A thorough history of medications and chemical exposure and an evaluation of dietary supplements and ingredients are essential when confronted with resorption or abortion of fetuses.

Table 94-1. COMMON DRUGS TO AVOID DURING PREGNANCY

Antifungals
Tetracyclines
Estrogens
Testosterones
Corticosteroids
Nonsteroidal anti-inflammatory drugs

- Consult the recommendations of the manufacturer before any drug is given to a pregnant bitch (Table 94-1).

Diseases of the Breeding Bitch

Failure to Have an Estrus Cycle

- Normal females can be up to 24 months of age before having a first estrous cycle.
- Bitches over 24 months with no clinical or physiologic signs of an estrus cycle should initially be tested for thyroid and cortisol abnormalities.
- A serum progesterone level of <2 ng/dl will rule out any missed or silent season during the previous 2 months.
- If normal hormonally, a karyotypic examination should be performed. Karyotyping is performed on a heparinized blood sample by specialty labs.
  - The normal karyotype of the canine consists of 78 chromosomes (78 XX for the bitch and 78 XY for the male).
- If no hormonal or chromosomal abnormalities are detected, consider endoscopic or surgical evaluation of the ovaries (see Chapter 91).

Prolonged Anestrus after an Estrous Cycle

- Normally, anestrus can vary from 4 to 12 months. Bitches in anestrus longer than 12 months should be examined for hormonal anomalies, including thyroid, cortisol (either elevated or decreased), and progesterone levels.
- Perform an ultrasound examination of the ovaries for cystic structures.
- Endoscopic examination or exploratory surgery may be necessary to rule out fibrotic or hypoplastic ovaries, an unknown ovariohysterectomy, or ovarian cysts (see Chapter 91).
- The fluid aspirated from the ovarian cyst should be evaluated for progesterone. Many of these cystic fluids will contain progesterone levels >50 ng/dl acting to suppress the estrous cycle.

Split Estrus Cycle

- A split cycle is characterized by the bitch entering proestrus but never ovulating.
- The bitch normally will recycle in 4 to 6 weeks, the "second" cycle usually being ovulatory and breedable.

- Split cycles are diagnosed more commonly because of the routine use of progesterone testing for breeding management.

Silent Seasons

- Silent seasons are characterized by a bitch ovulating but showing no external signs of an estrous cycle.
- A silent season is usually first suspected when a bitch, having had no observable estrous cycle, has a pseudocyesis or "false pregnancy." Pseudocyesis confirms that ovulation has occurred within the last 8 to 10 weeks.
- To determine when the estral phase of a silent season occurs, perform a weekly vaginal smear, observing the cellular changes from parabasalar and intermediate vaginal epithelial cells to superficial epithelial cells.
  - The cellular changes indicate a rise in estrogen. Once the rise in estrogen is confirmed, serum progesterone levels are performed to determine the day of ovulation.

Shortened Anestrus

- Due to the inflammatory effect of progesterone on the endometrium, a minimum of 135 days (4 months) is needed for endometrial repair following an ovulatory season.
- Bitches cycling at intervals of less than 135 days may have reduced fertility due to the lack of endometrial integrity.
- This symptom is most frequently seen in German shepherds, Newfoundlands, rottweilers, and Welsh corgis.
- Mibolerone, an androgenic medication, can be given daily to delay the onset of the estrous cycle and to allow endometrial healing.

Prolonged Estrus

- Prolonged bleeding can be commonly seen in young bitches having their first estrous cycle.
- Bitches may have multiple non-ovulatory cycles. Serum progesterone concentrations from these bitches remain below 2 ng/dl.
- In young bitches, no treatment is usually necessary, and bitches will begin normal interestrous intervals after they have had an ovulatory cycle. This is not an indication of cystic ovaries.
- A prolonged estrous cycle in older bitches is of much more concern. Estrogen-secreting ovarian cysts and tumors are prime etiologies.
- Vaginal cytology showing predominately superficial cells will confirm estrogen as the cause of the vaginal bleeding.
- Examine bitches with prolonged vaginal bleeding not caused by elevated estrogen for other causes, such as bleeding disorders, vaginal disease and neoplasia, as well as hemorrhagic bladder disease.

Puppy Vaginitis

- Puppy vaginitis is the term used to describe the vaginal mucus in puppy bitches yet to have their first cycles (also see Chapter 92).
- Puppy vaginitis is a physiologic syndrome that does not require treatment. The condition is self-correcting when the estrogen surges during the bitch's first estrous cycle.

Vaginal Discharge

- Evaluate all vaginal discharges microscopically. Characterize the discharge as hormonal versus non-hormonal, inflammatory versus non-inflammatory, and infectious versus non-infectious (see Chapter 92).
- Etiologies of vaginal discharge include vaginitis, pseudocyesis, pyometritis, cystitis, estrous cycle, pre-whelping, post-whelping, mibolerone therapy, and vaginal tumors.

▼ ***Key Point*** If vaginal discharge is determined to be infectious, perform cultures for aerobes, anaerobes, and mycoplasma or ureaplasma.

▼ ***Key Point*** *Staphylococcus* spp., *Streptococcus* spp., *Escherichia coli, Pasteurella,* and *Mycoplasma* make up the normal flora found in the vestibule and vagina of the bitch. The vaginal tract is not a sterile area. The misuse of antibiotics during breeding may allow pathogens to prevail. There is no justification for the routine use of antibiotics during breeding without signs of inflammation and infection.

Premature Luteolysis

- The ovary is the primary progesterone source in the bitch throughout the pregnancy. Unlike other species, progesterone production is not transferred to the placenta.
- A serum progesterone of >2.5 ng/dl is needed to maintain the canine pregnancy.
- Consider premature luteolysis in bitches having problems with premature loss of puppies when other causes cannot be found.
- Perform serum progesterone testing periodically (the frequency of testing depends on the results obtained). A drop below 5 ng with greater than 5 days of gestation remaining may require progesterone supplementation.
- Treat with progesterone in oil, as an injection (2.2 ng/kg IM), or altrenogest (Regu-Mate, Hoechst). Regu-Mate will not show on a serum progesterone test as it is a synthetic product. Progesterone in oil will show on a progesterone test and can be monitored to determine if and when further supplementation is needed.

▼ ***Key Point*** There can be associated birth defects of the vaginal tract in female pups if progesterone supplementation is not used judiciously.

Pyometritis

Pyometritis is a disease of the uterus caused by an inflammation of the uterine lining, allowing a secondary bacterial infection. Pyometritis can also be caused by the misuse use of estrogen for mismating while the uterus is under the effects of progesterone. See Chapter 90 for a complete discussion of pyometra in dogs and cats.

Vaginal Wall Edema (Vaginal Hyperplasia)

- Vaginal wall edema occurs during the estrogen phase of estrous cycle is due to fluid uptake by the vaginal tissue.
- Brachiocephalic breeds, Labradors, and coonhounds are more frequently affected.
- Ovulation and subsequent decrease in serum estrogen causes regression of tissues.
- Vaginal edema typically does not cause whelping problems.
- It may recur during subsequent heat cycles.
- Treatment consists of preventing trauma and keeping tissue from drying until edema regresses (see Chapters 92 and 93).

Diagnosis

See Chapters 90 to 93 for discussion of diagnosis and treatment of diseases of the ovaries, uterus, vagina, and vulva.

Prebreeding Evaluation

- Perform a complete physical examination of both the brood bitch and the stud dog, including evaluation of the external genitalia. The bitch and stud should be in good health and of good weight. Overweight bitches are associated with conception, whelping, and nursing problems when compared with non-overweight bitches.
- The bitch should be free of parasites, appropriately vaccinated, and on heartworm-preventative medication. Heartworm-preventative medication should be continued during pregnancy and after whelping.
- Routine vaginal culturing without abnormal discharge or signs of inflammation is not justified.
  - Mycoplasma and ureaplasma are considered normal flora in the vagina. Obtaining routine bacteriologic cultures and treating for mycoplasma or ureaplasma without clinical signs is of no value.
- Serum thyroid levels are of minimal importance in canine reproduction, whether discussing the male or the female. However, if clinical signs of hypothyroidism are evident, perform a diagnostic evaluation (see Chapter 31).
- Be aware of genetic defects associated with any given breed. Individuals to be used for breeding should be tested for as many genetic diseases as possible.
- Assure adequate immunity for reproductive diseases.

Brucella canis

- *Brucella canis* is the bacterial organism most commonly associated with abortion in the bitch and orchitis in the male (also see Chapter 19).
- Since *Brucella canis* is passed through all body discharges, including urine, individuals should be blood tested for brucellosis even if they are being bred for the first time.
- Test the bitch for brucellosis before each mating.
- Test frequently-used males every 6 months, even if only bred to *Brucella canis*-negative bitches.
- The rapid slide agglutination test (RSAT) commonly performed as a screening test can have false-positive results in the 20% range. A negative RSAT does confirm the *Brucella*-negative status.

▼ ***Key Point*** Isolate individuals testing *Brucella* positive on the RSAT from other dogs until further testing. Agar-gel immunodiffusion, immunofluorescent antibody, and blood culturing for *Brucella canis* are confirmatory tests for brucellosis.

Pregnancy Diagnosis

There is currently no early pregnancy diagnostic test for the canine. Available midgestation techniques include the following:

- Ultrasound—After day 19 post-ovulation
- Palpation—Between day 23 and day 30 post-ovulation
- Relaxin testing (Witness Test, Synbiotics, San Diego, California)—After day 26 post-ovulation
- Radiography—After day 47 post-ovulation

Ultrasound

Ultrasound confirms pregnancy and fetal viability. It is typically the earliest method to accurately confirm a pregnancy. Ultrasound is not considered an accurate method for predicting exact litter size.

Palpation

Palpation of the caudal abdomen in a relaxed patient can accurately determine pregnancy in many breeds of dogs.

- Palpation is most commonly performed between 21 and 30 days after ovulation.
- Palpation of distinct uterine swellings dorsal and cranial to the bladder typically signifies pregnancy.
- There is a narrow window of opportunity to accurately diagnose pregnancy by palpation. As the

pregnancy progresses, the uterus enlarges and the individual fetal swellings become less distinct.
- Palpation as a method of pregnancy diagnosis can be difficult in large or nervous bitches.

Relaxin

Evaluation of serum relaxin levels, a hormone produced by the placenta, can accurately confirm pregnancy. However, false negatives can occur in litters of small numbers.

Abdominal Radiography

- Plain abdominal radiographs can accurately determine pregnancy but not until 47 days after ovulation.
- Optimal time for radiographs is 52 to 56 days post-ovulation to assure mineralization of all fetal skeletons.
- Abdominal radiography are more commonly performed to determine litter numbers and size of pups. Litter size is determined by evaluating both the lateral and the ventrodorsal views and by counting the skeletal structures of each fetus (spine or calvarium).
- Radiographic signs indicating possible fetal death or problems include collapsed calvarium, reversed "c" sign, and gas within fetuses.

Treatment

Treat any underlying diseases or problems (also see Chapters 90 to 93). Improve management strategies, such as timing of breeding, using the recommendations previously discussed under "Etiology of Nonconception." If vaginal anomalies are present, correct them if possible (see Chapter 93).

Estrus Induction

- Clinical research is currently being done using various categories of drugs to induce ovulatory cycles in the bitch.
- An interval of 4 months is the minimum anestral interval required.
- Cabergoline (5 µg/kg PO q24h), a dopaminergic agonist will shorten anestrus by lowering prolactin levels.
- Desorelin, a gonadotropin-releasing hormone (GnRH) analogue, either as an injection or an implant has shown particularly promising results.

Artificial Insemination

Due to disease concerns, cost, and restrictions of airline travel, the shipping of fresh chilled and frozen semen has dramatically increased. Knowledge of techniques for collection, handling, and shipping of semen, as well as methods of artificial insemination, has become essential for successful canine breeding.

A number of methods have been devised based on the type semen being used, the semen quality, the age of the bitch, and the expertise of the veterinarian performing the insemination. Methods of artificial insemination include vaginal, transcervical, and endoscopic or surgical intrauterine deposition of semen.

Collection of Semen

Collection of semen from male dogs is routinely performed for vaginal or intrauterine artificial insemination, cryopreservation, extension, and chilling for the purposes of shipping for a distant breeding or for evaluation as a part of the breeding soundness examination.

- Male dogs can be easily collected manually.
  - The male is stimulated using a non-intimidating female demonstrating clinical signs of estrus.
  - Semen collection should be performed in a quiet environment.
  - The ejaculate is collected into a polyvinyl chloride sheath with an attached calibrated collection container.
  - Manual stimulation of the glans bulbous of the penis permits a semen sample to be obtained. Parasympathetic stimulation produces erection of the penis, and sympathetic stimulation results in ejaculation.
- The male dog ejaculates three distinct fractions:
  - First fraction—Prostatic fluid containing no spermatozoa.
  - Second fraction—Thicker milky white volume that contains spermatozoa.
  - Third fraction—Clear fluid containing prostatic secretions and no spermatozoa. It is not necessary to collect this fraction.
- Male dogs can be collected every other day, daily for 5 to 6 days, or twice on 1 day without affecting sperm numbers.
- Evaluation of semen is essential. Abnormal sperm cannot fertilize ova.

Characteristics of Normal Semen

- *Volume*—0.5 to 30 ml or more (depends on the length of the collection, breed of dog, and size of the prostate)
- *Total count*—22 million/kg of body weight
- *Motility*—>80%
- *Morphology*—<20% abnormal sperm
- *pH*—6.2 to 6.8

Vaginal Artificial Insemination

If a natural breeding is not possible or is undesirable, vaginal artificial insemination can be performed to deposit a quantity of semen at the external cervical opening. The site of semen deposition is critical. The semen is positioned so that it can be drawn from the vagina into the uterus. Fertilization of the ova occurs

within the fallopian tubes after ovulation. Correct timing of ovulation is essential for successful breeding. (See the previous discussion in this chapter under "Methods of Timing Ovulation.")

▼ ***Key Point*** When properly performed, conception rates from vaginal artificial insemination should rival those of natural mating.

Technique

1. Determine timing of ovulation using clinical signs, vaginal cytology, and serum progesterone concentrations. An increase in the concentration of serum progesterone greater than 5 ng/dl indicates ovulation has occurred.
2. The female is positioned with her rear elevated manually or using a step or breeding ramp.
3. Avoid pressure under the abdomen, which may increase intra-abdominal pressure and affect movement of semen from the vagina to the uterus.
4. The semen sample is drawn into a sterile syringe.
5. An insemination rod of appropriate length is used to reach the external cervical opening within the vagina.
6. Sterile gloves should be worn, and aseptic technique should be applied.
7. With the assistance of a gloved hand, the insemination rod is inserted through the vulvar orifice at an upward 45-degree angle through the vestibule into the vagina. The rod is carefully manipulated over the pubis along the dorsal median fold until it is parallel with the lumbar spine at the anticipated depth of the cervical os.
8. If resistance is met when passing the insemination rod, withdraw the rod a short distance and gently redirect it.
9. With the insemination rod in the proper position, the semen is gently inseminated. It is not necessary to flush the rod with air; bubbled air may result in damage to the fragile plasma membranes of the head of the spermatozoa.
10. Digital "feathering" of the vestibule is performed for approximately 1 minute with the rear quarters of the female in an elevated position to facilitate gravitation flow of semen into the anterior vagina.
11. When the insemination is complete, the owner is instructed to restrict the dog's activity for 1 to 2 hours.

Intrauterine Insemination Techniques

Two techniques for the deposition of semen directly into the uterine body have been shown to dramatically improve conception rates in a variety of breeding situations, including the following:

- Frozen semen
- Fresh cooled, extended semen
- Females with suspected uterine disease
- Reduced semen quality
- Female anatomic abnormalities—Vulvar, vestibular or vaginal stenosis, vaginal edema, secondary to traumatic pelvic injuries
- Specific breed indications—Giant and toy breeds with known infertility

Transcervical Insemination

- A rigid operating cystoscope is used to examine the luminal surface of the vestibule, vagina, and external cervical os.
- Direct examination of the uterus is not possible during this procedure.
- A flexible catheter is passed through the biopsy channel of the cystoscope or along the side of the endoscope and manipulated through the external os of the cervix, permitting deposition of semen directly into the uterus.
- This procedure does not require general anesthesia; however, light sedation may facilitate performing this procedure in some patients.

Surgical Insemination Technique

1. The bitch is prepared for surgical insemination; the ventral abdomen is clipped and aseptically prepared.
2. A small, 4- to 6-cm ventral midline incision is made halfway between the umbilicus and the pubis.
3. The uterus is identified and exposed to the level of the incision.
4. The semen is prepared for insemination. A volume of semen between 4 and 5 ml is prepared. If the volume is greater than 4 ml, the sample should be centrifuged for 5 minutes. The supernatant is decanted and disposed. The semen pellet is gently resuspended with a semen extender. The semen is gently drawn into a sterile 6-ml syringe using an insemination rod. A 22-gauge needle is attached for insemination.
5. The surgeon inserts the needle into the lumen of the uterine body at a 45-degree angle with the bevel of the needle oriented upward. The semen should be injected easily, distending the uterine body and horns. If any resistance is met, gently redirect the needle.
6. A saline-soaked sponge is place over the injection site as the needle is removed and held in place for 1 to 2 minutes.
7. Routine abdominal closure is performed. The rear quarters of the bitch can be mildly elevated during recovery from anesthesia.

Termination of Pregnancy for Mismating

The chemical removal of unwanted pregnancies can be achieved with no pathologic changes to the endometria. Current recommendations are directed toward lysis of the corpus luteum during the second half of pregnancy. Currently two drugs are appropriate for termination of pregnancy:

- Prostaglandin $F_2\alpha$ (Lutalyse, Pfizer) is used at a dosage of 1.1 to 2.2 mg/kg SC, q8-12h. The drug is given until the fetuses have been expelled. Normally the process takes 4 to 7 days. Confirmation that all fetuses have been expelled is necessary as cases of ovaries reluteinizing have been reported.
- Cabergoline, an antiprolactin drug (5 mg/kg PO daily), will also induce luteolysis. The drop in progesterone causes premature labor and the expulsion of the fetuses. The fact that all puppies have been passed needs verification.

▼ ***Key Point*** Do not use of diethylstilbestrol (DES) to prevent conception as it promotes the development of cystic endometrial hyperplasia, pyometritis, and potential bone marrow suppression.

MALE DOG

Etiology of Infertility

Insufficient Number of Sperm

Severe reduction in the numbers of spermatozoa in an ejaculate may impact conception rate. Although 200 million sperm is considered a normal number of spermatozoa in an ejaculate, it is unknown at what point conception is reduced. Reduced sperm numbers in an ejaculate may be the result of incomplete ejaculation, reduced production by the seminiferous epithelium, or compromised outflow from at least one testicle.

Aspermia

Multiple ejaculates without any visible spermatozoa are termed aspermia or azoospermia depending on whether the second fraction of the ejaculate has been obtained.

- Males with no sperm can be divided into five categories:
  - Incomplete ejaculation
  - Retrograde ejaculation
  - Blockage
  - Testicular dysfunction
  - Immune-mediated orchitis
- To determine if the second fraction of the ejaculate has been obtained during the collection, an alkaline phosphatase level is performed on the ejaculate.
- Prostatic fluid is low in alkaline phosphatase, <2,000 IU/dl; however, epididymal fluid is high in alkaline phosphatase, >5,000 IU/dl.
- An increased concentration of alkaline phosphatase in the ejaculate confirms that a total ejaculate has been obtained.

Incomplete Ejaculation

- Failure to ejaculate the second or sperm-rich fraction upon collection.
- Incomplete ejaculation is diagnosed by a low semen concentration of alkaline phosphatase.
- Causes of incomplete ejaculation include the following:
  - Novice stud dog
  - Submissive or timid stud dog
  - Uncomfortable environment for collection
  - Intimidation by the teaser bitch
- To overcome the male's reluctance to being collected, use a change of environment, patience, complete health evaluation, or a different teaser bitch in the estrus phase of her cycle.

Retrograde Ejaculation

Retrograde ejaculation is characterized by good reproductive instincts and strong pulsation but minimal or no ejaculate is obtained. A post-collection urine sample contains an extremely high number of sperm cells.

- Retrograde ejaculation is most often associated with the retriever breeds.
- Administration of phenylpropanolamine (an alpha-adrenergic stimulant) to increase tone of the urethral sphincter mechanism prevents retrograde flow of sperm into the bladder.

Obstruction

Granulation tissue formation can obstruct the opening of the vas deferens, prohibiting the exit of sperm into the urethra. This results from a breakdown of the barrier between semen and blood that normally prevents an immune reaction.

- Granulomas can occur as a result of trauma, previous surgery, infectious disease, or genetics.
- Some granulomas may be palpable or imaged using ultrasound or urethrocystoscopy.
- The concentration of alkaline phosphatase in the ejaculate will be increased if there is a unilateral obstruction and will be low with bilateral granuloma formation.
- Microsurgical bypass would be necessary to circumvent the obstruction in patients with bilateral obstructive disease.

Testicular Dysfunction

- An increased concentration of alkaline phosphatase in the ejaculate indicates that the second fraction of the collection is present.
- Numerous etiologies can result in lack of tubular function in the testicle, resulting in aspermia, low sperm numbers, or abnormal morphology, including genetics, tumors, drug therapy, and hormones.
- Testicular palpation may reveal a "softness" that may indicate that the seminiferous tubules are failing.
- Ultrasound can be used to image and biopsy the testicle in an attempt to determine the etiology of the dysfunction and possible treatment.

Immune-Mediated Orchitis

- Lymphocytes infiltrating the testicle(s) and subsequent testicular failure are thought to be genetic.
- Breeds most commonly associated with immune-mediated orchitis are English setters, Labrador retrievers, and sighthounds.
- The testicle usually palpates normally in males with immune-mediated orchitis.
- A testicular biopsy is necessary to diagnose this condition.
- The concentration of alkaline phosphatase in the ejaculate is expected to be very high.

Sperm Motility

Abnormal motility of spermatozoa is thought to hinder the sperm's ability to reach the fallopian tubes to achieve conception. If an increased percentage of the spermatozoa demonstrate complete lack of progressive motility, there may be environmental influences that have affected the collection of the ejaculate.

- A male that has not been collected for an extended period of time may have a large number of non-motile sperm due to prolonged storage in the epididymis.
- Increased environmental temperature affecting the epididymis or inflammation may result in non-motile or dead sperm.
- Improper collection techniques can result in "cold shock" injury to spermatozoa.

If a large percentage of non-motile sperm are identified, a second or third collection on the same day or next day can be evaluated for motility. With persistent collections of non-motile or "dead" sperm, consider re-evaluating the stud dog for infections or inflammation of the urinary or reproductive tracts. Consider testicular biopsy.

Sperm Morphology

Microscopic examination of the spermatozoa morphology should be performed as part of the semen evaluation.

- *Primary defects*—Greater than 20% of morphologic abnormalities involving the head, neck, and tail can result in reduced fertility. Primary defects occur in the seminiferous tubules during development.
- *Secondary defects*—Greater than 20% of morphologic abnormalities that occur after collection, including bent or coiled tails, can also result in reduced fertility. Review collection techniques and sample handling in this situation.

Diagnosis and Treatment

See Chapters 86 to 89 for discussion of diagnosis and treatment of testicular and penile diseases in dogs and cats.

FEMALE CAT

Queens are seasonally polyestrous with ovulation being induced by LH release stimulated by multiple copulations. Unlike the bitch, non-bred females will continue to cycle throughout the year. An anestrus will normally occur due to the shortened daylight hours of winter.

Normal Estrous Cycle

Anestrus

- The normal cycle of the queen consists of anestrus, the quiescent period during which ovarian activity is minimal. This period is longest during the time of shortest natural light exposure.

Proestrus

- The follicle begins to develop secreting estrogen.
- The period of male attraction is characterized in the female by her "calling vocally," rubbing, and raising her tail. The vocalization is often mistaken as a cry of pain or discomfort by new owners.
- Proestrus is identified clinically by identifying a beginning rise in the percentage of superficial epithelial cells and increased vaginal secretion on vaginal cytology.
- It is normal for proestrus to last 1 to 2 days.

Estrus

- The breeding phase (estrus) occurs when the ovarian follicle is mature.
- Vaginal cytology taken with a moistened Q-Tip shows predominately superficial epithelial cells (>60–70%).
- The queen does not show vaginal bleeding during this time.
- The male cat mounts the queen, biting her neck for stabilization as the erect penis penetrates the vulva. Penile spines on the penis of an intact male stimulate the vaginal receptor sites, triggering LH release.
- Multiple breedings are needed for complete ovulation and for the best chance of pregnancy.
- The female cat presents herself to the male with the rear elevated and the tail moved to one side. After the breeding act, the female normally vocalizes and rolls on the floor.
- The period of male acceptance can vary considerably based on the number of breedings and the LH release. The period of male acceptance can persist for a prolonged period of time (up to 2 weeks or longer) depending on the availability and the breeding aggressiveness of the male.

Interestrous

- An unbred female will have a normal interestrous period of 5 to 14 days before returning to proestral signs.
- The estrous cycle repeats itself until the female becomes pregnant or the length of daylight shortens enough to return the female to anestrus.

Diestrus

- The period of elevated progesterone will last for 45 to 50 days in the pseudo-pregnant female and 60 to 65 days in the pregnant queen.

Diseases of the Breeding Queen

See Chapters 90 and 93 for discussion of diseases of the ovaries, uterus, vaginal, and vulva.

Diagnosis and Prebreeding Evaluation

See "Prebreeding Evaluation" under the canine section in this chapter.

- The female should be of good flesh without being overweight. A balanced commercial diet should be fed.
- Females to be bred should be free of viral diseases including feline leukemia virus (FeLV), feline immunodeficiency virus (FIV) and feline infection peritonitis (FIP) (see Chapters 8, 9, and 10, respectively).
- Vaccinations for upper respiratory diseases and panleukopenia should be current.
- A good quarantine protocol should be established in a cattery to prevent the introduction of outside pathogens when new individuals are introduced.

Treatment

Inducing Ovulation

In situations that require the female to ovulate (e.g., artificial insemination), numerous methods have been attempted.

- ***Hormonal stimulation***—Injecting 25 mg of GnRH once a day (Cystorelin, Ceva Labs) or 250 IU of luteinizing hormone or human chorionic gonadotropin (HCG). Administer when the queen shows peak receptivity to a male. The injection may be repeated 24 to 36 hours later. If successful, the queen should show signs of reduced sexual activity in 24 to 48 hours.
- ***Vaginal stimulation***—Use a moistened Q-Tip or glass rod for repeated stimulation of the vaginal tract receptors to mimic natural breeding may induce ovulation. Vaginal stimulation is most successful when an intact tom is housed nearby as this may have a psychic effect on the female to help stimulate ovulation. Restrain the female (i.e., wrapped in towel) to prevent injury to the handler when stimulating the female.
- ***Vasectomized tom cat***—This is the most reliable method of stimulation for the queen to ovulate as the vasectamized tom cat completes the natural breeding act without placing sperm cells in the female. Repeat breedings are necessary (multiple over an 8–24-hour period) to ensure ovulation. Confirm ovulation by detecting a serum progesterone rise, usually 48 to 72 hours after breeding.

Stimulation of Estrus

Numerous medical therapies have been described to induce estrus in cats.

- Administration of 2 mg of FSH intramuscularly daily until estrus is exhibited (up to 7 days), followed by mating to induce LH release or by injecting human chorionic gonadotropin (250 IU) intramuscularly on day 2 and 3 of estrus or by injecting 25 mg of GnRH intramuscularly.
- A non-medical method used to induce estrus in the queen may include the use of full spectrum light bulbs to mimic the equivalent of 14 hours of daily sunlight.

Feline Artificial Insemination

Collection of Semen

- Collection of the semen for insemination, freezing, or evaluation is normally accomplished with an electroejaculator.
- Electroejaculation is performed under general anesthesia, and the male is pretreated with an antihistamine to diminish the retrograde movement of sperm into the bladder.

Vaginal Insemination

- Insemination can be performed using a lacrimal catheter with a conical tip or a shortened plastic artificial insemination rod similar to those used in bitches.
- A maximum volume of less than 0.1 to 0.2 ml is most desirable due to the relative size of the feline vaginal cavity.

Intrauterine Insemination

- Surgical exposure of the uterus for direct deposition of semen should be considered in queens for which uterine or ovarian disease may be suspected and direct examination is desired.
- The use of frozen semen has been shown to have the greatest chance of success with direct insemination into the uterus.
- Intrauterine insemination is performed through a 3- to 4-cm caudal abdominal incision to expose the uterus or laprascopically.

- The semen is injected into the uterine lumen through a 22-gauge hypodermic needle.

Estrus Suppression

Progestogens and androgens have been used to suppress the estrous cycle in the queen. However, both methods are associated with negative behavior and deleterious side effects.

- The administration of GnRH (25 mg IM) or LH (HCG at 250 IU IM) will induce ovulation in a queen at peak estrus and delay the next cycling for 45 to 50 days.

MALE CAT

See Chapters 86 to 89 for diagnosis and treatment of diseases of the testicle, penis, and prepuce.

ABORTION

- Fetuses and placentas of the aborted fetuses should be evaluated grossly, histopathologically, and microbiologically. Microorganisms, genetic defects, toxins, drugs, progesterone deficiencies, and diet have all been described as agents leading to litter loss.
- The histopathologic evaluation of the placenta for inclusive bodies, dehydration, and signs of inflammation is critical.
- Culture vaginal discharges and perform serum titers for viral diseases and other microbial agents (i.e., toxoplasmosis). Potential surgical examination of the uterus and ovaries may be required to achieve a diagnosis.
- See Chapter 90 for more information on etiologies, diagnosis, and treatment of abortion in dogs and cats.

Chapter

95 Postoperative Physical Rehabilitation

Darryl L. Millis

The appropriate postoperative management of small animals undergoing orthopedic or neurologic surgery is critical for a successful outcome. Inadequate surgical and postoperative treatment may result in fracture disease. The appropriate use of physical rehabilitation techniques in combination with pharmaceutical agents is necessary to achieve an optimal outcome.

GOALS OF POSTOPERATIVE PHYSICAL REHABILITATION

- Prevent loss of joint range of motion and stiffness
- Reduce the deleterious effects of disuse of musculoskeletal tissues
- Improve the rate of recovery
- Improve the quality and quantity of movement
- Enhance the ultimate outcome
- Enhance performance, conditioning, and endurance

PREOPERATIVE CONSIDERATIONS IN THE REHABILITATION PLAN

- Patient's age and physical condition. Obese patients and those with poor cardiovascular condition will require a less aggressive rehabilitation plan.
- Surgical condition and the repair technique. The stability of the surgical repair helps determine how aggressive the rehabilitation plan may be.
- Presence of concurrent injuries. Animals with multiple injuries generally undergo a less aggressive rehabilitation plan.
- Owner compliance. The therapist must consider the ability and willingness of the owner to participate in the rehabilitation plan.
- Expertise of the rehabilitation team.

PERIOPERATIVE PAIN MANAGEMENT

Institute preemptive pain management to allow postoperative therapy to be as comfortable and pain free as possible (see Chapter 6). Effective control of pain and postoperative inflammation allow rehabilitation to begin earlier with more rapid progress to functional activities.

Medications and Techniques

- Preoperative butorphanol or morphine.
- Epidural opioid analgesia.
- Intra-articular administration of local anesthetic agents such as bupivacaine.
- Morphine or buprenorphine are commonly used for immediate postoperative analgesia.
- Nonsteroidal anti-inflammatory drugs (NSAIDs), such as deracoxib or carprofen may be administered prior to or immediately after surgery and continued in the postoperative period in healthy patients free of renal and gastrointestinal disease or bleeding

tendencies. Knowledge of NSAID pharmacokinetics is important so that dosing strategies take advantage of peak drug effects. Medication is continued for 7 to 14 days after surgery.

- See Chapter 6 for further discussion of postoperative pain management.

REHABILITATION IN THE IMMEDIATE POSTOPERATIVE PERIOD

▼ ***Key Point*** The main objectives in the first 24 to 72 hours after surgery are to provide pain control, reduce joint effusion and tissue edema using cryotherapy, and reestablish normal joint range of motion (ROM) as soon as possible.

If normal motion is not established by 2 weeks, dogs may permanently lose some ROM. Prevention of muscle atrophy is also critical. Early use of the limb with functional weight bearing is the key to returning the patient to function as soon as possible.

Cryotherapy (Cold Packs)

- Cryotherapy is the therapeutic use of cold.
- The effects of cryotherapy include the following:
  - Vasoconstriction
  - Decreased blood flow
  - Reduced cellular metabolism and permeability
  - Attenuation of traumatic or exercise-induced edema
  - Decreased muscle spasm
  - Analgesia as a result of decreased sensory and motor nerve conduction velocity

Cryotherapy Devices

- Place crushed ice in a sealed plastic bag and wrap the bag in a thin cloth, such as a pillowcase or towel.
- Prepare a mixture consisting of two parts water and one part alcohol in a double-sealed plastic bag and place it in a freezer. The resulting pack is a frozen slush that conforms to any surface.
- Use commercially available cold packs.
- Use circulating cold water cryotherapy units.

Cryotherapy Technique

1. Apply to the affected area immediately after surgery during recovery from anesthesia.
2. Apply the cold pack for 15 to 20 minutes.
3. Use caution when applying cold packs to hypothermic or small patients.
4. Apply for 15 to 30 minutes every 6 to 8 hours for the first 3 or 4 days after surgery.
5. Monitor the patient for discomfort.
6. Do not use cryotherapy in patients with poor or absent pain sensation.
7. A compression bandage, such as a modified Robert Jones bandage, may be applied after cryotherapy to help prevent swelling and edema.

Range of Motion and Stretching Exercises

Perform ROM and stretching exercises to help maintain or improve flexion and extension of joints; improve flexibility of muscles, tendons, and ligaments; and help enhance awareness of neuromuscular structure and function. ROM exercises are important in dogs undergoing any joint surgery, especially cranial cruciate ligament rupture stabilization, elbow fractures, and fracture of the distal femoral physis in skeletally immature dogs.

Range of Motion Exercise Technique

1. Place the patient on soft padding in lateral recumbency.
2. Stabilize the limb proximal to the joint.
3. Gently grasp the limb below the affected joint. The closer the hands are placed to the joint, the lower the forces will be that are applied to the joint.
4. Slowly flex the joint over several seconds until there is the first indication of discomfort, such as tensing the limb, turning the head in recognition, or trying to gently push away. Under no circumstances should the animal vocalize in pain or attempt to bite. In general, joint flexion is more comfortable than joint extension.
5. Slowly extend the joint over several seconds until there is the first indication of discomfort.
6. Other motions may be appropriate, such as abduction and adduction or rotary motions, especially of the shoulder and hip.
7. Repeat for 10 to 30 repetitions depending on the animal's reaction to the motion, 3 to 6 times daily.
8. Do all joints in the affected limb, including the digits.

▼ ***Key Point*** Over-aggressive ROM exercises will result in pain, reflex inhibition, delayed use of the limb, and ultimately more fibrosis of the tissues around the joint.

The primary objective is to gently flex and extend individual joints through their comfortable ROM.

As the animal nears full ROM, more natural gait movement may be instituted by putting all of the joints of a limb through a ROM simultaneously, similar to the motion of riding a bicycle.

Stretching Technique

1. Stretching is often combined with ROM exercises in stiff joints with decreased ROM.
2. Stabilize the limb proximal to the joint, and grasp the limb below the affected joint and gently move it.

3. At the end range of flexion, hold the position for 15 to 30 seconds. Gradually attempt to increase flexion as long as the patient remains comfortable.
4. Extend the joint, and at the end range of extension, hold the position for 15 to 30 seconds. Gradually attempt to increase extension as long as the patient remains comfortable.
5. The main idea is to stretch and realign soft tissues and collagen, not to tear or damage tissues.
6. Repeat for two to five repetitions, 1 to 3 times daily.

THERAPEUTIC EXERCISES

Therapeutic exercises are an essential part of a physical rehabilitation program, whether a patient is being treated immediately after surgery or for chronic conditions. Therapeutic exercises may be performed by the therapist or as part of a home treatment program with owner involvement.

▼ ***Key Point*** When a home exercise program is prescribed, always demonstrate the exercise first and then have the owner demonstrate the exercises for you to ensure that they are properly performed.

Objectives

- Improve active pain-free ROM and flexibility
- Improve use of limb and reduce lameness
- Improve muscle mass and muscle strength
- Improve daily function
- Help prevent further injury

Considerations

▼ ***Key Point*** It is most important that exercises be performed correctly, rather than performing many repetitions incorrectly.

- Begin with standing exercises, assisted walking, and proprioceptive exercises in patients that have serious musculoskeletal injuries, neurologic conditions, or multiple limb involvement.
- Progress to slow, low-impact activities as the patient gains strength and stamina and is able to support its own weight.
- As the animal continues to recover, the speed, duration, and number of repetitions may be increased, and more challenging exercises may be added.
- Vary the routine so that the therapist and patient do not become bored with repetitive exercises.
- Try different activities to determine what works best in an individual patient.
- Allow the patient to guide an increase in activity, within reasonable limits. Increased activity must always be considered in response to the time frame of expected tissue healing and the strength of the healing tissues. This is especially relevant with the modern analgesic and surgical techniques used, which may result in less pain and attempts to do more activity.
- Conversely, some patients may need some encouragement if they are not progressing as expected.
- Do not hurt a patient during exercises or increase the activity level too rapidly. This may result in reflex inhibition and decreased use of the limb, which will ultimately slow progress.
- Pathologic reasons for delayed recovery should always be ruled out prior to increasing the level of activity.

Assisted Standing

These exercises bridge the gap between passive ROM and stretching exercises and more active exercises. They are useful for dogs recovering from neurologic conditions, such as intervertebral disk rupture, or severe musculoskeletal trauma, such as bilateral pelvic injuries. Assisted standing is useful for patients that have adequate strength to bear some weight but are too weak to bear complete weight.

- Position the dog with the feet squarely underneath the body.
- Support the animal with a towel or sling. Allow the dog to bear as much weight as it is able.
- As the animal weakens and begins to slowly collapse, lift it back to a standing position with the limbs squarely placed under the body.
- Start with 10 to 15 repetitions bid–tid, and gradually increase to 5 minutes per session.

Proprioceptive Exercises

These exercises help animals regain their ability to appropriately use and place their limbs, and they include weight shifting, balance board activities, and Swiss balls or PhysioRolls.

Weight Shifting and Perturbation Exercises

- Stand the dog squarely on firm footing.
- Place the hands on the side of the dog for support.
- Push the dog gently from side to side. In severely affected dogs, some support may be necessary to avoid falling. As the animal regains proprioceptive ability, the shifts may be more challenging.
- It may be necessary in some dogs to place mild pressure over the pelvis or shoulders to encourage greater stability and weight bearing.

Balance Boards

- Dogs may be placed on a traditional balance board with either the front or the hind limbs on the board, or special balance boards designed for quadruped animals may be made (Fig. 95-1).

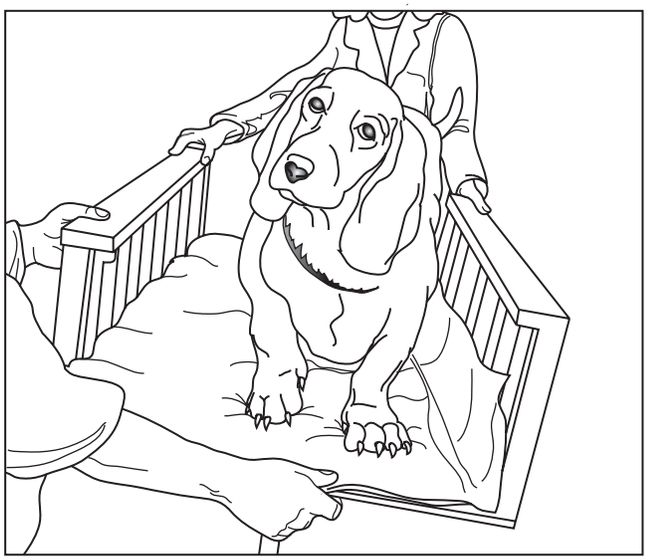

Figure 95-1. A specially made balance board may be used for proprioceptive training.

- Support the dog to avoid injury from falls.
- The balance board may be manipulated to rock the dogs from side to side, back and forth, or in all directions.

Side Bending and Cervical Flexion and Extension

With the dog standing squarely, use a treat so that the dog follows it from side to side and up and down. The ability to actively move while maintaining balance is the goal.

Swiss Balls and PhysioRolls

- Dogs with severe proprioceptive disability may be placed over a properly sized and inflated, large PhysioRoll to help provide support during weight bearing.
- As strength and ability return, the front half of the dog may be placed on the PhysioRoll, allowing some weight bearing and balancing to occur.
- To help aid limb awareness and neuromuscular activity, perform rhythmic stabilization exercises by standing the dog on a properly sized ball or PhysioRoll and gently "bouncing" the dog while maintaining support to prevent falling.
- Animals returning to good function may be challenged by standing the dog on a properly sized PhysioRoll and allowing it to bear weight while maintaining support to prevent falling.

Slow Walks

▼ ***Key Point*** Slow leash walks are the most important therapeutic exercise for patients recovering from surgery or affected with chronic musculoskeletal conditions, but they are also frequently performed incorrectly.

- Perform leash walks very slowly to allow the dog an opportunity to bear weight; perform at the speed of the dog, not the handler.
- For difficult situations, dogs may be gently "bumped" to challenge their balance and encourage touching the limb to the ground at the end of the swing phase of gait for the affected limb.
- Behavior modification is encouraged to train the dog to use the limb. Praise the dog when it touches the limb down.
- Initially perform leash walks for 2 to 5 minutes, 2 to 3 times daily. If lameness or limb use is not worse after the first couple of days, gradually increase the length and time of the walks 10% to 20% each week.
- Dogs may be walked up and down inclines, hills, or ramps to add more challenges and to encourage muscular and cardiovascular fitness.

Treadmill Walking

Treadmill walking is a useful modality to encourage use of the limb and early gait patterning. The ground moving under the dog often encourages a non–weight-bearing patient to begin using limb. Most dogs trained to leash will walk on a treadmill.

- Use a harness or sling to provide support and prevent falls. Sidewalls to prevent stepping off the treadmill, variable speed of the treadmill, a timer, and the ability to change the incline angle are all useful features for canine treadmills. Do not face the treadmill toward a wall.
- One person may be in front of the dog to encourage it.
- A person may stand beside the dog to lift and advance an affected limb during the normal gait sequence to encourage proper use of the limb for those patients with severe conditions (gait patterning training).
- Dogs may initially walk for 1 to 3 minutes, 2 to 3 times per day at a slow speed. If lameness is not worse after activity, increase the exercise increased 10% to 20% per week.

Stair Climbing

- This exercise is useful to improve power in the rear-limb muscles.
- Stair climbing may begin if the repair is stable and the dog is consistently using the limb at a walk with decreasing lameness over time.
- Walk the dog slowly up the stairs, being certain that the dog steps up with each limb rather than skipping up steps or jumping up steps by using both rear limbs ("bunny hopping").
- If possible, begin with low, gradually rising steps, and progress to increasingly steeper steps.

- Begin with 5 to 7 steps, and increase to two to four flights 1 to 3 times daily.

Sit-to-Stand Exercises

These exercises may be beneficial for dogs with hip dysplasia, a condition in which full extension of the hips is painful (see Chapter 108). Sit-to-stand exercises strengthen the gluteal muscles, but the hip joints only extend to a normal standing position, with no overextension of the hip.

- Back the dog into a corner, with the affected leg against a wall. This will encourage the dog to push up evenly with both rear limbs when rising, and not pushing up with a good leg, while pushing the affected leg out from the body.
- Concentrate on having the dog sit and stand correctly, with both rear limbs flexing equally while sitting, and pushing off evenly with both rear limbs to stand.
- Start with 5 to 10 repetitions once or twice daily, and work up to 15 repetitions 3 to 4 times daily.

Wheelbarrowing

- Wheelbarrowing exercises are designed to improve use of the forelimbs.
- Lift the rear limbs off of the ground, and move the dog forward. Dogs with normal proprioception will move the forelimbs so they do not fall.
- Some dogs with weakness of the forelimbs may require support to prevent them from collapsing.
- As dogs become stronger and endurance improves, dogs may be wheelbarrowed up and down inclines for greater effect.

Dancing Exercises

- Dancing exercises are designed to improve use and strengthening of the rear limbs.
- Because of the proximity of the handler to the dog's mouth, apply a muzzle.
- Lift the forelimbs off the ground and move the dog forward or backward. Dogs with normal proprioception will move the limbs so that they do not fall.
- In some situations, the handler should get behind the dog and place the arms under the axillary region of the dog to support it and walk forward.
- As dogs become stronger and endurance improves, dogs may dance up and down inclines for greater effect.

Jogging

- Jogging may be initiated in cases in which the fixation is stable and the dog is walking on the limb with minimal lameness and pain.
- Begin jogging slowly to improve muscle strength and cardiovascular fitness; 2 to 3 minutes, 2 to 3 times daily, and increase up to 20 minutes, 2 to 4 times daily.
- Be certain that lameness is not worse after jogging.
- The dog may jog up hills for greater effect if there are no problems jogging on flat surfaces.

Cavaletti Rails

- Cavaletti rails are raised rails or poles that are spaced apart on the ground to help increase stride length, limb use, and active ROM of joints. A ladder that is lying on the ground may act as Cavaletti rails.
- The height of the rails is raised to encourage greater active flexion and extension of the joints (Fig. 95-2).
- As the animal improves, the rails may be spaced at varying distances to provide challenges to proprioception.
- Begin with slow walking over the rails, and progress to trotting to add additional challenges to the patient.

Circling, Figure of Eight, Serpentine, and Pole Weaving

- These exercises are useful for encouraging lateral flexion of the spinal column, proprioceptive training, and weight shifting during gait in preparation for more challenging exercises, such as turning sharply while running.
- Walk the dog slowly in the desired pattern with frequent changes in direction, encouraging the dog to flex the body and spinal column and pivot on the affected limb.
- If vertical poles are used, the distance between the poles should be less than the length of the dog to encourage lateral bending of the spinal column and weight shifting.

Muscle Strengthening Activities

These exercises concentrate on strengthening muscles to improve power and speed. They include carrying weights, playing ball, and running for short distances at high speed.

- Place strap-on leg weights relatively proximal on the limb to reduce the muscle force and stress on joints during the early rehabilitation period.
- As strength and stamina improve, move the weights further distally to provide more challenges.
- In general, use 0.25-kg, 0.5-kg, 1-kg, and 2-kg weights for small, medium, large, and very large dogs, respectively.
- Use the weights 2 to 3 times per week during normal walking. Dogs may initially resist the leg weights, but most become accustomed to them and will walk with the weights.

Controlled Ball Playing

- Begin on a relatively short leash or in an enclosed kennel or room to avoid overly explosive activity in the early postoperative period.

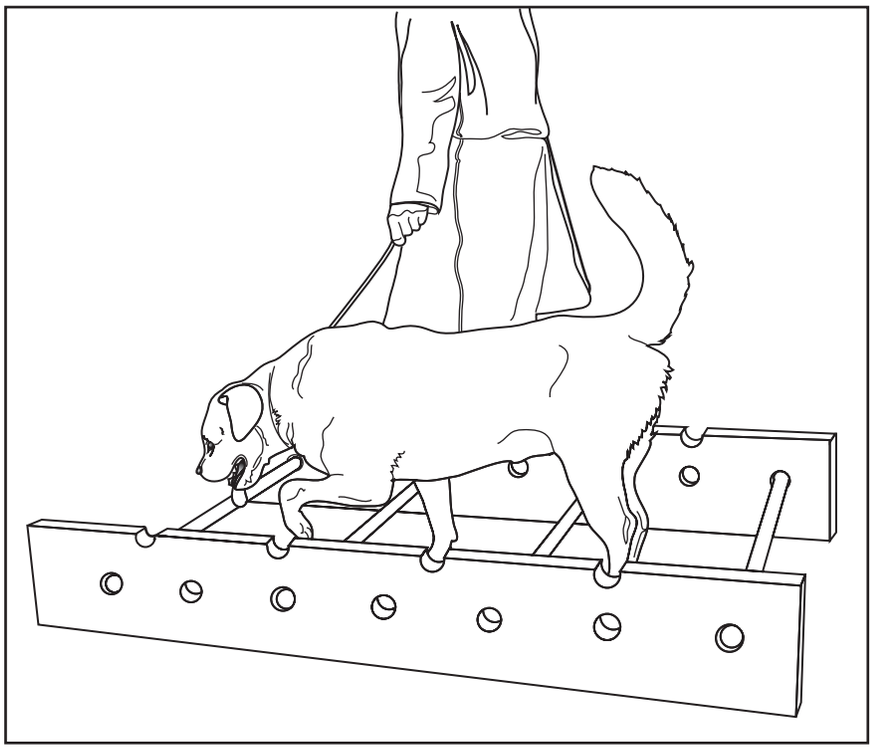

Figure 95-2. Walking over raised Cavaletti rails encourages increased active range of motion of joints and proprioceptive training of the limbs.

- Progress to ball playing in an enclosed area, such as a small dog run or room. As the animal nears full return to function, begin activity on a long leash, and if there are no problems, begin off-leash activity in a safe environment.

Aquatic Exercises

- Begin aquatic exercises when the incision is sealed. Gently test the incision to be certain that the edges do not separate. Do not perform aquatic exercises in patients with drainage from the incision, active infections, or if the incision is not sealed.
- Walking on an underwater treadmill may begin by day 5 to 7 after surgery in many patients.
- Fill the water level to the level of the elbow, and set the treadmill at a slow, comfortable walking pace for the dog.
- Initially walk dogs at a slow speed for 1 to 5 minutes, 2 to 3 times per day, gradually increasing the speed and length of activity as the patient allows.
- The goal is to exercise for 30 to 40 minutes twice daily, with some of the time spent jogging.
- Initiate swimming at a later time, generally 4 to 8 weeks after surgery. Swimming may be too stressful for some surgical procedures to begin earlier than this.

Chapter 96

Fractures of the Skull

Mark M. Smith

Fractures of the zygomatic arch require surgery if they interfere with mastication or compress ocular structures. The most common extracranial fracture requiring surgery is a depression fracture of the frontal sinus. Intracranial fractures that require surgery are those that depress into brain parenchyma, causing significant compromise of cerebral function. Most skull fractures are amenable to conservative management.

Weigh the complications of general anesthesia in a neurologically compromised patient against the positive effects of surgical intervention. Fine motor movement is not necessarily required of small animal pets; therefore, intracranial surgery rarely is performed.

ANATOMY

Zygomatic Arch

- The cranial portion of the zygomatic arch is formed by the zygomatic bone, and the caudal portion is formed by the zygomatic process of the temporal bone.
- The zygomatic arch forms the ventral and lateral rim of the orbit.

Calvarium

- The dorsal sagittal crest courses craniocaudal over the calvarium.
- The nuchal crest courses mediolateral over the caudal edge of the skull.
- The frontal sinus of the frontal bone comprises the frontal encasement of the brain.
- The diploic calvarium has two distinct cortical bone layers between which is an interstitial layer of honeycombed bone and vessels.
- The brain is encased by the frontal, parietal, temporal, and occipital bones.
- The temporalis muscles cover almost the entire calvarium.

ZYGOMATIC ARCH FRACTURE

Preoperative Considerations

- Before anesthesia and surgery, perform a complete neurologic examination on all head trauma patients.
- General anesthesia may alter intracranial pressure (ICP), leading to exacerbation of intracranial edema and/or hemorrhage.
- To reduce ICP, consider hyperventilation (to reduce $PaCO_2$), osmotic agents, corticosteroids, and an anesthetic protocol including barbiturates (see Chapter 2).
- Obtain skull radiographs to document fracture displacement and to screen for other, less apparent fractures. If possible, perform radiography immediately before surgery, thus avoiding the necessity for, and risk of, two separate anesthetic procedures.
- If available, computed tomography (CT) provides the most accurate assessment of the presence and severity of skull and cranial fractures. CT views avoid superimposition of overlying bone that makes the interpretation of plain skull radiographs difficult.
- Confirm the presence of an intact optic nerve and vision before surgery. Surgery for a zygomatic arch fracture may be contraindicated if ocular function is irreversibly impaired.

▼ ***Key Point*** Acepromazine may lower the central nervous system (CNS) seizure threshold, and ketamine increases cerebral blood flow. Do not use these drugs in patients with a history of brain trauma.

Surgical Procedure

Objectives

- Reduce fractures that can cause compression of the eye or cosmetic deformity.
- Avoid trauma to the zygomaticotemporal and zygomaticofacial nerves.

▼ ***Key Point*** Non-displaced fractures of the zygomatic arch have a good prognosis for uncomplicated healing with conservative management.

Equipment

- Standard general surgical pack and sutures
- Gelpi or Weitlaner self-retaining retractors
- Sharp periosteal elevator
- Small Steinmann pins and orthopedic wire (multiple sizes, 18–24 gauge)
- Small malleable retractor

Technique

1. Place the patient in ventral recumbency with the head supported. Attach tape to the mandibular canines and the table to secure the head position.
2. Prepare the periocular area for aseptic surgery. Ocular lubricating ointment avoids corneal damage from antiseptic agents.
3. Incise the skin directly over the zygomatic arch.
4. Incise and elevate the periosteum using a sharp periosteal elevator. Be careful to avoid the zygomaticotemporal and zygomaticofacial nerves (medial to the zygomatic bone).
5. Use a small malleable retractor to protect the orbit.
6. Reduce and secure fracture fragments using orthopedic wire (18–24 gauge, depending on the size of the animal). Small pins may be used to make holes in the bone for wire placement. Small orthopedic plates may be required to maintain reduction in extremely comminuted fractures or when cosmesis is of paramount importance.

▼ ***Key Point*** Do not use small pins as a component of the definitive repair, because pin migration following surgery may cause ocular and intracranial trauma.

7. Appose subcutaneous tissues in a simple interrupted pattern (absorbable suture).
8. Subcuticular sutures (absorbable suture) provide skin apposition and avoid suture irritation of ocular structures.

Postoperative Care and Complications

Short Term

- Perform serial neurologic examinations to monitor changes in neurologic status.
- Monitor for clinical signs of seroma and infection.

Long Term

- Excessive bony callus may compress ocular structures and interfere with mastication.
- Periarticular fractures may lead to degenerative joint disease of the temporomandibular joint (TMJ) and bony ankylosis.
- If normal function is inhibited or pain persists, resection of the affected segment of the zygomatic arch is indicated. Reconstruction of the muscle tissue provides acceptable appearance and function.

Prognosis

- The prognosis is good with conservative management.
- With operative management, the prognosis is good to excellent.

EXTRACRANIAL FRACTURES

Extracranial fractures include fractures of the nuchal crest, sagittal crest, and frontal sinus.

Preoperative Considerations

See “Zygomatic Arch Fracture.”

Surgical Procedure

Objective

- Maintain reduction of severely displaced fractures of the nuchal crest, sagittal crest, and frontal sinus.

▼ ***Key Point*** The cranial muscle mass usually prevents severe fracture displacement and provides enough fracture stability to allow conservative management of most extracranial fractures.

Equipment

- Standard general surgical pack and sutures
- Gelpi or Weitlaner self-retaining retractors
- Sharp periosteal elevator
- Small Steinmann pins and orthopedic wire (multiple sizes, 20–24 gauge)

Technique

1. Place the patient in ventral recumbency with the head supported. Attach tape to the mandibular canines and table to secure the head position.
2. Prepare the fracture area for aseptic surgery.
3. Make a skin incision directly over the fractured bony prominence.
4. Elevate the periosteum to allow anatomic reduction.
5. Frontal sinus fractures usually are depressed, requiring elevation and fixation with orthopedic wire.
6. Reduce and fix nuchal and sagittal crest fractures with orthopedic wire.

▼ ***Key Point*** Do not use small pins as a component of the definitive repair because pin migration following surgery may cause ocular or intracranial trauma.

7. Appose muscle fascia and subcutaneous tissues in individual layers, using absorbable suture in a simple interrupted pattern.
8. Close the skin similarly, using non-absorbable suture.

Postoperative Care and Complications

Short Term

- Perform serial neurologic examination to monitor for change in neurologic status.
- Monitor for clinical signs of seroma and infection.
- Subcutaneous emphysema may occur secondary to frontal sinus fracture. Whether management of the fracture is surgical or conservative, a compressive bandage minimizes continued formation of subcutaneous emphysema until organized hematoma and fibrin deposition provide a functional barrier to air migration from the frontal sinus. Thus, bandaging is recommended for 2 to 4 days.

Long Term

- Fractures usually heal without complications, providing acceptable cosmesis.
- Most complications are related to CNS trauma, such as seizures (see Chapter 127).

INTRACRANIAL FRACTURES

Preoperative Considerations

- Preoperative anesthetic and neurologic concerns are similar to those for zygomatic arch fractures.
- Fractures may be linear cracks, depressed bony fragments, or comminuted separate bony fragments.
- Intracranial fractures are usually closed fractures.
- Comminuted calvarial fractures may lacerate meninges, venous sinuses, or the cerebral cortex.
- Calvarial fractures usually are associated with CNS compromise. Medical management of CNS trauma is indicated before diagnostic procedures requiring anesthesia.
- Progressive deterioration in CNS status despite intensive medical management is an indication for skull radiography to determine fracture severity.

Surgical Procedure

Objectives

- Elevate depressed calvarial fractures that may cause extensive functional loss of cerebral mass.
- Remove large comminuted fragments of the calvarium that may cause cerebral laceration.

▼ ***Key Point*** Linear and minor depressed intracranial fractures are best managed conservatively.

Equipment

- Standard general surgical pack and sutures
- Gelpi or Weitlaner self-retaining retractors
- Sharp periosteal elevator
- Pneumatic or electric bur drill

Technique

1. Place the patient in ventral recumbency with the head supported. Attach tape to the mandibular canines and table to secure the head position.
2. Prepare the dorsal skull area for aseptic surgery.
3. Make a dorsal incision (Fig. 96-1*A*).
4. Incise the superficial temporal fascia and elevate the temporalis muscle ventrally to expose the fracture area (Fig. 96-1*B*).

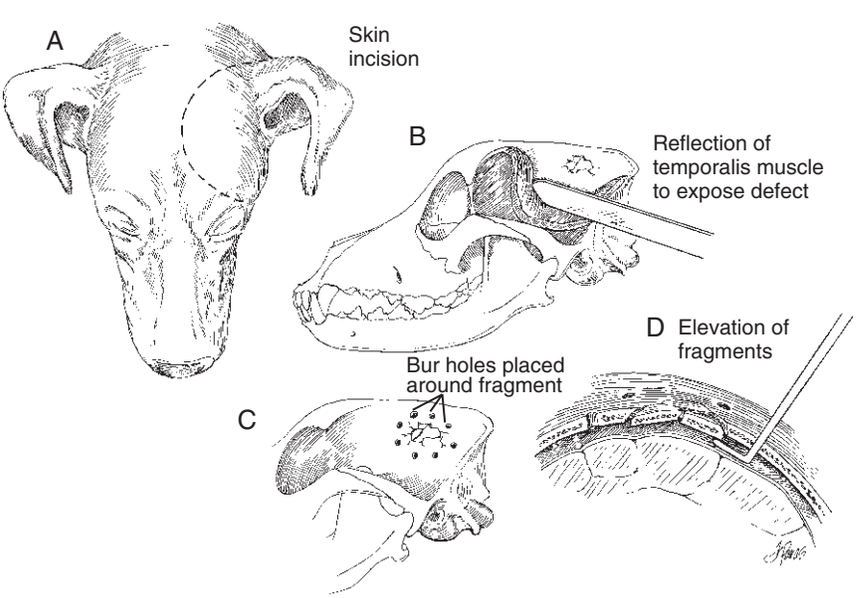

Figure 96-1. Procedure for repairing intracranial fracture. See text for explanation.

5. Drill multiple small bur holes through the calvarium around the periphery of the fracture area to allow elevation of the fracture fragments (Fig. 96-1*C*).
6. Elevate fragments with a small, blunt elevator (Fig. 96-1*D*).
7. Remove any large comminuted fragments that may cause laceration. Despite the potential for large calvarial defects, replacement of the temporalis muscle provides adequate coverage.
8. Replace the temporalis muscle and appose the superficial fascia using absorbable suture in a simple interrupted pattern.
9. Close the subcutaneous layers similarly, followed by skin closure using non-absorbable suture in a simple interrupted pattern.

▼ ***Key Point*** Meticulous, atraumatic surgical technique, prevention of cerebral edema, and removal of hematoma if calvarial fragments are removed are of the highest priority when operating on intracranial fractures.

Postoperative Care and Complications

Short Term

- Perform serial neurologic examinations to monitor for change in neurologic status.
- Monitor for clinical signs of seroma and infection.

Long Term

- Bony healing occurs without complication; however, neurologic recovery depends on the location and severity of the original traumatic incident.

Prognosis

- With cranial fracture repair, the prognosis is good.
- For neurologic recovery there is a guarded prognosis.

Chapter 97

Fractures and Dislocations of the Mandible

Richard M. Jerram

Mandibular fractures account for approximately 2% of all fractures in dogs and 15% of all fractures in cats. Most mandibular fractures occur as a result of automobile trauma, although dog bites and gunshots are also reported causes. Pathologic fractures can occur with severe dental or metabolic disease. Young cats and dogs (<2 years of age) are more likely to have mandibular fractures. Mandibular fractures present the veterinarian with some unique clinical management considerations. Concurrent head and thoracic trauma make anesthetic management challenging, the placement of oral endotracheal tubes makes an accurate assessment of occlusion difficult, and providing postoperative oral nutrition can be critical in determining clinical success. Dislocations of the temporomandibular joints occur less frequently and can occur in conjunction with mandibular fractures or other facial trauma.

ANATOMY

The mandible consists of left and right halves that are joined by a rigid fibrous symphysis at the rostral midline. Each half is further divided into the horizontal body and the vertical ramus.

- The horizontal body contains the teeth along the alveolar border. The alveolar border is the tension surface of the mandible.
- The mandible has a mandibular canal (not a medullary cavity like axial long bones) that contains the mandibular artery and vein as well as the mandibular alveolar nerve that supply the teeth and soft tissues of the lower jaw.
- The mandibular vessels and nerve enter the canal caudally at the mandibular foramen on the medial side at the junction of the body and ramus.
- The mandibular canal opens cranially at three mental foramina located lateral to the premolar teeth.
- The condyloid process of the ramus articulates with the temporal bone in the mandibular fossa forming the temporomandibular joint. This joint contains a thin articular disc (meniscus) in the dog.
- The muscles of mastication (masseter, temporalis, pterygoideus, and digastricus) insert on the coronoid and angular processes of the vertical ramus.

CLINICAL SIGNS

Clinical signs can vary but include the following:

- Asymmetry of the jaw
- Crepitus on mandible manipulation
- Oral hemorrhage
- Oral pain
- Concurrent head and thoracic trauma

DIAGNOSIS

- Diagnosis is usually based on history and clinical examination.
- Careful oral examination is necessary as there may be more than one fracture present.
- Standard dorsoventral and lateral radiographs are performed first.
- Oblique and open-mouthed views may highlight fractures undetected on standard radiographs.
- Carefully evaluate radiographs to identify other skull fractures.
- Computed tomography (CT) scans, where available, can provide a three-dimensional impression of the fracture(s) present.

SURGICAL PROCEDURES

Preoperative Considerations

▼ ***Key Point*** Manage concurrent head, upper airway, and thoracic trauma prior to performing mandibular fracture repair.

- Establish a patent airway, control hemorrhage, and treat shock.
- Obtain thoracic radiographs and manage any pleural space disease—that is, pneumothorax, hemothorax, diaphragmatic hernia, or pulmonary contusion.
- Record an electrocardiogram to assess for the presence of cardiac arrhythmias secondary to traumatic myocarditis.

- Complete a neurologic examination of the head and treat any possible brain edema or hemorrhage.

Anesthetic Considerations

- Endotracheal intubation is essential to reduce the risk of aspiration of blood and debris.
- To assess dental occlusion intraoperatively, place the endotracheal tube through a pharyngotomy incision.

▼ ***Key Point*** Use an endotracheal tube placed through a pharyngotomy incision to help establish normal occlusion during fracture repair.

- Most mandibular fractures are open; therefore, prophylactic antibiotics are recommended prior to surgery. Cefazolin (20 mg/kg IV) is preferred.

Surgical Principles

Adherence to several basic principles of mandibular fracture management will improve clinical success and reduce complication rates.

- Restore dental occlusion. Accurate anatomic reconstruction of fracture fragments will restore normal occlusion. Use an endotracheal tube placed through a pharyngotomy incision.

▼ ***Key Point*** The goal of mandibular fracture repair is to restore normal dental occlusion.

- Rigid fixation and neutralization of the fracture forces provides a rapid return to function.
- Carefully handle soft tissues. Avoid entrapment of soft tissues, remove devitalized tissue, and avoid excessive elevation of soft tissues from bone.
- Avoid further dental trauma. Remove only teeth that are luxated or fractured. Leave teeth in the fracture site that will contribute to stabilization of the fracture.
- Intramedullary pinning of mandibular fractures is not recommended due to the shape of the mandibular canal and the presence of the tooth roots, major vessels, and nerves.

Equipment

- Standard general surgical pack
- Orthopedic wire (various sizes) and wire twisters
- External skeletal fixation devices (generally small size)
- Bone plates and screws (generally sizes 1.5 mm to 2.7 mm)

Postoperative Care

- Provide appropriate nutrition during the recovery period.
- Cats, particularly, are less willing to eat after facial trauma. Place an esophagostomy feeding tube at the time of mandibular surgery.

▼ ***Key Point*** In cats, place an esophagostomy feeding tube for postoperative nutrition (see Chapter 3).

- Gastrostomy feeding tubes may be placed endoscopically if long-term tube feeding is expected (see Chapter 3).
- If a feeding tube is not used, feed a soft gruel for 4 weeks after surgery.
- Prevent animals from chewing toys or hard objects such as bones and sticks.
- Daily oral flushing with a dilute chlorhexidine solution will reduce oral bacterial contamination and clean implants placed around the teeth.

Complications

- Malocclusion is the most important complication postoperatively. Evaluate patients every 2 weeks to ensure normal occlusion is being maintained. Further surgery may be necessary if malocclusion occurs.
- Osteomyelitis occurs rarely; long-term (6–8 weeks) treatment with appropriate antibiotics is required.
- Implant failure and non-union can occur and are generally related to poor preoperative planning and implant choice.
- Damage to remaining teeth from either the original trauma or the surgery may result in dental pain or infection after the fracture has healed. Tooth extraction or endodontic therapy may be indicated.
- Temporomandibular joint ankylosis can occur following trauma to the condyloid process of the mandible. Resection of the condyloid process (condylectomy) or osteophytes may be necessary.

MANDIBULAR SYMPHYSEAL SEPARATIONS

Separation of the mandibular symphysis accounts for the majority of the mandible fractures identified in cats. Care should be taken to ensure that there is no concurrent trauma to the caudal aspect of the mandible, particularly in the area of the condyloid processes. The fixation method should provide normal occlusion. Wire stabilization is the technique of choice.

Technique

1. Place the animal in dorsal recumbency and clip and prepare the chin for aseptic surgery.
2. Make a small stab incision in the ventral mandibular skin at the level of the caudal edge of the mandibular symphysis.
3. Insert a hypodermic needle with an internal diameter larger than the intended orthopedic wire through the incision and lateral to one hemimandible. The needle should exit orally caudal to the canine tooth (see Fig. 97-1).

4. Pass orthopedic wire (generally 18–22 gauge, depending on the size of the animal) through the needle. Remove the needle, leaving the wire in place.
5. Insert the needle through the same incision lateral to the opposite hemimandible.
6. Pass the oral end of the wire, caudal to the canine tooth, through the needle to exit ventrally. Remove the needle, leaving both wire ends ventrally.
7. Twist the wire together using wire tighteners while maintaining mandibular alignment and normal occlusion until reduction and stability is achieved. Cut off the wire, leaving three twists.
8. Leave the ends exposed and remove in 6 to 8 weeks by cutting the exposed oral wire and pulling on the twisted end.

Alternative Techniques

Interdental wire with or without dental acrylic can be performed; however, medial rotation of each hemimandible can occur with overtightened wire.

MANDIBULAR BODY FRACTURES

The fixation method of choice for mandibular body fractures depends on the age and size of the animal, fracture location, fracture stability, degree of comminution, and amount of oral or dental trauma present. Numerous surgical techniques have been described; however, only the techniques that are used most commonly and have high reported success rates will be described here. Placing an intramedullary pin in the mandibular canal is strongly discouraged due to the likely damage to the intramandibular neurovascular structures and tooth roots, as well as the high rate of malocclusion and non-union.

Tape Muzzle

Fractures in young dogs with minimal displacement of fragments can be treated using a tape muzzle. Tape muzzles can also be used to augment other methods of fracture repair if fragment stability or dental occlusion is uncertain. Tape muzzles are difficult to place and maintain in cats and brachycephalic breeds of dog due to the short length of the muzzle.

1. Make a circular muzzle from adhesive non-elastic tape (sports-strapping type) by placing both sticky surfaces together. The diameter should allow the dog to open the mouth no more than 10 mm and to maintain dental occlusion.
2. Use additional pieces of tape to complete the muzzle around the head and behind the ears (see Chapter 98, Fig. 98-1 for an illustration of a tape muzzle.)

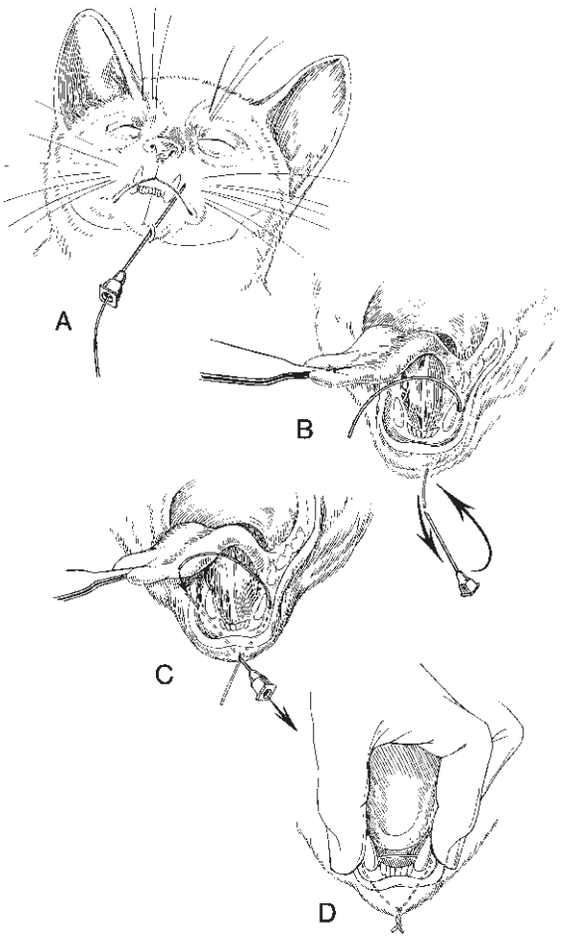

Figure 97-1. Wire stabilization for mandibular symphyseal fracture. See text for details.

3. Daily cleaning of the muzzle and underlying skin is necessary. Feed the dog a soft, gruel-type food that can be lapped through the gap remaining.
4. Alternatively, tape the mouth completely closed after an enteral feeding tube (esophagostomy, gastrostomy) has been placed.
5. The tape muzzle can be removed after 4 to 8 weeks depending on the degree of bone healing. Feed soft food for several weeks after removal of the muzzle.

Maxillary-Mandibular Fixation

Reduction of fracture fragments and dental occlusion can be achieved by securing the mandible to the maxilla, especially for animals (i.e., cats and small dogs) that have facial conformation or temperaments that make maintaining a tape muzzle difficult. Animals will be unable to reduce their body temperature by panting and should be kept out of warm environments to avoid hyperthermia during the healing phase. Animals are

also at increased risk for aspiration pneumonia if vomiting occurs. Wire loops or dental acrylic bonding have been reported.

Maxillomandibular Wiring

1. Drill a hole through the furcation of maxillary fourth premolar tooth and the mandibular first molar tooth on both hemimandibles.
2. Pass the end of a wire loop through the maxillary hole from lateral to medial. Pass the end from medial to lateral through the mandibular hole.
3. Twist the ends together laterally, ensuring dental occlusion and leaving an oral gap of up to 10 mm to enable to animal to lap gruel-type food.
4. An enteral feeding tube (esophagostomy, gastrostomy) can be used to provide nutrition during healing.
5. Alternatively, place orthopedic screws in both sides of the maxilla and mandible, avoiding tooth roots. Place an elastic band between the screw heads. This method allows simple removal of the band in an emergency.
6. The wires can be placed more rostrally at the level of the premolar teeth, but longer wires will be required due to the normal gap in dental occlusion in this region.

Acrylic Bonding of the Canine Teeth

1. Polish the canine teeth with a pumice material and etch using a phosphoric acid-etch gel.
2. Align the teeth and apply a dental self-curing, composite, temporary restorative material to cover the opposing canine teeth.
3. A gap of up to 10 mm is left to allow lapping of a gruel-type food.
4. Remove the dental acrylic using dental instruments 4 to 6 weeks after application, taking care to avoid damaging the teeth.
5. This technique requires that all four canine teeth be healthy and intact.

Interfragmentary Wiring

The wiring of mandibular fragments is acceptable for fracture fragments that are stable without loss of bone or comminution. Wires should be placed as dorsal as possible to neutralize the tensile forces acting on the oral margin of the mandible. The technique requires drilling through the mandible, so care must be taken to avoid tooth roots and neurovascular structures of the mandibular canal. Wire size is dependent on the size of the animal.

1. Make a skin incision over the ventral surface of the mandible, and elevate the soft tissues from the fragments adjacent to the fracture.
2. Drill a hole in each fragment using either an oscillating drill bit or a smooth K-wire to avoid damage to the vessels and nerve. The hole should be 5 to 10 mm from the fracture edge.
3. A loop of wire (the largest gauge that can be manipulated) is passed through the holes and tightened on the lateral aspect of the mandible.
4. The wire should be perpendicular to the fracture line to allow compression during tightening and to avoid shearing of the fracture fragments.
5. Cut the twisted wire and bend ventrally to avoid damage to the overlying skin.
6. If multiple wires are used, place all wires prior to tightening. Tightening should be performed from caudal to rostral while maintaining dental occlusion.

Intraoral Acrylic Splint

The conical shape of the teeth in cats and dogs makes application of interdental wires difficult without damage to the periodontal tissues. The use of finer orthopedic wire as support for an intraoral acrylic splint provides excellent stability for fractures without bone or tooth loss. The technique is best used for fractures rostral to the molar teeth.

1. Clean, polish, and acid-etch the teeth using a phosphoric acid gel.
2. Apply fine-gauge orthopedic wire (22–26 gauge) around the dentition in a Stout loop fashion. One end of the wire is placed along the medial surface of the teeth. The other end is passed laterally.
3. At each interdental space, pass the lateral wire medially and loop around the medial wire before returning to the medial side of the mandible. Repeat until all teeth are encircled with wire.
4. The loops of wire on the medial surface are twisted and flattened against the tooth surfaces.
5. Apply a dental self-curing, composite, temporary restorative material to cover the teeth and the preplaced wire. Acrylic should not enter the fracture site.
6. Cold-curing dental acrylic can also be applied by using dental wax to prevent acrylic from running off the teeth during the liquid phase of curing.
7. Check dental occlusion during curing and acrylic is removed from tooth surfaces where it prevents normal occlusion.
8. Perform daily intraoral flushing of the acrylic device to dislodge trapped food particles.
9. Remove the splint 6 to 8 weeks after application, following radiographic confirmation of bony healing.

External Skeletal Fixation

External skeletal fixation (ESF) is best applied to fractures that are comminuted, open, or involve bone loss. There must be sufficient bone on either side of the fracture to hold bone pins. Pin placement must be carefully

planned to avoid tooth roots. Pins should not cross the intramandibular space to avoid interfering with function of the tongue. Positive-profile threaded pins provide greater bone holding than smooth pins but may damage intramandibular neurovascular structures. Either standard metal connecting bars can be used or, more conveniently, an acrylic connecting bar can be molded to fit the pins using silicone tubing.

1. Make short stab incisions over the bone at the point of predetermined pin insertion.
2. Insert pins into the bone fragments, penetrating both the lateral and the medial cortices.
3. Connect the pins using ESF clamps and connecting bars, or place a length of silicone tubing over the bent pin ends. The connecting bars or tubing should lie approximately 10 mm from the adjacent skin.
4. Inject dental acrylic or polymethylmethacrylate bone cement into the tubing. The acrylic is allowed to cure while the mouth is held in normal occlusion.
5. An acrylic ESF device can be applied to bilateral fractures by molding the silicone tubing in a U shape around the rostral aspect of the mandible.
6. Clean the sites where the pins enter the skin daily.
7. Remove the ESF device after 6 to 8 weeks, following radiographic confirmation of bone healing, by cutting the pins against the connecting bar and removing each pin individually.

Bone Plating

Bone plating of mandibular body fractures provides rigid stability and a rapid return to normal function. The bone plate must be accurately contoured to the bone surface to avoid malocclusion, and screws should not damage tooth roots. It is often difficult to apply bone plates as close to the tension (oral) surface of the mandible as possible because screw holes are frequently over tooth roots. If the plate is secured to the ventral aspect of the mandible, then additional support with an interdental wire orally may be required. Recently, there have been reports of successful mandible fracture repair using miniplates. These small titanium plates are more easily applied to the dorsal aspect of the mandible, but special instruments are required for their application.

1. Place the animal in dorsal (for bilateral fractures) or dorsolateral recumbency (for unilateral fractures) and make a ventral incision over the mandibular body.
2. Elevate the subcutaneous tissues to expose the fracture ends.
3. Contour the bone plate to fit the mandible ventrolaterally, avoiding tooth roots. At least two screws should be placed on either side of the fracture.
4. Drill screw holes with an oscillating drill bit to avoid damage to the neurovascular structures.
5. Secure the bone plate to the mandible while normal dental occlusion is ensured.
6. The subcutaneous tissues and skin are closed routinely.
7. Place an interdental or interfragmentary wire more dorsally across the fracture line to counter tensile forces.
8. Feed soft, gruel-type food, and obtain radiographs 6 to 8 weeks later to evaluate bone healing.
9. Bone plates may need to be removed if they cause pain or erosion of the oral mucosa.

MANDIBULAR RAMUS FRACTURES

Fractures of the vertical part of the mandibular ramus are generally minimally displaced and do not require surgical treatment. The application of a tape muzzle or maxillary-mandibular fixation (previously described) may be necessary to provide adequate stability while the fractures heal. Unstable fractures may require interfragmentary wire or miniplate fixation. The surgical approach to the mandibular ramus requires elevation of the large masseter muscle.

Fractures of the condyloid process usually occur in association with other mandibular fractures. These fractures can be identified in cats with concurrent mandibular symphyseal separation that develop malocclusion following symphyseal stabilization. Treatment is generally non-surgical with a tape muzzle or maxillary-mandibular fixation. Acrylic bonding of the canine teeth is most successful in cats. In larger dogs, a lateral approach can be made to the condylar region and fracture fragments may be stabilized with interfragmentary K-wires.

Condylectomy

Intra-articular fractures may heal with ankylosis or arthrosis of the temporomandibular joint. These animals develop an inability to open the mouth and are unable to prehend solid food. Unilateral condylectomy (analogous to femoral head and neck ostectomy for severe hip fractures) is the treatment of choice for these patients.

1. Place the animal in lateral recumbency and make a skin incision along the ventral border of the zygomatic arch.
2. Approach to the temporomandibular joint by elevation of the masseter muscle from its caudal insertion on the zygomatic arch.
3. Identify the joint and resect the condyloid process. Resection can be performed using a rongeur or an osteotome.
4. Leave the temporomandibular joint meniscus in place. Closure of the muscle fascia, subcutaneous tissues, and skin is routine.
5. Postoperative physical therapy is encouraged.

TEMPOROMANDIBULAR JOINT DISLOCATIONS

Luxation of the temporomandibular joint (TMJ) is uncommon but typically occurs as a result of head trauma. TMJ luxation can be unilateral or bilateral and may occur concurrently with fractures of other areas of the mandible.

- The condyloid process generally displaces in a rostral and dorsal direction.
- The diagnosis is made on physical examination, palpation, and radiographic confirmation of luxation.
- A unilateral rostrodorsal luxation results in the mandible moving to the opposite side, whereas a bilateral luxation results in the mandible moving rostrally.
- Assess the entire mandible for other injuries.
- Most isolated luxations can be reduced using closed reduction.

Closed Reduction

1. Place the animal under general anesthesia and place in dorsal recumbency.
2. Place a rod or dowel in the mouth transversely between the mandibular and the maxillary molar teeth.
3. Using the rod as a fulcrum, close the mouth while the mandible is manipulated rostrally or caudally to reduce the condyloid process.
4. After reduction, use a tape muzzle or maxillary-mandibular fixation (as previously described) to support the reduction for 7 to 14 days.
5. If closed reduction is not possible, then open reduction or condylectomy may be necessary.

TEMPOROMANDIBULAR JOINT DYSPLASIA

TMJ dysplasia is seen in young dogs resulting from deformation of the condyloid process and mandibular fossa that causes subluxation of the TMJ and occasional open-mouthed locking of the mandible.

- Open-mouthed locking has been reported in Irish setters, basset hounds, and cocker spaniels.
- The condition presents as a locking of the mandible in an open position during yawning.
- The TMJ dysplasia results in the coronoid (vertical) process of the mandibular ramus being malpositioned lateral to the zygomatic arch.
- A subcutaneous bulge can be palpated over the zygomatic arch on the affected side.
- Some dogs will reduce the coronoid process unassisted.
- Closed reduction can be achieved by direct pressure over the palpable coronoid process while manipulating the mandible.
- Animals with chronic open-mouth locking may require surgical treatment with condylectomy or resection of the zygomatic arch.

Zygomatic Arch Resection

1. Place the animal under general anesthesia and position in lateral recumbency.
2. Make an approach directly over the zygomatic arch, and elevate the fascial attachments.
3. Manipulate the mandible to determine the portion of the zygomatic arch that is trapping the coronoid process.
4. Remove the identified section of zygomatic arch using a rongeur or a high-speed bone bur.
5. Closure is routine after ensuring that the coronoid process is no longer trapped by the remaining zygomatic arch.
6. Additional mandibular support should not be required.

Chapter 98

Fractures of the Maxilla

Richard M. Jerram

Fractures of the maxilla generally include all fractures rostral to the orbit—that is, the maxilla, nasal, and incisive bones. Most maxillary fractures occur as a result of automobile trauma, although dog bites and gunshots are also reported causes. Young cats and dogs (<2 years of age) are more likely to have maxillary fractures. Maxillary fractures present the veterinarian with some unique clinical management considerations. Concurrent head and thoracic trauma make anesthetic management challenging, the placement of oral endotracheal tubes makes an accurate assessment of occlusion difficult, and providing postoperative oral nutrition can be critical in clinical success.

ANATOMY

The upper jaw consists of paired incisive, maxillary, and nasal bones that vary greatly in size depending on the species or breed. Brachycephalic dog breeds and cats have shorter and smaller bones than dolichocephalic dog breeds.

- The incisive bones contain the upper incisor teeth; the maxilla bones contain the canine, premolar, and molar teeth.
- The bone between the roots of the teeth and the nasal cavity is very thin and easily damaged from trauma.
- The infraorbital artery and nerve travel through the infraorbital foramen located as an elliptical opening dorsal to the upper third and fourth premolar teeth.
- The palatal aspect of the maxilla is supplied by the major palatine artery that exits the major palatine foramen at the junction of the maxilla and palatine bones on the caudal aspect of the hard palate. The vessel travels rostrally medial to the teeth along the surface of the hard palate. There are numerous anastomoses among blood vessels of the maxilla.

CLINICAL SIGNS

Clinical signs can vary but include the following:

- Asymmetry of the maxilla
- Crepitus on maxillary manipulation
- Nasal hemorrhage
- Oral hemorrhage
- Oral pain
- Concurrent head and thoracic trauma

DIAGNOSIS

- Diagnosis is usually based on history and clinical examination.
- Carefully examine the oral and nasal cavities as there may be more than one fracture present.
- Obtain standard dorsoventral and lateral radiographs.
- Oblique and open-mouthed views may highlight fractures undetected on standard radiographs.
- Carefully evaluate radiographs to identify other skull fractures.
- Computed tomography (CT) scans, where available, can provide a three-dimensional impression of the fracture(s) present.

SURGICAL PROCEDURES

Preoperative Considerations

▼ ***Key Point*** Manage concurrent head, upper airway, and thoracic trauma prior to performing maxillary fracture repair.

- Establish a patent airway, control hemorrhage, and treat shock.
- Obtain thoracic radiographs and manage any pleural space disease—that is, pneumothorax, hemothorax, diaphragmatic hernia, or pulmonary contusion (see Chapter 166).
- Record an electrocardiogram to assess for the presence of cardiac arrhythmias secondary to traumatic myocarditis.
- Complete a neurologic examination of the head and treat any possible brain edema or hemorrhage.

Anesthetic Considerations

- Endotracheal intubation is essential to reduce the risk of aspiration of blood and debris.

- To assess dental occlusion intraoperatively, place the endotracheal tube through a pharyngotomy incision.

▼ ***Key Point*** Use an endotracheal tube placed through a pharyngotomy incision to allow observation of normal occlusion during fracture repair.

- Many maxillary fractures are open; therefore, administer prophylactic antibiotics prior to surgery (Cefazolin 20 mg/kg IV).

Objectives

Adherence to several basic principles of maxillary fracture management will improve clinical success and reduce complication rates.

- Restore dental occlusion. Accurate anatomic reconstruction of fracture fragments will restore normal occlusion. Use an endotracheal tube placed through a pharyngotomy incision.

▼ ***Key Point*** The goal of maxillary fracture repair is to restore normal dental occlusion.

- Rigid fixation and neutralization of the fracture forces provides a rapid return to function.
- Restore patent nasal passages in animals with severe fracture displacement or a blocked nasal cavity.
- Carefully handle soft tissues. Avoid entrapment of soft tissues, remove devitalized tissue, and avoid excessive elevation of soft tissues from bone.
- Avoid further dental trauma. Remove only teeth that are luxated or fractured. Leave teeth in the fracture site that will contribute to stabilization of the fracture.
- The surgical approach is usually made intraorally, although more dorsal fractures require an approach through the skin of the dorsal midline.

Equipment

- Standard general surgical pack
- Orthopedic wire (various sizes) and wire twisters
- External skeletal fixation devices (generally small size)
- Bone plates and screws (generally sizes 1.5–2.7 mm)

Midline Maxillary Separations (Traumatic Cleft Palate)

Separation of the midline junction of the maxilla bones accounts for the majority of the maxillary fractures identified in cats. These fractures are seen following trauma and present as a cleft defect in the mucosa of the hard palate. Wide defects are treated by surgical closure. (Also see Chapter 64.)

Technique

1. Place the animal in dorsal recumbency and prepare the palate for aseptic surgery.
2. Debride necrotic soft tissue and gently undermine the edges of the mucosa adjacent to the defect.
3. Use digital pressure to approximate the edges of the bony defect.
4. Suture the palate mucosa across the defect using monofilament absorbable suture material (e.g., 3-0 or 4-0 polydioxanone suture).

Alternative Technique

Apply interdental wire with or without dental acrylic between the opposing third incisor and the canine teeth if the defect is considerably displaced or unstable.

Maxillary Body Fractures

The fixation method of choice for maxillary body fractures depends on the age and size of the animal, fracture location, fracture stability, degree of comminution, and amount of oral or dental trauma present. Most maxillary fractures are minimally displaced and do not require surgical treatment. Interfragmentary wiring and interdental wiring with dental acrylic are good choices for fractures that are displaced or are resulting in dental malocclusion. More recently, excellent success rates have been reported with miniplate fixation.

Tape Muzzle

Fractures in young dogs with minimal displacement of fragments can be treated using a tape muzzle. Tape muzzles can also be used to augment other methods of fracture repair if fragment stability or dental occlusion is uncertain. Tape muzzles are difficult to place and maintain in cats and brachycephalic breeds of dog due to the short length of the muzzle.

Technique

1. Make a circular muzzle from adhesive non-elastic tape (sports-strapping type) by placing both sticky surfaces together. The diameter should allow the dog to open the mouth no more than 10 mm and to maintain dental occlusion.
2. Use additional pieces of tape to complete the muzzle around the head and behind the ears (Fig. 98-1).
3. Clean the muzzle and underlying skin daily. Feed soft, gruel-type food that can be prehended through the gap remaining.
4. Alternatively, completely close the mouth after an enteral feeding tube (esophagostomy, gastrostomy) has been placed (see Chapter 3).
5. Remove the tape muzzle after 4 to 8 weeks depending on the degree of bone healing. Continue soft food for several weeks after removal of the muzzle.

Interfragmentary Wiring

The wiring of maxillary fragments is acceptable for fracture fragments that are stable without loss of bone or comminution. Place wires as ventral as possible to neu-

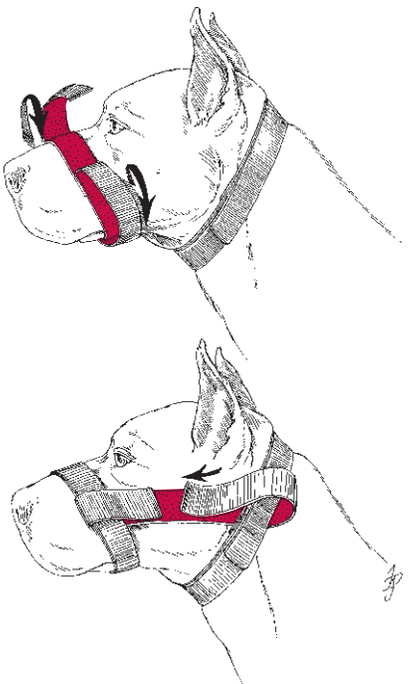

Figure 98-1. Procedure for creating a tape muzzle. See text for explanation.

tralize the tensile forces acting on the oral margin of the maxilla. The technique requires drilling through the maxilla, so take care to avoid tooth roots and neurovascular structures of the infraorbital canal. Wire size is dependent on the size of the animal.

Technique

1. Incise the skin or mucosa over the surface of the maxilla and elevate the soft tissues from the fragments adjacent to the fracture.
2. Drill a hole in each fragment using either an oscillating drill bit or a smooth K-wire to avoid damage to the vessels and nerve. The hole should be 5 to 10 mm from the fracture edge.
3. Pass a loop of wire (the largest gauge that can be manipulated) through the holes and tighten on the lateral aspect of the maxilla.
4. Place the wire perpendicular to the fracture line to allow compression during tightening and to avoid shearing of the fracture fragments.
5. Cut and bend the twisted wire ventrally to avoid damage to the overlying skin or mucosa.

Intraoral Acrylic Splint

The conical shape of the teeth in cats and dogs makes application of interdental wires difficult without damage to the periodontal tissues. Finer orthopedic wire as support for an intraoral acrylic splint provides excellent stability for fractures without bone or tooth loss.

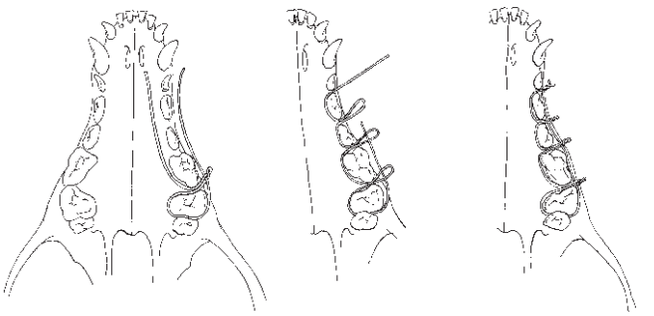

Figure 98-2. Initial *(left)* and final *(center* and *right)* appearance of Stout continuous loop wiring pattern. Note that the working wire is *not* twisted lingual to the stationary wire.

Technique

1. Clean, polish, and acid-etch the teeth using a phosphoric acid gel.
2. Place fine-gauge orthopedic wire (22–26 gauge) around the dentition in a Stout loop fashion. Place one end of the wire along the lateral surface of the teeth. Pass the other end medially.
3. At each interdental space, pass the medial wire laterally and loop it around the lateral wire before returning to the medial side of the mandible. Repeat until all teeth are encircled with wire (Fig. 98-2).
4. Twist the loops of wire on the lateral surface and flatten against the tooth surfaces.
5. Apply a dental self-curing, composite, temporary restorative material to cover the teeth and the preplaced wire. Do not allow acrylic to enter the fracture site.
6. Cold-curing dental acrylic can also be applied by using dental wax to prevent acrylic from running off the teeth during the liquid phase of curing.
7. Check dental occlusion during curing and remove acrylic from tooth surfaces where it prevents normal occlusion.
8. Perform daily intraoral flushing of the acrylic device to dislodge trapped food particles.
9. Remove the splint 6 to 8 weeks after application, following radiographic confirmation of bony healing.

External Skeletal Fixation

External skeletal fixation (ESF) is best applied to fractures that are comminuted, open, or involve extensive bone loss. There must be sufficient bone on either side of the fracture to hold bone pins. Pin placement must be carefully planned to avoid tooth roots. Positive-profile threaded pins provide greater bone holding than smooth pins but may damage maxillary neurovascular structures. Either standard metal connecting bars can be used or, more conveniently, an acrylic connect-

ing bar can be molded to fit the pins using silicone tubing.

Technique

1. Make short stab incisions over the bone at the point of predetermined pin insertion.
2. Insert pins into the bone fragments, penetrating both the lateral and the medial cortices.
3. Connect the pins using ESF clamps and connecting bars or place a length of silicone tubing over the bent pin ends. (See Chapter 111 for illustrations of the apparatus.) The connecting bars or tubing should lie approximately 10 mm from the adjacent skin.
4. Inject dental acrylic or polymethylmethacrylate bone cement into the tubing. Allow the acrylic to cure while holding the mouth in normal occlusion.
5. An acrylic ESF device can be applied to bilateral fractures by molding the silicone tubing in a U shape around the rostral aspect of the mandible.
6. Clean the sites where the pins enter the skin daily.
7. Remove the ESF device after 6 to 8 weeks, following radiographic confirmation of bone healing, by cutting the pins against the connecting bar and removing each pin individually.

Bone Plating

Bone plating of maxillary fractures provides rigid stability and a rapid return to normal function. The bone plate must be accurately contoured to the bone surface to avoid malocclusion, and screws should not damage tooth roots. It is often difficult to apply bone plates as close to the tension (oral) surface of the maxilla as possible because screw holes are frequently over tooth roots. Recently, there have been reports of successful maxillary fracture repair using miniplates. These small titanium plates are more easily applied to the dorsal aspect of the mandible, but special instruments are required for their application.

Technique

1. Place the animal in ventral (for bilateral fractures) or lateral recumbency (for unilateral fractures) and make an incision over the maxilla.
2. Elevate the subcutaneous tissues to expose the fracture ends.
3. Contour the bone plate to fit the maxilla, avoiding tooth roots. Place at least two screws on either side of the fracture.
4. Drill screw holes with an oscillating drill bit to avoid damage to the neurovascular structures.
5. Secure the bone plate to the maxilla while ensuring normal dental occlusion.
6. Close the subcutaneous tissues and skin routinely.
7. Feed soft, gruel-type food, and obtain radiographs 6 to 8 weeks later to evaluate bone healing.
8. Remove bone plates if they cause pain or erosion of the oral mucosa.

Postoperative Care

- Maintain appropriate nutrition during the recovery period.
- Cats, particularly, are less willing to eat after facial trauma.

▼ ***Key Point*** In cats, place an esophagostomy feeding tube for postoperative nutrition (see Chapter 3).

- Gastrostomy feeding tubes may be placed endoscopically if long-term tube feeding is expected.
- If a feeding tube is not used, feed a soft gruel for 4 weeks after surgery.
- Prevent animals from chewing toys or hard objects such as bones and sticks.
- Perform daily oral flushing with a dilute chlorhexidine solution to reduce oral bacterial contamination and clean implants placed around the teeth.

Complications

- Malocclusion is the most important complication postoperatively. Evaluate patients every 2 weeks to ensure normal occlusion is being maintained. Further surgery may be necessary if malocclusion occurs.
- Osteomyelitis occurs rarely; long-term (6–8 weeks) treatment with appropriate antibiotics is required.
- Implant failure and nonunion can occur and are generally related to poor preoperative planning and implant choice.
- Damage to remaining teeth from either the original trauma or the surgery may result in dental pain or infection after the fracture has healed. Tooth extraction or endodontic therapy may be indicated.
- Oronasal fistulation can occur at the site of missing teeth, resulting in passage of food from the oral cavity into the nasal cavity. Mucosal flap techniques may be required to provide complete closure of the defect.
- Altered maxillary growth resulting in facial deformity has been reported following repair of maxillary fractures in growing animals.

Chapter 99

Neoplasia of the Maxilla and Mandible

Matthew Palmisano

ETIOLOGY

The oropharyngeal region is the fourth most common site of malignant neoplasia in the dog.

▼ ***Key Point*** The most common oral neoplasms in the dog are malignant melanoma, squamous cell carcinoma (SCC), fibrosarcoma, and epulides. In the cat, SCC in the most common oropharyngeal cancer, followed by fibrosarcoma.

Malignant melanoma and epulides occur rarely in the cat. Odontogenic tumors are the most common benign tumor in the cat. Oral tumors tend to be locally aggressive and have a low metastatic rate, except for malignant melanoma, caudal tongue tumors, and tonsillar SCC.

Certain breeds of dogs appear to be predisposed to oral tumors, including boxers, golden retrievers, and cocker spaniels. Small-breed dogs have a greater tendency to develop malignant melanoma, and large-breed dogs are more prone to develop SCC and fibrosarcoma.

Morbidity and mortality often result from local disease rather than from distant metastasis. Therefore, local tumor control is paramount to a successful outcome. Surgical resection should be considered a first line of treatment for all oral neoplasms. See Table 99-1 for a summary of oral neoplasia in dogs and cats.

DIAGNOSIS

History

- Most patients with oral neoplasms present with a chief complaint of drooling, halitosis, and dysphagia.
- Deformity of the muzzle also may be noticed by the owners.
- Oral tumors are often large, ulcerated, and painful, so patients may be anorexic.
- Oral bleeding may occasionally be seen, and some owners report seeing blood in the water dish after the pet drinks.
- Loose teeth or delayed healing after dental extraction may be observed. In the cat, teeth that are excessively loose and easily removed should lead to a suspicion of neoplasia, particularly SCC.

Physical Examination

- Physical examination may reveal palpable swelling of the muzzle or lower lip.
- Oral bleeding and halitosis are common clinical findings.
- If the tumor is associated with the temporomandibular joint (TMJ), vertical ramus of the mandible, or caudal pharyngeal region, pain may be elicited when trying to open the mouth.
- The mass may be smooth, ulcerated, or firm on oral examination and palpation.
- Many patients do not allow a complete oral examination while they are awake due to pain; consider sedation of patients.
- Since many oral neoplasms metastasize via the lymphatic system, palpate the submandibular and regional lymph nodes for enlargement.

Diagnostic Evaluation

Blood Tests

- Many of these patients are older (>8 years of age), so perform a minimum database (complete blood count, serum biochemical profile, urinalysis) to look for systemic illnesses related to the tumor or concurrent metabolic disorders.

Imaging Studies

- Obtain three-view chest radiographs to identify metastatic disease to the lungs.
- Obtain skull radiographs under anesthesia to evaluate the extent of bony involvement into the maxilla or mandible. A skull series (lateral, ventral-dorsal, right and left oblique views) is required to fully evaluate the skull (see Chapter 4). Radiographic abnormalities include changes in cortical bone density, periosteal new bone formation, involvement of adjacent soft tissues, and loose teeth.
- Computed tomography (CT) scanning and magnetic resonance imaging (MRI) of the skull is very helpful in evaluating extent of tumor invasion and presurgi-

Table 99-1. SUMMARY OF COMMON ORAL CANCERS IN THE DOG AND CAT

	Feline	
	SCC	FSA
Frequency (%)	70	20
Age (yrs)	10	10

Prognosis	Good	Fair	Poor	Excellent

FSA; fibrosarcoma; MM, malignant melanoma; SCC, squamous cell carcinoma.

cal planning. These imaging modalities are especially helpful in evaluating caudal maxillary tumors or tumors involving the orbit, zygoma, TMJ, or vertical ramus of the mandible.

Biopsy

- Perform an incisional biopsy before surgery to obtain a definitive diagnosis.

▼ ***Key Point*** Obtain a tissue biopsy of any suspicious oral lesions. Early detection is critical to successful treatment.

- Biopsy is very important in determining the treatment, as well as the long-term prognosis, for the pet. Many oral tumors do not exfoliate easily, so fine-needle aspiration is usually not helpful. A wedge biopsy for histopathologic examination is necessary for a definitive diagnosis.
- Obtain fine-needle aspirates for cytology or histopathologic evaluation via biopsy of all enlarged, submandibular, or pharyngeal lymph nodes to look for metastatic disease. Perform fine-needle aspiration even on normal-sized regional lymph nodes. In one study, 40% of dogs with oral melanoma had normal-sized lymph nodes and had evidence of metastasis to the lymph nodes on cytologic evaluation.

TUMOR TYPES

Benign Non-odontogenic Neoplasms

Epulis

Epulides are fibrous tumors originating from the periodontal ligament. They are rarely seen in the cat but are one of the most common oral tumors seen in the dog. There is no sex predisposition, and a familial predisposition has been noted in the boxer.

Three types of epulides are characterized, based on histopathologic evaluation:

- *Fibromatous epulis* is a benign, noninvasive growth in which the periodontal ligament stroma is the predominant cell type. These epulides are pedunculated and often multiple.
- *Ossifying epulides* have a similar biologic behavior to fibromatous epulides, but histopathologically they have an osteoid component. Malignant transformation to osteosarcoma has been reported.

- *Acanthomatous epulis* is the most aggressive of the epulides. This type of epulis is characterized by extensive bony invasion into the alveolar bone and is most often seen in the rostral mandible. Acanthomatous epulides can become quite large but do not metastasize. However, approximately 30% of acanthomatous epulides undergo malignant transformation.

Treatment and Prognosis

- Since epulides are local tumors, they can be treated with aggressive curettage of the alveolar socket (with fibromatous and ossifying epulides). However, a better outcome can be achieved with en bloc resection of the tumor and surrounding bone. En bloc resection is recommended with acanthomatous epulides due to their extensive bony involvement. Recurrence rate is high if the tumor is only debulked, and a complete resection is considered curative.
- Radiation therapy of epulides without surgery can be effective and is often curative. Large or incompletely excised epulides can be treated with surgery, followed by postoperative radiation therapy. Chemotherapy is generally not effective for epulides.

Other Benign Non-odontogenic Neoplasms

Other rarely seen, benign non-odontogenic neoplasms include fibroma, hemangioma, lipoma, chondroma, osteoma, and histiocytoma. These tumors look grossly similar and require biopsy for histopathologic evaluation.

Malignant Non-odontogenic Neoplasms

Malignant Melanoma

Malignant melanoma is characterized by local invasion and early metastasis. They can be darkly pigmented (melanotic) or non-pigmented (amelanotic). Oral melanomas are often ulcerated and necrotic, so clinical signs frequently seen are halitosis and oral bleeding. Dogs with more heavily pigmented oral mucosa, such as the chow, are predisposed to malignant melanoma. Malignant melanoma is found (in order of decreasing frequency) on the gingival, buccal and labial mucosa, hard palate, and tongue.

Treatment and Prognosis

- Treatment of choice is early, complete en bloc surgical resection. Tumor size is important, as melanomas less than $50\,mm^2$ are associated with a better outcome.
- High-dose, fractionated radiation therapy has shown moderate success in treatment. One study showed an increase in survival time with surgery and radiation therapy when compared with surgery alone.
- Chemotherapy has not been effective to date in treatment of melanomas.
- Newer therapies, such as immunotherapy, have shown some promise in treatment.

▼ ***Key Point*** Overall prognosis with oral melanomas is poor, with a <10% 1-year survival even with treatment.

Squamous Cell Carcinoma

SCC is the second most common oral tumor in dogs, but it is the most common oral tumor in cats. SCC is characterized by local tissue invasion and late metastasis. SCC often looks ulcerative and friable on oral examination.

Two types of SCC are seen: non-tonsillar and tonsillar SCC. They have very different biologic behavior. *Non-tonsillar SCC* is locally invasive and slow to metastasize. SCC often invades bone, causing bony lysis and loosening of teeth. *Tonsillar SCC* is biologically very aggressive and is characterized by early metastasis to regional lymph nodes and lungs.

Treatment and Prognosis

- Wide surgical resection is the treatment of choice, with or without radiation therapy.
- Radiation therapy can be used as an adjunct for local control, especially with large tumors.
- The best long-term success can be achieved using surgical resection followed by postoperative radiation therapy.
- Chemotherapeutic agents, such as cisplatin and piroxicam, have been added to treatment protocols with some success.
- Overall prognosis is guarded. Local recurrence is high when the tumor is marginally resected, and approximately 50% of patients die within 1 year.

Fibrosarcoma

- Fibrosarcoma is the third most common tumor behind malignant melanoma and SCC, and it is the second most common tumor in cats.
- Fibrosarcomas are firm, slow-growing tumors that are characterized by locally aggressive behavior and late metastasis.
- Fibrosarcomas are seen most commonly on the gingival margin of the maxilla, between the upper canine tooth and the fourth premolar.
- Due to extensive tissue invasion, local recurrence is common, especially in tumors that cross the midline of the hard palate or are caudally located.

Treatment and Prognosis

- Wide surgical resection is the treatment of choice.
- Adjunctive radiation therapy, chemotherapy, or immunotherapy can be used to increase long-term survival.

- Overall prognosis is very guarded, since local tissue recurrence and late metastases are common.
- The 1-year survival rate has been reported to be 20%.
- Recently, a histologically benign but biologically aggressive form of oral fibrosarcoma has been described in younger golden retrievers.

Other Malignant Non-odontogenic Neoplasms

Much less common tumors include osteosarcoma, adenocarcinoma, undifferentiated carcinoma, transmissible venereal tumor, mast cell tumor, hemangiosarcoma, and tonsillar lymphosarcoma.

Malignant Odontogenic Neoplasms

Ameloblastoma arises from the dental laminar epithelium. These relatively rare tumors are seen more commonly in younger dogs and are often associated with loose teeth. Ameloblastomas are most commonly seen at the gingival margin. Radiographically, ameloblastomas are seen as expansile, bony lesions.

Odontomas are rare tumors of dental origin and can invade all of the dental tissues (enamel, cementum, dentin, and pulp).

Treatment and Prognosis

- Wide surgical resection is the treatment of choice and can be curative.
- Local recurrence is very common with inadequate excision.
- Radiation therapy has been used with some success, but recurrence locally is common.

See Table 99-1 for descriptions of common malignant oral cancers of dogs and cats and their response to therapy.

SURGICAL PROCEDURES

Preoperative Considerations

- A thorough working knowledge of anatomy is crucial to ensure a successful outcome for the patients, as well as to minimize any complications such as blood loss. In most cases, these patients should be referred to a veterinary surgeon or dentist.
- The extent of surgical excision is determined by radiographs of the skull, CT imaging, or MRI. This ensures adequate resection, especially at the deep tissue margins.
- Maxillectomies are often associated with significant blood loss, especially when the tumor is located caudally or crosses the midline. Temporary, bilateral carotid artery occlusion has been used with some success to minimize blood loss. This procedure is usually not necessary. In addition, a source of blood replacement should be available if necessary.
- Administer preoperative analgesia, using a nonsteroidal anti-inflammatory agent and fentanyl patches, to minimize postoperative pain (see Chapter 6). Since fentanyl patches need approximately 16 to 24 hours to reach therapeutic levels, place them on the skin the night before surgery. See the "Drug Appendix" for dosage guidelines.
- Place a cuffed endotracheal tube orally in the patient at induction of anesthesia. Count and place surgical sponges in the pharynx to minimize aspiration of blood and fluids.
- Nerve blocks can be useful for regional anesthesia of the surgical site and are helpful in providing local pain control while minimizing the amount of perioperative analgesia. A 2% lidocaine or 0.5% bupivacaine (with or without epinephrine) solution can be used for nerve blockage (see Chapter 6).
- Administer a prophylactic antibiotic suitable for the oral cavity (first-generation cephalosporin or synthetic penicillin) at induction of anesthesia. Due to the extensive blood supply to the oral cavity, postoperative infection is very uncommon, so antibiotics only need to be continued for 24 hours. If there is deep-seeded bone infection, continue antibiotic therapy for at least 14 days.
- Sutures recommended for oral surgery include polydioxanone (PDS, Ethicon; Somerville, NJ), polyglactin 910 (Vicryl, Ethicon), polyglycolic acid (Dexon, Davis and Geck; Manati, Puerto Rico), and polyglyconate (Maxon, Davis and Geck). 3-0 and 4-0 sutures on swaged-on cutting needles are recommended for wound closure. Simple interrupted, vertical mattress, and cruciate mattress suture patterns are recommended.

Anatomy

- The masseter muscle lies on the lateral surface of the ramus with some fibers of the superficial layer projecting around the ventral and caudal borders of the mandible to insert on the ventromedial surface.
- The temporalis muscle inserts on the coronoid process of the mandible, with some fibers inserting further down on the ventral margin of the masseteric fossa.
- The lateral pterygoid muscle inserts on the medial surface of the mandibular condyle.
- The medial pterygoid muscle inserts on the medial and caudal surfaces of the angular process of the mandible.
- The inferior alveolar artery and vein enter the mandibular foramen, which is located on the medial side of the mandible, 1 to 1.5 cm rostral to the angle of the mandible. The artery exits at the mental foramen of the mandible.
- The blood supply to the maxilla is via the major and minor palatine arteries, which lie just deep to the mucosa of the hard palate, and the infraorbital artery,

which exits through the infraorbital foramen dorsal to the upper third premolar tooth. The infraorbital vein and nerve parallel this artery.

Objectives

- Completely resection the neoplasm.
- Preserve local blood supply.
- Handle tissue atraumatically.
- Minimize the use of electrocautery. Excessive use of electrocautery has been shown to delay incisional healing and increase the dehiscence rate.
- Suture lines should be supported by bone if possible.
- Double-layer mucosal closure is preferred to single-layer closure.

▼ ***Key Point*** Avoid suturing tissues under line tension in the oral cavity. Incisions under tension are much more likely to dehisce.

- Make mucosa flaps 2 to 4 mm larger than the oronasal defect.
- Large oronasal defects, caudal defects, and oronasal defects that cross the midline have a higher dehiscence rate. Therefore, a plan for complete mucosal closure should be in place before tumor removal.

Equipment

- Standard surgical instrument pack and suture
- Oral speculum
- Electrocautery and suction
- Oscillating bone saw and osteotome and mallet
- Bone wax

Maxillectomy

Place the patient in dorsal recumbency. The mouth can be held open with an oral speculum, or the mandible can be held open with tapes attached to IV stands placed on each side of the table. Tie the endotracheal tube to the mandible.

Unilateral Premaxillectomy

Unilateral premaxillectomy is indicated for lesions that are located rostral to the second premolar and do not cross the midline.

Technique

1. Incise the labial and gingival mucosa rostral and lateral to the tumor at least 1 cm from the tumor margins. Control bleeding using either direct pressure or electrocautery. The hard palate tends to bleed profusely; use either ligation or electrocautery.
2. Cut the underlying bone with an oscillating bone saw or mallet and osteotome. Be sure to follow the mucosal incision lines.
3. Remove the incised segment of bone and tumor en bloc. Ligate or cauterize branches of the major palatine artery. After bone and tumor removal, copiously lavage the surgical site with saline.
4. Reconstruct the oronasal defect created by en bloc resection with a gingival mucosal-submucosal flap. Design the flap to allow coverage of the defect without excessive tension. Include as much mucosa, submucosa, and subcutaneous tissue as possible. Careful tissue handling is essential to preserve blood supply.
5. Suture the flap using either a one- or a two-layer closure. In the two-layer closure, suture the labial submucosa to holes predrilled into the bony hard palate. The second layer consists of simple interrupted sutures that appose the palatal mucosa to the labial mucosa. The palatal mucosa can be undermined help with mucosal apposition.
6. In most cases, a one-layer closure of palatal mucosa to labial mucosa is performed. If excessive tension is encountered, undermine the flap further, and use a vertical mattress pattern for mucosal apposition.

Bilateral Premaxillectomy

Bilateral premaxillectomy is indicated for tumors that are rostral to the second premolar and cross the midline.

Technique

1. This procedure is essentially the same as for the unilateral premaxillectomy, except that the entire rostral bony floor of the nasal cavity is removed.
2. Closure is the same as for the unilateral procedure. Undermine half of the flap from each side of the premaxillectomy defect. Suture the caudal half of each flap to the palate mucosa to the midline. Suture the rostral halves together, achieving a T-shaped closure. Use a simple interrupted or vertical mattress pattern for mucosal apposition.
3. A more secure technique for closure is the double-flap technique, in which a tissue flap is created from each side of the palatal defect. Rotate the first flap to cover the defect so that the labial mucosa is facing the nasal cavity. Rotate the second flap from the opposite side of the defect over the first flap and suture it into place (Fig. 99-1).

Hemimaxillectomy

This is the most aggressive of the maxillectomy procedures, and it leaves the largest defect to close. Hemimaxillectomy is indicated for tumors that involve the majority of the hard palate and do not cross the midline.

Any portion of the maxilla can be removed unilaterally, up to the entire hemimaxilla, and still can result in normal function and acceptable cosmesis. Caudal maxillary resections can be combined with resections of the inferior orbit, zygoma, or vertical ramus of the mandible, depending on the degree of tissue involvement.

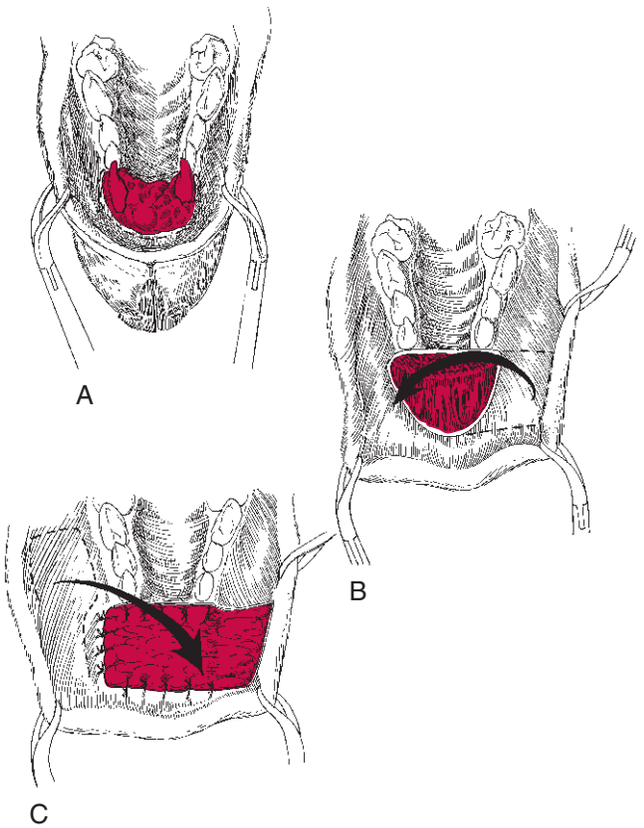

Figure 99-1. Bilateral premaxillectomy, double-flap technique. *A,* Site of incision. *B,* First flap parallel to the excised dental arch. This flap is flipped over (reversed) so that the labial mucosa is on the nasal cavity side of the defect. *C,* Second flap from the opposite side of the pre-maxilla.

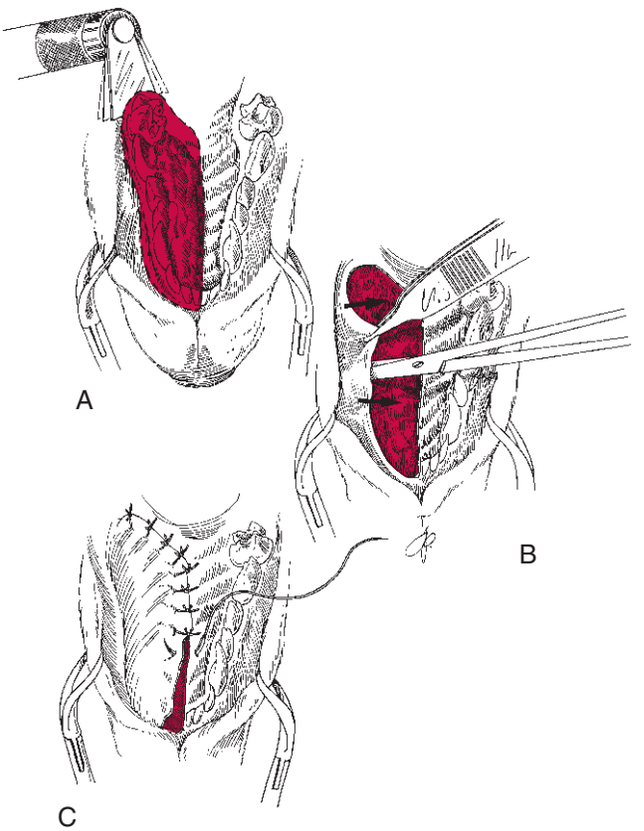

Figure 99-2. Hemimaxillectomy. Incise *(A)* around lesion, then remove the mass by ostectomy. Create *(B)* and close *(C)* the labial flap.

Technique

1. Place the patient in dorsal recumbency. Begin the mucosal incision rostrally at the labial-gingival junction and continue lateral and caudal as needed to achieve at least 1 cm of normal tissue around the tumor.
2. Use a periosteal elevator to expose the underlying bone. Osteotomize the underlying bone using either an oscillating bone saw or a mallet and osteotome (Fig. 99-2*A*).
3. Bleeding can be profuse, especially when making the caudal osteotomy. Remove the bone en bloc, and identify and ligate branches of the maxillary artery. Control bleeding from blood vessels with ligation, electrocautery, and pressure. Control bleeding from nasal turbinates with hemostatic sponges (Gelfoam).
4. Create a lip margin-based flap by undermining the labial mucosa and submucosa from the maxillectomy site toward the lip margin. Undermine the flap only enough to cover the defect without excessive tissue tension. Suture the labial mucosa-submucosal flap to the elevated edge of the hard palate mucoperiosteum with simple interrupted or vertical mattress sutures (Fig. 99-2*B,C*).

Mandibulectomy

Place the animal in lateral recumbency with the affected mandible placed dorsally. Clip the dorsal and ventral aspect of the muzzle, and flush the oral cavity with either dilute chlorhexidine or povidone-iodine solution. Tie an endotracheal tube to the maxilla, and place an oral speculum on the recumbent canine teeth.

Unilateral Rostral Mandibulectomy

Unilateral rostral mandibulectomy is indicated for tumors that are rostral to the second premolar teeth and do not cross the midline. Bilateral rostral mandibulectomy is indicated for tumors that cross the midline.

Technique

1. The labial mucosa in incised at least 1 cm outside the visible tumor margin. The dissection is continued around the body of the mandible until the symphysis and the caudal extent of the proposed ostectomy site are exposed.
2. Take care on the medial surface, making sure to identify and preserve the mandibular and sublingual salivary ducts. The ducts are located on the sublin-

gual caruncle. If the sublingual and mandibular ducts cannot be spared during the excision, ligate them.
3. After the symphysis is exposed, split the fibrous joint with a mallet and osteotome, which will separate the two hemimandibles.
4. Use an oscillating saw or Gigli wire to make the caudal osteotomy. Because the mandible is dense, do not perform the osteotomy with a mallet and osteotome.
5. Ligate or cauterize the inferior alveolar artery, and fill the marrow cavity with bone wax.
6. Extract tooth roots that have been traumatized during the osteotomy.
7. No attempt is made to fixate the two hemimandibles together.
8. Close the sublingual mucosa to labial mucosa using a one-layer, simple continuous or vertical mattress pattern using 3-0 or 4-0 absorbable suture (Fig. 99-3).

Bilateral Rostral Mandibulectomy

Bilateral rostral mandibulectomy is indicated for tumors rostral to the second premolar that cross the midline.

Technique

1. Dorsal recumbency allows the best exposure of the surgical site.
2. Perform the procedure similarly to unilateral rostral mandibulectomy.
3. Mandibular resection can be performed to the level of the first molar teeth without adversely affecting mandible function and prehension. However, warn the owner that the tongue will hang out past the lower lip after surgery.
4. Redundant skin may need to be removed before it is sutured to sublingual mucosa. A V-shaped wedge of skin can be removed from the rostral aspect of the lip. Suture the resultant skin edges in a one-layer, simple interrupted pattern. Some surgeons place tension-relieving stent sutures from holes made in the distal aspect of the mandibles to the outside surface of the lower lip. Polypropylene buttons or rubber tubing can be used to prevent these sutures from causing pressure necrosis of the skin.

Hemimandibulectomy

The most extensive of the mandibulectomy procedures, this involves total or subtotal removal of one hemimandible. This procedure is indicated for tumors that involve most of the mandible.

Technique

1. Place the patient in lateral recumbency. Incise the commissure of the lip full thickness to the rostral edge of the vertical ramus. Incise through the subcutaneous tissues to the level of the temporomandibular joint.
2. Incise the labial and buccal mucosa as needed to ensure a 1-cm tumor-free margin. The rostral aspect of the incision is to the mandibular symphysis and extends caudally to the angle of the mandible.
3. Dissect around the horizontal ramus of the mandible. Once the horizontal body is free of soft tissues, separate the mandibular symphysis using a mallet and osteotomy. Rotate the mandible laterally, allowing easier caudal dissection. Place bone-holding forceps (e.g., Kern) on the mandible to aid retraction.
4. If the tumor does not involve the caudal tissues, resect the body of the mandible at the rostral edge of the masseter muscle, leaving the vertical ramus

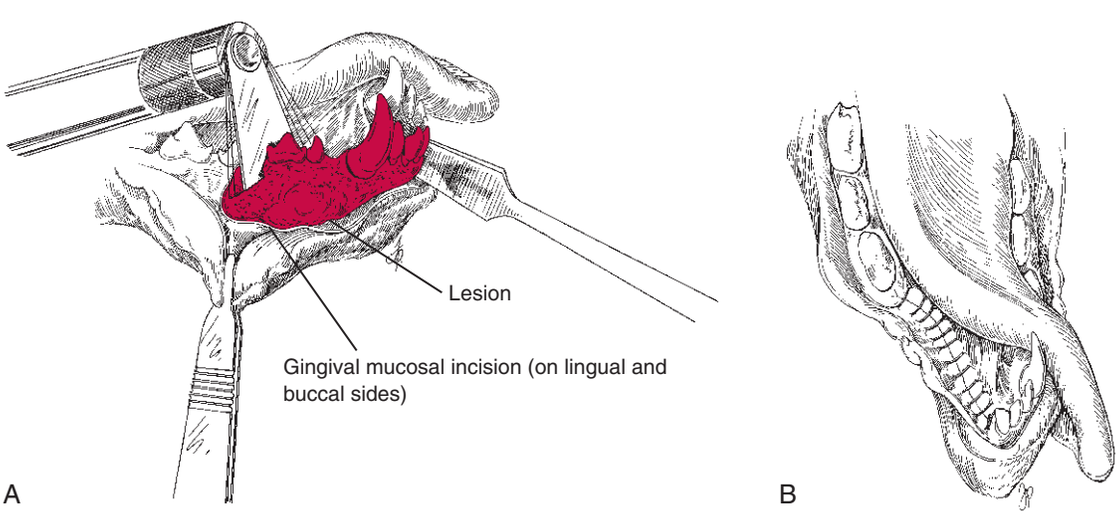

Figure 99-3. Unilateral premandibulectomy. *A,* Incise the gingival around the lesion, keeping at least 1 cm of normal tissue around it. Separate the mandibular symphysis and continue the original incision through the bone. *B,* Cover the bone and close the incision.

and the temporomandibular joint intact. Cut the bone with an oscillating saw. This procedure is technically easier than total hemimandibulectomy.

5. If total hemimandibulectomy is performed, sharply incise the masseter, digastricus, and pterygoideus muscles from the mandible. Avoid accidentally cutting the mandibular alveolar artery before identifying and ligating the vessel. This vessel passes across the lateral surface of the medial pterygoideus muscle before entering the mandibular foramen. Lateral retraction of the hemimandible helps expose this vessel for ligation.
6. Incise the capsule of the temporomandibular joint, and luxate the joint. Incise the temporalis muscle as it inserts on the coronoid process of the mandible. Incise any loose fascial attachments to complete resection.
7. Perform three-layer closure to minimize dead space. The first layer apposes remaining muscle tissue, followed by a submucosal closure. The mucosa is closed in a simple interrupted or vertical mattress pattern using 3-0 or 4-0 suture.
8. Hemimandibulectomy results in loss of lateral tongue support. Advance the commissure of the lip to provide a pouch for the tongue and to provide lateral support. Incise upper and lower lip full thickness to the level of the first premolar tooth. Perform three-layer suture closure of mucosa, subcutaneous tissues, and skin.

Postoperative Care

- Continue postoperative analgesia for pain control.
- Continue antibiotics IV for 24 hours postoperatively.
- Place an Elizabethan collar to prevent self-mutilation of the incisions by the patient.
- Feed soft food or gruel for the first month. Gently flush the oral cavity with water or saline after eating. Most dogs eat readily within 48 hours, but cats are often reluctant to eat after maxillectomy or mandibulectomy. If postoperative feeding is a concern, consider placing an esophagostomy tube for enteral nutrition.
- Chemotherapy or radiation therapy can be started if indicated 3 weeks after the surgery.
- Reevaluate the patient every 3 months for the first year. Perform an oral examination to evaluate for tumor recurrence. Palpate cervical lymph nodes for lymph node enlargement, and evaluate thoracic radiographs for metastasis.

Complications

- Transient facial edema and ranula formation after mandibulectomy usually resolve in 2 to 3 weeks. Drooling may occur for several days and improves in a few weeks.
- Nasal discharge, facial swelling, noisy respirations, and inappetence often occur after maxillectomy but usually improve in 5 to 7 days.
- Due to the vascular supply of the oral cavity, infections are relatively rare.
- Dehiscence of the suture line and oronasal fistula is the most common complication seen. Nasal discharge is often seen when this occurs. Minor dehiscences can be managed conservatively and often heal by second intension. For complete dehiscence or minor dehiscence that will not heal, resuture the mucosal edges. Most dehiscences are related to excessive flap tension. Minimize recurrence of dehiscence by elevating the labial and palatal mucosal-submucosal flaps and using a tension-relieving suture pattern such as a vertical mattress pattern.
- Postoperative cosmesis generally is good, even with major resections of the maxilla and mandible. Protrusion of the tongue often is seen with bilateral rostral mandibulectomy.
- Removal of the one hemimandible causes some medial drift of the other hemimandible due to loss of bony support and normal muscular contraction. Occasionally, it is necessary to the lower the crown height of the lower canine tooth to prevent chronic erosion and ulceration of the hard palate mucosa due to malocclusion (see Chapter 64).

▼ ***Key Point*** Owner satisfaction is high after mandibulectomy or maxillectomy. One study found that the percentage of satisfied owners is directly proportional to the increase in pet life span. Although difficulty in eating was noted in 44% of dogs, pain was perceived to be reduced by the surgery for most animals. All owners found the cosmetic appearance of their dogs acceptable after facial hair regrew.

Chapter

100 Fractures and Dislocations of the Spine

Matthew Palmisano

Congenital and acquired diseases of the spine are seen frequently in small animal practice. Early diagnosis and effective treatment are crucial for success in preservation or return of normal neurologic function in these patients.

ATLANTOAXIAL INSTABILITY

Anatomy

- The atlantoaxial joint is a pivot joint that allows the head and atlas to rotate around a longitudinal axis.
- The dens is a peg-like eminence along the ventral surface of C2 (axis) that projects rostrally to lie on the floor of C1 (atlas) in the spinal canal.
- The dens is secured to the ventral arch of the atlas by the transverse atlantal ligament, to the occipital condyles by the paired alar ligaments, and to the ventral aspect of the foramen magnum by the apical ligament. The dorsal arches of the atlas and axis are stabilized by the dorsal atlantoaxial ligament.

Etiology

Atlantoaxial instability can arise from either congenital or acquired etiologies.

Congenital Causes

Congenital causes are by far the most common presentation and are most often seen in the young, small, and toy-breed patient. Congenital instability arises from malformation (hypoplasia or aplasia) of the dens, nonunion of the dens with the body of the axis, or lack of ligamentous support, such as congenital absence of the transverse or atlantoaxial ligaments.

Acquired Causes

Acquired causes of atlantoaxial instability are usually the result of traumatic injury. Fracture of the dens and cranial body of the second cervical vertebra (C2) or rupture of the supporting ligaments is usually seen with traumatic injury. These injuries are the result of falls or automobile accidents that cause hyperflexion of the cranial cervical spine. In contrast to congenital atlantoaxial instabilities, acquired instabilities can occur in any age and any size dog and cat.

Clinical Signs

- Clinical signs vary from cervical pain alone to tetra-ataxia or tetraparesis and tetraplegia. The severity of clinical signs is usually dependent on the degree of atlantoaxial subluxation.
- The severity of clinical signs is also dependent on whether the patient has an intact dens. Luxation with an intact dens and luxation resulting from congenital dens malformation allows the dens to dorsally deviate into the spinal cord (Fig. 100-1). This will cause more spinal cord compression than in the patient with congenital atlantoaxial instability secondary to aplasia of the dens.
- In the most severe cases of spinal cord compression, respiratory arrest and death can occur.

▼ ***Key Point*** Use extreme care when performing a neurologic evaluation in these patients. Avoid flexion of the neck.

- Consider atlantoaxial instability as a diagnosis in any young patient with cervical pain and varying degrees of tetra-ataxia and paresis.

Diagnosis

- The diagnosis of atlantoaxial instability is usually made with radiography. Carefully flexed lateral radiographs of the atlantoaxial space will revealed a widened space between the dorsal arch of C1 and the dorsal spine of C2. Ventrodorsal and open-mouthed views may best outline the dens.
- Computed tomography (CT) imaging and magnetic resonance imaging (MRI) are usually not required for diagnosis. Myelography is contraindicated due to the degree of flexion required for cisternal needle placement and dorsal deviation of the spinal cord in the canal.

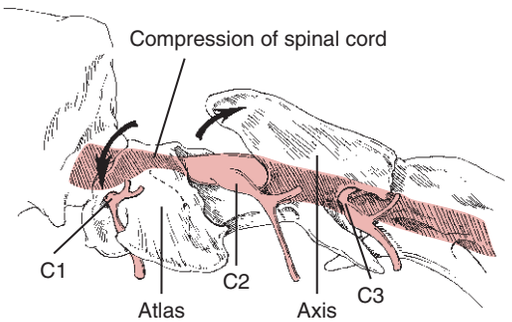

Figure 100-1. Dorsal displacement of the axis.

Surgical Procedures

Preoperative Considerations

- Be careful when manipulating the neck while under anesthesia. Do not flex the spine, which would exacerbate cord compression and cause respiratory arrest and death.
- Ventilator therapy is helpful in these patients, especially when there is concern about respiratory impairment.
- The surgical techniques are technically demanding, and intense perioperative care is crucial to a successful outcome. Therefore, refer these cases to a surgical specialist.

Objectives

- Remove the fractured or ununited dens
- Stabilize the C1 to C2 articulation
- Prevent spinal cord injury

Equipment

- Standard orthopedic and neurologic surgical pack
- Self-retaining retractors
- Reduction forceps
- High-speed air drill
- Kirschner wires and small Steinman pins
- Polymethyl methacrylate (PMMA)

Technique

Dorsal Approach (Overview)

- Dorsal approaches involve fixation of the dorsal spine of the axis to the dorsal arch of the axis using heavy-gauge suture material, orthopedic wire, or nuchal ligament grafts.
- Complications with the dorsal approach include breakage of the implant material and fracture of the dorsal arch of the atlas or dorsal spine of the axis. This can lead to acute reluxation of the atlantoaxial joint, which often causes acute neurologic decline.
- Although technically more demanding, most surgeons prefer ventral fixation of the atlantoaxial joint due to a higher success rate.

Ventral Approach

1. Place the patient in dorsal recumbency with a rolled towel positioned under the neck and the chin and chest gently taped to the table.
2. Make a skin incision on the ventral cervical midline extending from the laryngeal cartilages to the manubrium.
3. Separate the paired sternohyoideus muscles on the midline.
4. Bluntly dissect and lateralize the trachea, esophagus, and carotid sheath. Access to the ventral aspect of the atlantoaxial joint is made easier with myotomy of one of the sternothyroid muscles. Tag the cut muscle ends with suture to allow easier identification upon closure.
5. Separate and retract the paired hypaxial muscles ventral to the atlantoaxial joint using self-retaining retractors.
6. Identify and open the joint capsule of the atlantoaxial joint using a #11 scalpel blade.
7. The joint may be reduced into normal position using two-point reduction forceps placed on the body of the axis.
8. When the dens is either fractured or ununited, remove it through the atlantoaxial articulation. If necessary, remove a small window of bone from the ventral arch of the atlas to assist in dens removal.
9. To perform arthrodesis of C1 to C2, remove the articular cartilage using a high-speed air drill or bone curettes, then place bone graft obtained from the greater trochanter of the humerus.
10. Several modifications of ventral fixation using K-wires, screws, and PMMA bone cement have been described. The original description of ventral stabilization involved divergent Steinmann pins, K-wires, or cortical screws placed across the atlantoaxial joint. Recent studies suggest that strongest fixation involves placement of three pairs of pins, with one set going across the atlantoaxial joint and the other two pairs fixed to C1 and C2, respectively.
11. If only two pins are going to be used for fixation, drive them from the center of the axis across the atlantoaxial joint and seat them in the atlas just medial to the alar notch. This ensures that the pins do not enter the spinal canal (Fig. 100-2).
12. For additional stability, place the second set of pins into the atlas. Direct the pins perpendicular to the long axis of the spine from ventral to dorsal into each of the pedicles of the atlas. Leave the pins long and notch them using a pin cutter. This allows better bonding with the PMMA.
13. Place the third pair of pins into the caudal body of C2. Drive the pins from the center of the body obliquely to the origin of the transverse process, taking care not to enter the spinal canal. Leave these pins long and notch them.

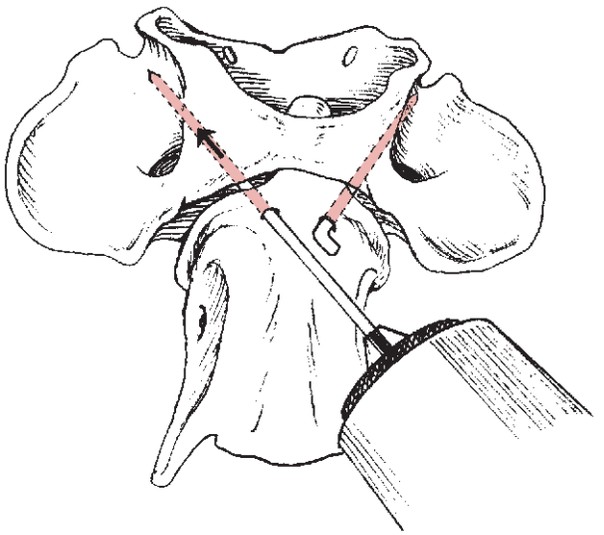

Figure 100-2. Divergent atlantoaxial pinning. The pins are kept out of the spinal canal by aiming for the medial aspect of the alar notch.

14. Place a small mass of PMMA ventrally to incorporate each pin, and apply cool saline flush during polymerization of the cement to dissipate heat and minimize tissue damage.
15. Close the sternothyroideus muscle if a myotomy was performed. The hypaxial muscles often cannot be reapposed due to the mass of cement.
16. Close muscle, subcutaneous, and skin closure routinely.

Postoperative Care and Complications

- Administer postoperative analgesics.
  - Place a Fentanyl patch at least 12 hours preoperatively, and give nonsteroidal anti-inflammatory drugs (NSAIDs) unless they are contraindicated (see Chapter 6).
- Give first-generation cephalosporin or potentiated penicillin PO for the first 5 days.
- Place an Elizabethan collar for the first 2 weeks postoperatively.
- Restrict exercise for 4 to 6 weeks. Avoid any high-impact activity. If necessary, confine the animal to a cage.
- Obtain radiographs monthly until a complete bony fusion of the atlantoaxial joint is seen. Radiographic fusion is usually seen by 8 to 12 weeks.
- Complications include infection of the PMMA, dysphagia, and laryngeal paralysis, which are usually related to technical issues with soft tissue handling. The most serious complication is implant failure, with recurrence or worsening of neurologic signs.

CAUDAL CERVICAL SPONDYLOMYELOPATHY

Caudal cervical spondylomyelopathy (Wobbler's syndrome) is a disease that encompasses several syndromes based on the location and nature of the compressive lesion. Understanding the pathogenesis of this complex disease is important when choosing the type of surgical treatment.

▼ ***Key Point*** It is crucial that the correct surgical procedure be picked based on the specific type of spinal cord compression affecting that individual dog.

For example, distraction and fusion techniques are most appropriate for dynamic disc lesions and dorsal laminectomy for articular process disease. In addition, early diagnosis and treatment of the disease is important to ensure the best outcome.

Anatomy

- Relevant anatomic structures in the dorsal compartment of the cervical spine that play a role in caudal cervical spondylomyelopathy include the dorsal vertebral lamina, the articular facets and joint capsule, and the ligamentum flavum.
- In the ventral compartment of the cervical spine, the vertebral bodies, the dorsal fibers of the annulus fibrosus of the intervertebral disc, and the dorsal longitudinal ligament are significant.

Etiology

- Two distinct populations of patients are seen, and their etiologies are somewhat different. Of dogs with Wobbler's disease, 10% to 15% are young, adolescent Great Danes with osseous malformations of the cervical spine.
- The remainder are middle-aged to older patients with acquired disease that is usually secondary to cervical vertebral instability. Doberman pinschers are the largest percentage of this group of dogs (approximately 80%), although dalmatians and Labrador retrievers are also predisposed.
- No sex predilection is seen.

Pathologic Changes Associated with Wobbler's Syndrome

Congenital Osseous Malformation

- This is seen in young Great Danes, with clinical signs occurring in the first or second year of life.
- The disease is characterized by malformation or malarticulation of the articular facets and vertebral bodies, causing dorsal and lateral stenosis of the canal.

- Congenital osseous malformation most commonly affects the C3 to C7 vertebral bodies.
- Vertebral canal stenosis is seen and usually worsens as the puppy grows.
- Proposed etiologies for this disorder include heredity, nutritional imbalances, and trauma. Osteochondrosis may also have a role in the pathology.

Vertebral Tipping

- This is usually seen in the middle-aged to older patient.
- There is a malposition of the vertebral body caudal to the affected intervertebral disc. The cranial aspect of the affected vertebra dorsally displaces into the spinal canal, causing ventral compression.
- This change is seen with chronic cervical vertebral instability and degenerative disc disease.
- The C5 to C6 and C6 to C7 intervertebral disc spaces are most commonly affected. The lesion can be either dynamic or static.

Chronic Degenerative Disc Disease and Cervical Vertebral Instability

- Most of these patients are middle-aged to older Doberman pinschers.
- The compression is caused by concurrent dorsal annulus and dorsal longitudinal ligament hypertrophy.
- The caudal cervical intervertebral disc spaces are most commonly involved.
- The compressive lesion is usually dynamic (i.e., the degree of compression changes).

Ligamentum Flavum Hypertrophy

- This disease causes dynamic, dorsal spinal canal compression. This lesion is often associated with vertebral arch abnormalities.
- The caudal cervical vertebra (C4–C7) is most commonly affected.
- The compressive lesion is often dynamic but can be static.

Hourglass Compression

- This combination of pathologies is associated with dorsal, ventral, and lateral compression. The young Great Dane is most commonly affected.
- Compression is caused by hypertrophy of the dorsal annulus fibrosis and dorsal longitudinal ligament ventrally, hypertrophy of the ligamentum flavum dorsally, and malformation or degenerative joint disease laterally.
- The lesion may occur at any level of the cervical spine and is often dynamic.

Clinical Signs

- Most patients have a chronic, progressive history of neck pain, hypermetria, tetra-ataxia, and tetraparesis.
- These dogs have a low-neck carriage due to the dynamic nature of the disease, and the compression worsens upon neck extension.
- Often, the clinical course is waxing and waning. Occasionally, chronically affected dogs will have an acute deterioration.
- Wide hind-limb stance with forelimb hypermetria and varying degrees of ataxia is often seen. Ataxia is often worse in the rear limbs. This is due to the greater degree of compression by the disc on the long motor tracts to the pelvic limbs, which are peripherally located within the spinal canal.
  - Proprioceptive deficits are seen, with paraparesis progressing to tetraparesis.
  - Evidence of lower motor neuron disease in the thoracic limbs is usually restricted to muscle atrophy of the spinatus muscles of the shoulder.

Diagnosis

Differential diagnoses include degenerative spinal cord disease, ischemic myelopathy, discospondylitis, congenital spinal cord disease, inflammatory central nervous system disease, spinal neoplasia, brachial plexus tumor, subarachnoid cysts, and trauma (see Chapter 128). Ischemic myelopathy (also called fibrocartilaginous embolization) can usually be ruled out because this process is not associated with cervical pain (see Chapter 128).

Blood Tests

Since many of these patients are older, perform a complete blood count, serum biochemical profile, and urinalysis to rule out other systemic illness. Submit a thyroid panel to rule out hypothyroidism. Studies have shown that neuronal regeneration is dependent on adequate levels of thyroid hormone, so postoperative recovery may be slowed in the undiagnosed hypothyroid patient.

Diagnostic Imaging

- Obtain thoracic radiographs to rule out metastatic disease and evaluate cardiac changes.
- Radiographs of the cervical spine in the non-sedated or anesthetized patient are usually not helpful, unless overt bony pathology (i.e., bony neoplasia or vertebral tipping) is present.

Myelography

- Cisternal myelography is helpful in identifying the site of compression (see Chapter 4). Perform a cisternal spinal tap, and obtain cerebrospinal fluid for analysis (see Chapter 125). Inject 0.33 ml/kg of iodinated contrast material into the subarachnoid space. After injection, obtain lateral and ventrodorsal projections of the cervical spine. Traction views of the

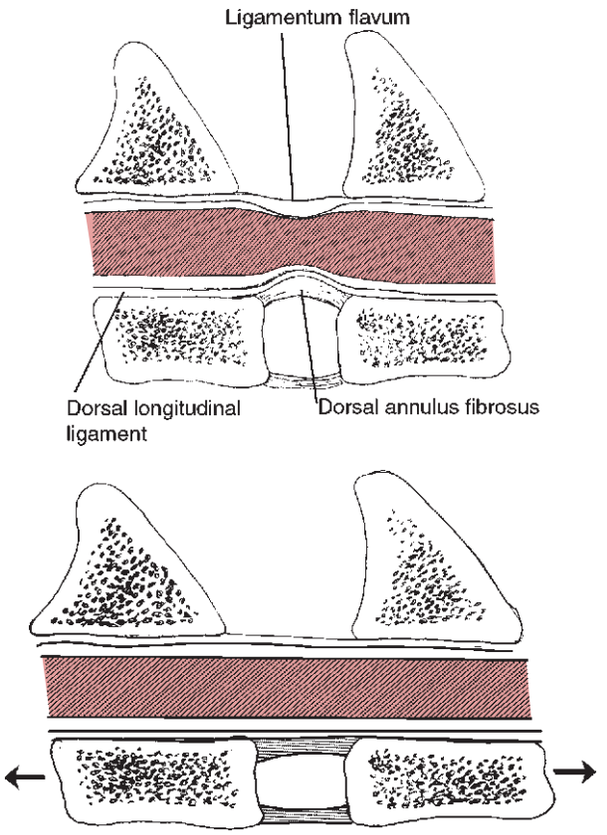

Figure 100-3. Dynamic compressive lesion. Spinal cord compression caused by hypertrophied ligamentum flavum, dorsal longitudinal ligament, and dorsal annulus fibrosus *(top);* alleviation of the compression by spinal traction *(bottom).*

spine are helpful in differentiating dynamic from static spinal cord lesions (see Chapter 4).

- If there is a reduction of spinal cord compression caused by redundant annulus fibrosis or ligamentous tissue during traction of the spine, the lesion is termed *dynamic* (Fig. 100-3). In contrast, herniation of the nucleus pulposus is not significantly improved by traction and is termed *static.* Differentiating between dynamic and static compression is important when deciding which surgical procedure to use.
- Avoid extended stress views of the spine because of increased compression of the spinal cord and the possibility of worsening clinical signs.

Computed Tomography and Magnetic Resonance Imaging

- A CT scan of the cervical spine is generally not rewarding in evaluating soft tissue changes to the cervical spine, but it may be helpful in identifying dorsal arch abnormalities and osseous malformations in the young Great Dane. A CT scan after a myelogram (CT myelography) may increase the diagnostic accuracy of CT.
- MRI is the diagnostic gold standard for imaging of the spine (see Chapter 4). MRI gives the greatest detail of soft tissue structures, including nerve roots and the intervertebral disc. In addition, signal changes within the spinal cord parenchyma may suggest chronic demyelination of the spinal cord (spinal cord atrophy), which will warrant a more guarded prognosis.

Preoperative Considerations

- Choose the most appropriate surgical procedure indicated by the nature and location of the compression. Table 100-1 provides guidelines for surgical decision making.
- The three primary decompressive surgeries used are the ventral decompression using a ventral slot technique, ventral distraction and fusion using a PMMA plug, and dorsal decompression using a dorsal laminectomy.
- These surgical procedures require clinical experience and appropriate instrumentation. Consider referral of these cases to a surgical specialist.

Surgical Procedures

Objectives

- See Table 100-1
- Ventral slot
  - Remove extruded disc material
  - Minimize surgical trauma to the spinal cord

Table 100-1. SURGICAL DECISION MAKING FOR CAUDAL CERVICAL SPONDYLOMYELOPATHY

Compression	Number of Spaces	Dynamic/Static	Surgical Procedure
Dorsal	One	Static	Dorsal laminectomy
Dorsal	Multiple	Static	Dorsal laminectomy
Dorsal	One	Dynamic	Distraction and fusion
Ventral	One	Static	Ventral slot
Ventral	One	Dynamic	Distraction and fusion
Ventral	Two	Dynamic	Distraction and fusion
Ventral	Multiple	Dynamic or static	Dorsal laminectomy

- Ventral distraction and fusion
  - Treat spinal cord compression by distracting and fusing the affected vertebral bodies
  - Minimize surgical trauma to the spinal cord
- Dorsal laminectomy
  - Decompress the spinal cord by removing the dorsal lamina of the appropriate vertebrae
  - Minimize surgical trauma to the spinal cord

Equipment

- Same as for atlantoaxial instability

Techniques

Ventral Slot

1. Place the patient in dorsal recumbency, with the front limbs tied caudally and the neck slightly hyperextended using a rolled towel.
2. Incise the skin from the laryngeal cartilages to the manubrium.
3. Separate the paired sternohyoideus muscles on the midline, and bluntly and laterally retract the trachea, esophagus, and neurovascular structures using Gelpi self-retaining retractors.
4. Elevate the longus colli muscles from the ventral aspect of the involved intervertebral disc space.
5. Landmarks on the cervical spine include a sharp ventral tubercle at C1 that marks the C1 to C2 intervertebral space cranially and the large, ventrally directed transverse processes at C6 caudally. The correct intervertebral disc space can be easily located using these two landmarks.
6. Make a small fenestration at the ventral annulus of the involved disc space. Perform the ventral slot in the bone using a high-speed surgical drill. Make an oval or rectangular slot, with the width of the slot being no greater than 50% of the diameter of the vertebral body. This minimizes the risk of postoperative subluxation of the slot site.
7. Visually determine the depth of the slot by looking for color change in the bone, going from the white ventral cortex of the vertebra to the purple color of the cancellous bone and finally white again as the dorsal cortex of the vertebra is approached. Take care at this point to avoid inadvertent entry into the spinal canal.
8. Control bleeding from the cancellous bone with bone wax.
9. Remove the dorsal part of the annulus fibrosus with a blunt tartar scraper or #11 blade. Avoid the venous sinuses to prevent excessive bleeding.
10. Any extruded or compressive disc material can now be removed from the spinal canal. A complete decompression is achieved when the dura (which is a light blue-gray) is clearly visible along the spinal canal floor. With caudal cervical spondylomyelopathy, it is uncommon to identify an obvious mass of herniated disc material as seen with the typical type I disc extrusions in the dachshund. Rather, the compression often appears to be caused by fibers of the annulus fibrosus infiltrated by degenerate nuclear material.
11. Close the longus colli and sternohyoideus muscles using an absorbable suture material in a simple interrupted or continuous pattern. Subcutaneous and dermal closure is routine.

Ventral Distraction and Fusion

Numerous techniques have been described for ventral distraction and fusion for dynamic disc lesions. A ventral distraction and fusion technique using an interbody PMMA plug is technically easier to perform that some of the other procedures, while providing consistently good to excellent results. In addition, there are fewer complications with this procedure when two concurrent spaces need to be distracted and fused at the same time.

1. Patient positioning and approach to the cervical spine are described above for the ventral slot technique. The only difference here is that the surgical prep and draping should be wider to include one or both greater tubercles of the humerus for procurement of bone graft.
2. After identification of the involved disc space, fenestrate the ventral annulus fibrosus and remove all of the nucleus pulposus using hemostats or a small rongeur.
3. Temporarily distract the vertebrae using Gelpi retractors that have been modified by blunting of the tips. Make two small slots in the ventral aspect of the vertebral bodies cranial and caudal to the involved disc that are just big enough to fit the tips of the retractors. Place the retractors in the slots, and perform the distraction.
4. Make two small holes in the cranial and caudal vertebral endplates using the surgical drill. This allows inflow of the bone cement for a more stable fixation.
5. Place mixed PMMA into the intervertebral disc space while still in the liquid phase. The PMMA creates an exothermic reaction when it cures; copiously lavage the surgical site with saline to prevent thermal damage to the surrounding tissues.
6. Once the cement has hardened, pack cancellous bone graft taken from the greater tubercle ventrally into the site (Fig. 100-4).
7. Closure is as described above for the ventral slot technique.

Dorsal Laminectomy

Dorsal laminectomy is indicated for dorsal bony or static soft tissue lesions of the spinal canal. In addition, dorsal laminectomy may be indicated for dogs with greater than two ventral compressive lesions. In these dogs, ventral techniques are less effective and have a higher complication rate when more than two spaces are involved.

1. Place the patient in ventral recumbency with the front limbs tied forward. In some cases of caudal cer-

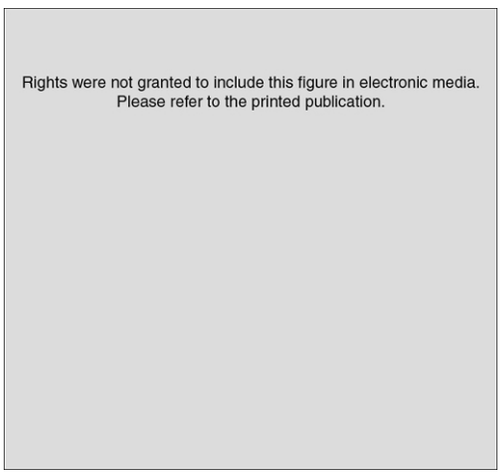

Figure 100-4. Insertion of polymethylmethacrylate plug (PMP) to maintain distraction. CG, cancellous bone graft; DAF, dorsal annulus fibrosus. (From Dixon BC, tomlinson JL, Kraus KH: Modified distraction-stabilization technique using an interbody polymethylmethacrylate plug in dogs with caudal cervical spondylomyelopathy. J Am Vet Med Assoc 208:61, 1996.)

vical vertebral involvement, the legs are crossed under the body, which will separate the spinal blades and allow easier dissection.

2. Incise the skin from the caudal aspect of the dorsal spine of C2 to T3.
3. Incise the muscles and aponeuroses along the midline until the nuchal ligament is identified. The nuchal ligament originates at the large dorsal process of C2 and inserts to the prominent dorsal spinous process of T1, continuing caudally with the supraspinous ligament. The ligament can be retracted laterally, divided on midline, or sectioned to gain exposure. If sectioned, the ligament will need to be repaired upon closure.
4. Separate the muscles from the spinous processes and lamina of the vertebra. Place two pairs of Gelpi self-retaining retractors to expose the laminae.
5. Remove the involved spinous processes using rongeur. Remove the fascia associated with the ligamentum flavum using a #11 blade. Take care to avoid trauma to the spinal cord, since it is unprotected under the larger interarcuate spaces.
6. Perform the laminectomy over the involved spaces using a bur, with close attention paid to the layers of bone as they are encountered.
7. The lateral limits of the laminectomy include the articular facets, but the laminectomy may be continued laterally to remove proliferative articular processes or to gain access to the nerve roots. Take care when dissecting lateral and ventral to the articular facets; inadvertent injury to the vertebral artery can result in severe hemorrhage.
8. Close the muscle in layers using an absorbable suture material. Repair the nuchal ligament if necessary. Close subcutaneous tissues and skin routinely.

Postoperative Care and Complications

- Pain management includes a transdermal Fentanyl patch (placed 12 hours preoperatively) plus NSAID therapy (see Chapter 6).
- Administer first-generation cephalosporin or potentiated penicillin PO for the first 5 days postoperatively.
- Use nursing care as needed for recumbent animals. Maintain clean, padded bedding to prevent decubital ulcers.
- Restrict activity and avoid all high-impact activity for 3 to 6 months postoperatively. Use a harness for the dog instead of a collar.
- With vertebral distraction and fusion, obtain radiographs monthly until a complete bony fusion of the atlantoaxial joint is seen radiographically. A radiographic fusion is usually seen by 8 to 12 weeks.
- Overall success with surgical management of caudal cervical spondylomyelopathy is an approximately 80% return to normal or near-normal neurologic function. However, approximately 30% of these patients will suffer a recurrence of neurologic dysfunction within approximately 2 years. This is due to increased stress at the disc space cranial or caudal to the original surgical site, leading to another compressive lesion (called a domino lesion).
- Positive prognostic factors for outcome include minimal neurologic signs at the time of diagnosis, a brief period of neurologic dysfunction, and one compressive lesion without evidence of spinal cord atrophy.
- Negative factors include moderate to severe clinical signs, a protracted time course of clinical signs, multiple levels of involvement, and spinal cord atrophy.

SPINAL FRACTURES AND DISLOCATIONS

Most cases of fracture and dislocation of the spinal cord are the result of high-impact trauma, such as automobile accidents. Repair of spinal fractures and dislocations depends on the area of spinal cord involvement, degree of neurologic dysfunction, patient size, amount of vertebral displacement ventral instability, concurrent injuries, and continued neurologic deterioration despite medical management.

- Consider surgical stabilization for animals with spinal fractures or dislocations that are unstable and are not responsive to medical therapy.
- The thoracolumbar and lumbosacral junctions are prone to fracture and luxation because they are the sites of marked transition between the stiff and the mobile sections of the spine.
- Due to the complex surgical anatomy and expertise required, promptly refer these cases to a surgical specialist or neurosurgeon.

Anatomy

- The overall stability of the spine is dependent on both the bony and the soft tissue structures that make up the dorsal and ventral compartments.
- The dorsal compartment of the spine consists of the vertebral arch (comprising the dorsal lamina and lateral pedicles), paired articular facets with joint capsule, the dorsal spinous process, interspinous and supraspinous ligaments, and the ligamentum flavum.
- The ventral compartment comprises the vertebral body, intervertebral disc (nucleus pulposus and annulus fibrosus), dorsal longitudinal ligament, and ventral longitudinal ligament.
- The paraspinal musculature is a strong auxiliary support, providing stability to both the dorsal and the ventral compartments.
- Other than the atlanto-occipital joint, atlantoaxial joint, and sacrum, all vertebrae articulate similarly.
- The basic motion unit of the spine consists of two adjacent vertebrae with an interposed intervertebral disc, paired dorsolateral articular facets, and supporting ligaments.
- The intervertebral disc forms an elastic cushion between adjacent vertebrae and functions to absorb shock and allow spinal movement.
- The dorsal and ventral longitudinal ligaments reinforce the annulus fibrosus of the intervertebral discs. These ligaments together limit the degree of vertebral flexion, extension, and transverse sliding motion.
- The articular facets are located at the junction of the pedicle and lamina and vary in shape and position within each segment of the vertebral column. Articular facets play an important role in spinal stability and provide landmarks for alignment during fracture or luxation reduction.
- The supraspinous and interspinous ligaments connect the dorsal spinous processes of adjacent vertebrae and resist flexion during hyperflexion.
- The cervical dorsal spinous processes are short and thin, whereas the dorsal spinous processes of the thoracic and lumbar spine are large and can support orthopedic implants if necessary.
- The cervical vertebral bodies are flat ventrally and are suitable for application of fixation devices. The ventral approach to the cervical spine is generally easier than the dorsal approach.
- The lumbar vertebral bodies are long, allowing orthopedic implant fixation on the dorsolateral surface if the major nerve roots from L4 to L5 through L7 to S1 can be avoided. The origin of the transverse processes provide an important landmark for screw or pin fixation as this site minimizes the risk of entrance of the implant into the spinal canal.
- Lateral surgical exposure to the thoracic vertebrae is hindered by the rib head and potential entrance into the thoracic cavity.

Etiology

Spinal fractures and dislocations are usually due to trauma, such as being hit by a car. Spinal fractures and luxations can be quite varied. An understanding of the forces causing the injury, and of the resultant pathology, is important in formulating a treatment plan and prognosis.

Biomechanics of Spinal Fracture and Luxation

Traumatic fractures and luxations are created by forces resulting in severe hyperextension, hyperflexion, compression, and rotation. Several forces may act together, and they often occur at or near the transition between a movable and an immovable vertebral segment.

▼ ***Key Point*** Fractures and luxations most commonly occur at the craniocervical, thoracolumbar, and lumbosacral junction.

Spinal fractures have a characteristic failure pattern that depends on the forces placed on them during failure. Understanding these forces is crucial in determining the resultant stability of the segment, which will help with the decision to institute conservative (nonsurgical) therapy or surgical fixation.

Hyperextension

- Hyperextension results from a direct blow to the dorsal aspect of the spine.
- Failure is usually due to collapse of the dorsal compartment, especially at the articular facets.
- Damage to the ventral compartment includes tearing of the ventral bands of the annulus fibrosus.
- Predicting inherent stability of these fractures can be difficult.

Hyperflexion

- This usually results in a wedge compression fracture of the vertebra, sparing the dorsal compartment.
- These fractures are generally stable.

Compression

- A compression fracture of the vertebral body occurs with axial load forces.
- Fragments and extruded nucleus pulposus can be driven into the spinal canal, contributing to spinal cord injury.
- The dorsal compartment may be involved, which will result in an unstable fracture.

Rotation

- This force seldom occurs alone and is usually associated with hyperflexion.

- Disruption of both ventral and dorsal compartments usually occurs, resulting in an unstable fracture or luxation with significant displacement.

Clinical Signs

- Depending on the severity of the fracture and associated compression of the spinal cord, animals with these injuries may present with signs ranging from pain or loss of proprioception to loss of motor function.
- See Chapter 128 for more information on clinical signs of spinal cord trauma.

Diagnosis

- Since most of these patients have suffered severe trauma, perform a complete general, neurologic, and orthopedic evaluation. Special care should be taken in evaluating the thoracic and abdominal cavities by thoracic auscultation and abdominal palpation.
- Perform a complete blood count to rule out anemia secondary to blood loss and a biochemical analysis to evaluate for other organ damage.
- Obtain thoracic and abdominal radiographs to rule out evidence of blunt trauma, such as rib fractures and pneumothorax with chest trauma (see Chapter 166). On abdominal radiography, loss of serosal detail may suggest peritoneal effusion, such as blood secondary to organ laceration or urine due to bladder rupture (see Chapter 76).

Neurologic Evaluation

- Once the patient is systemically stable, perform a complete neurologic evaluation to determine location and severity of neurologic injury (see Chapter 125). Overall prognosis is most dependent on the degree of neurologic impairment at the time of presentation.
- Patients with varying degrees of voluntary motor function have a good to excellent prognosis for return to normal neurologic function.

▼ ***Key Point*** The most important prognostic factor is the presence of deep pain sensation. Patients with intact deep pain sensation have an 85% to 90% chance to recover normal neurologic function. Patients with absent deep pain sensation have a 15% chance to recover neurologic function.

- In comparison to intervertebral disc extrusions, the prognosis with spinal fracture or luxation cases presenting with absent deep pain sensation may be even worse due to the amount of injury to the spinal cord.
- If the patient is to be managed medically, perform serial neurologic evaluations (i.e., every 6 hours) to evaluate changes in neurologic status.
- Immobilize the animal during the initial stabilization period to prevent additional spinal cord damage prior to imaging or surgery. Use a small cage, place a body cast, or strap the animal to a rigid body board.

Diagnostic Imaging

- Be very careful when manipulating the patient, since many spinal fractures and dislocations are associated with instability. Further shifting of fracture segments or dislocations from too much manipulation of the spine will result in more spinal cord injury and worsening neurologic function.
- In most cases, plain spinal radiography will identify spinal fracture or luxation (see Chapter 4). Myelography is generally not indicated and is usually an unrewarding method of identifying spinal cord compression due to the degree of spinal cord swelling, hematoma formation, and contrast leakage secondary to meningeal tearing at the trauma site.
- CT imaging of the spine is most helpful at identifying bony pathology, such as fractures of the articular facets. When there is concern for spinal cord compression from traumatic disc rupture, hematoma, or fracture fragment, then MRI is the diagnostic test of choice.

Preoperative Considerations

Patients can be managed conservatively (non-surgically) if they have good motor function with a stable and minimally displaced spinal fracture or luxation.

Indications for Spinal Fracture and Luxation Repair

- An unstable or significantly displaced spinal or fracture luxation
- Severe or persistent spinal pain despite medical therapy
- Diminished or absent motor function, or absent deep pain sensation on initial presentation
- Evidence of declining neurologic function on serial neurologic evaluations

Surgical Procedures

A thorough knowledge of the spinal anatomy and familiarity with surgical approaches is a must for consistent success. Surgical repair of spinal fractures and luxations requires experience and proper instrumentation.

Objectives

- Stabilize the spine
- Decompress the spinal cord, if indicated
- Minimize surgical trauma to the spinal cord

Equipment

- Same as for atlantoaxial instability, plus
  - Plastic spinal plates and associated nuts and bolts

Techniques

Cervical Fractures and Luxations

▼ ***Key Point*** Approximately 80% of fractures of the cervical spine occur at either the dorsal spine or the body of C2. Fractures and luxations rarely occur from C3 to C7.

- A propensity for traumatic luxation at C5 to C6 may occur.
- The choice of surgical fixation technique is dependent on location of the injury, skill level of the surgeon, and whether decompression alone or decompression with stabilization is indicated.
- The choice to perform a decompressive laminectomy will be dependent upon seeing significant compression from extruded disc material, hematoma, or fracture fragments within the spinal canal on myelography, CT, or MRI. Be cautious when performing decompressive procedures, as aggressive removal of the dorsal arch may lead to further instability at the fracture or luxation site. If a ventral slot is required to remove material from the canal at the traumatized space, also perform a stabilization procedure.
- Dorsal stabilization of cervical fractures or luxations is difficult because the thinner bone dorsally provides weak fixation of orthopedic implants. In addition, neurovascular structures make dorsolateral bone plating very difficult.
- Dorsal approaches to the cervical spine are most useful with alignment and fixation of dorsal facets and laminectomy for dorsal decompression.
- Fractures of the dorsal spine of C2 can be repaired dorsally using orthopedic wire or heavy-gauge suture material (toy- and small-breed dogs only), with the goal of anatomic reconstruction and re-establishment if ligamentous structures.
- Ventral approaches to the cervical spine provide the best bone structure for fixation. Ventral fixation using either plastic or metal bone plates can provide stable fixation. Place a minimum of two screws cranial and caudal to the fracture or luxation site for optimum stability. Start the screws on midline and angle as far laterally as possible to avoid penetration of the spinal canal. The difficulty with angling screws within the holes of a bone plate necessitates the use of shorter screws that only engage one cortex, which results in weaker fixation.
- One surgical technique that is adaptable to most fracture and luxation repairs is the use of pins and PMMA placed ventrally in the cervical vertebrae.

Ventral Fixation Using Pins and Polymethyl Methacrylate

1. The approach to the cervical vertebrae is the same as the previously described ventral slot technique (under "Caudal Cervical Spondylomyelopathy").

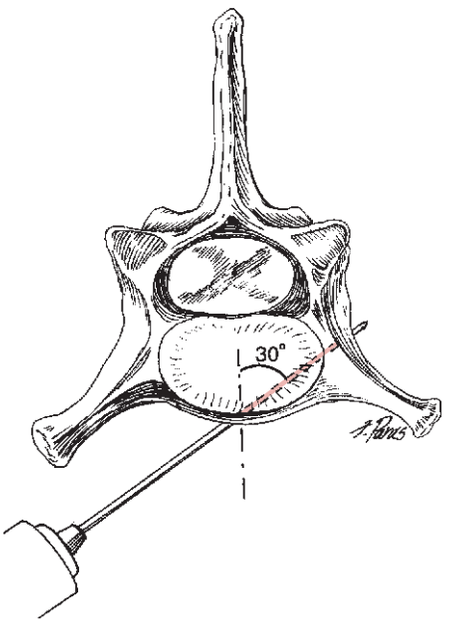

Figure 100-5. Proper pin placement for ventral fixation of cervical fractures. The pins enter the ventral cortex on midline and are angled approximately 30–35 degrees laterally to enter the lateral cortex and miss the spinal canal.

2. Reduce the fracture or luxation site. If decompression of the spinal canal is needed, perform a ventral slot. Reduction of the fracture fragments can be maintained using a Gelpi retractor with the tips blunted.
3. Place a minimum of two Steinmann pins in each cranial and caudal segment, respectively. Start the pins on midline, and angle 30 to 35 degrees laterally to prevent entrance into the spinal canal. Engage the lateral cortex of the lumbar vertebrae for best pin fixation (Fig. 100-5).
4. Cut the pins with 1.5 to 2 cm of pin exposed. Notch the exposed pin using pin cutters for increased bonding between the pin and the PMMA.
5. Place the PMMA ventrally, covering the exposed pins. Lavage the surgical site with cool sterile saline to dissipate the heat of polymerization and prevent thermal injury to the spinal cord.
6. Close the muscles, subcutaneous tissue, and skin routinely.

Thoracic and Lumbar Spinal Fractures and Luxations

▼ ***Key Point*** The most common locations of fracture or luxation of the thoracic and lumbar spine occur at the transition zones (thoracolumbar junction and lower lumbar-lumbosacral space).

Numerous stabilization techniques have been described for fixation of thoracic and lumbar spinal fractures and luxations. The two most common and

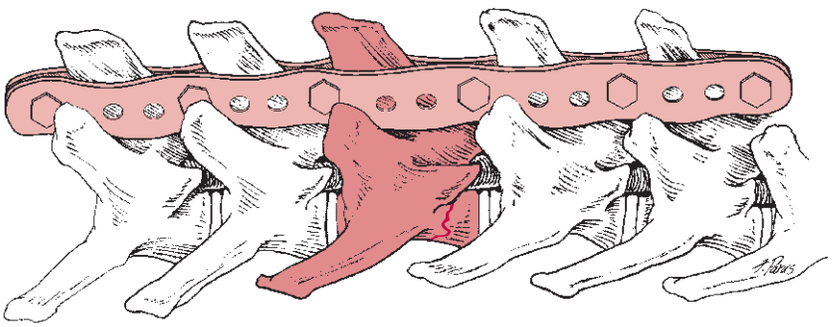

Figure 100-6. Dorsal spinal fixation of the thoracolumbar spine using plastic spinal plates.

technically easiest procedures for repair will be described here: dorsal spinous process plating using plastic spinal plates and pin and PMMA fixation. Dorsolateral vertebral body plating can be performed, but it is technically more demanding and requires removal of rib heads in the thoracic spinal segments.

Dorsal Spinous Process Plating Using Plastic Spinal Plates

1. Perform a dorsal approach to the thoracic and lumbar spine. Expose a minimum of three dorsal spines on each side of the fracture or luxation, and preserve the supraspinous and interspinous ligaments if possible.
2. Reduce the fracture or luxation site, which is dictated by the normal anatomic relation between the cranial and the caudal articular facets. For auxiliary fixation, place a pin or small bone screw across the involved articular facets if they are intact.
3. Place an appropriately sized plastic spinal plate on each side of the dorsal spinous process, with the rough side of the plate against the bone. Several sizes are available.
4. Attach the plates to each other using appropriately sized nuts and bolts between the dorsal spinous processes (Fig. 100-6). For optimal fixation, place the plates as close to the base of the dorsal spinous process as possible.
5. Close dorsal lumbar fascia, subcutaneous tissue, and skin routinely.

Pin and Polymethyl Methacrylate Fixation of Thoracic and Lumbar Fractures

1. Perform a dorsal approach to the involved segments. Expose the dorsal spinous processes, articular facets, and transverse processes bilaterally for pin placement.
2. Place two appropriately sized Steinmann pins into the vertebral bodies on each side of the fracture or luxation. In the thoracic vertebrae, landmarks for pin placement into the vertebral bodies include the tubercle of the rib heads and the base of the accessory process. For lumbar vertebrae, the landmarks for pin placement include the base of the transverse process.
3. Direct the Steinmann pins obliquely through the vertebral body, exiting approximately 2 to 3 mm from the ventral aspect of the vertebral body. Approximately 1.5 to 2 cm of pin is left exposed and is notched using a pin cutter to allow fixation of PMMA.
4. Apply PMMA in a mass, incorporating the Steinmann pins, as well as the articular facets and the dorsal spinous processes. Lavage the PMMA with saline during curing to dissipate the heat of polymerization.
5. Routinely close the lumbodorsal fascia, subcutaneous tissue, and skin.

The primary disadvantage of this procedure is the exposure needed for placement of the implants. Recently, reports describing fluoroscopic placement of the pins through the vertebral bodies using minimally invasive approaches and external spinal fixation have given encouraging results.

Fractures of L6, L7, and the Sacrum

- Fractures of this region are common because of the transition of the relatively mobile lumbar spine with the more rigid pelvis and sacrum.
- The spinal cord ends at the caudal aspect of L6. Fractures in this area usually involve the nerves of the caudal equina. Therefore, clinical signs relate to sciatic, femoral, and sacral nerve deficits.
- The peripheral nerves are more resistant to compression and tension that the spinal cord. Animals with as much as 60% to 70% compromise of the spinal canal may still have a favorable prognosis.

Transileal Pinning

1. Perform a dorsal approach to the lumbosacral region.
2. Since the caudal segment is often displaced cranially and ventrally, use bone forceps to bring the caudal segment into alignment.
3. Place an appropriately sized Steinmann pin through the wing of the ilium, across the dorsal lamina of L7,

and into the opposite wing of the ilium. The ends of the pins can be bent to prevent pin migration.

4. A modification of this technique that may provide more stable fixation involves the use of plastic dorsal spinous process plates and transileal pins. Place the plastic dorsal spinous process plate as described previously in this chapter, incorporating at least three dorsal spinous processes cranial to the fracture or luxation. The plastic plate extends cranial to S2 and S3.
5. Drive a Steinmann pin through one ileal wing, through the plastic plate at the level of L7 to S1, and through the opposite ileal wing. Bend both ends of the pins upward to prevent migration. A second pin may be placed in similar fashion for increased rigidity.
6. Routinely close the lumbodorsal fascia, subcutaneous tissues, and skin.

Postoperative Care and Complications

- Administer postoperative analgesics (see Chapter 6).
- Begin antibiotic therapy (first-generation cephalosporins, potentiated penicillins) intraoperatively and continue for 7 days after surgery.
- Turn recumbent animals every 4 to 6 hours. Maintain clean, dry, padded bedding to prevent decubital ulcers.
- A cervical collar or body cast may be placed for additional stabilization but is usually not necessary.
- Begin physical therapy soon after surgery (see Chapter 95). Passive range of motion exercises, massage therapy, and hydrotherapy are helpful in maintaining muscle mass and preventing joint contracture.
- If voluntary urinary control is absent, express the bladder every 6 hours. Intermittent catheterization can be performed, but avoid indwelling catheters due to the potential for ascending infection.
- The primary complications include loosening of orthopedic implants and infection due to the extensive soft tissue dissection required for exposure and use of large implants and bone cement.

Prognosis

Overall prognosis depends on the presenting neurologic evaluation. In patients with intact deep pain sensation, approximately 85% will regain normal or near-normal neurologic function. With absent deep pain sensation, the overall prognosis is very poor.

Chapter

101 Neoplasia of the Axial Skeleton

Mark M. Smith

ETIOLOGY

Osteosarcoma and chondrosarcoma are the two most common primary neoplasms affecting the axial skeleton. These neoplasms have a similar radiographic appearance, with osteolytic, osteoblastic, or mixed osteoblastic/osteolytic characteristics. Hemangiosarcoma and fibrosarcoma are other primary bone tumors that must be considered. Overall, these tumors more commonly affect the ribs and pelvis than the vertebrae. Multilobular osteoma (chondroma rodens) is the most common tumor of the skull.

Early recognition and accurate diagnosis are of paramount importance for client education and rationale for surgical intervention. Surgery may be diagnostic (vertebrae), palliative (pelvis), or curative (rib), depending on tumor invasiveness and location of axial skeletal involvement. Tumors of the mandible, maxilla, and nasal cavity are discussed in other chapters in this section. The types of neoplasms and principles of treatment discussed in this chapter are similar to those for tumors of the cranium. Removal of cranial tumors requires specialized equipment and skills and therefore is best handled by a surgical specialist. Tumors of the appendicular skeleton are discussed in Chapter 116.

CLINICAL SIGNS

- Patients usually are presented for swelling over a bony prominence.
- Intrathoracic extension of neoplasia of the rib may cause respiratory compromise.
- Pain or an unusual gait secondary to neurologic dysfunction (transverse myelopathy) may be related to neoplasms of the vertebrae.
- Animals with skull tumors usually are presented because of a palpable mass. Neurologic signs may develop if brain impingement occurs.
- Constipation may result from pelvic tumors.

DIAGNOSIS

Pelvis and Ribs

- Include two radiographic projections of the lesion.
- Radiographic signs of primary bone neoplasms (e.g., osteosarcoma, chondrosarcoma) may range from primarily lytic to proliferative lesions.
- Polyostotic lytic lesions are seen with malignant lymphoma and multiple myeloma (see Chapter 27).

▼ ***Key Point*** Do not use radiography as the sole basis for determining tumor type.

- Determine if metastatic disease is present.
- Perform palpation and fine-needle aspiration of enlarged regional lymph nodes.
- Perform abdominal palpation for mass lesions, vertebral palpation for metastasis-related pain, and a rectal examination for intrapelvic masses.
- Evaluate three-projection thoracic radiographs (ventrodorsal, left, and right lateral) to detect pulmonary metastasis.

Skull and Vertebrae

- Survey radiographs of the spine often show osteolysis secondary to primary bone neoplasia or to invasion of soft tissue neoplasia.
- Osteosarcoma or multilobular osteoma of the cranium appears radiographically as a proliferative bony lesion of the flat bones.
- Perform cerebrospinal fluid (CSF) analysis to rule out infection and inflammation (see Chapter 125). CSF of patients with vertebral neoplasia may have increased levels of protein and elevated pressure.

▼ ***Key Point*** Because most tumors affecting the spinal cord are extradural, cytologic examination of the CSF may be normal.

- Myelography and computed tomography (CT) are important to detect the exact site of the vertebral tumor and the extent of spinal cord compression (see Chapter 128).

▼ ***Key Point*** Metastatic lesions from remote malignant tumors may mimic primary neoplasms of the axial skeleton. Histopathologic examination of biopsy tissue is required for differentiation.

- CT or magnetic resonance imaging (MRI) is useful to evaluate intracranial effects of skull tumors (see Chapter 126).

Bone Biopsy

Objectives

- Obtain multiple tissue samples of the tumor for histopathologic diagnosis.
- Avoid causing iatrogenic trauma to the vertebrae or skull, if they are involved.

Equipment

- Small suture pack and suture material
- Jamshidi-type biopsy needle or bone trephine
- Sterile ruler

Technique

1. Prepare the cutaneous area over the tumor site for aseptic surgery.
2. Make a skin incision large enough to introduce the biopsy instrument over the center of the lesion.
3. Measure the center of the tumor from the nearest prominent anatomic landmark.
4. Take a minimum of two biopsies: one from the center of the tumor and one from the center directed to the periphery. Use extreme caution when performing biopsy of tumors of the cranium.
5. Using a horizontal mattress pattern, place sutures of absorbable material in the subcutaneous or fascial layers to minimize hemorrhage from the biopsy site.
6. Close the skin with non-absorbable suture material in a simple interrupted pattern.

▼ ***Key Point*** Biopsy of vertebral lesions is best performed during decompressive laminectomy or with the aid of fluoroscopy to guide biopsy needle placement.

TREATMENT

Surgical Procedures for Rib Neoplasia: Resection and Thoracic Wall Reconstruction

Objectives

- Completely remove the thoracic wall mass.
- Attempt to obtain wide tumor-free margins.
- Minimize hemorrhage.
- Provide rigid reconstruction to prevent abnormal chest wall movement.
- Perform airtight closure to prevent pneumothorax.

Equipment

- Standard general surgical pack and suture material
- Two large Gelpi or Beckman self-retaining retractors
- Gigli wire or Liston bone cutters
- Chest tube, three-way stopcock, and large syringe
- Polypropylene mesh

Technique

1. Place the animal in lateral recumbency with the hindlimbs extended caudally and the forelimbs extended cranially.
2. Prepare the lateral chest wall for aseptic surgery.
3. Incise the skin over the mass. If the tumor is adhered to the dermis, make a large, elliptical skin incision around the tumor.
4. Incise or, preferably, reflect the latissimus dorsi muscle if it is not adhered to the tumor.
5. Incise all remaining muscle layers one intercostal space cranial and caudal to the mass.
6. Cut all involved ribs and intercostal muscles 2 cm dorsal and ventral to the tumor, using Liston bone cutters and Metzenbaum scissors.
7. Clamp and ligate the intercostal arteries and veins.
8. Place a chest tube a minimum of two intercostal spaces cranial or caudal to the resection site.

▼ ***Key Point*** Consider giving an intraoperative lidocaine intercostal nerve block to decrease pain during the acute postoperative period (see Chapter 167).

9. Use polypropylene mesh (e.g., Marlex) to reconstruct large thoracic wall defects.
10. Place polydioxanone or polypropylene sutures, using an interrupted horizontal mattress pattern, in a paracostal location to secure the mesh.
    a. A slight fold may be created along all borders of the mesh to provide a double-thickness layer for holding sutures.
11. Secure the mesh to the cut ribs with sutures of similar material, using a circumferential simple interrupted pattern. Create slight tension on the mesh to provide rigidity.
12. Suture the latissimus dorsi and external abdominal oblique muscles over the defect with absorbable suture material in an interrupted pattern to provide a tissue seal.
13. Close subcutaneous tissues with absorbable suture material in an interrupted pattern to minimize dead space.
14. Appose the skin routinely, using non-absorbable suture material.

15. Use the chest tube system to reestablish negative intrathoracic pressure.

▼ ***Key Point*** Small thoracic wall defects may be closed using adjacent latissimus dorsi and external abdominal oblique muscles without the need for a mesh implant.

Postoperative Care and Complications

Short Term

- Closely monitor for hemorrhage, seroma formation, and pneumothorax.
- Apply a light chest bandage to minimize seroma formation and air migration along the chest tube.

▼ ***Key Point*** Place the bandage loose enough to allow normal chest excursion and optimal pulmonary function.

- Analgesics (hydromorphone, 0.05 mg/kg q4h IV) will be required in the acute postoperative period (see Chapter 6).

Long Term

- Repeat physical and radiographic examinations every 4 to 6 months to monitor for recurrence or metastasis.
- Consider adjuvant chemotherapy if the tumor is malignant or if tumor cells are present in resected tissue margins (see discussion of chemotherapy in Chapter 26).

Prognosis

- Chest wall neoplasms usually are malignant and carry a poor prognosis if incompletely excised. This is especially true for osteosarcoma.
- The prognosis is guarded even if the tumor is completely resected because subclinical distant metastasis may have occurred before surgery.
- Dogs with rib chondrosarcoma have longer survival than those with osteosarcoma.

Surgical Procedure for Pelvic Neoplasia: Resection of the Ilial Wing

Preoperative Considerations

Perform ilial wing resection for localized tumors. Invasive, malignant tumors may require hemipelvectomy, which involves resection of part of the lateral pelvis and hind limb. Refer the patient to a surgical specialist for hemipelvectomy.

Objectives

- Completely remove the pelvic mass.
- Obtain wide, tumor-free margins.
- Minimize hemorrhage.
- Avoid damage to major pelvic limb nerve tracts in order to maintain limb function.

Equipment

- Standard general surgical pack and suture
- Two large Gelpi or Beckman self-retaining retractors
- Gigli wire or osteotome and mallet

Technique

1. Place the animal in lateral recumbency.
2. Prepare the lateral pelvic area and proximal hindlimb for aseptic surgery.
3. Incise the skin over the mass. If the tumor is adhered to the dermis, make a large elliptical incision around the tumor.
4. Incise through the superficial, middle, and deep gluteal muscles cranial to the acetabulum.
5. Incise the sartorius and tensor fascia lata muscles before their insertion on the ilium.
6. Incise the iliocostalis and longissimus muscles cranial to the pelvic mass.
7. Incise the quadratus lumborum and iliacus muscles before their insertion on the medial aspect of the ilium.
8. Cut the sacroiliac joint and ilial body using a Gigli wire or osteotome and mallet.
9. Elevate the other fascial attachments to free the proximal ilial segment.
10. Control hemorrhage with electrocoagulation or individual vessel ligation.

▼ ***Key Point*** Maintain wide margins of excision with no gross evidence of tumor.

11. Closure
    a. Appose the resected muscle ends by simple interrupted sutures of absorbable material placed in the fascia.
    b. Extensive resection may require Penrose drain placement to minimize potential dead space.

▼ ***Key Point*** Make separate small incisions in the surgical area for entrance and exit of drains, avoiding the primary wound incision.

    c. Close subcutaneous tissues with absorbable sutures in a simple interrupted pattern.
    d. Appose the skin similarly, using non-absorbable sutures.

Postoperative Care and Complications

Short Term

- Use a modified Robert Jones bandage to decrease the incidence of seroma. Bandage application and maintenance is more cumbersome in male dogs.

- Monitor the wound for signs of seroma and infection.
- Administer analgesic therapy (hydromorphone 0.05 mg/kg q4h IV) during the acute postoperative period.

Long Term

- Repeat physical and radiographic examinations every 4 to 6 months to monitor for recurrence and metastasis.
- Consider adjuvant chemotherapy if the tumor was malignant or if tumor cells are present in resected tissue margins (see discussion of chemotherapy, Chapter 26).

Prognosis

- Prognosis is the same as for rib neoplasia.

Surgical Procedure for Vertebral Neoplasia: Dorsal Laminectomy

Because laminectomy is a difficult surgical procedure that should be performed only by surgical specialists, only an overview of the procedure is given here. (See Chapter 128 for more information on principles of surgery of the spinal cord.)

Objectives

- Debulk the tumor.
- Decompress the spinal cord.
- Obtain tissue for histopathologic diagnosis.

Equipment

- Standard general surgical pack and suture material
- Two large Gelpi or Beckman self-retaining retractors
- Pneumatic or electric power equipment for laminectomy
- Kerrison or Lempert bone rongeurs
- Iris scissors

Procedure Overview

- Preoperatively administer dexamethasone (0.5 mg/kg IV) to decrease edema of the spinal cord related to surgical manipulation.
- Save adequate amounts of tumor tissue in 10% buffered formalin for histopathologic evaluation.
- The laminectomy procedure ends when the spinal cord is relieved of the compression effect of the tumor.
- Dorsal laminectomy can be combined with hemilaminectomy if additional lateral exposure is required.

▼ ***Key Point*** Iatrogenic vertebral fracture/luxation is unlikely, because reactive bone and scar tissue secondary to the neoplasm compensates for the destabilizing sequelae of laminectomy and tumor debulking.

Postoperative Care and Complications

Short Term

- Monitor for seroma formation and infection at the wound site.
- Perform serial neurologic examinations to monitor neurologic status.
- Administer prednisolone (0.5 mg/kg q12h PO) for anti-inflammatory therapy (if necessary) until neurologic status is improved.
- Urine retention requires frequent manual decompression of the bladder or maintenance of a closed indwelling catheter system. Monitor for development of urinary tract infection.
- Turn the patient every 4 hours to prevent decubital ulcers secondary to prolonged recumbency.
- Administer analgesics as needed (see Chapter 6).

Long Term

- Supportive therapy and good nursing care are mandatory during the neurologic recovery period.
- Limit exercise but perform physical therapy as needed to regain limb function (see Chapter 95).
- Consider adjuvant chemotherapy and/or radiation therapy (see Chapter 26), based on the histopathologic diagnosis, because complete resection of the tumor is not possible.

PROGNOSIS

- The prognosis for malignant tumors of the vertebral axial skeleton is poor.
- Neoplasms secondarily affecting vertebrae (e.g., lymphoma) may warrant a guarded prognosis, based on responsiveness to chemotherapy.

Chapter

102 Fractures of the Shoulder

James K. Roush

Recognition of shoulder fractures is important to allow acute lameness diagnosis and treatment and to protect normal shoulder joint mobility and function. Fractures of the shoulder are often associated with concurrent thoracic trauma and may be associated with ipsilateral brachial plexus injuries or trauma to the overlying soft tissues.

ANATOMY

The shoulder is a diarthrodial joint with a shallow ball-and-socket configuration. Major support structures of the shoulder are the loosely defined medial and lateral glenohumeral ligaments and the joint capsule. Stability is also provided by a number of muscles and tendons that cross the joint to insert on the humerus, including the supraspinatus tendon, acromial and spinous heads of the deltoideus muscle, infraspinatus tendon, coracobrachialis tendon, and teres minor tendon. The biceps brachii tendon provides minimal cranial support to the normal shoulder but is commonly transposed to provide medial or lateral support after traumatic joint luxation.

The scapula is a broad, flat bone with a prominent spine and numerous muscle origins and insertions. It is loosely attached to the chest wall through the insertions of a number of muscles, including the rhomboideus, subscapularis, and trapezius. Scapular areas can be anatomically divided into the body, spine, neck, and glenoid cavity, with differing surgical approaches and treatments recommended for fractures in each area (Fig. 102-1). In immature animals, the dorsal border of the scapula serves as a physis for long bone growth. The distal scapula has no physis for long bone growth, but the supraglenoid tubercle is a secondary center of ossification in the immature dog and this apophysis is often misdiagnosed as a fracture in dogs until radiographic closure from 6 to 7 months of age.

The proximal humerus has a number of defined tubercles with important muscle insertions. The greater tubercle provides insertions for the supraspinatus tendon cranially and the infraspinatus and teres minor tendons laterally. The deltoid tuberosity is a linear protuberence on the lateral aspect of the humerus serving as the insertion for the acromial and spinous heads of the deltoid muscle. The coracobrachialis tendon inserts on the medially located coracoid process of the proximal humerus. There is a proximal humeral physis that closes functionally at approximately 8 months and radiographically at 10 months of age in the dog, and a secondary ossification center composing the greater tubercle is visible in dogs under 5 months of age.

Important soft tissue structures that may be affected by trauma or that are important during surgical approaches include the suprascapular nerve, which crosses the scapular neck from cranial to caudal beneath the acromion; the circumflex humeral vessels, which lie just distal to the teres minor muscle beneath the spinous head of the deltoideus muscle; and the cephalic vein, which lies superficially on the craniolateral aspect of the greater tubercle.

DIAGNOSIS

Clinical Signs

Clinical signs associated with canine scapular and proximal humeral fractures include partial or non–weight-bearing lameness of a forelimb, pain or crepitus during palpation of the scapula or proximal humerus, and pain during manipulation of the scapulohumeral joint. Malposition and soft tissue of the limb at the scapulohumeral joint may be visible and palpable during physical examination. It is important to apply direct pressure along all borders of the scapula and along the scapular spine while observing the animal for signs of pain to detect greenstick or minimally displaced scapular fractures.

Radiography

Definitive diagnosis of scapular fractures is by radiography. Reported radiographic views of the scapula include caudocranial, mediolateral, dorsally displaced mediolateral, and distoproximal. Any or all of these views may be useful for the surgeon's understanding of the fracture's configuration. Frequently, computed tomography (CT scan) of the scapula is useful to determine the degree of comminution and provide operative plan-

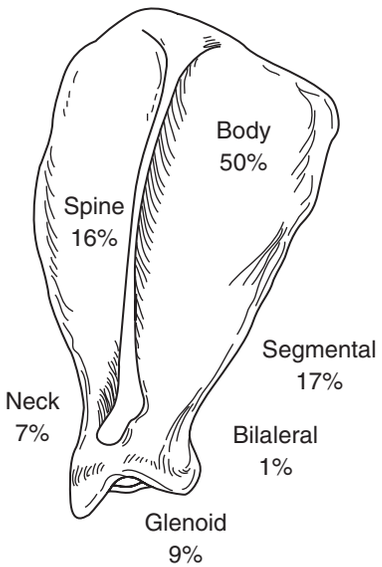

Figure 102-1. Percentage of canine scapular fractures occurring in various regions of the scapula from a study of 107 scapular fractures. (Rohn D, Roush JK: Unpublished data.)

ning, particularly with the addition of three-dimensional reconstructions of the fracture available in some software. In a study of 107 dogs with scapular fractures, 28% were comminuted fractures, but only one fracture was an open fracture. Nuclear scintigraphy of the scapula may be useful to identify non-displaced scapular fractures. In young animals, diagnosis of supraglenoid tubercle fracture should not be made until comparison with radiographs of the opposite scapula indicates an obvious displacement of the affected supraglenoid tubercle.

FRACTURES OF THE SCAPULA

Preoperative Considerations

- Treatment of scapular fractures varies by the location and configuration of the fracture, the degree of displacement of the fragments and their effect on distal limb position, and the location and degree of involvement of the articular surfaces by the fracture.
- In a study of 107 dogs with scapular fracture, the scapular body had the most fractures (50%). Fractures of the articular surface of the glenoid were found for only 9% of dogs, with 6 of 9 dogs involving only the supraglenoid tubercle (Fig. 102-1).
- Non-displaced or minimally displaced fractures of the scapula body and spine are best treated by strict cage confinement.
- Application of a Velpeau sling has been advocated, but it generally provides no advantages over adequate cage confinement and has the disadvantage of resulting in decreased humeral joint function and increased joint stiffness from the immobility period.
- Perform surgery for fractures of the scapula or proximal humerus in lateral recumbency with the limb prepared for aseptic surgery. Surgical approach is dependent on the area of exposure needed for the particular fracture, but a number of described surgical approaches are useful, including the lateral, craniolateral, and caudolateral approaches and variations of these approaches combined with acromion osteotomy, greater tubercle osteotomy, and infraspinatus tenotomy.
- Because of the extensive number of muscles and tendons crossing the joint, adequate exposure of the glenoid surface during surgery may require osteotomy of any or all supraglenoid or greater tubercles or of the acromion. These are reattached at the conclusion of the primary fracture repair by lag screw or tension band fixation.

Equipment

- Standard orthopedic pack and bone reduction forceps
- Orthopedic wire (20 and 22 gauge, or 0.8 and 1.0 mm) and wire twisters
- Selection of Kirschner wires and small Steinmann pins
- Bone plating sets, including 2.0-, 2.7-, and 3.5-mm screws to accommodate all animal sizes, and a variety of bone plates, including miniplates, dynamic compression plates, T plates, L plates, and reconstruction plates

Scapular Body Fractures

Fractures of the scapular body comprise 50% of all scapular fractures and are often transverse or oblique. The thinness of the scapular body results in difficulty in finding purchase for surgical implants; thus, minimally displaced or non-displaced fractures are treated by cage confinement. Fractures of the proximal half of the scapular body are often comminuted but are also adequately treated by cage confinement for an extended period.

Technique Overview

- If internal fixation is necessary to prevent limb shortening and malalignment, treat fractures of the scapular body by placement of appropriately sized plates across the fracture fragments.
- Surgical approach is by removal of the insertion of the trapezius, omotransversarius, and supraspinatus muscles from the scapular spine and by separation of the infraspinatus muscle from the spine for caudal fractures.
- Plates used in previous reports include standard DCP of all sizes, reconstruction plates, stackable miniplates, T and L plates, and semitubular plates.
- Fractures that transverse the scapular body may benefit from the addition of plates both cranially and

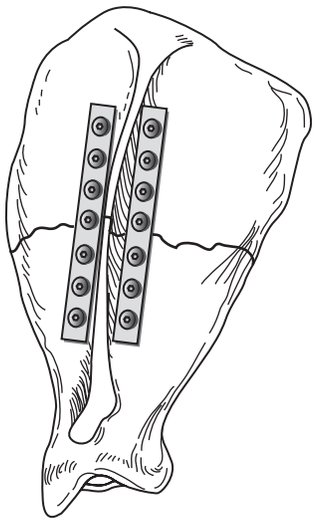

Figure 102-2. Transverse fracture of the scapular body stabilized with 2.7-mm hole dynamic compression plates along the scapular spine.

caudally to the scapular spine (Fig. 102-2). Comminuted fractures may be reduced individually by hemicerclage wire and may be stabilized individually by small bone plates or bridged with a plate in buttress fashion.

▼ ***Key Point*** When fracture configuration allows, screws near the scapular spine should be directed to the center of the scapula beneath the spine to take advantage of the thicker bone and better subsequent screw purchase in those areas.

Scapular Spine and Acromion Fractures

Fractures of the scapular spine comprise about 16% of scapular fractures and often do not require internal fixation because the origin of multiple muscles along the spine minimizes displacement and provides some stability.

Technique Overview

- Fractures of the spine not involving the acromion may be managed by cage confinement.
- Avulsions of the acromion require treatment to restore function of the deltoideus muscle group.
- Treat avulsions of the acromial process with tension band or lag screw fixation (Fig. 102-3). When the acromion is removed to facilitate surgical approach for glenoid or neck fractures, replace with tension band fixation.

Scapular Neck Fractures

Scapular neck fractures override due to conflicting muscle pulls on the proximal and distal fragments. Treat by internal fixation. Adequate surgical exposure requires acromion osteotomy and infraspinatus tenotomy to adequately visualize and expose fractures.

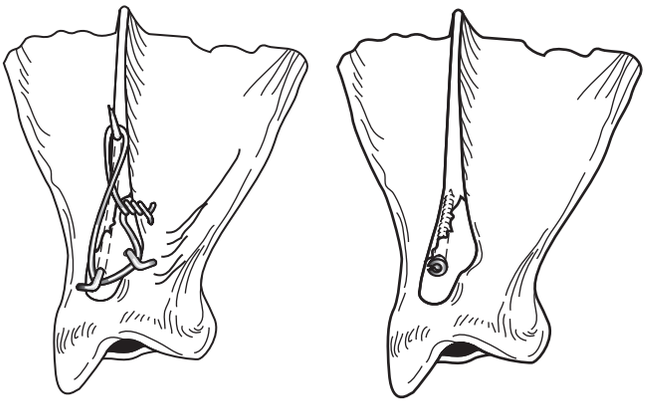

Figure 102-3. Fracture of the acromion stabilized with two Kirschner wires and a figure-eight cerclage wire applied in tension band *(left)* or lag screw *(right)* fashion.

▼ ***Key Point*** During surgery for scapular neck fractures, identify and protect the suprascapular nerve.

Technique Overview

- Adequate internal fixation is achieved by the use of 2.7- or 2.0-mm dynamic compression plates, miniplates, or reconstruction plates in a straight, T-shaped, or L-shaped fashion.
- Place the proximal aspect of these plates as close as possible to the scapular spine, and place the distal aspect with care taken not to impinge on the joint surface with the plate or screws (Fig. 102-4).

Supraglenoid Tubercle Fractures

Separations of the supraglenoid tubercle are avulsions of the tubercle with the biceps brachii origin attached and are often distally displaced. While it occurs frequently in immature animals, the secondary center of ossification of the supraglenoid tubercle should be differentiated from true fractures.

▼ ***Key Point*** In immature animals, base diagnosis of supraglenoid tubercle fractures on obvious distal displacement of the tubercle on comparison with radiographs from the opposite (unaffected) shoulder to avoid confusion with the normal apophyseal appearance.

Technique Overview

- Osteotomy of the greater tubercle of the humerus provides adequate exposure for this fracture.
- Stabilize the fracture with a lag screw and an antirotational Kirschner wire (Fig. 102-5).
- If there is difficulty in reduction, the biceps tendon may be transected from the origin to remove its opposing pull on the fragment. In this case, the

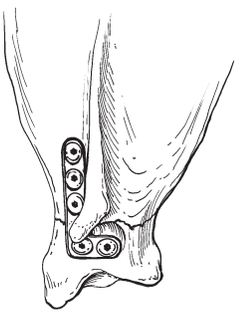

Figure 102-4. Fracture of the scapular neck stabilized with an L oblique bone plate of sufficient size.

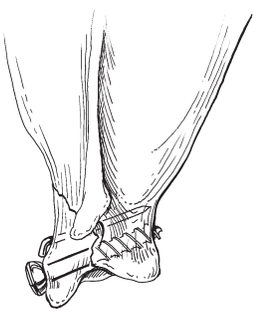

Figure 102-5. Fracture of the supraglenoid tubercle stabilized with a lag screw and antirotation Kirschner wire.

biceps brachii tendon should be transposed to the humerus and attached with a lag screw and spiked washer.

Glenoid Fractures

▼ ***Key Point*** Glenoid fractures are intraarticular and require open reduction and internal fixation for acceptable alignment and restoration of normal joint function.

Technique Overview

- Approach fractures of the glenoid by acromion osteotomy, greater tubercle osteotomy, transection of the insertion of the acromial and spinous heads of the deltoideus muscle, or a combination of these. The suprascapular nerve should be identified and protected.
- Fracture fragments are anatomically positioned and stabilized with a lag screw parallel to the joint surface or between the fragments and the scapular neck.
- Rotational stability of fragments is improved by addition of a second lag screw or Kirschner wire in each fragment.
- In the case of T-shaped combinations of glenoid and neck fractures, first reduce the articular surface with a lag screw parallel to the joint, and then repair the neck fracture with a T or L plate (Fig. 102-6).

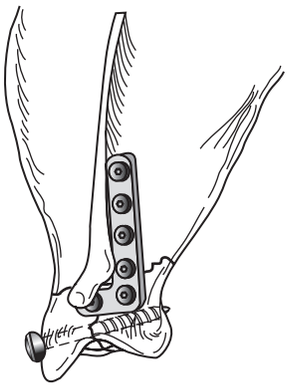

Figure 102-6. T fracture of the scapula stabilized with a lag screw and L bone plate.

Postoperative Considerations

- The prognosis is good for both fracture healing and normal shoulder function provided good orthopedic technique during implant fixation is followed.
- Restrict activity until healing is adequate as demonstrated on radiographs (8–12 weeks average).
- For animals treated only by cage confinement, periodic reexamination or radiographs may be required to evaluate fracture healing and guard against changes in limb alignment during healing.

Complications

- Injury of the suprascapular nerve can result in atrophy of the supraspinatus muscle.
- Malalignment at the articular surface leads to osteoarthritis and decreased limb function. Salvage procedures that provide good limb function include glenoid excision and total scapulectomy.
- Screw loosening and migration are common problems due to poor purchase in thin scapular bone. If implants move or migrate, fracture fixation is considered failing and further surgical intervention is indicated.
- Nonunion of scapular fractures is rare.

PROXIMAL HUMERAL FRACTURES

Preoperative Considerations

- Fractures of the proximal humerus occur rarely, but such occurrences are most common in skeletally immature animals in the form of a Salter-Harris type I, II, or III fracture.
- The proximal humeral physis functionally closes at approximately 8 months of age and is radiographically closed beginning at 10 months of age.
- If the proximal humerus is fractured in a mature, aged dog, radiographs of the fracture should be carefully evaluated for periosteal proliferation, bone lysis, bony sclerosis, or cortical thinning around the

fracture margins. Such findings indicate pathologic fractures likely due to osteosarcoma.

Surgical Procedures

- Perform a craniolateral approach to the scapulohumeral joint for Salter-Harris type I or II fractures.
- Salter-Harris type III or comminuted proximal fractures in mature animals require osteotomy of the acromion and scapulohumeral capsulotomy.
- Articular fractures of the humeral head require anatomic reduction of the articular surface to prevent later osteoarthritis.

Equipment

- Standard orthopedic pack and pointed bone reduction forceps
- Selection of Kirschner wires and small Steinmann pins
- Bone plating sets, including 2.0-, 2.7-, 3.5-, and 4.5-mm screws to accommodate all animal sizes

Fractures or Osteotomy of the Greater Tubercle or Lesser Tubercle

Technique Overview

- Fractures occur primarily in immature animals as avulsion fractures due to ligamentous attachments.
- Stabilize the tubercle with a tension band device or with a lag screw and an antirotational Kirschner wire through the tubercle into the metaphysis or caudal humeral cortex.

Salter-Harris I or II Fractures of the Proximal Physis

Technique

1. Place the animal in lateral recumbency and the limb is prepared for surgery.
2. Perform a craniolateral approach to the proximal humerus.
3. In very young (<7 months of age) animals, stabilize the fracture using two or more smooth Kirschner wires or Steinmann pins placed in parallel fashion from the greater tubercle into the proximal metaphysis or caudal cortex of the metaphyseal region (Fig. 102-7).
4. In older animals for which skeletal growth is complete, stabilize the fracture using one lag screw and a Kirschner wire or two lag screws placed from the greater tubercle into the proximal metaphysis (see Fig. 102-7).

Fractures of the Humeral Head (Salter-Harris III Fractures)

Technique

1. Place the animal in lateral recumbency and aseptically prepare the limb for surgery.

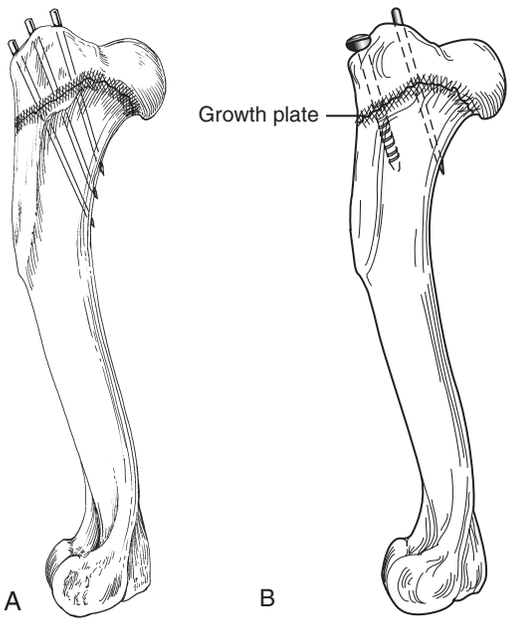

Figure 102-7. Salter-Harris type I fracture of the proximal humerus stabilized with multiple parallel Kirschner wires *(A)* or stabilized with a lag screw and Kirschner wire *(B)*.

2. Perform a craniolateral approach to the proximal humerus. Combine with an osteotomy of the acromion.
3. In young (<7 months of age) animals, reduce and stabilize the epiphyseal fragments with two lag screws or a lag screw and an antirotational Kirschner wire driven parallel to the joint surface from the greater tubercle into the caudal humeral head. The epiphysis is then reattached to the metaphysis using two or more Kirschner wires or Steinmann pins placed in parallel fashion from the greater tubercle into the proximal metaphysis.
4. Older animals may be repaired in a similar fashion or repaired using a T plate that spans the proximal humeral fragments cranially and caudally and reattaches them to the metaphysis.

Fractures of the Humeral Neck

Technique

These types of fractures occur in older animals.

1. Anatomically align the fracture fragment and then stabilize it with a T plate or other plate engaging six cortices on each side of the fracture.
2. Alternatively, stabilize the fracture using Rush pins or Kirschner wires placed in Rush pin fashion (Fig. 102-8).

Postoperative Care

- Restrict the animal to a cage until radiographic healing is demonstrated.

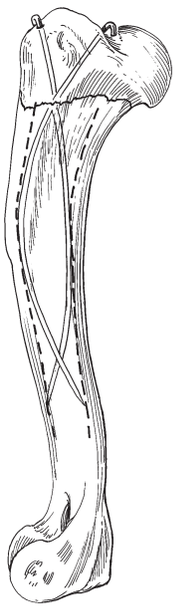

Figure 102-8. Fracture of the proximal humeral neck stabilized with pins in Rush fashion.

- Obtain appropriate radiographs immediately postoperatively and at 4-week intervals until the fracture is healed.
- Malalignment at the articular surface leads to osteoarthritis and decreased limb function. Salvage procedures that provide good limb function include glenoid excision and total scapulectomy.

Complications

- Nonunion or malunion occurs rarely.
- Premature closure of the proximal humeral physis may occur and may affect limb function in animals < 7 months of age at the time of fracture.

Prognosis

- If adequately reduced and stabilized, these fractures heal rapidly and consistently.
- Range of shoulder motion generally remains normal, provided that anatomic reduction of the articular surface was achieved.

Chapter

103 Scapulohumeral Luxation

Robert A. Taylor

Scapulohumeral luxation is an uncommon clinical condition. Both congenital and traumatic luxations occur; the latter is more common.

Medial luxation of the humeral head is most common, especially in smaller-breed dogs. Lateral luxation of the humeral head, while less common, usually occurs in larger dogs (Fig. 103-1). Cranial and caudal luxations are rare.

ANATOMY

- The shoulder joint is a ball-and-socket joint. The articular surface of the scapula forms the concave glenoid, and the convex humeral head articulates within it. Although the joint is capable of movement in any direction, its major actions are flexion and extension.
- The joint capsule is continuous and blends with the medial and lateral glenohumeral ligaments (Fig. 103-2). These ligaments help to support the joint and may be 2.0 mm or greater in thickness.
- The subscapularis, supraspinatus, infraspinatus, and teres minor muscles provide periarticular support.
- The tendon of origin of the biceps brachii and its sheath join with the joint capsule on its cranial medial aspect and provide additional stability. The bicipital tendon is held in the bicipital groove by the small but sturdy transverse humeral ligament.
- Luxation is not possible unless the glenohumeral ligaments and joint capsule have been ruptured.

CLINICAL SIGNS

- The principal signs are varying degrees of lameness, depending on the severity of the luxation.

DIAGNOSIS

- Diagnosis is made by physical examination and confirmed by radiography.
- Careful palpation of the area between the acromion of the scapula and greater tubercle can be helpful.
- In medial luxations, hold the elbow in a flexed position and abduct the lower limb.
- In lateral luxations, hold the elbow in a flexed position and adduct the lower limb.
- Examine both shoulders simultaneously and use the normal limb for comparison.

PREOPERATIVE CONSIDERATIONS

- Radiograph the shoulder to rule out intra-articular fractures.
- Use general anesthesia for all shoulder reduction procedures, whether open or closed.
- Closed reduction is a non-surgical treatment.

PROCEDURES FOR CLOSED REDUCTION

Procedure for Medial Luxation

1. Flex the elbow and pull the limb laterally while exerting digital pressure on the scapular spine.
2. Gently rotate the limb downward to reduce the luxation.
3. Place the limb in a Velpeau sling for 10 to 14 days.
4. If the joint is stable on removal of the sling, begin passive range-of-motion exercises. When possible, encourage swimming as an adjunct to physical therapy, but restrict exercise for 1 month.

Procedure for Lateral Luxation

1. Flex the elbow and extend the shoulder to reduce the luxation.
2. Gently rotate the humeral head upward to facilitate reduction.
3. Use a spica splint to support the joint for 10 to 14 days.

▼ ***Key Point*** Surgical stabilization of complete or partial luxations (chronic instability) can be challenging. When possible use tissue anchors and non-absorbable sutures to enhance the stability. In some cases of medial glenohumeral instability

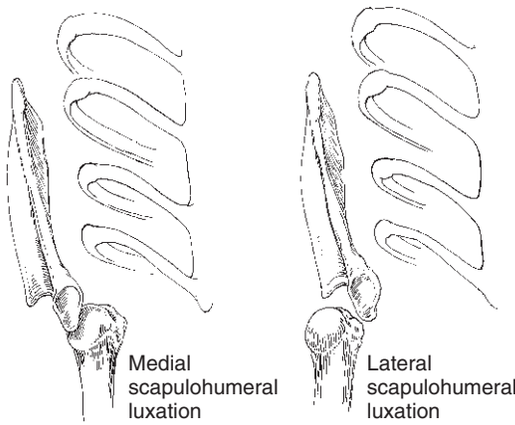

Figure 103-1. Medial *(left)* and lateral *(right)* luxations of the scapulohumeral joint.

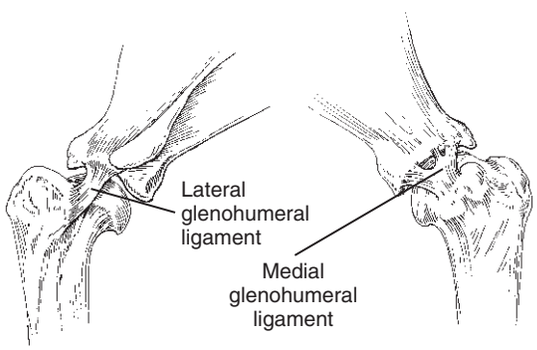

Figure 103-2. The glenohumeral ligaments.

I have successfully used radio-frequency tissue shrinkage to increase the stability of the joint. In cases with severe secondary changes consider scapulohumeral arthrodesis as a salvage procedure.

SURGICAL PROCEDURE FOR OPEN REDUCTION

Objectives

- Surgically repair the ruptured glenohumeral ligament and joint capsule.
- Stabilize the shoulder joint and prevent recurrent luxations.

Equipment

- Standard general surgical pack and suture material
- Standard orthopedic set
- Oscillating bone saw
- Osteotomes and mallet
- Kirschner wires and pin chuck
- Appropriate retractors

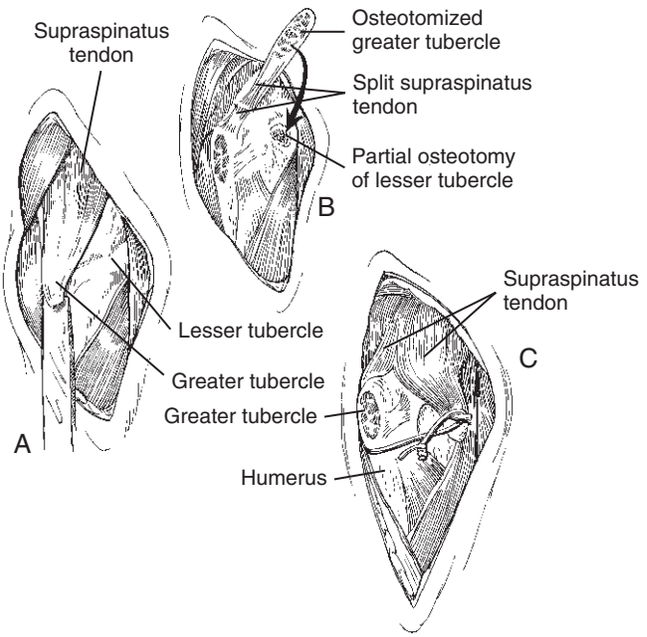

Figure 103-3. *A,* Use an oscillating bone saw or osteotome to partially osteotomize the greater tubercle. *B,* Split the supraspinatus tendon with a scalpel blade. *C,* Attach the split portion of the supraspinatus tendon to the region of the lesser tubercle.

Surgical Repair of Medial Luxation

Technique

1. Place the dog in lateral recumbency with the affected leg up. After preparing the limb for aseptic surgery, place the distal extremity in a sterile stockinette so that it is accessible to intraoperative manipulation. Make an incision on the craniomedial aspect of the joint.
2. Reflect the skin and subcutaneous tissue and incise the brachiocephalicus muscle along its medial edge and retract it.
3. Incise the superficial and deep pectoral muscles near their point of insertion on the humerus. Be sure to separate the supraspinatus muscle from the deep pectoral muscle.
4. Using an osteotome or oscillating saw (Fig. 103-3*A*), partially osteotomize the greater tubercle of the humerus. Hold the osteotome on the crest of the greater tubercle and make the medial line of the cut parallel to the humeral border of the transverse humeral ligament. Avoid cutting the infraspinatus tendon.
5. Using sharp dissection, carefully split the supraspinatus tendon (Fig. 103-3*B*).
6. Partially osteotomize the lesser tubercle and prepare it to accept the bony fragment of the greater tubercle. Secure the greater tubercle fragment (with the attached portion of the supraspinatous tendon) in place with two Kirschner wires (Fig. 103-3*C*). A tension band wire may be used.

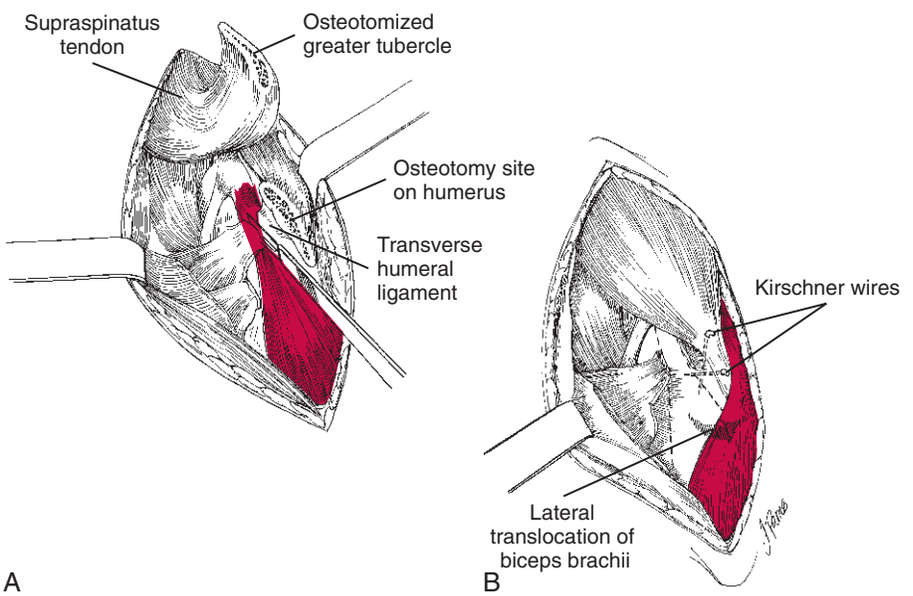

Figure 103-4. *A,* Transection of the transverse humeral ligament. *B,* Lateral translocation of the bicipital tendon. Use Kirschner wires to stabilize the greater trochanter back to its origin.

7. Suture the deep pectoral muscle over the lesser tubercle. Advance the superficial pectoral muscle over the proximal cranial border of the humerus and suture it to the deltoideus muscle. Suture the brachiocephalicus muscle to the brachial fascia.
8. Close the subcutaneous tissue and skin routinely.

Monitor for signs of seroma formation, hemorrhage, and infection.

Repair of Lateral Luxation

Technique

1. Positioning and draping is similar to that for surgical repair of medial luxation.
2. Skin incision and tissue retraction are the same as for medial luxation repair.
3. Incise the superficial and deep pectoral muscles. Incise the deltoideus muscle near the point of insertion on the cranial lateral aspect of the proximal humerus.
4. Transect the transverse humeral ligament and free the bicipital tendon from the surrounding tissue (Fig. 103-4*A*).
5. Completely osteotomize the greater tubercle to allow reflection of the intact tendon.
6. Translocate the bicipital tendon laterally on the opposite side of the osteotomized greater tubercle (Fig. 103-4*B*). Secure the greater tubercle with several Kirschner wires.
7. Reattach the muscles and close the skin and subcutaneous tissue routinely.

POSTOPERATIVE CARE

- Following open repair of a scapulohumeral luxation treat postoperative pain, minimize post-surgical inflammation, and encourage movement of the distal extremity. Use ice packs, gentle massage, and passive range of motion of the elbow and carpus to minimize these problems.
- If the limb is not bandaged, supervised weight bearing can occur. During the first 3 weeks after surgery strict crate confinement and careful leash walks must occur. Following skin staple removal, begin water therapy in an underwater treadmill with the water level at the top of the scapula. This type of rehabilitation allows early weight bearing, and the buoyancy of the water reduces the weight-bearing forces on the operated leg.
- As the surgical wound and repair heals, more directed and vigorous rehabilitation can occur.
- The goal is to match the rate of tissue repair and healing with the postoperative rehabilitation.

PROGNOSIS

The prognosis is good with adequate stabilization.

Chapter

104 Fractures of the Humerus

Robert B. Parker

ANATOMY

- The proximal portion of the humerus has strong, thick cortices cranially and extends to the large deltoid tuberosity. The musculospiral groove starts caudally and twists cranially over the lateral aspect of the bone. The brachialis muscle and neurovascular structures, including the clinically significant radial nerve, lie within the musculospiral groove.
- The lateral portion of the distal humeral condyle is termed the *capitulum* and the medial portion is termed the *trochlea*.
- When viewed cranially, the bone is essentially straight; however, the medullary canal runs slightly lateral to medial from proximal to distal. Distally, the trochlea is larger than the capitulum, and is in a more direct line with the medullary canal. The capitulum has a thinner epicondylar attachment to the bone and is the main weight-bearing surface for the radial head.
- Important muscles to identify laterally are the lateral head of the triceps, the brachialis, the brachiocephalicus, and the acromial head of the deltoid. The radial nerve is important to identify laterally.
- Important medial soft tissue structures include the medial head of the triceps, the biceps brachii, and the median and ulnar nerves.

ETIOLOGY

- Most humeral fractures occur secondary to motor vehicle trauma or are caused by a fall from excessive height.

DIAGNOSIS

- Rule out injuries associated with thoracic trauma. Perform a complete clinical and radiographic examination to rule out pneumothorax, hemothorax, diaphragmatic hernia, rib fractures, chylothorax, and traumatic myocarditis.

▼ ***Key Point*** Obtain thoracic radiographs in all animals with humeral fractures.

- The neurovascular integrity of the limb is of paramount importance. Fully assess the injured forelimb.
- Obtain radiographs of the involved humerus to characterize the fracture(s). If necessary (e.g., for prebending bone plates), obtain radiographs of the normal humerus.

PROXIMAL HUMERAL PHYSEAL FRACTURES

Preoperative Considerations

- This type of fracture is seen infrequently in young dogs prior to physeal closure. Closure of the proximal physis occurs between 9 and 15 months of age.
- The fracture typically is complete, but incomplete and impaction fractures can also occur.
- Except for incomplete fractures, closed reduction is very difficult. Open reduction of complete fractures is recommended.
- In selected cases (e.g., non-displaced fractures) use a Velpeau sling or spica cast to immobilize the shoulder joint.

Surgical Procedure

Objectives

- Provide stable fixation while allowing continued physeal growth.
- Provide early range of motion.

Equipment

- General surgical instrument pack
- Jacob's pin chuck and a complete assortment of Steinmann pins and Kirschner wires
- Bone-holding forceps
- Small and large reduction forceps with points
- Cerclage wire equipment
- Periosteal elevator
- Kirschner apparatus (external pin fixators)
- Additional (AO) equipment (Synthes, Wayne, PA) for plate and screw fixation (for selected fractures)

Technique

Open Reduction

1. After preparing the limb for aseptic surgery, use a cranial approach with cranial retraction of the brachiocephalicus muscle to elevate and expose the fragments.
2. Use small pointed forceps to carefully grasp the epiphysis and use the elevator to lever the fragments into reduction.
3. Achieve fixation with double Kirschner wires or Steinmann pins, beginning at the greater tubercle. To prevent compression of the physis, do not use a figure-eight tension band.
4. Cancellous lag screws have been used by some surgeons, but they can cause interfragmentary compression and premature physeal closure.
5. Close the incision routinely.

Postoperative Care

- Encourage early range-of-motion exercise by allowing restricted activity.
- Remove fixation devices when healing is complete.

▼ ***Key Point*** Premature closure of the physis may occur as a result of the initial or surgical trauma; however, this rarely causes a clinical problem.

PROXIMAL DIAPHYSEAL FRACTURES

Preoperative Considerations

- Proximal fractures are the least common diaphyseal fractures owing to the comparative strength of the humerus in this area.
- Most proximal diaphyseal fractures occur just proximal to the deltoid tuberosity. The distal fragment is displaced cranially due to the pull of the deltoid muscle, and medially due to the pull of the pectoral muscle.
- Evaluate the brachial plexus and the radial nerve. Accurate reduction is important because excessive callus production can produce postoperative pressure on these neural structures.
- Many of these fractures occur secondary to metabolic bone disease. Carefully evaluate radiographs of the fracture for evidence of bone disease. Perform appropriate tests if metabolic or neoplastic disease is suspected.

Surgical Procedure

Objective

- Because closed reduction with external coaptation probably is not an option, perform open reduction with internal fixation.

Equipment

- Same as for proximal physeal fractures

Technique

Open Reduction

1. For open reduction, use a cranial approach. Incise the skin along the craniolateral aspect of the humerus, beginning at the scapular tuberosity. Incise the fascial attachment of the brachiocephalicus muscle on the cranial aspect of the humerus to allow cranial retraction of the muscle. Elevate the deltoid muscle from the deltoid tuberosity and retract it caudally to gain access to the fracture site.
2. Place single or double Steinmann pins retrograde from the fracture site into the proximal fragment (Fig. 104-1), or place the pins normograde starting at the greater tubercle of the humerus.
3. Because the fractures often are transverse, a single intramedullary pin may not provide rotational stability. Use a type I external fixator (see Chapter 111) or hemicerclage wires to provide rotational stability in a transverse or short oblique fracture.
4. Alternatively, two Rush pins provide excellent rotational stability in fractures of this type.
5. In very large dogs, a bone plate applied to the cranial surface of the humerus is an excellent method of fixation. The basic principle of three screws (six cortices) above and three screws below the fracture site applies.
6. Close the incision routinely.

Postoperative Care

- External fixation is not desirable following internal fixation.

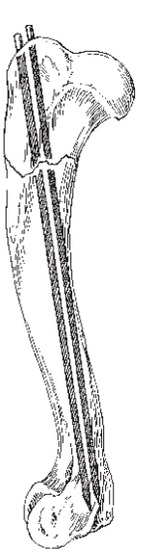

Figure 104-1. Steinmann pin placement for repair of a proximal diaphyseal fracture.

- Encourage early range of motion by allowing restricted exercise.

DIAPHYSEAL FRACTURES

Preoperative Considerations

- Muscle contracture causes overriding of the fragments.
- The fractures often are spiral or oblique and may entrap the radial nerve.
- Consider early closed reduction and closed normograde pinning. Attempt this only within the first few days following the injury.

Surgical Procedure

Objective

- Provide stable fixation without jeopardizing important neurovascular structures.

Equipment

- Same as for proximal physeal fractures

Technique

1. For open reduction, make a lateral approach to expose midshaft to distal fractures. Incise the fascia cranial to the lateral head of the triceps muscle to allow cranial retraction of the brachiocephalicus and superficial pectoral muscles, and caudal retraction of the triceps. At the distal one-third of the incision, use extreme care to identify the radial nerve as it crosses from caudal to cranial between the brachialis and lateral head of the triceps. Use the brachialis muscle as a cushion to protect the radial nerve. Retract the brachialis either proximally or distally to expose the fracture site. Reduction may be facilitated by careful myotomy of the brachialis.
2. Many humeral fractures in small to medium-sized dogs can be successfully repaired with a combination of pins, stacked pins, full or hemicerclage wires, or external skeletal fixation. This is especially true with oblique or spiral fractures.
   a. When using pin fixation, retrograde the pins into the proximal fragment from the fracture site. When the fracture is reduced, the pin should enter the trochlea when driven into the distal fragment. Correct pin placement is slightly lateral to medial to engage the trochlea (Fig. 104-2, *left*).

▼ ***Key Point*** Try to direct the pin slightly laterally when retrograding it into the proximal humeral fragment.

   b. Rotational stability may not be achieved without additional pins, orthopedic wire, or external skeletal fixation.

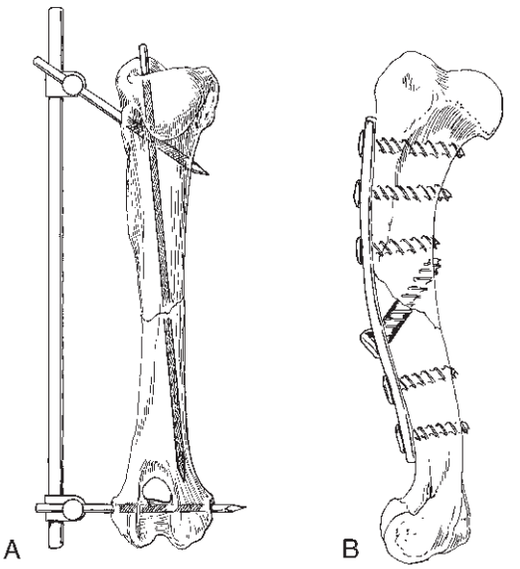

Figure 104-2. Fixation of diaphyseal fracture. *A,* External skeletal fixation. *B,* Internal cranial plate placement.

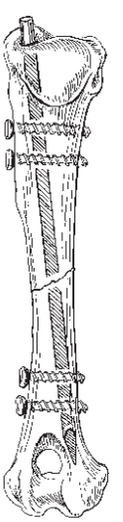

Figure 104-3. Caudo-cranial view of humerus with an interlocking nail and four locking screws.

3. Interlocking nails (Innovative Animal Products, Rochester, MN) have been successful in stabilizing diaphyseal fractures in larger breeds. By statically locking the nail both proximally and distally, rotational forces can be effectively neutralized (Fig. 104-3).
4. Because the humerus is difficult to expose and is an anatomically complex bone, the exposure for plate fixation can be difficult. However, cranial, lateral, or medial plate fixation can produce excellent results.
   a. Cranial plate placement is preferred for midshaft fractures. After exposure and reduction, contour an appropriately sized plate to fit the cranial

aspect of the bone (see Fig. 104-2, *right*). Protect the radial nerve distally. Freeing the origin of the extensor carpi radialis muscle may enhance distal exposure; however, the supratrochlear foramen may limit the distal extent of the plate.

b. Lateral plate placement is difficult because of the contours of the musculospiral groove and lateral epicondylar ridge.

c. Medial plate placement affords a fairly flat bony surface, and the plate can be contoured onto the trochlea. Medial placement is especially useful for distal diaphyseal fractures. The medial approach involves a medial skin incision and careful division between neurovascular structures. Retract the biceps brachii muscle, the median and musculocutaneous nerves, and brachial artery and vein cranially, and retract the medial head of the triceps and ulnar nerve caudally. The pectoral muscles limit exposure proximally.

5. Close the incision routinely.

Postoperative Care

- Restrict activity, but encourage early range of motion.
- If external skeletal fixation is used to supplement rotational or axial stability, remove it in 4 to 6 weeks.
- Remove intramedullary pins following fracture healing; supplemental cerclage or Kirschner wires are usually left in place.
- Do not remove bone plates unless they are causing a problem.

SUPRACONDYLAR FRACTURES

Preoperative Considerations

- The supratrochlear foramen creates a weak point in the distal humeral metaphysis.
- The trochlea is in a straight line with the diaphysis of the humerus. Additionally, the majority of the forces are transmitted through the capitulum, which articulates with the radial head. The capitular junction with the shaft in the area of the supratrochlear foramen is smaller and weaker than the medial side.
- Rigid internal fixation generally is indicated. Excessive callus formation from inadequate immobilization can result in impairment of normal elbow function.

Surgical Procedure

Objective

- Provide stable internal fixation to allow early weight bearing and range of motion.

Equipment

- Same as for proximal physeal fractures

Technique

1. The surgical approach is similar to the previously described lateral and medial approaches.
   a. The caudal approach to the elbow joint by olecranon osteotomy also provides excellent exposure to the supracondylar area. This approach is particularly useful for comminuted fractures in this area in large-breed dogs, when plating is anticipated.
2. Steinmann pin(s) placed well into the trochlea, with an additional cross-pin from the capitulum to produce rotational stability, may provide adequate stability. A type I external fixator, using a transcondylar distal fixation pin, can provide additional fixation and rotational stability.
   a. To seat the Steinmann pin adequately in the trochlea, initially retrograde the pin distally into the trochlea from the fracture site. The pin exits the condyle medial to the ulna and can be withdrawn until the tip is flush with the fracture site. After reduction, advance the pin proximally to exit the humerus at the greater tubercle. Withdraw the pin proximally until the distal tip is flush with the trochlea.
3. Alternatively, double Rush pins can provide excellent stability.
4. Because of the propensity for nonunion in medium- and large-sized dogs and in dogs with severely comminuted fractures, small bone plates can be applied to the caudal medial or lateral ridges of the epicondyles. This is usually done through a caudal approach (osteotomy of the olecranon). See Chapter 105 for repair of olecranon fractures.
5. Close the incision routinely.

Postoperative Care

▼ ***Key Point*** Physical therapy (e.g., active or passive elbow flexion and extension) is critical to prevent postoperative limitation of elbow function.

- See the previous discussion of postoperative care under Diaphyseal Fractures.

CONDYLAR FRACTURES

Preoperative Considerations

- About 90% of condylar fractures involve the lateral portion of the condyle.
  - The lateral portion of the condyle (capitulum humeri) carries most of the force through the elbow joint by way of its articulation with the radial head. The capitulum sits lateral to the humeral diaphysis when compared with the medial portion (trochlea humeri). Also, the lateral epicondylar crest is smaller than the medial epicondylar crest.

- Anatomic reduction is necessary to prevent secondary degenerative joint disease.
- Spaniel-type and Rottweiler dogs have been shown to have a heritable defect producing incomplete ossification of the humeral condyle, predisposing them to this injury.

Surgical Procedure

Objectives

- Achieve anatomic reduction and interfragmentary compression because the joint surface is involved.
- Restore range of motion of the elbow joint.

Equipment

- Same as for proximal physeal fractures

Technique

1. Open reduction and internal fixation usually are necessary. However, closed reduction maintained with a condyle clamp and fixation with a percutaneously applied transarticular lag screw has been described.
2. For open reduction, use a lateral or craniolateral approach.
3. Align intercondylar and supracondylar fracture lines perfectly and hold with a Vulsellum or AO pointed reduction forceps.
4. Use a transcondylar lag screw with an antirotation Kirschner wire to achieve interfragmentary compression (Fig. 104-4, *left*).
   a. The starting point for the drill bit is slightly distal and cranial to the most prominent point of the lateral epicondyle. Aim the drill at the corresponding point on the medial side. After measuring and tapping, place an appropriate screw.
   b. When using a fully threaded screw, overdrill the lateral fragment to achieve interfragmentary compression ("lag" effect).

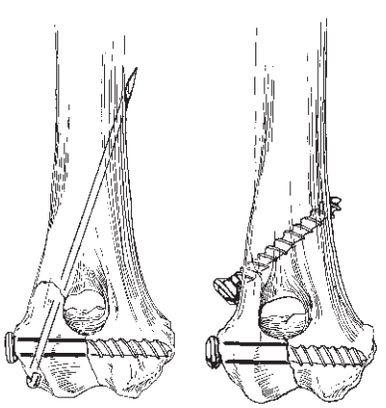

Figure 104-4. Fixation of condylar fractures. *Left,* Transcondylar lag screw and antirotation K-wire. *Right,* With oblique fractures, use two lag screws for increased stability.

   c. As an alternative method of achieving precise screw location with a fully threaded screw, use the overdrill bit to make the gliding hole in the capitulum. To do this, rotate the condyle laterally to expose the intercondylar fracture surface of the capitulum. Center the drill at the fracture surface and direct it laterally to exit the bone just distal and cranial to the lateral prominence. Then reduce the fracture and use a drill sleeve insert (in the drill hole in the capitulum) to direct the smaller drill (thread hole) into the trochlea. Place the screw routinely.
   d. Place an antirotational Kirschner wire across the condyles or across the distal diaphysis of the humerus (Fig. 104-4, *left*).
   e. If the supracondylar portion of the fracture is oblique enough, place additional screws along this aspect for additional stability (Fig. 104-4, *right*).
   f. Fixation of the condyle has also been achieved with self-compressing Orthofix pins.
   g. Using crossed Kirschner wires to achieve intercondylar stability is not recommended.
   h. Close the incision routinely.

Postoperative Care and Complications

- Encourage early range of motion but restrict activity.
- The lag screws usually are not removed.
- Reduced range of motion and arthritis of the elbow joint are the most common complications. Accurate alignment and apposition of fracture fragments reduces the incidence of these problems.

T OR Y (INTERCONDYLAR) FRACTURES OF THE HUMERAL CONDYLES

Preoperative Considerations

- In this type of fracture, both the lateral and medial portions of the condyle are fractured from the humeral metaphysis; in addition, an intra-articular fracture occurs, splitting the condyle.
- The basic principles of repair are the same as for supracondylar and single condylar fractures.
- These usually are very difficult to repair adequately. Consider referring these cases to an orthopedic specialist.

Surgical Procedure

Objective

- Achieve accurate anatomic reduction and stability in an unstable area.

Equipment

- Same as for proximal physeal fractures

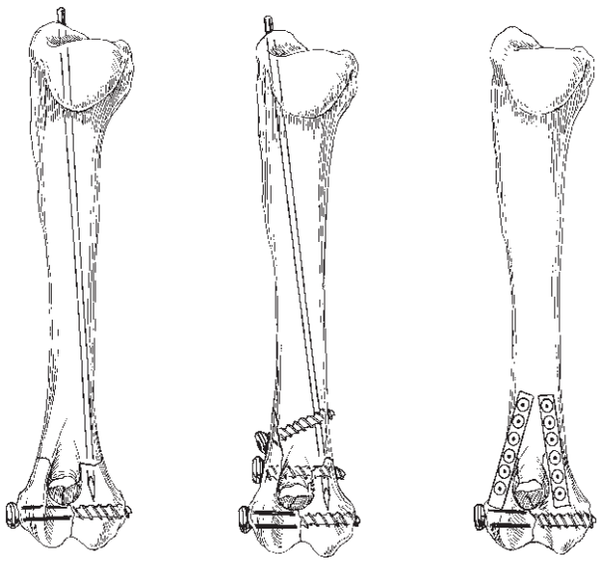

Figure 104-5. Fixation methods for intercondylar fractures. *Left,* Repair condyle with lag screw, then secure to humeral diaphysis with Steinmann pins. *Center,* Attach medial portion of the condyle to humerus with lag screw, then attach lateral portion of the condyle with lag screws and pin. *Right,* Caudal bone plates provide further stability.

Technique

1. Expose the fracture through a caudal approach via olecranon osteotomy (see Chapter 105 for olecronon repair).
2. Lag the condyles together initially to create a "two-piece fracture" (now similar to a supracondylar fracture), which is attached to the humeral diaphysis; or attach the trochlea to the humerus; follow with lag-screw fixation of the capitulum to the trochlea (Fig. 104-5, *left and center*).
   a. For more rigid stability, stabilize the supracondylar portion of the fracture with two small caudally placed bone plates (Fig. 104-5, *right*).
3. Close the incision routinely.

Postoperative Care and Complications

- Encourage early function or passive range-of-motion exercises.
- In one series, 46% of dogs regained moderate to normal limb function; 18% had severe lameness as a result of deformity and osteoarthritis.

Chapter

105 Fractures and Growth Deformities of the Radius and Ulna, Luxation of the Elbow

James Tomlinson

FRACTURES OF THE RADIUS AND ULNA

Fractures of the radius and ulna are commonly seen in small animal practice. Although most of these fractures occur as a result of automobile accidents, they also result from falling or jumping. Fractures of one or both bones and a wide variety of fracture types are seen. Open fractures of the distal one-half of the radius and ulna are common, owing to minimal soft tissue coverage. Complications include delayed union, nonunion, joint stiffness, and arthritis.

Anatomy

Radius

- The radius and ulna make up the antebrachium.
- The radius is the main weight-bearing bone of the antebrachium and is shorter than the ulna. The radius is composed of the head, neck, body, and distal extremity. The medullary canal is elliptical in shape owing to flattening of the radius.
- The radius is attached to the ulna by an interosseous ligament that helps to maintain their spatial relationship following fracture. The short radial collateral ligament runs from the styloid process of the radius to the radial carpal bone and provides medial support to the antebrachiocarpal joint.
- The cranial surface of the distal radius contains three grooves that contain (from medial to lateral) the tendons of abductor pollicis longus, extensor carpi radialis, and common digital extensor muscles.

Ulna

- The ulna is the longest bone in the body and is composed of the olecranon, trochlear notch, anconeus, body, and the distal extremity called the styloid process.
- The olecranon has a strong muscular attachment, the triceps muscle.
- The ulnar body tapers as it crosses caudal to the radius to articulate with the palmarolateral aspect of the carpus. The medullary canal of the ulna functionally ends about one-third from the distal end.
- The strong, short ulnar collateral ligament runs from the tip of the styloid process of the ulna to the ulnar carpal bone, giving lateral support to the antebrachiocarpal joint.

Vascular Supply

- The radial and interosseous arteries provide the main arterial supply to the antebrachium and are subject to injury from trauma or surgery.
- The radial artery travels along the palmaromedial aspect of the radius just under the flexor carpi radialis muscle.
- The interosseous artery branches into other interosseous arteries that run in the space between the radius and ulna.

Nerve Supply

- The radial, median, and ulnar nerves supply the antebrachium and manus.

General Preoperative Considerations

- Evaluate the thorax for pulmonary contusions, pneumothorax, and diaphragmatic hernia with thoracic radiography. Evaluate for traumatic myocarditis with electrocardiography.
- Examine the animal for concurrent injuries; inspect other limbs for fractures or other significant injury.
- Inspect the antebrachium for evidence of wounds indicating an open fracture.
- Evaluate nerve function of the affected limb by testing reaction to a painful stimulus to the skin of the various dermatomes and by withdrawal of the limb.
- Initially place the limb in a Robert Jones bandage or splint to prevent further soft tissue damage and

to prevent the fracture from becoming an open fracture.
- Obtain two radiographic views of the fractured limb to include the elbow and carpus.

General Objectives of Surgical Procedures

- Align and stabilize the fracture(s) to permit uncomplicated healing with normal joint and limb function.

▼ ***Key Point*** Exact anatomic alignment and rigid fixation (compression) of articular fractures is imperative.

- Allow early return to weight bearing.
- Preserve neurovascular structures during repair.

General Postoperative Care and Complications for Radial and Ulnar Fractures

- Place the limb in a soft padded bandage for 3 to 10 days to reduce postoperative swelling. Provide more rigid external support if needed.
- Reevaluate the fracture radiographically every 3 to 4 weeks until the fracture has healed.
- Restrict activity until the fracture has healed.

Complications

- Delayed and nonunion healing (see Chapter 122), osteomyelitis (see Chapter 121), and implant failure may occur.
- Joint fractures are prone to subsequent degenerative joint disease and callus that interferes with joint mobility if anatomic alignment and rigid stability have not been achieved.
- Joint stiffness can develop with articular fractures. Rigid stability of the fracture allows early, controlled use of the joint.

▼ ***Key Point*** Radius and ulna fractures in immature animals may cause premature closure of the growth plates and synostosis of the radius and ulna. Both conditions cause growth deformities of the limb. Early recognition and intervention is necessary to minimize growth deformities.

Olecranon Fractures

Objective

- Counteract the distractive force of the triceps and convert it into a compressive force using the tension band principle.

Equipment

- General surgery pack and standard suture material
- Monofilament stainless steel surgical wire (20 and 18 gauge)
- Intramedullary pins and Kirschner wires (K-wires)
- Jacobs chuck or power drill
- Wire-tightening device (vise grips or wire twister)
- Pin and wire cutter
- Bone reduction forceps

Technique

1. Place the patient in lateral recumbency, with the affected leg up, and prepare the limb for aseptic surgery.
2. Make a caudolateral skin incision centered over the olecranon.
3. Reflect the skin and subcutaneous tissue to expose the olecranon and proximal shaft of the ulna. Subperiosteally elevate the extensor and flexor carpi ulnaris muscles from the proximal shaft of the ulna.
4. Reduce the fracture and hold it in reduction with bone reduction forceps.
5. Drive two K-wires or small intramedullary pins parallel from the tip of the olecranon across the fracture line and into the distal segment of the ulna (in very small animals, drive only one K-wire).
6. Drill a hole (perpendicular to the ulnar long axis) in the distal ulnar segment 1.5 to 2 times the distance from the olecranon to the fracture line.
7. Insert surgical wire in the hole and place the wire around the pins in a figure-eight fashion.
8. Twist the wire to achieve equal tension on the wire.
9. Bend the pins over and cut them off short. Cut the wires leaving two to four twists and bend the wire tips over (Fig. 105-1).
10. Close the subcutaneous tissue and skin routinely.

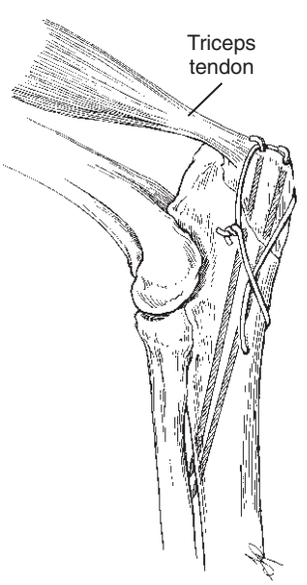

Figure 105-1. Pin and wire placement for olecranon fracture repair.

Trochlear Notch Fractures

Objectives

- Maintain precise anatomic alignment of the fracture (because it is an articular fracture).
- Perform rigid fixation of the fracture to minimize periosteal callus.
- Counteract the distractive forces of the triceps muscle using the tension band principle.

Equipment

- Same as for olecranon fractures with the addition of bone plating equipment.

Technique

Small and Medium-Sized Dogs; Cats; No Fracture Comminution Present

1. Repair the fracture with a tension band wiring technique, as described previously under Olecranon Fractures.
2. Maintain anatomic alignment of the fracture while driving the pins and tightening the wire in a figure-eight configuration.

Large Dogs; Fractures with Comminution

1. Expose the trochlear notch, as described for olecranon fractures.
2. Reattach butterfly segments of bone with lag screws and Kirschner wires.
3. Contour a bone plate to the caudal or caudolateral side of the ulna and secure it to the ulna with bone screws (Fig. 105-2).
4. If comminution is not present, apply the plate with a compression technique. If comminution is present, apply the plate in a neutralization manner (e.g., no compression).

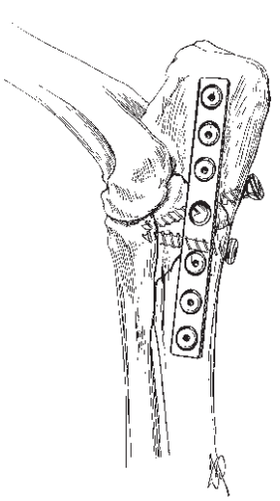

Figure 105-2. Bone plate and screw replacement for trochlear notch fracture repair.

Radial Head Fractures

Objective

- Perform precise anatomic reduction of the fracture with rigid fixation of the fragments.

Equipment

- General surgery pack and standard suture material
- Hohmann retractor
- Bone screws and bone screw insertion equipment
- Power drill and Jacobs pin chuck
- K-wires

Technique

1. Place the patient in lateral recumbency, with the affected limb up, and prepare the limb for aseptic surgery.
2. Incise the skin, beginning at the proximal end of the lateral epicondyle of the humerus and continuing distally over the radial head to the proximal one-fourth of the radius.
3. Incise the subcutaneous tissue and the antebrachial fascia along the same line to expose the extensor muscles of the antebrachium.
4. Dissect between the ulnaris lateralis muscle and the lateral digital extensor. Cut the ulnaris lateralis tendon, leaving sufficient tendon for suturing. If necessary, incise the anconeus muscle from the lateral epicondyle of the humerus.
5. Reflect the lateral digital extensor muscle cranially with a Hohmann retractor to expose the fracture.
6. Drive a K-wire across the fracture line to hold the fracture in reduction.
7. Insert a screw in "lag screw" fashion to compress the fracture line.
8. For small fragments, place two or three K-wires in a divergent pattern.
9. Reattach the ulnaris lateralis tendon with nonabsorbable monofilament suture material in a horizontal mattress pattern. Suture the muscle fascia and subcutaneous tissue in a simple continuous pattern, using absorbable suture material. Close the skin routinely.

Radial Neck and Proximal Physeal Fractures

Objectives

- Stabilize the fracture in immature animals without fracture compression to help prevent premature closure of the growth plate.
- Stabilize and align the radial head so that it articulates properly with the humeral condyle.

Equipment

- General surgery pack and standard suture material
- Jacobs pin chuck
- K-wires

Technique

1. Approach the fracture as described for radial head fractures, and reduce the fracture.
2. Stabilize the fracture with two K-wires placed in cross-pin fashion from the lateral side. Start one pin just below the articular surface of the radius and drive it distomedially. Start the second pin distal to the fracture and drive it proximomedially.
3. Bend the pins over and cut them off short.
4. Take care not to penetrate the articular surface of the radius.
5. Close the incision as described under Radial Head Fractures.

Postoperative Care

- Remove the K-wires in 3 to 4 weeks and monitor for premature closure of the growth plate.

Monteggia Fractures

This is a fracture of the ulna that can occur at various levels, combined with a radial head luxation.

Objectives

- Reduce and stabilize the radial head luxation.
- Align and stabilize the ulnar fracture.

Equipment

- General surgery pack and standard suture material
- Bone plating equipment
- Power drill
- Bone reduction forceps

Technique

1. Expose the ulnar fracture, as described under Olecranon Fractures and Trochlear Notch Fractures. Expose the ulna as far distally as needed.
2. Expose the radial head, as described under Radial Head Fractures, if the luxation cannot be reduced closed.
3. Reduce the ulnar fracture and hold it in reduction with bone reduction forceps.
4. If the annular ligament is ruptured, contour and apply a bone plate to the caudal aspect of the ulna. Insert a screw in "lag screw" fashion into the radius from the ulna through the plate to secure the radial head in position (Fig. 105-3).
5. If the annular ligament is intact, contour and apply a bone plate to the caudolateral aspect of the ulna.

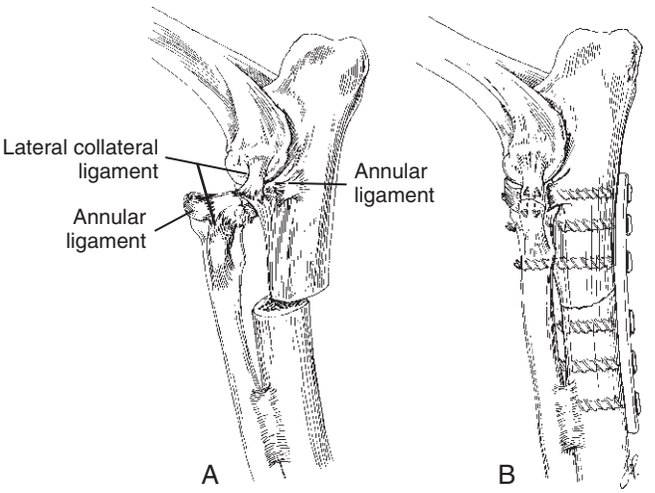

Figure 105-3. Monteggia fracture repair. *A,* Anatomy of fracture and ligament damage; *B,* plate placement and ligament repair. See text for details.

Mid-Shaft Radial and Ulnar Fractures

Objectives

- Achieve healing of the fracture with proper angulation, rotation, and length of the limb.
- Prevent synostosis of the radius and ulna in immature animals.

Equipment

- Fiberglass casting tape, stockinette, 1-inch–wide medical tape
- General surgery pack and standard suture material
- Bone reduction forceps
- Jacobs pin chuck and power drill
- Kirschner-Ehmer apparatus (external skeletal fixators)
- Bone plating equipment

Closed Reduction and Cast Fixation for Minimally Displaced Transverse Fractures

Technique

1. Place 1-inch–wide medical tape stirrups on the dorsal and plantar surface of the foot.
2. Apply a snug-fitting double layer of stockinette over the limb. Make the stockinette long enough to extend 1 inch past the tip of the toes and as far proximal above the elbow as possible.
3. Reduce the fracture and position the limb for correct angular and rotational alignment.
4. Place the carpus in a slight varus position, flexed 5 to 10 degrees.
5. Flex the elbow to a functional angle (approximately 140 degrees).
6. After wetting, apply the fiberglass casting tape, starting at the tip of the second and fifth nails.
7. Overlap the casting tape 50% with each wrap, working from distal to as far proximal as possible above the elbow.
8. Apply four or five layers of fiberglass casting tape.

9. Reflect the stockinette and stirrups over the end of the cast and incorporate them into the final layer of cast material.
10. Hold the limb in the proper position until the cast has set.

External Skeletal Fixation for Comminuted Fractures and Simple Fractures

Technique

1. Reduce comminuted fractures closed.
2. Use a limited open approach if the fracture cannot be reduced closed.
3. Make small stab incisions in the skin before driving the transfixation pins.
4. Drive the most distal transfixation pin across the radius perpendicular to the long axis of the radius from medial to lateral and parallel to the radial carpal joint (Fig. 105-4, pin a). Drive the transfixation pins through the skin on both sides of the limb.
5. Drive the most proximal transfixation pin (Fig. 105-4, pin b) in a similar manner, parallel to the articular surface of the radial head.
6. Apply connecting bars (Fig. 105-4, pin c) to the transfixation pins on both the lateral and medial sides.
7. Place the appropriate number of single connecting clamps on the connecting bar.

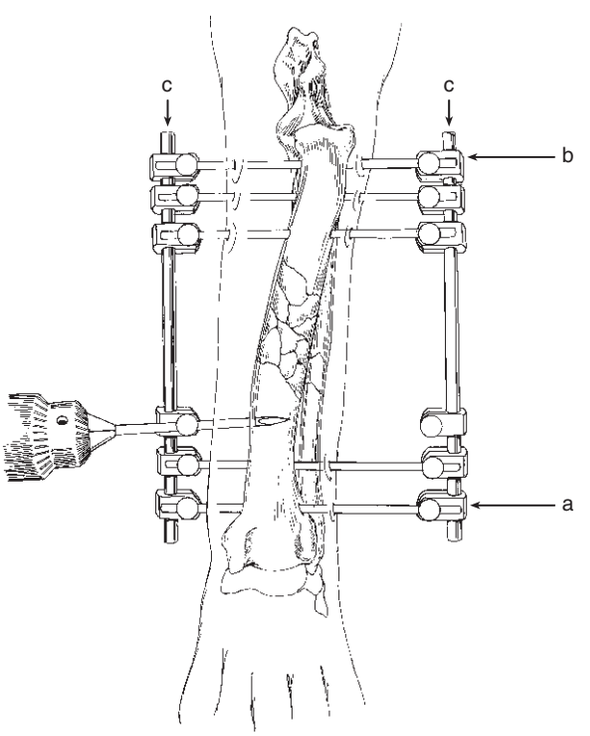

Figure 105-4. External skeletal fixation for radius and ulna fractures. See text for explanation.

8. Align the fracture and tighten the end connecting clamps to maintain reduction of the fracture.
9. Drive the remaining transfixation pins through the connecting clamps and tighten them (see Chapter 111).
10. If possible, place three or four transfixation pins on each side of the fracture line.
11. Cover the external skeletal fixation device with gauze and tape to protect the fixator and furniture surfaces. Clean pin tracts daily (see Chapter 111).

Plate Fixation for Distal Metaphyseal Fractures

These fractures occur primarily in small dogs. There is a high incidence of nonunion if these fractures are not treated correctly.

Objectives

- Achieve anatomic alignment with compression of the fracture.
- Insert a cancellous bone graft.

Equipment

- General surgery pack and standard suture material
- Mini-bone plating equipment (1.5- and 2.0-mm screws and plates)
- Power drill
- Curette (Brun 3-0)
- Small bone reduction forceps

Technique

1. Place the patient in lateral recumbency, with the affected leg up, and prepare the limb for aseptic surgery.
2. Make a skin incision on the dorsal aspect of the leg, starting at the cephalic vein and extending distally to the mid-metacarpus. Make the incision lateral to the cephalic vein.
3. Incise the subcutaneous tissue and fascia along the same line.
4. Identify the extensor carpi radialis and the common digital extensor tendons and subperiosteally elevate them from their grooves in the radius.
5. Incise the abductor pollicis muscle for additional proximal exposure.
6. Reduce the fracture and hold it in reduction with bone reduction forceps.
7. Contour a bone plate to the cranial surface of the radius and apply the plate. In small dogs, use a 1.5- or 2.0-mm bone plate.
8. Make a 2-cm–long incision over the craniolateral aspect of the greater tubercle of the humerus.
9. Incise the subcutaneous tissue along the same line. Drill a small hole in the greater tubercle.
10. Use a #3-0 Brun curette to collect a cancellous bone graft from the greater tubercle. During the collec-

tion process, place the graft on a blood-soaked sponge.
11. Pack the bone graft around the fracture site.
12. Close the subcutaneous tissue and the skin incisions routinely.
13. After surgery, apply a soft padded bandage to the leg.

Fractured Styloid Process of Ulna

Objective

- Reduce and stabilize the fracture to reestablish lateral support to the carpus.

Equipment

- General surgery pack and standard suture material
- Surgical stainless steel wire (20 and 18 gauge)
- K-wires
- Jacobs pin chuck
- Wire tightening device (vise grips, wire twister)
- Pin and wire cutter
- Bone reduction forceps

Technique

1. Place the patient in lateral recumbency with the affected leg up and aseptically prepare the limb.
2. Make a skin incision over the lateral aspect of the styloid process. Incise the subcutaneous tissue along the same line.
3. Dissect between and elevate the tendons of the lateral digital extensor and the extensor carpi ulnaris.
4. Reduce the fracture and drive a K-wire from the distal tip of the ulna just above the ulnar collateral ligament into the proximal segment.
5. Drill a hole in the proximal segment of the ulna and pass a wire through the hole.
6. Place the wire around the tip of the pin in a figure-eight configuration, and tighten the wire on both arms of the figure-eight.
7. Close the deep fascia and subcutaneous tissue with absorbable suture in a simple continuous pattern. Close the skin routinely.
8. Splint the fracture for 3 to 4 weeks postoperatively.

GROWTH DEFORMITIES OF THE RADIUS AND ULNA

Growth deformities of the radius and ulna result from trauma and disruption of the blood supply to the physis; retained cartilaginous cores (see Chapters 117 and 119); and synostosis (bony bridging) of the radius and ulna. Specific treatment depends on the physis injured, the extent of deformity, and the age of the animal.

Anatomy

- The radius and ulna form the largest paired bones of the body. Abnormal growth of one bone may affect the other bone, elbow, or carpus.
- In dogs, the growth plates (physes) of the radius and ulna close at about 7 to 9 months of age (see Chapter 119 for more information about physeal structure).
- The distal ulnar physis is conical in shape, making it vulnerable to crushing during trauma. The two radial physes are relatively flat.
- The distal ulnar physis contributes 85% to the longitudinal growth of the ulna; the proximal physis (olecranon) contributes 15%.
- The proximal and distal radial physes contribute 40% and 60%, respectively, to the longitudinal growth of the radius.
- The radius and ulna must grow in a synchronous manner to retain a normal shape and joint congruity. As the radius and ulna grow, they normally slide past each other.

Preoperative Considerations

- Early recognition and treatment of physeal injury of the radius and ulna is the key to prevention or minimization of deformities.
- Base treatment of a growth deformity on whether the dog is mature or immature (whether physes are still growing) and on the specific deformity.

▼ ***Key Point*** The general principles of treatment of growth deformities are prevention or correction of angular deformities and joint abnormalities and maintenance of acceptable leg length.

- Obtain lateral and craniocaudal radiographs of the affected and normal forelimbs. Include both the elbow and carpus.
- Preplan corrective procedures on paper or cleared radiographic film by making tracings and cutouts copied from the radiographs.

General Postoperative Care and Complications for Growth Deformities

- In immature dogs, splint the limb when ostectomy has been performed. The other intact bone will hypertrophy to withstand the added stress.
- Reevaluate the leg radiographically at least every 3 weeks until the dog has stopped growing.
- If bone bridges the ostectomized gap before growth has ceased, repeat the original surgery.
- If the procedure for immature dogs does not correct the deformity, perform the procedure recommended for mature dogs after bone growth stops.

General Prognosis

- The prognosis is guarded, especially for mature dogs with severe deformities.

Surgical Procedure to Correct Premature Closure of the Distal Ulnar Physis

Immature Dogs

Objectives

- Remove a section of the ulna to allow unrestrained growth of the radius.
- Prevent regrowth of the ulna by placement of a free fat graft.

Equipment

- General surgery pack and standard suture material
- Gigli wire saw or oscillating bone saw
- Gelpi retractor

Technique

1. Place the patient in lateral recumbency, with the affected leg up, and prepare the limb for aseptic surgery.
2. Make a 6-cm incision over the lateral aspect of the distal third of the ulna. Incise the subcutaneous tissue and antebrachial fascia along the same line.
3. Dissect between the extensor carpi ulnaris and the lateral digital extensor muscles to expose the ulna. Elevate the muscles and tendons from the ulna on top of the periosteum all the way around the bone.
4. Using the Gigli wire saw or the oscillating saw, osteotomize at least 2 cm of the ulna at the junction of the distal one-third and middle one-third of the bone.
5. Remove all the periosteum to prevent rapid bone regrowth.
6. Make a 3-cm incision over the flank just in front of the wing of the ilium.
7. Dissect down to the subcutaneous fat and collect a piece of fat large enough to completely fill the defect in the ulna.
8. Place the fat graft in the ulnar defect and close the antebrachial fascia in a simple continuous fashion with absorbable suture material.
9. Close the subcutaneous tissue and skin routinely.
10. Place the limb in a splint for the first month following surgery.

Mature Dogs

Deformities

- Cranial and/or medial bowing with lateral torsion of the radius
- Carpal valgus with external rotation
- Limb shortening
- Malalignment of radius and/or ulna in the elbow joint

Objectives

- Correct angular and rotational deformity.
- Correct joint incongruity.
- Maintain as much leg length as possible.

Equipment

- General surgery pack and standard suture material
- Gigli wire saw or oscillating bone saw
- Kirschner-Ehmer fixation device (alternatively: circular external skeletal fixator)
- Jacobs pin chuck or power drill

Technique

1. Place the patient in lateral recumbency, with the affected leg up, and prepare the limb for aseptic surgery.
2. Drive a transfixation pin across the most distal aspect of the radius, aligned parallel with the craniocaudal plane and mediolateral plane of the articular surface of the radius (Fig. 105-5).
3. Drive a second transfixation pin in the same manner as the first pin, except as far proximal as

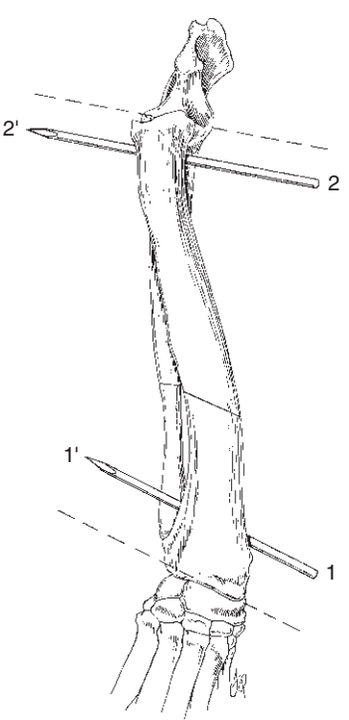

Figure 105-5. Pin placement for repair of premature closure of the distal ulnar physis. Place the first pin (1–1') parallel to the cranial-caudal and medial-lateral plane of the articular surface of the radius. The second pin (2–2') is parallel to the articular surface of the proximal radius.

possible and parallel to the articular surface of the proximal radius.
4. Approach the radius as described previously under Plate Fixation for Distal Metaphyseal Fractures.
5. Perform an osteotomy of the radius at the point of maximal curvature of the radius.
6. Fracture the ulna at the same level, either manually or with a saw.
7. Connect the transfixation pins on the lateral and medial sides with single connecting clamps and connecting bars. Place the appropriate number of single connecting clamps on the connecting bars.
8. Manually align the proximal and distal transfixation pins so that they are parallel to each other in both planes. Tighten the connecting clamps to hold the proper alignment (Fig. 105-6).
9. If there is any concern over the alignment, obtain radiographs of the leg at this point.
10. Drive the remaining transfixation pins through the open single connecting clamps.
11. Close the incisions routinely.
12. Cover the K-device with gauze and tape.
13. If elbow incongruity is not severe, it will resolve with weight bearing after the ulna is cut.

Surgical Procedure to Correct Premature Closure of the Proximal Radial Physis

Generally this deformity is recognized after the bone growth of the radius is finished. If it occurs in an immature dog, use the technique described for complete premature closure of the distal radial physis in immature dogs.

Deformities

- There is distal luxation of the radial head from the humerus.
- Leg is straight.

Objective (Mature Dogs)

- Reposition the radial head into the elbow joint so that it articulates properly with the humerus and ulna.

Equipment

- General surgery pack and standard suture material
- Bone plating equipment
- Power drill
- Oscillating saw

Technique

1. Place the animal in lateral recumbency, with the affected leg up, and prepare the limb for aseptic surgery.
2. Approach the radial head as described previously under Radial Head Fractures.
3. Approach the mid-shaft of the radius as described previously for mid-shaft radial fractures.
4. Perform a stepped radial osteotomy. Make the longitudinal arm of the osteotomy long enough to accept two bone screws (Fig. 105-7).

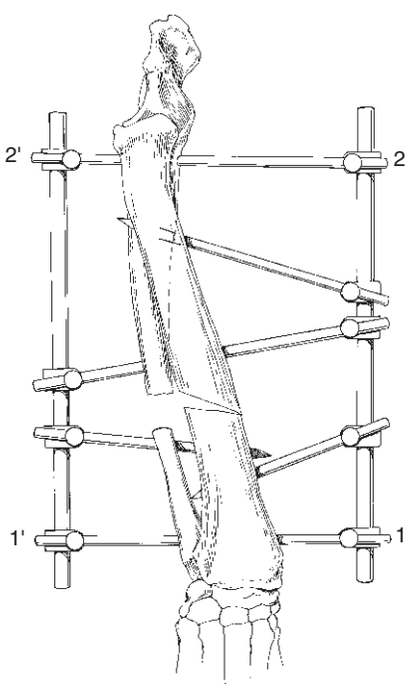

Figure 105-6. Final pin placement (see Fig. 105-5), osteotomy, and ulnar fracture for repair of premature closure of the distal ulnar physis.

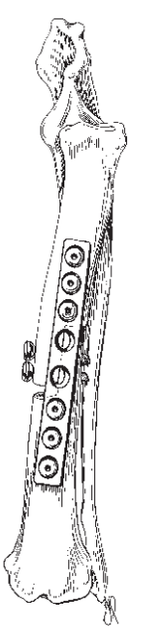

Figure 105-7. Plate and screw placement for stepped radial osteotomy performed for repair of premature closure of the proximal radial physis.

5. Slide the radial head proximally so that it articulates correctly with the humeral condyle and the ulna.
6. Place two screws, from medial to lateral, in "lag screw" fashion across the osteotomy site.
7. Apply a bone plate on the cranial aspect of the radius to further stabilize the osteotomy.
8. Collect a cancellous bone graft from the proximal humerus.
9. Place the bone graft in the defect in the radius.
10. Close the incisions routinely.
11. Place the leg in a soft padded bandage for 10 to 14 days postoperatively.

Surgical Procedure to Correct Premature Closure of the Distal Radial Physis

Premature closure of the distal radial physis can be complete or partial. If partial closure occurs, the lateral aspect of the physis usually is affected.

Complete Closure (Immature Dog)

Deformities

- Distal luxation of the radial head and elbow joint incongruity occur.
- The limb is shortened.
- Usually the leg remains straight.
- Bowing of the radius and ulna occurs rarely.

Objectives

- Remove a section of the radius to allow unrestricted growth of the ulna.
- Prevent regrowth of the radius until the other growth plates have stopped growing.

Equipment

- General surgery pack and standard suture material
- Gigli wire saw or oscillating saw

Technique

1. Place the animal in lateral recumbency, with the affected leg down, and prepare the limb for aseptic surgery.
2. Approach the mid-shaft radius as described previously for mid-shaft radial fractures.
3. Ostectomize a 2-cm section of radius, including the periosteum. Protect the interosseous artery.
4. Collect a free fat graft from the flank, as described previously for premature closure of the distal ulnar physis in immature dogs.
5. Place the fat graft in the radial defect and close the antebrachial fascia with absorbable suture material in a continuous pattern.
6. Close the incision routinely from the toes to the distal humerus.
7. Place the leg in a splint postoperatively.
8. When the dog has stopped growing, reconstruct the defect in the radius with a cancellous bone graft.

Partial Lateral Closure (Immature Dog)

Deformities

- Carpal valgus with external rotation
- Cranial and medial bowing of the forelimb
- Shortening of the limb
- Elbow joint incongruity

Objectives

- Remove the closed portion of the distal radial physis.
- Prevent bony bridging of the removed physis with a fat graft.

Equipment

- General surgery pack and standard suture material
- Curets

Technique

1. Place the patient in lateral recumbency, with the affected leg up, and prepare the limb for aseptic surgery.
2. Approach the distal radius as described previously for distal radial fractures.
3. Carefully expose the physis to minimize damage.
4. Probe the physis with a 25-gauge needle to determine the extent of the closure.
5. Use a curet to remove the closed section of the physis.
6. Place a free fat graft collected from the flank in the defect.
7. Close the incision routinely.
8. Splint the leg until bone growth is complete.
9. When bone growth is complete, remove the fat graft, if necessary, and graft the defect with cancellous bone.

Mature Dogs

Deformities

The deformities are the same as described for complete and incomplete closure in immature dogs.

Objectives

- Reestablish congruity to the elbow joint.
- Correct angular deformity of the limb.

Equipment

- Equipment is same as listed for premature closure of the proximal radius and distal ulna in mature dogs.

Technique

- If the radial head is luxated distally and the limb is straight, use the technique described previously for

correction of premature closure of the proximal radius in mature dogs.
- If angular and rotation deformity is present, use the techniques described previously for correction of premature closure of the distal ulna in mature dogs.

TRAUMATIC LUXATION OF THE ELBOW

- Lateral luxation of the elbow is common because the medial condyle of the humerus is larger and is slightly beveled downward, preventing medial luxation of the radius and ulna.

Clinical Signs

- The animals present with acute non–weight-bearing lameness.
- The foot and antebrachium are usually abducted, and flexion and extension of the elbow are not possible.

Diagnosis

- Obtain radiographs of the elbow (lateral and anteroposterior) to demonstrate the luxation.

Preoperative Considerations

- Most elbow luxations can be treated by closed reduction if the procedure is performed within the first 3 days after injury.
- If closed reduction is not possible, or if elbow fractures are present, open reduction is indicated. Open reduction of an elbow luxation can be a difficult procedure and is best handled by a surgical specialist.

Procedure for Closed Reduction

Objectives

- Reduce the luxation to reestablish normal function.
- Prevent recurrence of luxation with external coaptation.

Equipment

- Bandage material for constructing a spica, or lateral splint

Technique (Fig. 105-8)

1. Place the animal in lateral recumbency with the luxated leg up.
2. Place the elbow joint in full flexion.
3. With one hand on the radius and ulna, and the other hand on the distal humerus, pull the radius and ulna distally along the lateral aspect of the humerus.
4. While continuing distal traction on the radius and ulna, rotate the radius and ulna inward to place the anconeal process over the lateral humeral epicondyloid crest.

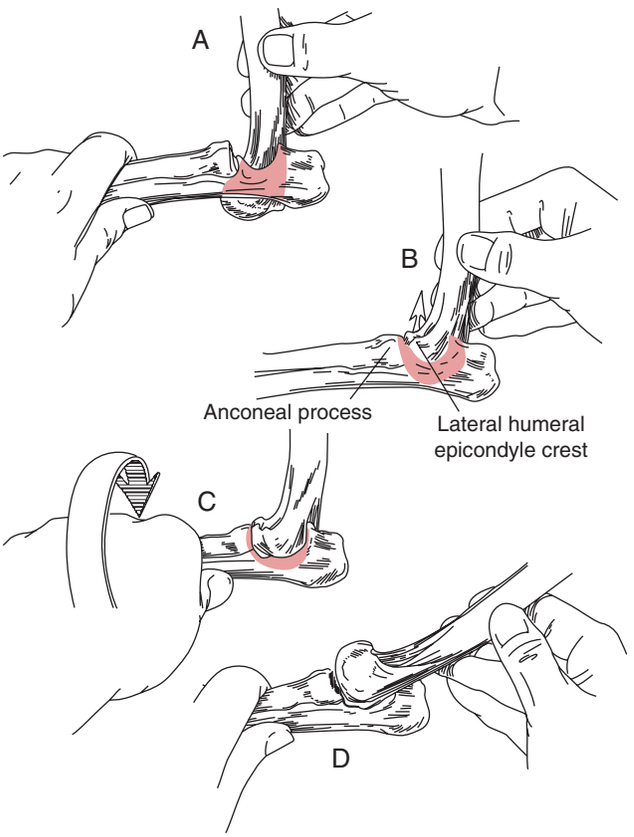

Figure 105-8. Reduction of the elbow. *A*, Hold the limb in traction. *B*, Pull radius and ulna distally. *C*, Internally rotate the ulna and radius. *D*, Extend the elbow.

5. Use the thumb of one hand to maintain lateral to medial pressure on the olecranon while slowly extending the elbow with the other hand.
6. Keep the elbow extended to maintain reduction.
7. Evaluate the joint for instability of the collateral ligaments.

Postoperative Care

- Obtain lateral and craniocaudal radiographs of the elbow to confirm reduction and evaluate for other injuries.
- Place the affected leg in a spica or lateral splint to keep the elbow in extension.
- Maintain the splint for 2 weeks, then allow leash walking only for another 2 weeks.
- Reevaluate at 2, 4, and 6 weeks postoperatively.
- If open reduction or ligament repair of the elbow is necessary, refer the patient to a surgical specialist.

Chapter

106 Fractures and Dislocations of the Carpus

Michael P. Kowaleski

Injuries to the carpus occur most commonly as a result of trauma, and consist primarily of ligamentous injury resulting in hyperextension, subluxation, luxation, or fracture. Isolated fractures of the carpus are rare, and occur most commonly in racing greyhounds and working dogs.

▼ ***Key Point*** Fractures of the carpus typically involve the articular surface, and therefore, anatomic reduction, rigid internal fixation, inter-fragmentary compression, and early return to function are essential for a successful outcome.

ANATOMY

The carpal joint is a complex three-level hinge joint. The seven bones of the carpus are arranged in a proximal and distal row, and articulate with the radius and ulna proximally and the metacarpal bones distally creating the antebrachiocarpal joint proximally, the middle carpal joint centrally, and the carpometacarpal joint distally.

Osseous Structures (Fig. 106-1)

- The seven bones of the carpus are arranged in two rows; a small sesamoid bone in the tendon of insertion of the abductor pollicis longus is regionally associated with the carpal joint.
- The proximal row consists of the radial, ulnar, and accessory carpal bones.
- The radial carpal bone is the largest of the carpal bones. It is located medially, and articulates with the radius proximally, and with the first, second, third, and fourth carpal bones distally.
- The ulnar carpal bone is the lateral bone of the proximal row. It articulates with the radius and ulna proximally, with the accessory carpal bone on its palmar aspect, and with the fourth carpal bone and fifth metacarpal bone distally.
- The accessory carpal bone is located on the palmar aspect of the lateral side of the proximal row. It articulates with the styloid process of the ulna proximally, and with the ulnar carpal bone.
- The distal row consists of the numbered carpal bones, the first (C1), second (C2), third (C3), and fourth (C4) carpal bones.
- C4 is the largest bone of the distal row, and articulates with the fourth and fifth metacarpal bones; the size of carpal bones C3 to C1 progressively decreases with the number of the bone.

Articulations

- The antebrachiocarpal joint is located between the distal radius and ulna, and the proximal row of carpal bones. It normally provides 70% of carpal range of motion.
- The middle carpal joint, between the proximal and distal rows of carpal bones, allows a small amount of flexion and extension, about 25% of carpal range of motion.
- The carpometacarpal joint, located between the distal row of carpal bones and the metacarpal bones, provides about 5% of carpal range of motion.
- The joints formed between the individual carpal bones are termed *intercarpal* joints; these articulations provide very limited movement.

Ligamentous Structures

- No continuous collateral ligament spans all three joints of the carpus.
- Support to the carpus is provided by two superimposed sleeves of collagenous tissue, with tendons in between.
- The superficial sleeve is a thickening of the deep carpal fascia.
- The deep sleeve is the thickened fibrous layer of the joint capsule.
- The two sleeves fuse laterally and medially to form short collateral ligaments.
- The short radial collateral ligament has two parts, both of which originate from the styloid process of the radius; the straight part inserts on the medial part of the radial carpal bone and the oblique part inserts on the palmeromedial surface of the radial carpal bone.
- The short ulnar collateral ligament extends from the styloid process of the ulna to the ulnar carpal bone.

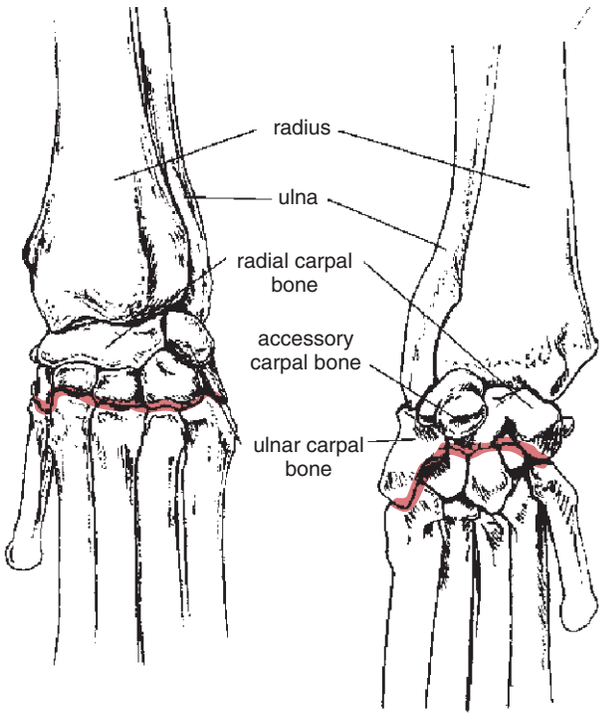

Figure 106-1. Osseous anatomy of the carpus. Left: red line denotes carpometacarpal joint. Right: red line denotes middle carpal joint.

- The flexor retinaculum (transverse carpal ligament) provides support to the palmaro-proximal aspect of the carpus; it attaches laterally to the medial part of the accessory carpal bone and medially to the styloid process of the radius, the radial carpal bone and the first carpal bone.
- The palmar carpal fibrocartilage is quite thick and well defined; it crosses the palmar surface of the carpus and attaches to all of the bones except the accessory carpal bone. It also has strong attachments to the proximal aspect of the third, fourth, and fifth metacarpal bones.
- The accessory carpal bone is stabilized distally by two ligaments, which originate from its free end; one attaches to the fourth metacarpal bone (accessoro-metacarpal IV ligament) and the other to the fifth metacarpal bone (accessoro-metacarpal V ligament).
- Many other small ligaments attach the carpal bones to each other and to the metacarpal bones.

FRACTURES OF THE RADIAL CARPAL BONE

Preoperative Considerations

- Fractures of the radial carpal bone are rare and most commonly occur in working dogs during strenuous activity, resulting from jumps or falls.
- Chip fractures of the proximal dorsal border result from hyperextension of the radio-carpal joint.
- Slab fractures occur from the dorsal surface.
- Body fractures and avulsion fractures may occur rarely.
- Moderate to severe lameness occurs immediately following the injury; however, in chronic cases only mild lameness, which resolves with rest, may be evident.
- Diagnosis requires a high index of suspicion since the majority of fractures are only minimally displaced.
- High-detail radiographs are frequently required.
- Oblique radiographic views are often necessary.
- Bone fragments rarely reattach, resulting in joint incongruency, synovitis, osteoarthritis, and periarticular fibrosis.

Surgical Procedure

Objectives

- Treat non-displaced or incomplete fractures with coaptation (Mason meta-splint) for 6 to 8 weeks.
- Remove small fracture fragments, which are too small to reattach.
- Stabilize larger fragments with internal fixation utilizing screws placed in lag fashion or multiple, divergent Kirschner wires.

Equipment

- General surgical pack and standard suture material
- Sterile elastic bandage material (Vetwrap) for Esmarch bandage, and tourniquet
- Small pointed bone-holding and/or pointed reduction forceps
- Orthopedic drill bits, taps, and bone screws or Kirschner wires (K-wires)

Technique

1. Place a tourniquet at the elbow and an Esmarch bandage from the nail bed to the proximal antebrachium.
2. Perform a dorsal approach to the carpus (see the description under Pancarpal Arthrodesis).
3. Reduction and anatomic alignment can be achieved with small, pointed bone-holding or reduction forceps.
4. Place bone screws in lag fashion across the fracture line, ensuring the screw head is adequately countersunk below the joint surface or positioned such that it does not interfere with joint motion.
5. If K-wires are used, ensure adequate interfragmentary compression is provided and maintained by the bone-holding forceps during wire insertion, and counter-sink the wires below the cartilage surface.

Postoperative Care and Complications

- A splint may be used 1 to 3 weeks postoperatively for support.
- Strict exercise restriction is necessary for 6 to 8 weeks, or until there is radiographic evidence of bony union.

- Osteoarthritis is common following these injuries, and may result in chronic intermittent lameness.

FRACTURES OF THE ACCESSORY CARPAL BONE

Preoperative Considerations

- Accessory carpal bone fractures are uncommon except in racing greyhounds.
- These fractures are typically avulsion fractures (Fig. 106-2). Treat with internal fixation if the fragments are large enough.

Surgical Procedure

Objectives and Equipment

- The same as for fractures of the radial carpal bone.

Technique

1. Perform a palmaro-lateral approach to the accessory carpal bone.
2. Excise fragments that are too small to reattach.
3. If the fragment is large enough, reduction and anatomic alignment can be achieved with small, pointed bone-holding or reduction forceps.

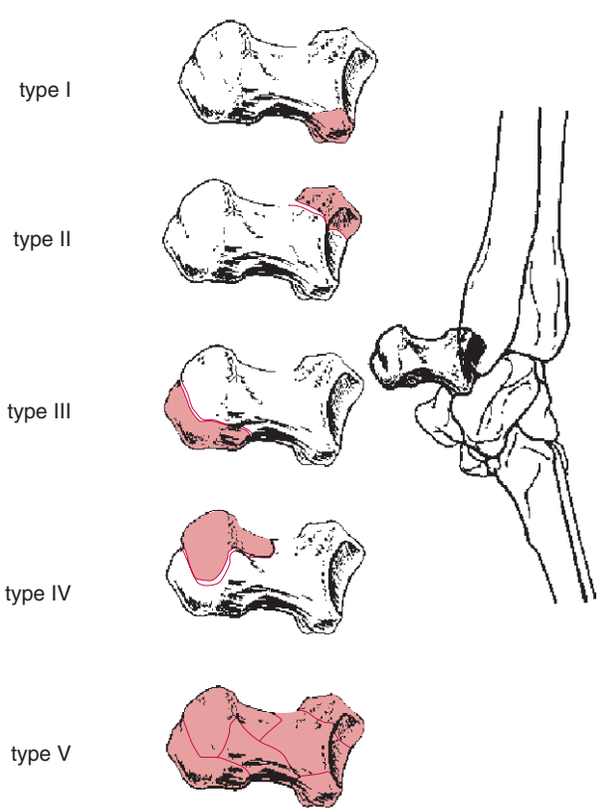

Figure 106-2. Classification of fractures of the accessory carpal bone.

4. Place bone screws in lag fashion across the fracture line, ensuring the screw head is adequately countersunk below the joint surface or positioned such that it does not interfere with joint motion.
5. If K-wires are used, ensure that adequate interfragmentary compression is provided and maintained by the bone-holding forceps during wire insertion.

Postoperative Care and Complications

- Place and maintain a splint for 4 to 6 weeks post-operatively.
- Working dogs may resume training 12 to 16 weeks post-operatively.

FRACTURES OF THE ULNAR CARPAL BONE AND THE NUMBERED CARPAL BONES

- Fractures of these bones are very rare even in the racing greyhound.
- Most often these are small chip fractures from the dorsal margin resulting from hyperextension injuries.
- Since these fragments are generally very small, fragment excision followed by splintage for 2 weeks and exercise restriction for 8 weeks is the usual treatment.
- Large fragments can be reattached as described for radial carpal bone fractures.
- Comminuted fractures of the ulnar carpal bone may necessitate pancarpal arthrodesis.

LUXATIONS, SUBLUXATIONS, AND HYPEREXTENSION INJURIES OF THE CARPUS

Luxations, subluxations, and hyperextension injuries are the most common injury of the carpus in non-working dogs. These injuries typically result from a fall or jumping from a height. The traumatic force causes tearing and rupture of the palmar joint capsule, ligaments, and fibrocartilage, resulting in a loss of support in any or all of the three carpal joint levels.

Clinical Signs and Diagnosis

- The injury typically results in an acute-onset, non–weight-bearing lameness; however, most animals begin partial or full weight bearing shortly after the injury.
- Regional or localized soft tissue swelling and discomfort are evident in the carpus, and manual extension demonstrates the area of instability.
- Carpal hyperextension results in a plantigrade stance, and in most animals, the carpal pad contacts the ground.
- This injury may occur bilaterally, and if so, bilateral surgery is indicated.

- Standard radiographic views generally do not demonstrate the injury, since the carpus is not loaded during the radiographic procedure. Obtain a stressed lateromedial projection to create carpal hyperextension to demonstrate the level(s) of the lesion.
- The distribution of joint involvement has been reported as antebrachiocarpal, 10% and 31%; middle carpal, 50% and 22%; and carpometacarpal, 40% and 47%.

▼ ***Key Point*** Splinting of the carpus is rarely if ever successful, since the randomly organized fibrous scar tissue does not have sufficient strength to support the carpus. In general, many injuries appear improved initially following splinting; however, recurrence of hyperextension occurs within 1 to 2 weeks of splint removal.

Preoperative Considerations

- Appropriate treatment depends on the joint level involved.
  - Pancarpal arthrodesis has been used to treat injuries to all levels of the carpus; however, partial carpal arthrodesis may be better for injuries involving only the middle carpal or carpometacarpal joint.
  - Although it is technically possible to fuse only the antebrachiocarpal joint, pancarpal arthrodesis is recommended in cases of isolated antebrachiocarpal injury. Partial carpal arthrodesis of the antebrachiocarpal joint results in increased stresses on the middle carpal and carpometacarpal joints, predisposing them to injury postoperatively.
  - Since 70% of carpal range of motion occurs in the antebrachiocarpal joint, preservation of this joint, if uninjured, results in very little gait alteration postoperatively.
- Bone plate fixation is the preferred method of pancarpal and partial carpal arthrodesis of most surgeons.

Surgical Procedure

Objectives

- Successful arthrodesis requires strict adherence to basic principles.
  - Debride the articular cartilage from the joint surfaces.
  - Apply an autogenous cancellous bone graft.
  - Provide rigid fixation (internal or external) until complete bony fusion has occurred.
  - Perform the arthrodesis at an appropriate angle.

Equipment

- General surgical pack and standard suture material
- Sterile elastic bandage material (Vetwrap) for Esmarch bandage, and tourniquet
- Sterile orthopedic drill and high-speed bur
- Bone curettes
- Kirschner wires (K-wires)
- Fixation devices
  - Orthopedic drill bits, taps, bone screws, and bone plates, or external skeletal fixation (circular or planar)

Technique

Pancarpal Arthrodesis

1. Place the patient in lateral recumbency with the affected limb up, and prepare the patient for aseptic surgery, including the site for bone graft collection.
2. Place a tourniquet at the elbow and an Esmarch bandage from the nail bed to the proximal antebrachium.
3. Make a skin incision centered on the dorsal midline and extending from the distal third of the radius to the distal extent of the third metacarpal bone, lateral to the accessory cephalic vein (Fig. 106-3).
4. Incise the deep fascia midway between the tendon of the extensor carpi radialis and the tendon of the common digital extensor; deepen the incision into the periosteum of the distal radius, and elevate the periosteum medially and laterally to retract the tendons to expose the joint capsule.
5. Perform arthrotomy incisions around each bone to expose the articular surfaces; exposure is enhanced by flexion of the carpus.
6. Débride the articular cartilage with a high-speed bur or curettes.
7. Collect an autogenous cancellous bone graft from the proximal humerus (or ilial wing) and place it in all joint spaces.
8. K-wires placed obliquely across multiple joint levels can be used to temporarily stabilize the joint intraoperatively.
9. Apply a dynamic compression plate dorsally to the radius, radiocarpal bone, and third metacarpal bone.
   a. A seven-hole bone plate is usually sufficient, with three screws in the radius, one in the radiocarpal bone, and three in the third metacarpal bone (Fig. 106-4, *left*). The bone plate should extend at least 50% of the length of the third metacarpal bone. Bone plates specifically designed for pancarpal arthrodesis are commercially available.
   b. Contour the plate to provide 10° to 15° of extension of the carpus primarily at the antebrachiocarpal joint, and ensure that the foot is aligned properly prior to and during plate application.
10. Alternatively, stabilize the joint with a Type II external skeletal fixator (Fig. 106-4, *right*), or a circular external skeletal fixator (Fig. 106-5), placing at least

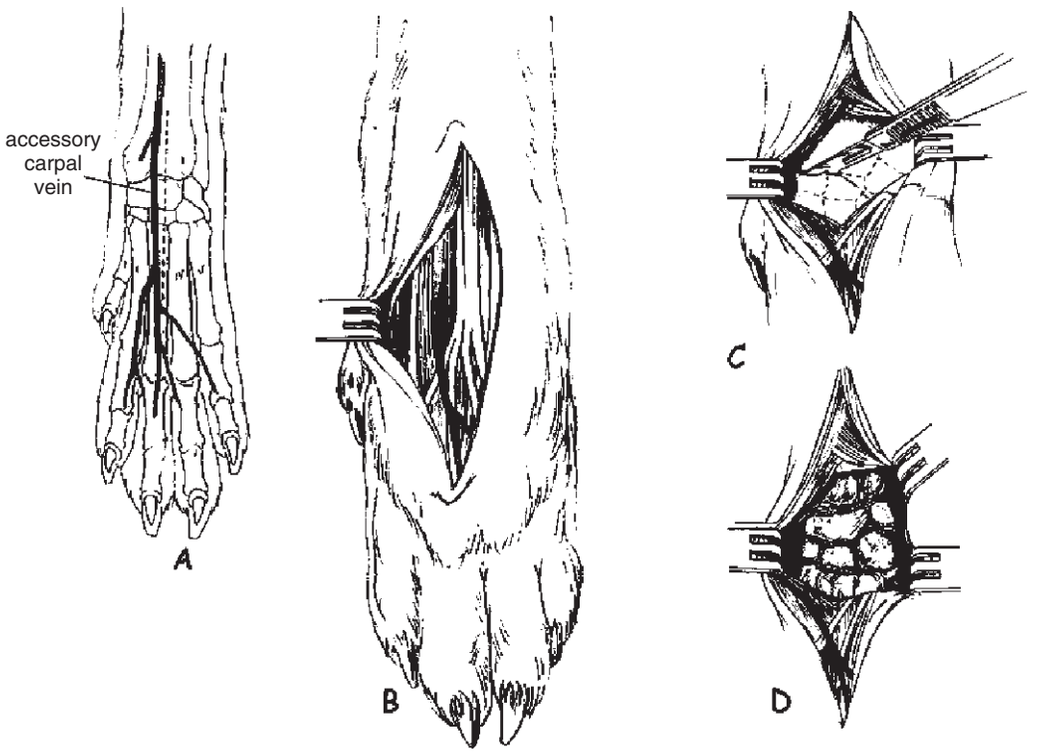

Figure 106-3. Dorsal approach to the carpus for pancarpal arthrodesis. The skin incision is centered on the dorsal midline and extends from the distal third of the radius to the distal extent of the third metacarpal bone, lateral to the accessory cephalic vein *(A)*. The deep antebrachial facial incision is located midway between the tendon of the extensor carpi radialis and the tendon of the common digital extensor *(B)*. Make arthrotomy incisions to expose each joint space *(C)*. Following débridement of articular cartilage, place autogenous cancellous bone graft in all joint spaces *(D)*.

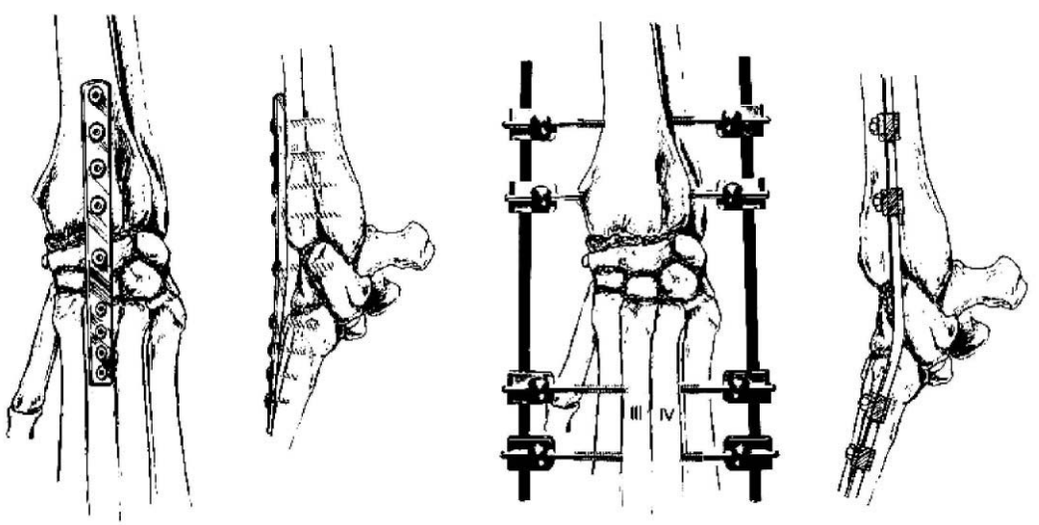

Figure 106-4. Pancarpal arthrodesis performed with a bone plate and screws *(left)* or a planar external skeletal fixator *(right)*.

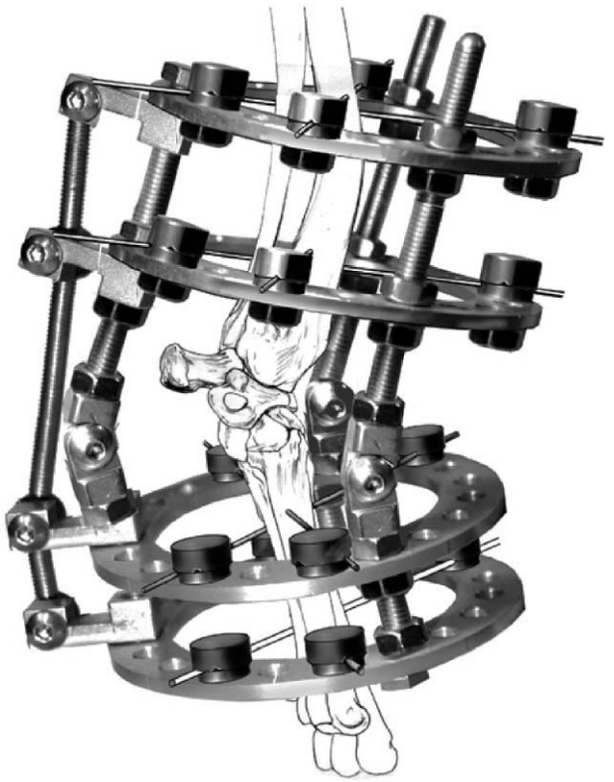

Figure 106-5. Pancarpal arthrodesis performed with a circular external skeletal fixator.

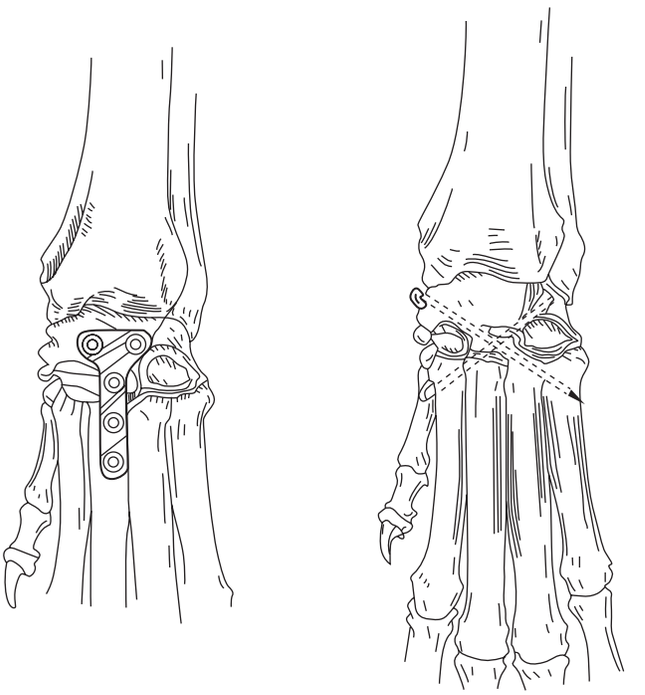

Figure 106-6. Partial carpal arthrodesis may be performed with a t-plate and screws *(left),* or cross pins *(right).*

two pins or wires in the distal radius and third and fourth metatarsal bone.

Postoperative Care

- In the case of bone plate fixation, place the limb in a palmar splint for 6 to 8 weeks after surgery, or until radiographic union is evident.
- The splint can be changed to a cast 3 to 5 days postoperatively once soft tissue swelling has subsided, if greater support of the limb and repair is desired.

Partial Carpal Arthrodesis

- Partial carpal arthrodesis is only indicated when the joint capsule, fibrocartilaginous, and ligamentous support of the antebrachiocarpal joint and accessory carpal bone are intact.

1. Place the patient in lateral recumbency with the affected limb up, and prepare the patient for aseptic surgery, including the site for bone graft collection.
2. Place a tourniquet at the elbow and an Esmarch bandage from the nail bed to the proximal antebrachium.
3. Perform a dorsal approach to the carpus and third metacarpal bone as described under Pancarpal Arthrodesis; however, limit the approach to the distal radius.
4. Perform arthrotomy incisions in the middle carpal and carpometacarpal joints only; exposure is enhanced by flexion of the carpus.
5. Débride the articular cartilage of the middle carpal and carpometacarpal joints with a high-speed bur or curettes.
6. Collect an autogenous cancellous bone graft from the proximal humerus (or ilial wing) and place it in the joint spaces.
8. Apply a T- or L-shaped dynamic compression plate dorsally to the radiocarpal bone and third metacarpal bone with the T- or L-shaped portion attached to the radiocarpal bone (Fig. 106-6, *left*).
   a. Ensure that the bone plate does not interfere with the distal radius during full extension of the antebrachiocarpal joint, and that the foot is aligned properly.
9. Alternatively, partial carpal arthrodesis can be performed with pin fixation.
   a. Place two cross pins to stabilize the middle carpal and carpometacarpal joints. Place the first obliquely from the proximal third of metacarpal II across the numbered carpal bones, into the ulnar carpal bone to a level even with the lateral styloid process of the ulna. Place the second

obliquely from the medial aspect of the radiocarpal bone immediately distal to the radius, across the numbered carpal bones, to exit from the proximal third of metacarpal V (Fig. 106-6, *right*).

Postoperative Care

- Place the limb in a palmar splint for 6 to 8 weeks after surgery, or until radiographic union is evident.
- The splint can be changed to a cast 3 to 5 days postoperatively once soft tissue swelling has subsided, if greater support of the limb and repair is desired.

Postoperative Complications

- Soft tissue swelling caused by surgical trauma and impaired lymphatic and venous drainage is common, and usually subsides within a few days.
  - Monitor the limb carefully during this period, and change the bandage if it becomes restrictively tight due to swelling.
- Complications are rare once bony fusion has occurred.
- Metacarpal bone fracture following pancarpal arthrodesis has been associated with bone plates, which extend less than 50% of the length of metacarpal III.
- The most frequent causes of arthrodesis failure are associated with failure to adhere to the principles of arthrodesis.
  - Incomplete removal of the articular cartilage.
  - Failure to apply sufficient bone graft.
  - Inadequately rigid internal or external support for a sufficient period of time to allow bony fusion to occur.

Chapter

107 Fractures of the Pelvis

Mark C. Rochat

Pelvic fractures in dogs and cats are extremely common. Severe trauma, such as motor vehicular accidents, is usually the cause of pelvic fractures. Concurrent injuries to other body systems, including life-threatening injuries, are also common and must be identified and treated in a timely fashion. Several specific types of injury occur in the pelvis, including sacroiliac luxation, fractures of the non-articular portions of the pelvis, and articular fractures. Specific management protocols for each are described below.

ANATOMY

- Each half of the pelvis is composed of the ilium, ischium, pubis, and acetabulum, which are fused as the os coxae, or hip bone (Fig. 107-1).
- The sacroiliac joint has a limited range of motion and is composed of a synchondrosis craniodorsally and a synovial articulation ventrally.
- The sacrotuberous ligament extends from the caudolateral part of the apex of the sacrum and the transverse processes of the first caudal vertebra to the lateral part of the ischiatic tuberosity. The sacrotuberous ligament is absent in the cat.
- The sacrum and pelvic bones form a complete bony canal. Therefore, pelvic fractures usually are multiple, or pelvic fracture may be accompanied by sacral fracture or sacroiliac luxation. If a pelvic fracture appears to be single, examine radiographs carefully for evidence of additional undisplaced fractures. There are two exceptions to this general rule: fractures in very young dogs and impaction fractures of the acetabulum in adult dogs and cats. In the former case, the bones of young dogs can allow a fracture in one location and an incomplete fracture or plastic deformation (bending) without actual fracture of the bones of the pelvis in other areas. In the second instance, the femoral head is driven through the acetabulum by a lateral blow to the greater trochanter.
- The major weight-bearing regions of the pelvis are the sacroiliac joint, body of the ilium, and acetabulum.

DIAGNOSIS

Concurrent Thoracic and Abdominal Injuries

- Thorough physical examination may be difficult in injured animals that are in pain or shock.
- Treat aggressively for shock and pain (see Chapters 6 and 156). After emergency treatment, complete the general physical examination as soon as possible.
- Concurrent thoracic, abdominal, intrapelvic, and spinal cord or peripheral nerve injuries are common with pelvic fractures. Management of cardiopulmonary, neural, and urinary system injuries and management of uncontrollable hemorrhage have priority over orthopedic injury.
- Radiograph the thorax routinely in animals with suspected pelvic fractures to identify pulmonary contusions, pneumo- or hemothorax, diaphragmatic herniation, and preexisting cardiac disease.
- Perform a 10-lead electrocardiogram and lead 2 rhythm strip every 12 hours for the first 48 to 72 hours following the trauma to identify cardiac dysrhythmias.
- Obtain abdominal radiographs, ultrasound examination, or diagnostic peritoneal lavage if free blood, urine, or bile is suspected in the abdomen.
- Perform excretory urography, cystography, or urethrography to identify the specific location of injury if rupture of the urinary tract is suspected.
- Urethral injuries are more common in male dogs where the urethra crosses through the ventral pelvic canal. The ability to urinate, presence of bruising or pubic fractures, and hematuria are not accurate predicators for or against urethral or bladder injury.
- Caudal abdominal hernias can also occur in conjunction with pelvic fractures, especially pubic fractures. Radiograph and carefully palpate the caudal abdomen to identify this injury.

Pelvic Injuries

- When the patient is in stable condition, perform an orthopedic examination.

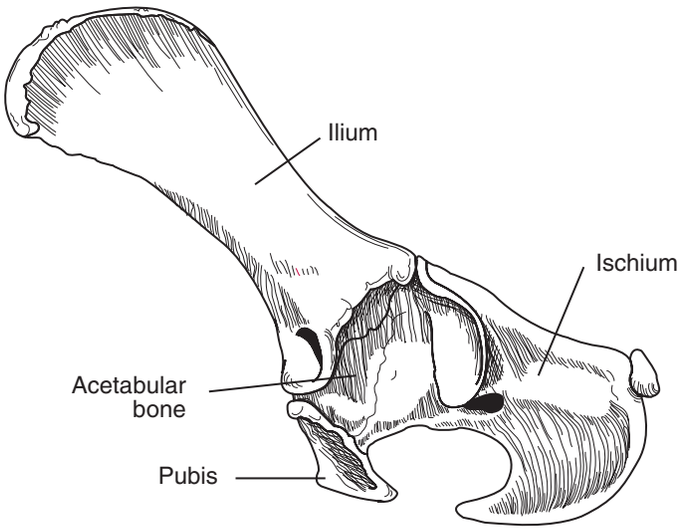

Figure 107-1. Bony anatomy of the pelvis. (From Evans S: Miller's Anatomy of the Dog, 2nd ed. Philadelphia: WB Saunders, 1993.)

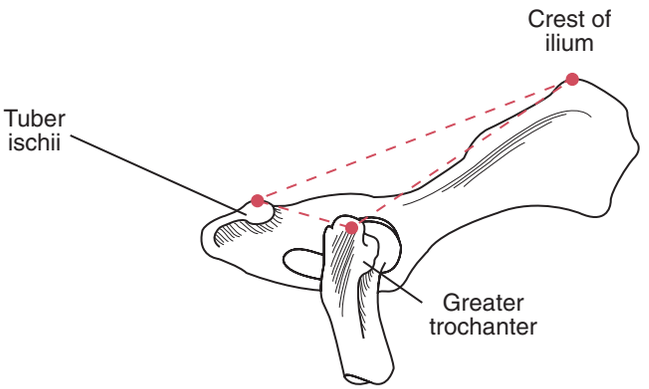

Figure 107-2. Diagram illustrating the normal position of the greater trochanter, iliac crest, and ischiatic tuberosity. (From Fossum TW: Small Animal Surgery, 2nd ed. St Louis: Mosby, 2002.)

- Carefully palpate the pelvic bones, manipulate the hip joints, and perform a rectal examination to detect pelvic fractures and to check for a palpable defect in the rectal wall.
- Palpate the craniodorsal iliac crest, greater trochanter, and ischiatic tuberosity for symmetry, motion, and pain (Fig. 107-2).
- Radiograph the pelvis in at least two projections to fully evaluate bone injury. Sedate or anesthetize the patient to obtain high-quality diagnostic radiographs. Closely examine the coccygeal vertebrae and sacral foramina for fractures that may result in neurologic injury to the tail, perineum, and bladder.
- Although rectal tears are not commonly associated with pelvic fracture, failure to make an early diagnosis usually results in severe pelvic infection, sepsis, and patient death.
- If an animal is not in shock but is unwilling to stand, do not attempt to make the animal stand unless you have palpated the dorsal spinous processes for malalignment and pain (point tenderness). Check the animal's spinal reflexes, including the sciatic and femoral nerve tracts; perception of noxious sensation over the pelvic limbs; withdrawal response; anal tone; and perineal sensation.

▼ ***Key Point*** If *any* question exists as to the integrity of the spinal column, do *not* allow the animal to stand or twist the spine until you have reviewed lateral and ventrodorsal radiographs of the spine. The ventrodorsal view can be made by either using a cross table lateral beam projection technique or carefully rolling the animal on its back without twisting the spine (known as a log roll maneuver).

- Pelvic fractures readily heal, but malunions are very common. Repair pelvic fractures as soon as the animal's general condition and anesthetic level of risk allow. Fractures that are over 5 days old are often difficult to repair anatomically.

TREATMENT

Non-surgical Treatment

In many animals with pelvic fractures, conservative treatment is all that is needed for successful fracture healing and normal pelvic limb function. However, careful nursing is required for several weeks because multiple fractures are often present. Patient size is an important consideration in making the decision to manage pelvic fractures without surgery. Small dogs and cats are much easier to manage for extended periods of time.

Indications

Medical management is a viable method of treatment for:

- Unilateral fractures
- Fractures that are minimally displaced
- Fractures of the non–weight-bearing portion of the pelvis (iliac wing, pubis, ischium)
- Animals with pelvic fractures that fit the above criteria and have intact neurologic function
- Animals with pelvic fractures that fit the above criteria and have no soft tissue injuries (urethral injury, prepubic tendon rupture, etc.) that require surgical repair

Nursing Care

- Dogs and cats with pelvic fractures often are reluctant to stand and may be unable to turn over. Turn these

animals regularly, use a padded bed, and keep these animals clean and dry to help prevent decubital ulcers.
- Give analgesics as needed. Typically, at least 1 to 2 weeks of analgesic therapy is indicated (see Chapter 6).
- Pain, bone instability, and neurologic injury may make it difficult for animals with pelvic fractures to urinate and defecate normally. If necessary, give a mild laxative or stool softener to prevent constipation.
- Empty the urinary bladder regularly by manual expression or catheter drainage, to prevent excessive distention, overflow incontinence, and urine soiling. If a urinary catheter is placed, follow strict aseptic technique to slow the onset of bacterial urocystitis.
- Some patients are able to stand and walk within a few days; however, restrict activity to a cage for 3 to 4 weeks followed by activity limited to only leash walking for 3 to 4 weeks. Avoid slick floors and any uncontrolled activity.
- Make certain the animal has access to food and water and assistance as needed to eat and drink.
- Physical therapy, in the form of passive range of motion, will lessen the degree of disuse atrophy and loss of joint range of motion.
- If limb adduction is weak as a consequence of ventral pelvic fractures or muscle trauma, use a body sling or towel support around the abdomen as necessary to assist recovery.
- Radiograph the pelvis every 4 to 6 weeks during recovery to monitor fracture healing.

Surgical Treatment

Indications

▼ ***Key Point*** The main advantages of surgical treatment of pelvic fractures are reduced pain, early return to normal function, avoidance of fracture-associated disease, and minimal hospitalization time.

Pelvic fractures may result in marked narrowing of the pelvic canal if left untreated, with the risk of subsequent obstipation, dystocia, dysuria, or sciatic nerve entrapment. If operative treatment of pelvic fractures is delayed beyond 5 days, muscle spasm and fibrosis may make reduction of the fracture fragments difficult, because of the large muscle mass surrounding the pelvis.

Surgical treatment is indicated for the following injuries:

- Fracture of the ilium with associated fracture of the pubis and ischium creating an unstable acetabulum.
- Intra-articular fractures (acetabulum).
- Markedly displaced, unstable, or excessively painful sacroiliac fracture or luxation.
- Severe bilateral fractures of the pelvis or displaced pelvic fractures associated with an additional major orthopedic injury of a pelvic limb, such as hip luxation or fracture of the femur.
- Fractures of the ischium that have an intra-articular component in the acetabulum, or that are suspected of entrapping the sciatic nerve.
- Fracture of the pubis or separation of the pubic symphysis associated with abdominal wall rupture and herniation of abdominal or pelvic organs.
- Gross displacement of the iliac crest or ischiatic tuberosity. These portions of the pelvis serve as the point of origin for the sartorius and semitendinosus and semimembranosus muscles, respectively. Significant distraction of these fragments may result in loss of mechanical advantage and proper function of these muscles.

FRACTURES OF THE ILIUM

Preoperative Considerations

- Fractures of the ilium are usually oblique and are often accompanied by fractures of other regions of the pelvis.

▼ ***Key Point*** If fracture displacement is present, the caudal fragment usually is displaced medially, and the pelvic canal is narrowed.

- Perform a thorough neurologic examination (see Chapter 125), particularly with markedly displaced fractures. Damage to the sciatic nerve may be present.
- Surgical repair of fractures of the ilium is generally recommended because most fractures of the ilium are displaced or unstable and the ilial shaft is a component of the weight-bearing portion of the pelvis.
- Precontouring the bone plate to the ilium of an intact pelvis from a cadaver of similar size reduces operating time for the inexperienced surgeon.
- Administer prophylactic antibiotics at the time of anesthetic induction. A first-generation cephalosporin such as cefazolin is generally appropriate.
- Have the radiographs (ventrodorsal and lateral projections) on a radiographic view box in the operating room for review.

Surgical Procedure

Objectives

- Anatomically reduce and stabilize the ilium.
- Relieve pain.
- Provide early restoration of pelvic limb function.
- Avoid damage to the sciatic nerve as it passes medial to the ilial shaft.

Equipment

- Standard general surgical pack and suture material.
- Hand-held retractors such as Myerding retractors and an assistant. Alternatively, Gelpi or Weitlaner self-retaining retractors can be used but generally are not as efficient at making adjustments as an assistant using a hand-held retractor.
- Orthopedic surgical pack with AO-ASIF "clamshell" and Kern bone-holding forceps and Hohmann retractors.
- Bone-plating equipment. Use dynamic compression plates (DCP) or the newer limited contact (LC-) DCP. For complex fractures, reconstruction plates can be used. The latest advance in plating, locking compression plates (LCP) allow the screws to be locked to the plate and are helpful for areas where the bone is weak or subject to failure. Avoid semitubular plates, finger plates, and other thin plates.
- Freer or Adson periosteal elevator.
- Suction with Frazier or Yankauer tips and electrocautery.

Technique

1. Perform a hanging limb prep by preparing the skin for aseptic surgery on the lateral and medial sides of the pelvic limb from the tarsocrural joint to the dorsal and ventral midline and from the midlumbar area to the base of the tail.
2. Place the animal in lateral recumbency on a circulating warm water blanket and stabilize the pelvis by placing sandbags under the animal and securing the animal to the table. Rotate the animal table toward the surgeon with towels, inflatable positioners, or a tilting table to improve exposure and reduce back strain of the surgeon.
3. Perform a ventrolateral (gluteal roll-up) approach to the ilium.
   a. Make a skin incision from the iliac crest to the greater trochanter.
   b. Incise the subcutaneous fat to expose the pelvic musculature.
   c. Achieve hemostasis by careful electrocoagulation.
4. Identify and separate the tensor fasciae latae and middle gluteal muscles. Retract the tensor fasciae latae muscle ventrally, and retract the middle gluteal muscle dorsally to expose the ilium (Fig. 107-3). Subperiosteal elevation of the middle and deep gluteal muscles ventrally from the surface of the ilium exposes the lateral surface of the body of the ilium. Retract the sartorius muscle cranially as needed. Remember that there is little to no plane of dissection at the confluence of sartorius, middle gluteal muscles, and tensor fasciae latae. Sharply incise these muscles where they join and continue the dissection dorsally along the cranial edge of the iliac crest as needed to "roll up" the gluteal to provide adequate exposure of the ilium. The iliolumbar artery is present along the ventral edge of the cranial ilium in these muscles and is usually severed during the muscular dissection. Electrocoagulate or ligate this artery when it is encountered.
   a. During exposure of the body of the ilium, it may be necessary to retract or transect branches of the cranial gluteal vein, artery, and nerve that supply the tensor fasciae latae muscle.
   b. Preserve the lateral circumflex femoral vessels immediately cranial to the acetabulum.

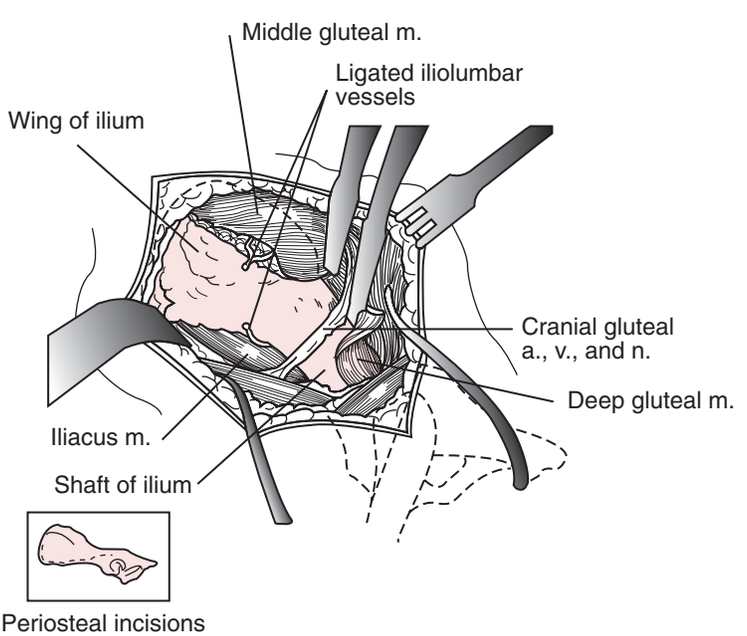

Figure 107-3. Diagram illustrating the final stages of the gluteal "roll-up" approach to the ilial wing and body.

▼ ***Key Point*** Avoid damage to the sciatic nerve, which lies dorsomedial to the ilium during reduction and stabilization of the fracture.

5. After exposing the fracture, carefully clean the ends of the fractured bone of hematoma and fibrin tags that interfere with accurate reduction. Do *not* overclean the fragments. Doing so may remove soft, cancellous bone from the edges of the fracture and damage the anatomic alignment between fragments. If reduction of the caudal ilial fragment is difficult, reduce the caudal fragment by grabbing the ischium with bone-holding forceps through a separate smaller incision over the ischiatic tuberosity.
6. After reducing the fracture, contour a bone plate to the body of the ilium. The tendency is to undercontour the plate, leading to under-reduction of the fracture. When in doubt, it is usually better to create more curve in the plate. If possible, position the plate so that one to two screws in the cranial fragment can be placed in the body of the sacrum to engage more bone. The cranial part (the wing) of the ilium is thin and screws strip easily if the body of the sacrum is not engaged.
7. Initially, attach the plate to the caudal fragment. Lateral traction on the caudal fragment or ischium assists final reduction of the fracture.
8. If the fracture is a transverse, linear fracture, compress the fracture by using the drill guide in the load position before screw placement. Place at least three screws on each side of the fracture. Select implant sizes according to the guidelines in Table 107-1.
9. If fracture comminution is present, smaller fracture fragments may be stabilized with Kirschner wires (K-wires) or lag screws to further assist fracture reduction. Do not compress the fracture in this situation.
10. It may be possible in some instances to stabilize oblique fractures of the body of the ilium with ventrodorsally oriented bone screws alone, particularly in large dogs. Use the screws for lag effect by overdrilling the cortex closest to the head of the screw, or use partially threaded screws. The fracture will be compressed as the screws are tightened (Fig. 107-4).
11. Closure. Irrigate the surgical site with saline and close the muscle and fascia (simple continuous or cruciate pattern, absorbable suture), subcutaneous tissue (simple continuous pattern, absorbable suture), and skin (interrupted or cruciate pattern, non-absorbable suture) or skin staples.

Table 107-1. GUIDELINES FOR IMPLANT SIZES FOR FRACTURES OF THE ILIUM OF DOGS AND CATS

Body Weight (kg)	Plate Size (mm)/Type
<10	2.0 DCP or 2.0 LRP or 2.4 LRP
10–20	2.7 DCP or 2.7 RCP or 2.4 LRP
>20	3.5 DCP or 3.5 RCP or 3.5 LCP or 2.4 LRP

DCP, dynamic compression plate; LCP, locking compression plate; LRP, locking reconstruction plate; RCP, reconstruction plate.

Postoperative Care and Complications

Short Term

- Evaluate immediate postoperative radiographs for plate contouring and screw placement, particularly any screws inserted into the body of the sacrum.
- Continue analgesic therapy for 10 to 14 days.
- Monitor for seroma formation. If a seroma occurs, warm compresses and time will resolve the seroma. Do *not* aspirate or place drains in seromas unless the seroma is extremely large and fails to resolve with conservative care. Any aspiration attempt should be done only with strict aseptic technique. If necessary, use a closed, suction-type drain that is emptied and maintained with strict aseptic technique.
- Good patient care is essential to encourage early mobility and return to normal function (see "Nonsurgical Treatment").
- Reassess the neurologic status of the patient.
- It is not necessary to continue antibiotic usage after surgery unless there was a break in aseptic technique during surgery or other risk factors for infection, immunosuppression, significant tissue injury, prolonged surgery time, etc.

Long Term

- Restrict activity to leash walking only on non-slick surfaces for 6 to 8 weeks to minimize the risk of fixation failure.
- If neurologic deficits are present, reevaluate these regularly.

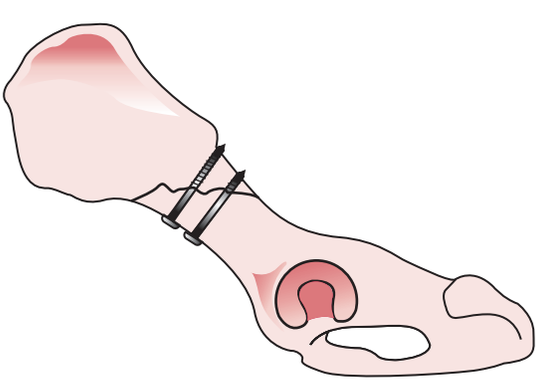

Figure 107-4. Diagram of an oblique ilial body fracture repaired with ventrodorsally oriented lag screws. (From Fossum TW: Small Animal Surgery, 2nd ed. St Louis: Mosby, 2002.)

- Obtain radiographs every 4 to 6 weeks to monitor fracture healing.
- Do not remove plate and bone screws unless there are clinical signs of implant-associated problems. Stress protection by the plate is not a recognized complication.

Prognosis

- The prognosis is very good with anatomic reduction, stable fixation, and no neurologic damage. Pelvic fractures usually heal in 6 to 10 weeks. Delayed union or nonunion is uncommon because the pelvic bones have a large proportion of cancellous bone, and the extensive muscle coverage maintains a good blood supply to the fractured bone and also provides some degree of fracture stabilization.
- If neurologic deficits are present after surgery, the prognosis is fair to poor, and recovery of normal function may be delayed by weeks to months, or may not occur at all.
- If the plate is too small or thin or if insufficient screws are placed on each side of the fracture, plate breakage or screw loosening may occur.

FRACTURES OF THE ACETABULUM

Preoperative Considerations

▼ ***Key Point*** Acetabular fractures are among the most difficult of all fractures to properly repair. The surgical approach is difficult, and anatomic reduction and rigid fixation are mandatory. Refer these cases to a surgical specialist.

- Fractures of the acetabulum are usually accompanied by fractures of other regions of the pelvis unless an impaction fracture has occurred. If other major weight-bearing regions of the pelvis are fractured, multiple surgical procedures may be necessary.
- Fractures of the acetabulum are classified by the anatomic region (cranial, central, or caudal acetabulum), the degree of comminution, and the degree of displacement.
- Historically, conservative management has been advocated for undisplaced and caudal fractures of the acetabulum. However, the treatment of choice for all intra-articular fractures of the acetabulum is surgical stabilization, because this minimizes the severity of subsequent osteoarthritis.

▼ ***Key Point*** When it is not possible to anatomically reconstruct comminuted acetabular fractures, conservative management or stabilization of the major fragments is indicated. Excision arthroplasty (femoral head and neck ostectomy) can be performed concurrently or after the fractures have healed (see Chapter 108). Total hip arthroplasty may be performed to relieve residual hip pain and improve hip function but must be done after the fractures have healed (see Chapter 108).

- Damage to the joint capsule may be associated with fractures of the acetabulum, especially if the hip is luxated.
- Evaluate withdrawal and femoral and sciatic nerve reflexes, particularly with displaced fractures of the caudal acetabulum. Damage to the sciatic nerve may be present.
- Administer prophylactic antibiotics (e.g., catrazolin) at the time of anesthetic induction.

Surgical Procedure

Objectives

- Anatomically reduce and stabilize the acetabulum to restore joint congruity and limb function.
- Relieve pain.
- Provide early restoration of pelvic limb function.
- Avoid iatrogenic sciatic nerve damage.

Equipment

- Standard general surgical pack and suture material.
- Hand-held retractors such as Myerding retractors and an assistant. Alternatively, Gelpi or Weitlaner self-retaining retractors can be used but generally are not as efficient at making adjustments as an assistant using a hand-held retractor.
- Orthopedic surgical pack with AO-ASIF "clamshell" and Kern bone-holding forceps and Hohmann retractors.
- Bone-plating equipment. Acetabular or reconstruction plates can be used. Acetabular plates are only useful for linear central or cranial fractures. Reconstruction plates can be contoured in multiple planes and lend themselves to the complex geometry of the acetabulum. The latest advance in plating, locking compression plates (LCP) allow the screws to be locked to the plate and are helpful for areas where the bone is weak or subject to failure or when precise anatomic reconstruction of the fracture is impossible. Avoid semitubular plates, finger plates, and other thin plates.
- Another method of fixation uses a combination of K-wires, screws, positional wire, and polymethylmethacrylate bone cement.
- Freer or Adson periosteal elevator.
- Suction with Frazier or Yankauer tips and electrocautery.

Technique

1. Prepare the patient as described under Fractures of the Ilium.
2. If the ischium will be approached as part of the reduction, place a tampon or lubricated gauze

sponge in the rectum, and place a pursestring suture in the anus. Place a piece of white 1-inch tape with a warning about the pursestring across the animal's forehead, or make a note on the anesthetic chart so the pursestring will not be forgotten at the conclusion of the surgery.

3. For fractures of the cranial, central, and caudal regions of the acetabulum, use a dorsal approach to the hip. For some central and all caudal fractures, use a combined dorsal and caudolateral approach to the hip joint. Make a separate surgical approach to the ischium and elevate the internal obturator and gemelli muscles to expose the table of the ischium. Place a Kern bone-holding forceps on the table of the ischium to manipulate the caudal bone fragment, while minimizing risk of iatrogenic damage to the sciatic nerve. If possible, precontour a bone plate to an intact pelvis of an equivalent-size cadaver to minimize operating time.
4. Make a curved skin incision, centered over the caudal surface of the greater trochanter, beginning close to the dorsal midline, and ending at the junction of the proximal and middle thirds of the femur. Achieve hemostasis by careful electrocoagulation.
5. Incise and retract the subcutaneous tissues to expose the underlying musculature.
6. Incise the fascia of the biceps femoris muscle along its cranial border.
7. Free the cranial part of the origin of the biceps femoris muscle from the sacrotuberous ligament. Transect the insertion of the superficial gluteal muscle on the third trochanter, and retract this muscle dorsally. Retract the biceps femoris muscle caudally. Identify and avoid the sciatic nerve.
8. Perform a dorsal approach to the hip by osteotomy of the greater trochanter of the femur. Alternatively, perform a tenotomy of the middle and deep gluteal muscles in young dogs. For a caudal approach to the hip, transect the combined tendons of the internal obturator and gemelli muscles close to their insertion in the trochanteric fossa or remove a small block of bone in the trochanteric fossa of the femur where these muscles insert. A small osteotome works well for this procedure. Retract these muscles and/or the block of bone with a stay suture in the tendons. Retraction of these muscles indirectly retracts the sciatic nerve caudally.
9. Retract the gluteal muscles dorsally. Part of the origin of the deep gluteal muscle may need to be elevated to expose the more cranial region of the acetabulum.
10. Preserve as much of the joint capsule as possible. Do not elevate it from the acetabular bone. To observe the joint surface, perform a small radial arthrotomy.
11. After exposing the fracture, use AO-ASIF small reduction forceps in combination with the Kern bone-holding forceps placed on the ischium to manipulate and reduce the fracture fragments. Bone-holding forceps placed on the greater trochanter also provide lateral traction and aid in manipulation of the femoral head for better identification of the fracture.
12. Fractures of the acetabulum are rarely stable immediately after reduction. If the fracture configuration allows, maintain reduction of the fracture by placing pointed bone-holding forceps craniocaudally across the acetabulum. If necessary, place shallow drill holes (1.1 or 1.5 mm) in each fragment to prevent the point-to-point forceps from slipping. This is usually only applicable to linear fractures. Other fracture configurations, including comminuted fractures, often require diverging K-wires or other methods of maintaining reduction while definitive fixation is applied.
13. After the fracture has been reduced, apply a precontoured bone plate. Stabilize the fracture with an acetabular plate, a reconstruction plate, or an LCP. Engage at least six cortices on each side of the fracture. Because of the thin cortical bone that is present in the pelvis, carefully drill and tap the screw holes. Select implants according to the guidelines in Table 107-2.
    a. Alternatively, if a combination of K-wires, screws, and bone cement is to be used, maintain fracture reduction crosspinning the fracture with K-wires. Place a screw on either side of the fracture line and a figure-of-eight wire around the screws. Encase the pins, screws, and wire in a moderate amount of bone cement.
14. Closure:
    a. If the joint capsule has been torn or incised, appose it with sutures in a simple interrupted pattern using monofilament absorbable suture. Reattach the tendons of the internal obturator and gemelli muscles using monofilament absorbable or non-absorbable suture and a tension-relieving suture pattern such as the horizontal mattress or locking loop pattern. Drill two small holes parallel to each other and perpendicular to the long axis of the femoral neck through the neck of the femur to pass the suture through. Tie the suture on the cranial aspect of

Table 107-2. GUIDELINES FOR IMPLANT SIZES FOR FRACTURES OF THE ACETABULUM OF DOGS AND CATS

Body Weight (kg)	Plate Size (mm)/Type
<10	2.0 AP, RCP, or LRP
10–30	2.0 or 2.7 AP; 2.7 RCP; or 2.4 LRP
>30	2.7 AP, 3.5 RCP, 3.5 LCP

AP, acetabular plate; LCP, locking compression plate; LRP, locking reconstruction plate; RCP, reconstruction plate.

the femoral neck. Stabilize the osteotomy of the greater trochanter of the femur with a tension band wire technique (Fig. 107-5), or reattach the gluteal muscles with a tension-relieving pattern such as a horizontal mattress or locking loop pattern. Reattach the tendon of insertion of the superficial gluteal muscle to the distal aspect of the greater trochanter (third trochanter).

b. Reattach the biceps femoris to the sacrotuberous ligament (cruciate or simple interrupted pattern, absorbable suture). Close the biceps femoris fascia (simple continuous pattern, absorbable suture), subcutaneous tissue (simple continuous pattern, absorbable suture), and skin (interrupted pattern, absorbable suture; or skin staples).

c. Remove the pursestring suture and tampon from the anus.

Postoperative Care and Complications

- See "Fractures of the Ilium."

Prognosis

- The prognosis is good if anatomic reduction of the acetabulum and rigid fixation are achieved and neurologic function is normal.

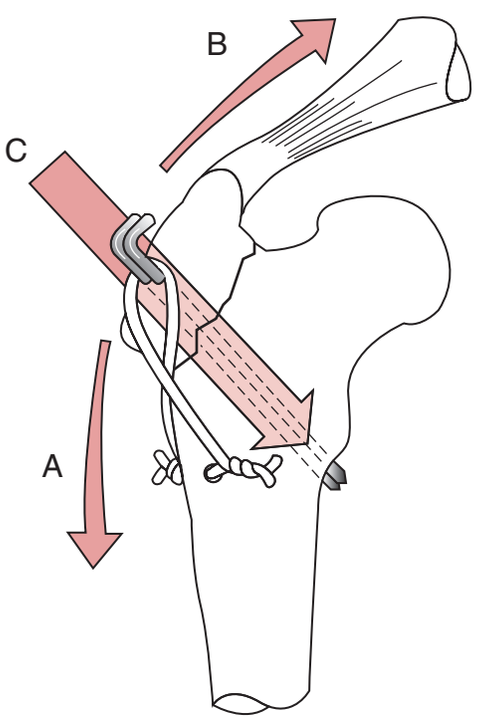

Figure 107-5. Diagram of the tension band principle. The distractive forces placed on the greater trochanter by the gluteal muscles is converted by the figure-of-eight tension wire to forces that compress the osteotomized greater trochanter against the femur. (From Slatter D: Textbook of Small Animal Surgery, 2nd ed. Philadelphia: WB Saunders, 2003.)

- If anatomic reduction and rigid fixation are not achieved, the prognosis is fair to poor. Osteoarthritis is likely to develop, and further surgical or medical treatment may be necessary.
- The prognosis is guarded to fair if femoral head excision is performed to repair a comminuted acetabular fracture.

SACROILIAC FRACTURE OR LUXATION

Preoperative Considerations

- If luxation of the sacroiliac (SI) joint has occurred, craniodorsal displacement of the ilium is usually present, together with fractures in other regions of the pelvis. Bilateral SI joint separation without concurrent fractures of the remainder of the pelvis may also occur.
- Perform a thorough neurologic examination (including bladder function, anal tone, and perineal sensation), particularly when displacement of the fracture is marked or SI joint luxation is severe, because damage to the cauda equina nerve roots may be present.
- Review dorsoventral radiographs carefully for sacral fractures. Fracture lines that traverse the spinal canal or sacral foramina are especially prone to suggest the likelihood of concurrent neurologic deficits and a poorer prognosis.
- Because surgical treatment of SI fracture or luxation is technically difficult, undertake surgical treatment only after careful consideration of other options, including conservative management or referral.

▼ ***Key Point*** In many animals with SI luxation the displacement is not severe and the injury responds well to conservative management. However, successful reduction and stabilization of the SI joint relieves pain more quickly and allows more rapid return to normal function. Anatomic reduction and rigid stabilization has a higher priority as a treatment option if neurologic deficits are present or if pelvic injuries are bilateral.

- Administer prophylactic antibiotics at the time of anesthetic induction.

Surgical Procedure

Objectives

- Anatomically reduce and stabilize the sacrum and SI joint.
- Relieve pain.
- Provide early restoration of pelvic limb function.
- Avoid iatrogenic damage to the cauda equina nerve roots and sciatic nerve.

Equipment

- Standard general surgical pack and suture material.
- Hand-held retractors such as Myerding retractors and an assistant. Alternatively, Gelpi or Weitlaner self-retaining retractors can be used but generally are not as efficient at making adjustments as an assistant using a hand-held retractor.
- Orthopedic surgical pack with AO-ASIF "clamshell" and Kern bone-holding forceps and Hohmann retractors.
- Bone screws and application equipment.
- Freer or Adson periosteal elevator.
- Suction with Frazier or Yankauer tips and electrocautery.
- Aiming device for bilateral luxations.

Technique

1. For unilateral SI luxation, perform a hanging limb prep by preparing the skin for aseptic surgery on the lateral and medial sides of the pelvic limb from the tarsocrural joint to the dorsal and ventral midline and from the mid-lumbar area to the base of the tail. For bilateral luxation, clip and prep the dorsal half of the pelvis from tail base to cranial to the ilial wings. For unilateral SI luxation, place the patient in lateral recumbency, and stabilize the pelvis by using a vacuum-assisted positioner bag. Secure the patient to the table. Rotating the operating table toward the surgeon with towels, inflatable positioners, or a tilting table greatly improves exposure and reduces back strain.
2. Make a dorsal approach to the sacroiliac joint.
   a. Make a skin incision over the crest of the ilium extending caudally along the shaft of the ilium.
   b. Incise and retract the cutaneous trunci muscle and the subcutaneous fat to expose the pelvic musculature.
   c. Obtain hemostasis by careful electrocoagulation.
3. Incise the middle gluteal muscle along its origin at the dorsal border of the wing of the ilium, and subperiosteally elevate it, beginning cranially. Medially, the sacrocaudalis and intertransversarius muscles and dorsal sacroiliac ligament are usually disrupted and therefore require little additional dissection.
4. Maneuver the ilium using Kern bone-holding forceps. Initially, displace the ilium ventrally and laterally to expose the articular surface of the sacrum.
5. Place a drill hole in the body of the sacrum. There is a C-shaped ridge that outlines the sacral body from caudodorsal, caudally to cranioventral (Fig. 107-6). Center the drill bit in the C for optimal alignment. Align the drill hole perpendicular to the midsagittal plane both dorsoventrally and craniocaudally. Make the depth of the drill hole at least two-thirds of the width of the sacral body, and measure the hole with a depth gauge and tap the hole. Be careful not to extend the tap to the end of the drill hole if the hole does not go all the way through the sacral body. Doing so will result in stripping of the threads in the drill hole and failure of the screw to properly engage the bone.
6. The site on the medial surface of the ilium that corresponds to the drill hole in the sacrum determines the exact location of the drill hole on the lateral surface of the ilium. The site can usually be felt but is often hard to see. Overdrill the hole in the ilium to allow compression of the SI joint with a fully threaded screw.
7. Determine the length of the screw by adding the thickness of the ilium to the depth of the sacral drill hole. Select the size of the bone screw using the guidelines in Table 107-3. Again, if the drill hole in the sacral body does not exit the opposite side of the body, do *not* place a screw that is longer than the hole and ilium. Doing so will result in stripping of the threads in the bone and failure of the screw to properly engage the bone. Use a screw that is 2 to 3 mm shorter than the measured depth to take into account slight errors in measurement.
8. Place the screw into the ilium until the tip of the screw just protrudes from the medial surface. Reduce the SI joint and insert and tighten the screw to stabilize and compress the joint.
9. Generally, a single large screw is sufficient. If indicated (usually only giant breed dogs or, occasionally, dogs with sacral fractures), place a second

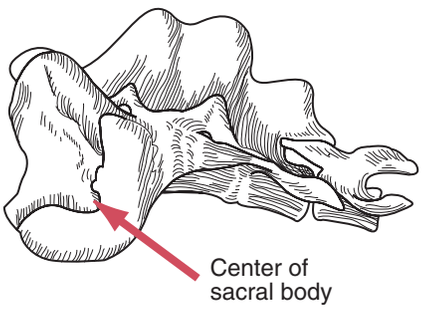

Figure 107-6. Anatomy of the sacrum. The sacroiliac joint surface appears as C, the center of which is the center of the sacral body. (From Evans S: Miller's Anatomy of the Dog, 2nd ed. Philadelphia: WB Saunders, 1993.)

Table 107-3. GUIDELINES FOR SCREW SIZES FOR REPAIR OF SACROILIAC LUXATION OF DOGS AND CATS

Body Weight (kg)	Screw Diameter (mm)/Type
<10	2.0–2.7
10–20	2.7–3.5
20–30	3.5–4.5
>30	4.5–5.5

screw to give two-point fixation. If two screws are to be placed, consider using the next size smaller screw than you would choose if only one screw is to be placed.

10. With bilateral fractures or luxations, screws may be placed bilaterally, or a single screw may be placed through both ilial wings and the sacral body. In the latter instance, use an aiming device to ensure that the drill hole is placed in the correct plane. The tip of the aiming device is placed in the center of the C of the contralateral surface of the sacrum and the drill guide placed on the C of the ipsilateral sacrum while the ilial bodies are depressed ventrally. If a single large screw is placed across both SI joints, the ipsilateral joint can be compressed but the contralateral joint is held in neutral fashion. If compression of both joints is desired and the size of the sacral body allows a 4.5-mm screw to be used, thread a nut onto the screw on the contralateral side for compression.
11. Close the middle and deep gluteal muscle fascia to the dorsal fascial insertion on the ilium or to the fascia of the sacrocaudalis and intertransversarius muscles with monofilament absorbable suture in a simple interrupted or cruciate pattern. Close the subcutis and skin as for other incisions.

Postoperative Care and Complications

Short Term

- See "Fractures of the Ilium."

Prognosis

- The prognosis is good to excellent with correct positioning of the bone screw and no neurologic damage.
- If the bone screw does not correctly engage the sacral body, fixation failure is more likely.
- If neurologic deficits are present after surgery, the prognosis is guarded.

FRACTURES OF THE ISCHIUM

- Fractures of the ischium are usually associated with fractures of other major weight-bearing regions of the pelvis. If appropriate surgery is performed to anatomically reduce and stabilize other, functionally more important fractures, additional fixation of ischial fractures is usually unnecessary.
- Fractures of the ischium are usually displaced ventrally as a consequence of tension created by the caudal thigh muscles (the biceps femoris, semitendinosus, and semimembranosus muscles).
- Occasionally, isolated fractures of the ischium may be encountered. If severe pain is associated with the fracture(s) or if displacement of the fracture fragments is such that the function of the hip joint is impaired, internal fixation may be indicated. Fixation of these fractures can be accomplished with small plates, lag screws, or diverging K-wires.

▼ ***Key Point*** Surgical repair of fractures of the ischium is usually unnecessary.

FRACTURES OF THE PUBIS

- Fractures of the pelvic symphysis, which is composed of the pubic and ischial symphyses, may be associated with fractures of other regions of the pelvis. This problem is more common in young animals in which bony union of the pelvic symphysis has not yet occurred.
- Anatomic reduction and stabilization of the other, functionally more important pelvic fractures usually makes surgical treatment of pubic fractures unnecessary. However, internal fixation of pubic fractures may occasionally be indicated.
- If pubic fractures are associated with a caudal abdominal wall rupture and herniation of abdominal or pelvic organs, surgical repair of the hernia may be assisted by internal fixation of the fractures. Interfragmentary wire is usually the preferred method for fixation.

NARROWED PELVIC CANAL ASSOCIATED WITH HEALED PELVIC FRACTURES

- Obstipation and dystocia are occasionally associated with healed pelvic fractures and a narrowed pelvic canal. This problem is most commonly encountered in cats and small dogs whose pelvic fractures are more likely to be managed conservatively.
- Manage dystocia by cesarean section or ovariohysterectomy (see Chapter 91).
- Operations designed to widen the pelvic canal have been described. Osteotomy of the ilium, the ischium, and the pubis, and lateralization of the caudal fragment with a plate, is the preferred method.
- In dogs and cats with obstipation as a consequence of a narrowed pelvic canal, subtotal colectomy may be necessary (see Chapter 70), because colonic dysfunction is not always relieved by corrective osteotomy or use of a motility modifier such as cisapride.

▼ ***Key Point*** If megacolon secondary to obstipation has been present for longer than 6 months, normal colonic motility does not always return after the bony pelvic canal has been widened, and obstipation can continue to be a problem. Subtotal colectomy is usually the preferred solution in cats. Resection of portions of the pelvic girdle is also an option and is probably preferred in dogs.

Chapter

108 Disorders of the Coxofemoral Joint

Marvin L. Olmstead

The coxofemoral joint is the most proximal of the free-moving joints of the pelvic limb. Surgery is frequently performed on or near this joint to treat conditions such as coxofemoral luxations and hip dysplasia. Avascular necrosis of the femoral head, which occurs infrequently, also can be treated surgically.

Anatomic considerations, diagnosis, and treatment of these conditions of the coxofemoral joint are discussed in this chapter.

ANATOMY

- The coxofemoral joint is a ball-and-socket joint made up of the femoral head and the acetabulum.
- In a normal animal, the joint capsule attaches to the rim of the acetabulum and around the circumference of the femoral neck just distal to the junction of the head and neck. When the limb is taken through range-of-motion exercises, the joint capsule helps maintain joint congruency.
- The ligament of the head of the femur runs between the acetabular fossa and the fovea capitis of the femoral head.
- The fovea and the fossa are sometimes mistakenly identified as radiographic abnormalities.

▼ ***Key Point*** The fovea causes a natural flattened area on the femoral head that can be mistaken for the flattening associated with hip dysplasia. The fossa creates a shadow that can be mistaken for a fracture line.

- The blood supply to the femoral head is extensive.
  - Small arterial loops arise from the iliolumbar artery cranially; the lateral circumflex femoral artery dorsally, cranially, and ventrally; and the medial circumflex femoral artery dorsally, caudally, and ventrally. They all penetrate the femoral head at the joint capsule attachment.
  - No significant blood vessels penetrate the femoral head from the ligament of the head of the femur.
- Several surgically important muscles have their insertions or origins close to the coxofemoral joint, either on the proximal femur or the pelvis (see Chapter 107).
  - The middle and deep gluteal muscles originate on the wing of the ilium and insert on the dorsal and cranial border of the greater trochanter.
  - The superficial gluteal muscle originates on the sacrum and the first coccygeal vertebra and inserts on the third trochanter.
  - The internal and external obturator and gemelli muscles insert in the caudal trochanteric fossa.
  - The vastus lateralis and intermedius muscles originate on the cranial aspect of the femur, whereas the rectus femoris originates on the pelvis cranial to the acetabulum.
  - The tensor fascia lata muscle originates along the caudolateral edge of the femur, covering the vastus lateralis muscle, and along the cranial edge of the biceps femoris muscle via three or more tissue slips.
  - The origin of the pectineus muscle is just ventral to the acetabulum.
- Two angles of surgical significance have been described in the proximal femur:
  - *Angle of inclination:* When the femur is viewed from a cranial position, the *angle of inclination* is the angle formed between a line that bisects the long axis of the femur and a line that bisects the femoral neck. In the normal dog, this angle is 135 to 145 degrees.
  - *Angle of anteversion:* When the femur is viewed from a straight lateral position, part of the femoral head is displaced forward of the femoral shaft due to the anteversion angle of the femoral neck. One method of measuring this angle involves taking radiographs of the femur with the dog on its back with the long axis of the femur positioned 90° to the radiographic plate and the stifle joint flexed 90°. The radiographic beam must pass directly down the center of the femur, parallel to its long axis. One line is drawn parallel to the caudal edge of the femoral condyles, and a second line is drawn that bisects the femoral head and neck. The angle created by the intersection of these two lines is the *anteversion angle,* which in normal dogs is 20 to 27 degrees.
- Abnormal alterations can occur in these angles during hip development, resulting in pathology in the hip or further distally in the limb.

COXOFEMORAL LUXATIONS

Most coxofemoral luxations are craniodorsal displacements of the femoral head; almost all others are caudoventrally displaced. Usually these are associated with motor vehicle accidents; thus, fully evaluate other organ systems for trauma (see Chapters 3 and 166), as well as coxofemoral joint evaluation.

Diagnosis

▼ ***Key Point*** Evaluate the coxofemoral joint for luxation by analyzing the gait, manipulating the hip, comparing hindlimb lengths, and obtaining two radiographic views of the pelvis.

- Animals with a luxated hip usually will not bear weight on the affected limb. If a craniodorsal luxation is present, the limb may be externally rotated and adducted.
- Range-of-motion evaluation of the hip may reveal grating and/or pain in the area of the coxofemoral joint.
- Evaluate the relationship between the caudal edge of the greater trochanter and the cranial edge of the ischiatic tuberosity to determine the position of the proximal femur.
  - If a craniodorsal luxation is present, there will be a wide space that does not close (as in the normal animal) when the limb is externally rotated.
  - If a caudoventral luxation is present, there will be no space between these two structures.
- When both hindlimbs are pulled directly caudally, they will be of equal length in a normal animal. If they are uneven in length, this is a strong indication that the coxofemoral joint is dislocated.
- The primary method of diagnosis is radiography of the coxofemoral joint to rule out fractures of the proximal femur, which can mimic a luxation on physical examination.
  - Evaluate the acetabulum for an avulsion fracture from the femoral head or acetabular fracture.

▼ ***Key Point*** Avulsion fracture of the femoral head is an absolute indication for surgery.

Treatment: Closed Reduction

If there is no avulsion fracture, perform closed reduction of the joint under general anesthesia.

- To perform reduction for a craniodorsal luxation:
  - Grasp the foot just distal to the talocrural joint and externally rotate the limb.
  - Then externally rotate the femoral head.
  - Apply distal traction to the limb until the femoral head is even with the acetabulum; then rotate the femoral head internally, causing it to drop into the acetabulum (Fig. 108-1).

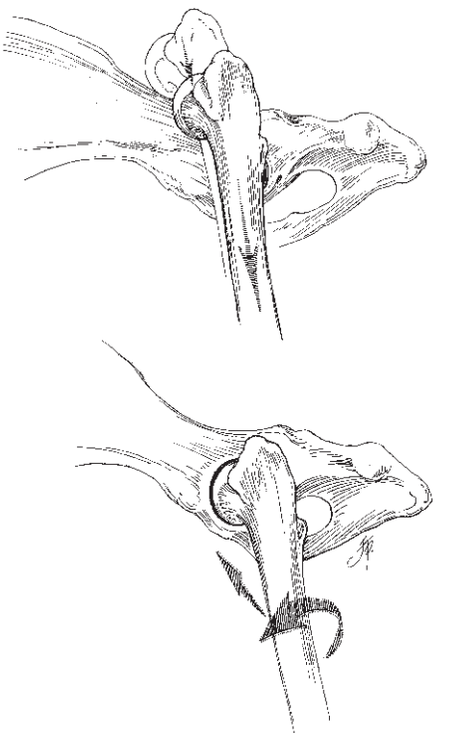

Figure 108-1. Closed reduction of the coxofemoral joint. External rotation and distal traction of the limb *(top)* is followed by internal rotation of the femoral head *(bottom)*.

- Reduce a caudoventral luxation by abducting and externally rotating the limb.
- The longer the femoral head is luxated craniodorsally, the more damage that is done to the dorsal joint capsule. An intact joint capsule is helpful in maintaining reduction.
- If the reduced hip easily luxates again, perform open reduction.
- If the reduced hip snaps solidly into position, place the hip in a flexion sling for a craniodorsal luxation; place the legs in hobbles for a caudoventral luxation (Fig. 108-2). Apply these restriction bandages for 10 to 14 days in the adult and 7 to 10 days in the immature animal. Limit exercise during this period, and for an additional 2 to 4 weeks.
- Examine the reduced hip physically on a daily basis or instruct the owner to do this, until the restriction bandage is removed.
- If there is any question about the hip's position, reevaluate with lateral pelvic radiographs. If the hip is reluxated, perform an open reduction.

Treatment: Open Reduction

Surgical Procedures

Objectives

- Reduce the luxated coxofemoral joint.
- Reconstruct as much soft tissue as possible.

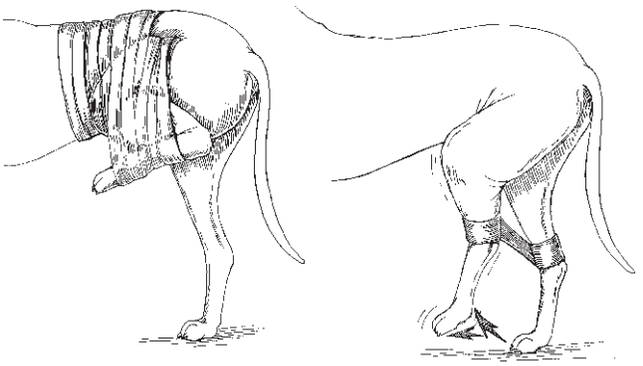

Figure 108-2. After reduction, use a flexion (Ehmer) sling for a craniodorsal luxation *(left)* and hobbles for a caudoventral luxation *(right)*.

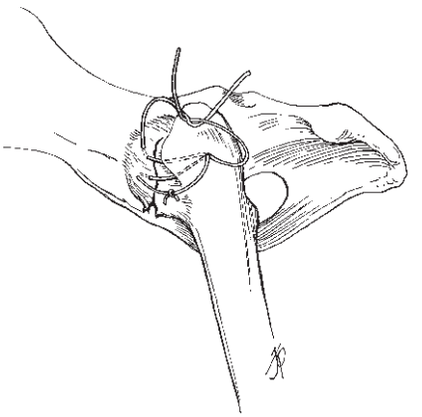

Figure 108-3. Surgical repair of luxation if adequate capsule remains attached to the acetabular rim. An anchor hole has been drilled in the proximal femur.

- Remove fibrous tissue from the acetabulum, remnants of the ligament of the head of the femur, and avulsed bone fragments that cannot be stabilized.

Equipment

- Standard surgery pack and suture material
- Special equipment as needed for specific procedures (noted in following text)

Techniques

1. The standard approaches used for surgical repair of luxations are the cranial lateral approach to the hip and the trochanteric osteotomy approach (see Chapter 107). Occasionally a caudal approach (caudal to the greater trochanter of the femur) to the coxofemoral joint may be used.
2. Initially, assess the overall damage and the status of supporting tissues, remove abnormal tissue and debris from the acetabular cup, and reduce the femoral head into the acetabulum.
3. Once reduced, use one or more stabilization techniques to secure the femoral head into the acetabulum.
4. If the joint capsule is minimally damaged and adequate capsular tissue is present on either side of the tear, suture the capsule (this may be the only support necessary).
   a. Use an absorbable monofilament suture of significant size (2-0, 0, or 1, depending on the animal's size), placed in a cruciate pattern.
   b. If adequate capsule is attached to the acetabular rim but not enough solid capsule is attached to the femoral neck, drill an anchor hole with lateral to cranial orientation in the proximal femur. Pass one-half of the suture strands through the hole and tie them tightly to the other half of the strands (Fig. 108-3).
5. The capsule may be so severely damaged that it cannot hold a conventionally placed suture. (This may occur if there is a long delay between the time of injury and repair.)
   a. In these cases suture support can be provided by making anchor points for the sutures. Drill a hole (as described in Step 4b above) for an anchor site in the femur. Place one to three bone screws (usually a 3.5-mm cortical screw) in the dorsal rim over the acetabulum as anchor points on the pelvis. Place the suture support between these to form a dorsal reinforcement (Fig. 108-4).
   b. Alternatively, place a temporary intramedullary pin in the proximal femur, parallel with the neck axis, and through the acetabular fossa. Be sure that the pin does not extend too far into the pelvic canal (Fig. 108-5). Keep the limb immobile with a flexion sling until the pin is removed, 7 to 10 days after surgery.

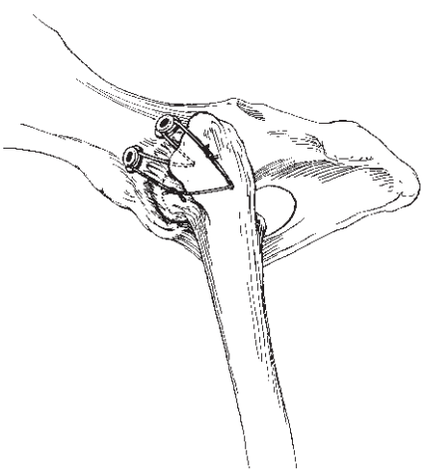

Figure 108-4. Suture support for coxofemoral luxation with a damaged joint capsule.

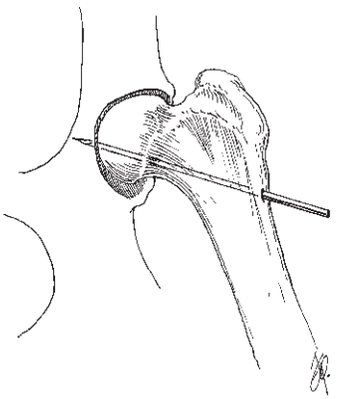

Figure 108-5. Temporary intramedullary pin for open reduction of coxofemoral joint.

   c. Another alternative is to place a toggle pin through a hole in the acetabular fossa with suture attached to it. This creates an artificial ligament between the head of the femur and the acetabulum. Pass the suture through a hole drilled, from lateral to medial, in the proximal femur. The hole enters the femur just dorsal to the third trochanter and exits at the insertion point of the ligament of the head of the femur on the femoral head. Pull all the suture strands through this hole, and then pass half the suture strands through a second hole in the femur drilled in a cranial to caudal direction. Tie the two sets of suture strands together.
6. Rotate the femoral head inwardly, and tighten the gluteal muscle pull on the femur by moving the greater trochanter to a position caudal and distal to its original location. This technique can be used with a trochanteric osteotomy approach.
   a. Do not depend on this technique as the sole means of stabilization.
   b. Any positional changes in gait caused by this relocation are temporary, because the gluteal muscles eventually will stretch.
7. If the femoral head does not remain in the acetabulum even with the application of support techniques, consider a primary salvage procedure such as excision arthroplasty or total hip replacement.

Postoperative Care and Complications

- If there is any doubt about the strength or security of the stabilization, place the limb in an immobilization sling or bandage for 7 to 14 days.
- Examine the sling or bandage and the visible parts of the limb daily for odor, chewing, swelling, pressure sore development, and slippage.
- Check the spatial relationship between the greater trochanter and the ischiatic tuberosity daily. If this changes, evaluate the position of the femur with lateral radiography of the pelvis. This can be accomplished without removing the sling.
- Restrict the animal's activity (leash walking only) for 1 month after the surgery.
- The most common complication following surgery or closed reduction is reluxation. If reluxation occurs after open reduction, consider excision arthroplasty or total hip replacement.

AVASCULAR NECROSIS OF THE FEMORAL HEAD

- This condition (also known as Legg-Perthes or Legg-Calvé-Perthes disease, osteochondritis juvenilis, and coxa plana) is most commonly found in adolescent, small-breed dogs of either sex; occasionally it occurs in large breeds.
- Trauma is not usually associated with the onset of lameness, and the lameness can progress to non–weight-bearing.
- The condition occurs bilaterally in about 15% of the animals.
- Changes in the proximal femur seen radiographically and grossly are the result of collapse and remodeling of the trabecular bone of the femoral head following the avascular episode.
- It is not clear what causes the femoral head to become avascular; following this, the bone revascularizes and remodels as the dead bone undergoes resorption.
- Weight bearing causes the weakened subchondral bone to collapse, which, in turn, leads to fracture of the cartilage.

Diagnosis

- Base the diagnosis on physical examination and radiographic findings. Abduction of the limb often elicits a pain response, even before radiographic signs are evident. Crepitus is sometimes observed with flexion and extension of the joint.
- The limb may be shortened and the muscles atrophied.
- Radiographs are needed for a definitive diagnosis. The ventrodorsal straight-leg view of the pelvis is the most helpful in assessing the femoral heads.
  - The joint space may be widened, and numerous foci of decreased bone density may be seen in the femoral head and neck.
  - In advanced stages, there may be irregular indentations, flattening, and possibly fragmentation of the femoral head. Osteophytes on the acetabular rim and secondary osteoarthritis in the joint may also be seen.

Treatment

Some dogs respond to non-surgical treatment including limited activity and analgesics. However, in most cases surgery is ultimately necessary.

▼ ***Key Point*** Surgical treatment of avascular necrosis of the femoral head has a much higher success rate than non-surgical treatment.

Preoperative Considerations

- Because most of the dogs with this condition are small breeds, excision arthroplasty (discussed below) is the most common procedure performed for this disease.
- In large dogs, consider total hip replacement (see next section) as an option.

Surgical Procedures

Objectives

- Eliminate painful bone-to-bone contact.
- Preserve hip motion as close to normal as possible.

Equipment

- Standard surgical pack and suture material
- Specialized equipment, depending on the specific procedure

Technique

- Perform either excision arthroplasty or total hip replacement (see subsequent sections in this chapter).

HIP DYSPLASIA

Hip dysplasia is a faulty development of the hip joint characterized by varying degrees of joint laxity that permit subluxation early in life. As the condition progresses, deformation of the architecture of the acetabulum and femoral head is accompanied by the development of degenerative joint disease.

▼ ***Key Point*** Hip dysplasia is the most prevalent disorder of the canine hip and the most important cause of osteoarthritis in that joint.

- Although almost all breeds are at risk, hip dysplasia most commonly affects large- and giant-breed dogs, and its mode of inheritance is polygenic.
- Joint instability occurs as muscle development and maturation lag behind the rate of skeletal growth.
- The first 60 days of life are the most critical period for the developing soft tissue structures.
- When the stress and weight exerted at the hip joint exceed the strength limits of the supporting soft tissues, joint instability results.

Diagnosis

Base the diagnosis of hip dysplasia on the history, physical examination, and radiographic evaluation of the coxofemoral joints.

Physical Examination

- Lameness of the hindlimb and gait abnormalities frequently are seen, especially after exercise periods; motion of the coxofemoral joint often is limited because of joint pain.
- Joint laxity and pain may be elicited by examination of the range of motion of the coxofemoral joint. Joint laxity is present in mild to moderately dysplastic animals.
- *Ortolani sign:* With a hand placed on the knee of the affected limb, apply dorsal pressure to the femur while moving the bone from an adducted to an abducted position.
  - The click or pop that is heard or felt as the femoral head reenters the acetabulum is a positive Ortolani sign and an indication of joint laxity.
  - If the hip is normal or if arthritic changes in the acetabulum preclude movement of the femoral head in and out of the acetabulum, the Ortolani sign is negative.

Radiography

Radiographs are needed for a positive diagnosis of hip dysplasia.

- In early cases, proper positioning of the ventrodorsal view is extremely critical; in advanced stages, the changes are pronounced and positioning is less important.
- Radiographic changes associated with hip dysplasia range from subluxation of the femoral head to severe secondary degenerative joint disease, with marked alterations in the architecture of the femoral head and the acetabulum.

Treatment

Medical

Non-surgical therapy is recommended for animals mildly affected by hip dysplasia and those with an initial episode of lameness.

- Restrict activity to allow the inflammatory response within the joint capsule to subside.
- Give medication to relieve pain and reduce the inflammation associated with the degenerative joint disease. Carprofen (2.2 mg/kg q12h PO) or deracoxib (1–2 mg/kg q24h PO) is sometimes adequate.

▼ ***Key Point*** When non-surgical therapy is no longer effective or if the patient is constantly disabled over an extended period, consider one of the following surgical therapies.

Surgical Procedures

Various surgical procedures that have been effective in the treatment of hip dysplasia are discussed. An improved quality of life for the patient is the ultimate goal. The procedures are not listed in any order of preference.

Triple Pelvic Osteotomy

Preoperative Considerations

- In the ideal candidate for the procedure, there is some coverage of the femoral head by the acetabulum, the Ortolani sign is positive, and there are no signs of degenerative joint disease in the hip.
- Most dogs that meet the above criteria are 5 to 11 months of age.
- The animal should show clinical signs associated with hip dysplasia.

Objectives

- Increase the amount of acetabular coverage over the femoral head by rotating the acetabular portion of the pelvis.
- Maintain the normal architecture and congruency of the femoral head and acetabulum.
- Prevent or minimize the development of degenerative joint disease.

Equipment

- Standard surgical pack and suture material
- Equipment necessary to insert bone screws
- Bone plates designed for pelvic osteotomy (e.g., pelvic osteotomy plate; Synthes USA, Paoli, PA; Slocum Enterprises, Inc., Eugene, OR)
- Orthopedic wire
- Oscillating bone saw
- Osteotomes

Technique

1. Expose the ilium, pubis, and ischium.
   a. Make a lateral approach to the wing of the ilium with dorsal elevation of the middle and deep gluteal muscles (see Chapter 107).
   b. Approach the pubis through a second incision over the pectineus muscle or through the lateral approach to the ilium by retracting the vastus muscles caudally and the rectus femoris muscle cranially.
   c. The approach to the ischium depends on the site of the osteotomy. If the osteotomy is performed from the ischial tuberosity cranial to the obturator foramen, make an approach directly over the tuberosity. If the osteotomy is performed just caudal to the acetabulum, extend the lateral incision and reflect the biceps femoris muscle caudally.
2. Perform osteotomies at the ilium, pubis, and ischium so that the acetabulum can be rotated in a manner that provides more dorsal coverage of the femoral head.
3. Hold the tilt on the acetabulum in place with bone plates if a transverse osteotomy has been performed, or with screws and orthopedic wire if a stair-step osteotomy is done.
4. The osteotomy of the ischium may be stabilized with orthopedic wire.
5. Close the incisions routinely.

Postoperative Care and Complications

- Restrict activity for 8 weeks.
- Immediate postoperative radiographs may indicate no apparent change in the acetabular coverage of the femoral head. In some cases, subsequent radiographic evaluations reveal improved acetabular coverage and a femoral head well seated in the acetabulum.
- Occasionally, the desired amount of femoral head coverage is never achieved. This most often occurs when a patient has a totally luxated hip or when many degenerative changes are present at the time of surgery.
- If the acetabulum is rotated too far at the time of surgery, extension of the coxofemoral joint will be limited and result in a gait alteration.

Femoral Head and Neck Excision Arthroplasty

Preoperative Considerations

This palliative, salvage procedure can be performed in dogs of all ages; it is most successful in dogs weighing less than 18 kg. This procedure does not preserve the bony articulation of the head of the femur to the pelvis. Therefore, full locomotive potential of the leg will not be achieved.

Objectives

- Remove the femoral head and neck.
- Eliminate painful contact points in the joint.
- Allow a fibrous tissue joint ("false joint") to replace the ball-and-socket joint.

Equipment

- Standard surgical pack and suture material
- Mallet and osteotome, oscillating bone saw, or bone cutter
- Rongeur or rasp

Technique

1. Use a cranial lateral approach or a ventral approach (pectineal myotomy near its origin on the prepubic tendon).

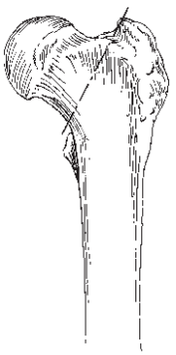

Figure 108-6. Site of osteotomy for femoral head and neck excision arthroplasty.

2. Perform osteotomy of the femoral neck by cutting the bone from the lateralmost edge of the trochanteric fossa to a point just dorsal to the lesser trochanter (Fig. 108-6).
3. Remove the femoral head and neck. It may be necessary to incise the ligament of the head of the femur. If using a ventral approach, this is done following osteotomy of the femoral neck. If using a cranial lateral approach, this is done before osteotomy so that the head and neck can be better exposed by rotating the femur externally 90° and luxating the femoral head from the acetabulum.
4. Examine the remaining portion of the proximal femur for rough areas or bone spurs and remove any, if present.
5. If necessary to eliminate bony contact, remove a portion of the dorsal acetabular rim.
6. Close the incision routinely.

Postoperative Care and Complications

- Encourage use of the operated limb 3 to 7 days postoperatively. Use passive range-of-motion exercise on patients that do not willingly use the limb. (See Chapter 95 for more information on physical therapy.)
- Obtain radiographs to document the amount and configuration of the remaining bone.
- On the average it will take 2 to 3 months for the limb to reach its satisfactory functional level. In some animals the gait is indistinguishable from normal; in others an obvious gait abnormality is present.
- Because a false joint is formed after surgery, all animals have a limited range of motion. The clinical significance of this limitation depends on the activity of the animal, the animal's size, and the amount of restrictive scar tissue that is present.
- Because normal muscle mass is not regained, there may be marked atrophy of the limb.
- The femur may displace dorsally relative to the pelvis. If the displacement is large, a post-legged gait with the stifle at nearly full extension can result.

Pectineal Myectomy

Preoperative Considerations

- This procedure can be done on dogs of all ages.
- Performance of this procedure does not exclude attempting other procedures, should this be unsuccessful.
- This procedure does not alter the progression or intensity of changes in the joint caused by hip dysplasia, but may palliate joint pain.

Objectives

- Remove all of the belly of the pectineus muscle bilaterally.
- Decrease tension on the medial aspect of the coxofemoral joint capsule.

Equipment

- Standard surgical pack and suture material

Technique

1. Place the patient in a dorsal recumbent frog-leg position.
2. Make an incision 10 to 16 cm long over the pectineus muscle on the medial aspect of the thigh.
3. Isolate and incise the muscle at its origin proximally and its muscle-tendon junction distally. Take care to avoid the femoral artery and vein that pass just lateral to the middle of the muscle belly.
4. Close the dead space by meticulous suture of the fascia and subcutaneous layers.

Postoperative Care and Complications

- Restrict activity for 2 weeks.
- The most common postoperative complication is seroma formation. This requires aspiration or drainage only if the seromas become very large. Usually the fluid is absorbed and no treatment is needed.
- In some dogs, the gait is noticeably improved and there seems to be marked pain relief. The length of time for which this relief persists varies.

Total Hip Replacement

This procedure, which provides an artificial femoral head and artificial acetabular cup, demands a high degree of technical proficiency and strict adherence to good aseptic and surgical techniques. Refer the patient to an experienced specialist.

Preoperative Considerations

- The growth plates must be closed before this procedure can be performed; thus, the animal must be at least 9 months of age. There is no upper age limit,

but older animals should be fully evaluated for systemic disease.
- Depending on the size of the femur and the depth of the acetabular cup, the minimum weight of the animal is 13 to 18 kg.
- Consider total hip replacement when a disabling condition of the hip exists with no other systemic or hindlimb pathology. The dog must be totally free of infection anywhere in the body.

▼ ***Key Point*** Both cemented and cementless hip prostheses are available for use in dogs, but clinical studies have not indicated superiority of one system versus the other.

Objectives

- Replace the degenerative coxofemoral joint with one of the following:
  - Cemented implant: high-density polyethylene cup and a cobalt chrome femoral prosthesis.
  - Cementless implant: metal-backed high-density polyethylene cup and a cobalt chrome stem.
  - Hybrid implant: cemented prosthesis on one side of the joint, cementless prosthesis on the other side of the joint.
- Provide a mechanically sound, pain-free joint that will last the dog's life.

Equipment

- Standard surgical pack and suture material
- Reaming and implantation instruments designed specifically for canine total hip replacements (BioMedtrix, Allendale, NJ)
- High-density polyethylene cup or a metal-backed polyethylene cup that promotes bone in-growth into the metal surface, a cobalt chrome femoral head, and a cobalt chrome femoral stem, or a special chrome stem that promotes bone in-growth into a portion of the stem (BioMedtrix)
- Oscillating bone saw
- Power drill

Technique

1. Approach the coxofemoral joint through a craniolateral approach.
2. Remove the femoral head and a portion of the neck along an osteotomy line that parallels the collar of the prosthesis, and ream the acetabular cup to the medial pelvic wall. Ream and broach the medullary cavity of the femur to accept a trial femoral stem.
3. Cement the prosthetic acetabular cup and the femoral stem into position with polymethylmethacrylate (Howmedica) or impacted into place so that a press fit secures the prosthesis until bone grows into the metal surface.
4. After the femoral head is secured onto the stem, reduce it into the cup.
5. Close the joint capsule tightly; close the remaining tissues in layers.

Postoperative Care and Complications

- Restrict activity to leash walking for 2 months, after which the dog can return to full activity, even if it includes vigorous work.
- Over 95% of dogs treated with this procedure have satisfactory function if established techniques are followed. Increased muscle mass, extended exercise tolerance, and improved hip motion commonly are observed.
- Although degenerative joint disease usually is present in both hips, 80% of dogs receive sufficient relief that the other hip does not need to be replaced. The limb with the hip replacement becomes dominant, thus reducing the unoperated limb's weight-bearing load.
- Complications include infection, implant loosening, luxations, fractures, and neurapraxia. The majority of these can be successfully treated.

Chapter

109 Fractures of the Femur

Peter Shires

Surgery of the femur usually is performed to repair fractures. Biopsy of tumors or cysts and obtaining samples for bone cultures are less common reasons for femoral surgery. The femur is the bone most commonly associated with traumatic fractures in the dog. Surgical repair of femoral injuries may be divided into surgery of the proximal, diaphyseal, and distal femur.

PROXIMAL FEMUR

Anatomy

- The proximal femur includes the femoral head, the femoral neck, the trochanters, and their attachments to the femoral shaft.
- The ligament of the head of the femur runs from the fovea capitis of the femoral head to the acetabular fossa.
- The articular surface and epiphysis of the femoral head are separated from the femoral neck by the capital physis.
- The joint capsule of the hip joint inserts at about the midpoint of the femoral neck.
- The primary blood supply to the epiphysis of the femoral head is through vessels running longitudinally in folds of the joint capsule (Fig. 109-1).
- The greater trochanter is the point of attachment for the deep and middle gluteal muscles and the piriformis muscle (see Fig. 109-1).
- The trochanteric fossa is the site of insertion of the internal obturator, external obturator, and the gemelli muscles.
- The articularis coxae inserts on the cranial aspect of the femoral neck.
- The lesser trochanter on the medial aspect of the proximal femur is the site of insertion of the iliopsoas muscle.
- The third trochanter (lateral and distal to the greater trochanter) is the site of insertion of the superficial gluteal muscle and the origin of the quadratus femoris muscle and part of the vastus lateralis muscle.
- The proximal femur is the site of origin of the vastus lateralis, vastus medialis, vastus intermedius, quadratus femoris, and adductor longus muscles and of the proximal part of the adductor magnus and adductor brevis muscles.
- The deep muscles of the femur are covered by the tensor fasciae latae and biceps femoris muscle confluence.
- The sciatic nerve runs caudal to the hip on top of the gemelli, internal obturator, and quadratus femoris muscles. It is covered by the biceps femoris and the superficial gluteal muscles.
- The femoral artery, nerve, and vein are very superficial in the femoral triangle on the medial aspect of the proximal to midfemur.
- The nutrient artery for the femur enters caudally just distal to the greater trochanter as a branch of the medial circumflex femoral artery.

PROXIMAL FEMORAL FRACTURES

Preoperative Considerations

▼ ***Key Point*** Evaluate the entire patient for trauma-related problems; neurologic, urologic, and intrathoracic injuries are common with blunt trauma.

- Stabilize the patient before considering surgery.
- Obtain a minimum of two radiographic views to evaluate the proximal femur.
- Give intraoperative broad-spectrum antibiotics intravenously (at induction of anesthesia; repeat if necessary) if the surgery will take longer than 2 hours.
- Continue treatment with systemic antibiotics if the fracture is open (see Chapter 120).

Surgical Procedure

Objectives (for All Proximal Femoral Injuries)

- Expose the femoral neck.
- Osteotomize the femoral neck.
- Repair fractures of the capital physis and femoral neck.

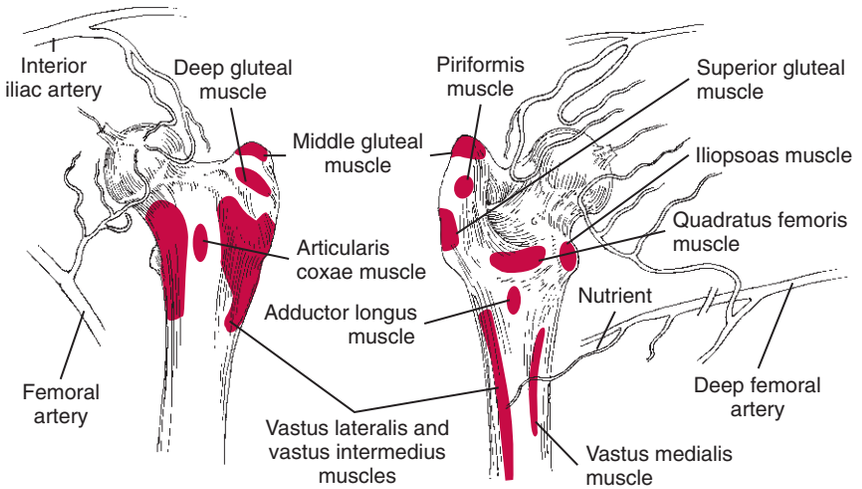

Figure 109-1. *Left,* Cranial view; *right,* caudal view. Proximal femur showing the muscle attachments and main blood supply.

- Expose the greater trochanter for osteotomy and fixation.
- Expose the proximal femur for fracture repair.

Equipment

- Standard general instrument pack and suture material
- Orthopedic instruments, as required (e.g., for fracture fixation, ostectomy, subtrochanteric derotational osteotomy), including:
  - Intramedullary pins
  - Orthopedic and Kirschner wires (K-wires)
  - Osteotomes and mallet or oscillating bone saw
  - Plates and screws
  - Bone reduction forceps
- Self-retaining retractors (e.g., Gelpi, Weitlaner)
- Hohmann retractors (for femoral head ostectomy)

Operative Techniques

Techniques are similar for all objectives listed. Increased exposure is necessary to accomplish more complicated procedures. Techniques are described in order of procedure completion.

Common (Craniolateral) Approach

Technique

1. Prepare the affected leg for aseptic surgery.
2. Make a linear or slightly curved skin incision centered over the cranial aspect of the greater trochanter, starting near the dorsal midline and ending on the cranial aspect of the proximal one-third of the femur.
3. Incise the subcutaneous tissue to expose the tensor fasciae latae muscle. Incise two layers of the fasciae latae along the cranial border of the biceps femoris muscle to expose the underlying vastus lateralis muscle.
4. Extend the fascial incision proximally through the gluteal fascia along the cranial border of the superficial gluteal muscle.
5. Bluntly dissect the loose connective tissue between the vastus lateralis muscle and the gluteal muscles to allow insertion of self-retaining retractors to expose the joint capsule.

▼ ***Key Point*** Several vessels, including the cranial femoral artery and vein and the branches of the femoral nerve, crisscross the connective tissue and will be significantly damaged if dissection is rough.

6. Using a scalpel, incise through the joint capsule from the acetabulum, longitudinally along the femoral neck, to the proximal femur at the insertion of the vastus lateralis muscle.
7. If necessary, partially incise the tendon of insertion of the deep gluteal muscle and the origin of the vastus lateralis muscle to increase exposure of the femoral neck.

Femoral Head and Neck Ostectomy

- See Chapter 108.

Femoral Neck/Capital Physeal Fracture Repair

Technique

1. Rotate the femur outward to expose the fractured surface.
2. Retrograde a K-wire of appropriate size through the femoral neck fracture surface to exit the lateral surface of the proximal femur.
3. If a compression (lag) screw is used, drill a gliding hole through the center of the femoral neck to exit the lateral surface of the proximal femur.
4. If multiple K-wires are used, preplace them all through the femoral neck, using the same technique as described in Step 2 above.

5. Withdraw the wires from the lateral surface until the pinpoints are flush with the fracture surface.
6. Rotate the femur inward to reduce the fracture.
7. Rotate the femoral head until the fracture is anatomically aligned.
8. Advance one K-wire into the femoral head without penetrating the articular surface (Fig. 109-2, *left*).
9. If a compression screw is used, insert a drill sleeve into the gliding hole and drill into the femoral head. The articular cartilage should not be penetrated. Measure and tap the hole and place a screw of suitable length. Compress the fracture without penetrating the articular surface with the screw (Fig. 109-2, *right*).
10. If K-wires are used, drive these individually into the head without penetrating the articular cartilage.

▼ ***Key Point*** Lifting and rotating the proximal femur allows limited examination of the femoral head surface to check for penetration by the implants. Movement of the femur should be unrestricted and smooth and should not produce crepitation.

11. Bend the K-wires over close to the lateral aspect of the trochanter and cut them off as short as possible.

Trochanteric Osteotomy

This technique is used for exposure of the hip joint as part of open reduction of coxofemoral luxation or as an approach to acetabular fractures (see Chapters 107, 108).

Technique

1. Incise the tendon of the superficial gluteal muscle near the third trochanter.
2. Retract the belly of the superficial gluteal muscle proximally.
3. Incise the proximal origin of the vastus lateralis muscle and elevate the muscle to expose the trochanteric osteotomy (or fracture) site, or the femoral neck fracture site.
4. If necessary for exposure, incise and elevate the adductor muscle origin caudally.
5. If a trochanteric osteotomy is planned, pass a curved Kelly forceps under the deep gluteal insertion.
6. Using the curved Kelly forceps as a guide, direct the osteotome (or pull the Gigli wire through), and osteotomize the trochanter off the proximal femur, leaving the medial and deep gluteal muscles attached to the osteotomized bone.

▼ ***Key Point*** Identify and protect the sciatic nerve, which is caudal to the femur and can be traumatized by excessive manipulation.

Trochanter Fracture Osteotomy Repair

Technique

1. Drill a hole transversely through the femur at least 1 cm distal to the osteotomy (fracture) site.
2. Thread a strand of 18-gauge orthopedic wire through the hole.
3. Clamp the proximal fragment in its anatomic position with a small-fragment bone reduction forceps.
4. Drive two appropriate-size K-wires from the proximal end of the trochanter, across the osteotomy (fracture) line, and into the femur until they are seated in compact bone.
5. Pass one free end of the orthopedic wire proximal to the pins and under the gluteal tendons (Fig. 109-3).

▼ ***Key Point*** Form a figure-eight configuration (tension band wire) around the pin ends and through the hole.

6. Twist the free ends of wire together and twist a loop of wire on the other crossover strand.
7. Tighten both twists evenly until the osteotomy (fracture) is securely closed.
8. Bend the pin ends over laterally and cut off the excess.
9. Cut the twisted wire, leaving two twists in place.

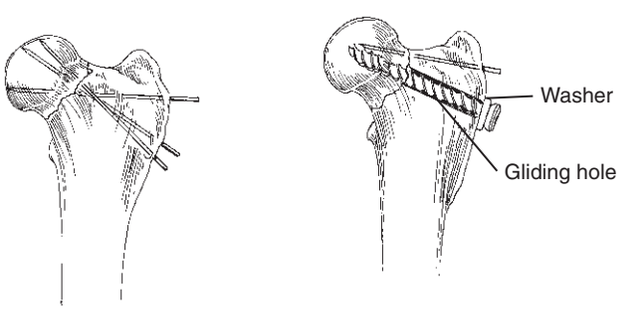

Figure 109-2. Fixation of femoral neck fractures. *Left,* Multiple Kirschner wires; *right,* compression screw and Kirschner wire.

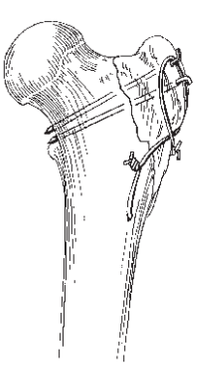

Figure 109-3. Tension band fixation of trochanter fracture or osteotomy.

Proximal Femoral Shaft Fracture Repair

Technique

1. Extend the subperiosteal/sub–vastus lateralis dissection distally and elevate the adductor caudally until the fracture is adequately exposed.

▼ ***Key Point*** Both muscles (vastus lateralis and adductor) can be entirely released if necessary, but they must be reattached.

2. Repair the fracture(s) with appropriate orthopedic techniques and implants.
3. Use cerclage wires, hemicerclage wires, pins, K-wires, skewers, and lag screws to rebuild the fragments into a two-piece fracture.
4. Stabilize the fracture with a plate and screws or an interlocking nail.

▼ ***Key Point*** The femoral neck and trochanters provide excellent anchors for screw fixation.

5. Place an autogenous cancellous bone graft harvested from another site (e.g., proximal tibia or wing of ilium) around the fracture to aid in healing.
6. Reattach the vastus lateralis and adductor muscles to their origins with absorbable sutures.
   a. If necessary, elevate the periosteum to obtain enough tissue for suturing.
   b. Alternatively, use surrounding musculature or drill holes in the femur to anchor the proximal ends of these muscles.

Closure

1. Close the incised tendon of the superficial gluteal muscle with several mattress sutures using absorbable suture material.
2. Close the fascia of the gluteal muscles to the cranial edge of the superficial gluteal muscle with a simple continuous absorbable suture.
3. Close the fascia of the tensor fasciae latae muscle to the cranial edge of the biceps femoris muscle with a simple continuous absorbable suture.
4. Close the subcutaneous tissue with a simple continuous absorbable suture.
5. Close the skin with simple interrupted, monofilament, non-absorbable sutures.

Postoperative Care

Femoral Neck/Capital Physeal Fracture Repair

- Take two radiographic views of the repair.
- Restrict activity (cage rest) for 3 days, and then allow leash walking only for 2 to 3 weeks.
- Perform non–weight-bearing physical therapy (swimming, passive flexion-extension exercises).
- Repeat radiographs of the fracture at 4 weeks to evaluate healing.
- If healed, start a gradual return to full function.
- Remove pins (K-wires) if palpable, any time after 6 weeks if the bone has healed radiographically.
- Remove screws and plate only if causing a problem and only after 6 months.

Trochanteric Osteotomy/Fracture

- Recommendations are the same as for femoral neck/physeal fracture repair, except:
  - Restrict activity (cage rest) for at least 24 hours.
  - Repeat radiographs at 6 weeks to evaluate healing.

Proximal Femur Fracture

- General recommendations are the same as for femoral neck/physeal fracture repair, except:
  - Remove implants, if indicated, after 3 to 6 months.
  - The proximal femur is subject to considerable and variable stresses that jeopardize all fixations. If any doubt exists as to the stability of a fracture fixation, a conservative postoperative approach is recommended.
  - Apply an Ehmer sling (see Chapter 108) to prevent weight bearing during the initial 1 to 2 weeks of healing.
  - Start physical therapy (non–weight-bearing) and gradually increase controlled activity from week 2 to week 4.
  - After week 4 obtain repeat radiographs before starting significant activity levels.

Postoperative Complications

- Femoral neck/physeal fracture healing includes a period during which increased vascularity causes bone demineralization of the femoral neck. This "apple coring" effect is transient and of no significance unless the fracture is unstable or infected. Monitor with serial radiographs if necessary.
- Implant failure and improper selection or application of orthopedic techniques can lead to failure of healing.

FEMUR DIAPHYSIS

Anatomy

- The shaft of the femur has muscle attachments on its caudal and medial aspects. Proximally and laterally, the adductor muscles are attached to most of the length of the femur. The origin of the vastus medialis muscle is found medial and proximal, whereas the insertion of the pectineus muscle is medial and distal. The insertion of the semimembranosus muscle is distal and medial.
- The femoral shaft is encased in a sheath of muscles including the vastus medialis, lateralis, and inter-

medius; rectus femoris; semimembranosus; semitendinosus; and pectineus muscles.
- On the lateral aspect, this muscle mass is surrounded by a fascial compartment made up of the tensor fasciae latae and biceps femoris muscle sheaths. Medially the sartorius muscle continues this fascial sheath.
- The femoral artery and nerve pass medially down the length of the shaft within this compartment.
- The sciatic nerve is lateral to the semimembranosus muscle and caudal to the vastus lateralis muscle.

FEMORAL SHAFT FRACTURES

Preoperative Considerations

- See under "Proximal Femur."

Surgical Procedure

Objectives

- Expose the femoral shaft.
- Repair fractures of the femoral shaft.

Equipment

- Standard general instrument pack and suture material
- Orthopedic instruments as required for pinning, wiring, interlocking nail, and plating
- Self-retaining retractors (e.g., Gelpi, Weitlaner) or an assistant with hand-held retractors (e.g., Army-Navy)
- Several bone-holding forceps (e.g., Self-Retaining Speed Lock, Synthes; Lane, Kirschner)

Technique

1. Prepare the patient's leg for aseptic surgery.
2. Incise the skin from the trochanter to the patella on the cranial lateral aspect of the femoral shaft.
3. Expose the tensor fasciae latae muscle where it joins the biceps femoris muscle aponeurosis.
4. Incise both fascial layers, from the trochanter to the patella.
5. Retract the biceps femoris muscle caudally and the vastus lateralis muscle cranially.
6. Incise the intermuscular septum between the vastus lateralis and the biceps femoris muscles to expose the femoral shaft.
7. Bluntly separate the vastus intermedius muscle from the cranial aspect of the femur (Fig. 109-4).
8. Elevate (only as much as necessary) the adductor muscles subperiosteally on the caudal aspect of the femur; minimal elevation helps to preserve the blood supply to the bone.
9. Isolate the bone fragments and clean the fracture surfaces carefully.

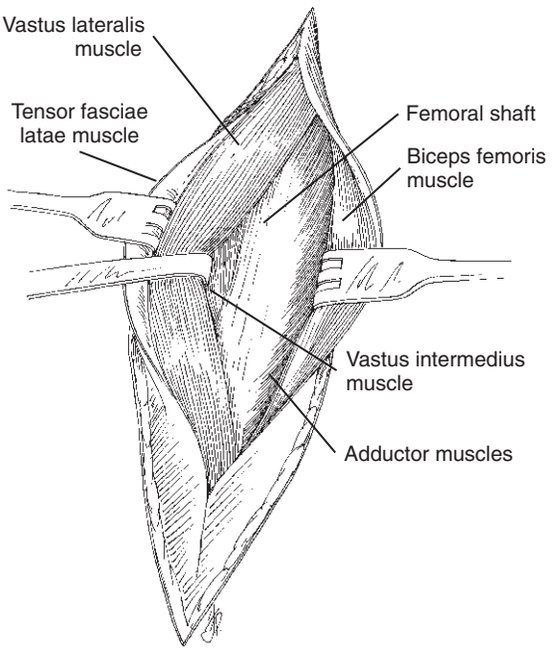

Figure 109-4. Lateral approach to the midshaft of the femur.

▼ ***Key Point*** Remove fragments that are without muscle attachments and wrap them in blood-soaked sponges; maintain all soft tissue attachments to the remaining fragments.

10. Rebuild the proximal and distal fragments with the appropriate orthopedic devices until a two-piece fracture remains. A combination of cerclage, hemicerclage, and K-wires and interfragmentary screws, skewer pins, and figure-eight wire can be used to achieve a stable, two-piece fracture.
11. Use avascular bone fragments only if they are necessary to obtain stability in the fracture. These fragments must be securely fixed in order to be incorporated into the healing callus.
12. Reduce and align the two major fragments and apply the appropriate orthopedic fixation device to maintain these in alignment under stable conditions.
13. In general, a two- or three-piece fracture with long oblique fracture lines can be rebuilt with cerclage wire and supported with one or more normograde (driven proximal to distal) intramedullary pins (Fig. 109-5, *left*). Intramedullary pins also can be driven retrograde from the fracture site to the proximal femur.

▼ ***Key Point*** Extend and adduct the hip joint while driving the intramedullary pin through the proximal femur to avoid trauma to the sciatic nerve.

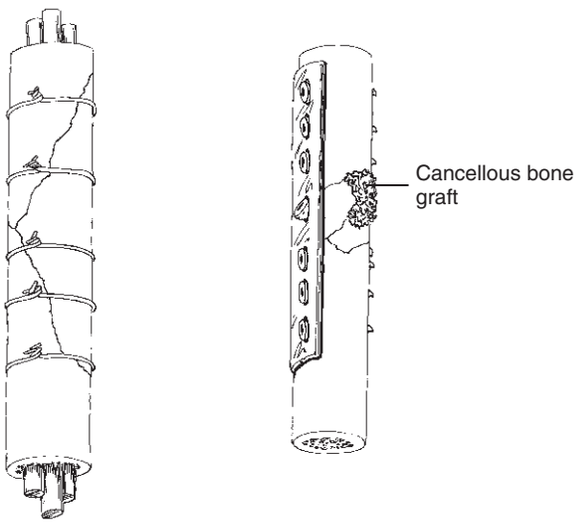

Figure 109-5. Diaphyseal femoral fracture fixation. *Left,* Simple long oblique fracture repaired with cerclage wires and intramedullary pins; *right,* comminuted transverse fracture repaired with a plate, screws, and cancellous bone graft.

a. Reduce the fracture and drive the pin into the distal fragment.
b. Highly comminuted fractures are relatively unstable after being rebuilt and require added fixation devices to maintain alignment and stability. In these less stable situations, plating techniques or a combination of intramedullary and external skeletal fixation may be necessary to achieve stability (Fig. 109-5, *right*).

▼ ***Key Point*** All implants should lie directly against the bone; hence limited local muscle elevation is necessary to attach wires and plates.

14. Where accurate reconstruction and stabilization of the bone fragments is considered inappropriate because of small size and a high degree of comminution, one of several minimally invasive techniques should be considered. Closed or limited exposure of the bone through keyhole incisions can be used to apply interlocking nails, plates, and pin-plate combinations.
15. Harvest autogenous cancellous bone graft from another site and pack around the fracture before closure. This is especially prudent if defects are present after reconstruction.
16. Flush the area copiously with warm normal saline solution *before* placing the cancellous bone graft in defects.

Closure

1. Close the fascia of the tensor fasciae latae to the biceps femoris with absorbable sutures in a simple interrupted pattern.
2. Close the subcutaneous tissue and skin routinely.

Postoperative Care

- General measures are the same as for femoral neck/physeal fracture except
  - Use a non–weight-bearing sling if the fixation is unstable in any respect.
  - Start leash walking at 3 to 5 days if the fixation is stable. Increase exercise slowly over a 4-week period.
  - Repeat radiographs at 6 weeks to evaluate fracture healing.
  - Remove implants, if indicated (e.g., intramedullary pins usually are removed), when there is radiographic evidence of healing; with intramedullary pins this is generally 6 to 8 weeks postoperatively.

Postoperative Complications

- Orthopedic implant failure, improper implant selection, and improper use of implants are the most common causes of fracture collapse, malunion, and nonunion (see Chapter 122). Osteomyelitis may result from contamination.
- Large devitalized bone fragments that are not stabilized can lead to chronic draining tracts and osteomyelitis.
- Extensive subperiosteal dissection and rough handling of bone can produce an excessive periosteal reaction and large callus formation.

DISTAL FEMUR

Anatomy

- The distal femur includes the metaphysis, condyles, trochlea, and patella.
- The quadriceps muscle group inserts on the proximal tibia through the patellar tendon, which includes the patella within it.
- The two heads of the gastrocnemius muscle originate on the distal, caudal aspects of the medial and lateral metaphyses, and include the fabellae in their tendons of origin.
- The superficial digital flexor muscle originates just medial to the lateral head of the gastrocnemius muscle next to the fabella.
- The long digital extensor muscle originates in a fossa on the distal lateral condyle.
- The popliteus muscle originates on the caudal lateral condyle.
- The joint capsule on the stifle extends from above the trochlea, around both condyles, and underneath the fabellae bilaterally.
- The aponeuroses of the biceps femoris muscle laterally and the sartorius muscle medially blend with the fibrous joint capsule over the distal femur.
- The femoral artery divides into the popliteus and saphenous arteries, which run laterally and medially, respectively, on the caudal aspect of the distal femur.

- Several small branches of these two arteries supply the femur, the patella, and the vastus lateralis muscle.
- The muscular branch of the caudal femoral artery bridges the fascial separation between the biceps femoris muscle and the vastus lateralis muscle just above the lateral fabella.
- The peroneal and saphenous nerves supply the lateral and medial aspects of the distal femur, respectively, and run caudal to the femur.

FRACTURES OF THE DISTAL FEMUR AND PATELLA

Preoperative Considerations

- Obtain a minimum of two radiographic views for evaluation of the distal femur.
- Palpate joint stability with the animal under sedation or anesthesia to investigate the possibility of simultaneous ligamentous injuries in the stifle.
- The age of the patient influences choice of implant for repair of distal femoral fractures. In young animals, bone is softer, and healing is more rapid than in older animals (see Chapter 119).
- The majority of distal femoral fractures are physeal fractures; warn owners of the consequences of physeal closure in younger animals.

Surgical Procedure

Objectives

- Expose the distal femur and repair fractures of the metaphysis and epiphyses of the distal femur.
- Expose the articular surface of both distal femoral condyles for accurate intra-articular fracture reconstruction.
- Expose the patella and repair fractures of the patella.

Equipment

- Standard general instrument pack and suture material
- Orthopedic instruments as required for specific procedures, including pinning, wiring, and screw fixation

Technique

1. Prepare the patient's leg for sterile surgery.
2. Expose the distal femur and patella using a lateral, medial, or cranial approach. For patient positioning convenience, the lateral approach is most frequently used.
3. Extensive reconstruction of the articular surface may require an osteotomy of the tibial crest for added exposure of the distal femur.

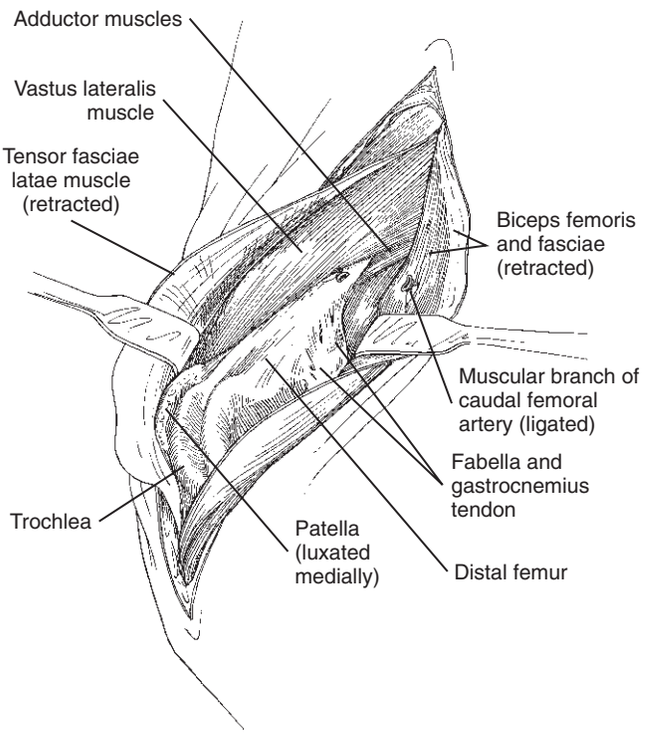

Figure 109-6. Lateral approach to the distal femur.

Lateral Approach

1. Make a slightly curved skin incision from the distal one-third of the femur to the tibial crest just lateral to the patella.
2. Incise the subcutaneous tissue to expose the fascial layer.
3. Incise the fibrous joint capsule and fascia starting at the tibial plateau just lateral to the patella tendon and extending proximally, parallel to the patellar tendon and the patella.
4. Follow the border of the vastus lateralis muscle caudally to the septum between the biceps femoris and the vastus lateralis muscles. Separate these two muscles, double-ligating the muscular branch of the caudal femoral artery that bridges them distally.
5. Bluntly elevate the quadriceps muscles from the distal femur and luxate the patella medially to expose the distal femur (Fig. 109-6).
6. Expose and gently clean the fracture ends.

▼ ***Key Point*** Handle the metaphyseal bone gently, especially in young animals.

7. Apply the appropriate orthopedic implants as indicated by the fracture type. For simple physeal fractures, cross-pinning, multiple pinning, and modified Rush pinning techniques are appropriate.

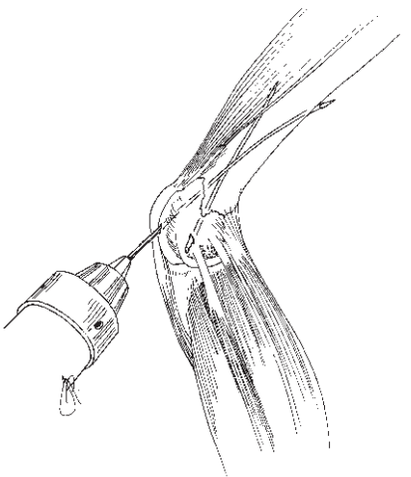

Figure 109-7. Cross-pinning of a distal femoral physeal fracture using a lateral approach.

a. Start the pins from the fracture line and retrograde distally out through the epiphysis, avoiding the articular surface; or start from the caudolateral and caudomedial aspect of the epiphysis and drive (normograde) pins to the fracture line.
b. With retrograde pinning, adjust the pins until the pinpoint is flush with the fracture line, realign the fracture anatomically, and drive the pins proximally up the shaft of the femur in one of the previously mentioned configurations (Fig. 109-7).
c. Cut off the pins flush with the condyles and lavage the joint copiously with saline solution before closure.

Bendable plates can be configured to the bowing and flare of the distal femur and condyles but the plate strength is relatively low so consider double, or bilateral, plate application if this method is chosen.

Medial Approach

1. The technique is basically identical to that for the lateral approach except that it is made on the medial aspect of the distal femur.
2. In addition, one may substitute medial for lateral (vastus medialis muscle for vastus lateralis muscle, and cranial sartorius muscle for biceps femoris muscle) to achieve medial exposure of the distal femur.

Cranial Approach

1. Incise the skin from the lateral distal one-third of the femur to the medial aspect of the proximal tibia.
2. Separate the fascia as described for the medial and the lateral approaches, which are combined to give wider bilateral exposure of both condyles.

Tibial Crest Osteotomy

1. A tibial osteotomy can be combined with any of the previously described approaches to achieve additional exposure for complicated fractures.
2. Isolate the patellar tendon through the original skin incision.
3. Place an osteotome under the patellar tendon, aimed distally, and osteotomize the tibial crest free from the proximal tibia.

▼ ***Key Point*** Be sure to remove enough bone to facilitate fixation when reattaching the tibial crest.

4. Retract the quadriceps muscle proximally to fully expose the joint.
5. Repair intra-articular fractures with good visibility of the critical articular surface.
6. Compression (lag) screw fixation of intra-articular fracture fragments is recommended to allow accurate reconstruction and avoid movement, thus reducing the potential for arthritis.
7. Repair the osteotomy by pinning the tibial crest into position with two large K-wires transversely placed through the osteotomized bone fragment and into the proximal tibia. Place a figure-eight tension band wire around the base of the pins and through a hole in the cranial tibia, distal to the osteotomy site.

Patella Fracture Repair

1. Expose the patella via the lateral approach, as previously described. Identify the patella by rotating the distal quadriceps muscle.
2. Pass two K-wires lengthwise through the patella across the fracture line.
3. Rotate the quadriceps muscle back to its normal position and loop a figure-eight orthopedic wire around the pin ends on the cranial surface of the patella.
4. Twist both long strands of the figure-eight wire to tighten the tension band apparatus and close the fracture line of the patella.
5. Cut the pin ends as short as possible. Cut the twisted wire, leaving two twists.

Closure

1. Close the joint capsule with monofilament absorbable suture in a simple continuous pattern.
2. Close the fascial layer with absorbable sutures in a simple interrupted pattern.
3. Close the subcutaneous tissue and skin routinely.

Postoperative Care

- General recommendations are the same as for femoral neck/physeal fracture except:

- Restrict activity (cage rest) for at least 24 hours.
- If fixation is judged to be stable, start leash walking 1 to 2 days postoperatively.
- If fixation is unstable, support the leg in a flexion sling.

Postoperative Complications

- Quadriceps tie-down (contracture) occurs when adhesions form between the healing fracture callus and the overlying quadriceps muscle and the patella tendon. This is most likely to happen if the leg is fixed in an extended position (e.g., with a Thomas splint). Tie-down can be prevented by early mobilization and/or a flexion sling for support.

▼ ***Key Point*** To help avoid quadriceps tie-down, do not apply splints that place the stifle in extension.

- If intra-articular fractures are not reduced anatomically, degenerative joint disease and postoperative joint pain can result. Accurate reduction and stable fixation is essential.
- If the animal is very young at the time of the physeal fracture, femoral shortening is to be expected if premature physeal closure occurs. If shortening is less than 20% compared with the normal leg, clinical signs are unlikely.

Chapter

110 Orthopedic Disorders of the Stifle

R. Tass Dueland / Matthew Palmisano

Common traumatic and congenital or developmental conditions of the stifle include patella luxation, cruciate disruptions, meniscal problems, collateral ligament injuries, and stifle luxation. The first three listed (excluding fractures) comprise 95% of stifle disorders in dogs and cats.

ANATOMY

Cranial Stifle

- The quadricep muscles, patella, trochlear groove and notch, patellar tendon, and tibial tuberosity are linearly aligned with the coxofemoral joint, talocrural joint, and paw. Normally there is no medial or lateral deviation of these structures.
- Craniomedial and caudolateral ligamentous bundles constitute the cranial cruciate ligament, which originates on the caudomedial aspect of the lateral femoral condyle and inserts centrally on the tibial plateau caudal to the cranial intermeniscal ligament (Fig. 110-1).
- The caudal cruciate ligament originates on the craniolateral aspect of the medial femoral condyle and inserts on the caudocentral tibial plateau and medial popliteal notch.
- The fat pad lies caudal to the patella tendon.
- The long digital extensor tendon originates on the lateral femoral condyle cranial to the lateral collateral ligament and popliteus muscle.
- Retinacular fibrous tissue overlies the craniolateral and craniomedial aspects of the stifle joint.
- The trochlear notch is the more distal non–weight-bearing portion of the trochlear groove.

Caudal Stifle

- Medial and lateral fabellae articulate intracapsularly with the femoral condyles and have strong fabellofemoral ligaments (Fig. 110-2).
- The medial meniscus is attached to the tibia and to the medial collateral ligament, whereas there are tibial and femoral attachments of the lateral meniscus.
- The popliteus muscle courses under the lateral collateral ligament.
- Neurovascular structures run longitudinally and centrally close to the caudal joint capsule.

GENERAL PREOPERATIVE CONSIDERATIONS

- Client communication and cooperation and a successful return to function by the patient are enhanced by meticulous evaluation of the stifle joint preoperatively and intraoperatively. This facilitates an accurate diagnosis and selection of the appropriate procedure(s).
- Radiography is useful for the following:
  - To confirm the diagnosis
  - For comparison with the opposite joint
  - For medical and legal documentation
- Perform a thorough orthopedic examination, including the joints, bones, and muscles of the affected extremity.

Orthopedic Evaluation

Include the following maneuvers in palpation of the stifle:

- Palpation of the patellar tendon and parapatellar tissue should reveal a distinct “sharp” feel to the tendon edges. If they feel indistinct or “doughy,” this indicates stifle effusion, which is often associated with cranial cruciate rupture or degenerative joint disease secondary to rupture.
- Perform gentle, full range of stifle motion in normal flexion and extension, then repeat with internal and external rotation.
- Often, clicks caused by meniscal pathology and crepitation from osteoarthritis can be detected.
- With the femur held motionless with one hand and the proximal tibia held securely by the other hand, attempt cranial movement of the tibia after placing the stifle in slight to moderate flexion (drawer sign or Lachman test).
- With a finger held over the tibial tuberosity and the femur held securely, flex the hock to detect cranial movement of the tibia (tibial compression test). This

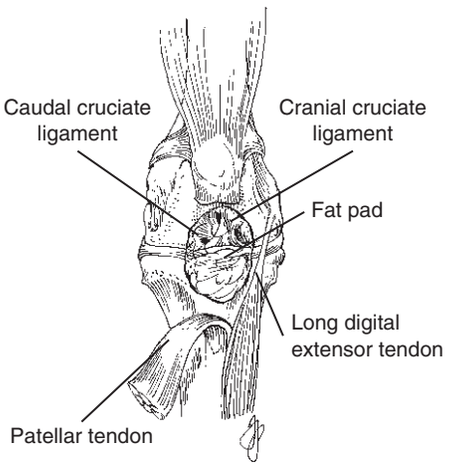

Figure 110-1. Anatomy of the cranial stifle.

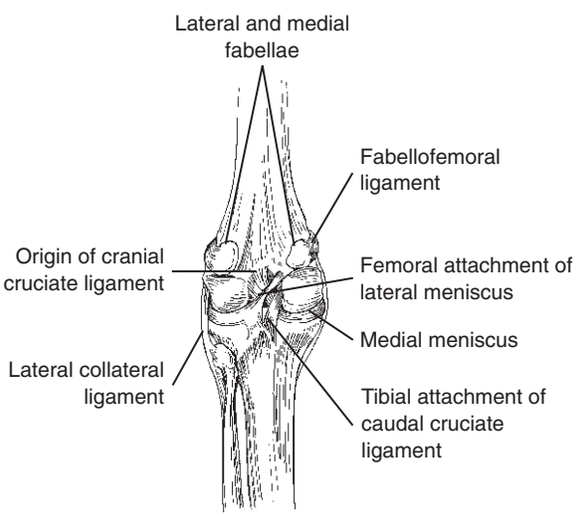

Figure 110-2. Anatomy of the caudal stifle.

test (and the Lachman test) indicates laxity of the cranial cruciate ligament.

- With the femur held motionless, determine internal and external movement of the tibia on the femur by grasping the hock and rotating the tibia. Normal range of motion is 20 to 30 degrees of internal rotation and 5 to 10 degrees of external rotation with the stifle in flexion.
- Exert medial and lateral digital pressure on the patella while putting the stifle through its range of motion to detect any patellar luxation.
- Exert pressure with the thumbs on the lateral side of the femoral condyle and proximal tibia, and then repeat on the medial side. Laxity of the collateral ligaments is detected by increased laxity of the joint space.
- Exert deep pressure of the stifle area with a fingertip to ascertain focal points of pain from soft tissue tears and bone bruises.

▼ ***Key Point*** Perform the tests sequentially while the animal is conscious, and repeat when the animal is sedated or anesthetized. Plan appropriate surgical procedures based on this diagnostic information.

PRINCIPLES OF STIFLE SURGERY

- For the majority of the surgical procedures, place the dog in dorsal recumbency with the forelegs and unaffected rear limb secured. This gives good access to both sides of the stifle in a comfortable operating position. Place the instrument table over the dog's trunk.
- Perform an arthrotomy of sufficient length to facilitate luxation of the patella. Using flexion and retraction, identify, inspect, and assess the articular surfaces of the patella, trochlear groove, tibial plateau, pericondylar, and supracondylar areas of the femur, patellar tendon, fat pad, and long digital extensor tendon.
  - When operating alone, place the sterile, covered paw on your (gowned) abdomen.
  - By moving your body forward and backward you can adjust the amount of flexion of the stifle.
- Place a small, sharp rake retractor (Senn) deeply behind the fat pad; retract cranially and inspect both cruciates.
- Place a second retractor on either side of the first to examine the menisci.
  - To see the caudal horns well, place the tip of a narrow Hohmann retractor (Synthes 399.18) or curved hemostat just behind the tibial plateau. Positioning the instrument against the trochlear notch acts as a lever to move the tibia forward and increase exposure.

PATELLAR LUXATION

Medial and parapatellar luxations affect miniature breeds most commonly and large and giant breeds less often. Medial patellar luxations are most common in both small- and large-breed dogs. However, when lateral patellar luxations occur, they most commonly occur in large and giant breeds. Patellar luxations generally are congenital or developmental. Contributing factors include structural abnormalities such as coxa vara and coxa valga (decrease and increase, respectively, in the angle formed by the head and neck of the femur and the axis of its shaft), bowing or torsion of the distal portion of the femur, shallow trochlear groove, increased internal or external tibial rotation, and malpositioned tibial tuberosity.

Patellar luxations are classified as follows:

- Grade I—The patella lies in the trochlear groove but can be manually subluxated or luxated.

- Grade II—Spontaneous luxation occurs clinically. The patella can be luxated manually but reduces spontaneously or with gentle manipulation.
- Grade III—The patella is luxated most of the time but can be reduced manually.
- Grade IV—The patellar luxation cannot be reduced manually. Often, flexure contracture has occurred and limb use is minimal.

Diagnosis

- History usually reveals intermittent rear-leg lameness. The lameness classically is characterized by rapidly alternating use and disuse of the limb, particularly during exercise.
- Definitive diagnosis is based on physical examination. Palpate the patella while placing the stifle through its full range of motion. In a grade I or II patellar luxation, the patella can often be luxated when the stifle is in extension.

Preoperative Considerations

- Evaluate the maximum internal and external rotation of the tibia on the femur. An increase in internal rotation of >30 degrees (often occurring in miniature breeds) indicates lateral retinacular laxity and the need for lateral imbrication.
- Patellar luxation procedures vary; some animals require only one step, whereas others need combined procedures.
- In some cases, combined parapatellar arthrotomy and release is necessary (to release means to diminish the pull or tension on tissue, often accomplished by incising perpendicularly to the line of tension).
- In other cases, combined arthrotomy and imbrication is needed (to imbricate means to tighten, either by suturing alone or by excision and subsequent closure of tissue).

Surgical Procedures

Objective

- Stabilize the patella anatomically in the trochlea while maintaining the full range of pain-free motion.

Equipment

- Standard orthopedic surgical pack and suture material
- Preferably power bur, oscillating saw, and drill *or*
- Double-action rongeur, bone curettes, and fine handsaw (hacksaw or Exacto saw #236), file, or rasp
- Sharp osteotomes and mallet

Surgical Principles

- Reduce the patellar luxation and determine whether the tissues are tight on the side toward which the patella luxates and whether the tissues opposite the luxated side are very lax.
- If the former is present, perform combined parapatella arthrotomy and release to diminish the pull of the tissues.
- If the latter is present, combined arthrotomy and imbrication is indicated to tighten the lax side.
- With an adequately deep trochlear groove and no excessive tibial rotation, a release may be the only step needed to maintain the patella in its anatomic position.
- With a shallow trochlea, deepening can be accomplished by trochleoplasty, chondroplasty, or wedge resection. Techniques in which the articular cartilage is preserved (e.g., wedge resection) are preferred over those in which articular cartilage is not preserved.
- Correct excessive medial rotation of the tibia with a lateral antirotational nylon suture (fabella to tibial tuberosity drill hole; see Fig. 110-4) or by translocation of the tibial tuberosity laterally.

Techniques

Trochleoplasty

1. Following arthrotomy and inspection of the stifle, mark the medial and lateral boundaries of the planned trochlear groove by longitudinal cuts in the trochlear cartilage using a scalpel blade. To prevent fracture, try to obtain as much width and height as possible without weakening the remaining condylar bone.
2. Remove the articular cartilage within the marked lines by power burring or with a rongeur.
3. Reduce the luxated patella for a trial fit and, if necessary, smooth the new surface with a fine, half-round file, or rasp. The depth of the new trochlea should accommodate the patella so that one-half to two-thirds of the patella's height is in the groove.
4. Verify depth, smoothness, and stability by palpating the patella while putting the joint through its range of motion (flexion and extension with internal and external rotation of the tibia).
5. Close the synovia and joint capsule with appropriately sized monofilament nylon sutures in an interrupted cruciate pattern. If possible, perform partial-thickness closure whereby the suture is not within the joint. Close skin and subcutis routinely.

Postoperative Care

- Begin physical therapy, consisting of ice packs and gentle, passive flexion and extension to half the normal range of motion on the day of surgery. Twenty repetitions 4 to 6 times daily are recommended. Swimming after suture removal is permitted.
- Restricted activity (leash walking only, no stairs, no ball playing, etc.) for 1 month.

- Give analgesics as needed (Bufferin, 10 mg/kg PO bid; Carprofen, Rimadyl, 2.2 mg/kg PO bid; Deracoxib, Deramaxx, 2–4 mg/kg PO sid, with food). (See Chapter 6.)

Chondroplasty

1. Make a trochlear outline, as described for trochleoplasty, down to subchondral bone (Fig. 110-3).
2. Using a thin, sharp, curved osteotome (Zimmer #2881-00-01, #2881-00-02) perform an osteotomy and create a rectangular cartilage flap with the hinge either proximally or distally. Include 1 to 2 mm of bone in the thickness of the flap.
3. Remove underlying bone with power burring, a bone curette, or a rongeur.
4. After adequate depth is obtained, press the flap manually into the new groove. Pressure from the patella helps keep the flap in position.
5. Close the skin and subcutis routinely.

▼ ***Key Point*** This technique is best used in dogs less than 6 months of age in which the mineralized tissue is relatively soft and pliable for creating a flap.

Postoperative Care

- Perform physical therapy and administer analgesics, as described previously for trochleoplasty.

Wedge Resection

1. Make a trochlear outline as described for trochleoplasty.
2. With a power saw or fine handsaw, make two pie-shaped cuts at the peripheral borders previously outlined. Medial and lateral condylar osteotomies should meet centrally. Remove this central piece of bone and articular cartilage and place it in a blood-soaked sponge.
3. The shallowness of the trochlea determines the width of the next two saw cuts, which are parallel and peripheral to the first cuts. Remove these two pieces of bone. Place the trochlear segment with its intact cartilage into the recess; this results in a deeper trochlea with preservation of most of the articular surface.
4. Pressure of the articulating patella ensures good contact of the osteotomized segment.
5. Close the skin and subcutis routinely.

Postoperative Care

- Perform physical therapy and administer analgesics, as described for trochleoplasty.

▼ ***Key Point*** Use caution with this technique in immature animals with open physes. Premature closure may occur; therefore, it is better suited for animals older than 8 months.

Imbrication

After the depth of the trochlear groove is reestablished, reevaluate the status of tibial rotation. If there is medial or lateral rotary instability, perform imbrication of the lax side using one of several techniques.

1. DeAngelis technique (fabella to patellar tendon; Fig. 110-4, *left*): Using non-absorbable monofilament suture, place mattress pattern sutures around the medial and lateral fabellae and running extracapsularly, engaging the distal patellar tendon.
2. Flo technique (see Fig. 110-4, *right*): Place the proximal aspect of the sutures similarly, but distally engage the proximal tibia through a transverse drill hole in the tibial tuberosity.
3. Place additional sutures, if needed, in a fan-like pattern, originating at the fabella and engaging the parapatellar tissue.

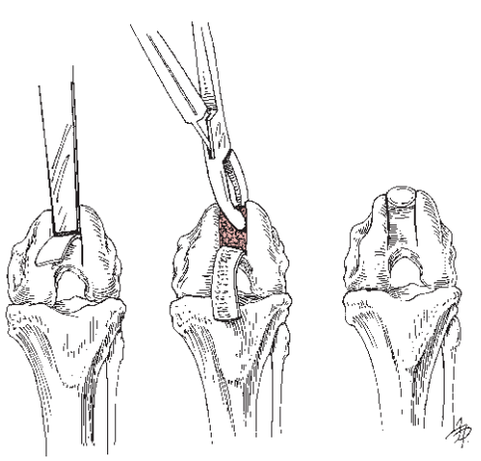

Figure 110-3. Chondroplasty procedure. See text for details.

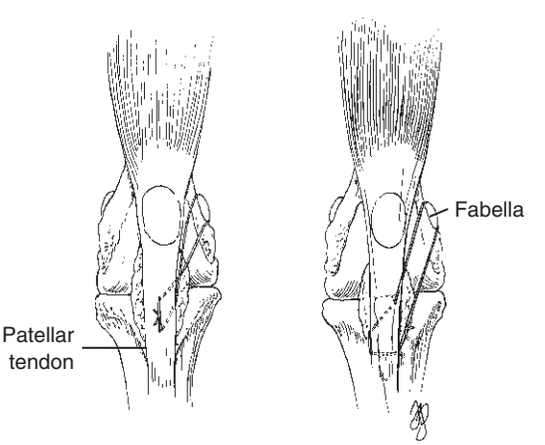

Figure 110-4. Imbrication techniques of DeAngelis *(left)* and Flo *(right)*. These techniques are used for cruciate stabilization and for antirotation purposes with patella luxations.

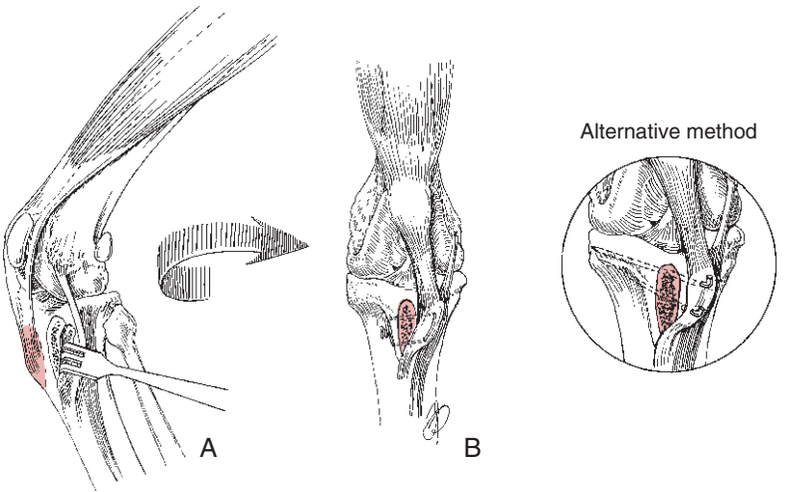

Figure 110-5. Tibial tuberosity transposition: *A,* Area of partial osteotomy of tibial tuberosity is shown in color; the cranial tibial muscle is reflected. *B,* The newly positioned segment is wired in place. Alternate fixation method: (inset) Kirschner wires holding osteotomized tibial tuberosity in transposed position.

4. Alternatively, scarify the retinacular tissue with the scalpel blade and use a Lembert suture pattern to place several bilateral parapatellar sutures.
5. If there is redundant tissue on one side of the patella after reduction, make two elliptical incisions through retinaculum, capsule, and synovia. Remove the redundant tissue and imbricate using routine closure or a vest-over-pants suture pattern.

▼ ***Key Point*** As a rule, when suturing is the main component of imbrication, physical therapy should be gentle to diminish stress upon the suture material and allow adequate time for tissue healing.

Tibial Tuberosity Translocation

Equipment

- Osteotome and mallet or a dental molar cutter
- Orthopedic Kirschner wires

Technique

1. Perform medial and lateral parapatellar arthrotomies. For lateral translocation, reflect cranial tibial muscle.
2. With an osteotome, mallet, or molar cutter, make an osteotomy of the tibial tuberosity, leaving the soft tissue still attached distally if possible (Fig. 110-5, *center*).
3. Hold the osteotomized tibial tuberosity in position with a bone clamp (Synthes 399.07) after creating a bed in the tibia by roughening the site with a rongeur or curette.
4. Using a power or hand drill, make two small holes through the newly positioned osteotomized segment and through the base of the tibial tuberosity (see Fig. 110-5).
5. Place an appropriately sized (20–22 gauge) orthopedic wire through the holes in a mattress pattern and twist tightly medially to secure the bone in the new site. Cut the wire, leaving two to three twists. The new location of the insertion of the patellar tendon should realign the forces to maintain the patella in position, assuming other disruptive forces have been corrected.
6. If the new position is not closely adjacent to the osteotomy site, insert Kirschner wires (Fig. 110-5*B*), a tension band, or a lag screw obliquely for stable fixation.

▼ ***Key Point*** Exercise great care in young animals not to cause physeal growth arrest by inappropriate placement of Kirschner wires through the proximal tibial growth plate.

7. If the wire ends cause skin irritation, they may be removed after bony union has occurred.

▼ ***Key Point*** Because medial and lateral rotary instability and laxity contributes significantly to malalignment of the tibial tuberosity, correction of the laxity by imbrication (Flo technique) may eliminate the need for transposition of the tuberosity.

CRANIAL CRUCIATE LIGAMENT RUPTURE

Diagnosis

- The history usually reveals an acute onset of rear-limb lameness, particularly during exercise.
- Chronic and persistent lameness may also be seen, especially in older, overweight dogs.
- Firm swelling of the medial aspect of the joint can be palpated when a chronic cruciate ligament (CL) rupture is present.

Diagnostic Manipulations

Two diagnostic manipulations can confirm abnormal cranial movement of the tibia at the stifle.

Cranial Drawer

- Position the thumbs on the caudolateral aspect of the stifle so that the lower thumb engages the head of the fibula while the upper thumb is placed in the region of the lateral fabella or the edge of the lateral femoral condyle.
- Wrap the other fingers of the upper hand around the cranial aspect of the lower thigh, keeping the femur motionless and the patella in the trochlear groove.
- Test the cranial laxity of the stifle joint with the tibia in modest flexion (15–30 degrees) (Lachman test) and in 45 to 90 degrees (or more) of flexion (cranial drawer sign).
- Do not test for cranial drawer with the stifle in full extension. The medial and lateral collateral ligaments will tighten in this position, thereby limiting cranial translation of the tibia.
- With complete rupture of both bands of the cranial CL, cranial laxity is detected at each position.
- With partial rupture, laxity may be detectable at only one of these positions.
- Severity of laxity is subjectively ranked in 2-mm increments (e.g., 1+ = 2 mm, 2+ = 4 mm, 3+ = 6 mm, and 4+ = 8 mm) of cranial displacement (translation) of the tibia on the femur.

Tibial Compression

- Use one hand to hold the femur motionless, with the index finger resting on the tibial tuberosity; gently dorsiflex the hock with the other hand.
- The gastrocnemius muscle will tighten and, when cranial CL laxity is present, the tibia can be felt to move cranially under the index finger.
- In our experience, the cranial drawer test is more consistent than the tibial compression test. However, perform both tests. A diagnostic impression is obtainable in 90% of anesthetized dogs if proper positioning and a calm approach are used.

Preoperative Considerations

- Obtain preoperative stifle radiographs to document joint effusion, extent of degenerative joint disease, normal fabellae, and avulsions of the ligamentous attachments.
- To rule out predisposing or concurrent diseases, consider obtaining a routine laboratory database of complete blood count (CBC), serum chemistry profile, and urinalysis.

Comparison of Surgical Techniques for Cranial Cruciate Ligament Repair

Much debate currently exists regarding the optimal method for cranial CL repair. Subjectively, more surgeons are turning to tibial plateau leveling osteotomy (TPLO) for repair due to the perceived earlier return to function and more complete weight bearing. However, objective studies showing a statistically significant difference between the lateral imbrication techniques and the TPLO are lacking. Some studies have shown an improved return to function with the lateral imbrication and TPLO procedures over intracapsular repairs.

The choice of surgical techniques largely depends on surgeon preference, which is related to success with the various techniques and comfort level.

One study showed 36% of surgeons use the lateral retinacular imbrication technique as the primary method of repair, while 13% routinely performed the fascial strip "over-the-top" technique and 25% performed the TPLO.

Surgical Procedures

- The procedures to correct CL rupture are broadly classified as either intracapsular (stabilization from within the joint) or extracapsular (stabilization outside the joint).
- Intra-articular repairs utilize autogenous or synthetic materials to re-create an intact cranial CL. Examples of intracapsular repairs include patellar tendon techniques, over-the-top repairs, and under-and-over repairs.
- While many intracapsular repairs are still performed today, subjective and more recent objective data suggests that these repairs may be inferior to the extracapsular techniques, such as the lateral imbrication technique and TPLO. This is especially true in large-breed dogs.

Objectives

- Visually assess the extent of joint damage.
- Slow the progression of degenerative joint disease by stabilizing the joint.
- Reduce or eliminate the drawer sign.
- Inspect the meniscus for tears (usually caudal horn of medial meniscus).

Equipment

- Standard orthopedic pack and suture
- Intramedullary pin pack
- Orthopedic wire passer

Techniques

Fascial Strip Over-the-Top Technique

1. The fascial strip over-the-top technique is an intracapsular repair and is most suitable for dogs weighing less than 40 lb.
2. Place the dog in dorsal or lateral recumbency and prepare the stifle for aseptic surgery.
3. Make a cranial skin incision extending from 2 inches above the patella to the tibial crest.
4. Perform a craniolateral arthrotomy with formation of a distally based fascial strip. For adequate bio-

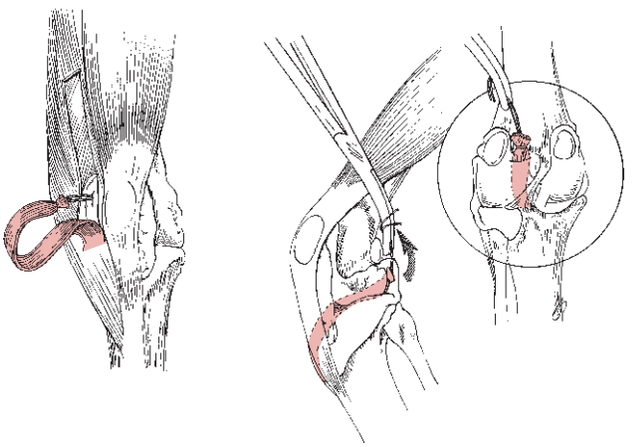

Figure 110-6. Fascial strip over-the-top technique for repair of cranial cruciate rupture. See text for details.

mechanical strength, make the width of the strip 2 to 3 times the width of the patellar tendon. The length needed is twice the distance from the proximal patella to the tibial tuberosity. The base of the strip is at the level of the joint line.

5. Cut the fascial strip proximally and insert it, lateral to medial, through a fat pad tunnel made with a hemostat (Fig. 110-6). Enter the caudolateral joint capsule caudal to the lateral fabella and gently advance the hemostat through the intercondylar notch, keeping the hemostat tip lateral to the caudal CL. Grasp the proximal end of the graft in the joint and pull it through the intercondylar notch lateral to the caudal CL and over the top of the lateral condyle. Make a small incision through the joint capsule, pull the fascial strip through it, and secure it to the capsular reflection onto the lateral femoral condyle with six to eight monofilament nylon sutures (2-0) with the appropriate tension to achieve a minimal drawer sign.
6. Close the arthrotomy incision with interrupted absorbable suture material. Complete closure may not be possible distally, depending on the width of the graft harvested.
7. Routinely close the remaining tissues.

Lateral Retinacular Imbrication Technique

The lateral retinacular imbrication technique is the most common extracapsular technique performed in practice and can be performed in any size patient.

1. Place the dog in lateral recumbency and prepare the stifle for aseptic surgery.
2. Make a lateral parapatellar skin incision.
3. Perform a lateral arthrotomy. The cranial CL and meniscus are evaluated and debrided if torn.
4. Separate the lateral joint capsule from the biceps femoris muscle. Severe the distal insertion, and reflect the biceps femoris fascia caudally as far back as the lateral head of the gastrocnemius muscle.
5. Close the joint capsule using interrupted absorbable suture material.
6. Drill a hole in the tibial tuberosity with an intramedullary pin that is larger than the diameter of the suture material chosen. Drill the hole medial to lateral, just caudal to the tibial insertion of the straight patellar ligament.
7. Pass an orthopedic wire passer (Small Graft Passer, Jorgensen Labs, Loveland, CO) around the lateral fabella. The pointed tip of the wire passer is started between the gastrocnemius muscle and the lateral femoral condyle just distal to the lateral fabella. It is pushed around the fabella and allowed to penetrate through the musculature just proximal to the fabella.
8. Placed appropriately sized nylon leader line (NLL) through the slot in the wire passer, and pull the passer around the fabella, taking the suture material with it. One to two strands of either 80 or 125-lb test NLL are most suitable for elimination of cranial drawer.

▼ ***Key Point*** Use one strand of 80-lb test NLL in dogs <50 lb, two strands of 80-lb test NLL in dogs 50 to 100 lb, and two strands of 125-lb NLL in dogs over 100 lb.

9. Pass the NLL through the bone tunnel created in the tibial tuberosity, from lateral to medial. Then place the NLL behind the straight patellar ligament, just cranial to the intrapatellar fat pad (see Fig. 110-4, *right*).
10. Place the knee in an approximate standing position (about 30 degrees of flexion). Tighten the NLL until cranial drawer is eliminated.
11. The NLL can be tightened by hand then secured using at least two square knots. Alternatively, in order to eliminate the bulky knots, the NLL can be tightened and fixated using the Securos crimp-clamp system (Securos, Charlton, MA).
12. Anchor the biceps femoris fascia back to the patellar ligament using absorbable suture material in either a Lembert or a vest-over-pants suture pattern.
13. Close subcutaneous tissues and skin in routine fashion.

Tibial Plateau Leveling Osteotomy

TPLO is an increasingly popular method of stabilization of the cranial CL–deficient stifle. Both the intracapsular and the extracapsular techniques work at eliminating the cranial drawer sign, which is a passive movement that does not take into account the forces of weight bearing.

TPLO is designed to eliminate tibial thrust. Tibial thrust (see above) is a motion where the tibia translates

forward during active weight bearing in the cranial CL–deficient stifle. Cranial tibial thrust occurs after cranial CL rupture because of contraction of the stifle and tarsal extensor muscles.

By leveling the tibial plateau to nearly perpendicular to the long axis of the tibia, the active forces of the stifle flexors are enhanced so that cranial tibial thrust experienced during weight bearing is eliminated.

One study showed that the cranial tibial thrust is actually converted to a caudal thrust, which requires an intact caudal CL.

The TPLO is applicable to any size or type of patient. In our opinion, TPLO is best suited for large- or giant-breed dogs; hunting, agile, or otherwise very active dogs; and dogs with partial cranial cruciate ligament tears. Subjectively, dogs appear to put weight on the limb earlier and have more complete weight bearing while having a better range of motion than the other surgical techniques at the final recheck examination. However, objective clinical data is lacking.

Disadvantages of TPLO include equipment costs, the large learning curve due to the technical demand of the procedure, and the training involved in certification. TPLO requires specialized equipment and expertise, and its use is largely confined to surgical specialists.

Postoperative Care

Short Term

- Administer analgesics as needed (see Chapter 6).
- Apply a padded bandage for the first 24 to 48 hours if desired to reduce tissue swelling.
- Remove skin sutures and reevaluate the leg 10 to 14 days postoperatively.

Long Term

Fascial Strip Technique

- Protect the leg with a lateral splint, that is, a padded bandage combined with a strip of fiberglass cast material that is molded to the shape of the lateral aspect of the leg and then incorporated into the bandage. Replace this bandage as needed, but use it for the first month postoperatively to prevent stifle motion.
- Restrict exercise to leash walking only for the first 3 months.
- Gradually increase the activity level over the next 3 months, and allow return to normal function after 6 to 9 months.
- Perform physical therapy as needed (see Chapter 95).

Lateral Retinacular Imbrication Technique

- Limit exercise for 6 weeks postoperatively. Do not allow any high-impact activity during this time (e.g., running, jumping, or playing).
- Gradually return the animal to normal activity over the next 2 to 4 weeks.
- Perform physical therapy as needed (see Chapter 95).

Tibial Plateau Leveling Osteotomy

- Limit exercise for 8 weeks postoperatively. Do not allow any high-impact activity during this time (e.g., running, jumping, or playing).
- Obtain radiographs of the leg 8 weeks postoperatively to assess for bone healing. If healing is not complete, re-radiograph at 4-week intervals until the osteotomy is healed. Continue to limit exercise until bone healing is complete, then gradually increase exercise over the next several weeks.
- Perform physical therapy as needed (see Chapter 95).

CAUDAL (POSTERIOR) CRUCIATE LIGAMENT RUPTURE

The importance of the caudal CL is controversial in both dogs and humans. A study in humans (Clancy et al., 1983) indicated severe pathology results with time. In dogs, isolated rupture of the caudal CL without bony avulsion is, in our experience, extremely rare.

Diagnosis

Diagnosis is based on the following:

- History of acute lameness and caudal drawer sign tested at 90 degrees of stifle flexion
- Caudal sag of the proximal tibia, compared with the normal opposite side, viewed on a lateral radiographic projection
- Avulsion of the bony attachment

Surgical Procedure

Objectives

- Similar to those for cranial CL except rupture repair

Equipment

- Similar to that for the patellar tendon procedure for cranial CL rupture

Technique

1. Make a cranial skin incision extending from 4 cm above the patella to 4 cm below the tibial tuberosity.
2. Perform a medial arthrotomy and debridement of the caudal CL.
3. Drill two tunnels. Extend one tunnel from the origin of the caudal CL at the non-articulating portion of the trochlear groove, exiting on the medial side of the medial femoral condyle. Extend the second tunnel from a point approximately 2 cm below the tibial plateau just medial of the midline, directed

caudally to exit just below the centromedial portion of the tibial plateau.

4. Harvest a patellar tendon graft as in the cranial CL patellar tendon procedure; in addition, obtain a piece of tibial tuberosity bone (4 mm wide × 6 mm long × 2 mm thick), including its patellar tendon insertion (i.e., making a free graft). Drill holes in each of the patellar and tuberosity pieces of bone and pass long nylon suture strands through the holes.
5. Using a suture passer, introduce the sutures that are attached to the patellar segment into the tibial tunnel in a cranial to caudal direction and pull the patellar portion of the graft through, leaving the tibial graft segment in the tibial tunnel. Similarly, draw the patellar piece into the femoral tunnel.
6. Insert partially threaded 4-mm Synthes screws, with the far cortex engaged, near the cranial tibial tunnel and at the exit of the femoral tunnel. Use these to anchor the tuberosity and patellar sutures after adjusting the graft to its proper tension.
7. Close the incision and tissues routinely. Place the limb in a Robert Jones bandage (RJB) for 1 month, as described in the patellar tendon procedure for cranial CL rupture repair.
8. An alternate technique for caudal cruciate rupture is to place two imbricating nylon sutures (Fig. 110-7). Place the first suture from the proximal patellar tendon to a drill hole through the proximal head of the fibula. Place the second suture from the proximal patellar tendon through a drill hole in the caudomedial aspect of the proximal tibia. Tighten these sutures with the stifle held in slight extension.
9. For bony avulsion injuries, if the bony portion is large enough, drill holes in the *bony* segment (lag screws or a Bunnell suture pattern can be used). Pass the suture through the ligament using a Bunnell pattern, and pass the suture ends through the bony drill holes. This gives firm fixation of the sutures to the ligament.
   a. Make two drill holes through the avulsion site, exiting on the medial side of the femur or on the cranial surface of the tibia.
   b. Using a suture passer, pass the sutures through the drill holes and tie them securely; this anatomically reduces the avulsion fracture and restabilizes the caudal CL.

Postoperative Care

See "Postoperative Care" under "Cranial Cruciate Ligament Rupture."

MENISCAL PROBLEMS

Preoperative Considerations

- An isolated meniscal tear or laxity is rare in dogs, compared with humans. More commonly, meniscal pathology is associated with a partial or a complete cranial cruciate tear.
- Secondary meniscal damage can occur in the weeks and months following an unrecognized or untreated cruciate injury.
- The resultant craniocaudal and rotational laxity allows the femoral condyles to traumatize the caudal horn of the medial meniscus (Fig. 110-8*A*). A common lesion is a folding cranially of the caudal horn of the medial meniscus.
- Diagnose by palpating a click or clunk during range of motion as the femoral condyle slips over the double thickness of the folded meniscus.

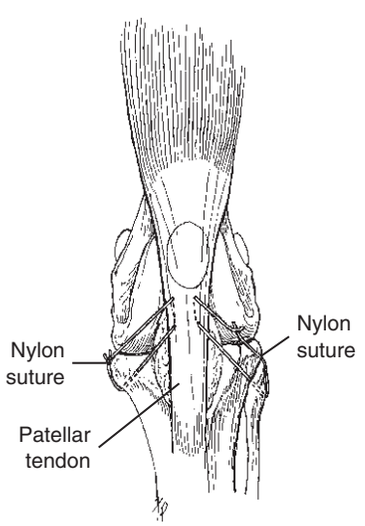

Figure 110-7. Imbrication technique for rupture of caudal cruciate ligament.

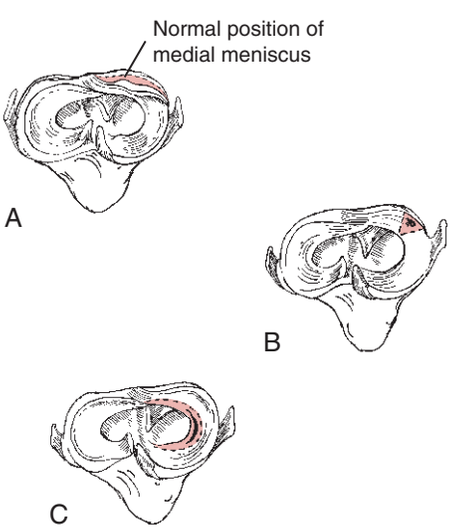

Figure 110-8. Repair of medial meniscal injuries. See text for details.

- Total (complete) meniscectomy is not advised unless there is severe damage of both caudal and cranial horns.

Surgical Procedure

Objective

- Remove or repair damaged portions of the menisci

Equipment

- Standard orthopedic pack and suture material
- Narrow Hohmann retractor (Synthes #399.18)
- Scalpel blade (#15)

Technique

1. Place the dog in dorsal recumbency with the forelegs and unaffected rear limb secured. Perform sterile preparation, stockinette, draping, and suturing in of the stockinette to the skin incision.
2. Because meniscectomy usually is performed in conjunction with CL reconstruction, use the arthrotomy approach (medial or lateral) appropriate for the cruciate technique. Make the arthrotomy of sufficient length to permit adequate retraction and exposure of both menisci.
3. After dislocating the patella from the trochlea, insert a small, sharp Senn retractor behind the fat pad and exert traction cranially. Keep the retractor in position until all internal joint manipulation is completed.
   a. Avoid unnecessary trauma to the fat pad with retractors to prevent damage to the vascular supply.
4. Debride cruciate and meniscal remnants, as necessary, and evaluate all joint structures for damage.
5. Place a second, dull Senn retractor on the medial side of the central Senn retractor to identify the medial meniscus, and then place it laterally to observe the lateral meniscus.
6. To facilitate exposure of the caudal horns, insert a narrow Hohmann retractor or hemostat to gently pry the tibial plateau forward (see "General Principles of Stifle Surgery").
7. Use a probe to determine laxity of the menisci and the extent of any tears.
8. Grasp the partially detached, forward-displaced caudal horn with a hemostat at the midportion. Often, the medial caudal horn is still attached peripherally to the medial collateral ligament and to the caudal tibial insertion.
9. With traction on the caudal horn, use a #15 scalpel blade to make a perpendicular cut to sever the caudal horn from the normally attached cranial horn. The meniscal-medial collateral attachment is usually cranial to the folded caudal horn.
10. Cut the remaining attachment (to the tibia) by placing the blade horizontally under the remaining caudal horn, and remove the caudal horn.
    a. Be careful to avoid cutting into the cartilage of the condyle or tibial plateau or lacerating the caudal CL or popliteal vessels caudal to the meniscus.
11. Flush the joint well with sterile lactated Ringer's solution, reposition the patella, and run the joint through a range of motion. No crepitation or clicks should be felt.
12. Remove any areas of localized injury or tears with a scalpel and create a vascular access channel running from the peripheral synovium (see Fig. 110-8*B*). In "bucket handle" tears (see Fig. 110-8*C*), the vascularity of central area (shaded area of Fig. 110-8*C*) is compromised and therefore is removed by sharp dissection.

Postoperative Care

See "Postoperative Care" under "Cranial Cruciate Ligament Rupture."

COLLATERAL LIGAMENT DISRUPTIONS

Preoperative Considerations

- Collateral ligament injuries usually occur as a result of severe medial (varus) or lateral (valgus) stress to the stifle by blunt force to the joint with the paw fixed during weight bearing.
- Collateral ligament strains are graded as to severity:
  - First degree—Stretching and minor disruption of collagen fibers
  - Second degree—Partial tearing
  - Third degree—Complete discontinuity of the substance of the ligament or avulsion of a bony attachment
- Animals usually are presented with acute lameness.
- Verify joint instability with stress radiographs.
- First- and second-degree injuries respond well to rest, restricted exercise, or a modified RJB.
- Third-degree injuries require surgical repair and partial immobilization for a few weeks using a modified RJB.

Surgical Procedure

Objective

- Restore the integrity of the injured ligament and the stability of the stifle.

Equipment

- Standard orthopedic pack and suture material
- Power drill
- Spiked washers and screws

Technique

1. Surgical approach is directly over the damaged ligament.
2. For complete ligament tears, use a Bunnell, locking loop, or triple-pulley suture pattern (see Chapter 115) for primary repair.
3. For bony avulsion, use a screw and spiked washer (Synthes 219.9, 219.93–95) if the bony portion is large enough to accept a screw. When the bony portion is small, use a ligament fixation plate (Synthes #65.00.1, 65.00.10, 65.00.11).
4. Reinforce a severely traumatized ligament by forming a supplemental fascial strip with two parallel incisions cranial and caudal to the involved collateral ligament: Then suture the fascial strip to the repaired collateral ligament. Alternatively, a fascial strip can be folded down and sutured to the ligament to reinforce the primary repair (see "Fascial Strip Over-the-Top Technique").
5. Alternatively, place screws at the origin and insertion of the collateral ligament and make a prosthetic ligament by looping monofilament nylon (or #1- to 50-lb test, depending on the size of the dog) in a figure-eight pattern around the screws. The wire or nylon usually breaks with time, but enough scar tissue forms to stabilize the joint.

Postoperative Care

See "Postoperative Care" under "Cranial Cruciate Ligament Rupture."

STIFLE LUXATION

Preoperative Considerations

- Severe trauma is necessary for complete stifle luxation to occur. The condition is more common in cats.
- Physical examination reveals total laxity in all directions: cranial, caudal, and rotational; the medial and lateral aspects of the stifle joint open up excessively.
- Usually, the patellar tendon is not disrupted; however, the popliteus and long digital extensor tendons may be torn, as well as both cruciates, both collaterals, and, in varying degrees, the meniscal attachments.

Surgical Procedure

Objective

- Repair ligaments and tendons to reestablish joint stability.

Equipment

- Standard orthopedic pack and suture material
- Power drill and drill bits
- Kirschner-Ehmer pins and clamps

Technique

1. Make a long lateral parapatellar skin and arthrotomy incision and assess the damage to ligaments, tendons, menisci, and cartilage.
2. If possible, stabilize the menisci by suturing peripheral attachments; otherwise, perform meniscectomy.
3. Repair the long digital extensor tendon, popliteus, and collateral ligaments with locking tendon loop, pulley, or Bunnell suture patterns; spiked washer and screw; or fascial reinforcement, as described previously under collateral ligament repair.
4. Cruciate stabilization may be done by intracapsular replacement or extracapsular imbrication techniques, as previously described in this chapter.

Postoperative Care

- To allow adequate healing, place a transarticular external skeletal fixation device, setting pins in the distal femoral and proximal tibia. This device is maintained for 3 to 4 weeks, followed by gradual motion using an RJB for 2 weeks and then a light wrap for 2 weeks. An alternative to the transarticular external skeletal fixation would be a full cast.
- With any form of immobilization of the stifle, place the joint in a functional (partially flexed) position.
- Some limitation of joint range of motion is acceptable and preferable to instability.

▼ ***Key Point*** For complete, multiple, midsubstance ligament disruptions, apposition of ligament ends is important for healing to occur; however, early mobilization also is important for complete biomechanical recovery.

Chapter

111 Fractures of the Tibia and Fibula

Erick L. Egger

Fractures of the tibia and fibula compose a significant proportion (15–20%) of all long bone fractures in small animals. In addition, the minimal soft tissue coverage of these bones increases the incidence of contamination of open fractures, which may result in infection and healing complications. Proper treatment of tibial and fibular fractures requires

- An understanding of the disruptive biomechanical forces that must be controlled to promote the healing process.
- Selection of a fixation technique that will control these forces.
- Application of fixation without damaging the fracture healing process or compromising the function of the limb.

ANATOMY, FUNCTION, AND BIOMECHANICS OF THE TIBIA AND FIBULA

The anatomy of the tibia and fibula can be divided into regions based on their location, function, architecture, and the forces acting on them.

Epiphysis

- Proximally the epiphysis consists of
  - The tibial plateau, which provides support for the articular cartilage of the distal stifle joint (for information concerning the stifle joint, see Chapter 110).
  - The fibular head, which serves as the distal attachment for the lateral collateral ligament.
  - The tibial tubercle, which is the insertion point of the patellar tendon of the quadriceps muscle.
- Distally, the epiphyseal region consists of
  - The cochlea tibia, which supports the distal articular cartilage and articulates with the tibial tarsal bone.
  - The medial malleolus, which is the proximal attachment of the medial collateral tarsal ligaments.
  - The fibular epiphysis (lateral malleolus), which acts as the proximal attachment of the lateral collateral tarsal ligaments.
- The epiphyseal regions of the tibia and fibula are primarily composed of loosely woven, trabecular bone surrounded by a thin shell of dense cortex. This architecture limits the holding power of fixation implants, requiring extra care in their application.
- The epiphyseal regions that serve as ligament and tendon attachments are subjected to distractive forces. Consequently, repair of avulsion fractures of these areas must control these tensile forces.
- The epiphyseal regions that support articular cartilage are subjected to compressive loads that tend to separate the fragments, resulting in articular incongruity, instability, and eventually degenerative arthritis. Fixation of these fractures must provide anatomic reduction and rigid immobilization so that the fracture will heal with minimal callus formation, and so that early joint motion can be initiated to avoid joint stiffness.
- Because of ample blood supply and preponderance of cancellous bone in the epiphysis, fracture healing tends to be rapid. Consequently, fixation of these fractures usually is not prolonged or robust.

Physis

- The physeal regions of the tibia and fibula are located adjacent to the epiphysis and exist only in growing immature animals.
- The hypertrophied layer and calcifying layers of the physis are relatively fragile, and are commonly fractured with trauma.
- Because the cartilage layers are irregular and transverse, fractures tend to interdigitate well when reduced and require only control of bending forces.
- Because the physis is the origin of long bone growth, injuries to this region can cause premature cessation of growth resulting in shorter bone or angular deformity. Warn clients of this possibility, particularly in very young, actively growing patients.

Metaphysis

- The metaphysis is an indistinct region of bone located between the physis and the diaphysis (central shaft).

- The function of the metaphysis in the mature animal is the gradual alteration of the general construction of the bone from the wide-diameter thin cortex of the epiphysis to the narrow-diameter thick cortex of the diaphysis. The biomechanics and architecture of these regions change along their length.

Diaphysis

- The diaphysis is the central portion of the tibia and makes up the majority of its length.
- The tibial diaphysis is subjected to severe bending and torsional forces, in addition to axial compressive loads. Its hollow tubular construction of relatively thick cortical bone maximizes its effectiveness in resisting these forces.
- Relatively poor blood supply in cortical bone and longer moment arms associated with diaphyseal fractures generally mean these fractures heal slowly and require prolonged robust fixation.

PREOPERATIVE CONSIDERATIONS

General Considerations

- Examine the animal carefully for non-orthopedic injuries.
  - Evaluate cardiovascular status. If cardiopulmonary problems are suspected, radiograph the thorax.
  - Evaluate neurologic status. Determine deep pain perception in the fractured limb for local nerve damage, and proprioceptive and sensory perception in the other limbs for evidence of nerve or spinal cord trauma.
- Examine the animal carefully for concurrent musculoskeletal injuries.

▼ ***Key Point*** Nearly all small animals with tibial and/or fibular fractures are able to support themselves on the remaining three limbs. If not, suspect additional injuries.

- Determine the extent of soft tissue injury and fracture contamination.
  - Cover all open fractures with sterile bandages to prevent further contamination, and debride as soon as possible.
  - Broad-spectrum antibiotics are indicated if the fracture is open. Obtain samples for culture and sensitivity testing from the fracture site before beginning antibiotic therapy.
  - Until definitive treatment is possible, support all tibial fractures with a compressive wrap (Robert Jones bandage) or splint to prevent additional soft tissue injury.

Specific Considerations in Selecting a Fracture Fixation Technique

- Determine the potential axial stability of the reduced fracture based on preoperative fracture radiographs.
  - Stable fractures generally are simple transverse or short oblique. They tend to impact and become more stable upon weight bearing.
  - Unstable fractures have patterns, such as long oblique or comminuted, which tend to override or collapse upon axial loading.
- Perform rigid fixation of extensively contaminated open fractures. However, avoid placing large implants in the fracture site.
- Fractures in immature animals heal quickly, but
  - Premature physeal closure can occur with or without internal fixation.
  - Immature animals rapidly develop joint stiffness with limb immobilization.
  - Implants quickly loosen in the soft bone of immature animals.
- Fractures in very old animals heal slowly.
  - Brittle bone in older animals often splinters when implants are applied.

SURGICAL PROCEDURES

Objectives

- Provide adequate stability for fracture healing to occur while causing minimal damage to the biologic healing process.
- Restore normal limb function by minimizing joint stiffness and muscle atrophy and avoiding subsequent degenerative joint disease.

Pin and Tension Band Wire Fixation

Indications

- Avulsion fractures of the fibular head
- Avulsion fractures of the lateral (fibular) malleolus and medial (tibial) malleolus (Fig. 111-1)
- Avulsion fractures of the tibial tubercle

Equipment

- General orthopedic pack
  - Standard surgical pack
  - Bone and fracture reduction forceps
  - Periosteal elevator
  - Jacob hand chuck
  - Wire pliers and cutters
- Stainless steel monofilament orthopedic wire (18–22 gauge)
- Kirschner wires (0.035–0.062 inch)

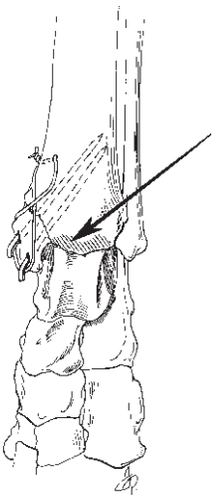

Figure 111-1. Pin and tension wire fixation of a medial malleolar avulsion fracture. Do not violate the cochlear articular surface with the Kirschner wire *(arrow)*.

Technique

1. Incise the skin directly over the affected bone.
2. Reduce and stabilize fracture with small fragment reduction forceps.
3. Create a transverse hole through the intact tibia approximately equidistant from the fracture line with the hand chuck and a Kirschner wire.
4. Insert two parallel Kirschner wires through the fragment, across the fracture, and into the parent bone.

▼ ***Key Point*** In the treatment of malleolar fractures, avoid penetrating the articular surface of the distal cochlea.

5. Pass orthopedic wire (18 gauge for most dogs, 20–22 gauge for small dogs and cats) through the transverse hole, cross the wire over the fracture site, and pass one end under the ligament or tendon attachment.
6. Twist both ends of wire together to form a figure eight. Tighten the wire just enough to compress the fracture (see Fig. 111-1).
7. Cut off excess orthopedic and Kirschner wires. Bend the Kirschner wires over and embed them in the soft tissues to trap the orthopedic wire loop and minimize soft tissue irritation.
   a. In the treatment of tibial tubercle fractures, if the animal still has significant growth potential, do not use tension band wires because this procedure can induce premature physeal closure. If necessary, use additional Kirschner wires oriented perpendicular to the physis for fixation stability.
8. Close soft tissues routinely.

Interfragmentary Lag Screw Fixation

Indications

- Intra-articular fractures of the proximal epiphysis (tibial plateau) and distal epiphysis (tibial cochlea)
- Reconstruction of comminuted shaft fractures prior to neutralization plating (see Fig. 111-7)

Equipment

- General orthopedic pack
- Bone screws and application instrumentation
- Power drill
- Kirschner wires

Technique

1. Manipulate fragments to obtain anatomic reduction of the intra-articular portion of the fracture and temporarily stabilize with fracture forceps.
2. Insert an interfragmentary screw and compress the intra-articular fracture line, using either a partially threaded screw or over-drilling the near fragment to create a gliding hole for fully threaded screws. Orient the screw perpendicular to the fracture line.
3. Insert additional screws or cross pins, depending on the fragment size, to prevent rotation around the first screw and to provide additional support.

Cross Pin and Rush Pin Fixation

Indications

- Transverse fractures of the epiphysis (may be combined with interfragmentary lag screw technique if the fracture extends into a joint)
- Axially stable fractures of the metaphysis (Fig. 111-2)
- Salter I and II fractures of the proximal and distal physis

Equipment

- General orthopedic pack
- Kirschner wires or small Steinmann pins ($^1/_{16}$–$^1/_8$ inch in diameter)
- Pin cutter

Technique

1. Manipulate the fracture and reduce through an open approach. Medial approach to the tibial shaft is preferred owing to relative lack of soft tissues.
2. Select the proper pin diameter (approximately 15% of bone diameter for cross pins, 10% for pins placed in the Rush technique).
3. With a hand chuck (a power drill can be used for cross pins), insert pins from the medial and lateral aspect of the fragment across the fracture into the medullary canal of the parent bone.

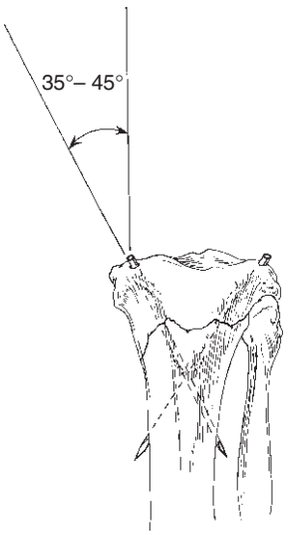

Figure 111-2. Fracture of the proximal tibial metaphysis fixed with cross pins. Note the angle of pin insertion and penetration of the parent diaphyseal cortex.

4. Orient cross pins obliquely to the long axis (35–45 degrees) so that they penetrate the far cortex (parent bone) when inserted (see Fig. 111-2).

▼ ***Key Point*** Cross pins provide excellent fracture fixation, but because they can interfere with normal function of the growth plate, use them with caution in immature animals.

5. Orient pins placed in the Rush technique more parallel (25–35 degrees) to the long axis. During insertion they bounce off the inner cortex of the medullary canal and are driven in to impact into the trabecular bone of the distant metaphysis.
   a. Pins placed in the Rush technique may be preferable for physeal fractures because of their smaller diameter (resulting in less damage to the proliferative zone of the physis) and because of their more perpendicular orientation to the physis (allowing sliding of the physis along the pins as it grows).
   b. Prebend the pins to facilitate reflection of the pins off the inner cortical wall as they are inserted.
6. Cut off excess pin length and countersink the ends below bone level (if the pins will not be removed) or bend the ends over to avoid soft tissue interference.

Intramedullary (IM) Pin and Wire Fixation

Indications

- Simple, axially stable fractures of the tibial diaphysis
- Other selected reducible tibial diaphyseal fractures

Contraindications

- Infected or significantly contaminated open (grade 3) fractures (see Chapter 120)
- Fractures that cannot be reconstructed

Equipment

- General orthopedic pack
- Steinmann pins
- Pin cutter

Technique

IM Pinning Technique for Simple, Axially Stable Tibial Fractures

1. Select a pin diameter 50% to 60% of the smallest medullary canal diameter.
2. Reduce the fracture, usually by manipulation through a medial open approach.
3. Insert the pin at a point midway between the tibial tubercle and medial collateral ligament along the edge of the tibial plateau (slightly distal to the articular surface).
4. Drive the pin distally (normograde) down the proximal fragment and across the fracture to impact into the distal metaphyseal bone.
5. Determine the pin insertion length by comparison with a second pin, identical in length, held along the side of the bone.

▼ ***Key Point*** Avoid driving IM pins through the articular cartilage of the cochlea, because this can result in development of significant arthritis.

6. Remove excess pin length with a pin cutter.
7. Determine rotational stability. If significant rotational motion persists, apply interfragmentary wire or a two-pin external fixator.
   a. An ancillary external fixator is similar to type I external skeletal fixation (described later) but uses fewer fixation pins, one above and below the fracture, which controls rotation but not bending forces.

Technique

Wiring Techniques for Fracture Reconstruction Prior to IM Pinning

With Cerclage Wires

Cerclage wires can be used only on long oblique fracture lines (fracture line length a minimum of twice the bone diameter), which can be very accurately reduced (Fig. 111-3).

1. Use large (18 gauge for medium and larger dogs; 22 gauge for toy breeds and cats) monofilament wire.
2. To control motion, at least two wires must cross the complete fracture line.

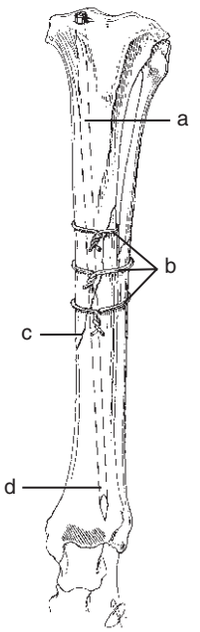

Figure 111-3. Use of cerclage wire to prevent axial collapse of a long oblique fracture stabilized with an intramedullary (IM) pin. (a) Pin diameter equals 50% to 60% of the medullary canal; (b) wires must be perpendicular to bone axis and one-half bone diameter apart; (c) fracture length must be a minimum of twice the bone diameter; (d) stop pin insertion short of cochlea.

3. Orient wires perpendicular to the long bone axis, space apart at least one-half bone diameter, and twist to tighten.
4. Use cerclage wires for fissure fractures as necessary.
5. Always use an IM pin in addition to the cerclage wires to control bending forces.

With Interfragmentary Wires

Use interfragmentary wires to stabilize short oblique patterns (fracture length greater than twice the bone diameter) when only one wire can be applied.

1. Create holes in each bone fragment with a hand chuck and Kirschner wire. Position the holes so the wire crosses the fracture perpendicular to the fracture line, thus providing maximum interfragmentary compression when the wire is tightly twisted.
2. Thread the wire through the holes and incorporate the IM pin that has been inserted to the level of the fracture as described previously.
3. Reduce the fracture, complete the IM pin insertion, and tighten the interfragmentary wire.

External Skeletal Fixation (ESF)

Indications

- Stable, reducible, and non-reducible fracture patterns depending on ESF frame configuration:
- The use of "positive profile" design pins, increased number of fixation pins, new connecting clamp design, and stiffer connecting bar materials has increased the stiffness and decreased pin problems of Type I (unilateral) frames. Therefore, even more unstable fractures can be treated with simpler frame configurations (Fig. 111-4).
- Type II (bilateral) and type III (trilateral) configurations (Fig. 111-5) have axial rigidity comparable to that of plates and newer design aiming devices make pin placement more accurate.
- "Moldable connecting columns" (Fig. 111-6) and biplanar configurations allow placement of an adequate number of pins in short metaphyseal fragments while avoiding significant soft tissue tethering problems by not requiring fixation pin alignment.
- Open fractures with significant soft tissue damage or infected fractures, because rigid fixation can be obtained without large implants (e.g., IM pins, plates) in the fracture site.
- Contraindications:
  - Intra-articular fractures
  - Avulsion fractures of ligament and tendon epiphyseal attachments

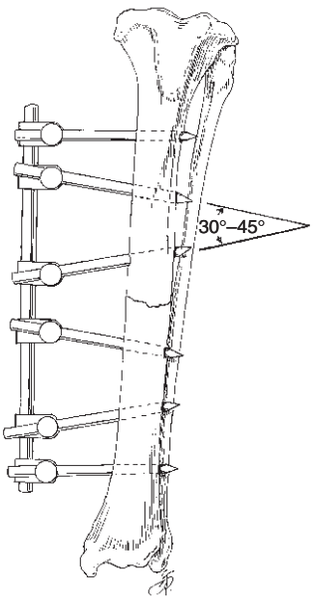

Figure 111-4. A six-pin type I (unilateral) external skeletal fixator applied to the medial side of a relatively stable tibial fracture. Addition of a lateral connecting bar would convert this to a type II (bilateral) fixator.

Equipment

- General orthopedic pack
- Low-speed power drill
- The newer IMEX SK (IMEX Veterinary Inc., 1001 McKesson Dr., Longview, TX) and Securos (Securos, 278 Southbridge Rd., Rte. 169, Charlton, MA) systems provide a wide variety of fixator systems and features for small animal application

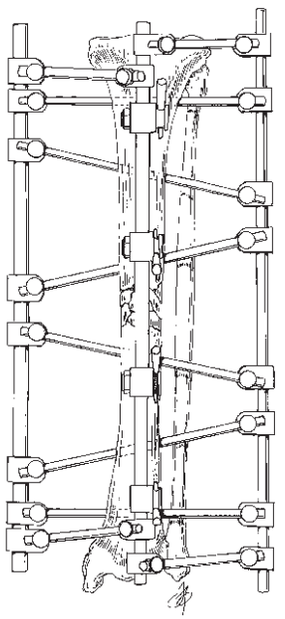

Figure 111-5. A very rigid type III (trilateral) external skeletal fixation (ESF) configuration applied to a non-reconstructible diaphyseal fracture.

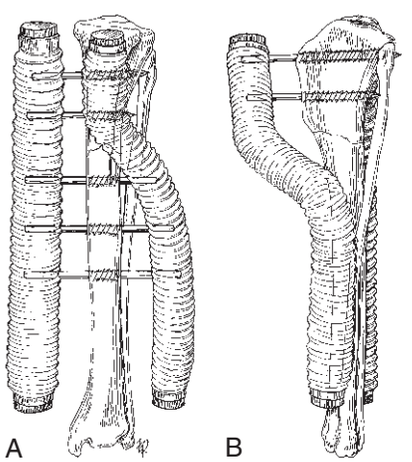

Figure 111-6. Use of a "hybrid" circular-traditional external fixator to stabilize a very distal metaphyseal tibial fracture.

- The acrylic pin external fixator (APEF) system creates "moldable connecting columns" in three sizes.

Technique for Mechanical External Fixator

1. Fixation usually is placed on the medial side of the tibia. However, it can be oriented laterally or cranially to avoid soft tissue injuries.
2. Position the patient in dorsal recumbency with the leg left hanging under tension from a secure attachment to the ceiling (hanging leg prep), to achieve reduction and simplify fixator application.
3. Hold the fracture in approximate reduction, and insert the most proximal and distal fixation pins through small skin incisions into each fragment, using a low-speed power drill. Predrill holes with a drill bit that is 90% of the pin diameter before inserting threaded pins. Threaded pins reduce the incidence of loosening of pins, and preclude need for pin angling.
4. Slide a connecting bar with the appropriate number of clamps onto the end fixation pins (at least three pins in each fragment).
5. Reduce the fracture, using closed manipulation on more comminuted fractures or a limited open approach on simpler fractures, and tighten the end clamps.
6. Insert fixation pins through the remaining open clamps into the bone. The Securos (Securos, 278 Southbridge Rd., Rte. 169, Charlton, MA) aiming device is useful for aligning full pins for Type II and III configurations. Tighten each connecting clamp after placing the pin. If threaded pins are not used, obtain a 30° angle between at least two of the pins in each fragment.
7. For unstable fractures, insert additional pins and bars in other planes to create more rigid frame configurations.
8. Circular fixators are now available for veterinary application from IMEX (IMEX Veterinary Inc., 1001 McKesson Dr., Longview, TX) and use small-diameter Kirschner wires placed at divergent angles and attached under tension to metal rings surrounding the bone instead of traditional fixation. This allows adequate grasp of a very short segment as occurs with distal metaphyseal fractures. Multiple rings can be connected together with threaded rods to create the fixator, or a ring can be combined with traditional fixator components placed in the longer segment in a "hybrid" configuration.
9. Collect autogenous cancellous bone graft from the proximal medial tibial tuberosity, and place it in any bony defects remaining after open fracture reduction.
10. Do not completely close incisions or wounds of open or infected fractures (see Postoperative Care and Complications).

Technique for APEF System Application

1. Insert fixation pins (using positive profile threaded pins for optimal bone-pin integrity) in the bone fragments oriented to best meet the mechanical needs of the fracture and minimize soft tissue tethering.
2. Attach the APEF alignment frame to pins on both sides of the fracture close to the skin level. Reduce the fracture (using closed manipulation or open reduction), and tighten the alignment frame clamps.

3. Close open reduction incisions or pack open wounds aseptically. Adequacy of closed reduction can be checked with radiographs.
4. Cut pins approximately 4 to 5 cm from the skin level.
5. Impale the acrylic column molding tubes on the pin ends and position the tubes adjacent to the alignment frame, parallel to the limb about 2 to 3 cm from the skin.
6. Plug the most dependent end of each molding tube.
7. Premeasured acrylic is mixed for 2 to 3 minutes to a smooth consistency.
8. Cut a corner of the bag with scissors, then pour the acrylic into the open end of each tube.
9. Allow the acrylic to cure (10–12 minutes).
10. Remove the alignment frame, plugs, and excess molding tube.

Plate and Screw Fixation

Indications

- The stabilized limb is needed for immediate weight bearing because of orthopedic or neurologic injuries to the other limbs.
- Restricted activity or adequate postoperative care is not possible.
- Rigid fixation is necessary (e.g., in large, very active dogs).

Equipment

- General orthopedic pack
- Plates, screws, and specialized instrumentation for their implantation
- Power drill

Technique

1. Contour an appropriate-size plate to the shape of the intact bone and apply the plate to the medial (tensile) side of the tibia.
2. If the fracture pattern is axially stable, compress the fracture by applying the plate in the compression mode. When using dynamic compression plates, compression is achieved by drilling screw holes such that the screw slides toward the fracture line.
3. Initially, rebuild long, oblique, and reducible comminuted fractures with interfragmentary lag screws and/or wires. Apply a plate to the tibia without compression to protect the interfragmentary fixation from bending forces (i.e., neutralization mode) (Fig. 111-7).
4. To prevent collapse under loading, apply a heavy plate in the buttress mode for non-reducible fractures.
   a. Add cancellous autograft to the fracture to stimulate rapid formation of load-sharing callus.
   b. Alternatively, remove detached bone fragments (break into small pieces and add to bone graft), transversely osteotomize fragment ends, and collapse the fracture to reestablish good cortical contact and a stable repair. As much as 20% of the tibial length may be removed without causing permanent dysfunction.

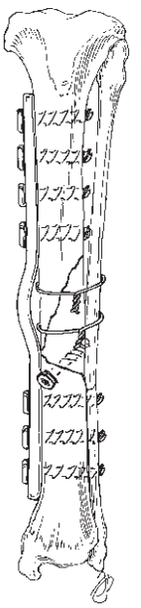

Figure 111-7. Use of a plate to protect a reconstructed comminuted tibial fracture from excessive bending forces. The screw and wires maintain reduction, and the plate "neutralizes" the weight-bearing forces.

POSTOPERATIVE CARE AND COMPLICATIONS

Immediate Postoperative Care

- Apply a compressive wrap (Robert Jones bandage) for 3 to 5 days to prevent soft tissue swelling and to protect the incision.
- Use gauze and tape to cover the connecting bars and clamps of external fixators. This decreases the incidence of the fixator "hanging up" on objects in the environment and protects the opposite limb.

▼ ***Key Point*** Do not primarily close infected and severely open fractures. Lavage and debride the wound q24–48h until healthy granulation tissue covers the wound (7–10 days). Complete wound closure at that time or allow healing by second intention if there is tension at the wound margins.

Implant Removal

- Do not routinely remove small implants such as cross pins, cerclage wires, lag screws, and tension band wires unless they cause problems such as joint interference or chronic drainage.

- Remove large IM pins unless the proximal pin end has been buried by tibial growth.
- Partially disassemble (destabilize or dynamize) rigid external fixation frames to a flexible configuration after early osseous bridging has occurred (about 6 weeks postoperatively). This increases fracture loading, stimulating callus hypertrophy and remodeling while protecting the fracture from excessive forces that might cause refracture. Remove the balance of the fixator when fracture healing is complete.
- Remove bone plates in the following situations:
  - Animal with short hair coat develops pain in limb when exposed to cold ambient temperatures.
  - Stiff plate design induces bone atrophy due to stress protection.
  - Chronic infection and drainage does not resolve.

Complications

Nonunion

- Hypertrophic nonunion:
  - There is exuberant callus proliferation without fracture bridging because of inadequate fracture immobilization. These fractures are biologically active and require only adequate immobilization.
  - Augment existing fixation or replace with a more rigid fixation technique to allow the fracture to heal.
- Atrophic nonunion:
  - There is lack of callus production, bone sclerosis, and bone resorption, reflecting a loss of biologic healing potential. These nonunions usually result from significant vascular damage from the trauma, surgical manipulation, or unstable fixation.
  - Treatment includes resection of non-viable bone, reestablishment of vascularity, control of infection, rigid fixation, and induction of new bone proliferation with an autogenous cancellous bone graft.

Malunion

- Malunion occurs when the fracture heals but poor alignment results in abnormal limb function. This may reflect inadequate initial reduction or loss of reduction owing to inadequate fixation.
- Treatment includes osteotomy, realignment, and adequate fixation.

Infection

- Acute infection of a tibial fracture occurs when bacterial proliferation overwhelms the body's defense mechanisms.
- Clinical signs include pain, swelling, and erythema that reflect the underlying accumulation of exudate and necrotic tissue.
- Immediate aggressive treatment is indicated to avoid progression to chronic osteomyelitis and nonunion:
  - Open the incision and extend the margins, if necessary, to ensure adequate drainage.
  - Culture the wound for aerobic and anaerobic organisms to determine specific antibiotic sensitivity.
  - Repeatedly lavage and debride the fracture site to remove exudate and necrotic soft tissue.
  - Initiate systemic broad-spectrum antibiotic therapy (e.g., cephalothins) until culture and sensitivity testing indicate specific therapy.
- See Chapter 121 for management of chronic osteomyelitis.

Growth Deformities

Growth deformities can result from trauma to the proliferative layer of one of the physes, or from application of fracture fixation that limits physeal elongation. Angular deformities become apparent about 3 weeks after physeal injury; arthritic changes follow if the condition is not corrected. Treatment depends on the cause of physeal dysfunction and the animal's maturity.

- In actively growing animals:
  - Resect the osseous bridge crossing the physis and replace with autogenous fat graft.
  - Remove fixation implants that might be inhibiting physeal growth.
- In mature animals:
  - Perform corrective osteotomy and articular realignment.

Chapter

112 Luxation, Subluxation, and Shearing Injuries of the Tarsal Joint

Dennis N. Aron

Luxation, subluxation, and shearing injuries of the tarsus involve damage to the supporting ligaments of the joint. Treatment and prognosis of these injuries depend on the location of the ligament damage and subsequent joint instability. Subluxations can be caused by spontaneous overstress or external trauma. Vehicular trauma usually causes luxations and shear injuries. Conservative treatment of most of these injuries with external coaptation is not advised, because continued instability and the development of degenerative joint disease are the likely outcomes.

▼ ***Key Point*** Surgical stabilization and appropriate postoperative rehabilitation gives the most consistent results in repair of luxation, subluxation, and shearing injuries of the tarsus.

ANATOMY AND SPECIAL CONSIDERATIONS

General

- The tarsus consists of the tibia, fibula, metatarsal bones, and seven specific tarsal bones orderly stacked in levels (Fig. 112-1).
- A multiple complex arrangement of ligaments connects the bones of the joint and helps to prevent luxation (Fig. 112-2).
- The *tarsocrural* joint is formed by the tibia and fibula at the proximal level and by the talus and calcaneus at the distal level.
- The *intertarsal* joints are all the articulations between the tarsal bones. Several of these joints are named and include the
  - Talocalcaneal joint—between the talus and calcaneus
  - Talocalcaneocentral joint—between the talus and central tarsal bone (includes a small communication with the calcaneus)
  - Calcaneoquartal joint (proximal intertarsal joint)—between the calcaneus and fourth tarsal bone
  - Centrodistal joint (distal intertarsal joint)—between the central tarsal bone and distal numbered tarsal bones
  - Tarsometatarsal joints—between the distal tarsal and metatarsal bones

Tarsocrural Joint

- Synonyms for this joint are the tibiotarsal, talocrural, ankle, and hock joint.
- Most luxations, subluxations, and shear injuries directly involve this joint.
- The major ligaments providing stability on the medial side of the joint are the long medial ligaments and tibiotalar short component ligament (Fig. 112-3*A*).
- The major ligaments providing stability on the lateral side of the joint are the long lateral ligament and the calcaneofibular short component ligament (Fig. 112-4*A*).
- The components of the medial and lateral ligaments complement each other in maintaining the talus in the mortise provided by the tibia and fibula.
- Certain parts of the ligament complexes are tighter in extension (long lateral and long medial ligaments) or flexion (calcaneofibular and tibiotalar short component ligaments).
- The tibiotalar and calcaneofibular short component ligaments of the medial and lateral sides, respectively, are especially important for maintaining stability of the joint. The joint capsule and malleoli also contribute to joint stability.
- The gross anatomy of the medial and lateral collateral ligament complexes is similar (see Figs. 112-3 and 112-4). The components cross at the tarsocrural joint space, providing the greatest amount of ligament and an advantageous spatial arrangement directly over the joint.

▼ ***Key Point*** In the reconstruction of the collateral ligamentous supporting structures of the tarsocrural joint, consider the complementary nature of ligamentous structure and function.

Intertarsal and Tarsometatarsal Joints

- The most common injury is damage to the plantar ligaments and tarsal fibrocartilage (see Fig. 112-2).
- The plantar ligaments and tarsal fibrocartilage limit extension of the intertarsal joints.

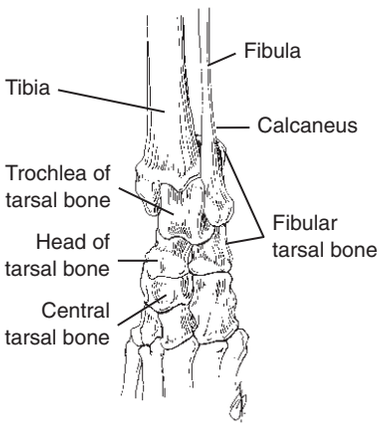

Figure 112-1. Anatomy of the bones of the tarsus.

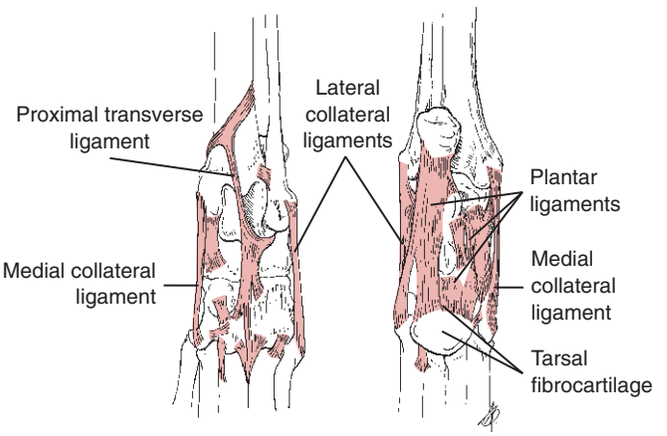

Figure 112-2. Cranial *(left)* and caudal *(right)* views of the ligamentous anatomy of the tarsus.

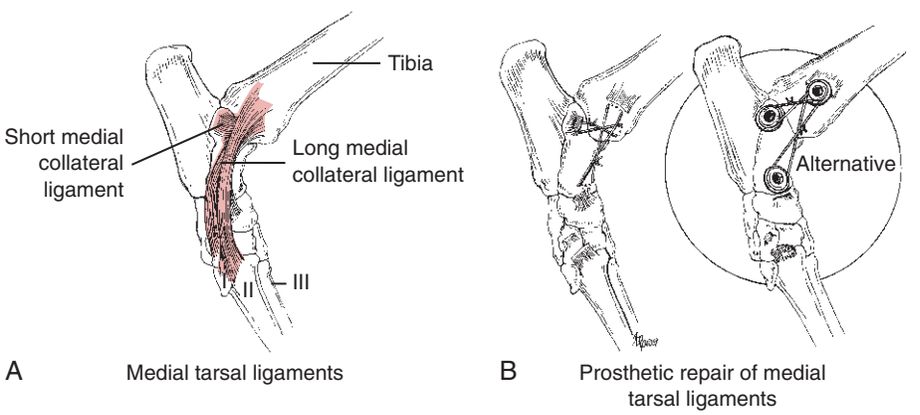

Figure 112-3. *A,* Medial ligamentous anatomy of the tarsus. *B,* Suture prosthesis repair of medial ligament injury. Tunnel sutures through the bones at points where the ligaments attach. Alternatively, place bone anchors or bone screws at these points.

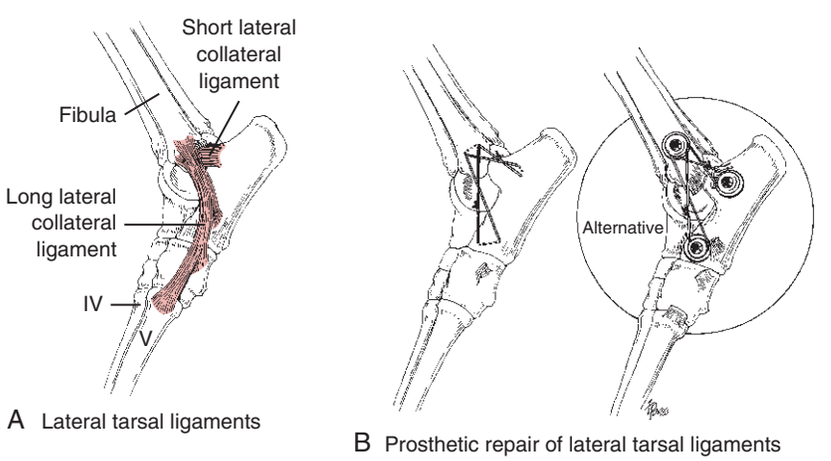

Figure 112-4. *A,* Lateral ligamentous anatomy of the tarsus. *B,* Suture prosthesis repair of lateral ligament injury. Tunnel sutures through the bones at points where the ligaments attach. Alternatively, place bone anchors or bone screws at these points.

- Most of the intertarsal joint stability is provided by three distinct plantar ligaments. These ligaments fuse, with a thickening of the joint capsule (the tarsal fibrocartilage), at the tarsometatarsal joint.
- The first ligament originates from the plantar surface of the sustentaculum tali and attaches to the central tarsal bone and tarsometatarsal joint capsule.
- The second ligament originates from the plantarlateral surface of the calcaneus. It joins with the long component of the lateral collateral ligament complex and attaches to the base of the fifth metatarsal bone.
- The third ligament originates from the body of the calcaneus and attaches to the fourth tarsal bone and the base of the fourth and fifth metatarsal bones.

TARSOCRURAL LUXATION AND SUBLUXATION

Surgical methods are recommended for treatment of luxation or subluxation injuries of the tarsocrural joint. Luxation and subluxation usually are the result of rupture of the medial or lateral collateral ligament complex.

Double-Prosthesis Replacement

- Double-prosthesis replacement (described later) closely reproduces the components of the intact medial and lateral collateral ligament complexes, thus allowing nearly normal joint stability to be maintained throughout a functional range of motion.
- Similar to the components of the normal collateral ligaments, double-suture prostheses become taut and lax with flexion and extension. Because of this, wire is not useful. Certain sutures (see later) give more successful results, most likely owing to the retention of elasticity upon cyclic loading.
- Clinically, double-ligament replacement gives results superior to conservative management with splints or non-anatomic single ligament replacement methods. The prognosis is good for long-term function with most closed luxation and subluxation injuries, depending on timely repair (within 5 days of injury) and absence of articular damage.

Preoperative Considerations

- Tarsocrural luxation results from different combinations of injuries, including
  - Fractures of both malleoli.
  - Fracture of one malleolus and damage to the contralateral ligament complex.
  - Fracture of the fibula and damage to the medial ligament complex.
  - Uncommonly, damage to both the lateral and medial collateral ligament complexes and no fractures.
- Tarsocrural subluxation usually results from complete rupture or avulsion of either the lateral or medial collateral ligament complex.
- In medial ruptures, the paw tilts abnormally toward the lateral direction with a laterally (valgus) applied force.
- In lateral ruptures, the tilt is in a medial direction with a medially (varus) applied force.
- Occasionally, there is rupture of only the long or short components of the medial or lateral ligament complexes. Less joint laxity makes these subluxation injuries more difficult to diagnose. Determine joint laxity using the following methods:
  - Place lateral and medial tilt forces on the hock at different joint angles: Laxity in extension but not flexion suggests major damage to the long medial ligament, or long lateral ligament; laxity in only flexion suggests that most damage is isolated to the tibiotalar or calcaneofibular short components.
  - Make a dorsoplantar (stress) radiograph while applying lateral and medial tilt forces on the hock: Take the stress radiograph at the tarsocrural joint angle that produces the subluxation; for subtle subluxations, compare this radiograph with a similar radiograph of the contralateral (normal) hock.

▼ ***Key Point*** Routine dorsoplantar and lateral radiographic views are always needed to check for concomitant tarsal injuries. Stress radiographs are useful to confirm the diagnosis but are not always necessary.

Surgical Procedure

Objectives

- Stabilize the joint.
- Maintain an adequate range of motion.
- Avoid trauma to the articular surfaces.
- Achieve pain-free weight bearing.
- Minimize patient morbidity and owner expense.

Equipment

- Standard orthopedic instrument pack and suture material
- Gelpi self-retaining retractors
- Small periosteal elevator
- Orthopedic drill (power drill preferred)
- Orthopedic anchors, screws, washers, and insertion equipment
- Kirschner wires (K-wires)
- Assortment of straight and curved needles
- Coaptation splint
- Coated braided polyester or monofilament polybutester (Polydek or Tevdek, Deknatel, Inc., Teleflex Medical, Mansfield, MA)

Technique

1. Clip the injured limb from the level of the proximal femur, extending distally to include the paw. Include the paw in the sterile field to allow direct manipulation.
2. Place the patient in lateral recumbency, with the injured limb up for lateral replacement or down for medial replacement, and prepare the limb for aseptic surgery.
3. Expose the subluxation through a curved skin incision centered over the medial or lateral malleolus.
   a. Begin from the distal one-fourth of the tibia and continue to the proximal metatarsal bones.
   b. Locate the medial or lateral collateral ligament complex along the same line by incising the subcutaneous tissue and deep fascia.
4. Inspect the components of the ligament complexes for damage.

a. To help assess the damage, stress the ligament components with a varus or valgus tilt in both flexion and extension.
b. It is unlikely that there will be a totally isolated injury to only one component of the ligament complex. The ligaments can appear intact but may have lost considerable function owing to internal derangement of the collagen fibers.

▼ ***Key Point*** Usually, the ligament components are too badly damaged to allow primary suturing of the torn ends or reattachment to bone. Replace irreparable ligaments and protect repaired ligaments with prosthetic sutures.

5. Replace or protect the medial or lateral ligament complexes with two figure-eight heavy sutures fastened to the bone directly, with bone anchors (BoneBiter Suture Anchor System, FlexiTwist Suture Anchor, Innovative Animal Products, Rochester, MN; SECUROS Bone Anchor, SECUROS, Charlton, MA), or with bone screws.
   a. Drill bone tunnels in the malleolus in locations similar to the origins of the components of the ligament complex (see Figs. 112-3 and 112-4). Bone tunnels serve as anchors for the suture prostheses.
   b. Secure the suture prosthesis that mimics the lateral or medial short components to tags of the torn ligament at the insertion site. Use a locking loop suture pattern to grip the torn ligament (see Chapter 115). A bone anchor or bone screw (see "Shear Injury") may be needed to fix the prosthesis to the insertion site (see Figs. 112-3*B*, 112-4*B*).
   c. Secure the suture prosthesis that mimics the lateral or medial long components to a drill hole in the tubercle of the distal talus or distal calcaneus (see Figs. 112-3*B* and 112-4*B*). A bone anchor or bone screw (see "Shear Injury") may be used to fix the prosthesis (see Figs. 112-3*B* and 112-4*B*).
6. Use one or two (for large patients) strands of #1 to #5 braided polyester or monofilament polybutester sutures for prosthetic replacement or protection.
   a. Set the sutures in a figure-eight pattern.
   b. Do not use absorbable sutures.
   c. Do *not* use monofilament nylon and monofilament polypropylene for sutures. They tend to stretch permanently and are better suited for primary repair of torn ligaments.
7. Tie the long and short suture prostheses.
   a. Tie the short prosthesis with the tarsocrural joint held in approximately 90 degrees flexion for dogs and 70 degrees for cats.
   b. Tie the long suture prosthesis with the joint in a functional standing angle of 135 degrees for dogs (varies with breed) and 120 degrees for cats.
   c. After the sutures are tied, tighten the screws or bone anchors against the bone.
8. Expose the luxation injury through separate surgical incisions on the medial and lateral sides of the joint.
   a. Fix the malleolar fracture with a tension band technique.
   b. Replace or protect the contralateral ligaments.
9. To manage luxations due to fracture of the fibula and damage to the contralateral ligament complex:
   a. Replace or protect the medial ligaments.
   b. Stabilize the fibula to the tibia with K-wires or bone screws.

Postoperative Care

- Protect the tarsocrural joints but allow weight-bearing mobilization of the limb with a short, three- to eight-layer semi-supple softcast (3M Scotchcast Soft Cast Casting Tape, St. Paul, MN) coaptation splint. The amount of layers used depends on the size and activity level of the animal and amount of microstrain to be allowed.
- Extend the splint from just below the stifle distally to include the digits.
- Place the hock in a functional standing angle.
- Provide semi-supple softcast coaptation as a full circular cast.
- Maintain the semi-supple softcast coaptation splint for 4 to 12 weeks; the length of time depends on the amount of initial trauma, joint instability, and health issues. A longer time is required for luxation and major subluxation injuries and older animals, a shorter time for incomplete tears and partial injuries and younger animals.
- The semi-supple softcast allows for controlled mobilization by progressive unwrapping of layers to increase tissue microstrain as healing advances.
- Once all coaptation is removed, continue progressive controlled mobilization by slowly increasing the animal's activity over another 4- to 12-week period. During this period, if the animal shows signs of increased lameness or pain, progress more slowly with controlled mobilization in a manner that does not create lameness or discomfort.

▼ ***Key Point*** Do not allow immediate uncontrolled activity of an animal after removal of coaptation.

SHEAR INJURY

Preoperative Considerations

- Shear injury usually occurs when an animal is trapped by a moving vehicle, resulting in shearing by the road surface of supporting ligaments, joint capsule, and malleolus.
- The medial side of the joint is injured more commonly than the lateral side of the joint.
- Perform wound management and ligament replacement when the bone and cartilage damage is mostly

isolated to the malleolus. Severe soft tissue damage makes stabilization difficult and prolongs healing.
- Although a successful ligament replacement gives better results than a tarsocrural joint arthrodesis, consider joint arthrodesis if there is extensive bone and cartilage damage.

Surgical Procedure

Objectives

- Prevent infection.
- Anatomically stabilize the tarsocrural joint, eliminate pain, and maintain a functional range of motion.
- Avoid trauma to the articular surfaces.
- Attain wound coverage with strong epithelial tissue.
- Minimize patient morbidity and owner expense.

Equipment

- Equipment is the same as for tarsocrural luxation and subluxation plus
  - Wound dressing materials
  - Coaptation splint materials

Wound Management and Debridement

Technique

1. Before debridement and ligament replacement, cover the shear wound with a temporary sterile dressing (see Chapter 56 for open wound management) and apply a temporary splint to prevent further damage to the unstable joint. Exteriorized material will contaminate deeper recesses if replacement into the wound is attempted.
   a. Do not push or "stuff" extruded soft tissue, bone, or cartilage back into the wound.
   b. Do not soak the wound.
2. Perform debridement as soon as the animal is a stable candidate for surgery, ideally within 6 hours from the time of injury for moderate wounds, and within or less than 1 to 2 hours for severe wounds.

▼ ***Key Point*** Ligament reconstruction and wound closure can be delayed, but do not delay wound debridement.

   a. Anesthetize the animal and remove the temporary splint.
   b. Keeping the wound covered, clip the limb, and cleanse with an appropriate antiseptic.
   c. Remove the dressing and thoroughly irrigate the wound with copious amounts of a prewarmed balanced electrolyte solution (see Chapter 56).
   d. Obtain cultures of the joint surface for identification of contaminating organisms and their sensitivity to antibiotics. A Gram stain may be helpful in identifying bacteria type.
3. After moving the animal to the operating area, perform a final surgical scrub and drape the limb.
4. Debride the wound of all visible necrotic tissue and debris. Be careful to avoid damage to articular surfaces.
   a. During the debridement process, lavage continuously with copious amounts (1 L or more) of a balanced electrolyte solution such as lactated Ringer's, using a moderate amount of pressure, through a 30- to 60-ml syringe and 18- or 19-gauge needle or catheter. Fluid pressure on the tissues should approximate 7 psi. Pulsatile suction and lavage is ideal.
5. Perform ligament replacement at this time or delay for repeat wound debridement or orthopedic referral. If delaying replacement:
   a. Cover the wound with an absorbent dressing to keep the wound moist (e.g., wet-to-dry dressing; see Chapter 56).
   b. Stabilize the joint with a rigid coaptation splint such as a fiberglass slab incorporated into a padded wrap.
   c. Change the dressing once a day or more frequently if necessary.
6. Repeat wound debridement if necrotic tissue is left in the wound after the first procedure. Continue this process until only viable tissue is present in the wound.

Ligament Replacement

The prosthetic ligament replacement technique usually requires three bone anchors or bone screws and figure-eight heavy sutures.

Technique

1. Use bone anchors or 4.0-mm partially threaded cancellous screws or 2.7-mm cortical screws with 2.7-mm spiked washers (Synthes Ltd., West Chester, PA), depending on the size of the animal. Place the screws as close as possible to the origin and insertion of the components of the ligament complex (see Figs. 112-3*B* and 112-4*B*).
2. Position the origin fastener, anchor or screw, in the distal tibia for the medial ligament or the distal fibula and tibia for the lateral ligament. Direct this fastener slightly proximal to avoid penetrating joint cartilage and to obtain maximum bony purchase.
3. Position the insertion fastener for the medial tibiotalar short ligament in the proximoplantar quadrant of the medial trochlear facies of the talus. Direct this fastener slightly distal to avoid the trochlear sulcus of the talus.
4. Position the fastener corresponding to the insertion of the medial long ligament through the tubercle at the plantar base of the talus. Direct this fastener slightly proximodorsally.
5. Position the fastener corresponding to the insertion of the calcaneofibular short ligament proximoplantar to the base of the lateral articular facies of the tuber calcis.

6. Position the insertion fastener for the long ligament through the tubercle at the dorsal extent of the base of the calcaneus. Direct this fastener slightly proximoplantar.
7. Using one or two (for large patients) strands of #1-5 polyester sutures or monofilament polybutester sutures as prosthetic replacements, place suture(s) around the origin fastener and the short insertion fastener, and separate suture(s) around the origin fastener and long insertion fastener.
   a. Set the sutures in a figure-eight pattern.
   b. Tie taut the tibiotalar or calcaneofibular short suture prosthesis with the tarsocrural joint held in approximately 90 degrees flexion for dogs and 70 degrees for cats. Tie taut the medial long or lateral long suture prosthesis with the tarsocrural joint in a functional standing angle of 135 degrees for dogs (varies for some breeds) and 120 degrees for cats.
   c. Tighten the fasteners against the bone.

▼ ***Key Point*** Never perform primary soft tissue closure over a shear injury.

8. If possible, allow second intention healing; alternatively, perform delayed closure or apply a skin graft (see Chapters 56 and 57) after all surfaces of the wound and prosthetic sutures are covered with healthy granulation tissue.

Postoperative Care

- Firmly immobilize the tarsocrural joint until the wound shows healthy granulation tissue and has begun to contract, is sutured closed, or the wound has been covered by a viable skin graft. This can be done several ways such as with a fiberglass slab or aluminum rod incorporated into a padded wrap. This type of wrap will allow frequent bandage changes. Try to avoid using a transarticular external skeletal fixator (ESF) as this rigid form of immobilization is very detrimental to the joint. However, if an ESF is used, maintain it for 2 weeks or less.
- After the firm coaptation is removed, semi-mobilize the hock for 6 to 12 weeks with a 4- to 10-layer short semi-supple softcast coaptation splint. If the wound has not completely been covered by healthy epithelial tissue a "window" can be cut into the softcast. The softcast allows one to progressively increase microstrain to the joint but does not risk failure of the prosthetic sutures.
- During use of the semi-supple softcast coaptation splint, perform controlled mobilization by allowing increasingly longer controlled walks and by progressively unwrapping layers to increase tissue microstrain as healing advances.
- Once all coaptation is removed, continue progressive controlled mobilization by slowly increasing the animal's activity over another 8- to 16-week period. Controlled muscle building techniques are valuable during this stage of rehabilitation. During this time, if the animal shows signs of increased lameness or pain, progress more slowly with controlled mobilization in a manner that does not create lameness or discomfort.

Prognosis

The prognosis is good to guarded for long-term pain-free function if there is no damage to the articular surfaces other than the malleolus. Careful rehabilitation through progressive controlled mobilization is critical to success.

TARSOCRURAL JOINT ARTHRODESIS

Tarsocrural joint arthrodesis can be done by tarsocrural joint fusion or pantarsal fusion.

- Pantarsal arthrodesis includes fusion not only of the tarsocrural joint but also of the intertarsal and tarsometatarsal joints.
- Pantarsal arthrodesis gives more consistent functional results and there is less patient morbidity.

Preoperative Considerations

Indications for performing tarsocrural joint arthrodesis instead of ligament replacement include

- Moderate to severe osteochondral damage to the joint mortise
- Prolonged tarsocrural joint subluxation or luxation causing moderate to severe degenerative joint disease
- Failure of reconstructive surgery or postoperative development of painful degenerative joint disease

Surgical Procedure (Pantarsal Arthrodesis)

Objectives

- Fuse the tarsocrural, intertarsal, and tarsometatarsal joints.
- Fuse the hock at a functional angle.
- Allow pain-free use of the limb.
- Minimize patient morbidity and owner expense.

Equipment

- Standard orthopedic instrument pack and suture material
- Gelpi self-retaining retractors
- Power drill
- Power saw or osteotome and mallet
- Pneumatic surgical bur (optional)
- Bone curettes
- K-wires

- Reconstruction bone plates, screws, and application equipment
- Coaptation splint

Technique

1. Approach the joint laterally from the distal one-third of the tibia, extending over the tarsal bones and ending at the proximal one-third of the fifth metatarsal bone.
2. Using a power saw or osteotome, cut the articular cartilage from the distal tibia and trochlea of the talus.
   a. Cut the distal tibia perpendicular to the longitudinal axis.
   b. Cut the trochlea of the talus at an appropriate angle, allowing the distal tibia to rest flush on the talus and form the proper weight-bearing angle at the hock. Before surgery, use the animal's contralateral limb to determine the correct weight-bearing angle (approximately 140 degrees for dogs [varies with certain breeds] and 120 degrees for cats).
3. Match the tibia to the talus at the appropriate angle and temporarily fix the two bones with K-wires.
4. With a bone curette or pneumatic bur, remove as much cartilage as possible from the intertarsal and tarsometatarsal joints.
5. Obtain autogenous cancellous bone from the ipsilateral greater tubercle of the humerus. Pack cancellous bone into the intertarsal and tarsometatarsal joints and around the tarsocrural joint.
6. Apply a contoured reconstruction bone plate to the lateral surface of the distal tibia, tarsus, and fifth metatarsal bone. Ostectomize the fibula to achieve a good fit. Place at least three screws in the tibia and metatarsasl bones. Alternatively, a standard bone plate can be placed dorsally (Fig. 112-5).
   a. Bend an appropriately sized 8- to 10-hole plate to the proper fit.

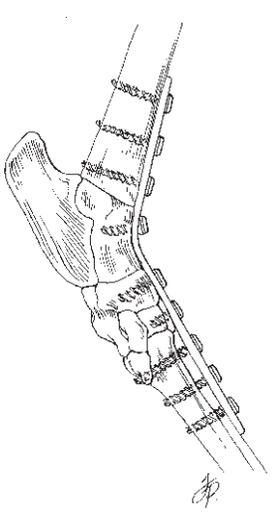

Figure 112-5. Pantarsal arthrodesis by dorsal application of a bone plate.

   b. Fix three cortical screws and the plate to the tibia, three or four screws to the tarsal bones, and three screws to the fifth and fourth metatarsal bones.
7. Maintain or remove the K-wires, pack more cancellous bone around the tarsocrural joint, and perform routine closure.

Postoperative Care

- Apply a short, rigid coaptation splint or full cylinder cast from the foot to just below the stifle until there is radiographic evidence of bone fusion.
- Remove the bone plate after there is complete bone union, usually in 6 to 9 months.
- Protect the arthrodesis for 6 weeks following plate removal with a semi-supple softcast coaptation splint; restrict exercise.

OVERVIEW OF INTERTARSAL LUXATION AND SUBLUXATION INJURIES

- Many intertarsal ligament injuries are a result of daily activity and occur without known trauma.
- Acute loading (e.g., with jumping) can damage plantar ligaments and cause a hyperextension injury.
- Affected animals usually are non–weight bearing or walk plantigrade, have variable swelling in the tarsal region, and have instability of the tarsus.
- Palpation and stress radiographs (see Chapter 4) usually can localize the area of injury.
- Hyperextension injuries are repaired by arthrodesis or tension band wire stabilization.
- Because surgery is performed only on the low-motion intertarsal or tarsometatarsal joints, the prognosis usually is excellent for pain-free normal function.

PROXIMAL INTERTARSAL SUBLUXATION WITH PLANTAR INSTABILITY

Preoperative Considerations

- Injury to the plantar ligaments of the calcaneoquartal and talocalcaneocentral joints results from excessive dorsiflexion; the hock collapses and the animal walks plantigrade.
- A traumatic episode usually is not identified.
- Diagnose by palpation and stress radiographs (see Chapter 4).
- This condition does not respond to conservative management with coaptation splints. Treat surgically by arthrodesis of the calcaneoquartal joint.

Surgical Procedure

Objectives

- Fuse the calcaneoquartal joint.
- Avoid trauma to the tarsocrural joint.

- Achieve pain-free, normal weight bearing.
- Minimize patient morbidity and owner expense.

Equipment

- Standard orthopedic instrument pack and suture material
- Gelpi self-retaining retractors
- Intramedullary pins
- Bone curettes or pneumatic bur
- Bone drill and assorted drill bits
- K-wires
- Orthopedic wire (18 or 20 gauge)
- External coaptation devices

Technique

1. Expose the joint plantar-laterally with medial retraction of the tendon of the superficial digital flexor (SDF). This may entail incising the lateral retinaculum, which normally secures the SDF tendon to the lateral process of the calcaneal tuber.
2. Using a bone curette or pneumatic bur, remove articular cartilage from the surfaces of the calcaneus and fourth tarsal bone.
3. Insert an appropriate-size single intramedullary pin ($^5/_{64}$–$^1/_8$ inch) from the proximal calcaneus down the shaft.
   a. Drill a pilot hole in the (very hard) calcaneus before inserting the intramedullary pin.
   b. Position the pin in the calcaneus.
4. Obtain autogenous cancellous bone from the ipsilateral greater tubercle of the humerus and pack it into the joint space.
5. Reduce the joint, drive the intramedullary pin across the joint, and fix the pin in the distal end of the fourth tarsal bone (Fig. 112-6).

Figure 112-6. Fusion of the calcaneoquartal joint via pin and tension band wire fixation and cancellous bone graft.

6. Retract the intramedullary pin slightly, cut it short, and countersink it beneath the cartilage of the tuber calcis.
7. Drill a transverse hole across the distal portion of the fourth tarsal bone and the middle section of the calcaneus.
8. Place an orthopedic tension band wire (18 or 20 gauge) in a figure-eight pattern through the drilled holes (see Fig. 112-6).
   a. Set the wire directly against the bone under all soft tissue.
   b. Tighten the wire evenly with a double-twist method and bend the twists over to rest against bone.
9. Reduce the superficial digital flexor tendon and suture the lateral retinaculum to stabilize the tendon.
10. Close the subcutaneous tissue and skin routinely.

Postoperative Care

- Place a short (from the proximal tibia to the paw) semi-supple softcast coaptation splint for 4 to 8 weeks. Perform progressive controlled mobilization with the softcast.
- Restrict activity until bony fusion of the joint is evident on radiographs (usually 6–8 weeks).

PROXIMAL INTERTARSAL LUXATION WITH PLANTAR INSTABILITY

Preoperative Considerations

- This condition occurs infrequently, compared with subluxation injury.
- Trauma results in a high-energy hyperextension injury. There is more joint displacement and instability than with subluxation injury.
- Because of the severe instability in this condition, perform arthrodesis of the intertarsal joint with a bone plate rather than with a less rigid pin and wire tension band technique.

Surgical Procedure

Objectives

- Fuse the proximal intertarsal joint. Otherwise, objectives are the same as for proximal intertarsal subluxation.

Equipment

- Standard orthopedic instrument pack and suture material
- Gelpi self-retaining retractors
- Bone curettes or pneumatic bur
- Power drill

- Bone plates, screws, and application equipment
- External coaptation devices

Technique

1. Make a lateral approach from the tuber calcis, extending over the calcaneus and fourth tarsal bone and ending over the proximal one-third of the fifth metatarsal bone.
2. Using a bone curette or pneumatic bur, remove articular cartilage from the bones of the proximal intertarsal joint.
3. Place autogenous cancellous bone in the joint space. Reduce the joint.
4. Place a bone plate on the lateral aspect of the calcaneus, fourth tarsal bone, and proximal fifth metatarsal bone (Fig. 112-7).
   a. Shape the bones slightly to accommodate the plate.
   b. Secure an appropriate-size seven-hole plate with two screws in the calcaneus, one in the calcaneus and talus, one in the fourth and central tarsal bones, and three in the fourth and fifth metatarsal bones.
   c. Alternatively, do not place the screw in the fourth and central tarsal bones, and pack this area with cancellous bone.
5. Close the tissue and skin routinely.

Postoperative Care

- Protect the arthrodesis with a short semi-supple soft-cast coaptation splint. Remove the splint when there is radiographic evidence of bony fusion.
- Remove the bone plate after the arthrodesis is complete. If retained, the plate usually loosens, causing pain and lameness.

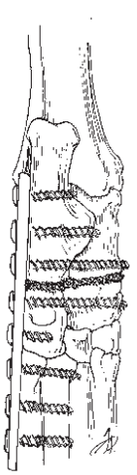

Figure 112-7. Proximal intertarsal joint fusion via lateral application of a bone plate and cancellous bone graft.

DISTAL INTERTARSAL (TARSOMETATARSAL) SUBLUXATION WITH PLANTAR INSTABILITY

Preoperative Considerations

- This condition is less common than proximal subluxation injury.
- The cause is tearing of the plantar tarsal fibrocartilage and usually is associated with trauma.
- A few days after the injury the animal attempts weight bearing and walks plantigrade.
- Consistent with hyperextension injuries, surgical arthrodesis is the treatment of choice.

Surgical Procedure

Objectives

- Fuse the distal intertarsal joint. Otherwise, objectives are the same as for proximal intertarsal subluxation.

Equipment

- See "Proximal Intertarsal Subluxation with Plantar Instability."

Technique

1. Expose the injury by an incision over the plantarlateral calcaneus, fourth tarsal bone, and metatarsal bones.
2. Retract the superficial and deep digital flexor tendons medially and laterally to expose the joints.
3. Remove articular cartilage from the distal intertarsal joint surfaces.
4. Pack autogenous cancellous bone into the joint space.
5. Use a pin and tension band wire technique similar to that described for proximal intertarsal subluxation with plantar instability, but slightly modified.
   a. Insert an appropriate size intramedullary pin ($^{5}/_{64}$–$^{1}/_{8}$ inch) down through the calcaneus; extend through the fourth tarsal bone and continue into the distal half of the fourth metatarsal bone.
   b. Drill transverse holes for the tension band wire (18 or 20 gauge) in the distal one-third of the calcaneus and the bases of two or three of the metatarsal bones.
   c. Place the wire in a figure-eight pattern under the superficial digital flexor tendon.
6. Alternatively, perform the tarsometatarsal arthrodesis with a bone plate. Use bone screws to secure two holes of a five-hole plate to the fourth and central tarsal bones and distal tarsal bones proximal to the subluxation, and three holes to the metatarsal bones distal to the subluxation.

Postoperative Care

- Maintain a short semi-supple softcast coaptation splint until there is radiographic evidence of bony fusion.

OTHER INTERTARSAL-TARSOMETATARSAL SUBLUXATION INJURIES

Proximal Intertarsal Subluxations with Dorsal Instability

- Physical examination findings include
  - Primary damage of the dorsal ligaments and dorsal joint capsule.
  - Frequently, concurrent lateral or medial instability.
  - Usually, no evidence of external trauma.
- The animal places full weight on the limb with only periodic lameness, which is made worse by coincident lateral or medial instability.
- Diagnose by palpation and stress radiographs.
- Slight dorsal swelling and increased flexion and opening of the dorsal joints are seen.
- Lateral or medial instability may be concurrent with dorsal laxity.

Treatment

- If possible, manage the instability with rigid coaptation splints.
- Surgical repair may be necessary if
  - Injuries are severe.
  - The instability does not respond to splinting.
  - Dorsal ligament damage is associated with lateral or medial damage.
  - The affected animal is a large, athletic dog.

Surgical Technique

1. Fix the dorsal instability with a neutralization bone screw placed from the medial side of the head of the talus, diagonally into the distal tarsal bones.
2. Remove articular cartilage before screw placement.
3. Supplement with an appropriately positioned figure-eight tension band wire for concurrent lateral or medial instability; a neutralization screw may not be needed.

Postoperative Care

- Postoperatively, maintain a semi-supple softcast coaptation splint for 6 weeks.
  - Perform progressive controlled mobilization with the softcast.
  - Remove the screw or tension band wire if it loosens.

Distal Intertarsal Subluxation with Dorsomedial Instability

- This type of subluxation can occur alone or combined with other areas of instability involving the tarsus.
- Diagnose by palpation and stress radiographs.
- Valgus deformity and dorsomedial instability are seen.
- Stabilize with a medially positioned tension band wire.

Surgical Technique

1. Place a bone screw in the central and fourth tarsal bones proximally, and a second screw in the second, third, and fourth tarsal bones distally.
2. Secure a figure-eight wire (20 or 22 gauge) around the screws.

Postoperative Care

- Postoperatively maintain a semi-supple softcast coaptation splint below the stifle for 6 weeks. Perform progressive controlled mobilization with the softcast.

Tarsometatarsal Subluxation with Dorsomedial Instability

- Stabilize with a medially positioned tension band.

Surgical Technique

1. Place a bone screw in the central and fourth tarsal bones proximally, and a second screw in the second and fourth metatarsal bones distally.
2. Secure a figure-eight wire around the screws.

Postoperative Care

Postoperatively, maintain a semi-supple softcast coaptation splint below the stifle for 6 weeks. Perform progressive controlled mobilization with the softcast.

Tarsometatarsal Subluxation with Dorsal Instability

- This is a subtle injury that requires stress radiographs to confirm the diagnosis.
- If possible, stabilize with rigid coaptation splints.
- Injury in a large dog or chronic injury may require surgical arthrodesis, using a pin and tension band wire or bone plate technique.
- Alternatively, the arthrodesis can be done by inserting cross-pins from the proximal metatarsal bones into the distal tarsal bones.
- Postoperatively, maintain a semirigid softcast coaptation splint below the stifle for 6 weeks. Perform progressive controlled mobilization with the softcast.

Luxation of the Head of the Talus, the Central Tarsal Bone, and the Talocalcaneus

- These types of luxation occur as an isolated injury or with concomitant tarsal joint instability. Usually, luxation of the head of the talus and the talocalcaneal luxation are the result of relatively high-energy trauma.

Surgical Technique

1. Reduce the luxated tarsal bone(s) and stabilize with a cortical bone screw.
   a. For luxation of the head of the talus or talocalcaneal luxation, insert a neutralization screw from the talus to the calcaneus.
   b. For the central tarsal bone luxation, insert a neutralization screw from the central tarsal bone to the fourth tarsal bone.
   c. Place the screw so that the luxated bones are held in position (neutralized). Do not compress the bones.

Postoperative Care

- Postoperatively, maintain a semirigid softcast coaptation splint below the stifle for 6 weeks. Perform progressive controlled mobilization with the softcast.

Chapter

113 Orthopedic Disorders of the Distal Extremities

Steven C. Budsberg

Disorders of the extremities distal to the carpus and tarsus usually result from direct trauma. Most abnormalities involve bone fracture and/or ligament damage associated with joint instability. The majority of fractures involve the metacarpal and metatarsal bones. Animals are usually presented with acute, non–weight-bearing lameness. Regardless of the bone being managed, internal fixation, external coaptation, or a combination of both can be used. Most surgeons prefer to use external coaptation whenever possible to manage fractures in these areas. In contrast, ligamentous injuries and associated joint instability rarely respond to external coaptation and often require surgical intervention. If fractures are open, proper open wound management is required before fracture fixation. Follow the generally accepted principles of fracture repair, including adequate reduction, alignment, and stable fixation, for the successful management of these injuries.

METACARPAL AND METATARSAL FRACTURES

Anatomy

The metacarpal and metatarsal bones are numbered 2 to 5, from medial to lateral. There are usually five metacarpal and four metatarsal bones. The third and fourth bones bear most of the forces transmitted through the foot.

Each bone is divided into the proximal base, middle body, and distal head.

Body Fractures

Body fractures may involve one or more bones. Racing animals may develop stress fractures of these bones. Closed reduction and coaptation usually are effective, but internal fixation may be required in cases involving multiple limb trauma, multiple bone fractures, and comminuted, severely displaced, or unstable fractures.

Preoperative Considerations

- Rule out associated injuries with a thorough physical examination and appropriate diagnostic tests.
- Identify the bone and region involved.
- Determine the type of injury (e.g., soft tissue, open or closed fracture, degloving injury).
- The number of bones involved affects treatment.
- Indications for external coaptation include
  - Single-bone fractures.
  - Multiple, non-displaced fractures without other limb trauma.
  - Fractures that have a combination of external coaptation with appropriate internal fixation (e.g., intramedullary pins, screws, plates).
- Indications for internal fixation include
  - Multiple bone fractures with severe displacement.
  - Combined fractures of the third and fourth bones.
  - Additional limb injury.
  - Fracture in working or show dogs.
  - Open fractures.
  - Articular fractures.

Surgical Procedure

Objectives

- Reduce and stabilize the fractures.
- Maintain viable soft tissues.
- Preserve joint function.

Equipment

- Standard surgical pack and suture material
- Kirschner wire (K-wire) (various sizes)
- Mini-fragment plates and screws (1.5, 2.0, and 2.7 mm)
- Small self-retaining retractors
- Small bone-holding forceps

Technique

1. Place the patient in dorsal recumbency, clip the hair, and prepare the extremity for aseptic surgery.

▼ ***Key Point*** Because of the central (metacarpal, metatarsal) and digital pads, surgical approach via the palmar or plantar surfaces of the metacarpal and metatarsal bones is contraindicated.

2. Make a dorsal incision directly over the affected bone or joint.
   a. To approach a single bone, make a longitudinal incision directly over the bone. To expose adja-

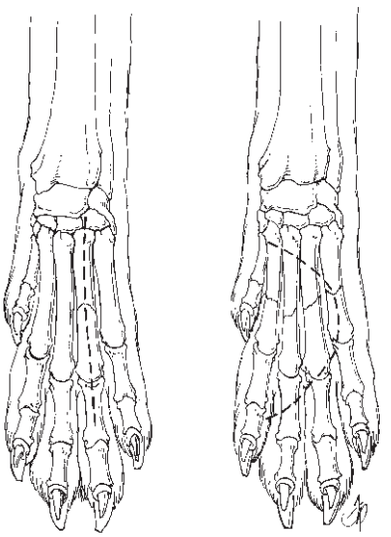

Figure 113-1. Dorsal incision lines for metacarpal fractures of a single bone *(left)* or multiple bones *(right)*.

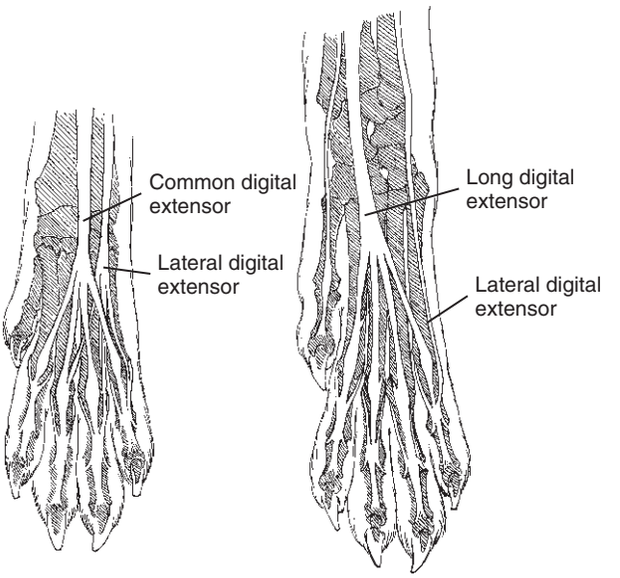

Figure 113-2. Important tendons of the metacarpus *(left)* and metatarsus *(right)*.

cent bones, make the incision between them, if necessary.

b. To approach multiple bones, make two parallel longitudinal incisions or a curved incision incorporating the entire dorsal region (Fig. 113-1).

3. Incise the deep fascia directly over the bone.
   a. In the metacarpus, identify and retract the major tendons (i.e., the tendons of the common digital extensor and lateral digital extensor muscles).
   b. In the metatarsal region, take care to protect the tendon of the long digital extensor muscle (Fig. 113-2).
4. Intramedullary pinning for fracture repair:
   a. Antegrade the pins from distal to proximal through a predrilled hole in the dorsal surface (Fig. 113-3). (Make the predrilled guide hole with a pin one size larger than the intended intramedullary pin.) Bend the pin ends slightly to facilitate removal and to avoid entering the metacarpo(tarso)phalangeal (MP) joint.

▼ ***Key Point*** When passing pins in an antegrade fashion, use a hand drill rather than a power drill to allow the pins to "bounce off" (instead of penetrating) the palmar/plantar cortex.

   b. Alternatively, retrograde the pins from the fracture site to the predrilled hole in the dorsal cortex, reduce the fracture, and seat the pins in the proximal segment (Fig. 113-4).

▼ ***Key Point*** Fixation with single intramedullary pins can accomplish reduction and alignment; however, this procedure does not provide rotational stability to the fracture.

   c. Use supplementary external coaptation of fiberglass (molded half-circumference cast) or metal

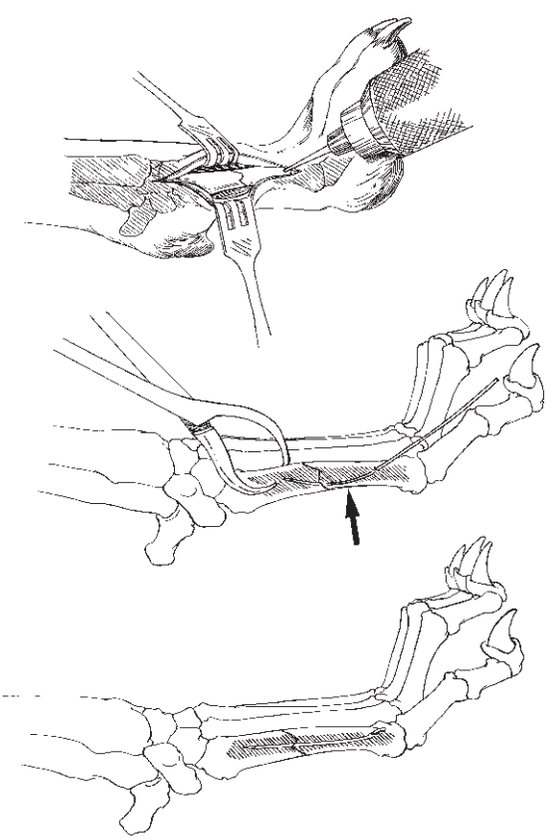

Figure 113-3. Placement of an intramedullary pin for repair of a metacarpal fracture. The center view shows how the pin is "bounced off" the palmar cortex *(arrow)*.

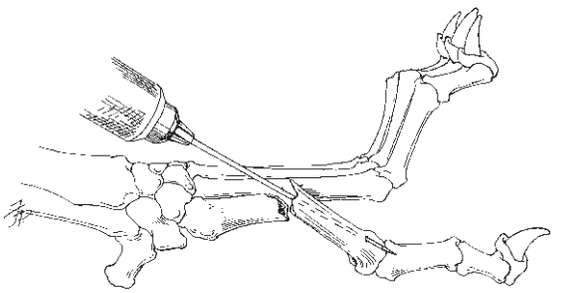

Figure 113-4. Retrograde placement of an intramedullary pin from the fracture site to a predrilled hole in the dorsal cortex.

(palmar/plantar splint) to augment internal fixation.

5. Plate fixation:
   a. For fixation of the third and fourth bones, place the plates on the dorsal surface. For fixation of the second and fifth bones, place the plates on the medial and lateral surfaces, respectively, or dorsally.
   b. A minimum of four cortices of screw purchase above and below the fracture is required.
   c. Perform supplementary external coaptation, as described previously.
6. Lag screw fixation:
   a. Use in oblique fractures, primarily the first, second, and fifth metacarpals and the second and fifth metatarsals.
   b. Perform supplementary external coaptation.
7. Close the incision routinely.

Base and Head Fractures

Preoperative Considerations

- Base fractures usually involve the second and fifth metacarpals, owing to ligamentous attachment; avulsion fractures commonly are seen. Valgus and varus displacement often is noted.
- Internal fixation is strongly recommended.
- Non-displaced fractures may be treated with a palmar splint; however, some displacement usually occurs. Delayed union may be a problem because of the motion from ligamentous attachment.
- Head (articular) fractures usually have concurrent subluxation or complete luxation of the MP joint owing to the collateral ligament attachment.
- Reconstruction of the articular surface is required.

Surgical Procedure

Objectives

- Reduce and stabilize the fracture.
- Repair or reconstruct ligament instability of the joint.
- Reconstruct the articular surface, if necessary.

Equipment

- Same as for body fractures, described previously.

Technique

1. The approach is the same as for body fractures, described previously.
2. In base fractures, fix with lag screws or a tension band technique. Use supplementary external coaptation.
3. In head fractures, use Kirschner and cerclage wires or a combination K-wire and hemicerclage technique. Use supplementary external coaptation.
4. Close the incision routinely.

Postoperative Care and Complications

▼ ***Key Point*** Management of soft tissue injuries in open fractures is as important as internal fixation.

- Maintain external coaptation in combination with intramedullary pins and lag screw fixation until there is clinical union of the fracture. Animals with plate fixation require coaptation for approximately 4 weeks.
- Remove intramedullary pins following clinical bone union. In working dogs, also remove plates. Lag screws and plates in non-working animals may be left in permanently.
- If postoperative bleeding is anticipated, apply a pressure bandage for 48 to 72 hours to minimize hemorrhage.
- In all cases, control and limit exercise until clinical bone union (usually 6–10 weeks).
- Rarely, delayed union and nonunion may result from inadequate stabilization. Excessive proliferative callus formation may cause tendon entrapment and/or pain.
- Valgus or varus deviation may result from undetected or untreated concurrent collateral ligament damage.
- If joint surfaces are involved, degenerative joint disease may develop.
- Treat tissue swelling with warm compresses or hydrotherapy.

PHALANGEAL FRACTURES

Phalangeal fractures are similar to metacarpal and metatarsal fractures. They usually are single injuries; however, they may occur in association with other, more severe multiple injuries to the paw.

Anatomy

- Each digit consists of a proximal phalanx and a distal phalanx. The phalanges are numbered similar to the metacarpals and metatarsals.
- The proximal and middle phalanges are divided into a proximal base, middle body, and distal head.
- The distal phalanges are approximately the same size in all digits and are partially covered by the nails.
- *Dewclaw* is the term applied to the variably developed first digit of the hind paw.
- Polydactyly (extra digits) is common in cats.

Preoperative Considerations

- Same considerations as metacarpal and metatarsal fractures.
- Open, severely comminuted fractures may require digit amputation (see Chapter 114).
- Most fractures can be reduced closed and immobilized in a fiberglass splint.
- Some of the indications for internal fixation include
  - Large working dogs or racing animals.
  - Articular fractures involving the base or head.
  - Failed external coaptation.

Surgical Procedure

Objectives

- See under "Metacarpal and Metatarsal Fractures."

Equipment

- The same as for metacarpal and metatarsal fractures, discussed previously

Technique

1. Make an incision directly over the affected bone.
2. Articular fractures require anatomic reduction and fixation with lag screws, orthopedic wire sutures, K-wire, or a combination of these.
3. Treat body fractures with miniplates or (for oblique fractures) cross pins and lag screws.

Postoperative Care and Complications

- See under "Metacarpal and Metatarsal Fractures."
- External coaptation is required until clinical bone union.

PALMAR AND PLANTAR SESAMOID INJURIES

Fractures of the sesamoid bones of the MP joints usually are seen in racing greyhounds. However, they can cause lameness in any dog, particularly large-breed animals. Signs include sudden lameness with swelling and pain on palpation. Injuries of the second and seventh sesamoids are reported to be the most common.

Anatomy

- The sesamoid bones are numbered 1 to 8 medial to lateral (two for each MP joint).
- The sesamoid bone articulates primarily with the head of the metacarpal/metatarsal bone and secondarily with the palmar tubercles of each proximal phalanx.
- Occasionally, bipartite sesamoid bones are present and may be mistaken for fractures.

▼ ***Key Point*** Old sesamoid fractures or bipartite sesamoid bones may be mistaken as the cause of lameness.

Preoperative Considerations

- An acute injury requires external coaptation. Place the foot in a splint in slight flexion.
- Recurrent lameness requires surgical intervention.

Surgical Procedure

Objective

- Remove the damaged sesamoid.

Equipment

- Standard surgical pack and suture

Technique

1. Make an incision adjacent to the metacarpal/metatarsal pad, with the middle of the incision directly over the MP joint.
2. Slightly undermine the pad to allow retraction and further deep dissection of the affected sesamoid bone.
3. Identify the distal venous arch on the proximal aspect of the incision.
4. Dissect directly over the sesamoid bone and move the flexor tendon to the side if necessary.
5. Transect the sesamoid ligaments and remove the offending fragments.
6. If less than one-third of the total bone is fragmented, leave the larger fragment and remove the smaller one.
7. Close each incised fascial plane with simple interrupted sutures of an absorbable suture material.
8. Close the remainder of the incision routinely.

Postoperative Care and Complications

- Place a snug padded bandage on the paw for 7 to 10 days.
- Limit exercise for 2 weeks and gradually increase to normal by 6 weeks.
- Complications are rare.

Chapter

114 Amputation of the Digit

Mark C. Rochat

ANATOMY

Distal Phalanx (Cats)

- The proximal end of the third or distal phalanx (P_3) is concave and has a dorsal ungual crest (Fig. 114-1).
- The distal end of P_3 (the ungual process) is covered by a keratinized claw or unguis.
- The ungual crest is a crest-shaped bony shelf that overlies the root of the claw.
- The stratum germinativum contains the germinal cells of the claw and extends into the ungual crest.

Dewclaw (Dogs)

- The dewclaw is the medial or first digit of the rear limb in the dog. The first phalanx and P_2 are often missing, and P_3 and the claw are attached only by skin and fibrous tissue.
- In some breeds, there are two dewclaws. Double dewclaws are breed standard specific in Great Pyrenees and briards and should not be removed.
- The dewclaw articulates with metatarsal bone I, which is often small and may be fused to tarsal bone I.
- If two dewclaws are present, there may be, on occasion, complete duplication of the phalanges and metatarsal bone I. Metatarsal bone I may also exist as two segments united by fibrous tissue or present with a distinct joint between the segments.

Digits (Dogs and Cats)

- The digits consist of three phalanges (P_1, P_2, and P_3) and a nail or claw. The first digit in the front foot does not have a middle phalanx (P_2); the first digit in the rear foot is properly termed the dewclaw.
- The proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints are connected axially and abaxially by collateral ligaments. The DIP joint is also connected by a dorsal elastic ligament that spans from the dorsal aspect of P_2 to the ungual crest of P_3.
- The superficial digital flexor tendon attaches to the proximal (palmar or plantar) end of P_2; the deep digital flexor attaches to a rounded tubercle on the palmar or plantar aspect of P_3; the lateral and common digital extensor tendons attach to the extensor processes of P_3.
- A digital pad is located on the palmar and plantar aspect of the distal interphalangeal joint of each digit, except for the first one. A single large metacarpal or metatarsal pad is located on the palmar and plantar aspects, respectively, of the metacarpophalangeal and metatarsophalangeal joints.
- The blood supply is via dorsal and palmar (or plantar) proper digital arteries; venous drainage is via dorsal and palmar (or plantar) proper digital veins.
- The nerve supply to the digits is the dorsal and palmar (or plantar) dorsal digital and dorsal proper digital nerves. Of more functional significance are the nerves that innervate the foot as a whole, the superficial radial, ulnar, and median in the front foot and the tibial, peroneal, and saphenous in the rear foot. Perform nerve blocks with long-acting local anesthetics whenever foot surgery is performed (see Chapter 6).

ONYCHECTOMY (CATS)

Onychectomy often is performed on house cats as an elective procedure; however, it may be necessary to perform this procedure when a claw is severely traumatized or infected or when neoplasia is present.

Preoperative Considerations

- Kittens and young cats recover from declawing quicker than older cats.
- Many owners are unaware of what a declaw procedure involves. An accurate and frank discussion of the procedure, with anatomic charts, often eliminates confusion and misinformation about the procedure and allows the owner to make an informed decision.
- Inform owners that declawing removes, to varying degrees, the cat's ability to escape or defend itself. This is especially true when all four feet are declawed. Therefore, most cats should be kept indoors as house pets after declawing. Behavioral issues may develop in multi-cat households when some cats are declawed and others are not.
- It is seldom necessary to remove the claws of the rear limbs. If the owner desires declawing of the rear feet, the consequences should be frankly discussed and

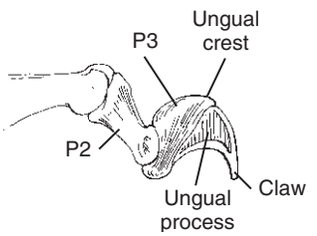

Figure 114-1. Regional anatomy of the distal phalanx of the cat.

other options explored prior to performing the procedure.
- Alternatives to declawing include simple nail trimming on a regular basis, behavioral modification, vinyl caps, and deep digital flexor tenectomy.

▼ ***Key Point*** The germinal cells of the claw extend into the ungual crest. To prevent claw regrowth, completely remove the ungual crest.

Surgical Procedure

Objectives

- Completely remove the claw(s).
- Protect the digital pad.
- Prevent excessive blood loss.
- Prevent nerve and vascular damage to the limb.

Equipment

- Appropriate tourniquet (e.g., Penrose drain)
- Sterile Kocher forceps
- Sterile scalpel blade (#11) and handle (#3 or #7)
- Sterile surgical gloves

Or:

- Appropriate tourniquet
- Sterile Kocher forceps
- Sterile guillotine-type nail trimmers (e.g., Resco); reserve a clean, sharp trimmer for declaws only and replace the blade periodically as it dulls
- Sterile surgical gloves

Or:

- Kocher forceps
- Sterile surgical gloves
- CO_2 laser

General Technique

1. Prepare the entire foot with a germicidal soap followed by solution. Chlorhexidine is preferred.
2. Block the regional nerves with bupivicaine (0.2–0.15 ml of a 0.5% solution at each site).
3. Place a tourniquet below the elbow. Exsanguinate the limb to the level of the tourniquet with an Esmarch bandage or hands prior to tightening or inflating the tourniquet. A Penrose drain and Kelly forceps (with tips curving away from the limb if using curved forceps) work reasonably well. Do not use rubber bands or black rubber tourniquets. Use of a CO_2 laser may eliminate the need for a tourniquet.

Scalpel Technique

1. Extend the claw by grasping the claw with Kocher forceps. Rotate the forceps and claw downward while tractioning the limb towards you.
2. Hold the scalpel like a paintbrush. Orient the blade transversely to the digit. Beginning at the junction of skin and claw, push the skin proximally, tensing the skin over the DIP joint, and press the scalpel blade downward to cut through the skin, dorsal elastic ligament, digital extensors, and joint capsule.
3. Without removing the blade, rotate the blade either laterally or medially to incise the skin from the dorsal incision to the distal aspect of the footpad. Remove the blade and incise the skin on the opposite side of the claw.
4. Further rotate the forceps and claw downward with distal traction to open the DIP joint. While mentally visualizing the shape of the DIP joint, carefully incise the joint capsule and collateral ligaments on either side of the joint. Stressing the joint laterally or medially will make the tissues give way as they are incised and make it easier for you to define the dissection plane.
5. When you reach the caudal aspect of the DIP joint, relax the limb tension to lessen the risk of cutting through the pad. Continue to rotate the forceps and P_3 downward and keep the edge of the blade always directed towards P_3. The attachment of the deep digital flexor tendon to P_3 can make dissection more difficult. Careful filleting of the tendon from the bone is required to avoid cutting downward through the pad (Fig. 114-2).
6. Continue the dissection distally around the palmar aspect of P_3 with the blade directed towards the bone until P_3 is severed. When the dissection is complete the digital pad should be intact and separated from the small hole by a short span of skin.
7. Removal of the claw on the first digit is more difficult because of the way the digit projects medially. While holding the Kocher forceps with thumb and forefinger, the remainder of the paw can be pushed away from the digit (in effect, adducting the digit) with your remaining fingers (right paw for a right-handed surgeon) or with your thumb (left paw for a right-handed surgeon).

Nail Trimmer Technique

1. Position the nail trimmer so the arch encircles the dorsal aspect of the distal interphalangeal joint and the blade rests at the distal margin of the digital pad. The trimmer can be used upright or tuned upside down, depending on the preference of the surgeon.

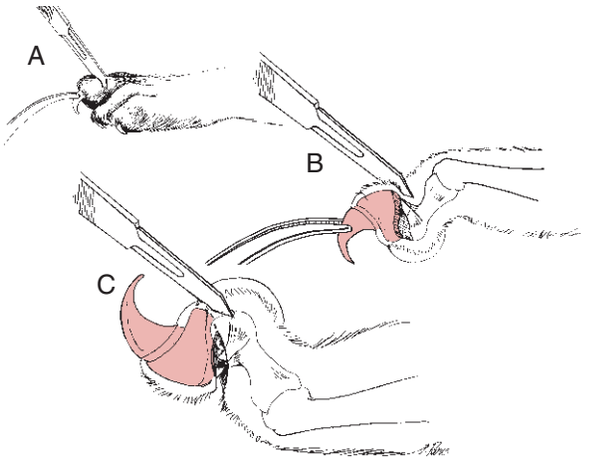

Figure 114-2. Scalpel technique for cat declaw. The deep digital flexor tendon is filleted from its attachment to the base of P_3. See text for details.

2. Use either fingers or forceps to hold the claw.
3. Pull the arch of the trimmer over the ungual crest and into the gap between P_2 and P_3 as much as possible. While holding the trimmers in the gap between P_2 and P_3, close the blades. Slightly release the tension on the blade as you rotate the claw upward to allow the blade to slip proximal to the flexor process. Squeeze the trimmer handle to cut through P_3.
4. When using nail trimmers, it is common to leave a small portion of the flexor process of P_3. This piece of bone, if the trimmers were properly positioned, is usually small and of no functional significance. If the piece seems subjectively large, grasp with forceps and remove with a scalpel.

Carbon Dioxide Laser Technique

1. Grasp the claw with Kocher forceps in the same manner as for the scalpel technique. Use the CO_2 laser in much the same manner as the scalpel. Direct the laser beam towards P_3 to avoid injury to the adjacent condyle of P_2 and the digital pad. Use standard laser safety precautions at all times.

Closure and Bandaging

1. Count all claws when you are finished to make certain all claws have been removed.
2. Leave the incisions open or, alternatively, close the incisions with tissue glue or with a single, absorbable, 4-0, monofilament suture. Tissue glue impedes wound healing and enhances the risk of infection if the glue is placed between the skin edges of the incision. Apply tissue glue on the surface of the skin at the incision site after careful apposition of the incision edges.
3. After completion of the procedure, apply a snug-fitting bandage to the level of the distal antebrachium. Avoid excessive tightness of the proximal portion of the bandage to ensure adequate blood supply to the paw. Declaws performed with a CO_2 laser may not require bandaging.
4. If a bandage is applied, do so prior to removing the tourniquet.

Postoperative Care and Complications

Short Term

- Bleeding after bandage removal occasionally is a problem and is usually self-limiting. Remove the bandages and observe the cat for several hours prior to discharging the cat to its owner. Hemorrhage from the site often appears significant but is usually less severe than it initially appears. If hemorrhage is truly severe, replace the bandage, and then remove in 12 to 24 hours. Do *not* place the bandage too tightly in an effort to achieve hemostasis; tissue necrosis may result.
- Lameness and pain are prolonged if the pad is cut. Careful technique prevents this complication.
- Neuropraxia and/or tissue necrosis may occur if the tourniquet is improperly used. Neuropraxia usually resolves in 4 to 6 weeks but may be permanent. Proper technique prevents this complication.
- Excessively tight bandages can result in tissue necrosis. Proper technique prevents this complication.
- Protrusion of the second phalanx can occur, especially if the skin incision is large or part of the pad has been removed. Debride the bone end if necessary, irrigate and close the wound, and administer oral antibiotics for 7 to 10 days.
- Infection is uncommon if the surgical site is properly prepped, the surgical dissection and operative time are kept to a minimum, and the cat is confined indoors and uses paper litter until the incision is healed. Treat infection by establishing drainage at the distal extremity and administering systemic antibiotics.

▼ ***Key Point*** Keep the cat indoors, and use shredded paper as cat litter for 2 weeks after surgery. Never use commercial cat litter because it will work its way into the wound and create tissue irritation and infection. The cost, lost time, client dissatisfaction, and pain for the cat are often significant and best avoided by stressing the need for paper litter verbally to the owner and in written discharge orders.

Long Term

- Regrowth of a deformed nail can result from incomplete removal of the ungual crest. Perform disarticulation of the distal interphalangeal joint with a scalpel.

- Chronic lameness may result from incomplete removal of P_3 or trauma to the digital pad. Remove the piece of bone with a scalpel.

DEWCLAW REMOVAL (DOGS)

Dewclaw removal is usually an elective procedure, although the claw may become traumatized, especially if it is only loosely attached to the skin.

Preoperative Considerations

- Removal of the dewclaw for cosmetic reasons is best performed in the neonate.

Surgical Procedure

Objectives

- Remove dewclaw and minimize scarring on the medial aspect of the foot.

Equipment

- Standard surgical pack including #3 scalpel handle and #15 scalpel blade, curved Mayo scissors, Kelly forceps, Adson or Brown-Adson tissue forceps, curved Halsted mosquito forceps, needle holders, operating scissors
- Suture material, 3-0 to 4-0 monofilament, absorbable on a cutting needle
- Bone cutters if the metatarsophalangeal articulation exists
- Sterile surgical gloves

Technique

Neonates

1. Surgically scrub the dewclaw and surrounding area.
2. Infiltrate the base of the claw with 0.75 to 0.5 mg/kg of lidocaine (without epinephrine) and 0.5 to 0.25 mg/kg of bupivicaine mixed together in a tuberculin syringe and inject using a 25-gauge needle.
3. Grasp the nail with small forceps and abduct it from the metatarsal bone.
4. With scissors, cut the dewclaw from its attachment to the metatarsal bone.
5. Achieve hemostasis by direct pressure or silver nitrate sticks.
6. Use a single absorbable suture to close the skin or leave the small incision open. No bandage is necessary.

Older Animals

1. Anesthetize the animal and block the saphenous, tibial, and peroneal nerves with 0.2 to 0.4 ml of 0.5% bupivicaine at each site.
2. Prepare the foot for aseptic surgery.
3. Make an elliptical incision around the base of the dewclaw.
4. Ligate the metatarsal and the dorsal proper digital arteries.
5. If only soft tissue attachment exists from the dewclaw to the metatarsal bone, remove the dewclaw and close the skin. If a bony attachment exists, disarticulate P_1 from metatarsal bone I with a scalpel.
6. Alternatively, use bone cutters to transect P_1 close to its base.
7. Close the skin routinely.
8. Place a bandage over the foot for 5 to 7 days.

Postoperative Care and Complications

- Prevent infection by good surgical technique
- Treat infection by drainage and oral antibiotics for 7 to 10 days.
- For adult dogs, treat pain with NSAIDs for 2 to 3 days.
- Hemorrhage is treated by direct pressure and bandaging. Ligate the bleeding vessel if the hemorrhage is severe and uncontrolled by the above methods.
- Scar formation at the site may be caused by the animal removing sutures prematurely, leading to wound dehiscence. Prevent this complication with good surgical technique and an Elizabethan collar and/or a bandage.

DIGIT REMOVAL (DOGS AND CATS)

Digit amputation in dogs and cats usually is performed because of severe trauma, osteomyelitis, or neoplasia. The level of amputation depends on the condition and the site of involvement. The digit may be removed at the metacarpophalangeal joint, metatarsophalangeal joint, PIP joint, or DIP joint or by osteotomy of the bones of the affected digit.

Preoperative Considerations

- Digit amputation proximal to the distal interphalangeal joint may necessitate digital pad removal, but it is preferable to maintain the digital pad when possible.
- The primary weight-bearing digits are the third and fourth, but significant weight is also borne by the second and fifth digits.

Surgical Procedure

Objectives

- Remove the digit.
- Minimize blood loss.

Equipment

- Standard surgical pack including #3 scalpel handle and #15 scalpel blade, curved Mayo scissors, Kelly forceps, Adson or Brown-Adson tissue forceps, curved

Halsted mosquito forceps, needle holders, operating scissors
- Suture material, 3-0 to 4-0 monofilament, absorbable on a cutting needle
- Bone cutters if osteotomy is to be performed

Technique

1. Anesthetize the animal and block the median, ulnar, and radial nerves (front foot) or the tibial, peroneal, and saphenous nerves (rear foot) with 0.2 to 0.4 ml of 0.5% bupivicaine at each site (see Chapter 6).
2. Prepare the foot for aseptic surgery. A hanging limb technique is often helpful.
3. Place a tourniquet below the elbow. Exsanguinate the limb to the level of the tourniquet with an Esmarch bandage or hands prior to tightening or inflating the tourniquet. Non-adhesive bandage material that stretches can be used but may not adequately control arterial inflow and may worsen the hemorrhage at the surgical site. Do not use black rubber tourniquets because there is a greater risk of nerve and muscle damage due to the tight narrow band of compression they create. Do not use rubber bands as tourniquets.
4. For digit removal distal to mid-P_2, make a transverse incision on the dorsal aspect of the digit around to the digital pad.
   a. Ligate the digital arteries and veins.
   b. Disarticulate the digit at the distal interphalangeal joint, after transecting the flexor and extensor tendons. Alternatively, use bone cutters and transect P_2.
   c. Suture the subcutaneous tissue of the pad to the extensor tendon with absorbable suture material and close the skin routinely.
5. For digit removal proximal to mid-P_2, make an elliptical incision at the base of the digit (Fig. 114-3).
   a. Ligate the vessels and disarticulate the digit with a scalpel or cut the bone with bone cutters (see Step 2b previously).
   b. A proximal extension of the elliptical skin incision usually facilitates cosmetic closure of the skin (see Fig. 114-3).
   c. If digit 2 or 5 is amputated, an oblique osteotomy facilitates a tension-free closure and provides a more cosmetic appearance to the foot.
   d. Close the subcutaneous and skin layers routinely.

Figure 114-3. Skin incision for digital removal proximal to mid-P_2.

Postoperative Care and Complications

- Apply a bandage to the foot for 7 to 10 days. Keep the bandage clean and dry.
- Remove skin sutures 10 to 14 days postoperatively.
- Submit the removed tissue for histopathologic examination.
- Hemorrhage is usually controlled with ligation of the associated vessels and direct pressure via bandages.
- Infection is prevented by proper surgical technique. Treat by drainage and oral antibiotic therapy until the infection is resolved (usually 7–14 days).
- Treat dehiscence by proper wound management until the incision is healthy followed by wound closure without tension. Apply padded bandage to reduce the tension on the incision and lessen the risk of dehiscence recurring.
- Neuropraxia and/or tissue necrosis may occur if the tourniquet is improperly used. Neuropraxia usually resolves in 4 to 6 weeks but may be permanent. Proper technique prevents this complication.
- Recurrence of tumor can occur depending on the tumor type and surgical technique. Preoperative review of fine needle aspirates or incisional biopsies will usually identify tumors that are likely to have extended margins. The risk of recurrence of tumor at the surgical margins is best prevented by wide resection of the tumor.

Chapter

115 Surgery of Skeletal Muscle and Tendon

Matthew Palmisano

Injuries to skeletal muscle and tendon are frequently seen in small animal practice. Injuries to skeletal muscle can either occur secondary to strain from high-impact activity, or result from lacerations, either externally from sharp objects or internally from fracture ends. Injuries to tendons most commonly occur secondary to sharp trauma.

Muscles and tendons heal by the same mechanism found in all tissues of the body. However, muscles and tendons are unique in that they have to be able to generate and resist great tensile forces in order to function properly. Minimizing scar tissue formation is clinically important because it is weaker than healthy muscle and tendon. Apposition of the ruptured ends (i.e., with suture) minimizes scar tissue formation. Early but controlled motion and stress across the wound results in a stronger healed wound. Balancing early motion against protecting the healing tissue from re-rupture is a clinical dilemma that is crucial to optimal healing of the injured tissue.

ANATOMY

Skeletal Muscle

- Skeletal muscle is composed of many muscle fibers, which are very long and cylindrical muscle cells. Each fiber has many peripherally located nuclei. Muscle fibers are grouped into bundles, or fascicles. Each muscle fiber is composed of myofibrils, which are the basic subunit of skeletal muscle.
- The whole muscle is encased in a thick connective tissue called the epimysium. The perimysium binds myofibers into groups to form fasciculi and carries blood vessels and nerves. The endomysium is a sparse, reticulated connective tissue between the muscle fibers and carries blood capillaries and nerve fibers.
- Each myofiber contains a single terminal branch of a motor axon that finishes close to the sarcolemma (muscle cell wall) at the motor end plate.

Tendon

- Tendons are composed of long bands of collagen fibers arranged in parallel rows and are embedded in ground substance and extracellular fluids. The fibroblast (or tenocyte) is the cellular component of tendon fibers.
- Collagen fibers are surrounded by a woven mesh of loose areolar connective tissue called the endotenon. The endotenon allows longitudinal movement of the collagen bundles and carries all of the blood vessels, lymphatics, and nerves. The epitenon covers the entire tendon, and is continuous on its undersurface with the endotenon.
- Free gliding is provided by the outer sheath of the tendon called the paratenon. The paratenon covers and separates tendons from each other. The paratenon forms a synovial membrane in areas of local pressure.
- Blood supply to tendons enters at three locations. Blood vessels entering at the musculo-tendinous junction supply the proximal one-third of the tendon. Blood vessels penetrating longitudinally in the paratenon or synovial sheath supply the middle one-third of the tendon, while the distal one-third of the tendon is supplied by vessels at the bone-tendon insertion.
- Vascular tendons are surrounded by soft tissue, while avascular tendons are surrounded by a tendon sheath. Avascular tendons have the disadvantage of a poor blood supply, which may lead to poor healing and adhesions between the tendon and tendon sheath.

Healing of Muscle

- Muscle can be injured by contusion, ischemia, denervation, sprains, and ruptures. The type and severity of the injury determines whether the muscle will heal with functional myofibers or scar tissue.

▼ ***Key Point*** Healing of muscle by scar tissue is undesirable because it decreases the ability of the muscle to produce tension by 50%.

- The following classification system for muscle injury is based on the severity of the injury and resulting muscle damage:
  - Grade I: Tearing of a few muscle fibers, intact muscle fascia and minimal hemorrhage.
  - Grade II: More severe muscle tearing than grade I, with hematoma formation.
  - Grade III: Tearing of a large amount of muscle. Muscle fascia is torn, so hemorrhage can be diffuse.
  - Grade IV: Complete rupture of one or more muscle bellies.
- Factors that cause an increase in the amount of scar tissue are a poor source of healing myoblasts, poor vascularization or innervation, and excessive stress across the healing wound. Vascular supply is a very important factor for healing. The rate of vascular ingrowth is approximately 0.5 to 1 mm per day. Therefore, large areas that cannot revascularize quickly heal with scar tissue.
- Dense fibrous tissue prevents regeneration of muscle fibers across the wound. Factors causing excessive scar tissue formation include a large gap across the wound and inappropriate stress or motion across the wound during the healing period. Therefore, there is a delicate balance between early return to function versus immobilization. Early motion across the wound promotes desirable parallel orientation of regenerating muscle fibers, but it may also promote excessive granulation tissue formation. This would cause poor penetration of regenerating muscle fibers through the connective tissue scar.
- Conversely, prolonged immobilization decreases scar tissue formation and allows penetration of regenerating muscle fibers, but also causes irregular orientation of muscle fibers, which would cause a decrease in tensile strength.
- Muscle fibers do not go across scar tissue, and only limited myofibril regeneration occurs in directly apposed muscle edges.

▼ ***Key Point*** Approximation of wound edges and duration of wound immobilization are critical for optimal healing of muscle injuries.

Healing of Tendon

- Tendons are often injured by sharp trauma, or the tendon may be surgically cut in order to increase exposure to a joint. Medical conditions, such as Cushing's disease, can cause tendon weakening and tearing. Injections of steroids into or around tendons can substantially weaken tendons for 2 weeks, and weakness persists for greater than 1 year.
- Tendons and ligaments follow the same pattern of healing. Factors affecting the quality of healing include
  - Healing across a gap versus apposition with suture.
  - Early mobilization versus immobilization.
  - Cause and location of the injury.
- Direct apposition of tissues using sutures and <1 mm gap provides optimal tendon healing. Fibroblasts within a wound form collagen by the fourth to fifth day. The border between the undamaged tendon and area of injury becomes indistinguishable by day 21. From 21 days to 1 year, scar tissue progressively recedes toward the site of initial injury until there is a small width of scar tissue interposed between readily distinguished tendon ends. The diameter of healing tendon is greatest at 3 weeks, decreases until week 14, and is unchanged 2.5 years after surgery. Tendons held in apposition with suture heal without interposed scar tissue and are difficult to distinguish from controls.
- Suturing must adequately prevent formation of a gap when the tendon is under tensile load for optimal healing.

Diagnosis of Muscle and Tendon Injury

- Muscle ruptures can be palpated as areas of discontinuity in muscle fibers or sheaths. In addition, there may be bruising or hematoma formation at the injury site. The degree of lameness and pain on palpation varies with the severity and chronicity of the injury. With tendons and ligaments, there may be abnormal laxity with the involved joint.
- Radiographs may show increased soft tissue opacity at the injury site due to swelling and hematoma. In addition, an avulsion fracture may be seen if the tendon has pulled off of the bone. Other imaging modalities that have recently shown promise in characterizing muscle or tendon injury include ultrasound and magnetic resonance imaging.

SURGERY OF SKELETAL MUSCLE

Surgical Procedure

Objectives

- Use gentle tissue handling.
- Preserve blood supply.
- Create a tension-free anastomosis.
- Remove excessive scar tissue or hematoma and perform accurate apposition of the muscle ends.

Equipment

- Standard soft tissue surgical instrument pack
- Self-retaining and hand-held retractors
- Non-absorbable, monofilament suture (e.g., polypropylene)
- Rubber tubing or Silastic buttons for tension relieving sutures

Technique

1. Use large non-absorbable monofilament suture, such as 2-0 or 0 prolene or nylon.

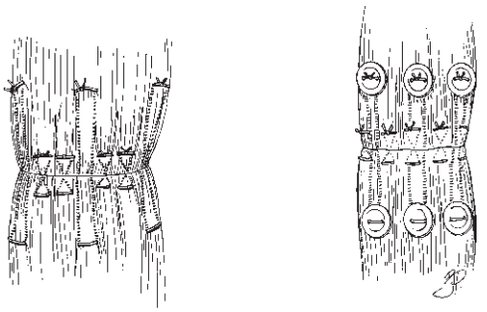

Figure 115-1. Suture patterns for muscle apposition. *Left,* Interrupted cruciate sutures with interposed deeper horizontal mattress sutures. *Right,* Silastic buttons prevent deep tension sutures from pulling out.

2. Use tension relieving suture patterns, such as horizontal mattress or cruciate patterns.
3. Muscle tissue holds suture poorly. Therefore, take large bites of tissue and utilize the dense, outer fascial layer to minimize suture pull-through.
4. If necessary, place plastic stents for greater holding power (Fig. 115-1).
5. Use Penrose drains or closed suction drains (e.g., Jackson-Pratt) if there is excessive dead space. Cover the drain with a soft padded bandage.

Postoperative Care

- Immobilize the limb using cast or splint coaptation for 2 to 3 weeks. After, gradually return to normal activity for another 4 weeks.
- Start physical therapy (see Chapter 95) after the immobilization period. Proper physical therapy is crucial for optimal return to function.

SURGERY OF TENDON

Preoperative Considerations

Many of the same surgical principles apply for surgery of tendon as surgery of skeletal muscle, such as direct apposition of tendon ends, gentle tissue handling, and postoperative immobilization to protect the tenorrhaphy.

Clean dirty or contaminated wounds and manage until tissues are healed enough to perform a delayed primary tenorrhaphy. Debride necrotic tissue. If tendons cannot be sutured at the time of the initial surgery, tag the tendon ends with suture in order to assist in identification later, when delayed primary tenorrhaphy can be performed. Manage open wounds with daily or twice-daily bandage changes. Wet-to-dry bandages may be useful in helping to further debride unhealthy tissue.

Surgical Procedure

Equipment

- Same as for muscle repair, described previously

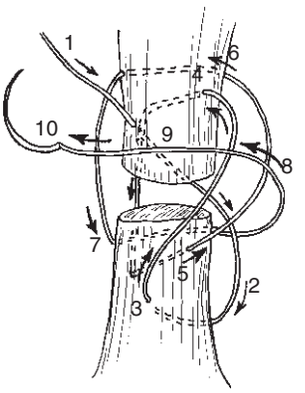

Figure 115-2. Three-loop pulley tenorrhaphy suture pattern. Needle passes follow numbered sequence and alternate in a near-far, middle-middle, and far-near pattern. Loops are oriented in separate planes and rotate approximately 120 degrees from each other.

Technique

1. Remove hematoma and scar tissue. Debride tendon ends to healthy tissue.
2. Two commonly used suture patterns are the locking loop (Kessler) and three-loop pulley. Use the largest diameter, non-absorbable, monofilament suture that will atraumatically pass through the tendon. 2-0 or 0 nylon or prolene is preferred.
3. The locking loop pattern is useful for flat tendons, such as the superficial digital flexor tendon and infraspinatus tendon. Recent studies have shown that more than one locking loop may be placed in order to increase tensile strength.
4. The three-loop pulley suture pattern is applicable to round tendons, such as the common calcaneal tendon. Studies have shown the three-loop pulley suture pattern to be superior to the locking loop pattern in regards to tendon-holding power and resistance to gap formation.
5. With the three-loop pulley suture pattern, place three different loops. Place the three loops, respectively, in a near-far, middle-middle, and far-near pattern. Rotate each loop 120 degrees in a different tissue plane (Fig. 115-2).
6. If the area of tendon injury is close to the bone, consider passing one or more of the suture loops through a bone tunnel in order to increase holding strength of the tenorrhaphy.

Postoperative Care

▼ ***Key Point*** Proper postoperative support of the repaired tendon, and staged return to activity, is critical for a successful repair.

- Place Penrose drains or closed suction drains if there is excessive dead space. Cover the drain with a soft padded bandage.

- Rigidly immobilize the joint involved using either a cast or transarticular external skeletal fixator in order to protect and prevent tension on the tenorrhaphy. Immobilize the joint for the first 4 to 6 weeks.
- After the fixation is removed, allow gradual return to normal activity for another 4 weeks. Consider placing a partial cast or splint during this period to allow partial weight bearing.
- See Chapter 95 for discussion of physical therapy after musculoskeletal injury.

Chapter

116 Neoplasia of Thoracic and Pelvic Limbs

Matthew Palmisano / Milan Milovancev

Tumors of the appendicular skeleton can occur either as a primary or metastatic lesion. Primary bone tumors occur most commonly in middle-aged and older animals. However, younger dogs 18 to 24 months of age can be affected.

▼ ***Key Point*** Primary bone neoplasms are usually metaphyseal in location, involve one bone, and usually do not cross a joint space.

Metastatic bone tumors may occur anywhere along the bone, and can affect multiple bones. Metastatic lesions can occur with any tumor type, but tumors of epithelial origin are more commonly seen to metastasize to bone.

ETIOLOGY

Primary Skeletal Neoplasms

Osteosarcoma

▼ ***Key Point*** Osteosarcoma (OSA) accounts for approximately 85% of all primary bone tumors in dogs.

- 75% of OSA occurs in the appendicular skeleton.
- OSA is usually an aggressive lesion originating in the metaphysis of long bones.
- The distal radius is the most common site for OSA, making up 40% of all skeletal OSA. Other common sites include the proximal humerus, distal femur, and proximal tibia.
- OSA is a biologically aggressive neoplasm, with a doubling time of 21 days.
- Although 80% to 90% of dogs lack radiographic evidence of pulmonary metastases at time of diagnosis, most dogs are euthanized due to complications associated with metastatic lung disease.
- Large- and giant-breed dogs are over-represented in most studies. Only 5% of OSA occurs in dogs weighing less than 15 kg.
- One study found that OSA in small-breed dogs behaves differently than in their large-breed counterparts, representing less than 50% of all skeletal neoplasms and with no apparent predilection for the distal radius. The proximal humerus is the most common site in the small-breed dog.
- Appendicular OSA in cats behaves less aggressively than canine OSA, with affected cats surviving a mean of 14.8 months following amputation. The hind limb is more commonly affected in the cat.
- Cisplatin, carboplatin, and doxorubicin are chemotherapeutic agents frequently used in treatment of OSA. Survival rates reported with chemotherapy are 45% survival to 1 year, and 30% 2-year survival.
- Poor prognostic indicators in dogs with OSA include a preoperative alkaline phosphatase level greater than 110 U/L, OSA in young patients, high tumor grade, and radiographic evidence of pulmonary metastases.
- Long-term prognosis is poor. Survival rates in dogs diagnosed with OSA are 10% survival at 1 year without chemotherapy. Amputation will achieve local tumor control and relief from pain, but the procedure does not extend long-term life span.

Chondrosarcoma

- Chondrosarcoma represents 5% to 10% of primary tumors of the appendicular skeleton.
- Medium- to large-breed dogs are most commonly affected.
- Unlike OSA, surgical resection of chondrosarcoma is associated with an increased long-term survival when compared to non-surgical management.
- However, long-term prognosis is still guarded, with a 30% 1-year survival seen with treatment.

Fibrosarcoma and hemangiosarcoma are the third and fourth most frequently seen primary tumors of bone, respectively. Both tumors together comprise slightly less than 5% of primary tumors of bone.

See Table 116-1 for biologic behavior, treatment, and prognosis of the most common canine malignant appendicular skeletal tumors.

Table 116-1. COMMON CANINE MALIGNANT APPENDICULAR SKELETAL TUMORS

Tumor Type	Metastatic Rate	Treatment Options	Prognosis
Osteosarcoma	+++	Amputation and chemotherapy Palliative amputation Palliative radiation	MST about 6 months with surgery alone MST 9–12 months with surgery and chemotherapy
Chondrosarcoma	+	Amputation	Good if complete excision
Fibrosarcoma	++	Amputation	Poor
Hemangiosarcoma	+++	Amputation	Poor, MST <5 months

MST, median survival time; +, slow; ++, moderate; +++, high.

Other Primary Skeletal Neoplasms

Other rare bone tumors include osteoma, chondroma, osteochondroma, enchondroma, malignant mesenchymoma, liposarcoma, plasma cell myeloma, lymphosarcoma, and giant cell tumor.

Primary Soft Tissue Neoplasms

Synovial Cell Sarcoma

- Synovial cell sarcomas are tumors that arise from the joint capsule.
- Most commonly seen in middle-aged to older animals.
- The stifle and elbow joint are affected in nearly 75% of cases.
- Radiographs reveal an osteolytic pattern associated with a joint. Classically, this tumor crosses the joint space. This differs from primary tumors of bone, which characteristically do not cross the joint space.
- Histologic grading carries prognostic significance, as tumors with higher biologic grading are more likely to metastasize. The metastatic rate varies from 20% to 70%, depending on histologic grading.
- Recurrence is common after local surgical resection. Therefore, limb amputation is recommended for local tumor control.

Other Primary Soft Tissue Neoplasms

Other primary soft tissue appendicular tumors include hemangiosarcoma, rhabdomyosarcoma, lymphosarcoma, fibrosarcoma, and malignant histiocytosis. These tumors are rarely seen and require histologic analysis for diagnosis and prognosis. Since sarcomas do not exfoliate easily, fine-needle aspiration is generally unrewarding. Therefore, incisional or excisional biopsies are required for diagnosis.

Metastatic Neoplasia

- Metastasis to bone from primary neoplasms located elsewhere in the body is occasionally seen.
- Any neoplasm may metastasize to bone, but carcinomas are more likely to metastasize to bone than sarcomas. In particular, urogenital neoplasms such as prostatic carcinoma, transitional cell carcinoma of the bladder, and mammary carcinomas tend to metastasize to bone.

▼ ***Key Point*** Tumors that metastasize to bone are usually seen in the diaphysis, whereas primary tumors of bone are usually metaphyseal in location.

- A thorough diagnostic workup (bloodwork, three-view chest radiography, abdominal ultrasonography) is essential to determine the primary source of neoplasia.
- Biopsy of both the primary mass and bone lesion is important for accurate diagnosis and staging of disease.

CLINICAL SIGNS

- Clinical signs are variable and range from a subtle lameness and non-painful swelling to a non–weight bearing lameness with obvious limb deformation.
- Occasionally, acute lameness will be seen secondary to pathologic fracture through the diseased bone.
- Rarely, dogs will have respiratory signs at presentation due to metastatic pulmonary disease.

DIAGNOSIS

- A presumptive diagnosis is usually made based on signalment, history, physical examination, and radiographic findings.
- A thorough physical examination, complete blood count, serum biochemical profile, and urinalysis are important to assess the patient's overall health status and check for concurrent conditions that may affect treatment options.

Diagnostic Imaging

- Obtain a three-view thoracic radiographic study (i.e., right lateral, left lateral, and ventrodorsal or dorsoventral views) to evaluate the patient for pulmonary metastasis.
- Chest radiography and nuclear imaging are two modalities that, when used together, detect metastasis in about 18% of cases. Availability of nuclear imaging is limited in private practice.
- Other advanced imaging modalities, such as computed tomography (CT) and magnetic resonance imaging (MRI), are useful in locating metastasis to lung and other extra-skeletal sites. Use of imaging to estimate tumor margins is important in limb-sparing surgeries and in radiation therapy planning.
- Radiographic patterns of both primary and secondary bony neoplasia are very similar, with a combined osteolytic-osteoproliferative pattern seen. Aggressive radiographic features such as cortical lysis, periosteal reaction, and bony proliferation strongly support neoplasia.

Biopsy

- Definitive diagnosis requires representative biopsy performed either using a bone core biopsy (Jamshidi needle, Michel trephine, or open-incisional) in the radiographic middle of the lesion or a wedge biopsy if the mass is soft tissue in origin (Fig. 116-1).
- Jamshidi needle biopsy has an accuracy rate of 91.9% for detection of tumor versus other disease processes and 82.3% for diagnosis of exact tumor type.
- Perform a fine needle aspirate on all enlarged lymph nodes and evaluate cytologically for metastasis.

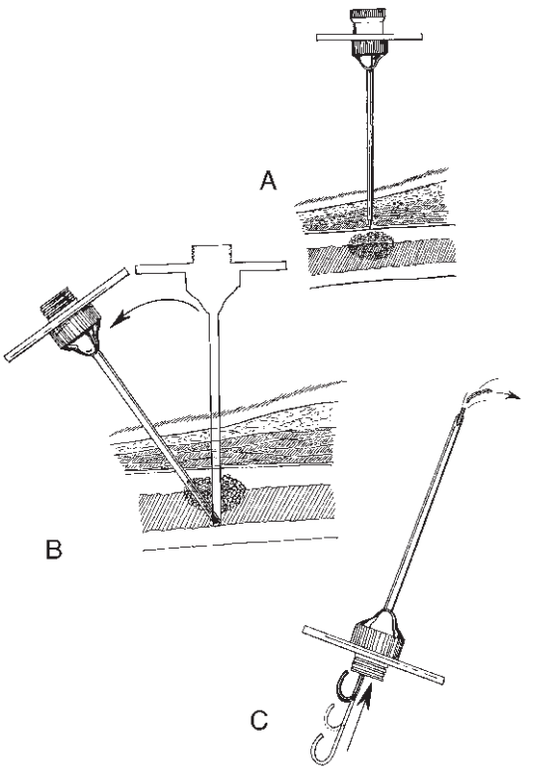

Figure 116-1. *A,* Biopsy of bone by closed technique with a Jamshidi needle. *B,* With the stylet locked in place, advance the cannula through soft tissue until bone is reached. *C,* Remove the stylet and penetrate the one cortex with the cannula. Withdraw the cannula and repeat the procedure with redirection of the needle.

TREATMENT

- Treatment recommendations depend on tumor type and location.

Surgery

- Although some small or benign tumors may be treated by local resection, most appendicular neoplasms require complete or partial amputation of the affected limb, primarily for palliation of pain (see discussion of amputation later in this chapter). Evaluate the patient's other limbs to ensure that adequate function can be carried out with the remaining three limbs.

▼ ***Key Point*** Limb amputation is contraindicated in patients that will have difficulty ambulating with three limbs. This includes overweight and obese patients or patients that have significant orthopedic disease in the other three limbs that will affect postoperative ambulation.

- Some giant-breed dogs have difficulty ambulating initially following amputation due to their large size and require some assistance postoperatively. Most of these patients adjust quickly.

▼ ***Key Point*** Perform the amputation at least one joint above the involved bone.

- Limb-sparing procedures are associated with a higher complication rate than limb amputation, are technically difficult to perform, and require access to a bone bank, which limits its use in private practice.
- Because most malignancies of the appendicular skeleton carry a poor long-term prognosis with amputation alone, follow-up adjunctive therapies are recommended. Adjunctive therapies include radiation therapy to enhance local tumor control and chemotherapy to treat metastatic disease.
- Radiation therapy or chemotherapy can be used alone as palliative therapy for pain control in patients that are not candidates for amputation.

Chemotherapy

- Postoperative chemotherapy is the most important modality for increasing long-term survival for canine osteosarcoma (see Chapter 26).
- Chemotherapy increases survival rates significantly over amputation alone, with reported 45% survival at one year and 30% at 2 years.
- Patients undergoing chemotherapy should have >3,000 neutrophils per µl, >150,000 platelets per µl, and normal renal function.
- Due to potential side effects of chemotherapeutic agents, consult a veterinary oncologist when treating these patients.

Cisplatin and Carboplatin

- Always check for evidence of myelosuppression before administering any chemotherapeutic agent.
- Myelosuppression and nephrotoxicity are dose-dependent, potentially life-threatening complications of cisplatin therapy.
  - Saline diuresis prior to cisplatin treatment helps prevent nephrotoxicity.
- Administer *cisplatin* at a dose of 70 mg/m^2 IV. Start therapy after the skin sutures are removed. Repeat at 21-day intervals for three to six treatments.
- *Carboplatin* is less nephrotoxic than cisplatin, and can be administered intravenously without pre-treatment diuresis, as required for cisplatin.
- Carboplatin is administered at 300 mg/m^2 IV. Start therapy after the skin sutures are removed. Repeat at 21-day intervals for three treatments provided there is no bone marrow suppression.
- In earlier studies, carboplatin had been shown to possess similar antitumor effects to cisplatin. However, recent studies have not found similarly favorable survival times.

Doxorubicin (see Chapter 26)

- Results are mixed in different studies.
- One-year survival rate of 50.5% was reported in 35 dogs treated with doxorubicin.

Combination Chemotherapy

- Few studies are available, but a recent large study reported median survival times greater than 11 months in 102 dogs treated with surgery, doxorubicin, and cisplatin.

Radiation Therapy

- Radiation therapy is an effective treatment modality for relieving pain and dysfunction associated with primary and metastatic bone neoplasia.
- Recently described four fraction treatment protocols for osteosarcoma are effective for palliation of clinical signs (median survival time of 313 days) and may result in a higher response rate than traditional three fraction protocols.
- Certain tumor types (i.e., mast cell tumors) are relatively radiosensitive, so these patients may be better candidates for radiation therapy.
- Development of sarcoma within a previously irradiated site several years after radiotherapy has been reported.

Other Modalities

- Immunotherapy and vehicle-based chemotherapies are currently being investigated as an adjunct treatment modality for canine osteosarcoma. Mixed results have been reported.

LIMB AMPUTATION

Anatomy

A thorough knowledge of limb anatomy is essential to achieve a successful outcome with minimal complications. Blood loss is a significant complication with limb amputation and is minimized with accurate dissection, hemostasis of smaller vessels with cautery, and preemptive ligation of larger arteries and veins.

Thoracic Limb

- The axillary artery extends from the cranial border of the first rib to the joint tendinous insertion of the teres major and latissimus dorsi muscles. It lies deep to the brachial plexus.
- Major veins include the cephalic vein (deep to the cleidobrachialis muscle), the brachial vein, and the axillary vein (caudal and cranial to the axillary artery, respectively).

Pelvic Limb

- The femoral artery lies superficially in the femoral triangle, caudal to the caudal belly of the sartorius muscle, and cranial to the pectineus muscle.
- The femoral vein lies caudal and deep to the femoral artery.

Preoperative Considerations

- Amputation of a limb involves loss of a large amount of fluid and blood. Therefore, use appropriate fluid therapy during and after surgery.
- Have blood products available if excessive blood loss is anticipated during surgery.
- Administer preoperative analgesia (e.g., fentanyl patch) (see Chapter 6).
- Begin antibiotics IV at induction of surgery, and continue postoperatively PO for an additional 3 to 5 days. First-generation cephalosporins (e.g., cephazolin) and amoxicillin/clavulanic acid are the antibiotics of choice.

- Many patients with appendicular neoplasms are older (>8 years of age). Therefore, identify other concurrent diseases and treat accordingly.
- Amputation of a limb is often difficult for owners to accept. Prior to surgery, explain the functional and cosmetic changes resulting from amputation. Most patients function very well after amputation, and cosmesis is acceptable. One study found a direct relationship between owner satisfaction and long-term survival.
- Most clients were happy with their decision to amputate their pet's limb if the pet lived a longer, good-quality life.

Surgical Procedures

Thoracic Limb Amputation with Removal of the Scapula

Use this technique when the tumor involves the humerus or scapula. Scapulohumeral joint disarticulation can be performed when the scapula is not involved, but it is technically harder to perform than amputation with scapula removal. Thoracic limb amputation at mid-humerus is technically easier to perform and causes less blood loss than removal of the scapula because it requires no major muscle belly transection. However, owners often find this procedure cosmetically unacceptable, because both the proximal humerus and scapula are easily visible as the muscles atrophy after surgery.

Objectives

- Complete tumor resection with wide margins of normal tissue
- Minimize blood loss
- Close or drain large areas of dead space

Equipment

- Standard general surgery instruments and suture
- Electrocautery
- Closed suction drainages (preferable) or Penrose drains

Technique

1. Place the dog in lateral recumbency and aseptically prepare the entire leg and chest wall for surgery.
2. Incise the skin along the spine of the scapula to the greater tubercle of the humerus. Carry the incision circumferentially to the medial side of the shoulder joint.
3. Ligate and divide the cephalic vein as it runs deep to the cleidobrachialis muscle.
4. Sharply separate the omotransversarius and the cervical and thoracic parts of the trapezius muscles from the scapular spine (Fig. 116-2*A,B*).
5. Subperiosteally elevate the rhomboideus and serratus ventralis muscles from the medial aspect of the scapula, and abduct the latter from the chest wall (Fig. 116-2*C,D*).
6. Sever the common insertion of the latissimus dorsi, teres major, and cutaneous muscles from the teres tubercle of the humerus. The axillary lymph node can be identified at this location, and should be removed and submitted for evaluation of metastasis.
7. Ligate and divide the thoracodorsal artery and vein and cut the thoracodorsal nerve. Further abduct the scapula and rotate it medially.
8. Ligate and divide the axillary and lateral thoracic arteries and the brachial and axillary veins.
   a. To avoid pooling of large amounts of blood in the limb, double-ligate arteries before veins. Ligate veins first if dissemination of disease is a major concern (Fig. 116-3, *top*).
9. Transect the brachial plexus of nerves with scissors or a scalpel.
10. Complete the amputation by cutting the pectoral and cleidobrachialis muscles away from the humerus (Fig. 116-3, *bottom*).
11. If dead space cannot be closed, place a closed suction drain (e.g., Jackson-Pratt) or passive drain (Penrose). Routinely close the muscles, subcutaneous tissues, and skin (Fig. 116-4). Make sure to eliminate dead space during closure, and do not close tissues under tension.

Pelvic Limb Amputation at Midfemur

Use this procedure when the tumor does not involve the femur. This method provides a stump, which provides lateral protection of genitalia in males.

Objectives

- Same as for thoracic limb amputation.

Equipment

- Same as for thoracic limb amputation, plus
  - Bone cutting instrument (oscillating saw, Gigli wire, bone cutting forceps)

Technique

1. Place the dog in lateral recumbency and aseptically prepare the entire limb and pelvis for surgery.
2. Incise the skin in two connected semicircles; ventrolaterally from the tuber ischii down to the patella and up to the flank and ventromedially from the ends of the lateral incision to midthigh.
3. Transect the caudal belly of the sartorius and gracilis muscles at midthigh.
4. Isolate, ligate, and divide the saphenous nerve and femoral artery and vein.
5. Transect the pectineus muscle at its insertion on the femur, and the cranial sartorius and quadriceps muscles proximal to the patella.

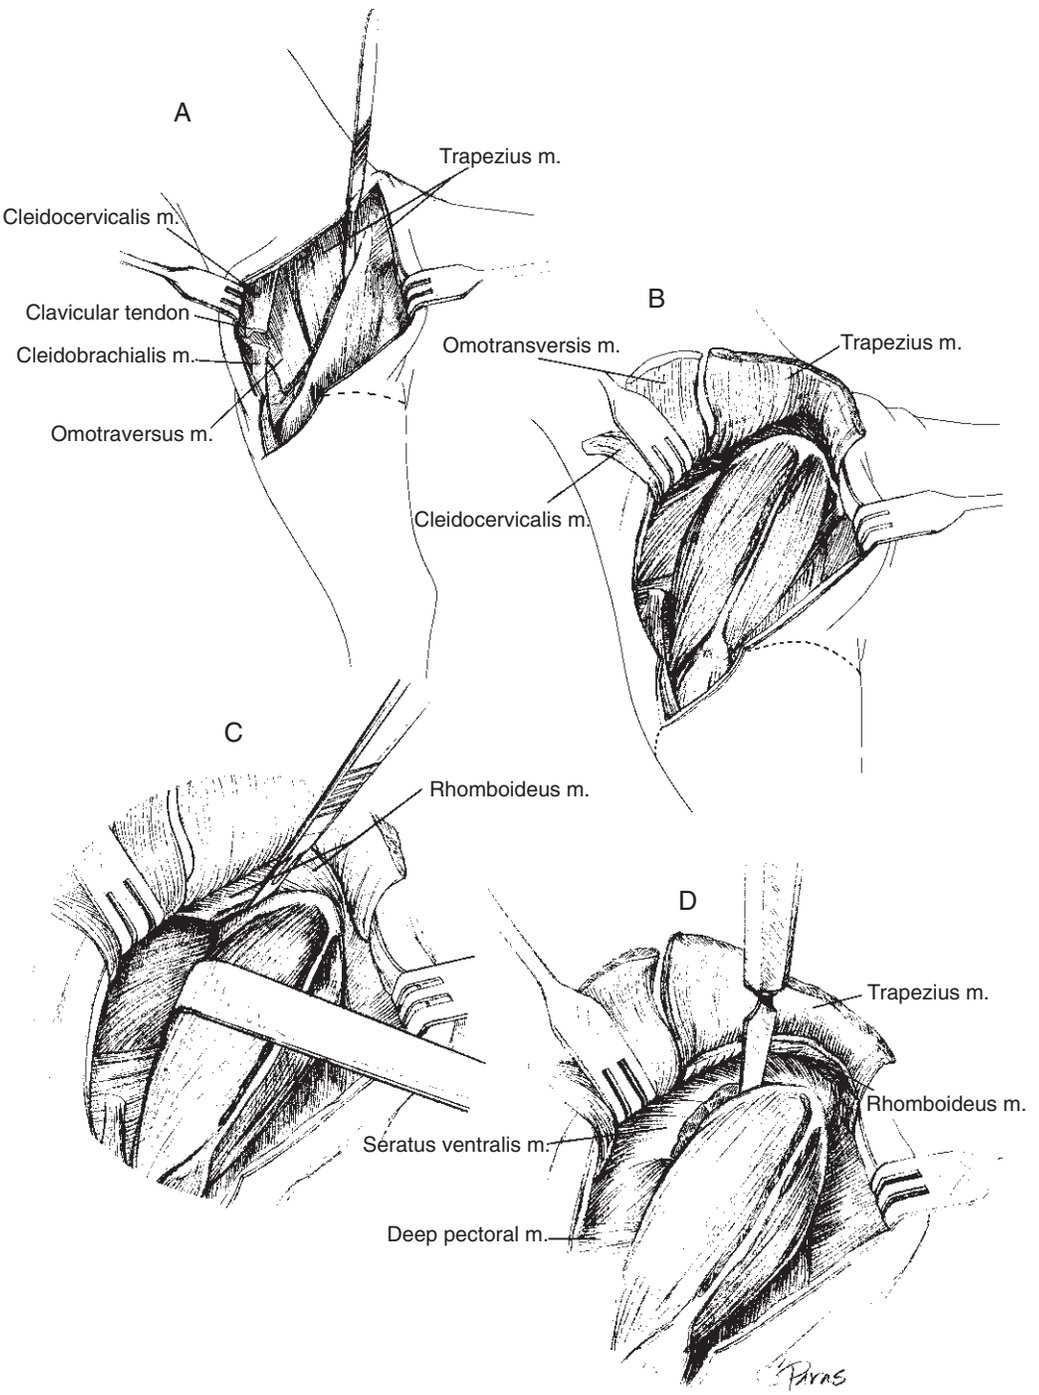

Figure 116-2. Initial dissection of muscles for thoracic limb amputation.

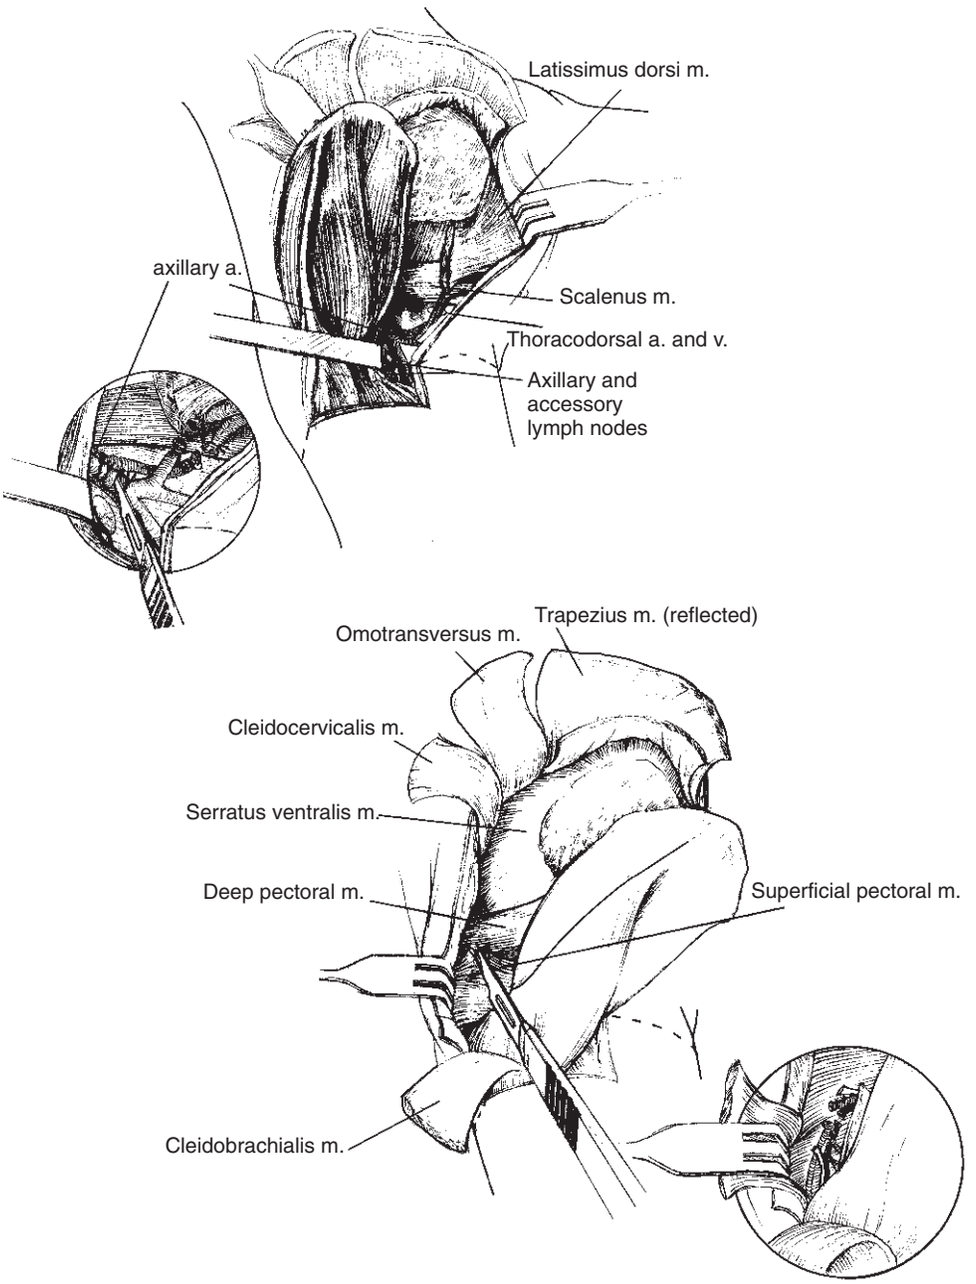

Figure 116-3. Ligation and severing of axillary artery and continued dissection for thoracic limb amputation.

6. Incise the tensor fasciae latae and biceps femoris muscles along the skin incision.
7. Isolate the sciatic nerve trunk and sever it at the greater trochanter.
8. Transect the abductor cruris caudalis, semitendinosus, semimembranosus, and adductor magnus et brevis muscles at midthigh.
9. Complete the amputation by osteotomy of the femur using a Gigli wire or oscillating bone saw, leaving the proximal one-third of the femur. Bone wax is packed into the cut end of the osteotomy.
10. If necessary, place a closed suction drain (e.g., Jackson-Pratt) or passive drain (e.g., Penrose) to drain dead space. Routinely close the muscles, subcutaneous tissues, and skin.

Pelvic Limb Amputation by Hip Disarticulation

Use this procedure when there is tumor involvement of the mid- to distal femur. Tumors of the proximal femur and hip joint may require en bloc resection of the acetabulum and part of the pelvis (subtotal

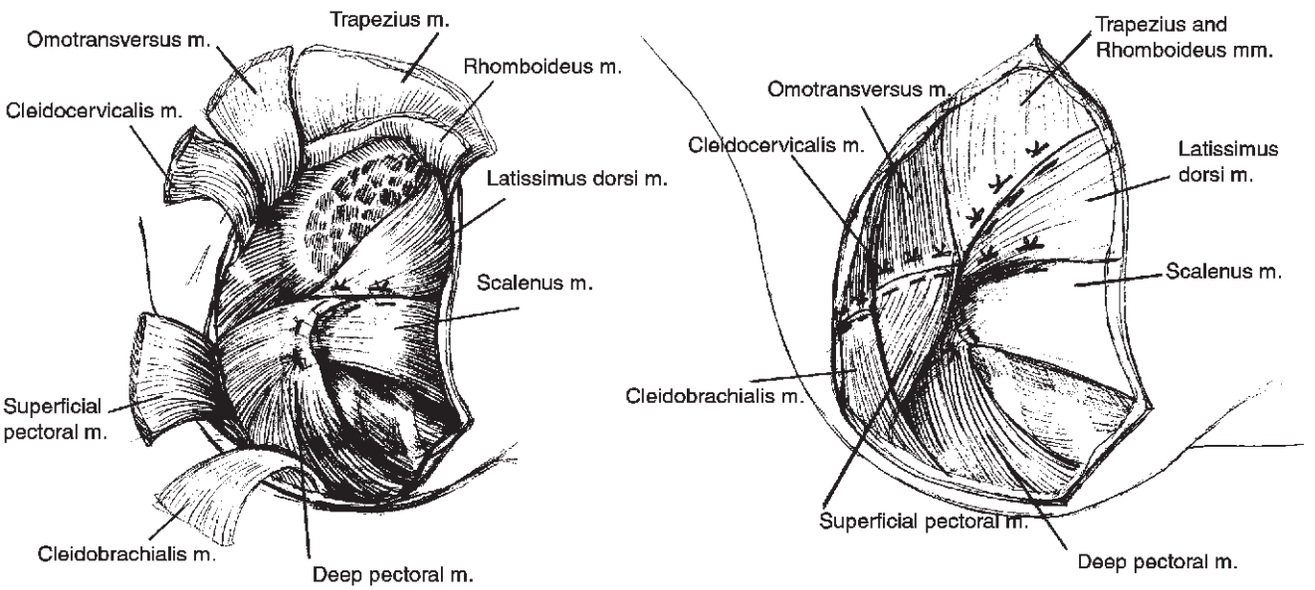

Figure 116-4. Muscle closure after thoracic limb amputation.

hemipelvectomy) with the femur to ensure complete removal.

Objectives

- Same as for thoracic limb amputation.

Equipment

- Same as for thoracic limb amputation

Technique

1. Place the dog in lateral recumbency and aseptically prepare the entire limb and pelvis for surgery.
2. Incise the skin in two connected semicircles, ventrolaterally from the tuber ischii down to the midthigh and up to the flank, and ventromedially from the ends of lateral incision down to the inguinal fold.
3. Isolate, ligate, and divide the femoral and superficial circumflex femoral arteries and femoral vein.
4. Transect the sartorius, pectineus, gracilis, and adductor magnus et brevis muscles 2 cm from their origin (Fig. 116-5*A,B*).
5. Ligate and divide the medial circumflex femoral artery and vein.
6. Elevate the iliopsoas muscles from the lesser trochanter of the femur.
7. Sever the saphenous and femoral nerves.
8. Cut the medial coxofemoral joint capsule and round ligament.
9. Transect the tensor fasciae latae, biceps femoris, abductor cruris caudalis, semitendinosus, and semimembranosus muscles in their proximal one-third.
10. Sever the sciatic nerve distal to its branches to the upper thigh muscles (Fig. 116-5*C*).
11. With the limb in flexion and abduction, sever the hip rotator muscles, including the internal and external obturator and gemellus muscles.
12. Complete the amputation by severing the three gluteal muscles (superficial, middle, and deep), and the lateral joint capsule and by elevating the rectus femoris muscles from the iliopubic eminence (Fig. 116-5*D*).
13. If necessary to drain excessive dead space, place a closed suction drain (e.g., Jackson-Pratt) or passive drain (e.g., Penrose). Routinely close the muscles, subcutaneous tissue, and skin.

Postoperative Care and Complications

Short Term

- Always submit the amputated limb for histopathologic confirmation of the preoperative diagnosis.
- Monitor the patient closely for pain, hemorrhage, hypotension, or electrolyte disturbances.
- Routinely administer analgesics (see Chapter 6).
- With proper surgical technique minimizing dead space, seroma formation should be minimal but can be managed with pressure bandages, warm compresses three to four times daily, or drain placement. Remove drains when drainage is minimal.
- Nursing and supportive care will be required until the patient has recovered and adapted enough to function well on three limbs.
- Start chemotherapy after skin suture removal.

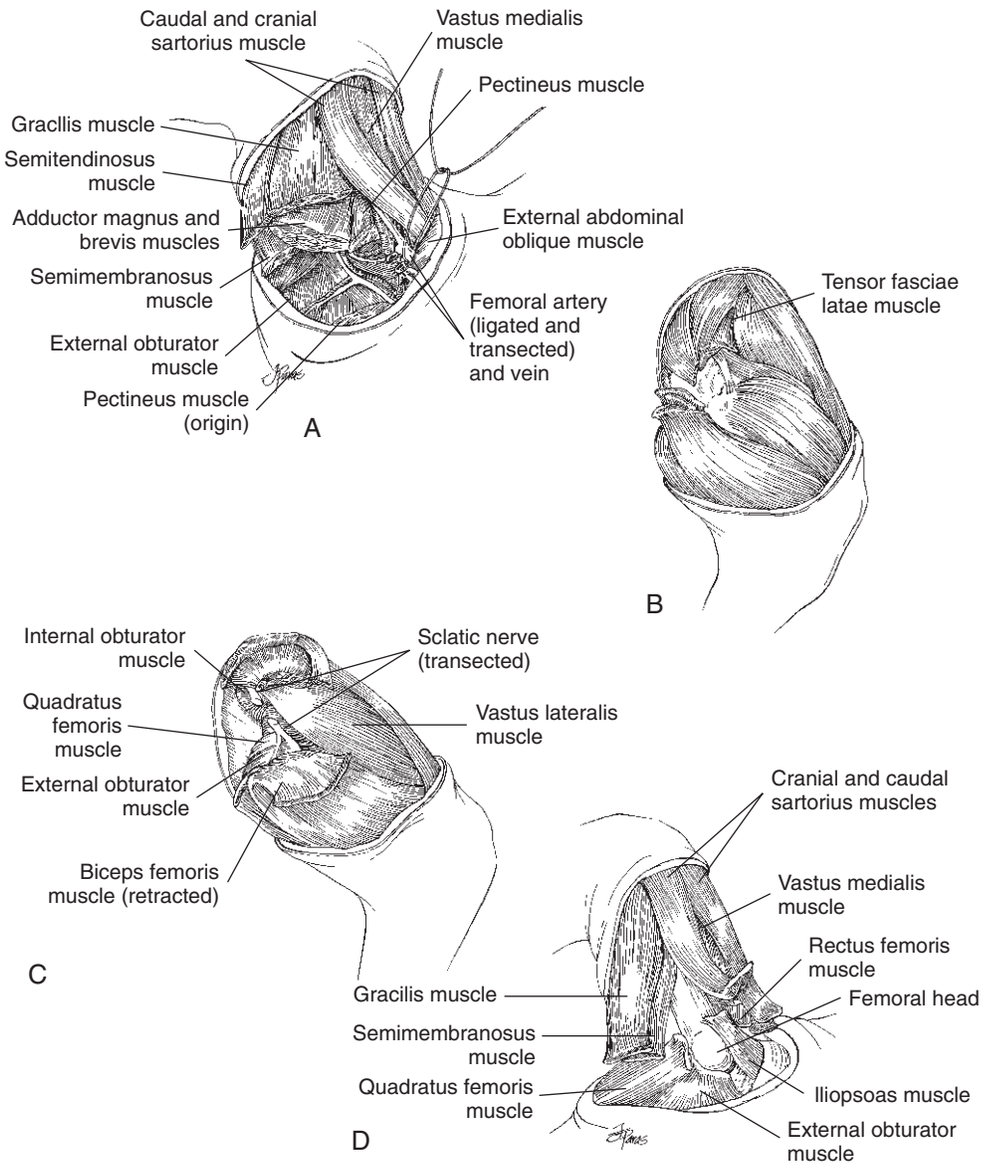

Figure 116-5. Dissection of muscles, vessels, and nerves for pelvic limb amputation by hip disarticulation. *A* and *D,* medial views; *B* and *C,* lateral views.

Long Term

- Evaluate the patient clinically and radiographically every 8 to 12 weeks to look for tumor recurrence at the surgical site and pulmonary metastasis.
- Institute a strict weight loss program, especially with forelimb amputation in overweight patients.

MANAGEMENT OF METASTATIC DISEASE

As a general rule, chemotherapy is ineffective in patients with radiographically detectable pulmonary metastasis secondary to OSA. In some cases, lung lobectomy to remove metastatic tumors can significantly prolong survival time (see Chapter 167). Patients that are candidates for removal of lung metastasis should satisfy the following criteria:

- Primary tumor in complete remission for >300 days.
- No greater than two nodules visible on plain radiographs.
- Metastatic disease restricted to the lung only (negative bone scan or survey radiographs).

Median survival time in 36 dogs after removal of lung metastasis was approximately 6 months.

LIMB-SPARING PROCEDURES

- Limb-sparing procedures are indicated in patients that are not good candidates for limb amputation, or when clients refuse amputation. With this procedure, the affected bone is resected and is replaced with a normal bone allograft. The site that is most amenable to limb-sparing surgery is the distal radius. Other sites (proximal humerus, proximal tibia) are not amenable to limb-sparing surgery because complication rates are unacceptably high. In addition, patients typically have poor limb function because the procedure requires arthrodesis of the joint closest to the tumor.
- Limb-sparing procedures are associated with a higher complication rate than limb amputation, are technically difficult to perform, and requires access to a bone bank, which limits its use in private practice. Consult a surgical specialist.

Indications

- Tumor involving 50% or less of the length of the bone.
- Tumor that does not extend across the joint, into the adjacent ulna, or into the surrounding soft tissues.
- A patient that is free of metastatic or other concurrent diseases.

Complications

- Infection (45–55% of cases)
- Recurrence (25% of cases)
- Plate breakage
- Host bone fracture
- Sequestrum formation

In patients with a failed limb-sparing procedure, limb amputation can be performed as a salvage procedure.

Chapter

117 Miscellaneous Diseases of Bone

James K. Roush

Some of the diseases affecting bone are discussed in this chapter. See respective chapters for other bone and cartilage diseases, such as hip dysplasia, avascular necrosis of the femoral head, and osteochondrosis.

PANOSTEITIS

Panosteitis is a disease of young large-breed dogs manifested by intermittent lameness of one or more limbs. Onset usually occurs in the first year of life. The disease is self-limiting, but clinical signs may persist in one or more limbs for months. Differentiate panosteitis from other causes of lameness in young dogs, such as hip dysplasia and osteochondritis dissecans.

Etiology

- The etiology of panosteitis is unknown.
- Panosteitis may have a polygenetic origin, because German shepherd dogs are commonly affected.
- Contributing causes include stress, transient vascular abnormalities, metabolic disorders, allergies, hyperestrogenism, and autoimmune reaction following viral infection.
- The characteristic histopathologic lesion is degeneration of medullary adipocytes, followed by stromal cell proliferation, intramembranous ossification, and regeneration of the adipose bone marrow.

Clinical Signs

Signalment

- Panosteitis usually is seen in large and giant-breed dogs, most often 5 to 12 months of age; however, it has been reported in dogs up to 5 years of age, and I have seen it in a 7-year-old dog.
- Male dogs are affected more frequently than females (4:1 ratio). In females, the first episode of the disease often occurs in association with the first estrus.
- Panosteitis has been reported in the German shepherd, Great Dane, Irish setter, St. Bernard, Doberman pinscher, Airedale, basset hound, and miniature schnauzer.

Lameness

- There is acute onset of weight-bearing lameness without a history of recent trauma.

▼ ***Key Point*** Lesions often resolve in one bone and develop in another, resulting in the classic history of "shifting leg" lameness.

- Pain due to the disease is of intermittent duration and severity, but the dog rarely, if ever, is completely non–weight bearing on the affected limb or limbs.
- Lameness or radiographic lesions may occur simultaneously in multiple limbs or bones, or lameness may resolve for a period of time, only to recur in another limb. After a bone passes through the lesion cycle, it is unlikely that it will be affected again, but lameness may occur in that limb if the disease affects another bone in the limb.
- Clinical signs often continue for several months and usually resolve by 18 to 20 months of age.

Diagnosis

▼ ***Key Point*** Diagnosis of panosteitis is established by eliciting pain on firm palpation of a long bone and by characteristic radiographic lesions.

Physical Examination

- Applying firm pressure to the diaphyses of the affected bone results in clinical signs of discomfort.

Laboratory Evaluation

- Hematology and serum chemistry profiles usually are normal.
- Eosinophilia occurs inconsistently (this disease was previously referred to as eosinophilic panosteitis).

Radiography

Confirm suspected cases by survey radiography of the affected bone(s).

Table 117-1. CHARACTERISTIC RADIOGRAPHIC LESIONS SEEN IN DISEASES AFFECTING BONE

Disease	Lesion
Panosteitis	Increased opacity in medullary cavity of diaphysis
Hypertrophic osteodystrophy	Radiolucent metaphyseal line adjacent to physis
Hypertrophic osteopathy	Periosteal reaction beginning on metacarpals or metatarsals, bilaterally symmetric
Craniomandibular osteopathy	Bony proliferation on ventral mandible and skull
Cartilaginous exostosis	Large, smooth bony protuberance in metaphyseal area
Bone cyst	Well-circumscribed, radiolucent metaphyseal defect
Retained enchondral	Longitudinal, linear radiolucent cartilaginous core defect in distal ulna

- Early radiographic lesions are characterized by areas of increased density and accentuated trabecular pattern within the medullary cavity (Table 117-1).
- These areas may be focal or multifocal and commonly occur near the nutrient foramen.
- Bone cortices may be thickened, and progressive mottling and opacification of the medullary cavity occur.
- A smooth, linear periosteal proliferation may develop.
- During resolution, sclerotic areas gradually decrease in size and density. Radiographic signs may persist for several months after lameness resolves.
- There is no correlation between the radiographic lesions and severity of clinical signs.

Differential Diagnoses

- Differentiate panosteitis as a cause of lameness from other diseases that are characterized by onset during or shortly after the rapid-growth phase in large-breed dogs.
- In particular, eliminate hypertrophic osteodystrophy, osteochondritis dissecans of the shoulder or elbow (see Chapter 118), ununited anconeal process (see Chapter 118), and hip dysplasia (see Chapter 108) as a cause of lameness before ascribing clinical signs to panosteitis.

Treatment

▼ ***Key Point*** Panosteitis is a self-limiting disease.

- No specific therapy for panosteitis exists.
- Administer a nonsteroidal anti-inflammatory drug approved for dogs, as needed, to alleviate pain (see Chapter 6).
- Restrict exercise in severely affected animals.
- Inform clients that the lameness may shift to other limbs and that the animal may be intermittently lame for 6 to 18 months.

HYPERTROPHIC OSTEODYSTROPHY

Hypertrophic osteodystrophy (HOD) is a developmental disease of young, rapidly growing large- and giant-breed dogs. Dogs with HOD exhibit lameness in one or more limbs in association with swelling and inflammation of the metaphyseal regions of long bones. Complications related to prolonged recumbency, anorexia, and hyperthermia have been reported in severely affected animals. The overall prognosis for HOD is guarded. Although many dogs recover spontaneously, permanent bone changes and physical deformities may develop.

Etiology

- The etiology of HOD is unknown.
- Historically, the disease has been attributed to vitamin C deficiency, but decreased levels of ascorbic acid in the serum or urine do not appear to be related to the disease.
- Skeletal lesions similar to those of HOD have been produced experimentally by feeding a free-choice diet abnormally high in protein, calories, and calcium.
- Canine distemper virus may be involved as a causative agent.

Clinical Signs

Signalment

▼ ***Key Point*** HOD occurs only in growing animals with open physes.

- Onset of clinical signs usually occurs at 3 to 4 months of age (range, 2–8 months).
- HOD has been reported in the Great Dane, Irish wolfhound, St. Bernard, Irish setter, Labrador retriever, basset hound, greyhound, German shepherd, German short-haired pointer, borzoi, boxer, Dalmatian, Weimaraner, Doberman pinscher, and collie.

Systemic Signs

- The severity of HOD varies, ranging from an absence of systemic signs to severe anorexia, weight loss, fever, and depression.
- Clinical signs are episodic in nature, and lameness often is bilaterally symmetric.

Lameness

- Lameness varies from a mild limp in minimally affected dogs to non–weight bearing lameness in severely affected animals.

- Affected long bone metaphyses are extremely swollen, warm, and painful in animals with severe disease.
- Multiple long bones and limbs are affected, and, in extreme cases, dogs are reluctant to stand or move.

Diagnosis

History/Physical Examination

- The history may include recent weight loss, reluctance to move, and anorexia.
- Affected metaphyses are warm and swollen on palpation.
- Signs of pain may be elicited on palpation of the metaphyseal areas.
- Pyrexia of up to 106°F may be present.

Laboratory Evaluation

- Laboratory data are normal, or mild abnormalities related to anorexia and stress may be present.

Radiography

- Radiographic changes usually occur in the metaphyses of the long bones and are bilaterally symmetric. Other bones, including the mandible, ribs, and scapula, may be affected.
- The characteristic radiographic lesion is generalized sclerosis and enlargement of the metaphysis.

▼ ***Key Point*** Radiolucent areas form in the metaphysis and coalesce to form an area of radiolucency parallel to the growth plate, called a double physeal line (Fig. 117-1).

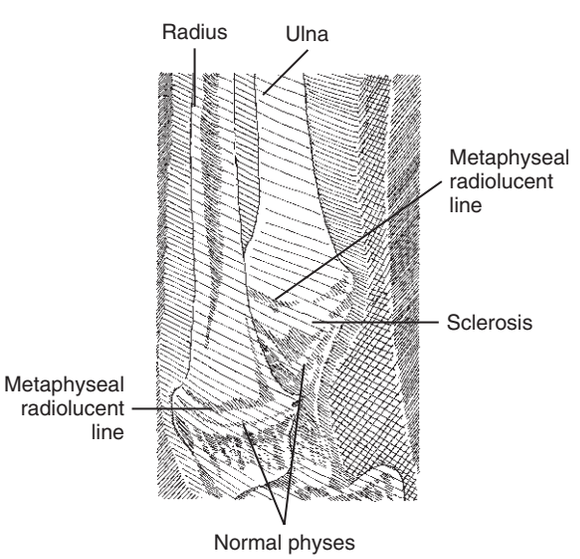

Figure 117-1. Metaphyseal radiolucent lines and metaphyseal sclerosis proximal to distal radial and ulnar physis in a dog with hypertrophic osteodystrophy.

- Irregular widening of the physis may be seen in later stages of the disease.
- Subperiosteal or extraperiosteal bone formation is seen in metaphyseal regions and may involve the diaphysis.

Differential Diagnoses

- Differentiate HOD from other causes of lameness in immature large- or giant-breed dogs.
- Other diseases that result in metaphyseal swelling or in signs of pain during palpation of long bones include panosteitis, bone-associated neoplasms, and hypertrophic osteopathy. Radiographic lesions in these diseases are distinct and allow easy differentiation; the last two diseases are unlikely to be the cause of lameness in young dogs.

Treatment

▼ ***Key Point*** There is no specific treatment for HOD.

- In mild or moderately affected dogs, there is often spontaneous remission.
- Correction of dietary imbalances and decreased caloric intake may be beneficial.
- Good supportive care of severely affected dogs is essential to prevent decubital ulcers, provide nutrition (see Chapter 3), and maintain hydration (see Chapter 5).
- Give nonsteroidal anti-inflammatory analgesics, as needed, to relieve discomfort (see Chapter 6).
- Severely affected animals may require nutritional intake via force-feeding or gastrostomy tube (see Chapter 3). Parenteral fluids may be needed to prevent dehydration in these animals (see Chapter 5).
- There is no evidence that mineral, vitamin C, or vitamin D supplements are beneficial; these substances actually may accelerate the rate of dystrophic calcification.

HYPERTROPHIC OSTEOPATHY

Hypertrophic osteopathy (HO) is a pathologic disease process affecting long bones secondary to a space-occupying mass in the abdominal or thoracic cavities. The disease has been reported in many species, including dogs, cats, and humans. HO is characterized by bilateral symmetric swelling of the distal limbs accompanied by periosteal bone formation. HO has been referred to as hypertrophic pulmonary osteoarthropathy, pulmonary osteoarthropathy, and hypertrophic pulmonary osteopathy. Hypertrophic osteopathy is the term that most accurately reflects the rare joint involvement and the variable site of the primary space-occupying lesion.

Etiology

- Hypertrophic osteopathy occurs secondary to a variety of diseases and occurs in dogs and cats of all breeds and ages.
- HO is most often secondary to metastatic pulmonary neoplasia, although it has been reported with primary pulmonary neoplasia, pulmonary abscesses, pulmonary tuberculosis, chronic bronchopneumonia, spirocercosis, dirofilariasis, rib tumors, bacterial endocarditis, hepatic adenocarcinoma, and various primary bladder neoplasms (neurofibrosarcoma, botryoid rhabdomyosarcoma, and transitional cell sarcoma).
- The pathogenic mechanisms underlying the bone pathology are unknown. Evidence points to an increased peripheral vascular supply secondary to the pulmonary lesion. This increased peripheral blood flow has been observed both in dogs and humans and may be related to irritation of afferent nerve pathways and stimulation of a nervous reflex.

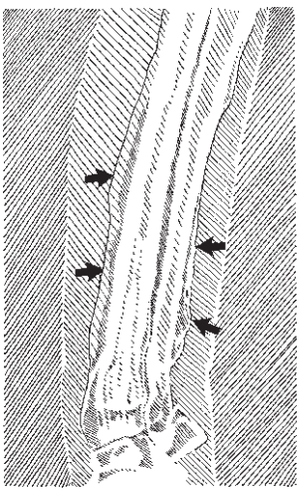

Figure 117-2. Smooth periosteal proliferation *(arrows)* on radius and ulna characteristic of hypertrophic osteopathy.

Clinical Signs

▼ ***Key Point*** Signs of HO may be present months before onset of clinical signs relating to the underlying disease; early recognition is important for diagnosis and treatment of the primary disease.

Signalment

- Dogs and cats with HO may be of any breed and usually are affected late in life.
- A reported increased incidence of the disease in female and large-breed dogs may be due to the increased incidence of mammary tumor metastasis in female dogs, and of primary bone tumors in large-breed dogs.

Lameness

- Most animals present with acute or gradual lameness of all four limbs and with reluctance to move.

Diagnosis

Physical Examination

- The distal limbs are swollen, firm, and warm.
- Signs of pain may be elicited on deep palpation of the long bones.

Laboratory Evaluation

- Laboratory findings reflect the underlying disease process and are not characteristic of HO.

Radiography

- Survey radiographs demonstrate a bilateral, symmetric, generalized periosteal proliferative reaction affecting the long bones of the appendicular skeleton (Fig. 117-2). Endosteal bone proliferation does not occur.
- Distal portions of the limbs, especially the metatarsals and metacarpals, are involved first, but periosteal proliferation eventually may involve the more proximal long bones and occasionally the mandible, pelvis, ribs, and vertebrae.
- In very early cases, periosteal new-bone formation is not evident, but symmetric soft tissue swelling is present.
- If the primary disease resolves, the bony and soft tissue radiographic abnormalities regress.

▼ ***Key Point*** Thoracic and abdominal radiographs are essential to evaluate the underlying disease process and to confirm the diagnosis of HO. Abdominal ultrasound may also be helpful in identifying a mass lesion.

Differential Diagnoses

The bony periosteal reactions of hypertrophic osteopathy are similar to those of panosteitis and hypertrophic osteodystrophy, but HO will not exhibit the increased medullary opacities of panosteitis, nor the radiolucent metaphyseal line characteristic of HOD. It is rare to see HO in a young (adolescent) animal.

Treatment

▼ ***Key Point*** Removal of the underlying primary lesion usually results in regression of the lameness and distal limb lesions.

- Resection of primary or metastatic pulmonary neoplasms provides temporary relief of signs related to

HO, but long-term survival is dependent on the type of neoplasm.
- Appropriate treatment of dirofilariasis, spirocercosis, and primary lung disease may increase the chances for long-term survival.
- Inflammation and clinical signs of pain resolve 1 to 2 weeks after removal of the thoracic or abdominal mass. Periosteal reactions regress in 3 to 4 months, but residual radiographic changes may persist in severe cases. Lameness may persist in some animals even after removal of the mass.
- When resection of the primary mass is not feasible, unilateral vagotomy (on the side of the lesion) may provide temporary regression of clinical signs.

CRANIOMANDIBULAR OSTEOPATHY

Craniomandibular osteopathy (CMO) is a non-neoplastic, noninflammatory proliferative bony disease in growing dogs that affects bones of endochondral origin, most commonly the mandibles, occipital bones, or temporal bones. Bony lesions are bilateral and symmetric. CMO occurs predominantly in terriers, especially Scottish, West Highland white, and Cairn terriers, but the disease also has been reported in the boxer, Labrador retriever, Great Dane, and Doberman pinscher.

Etiology

- CMO is likely of heritable origin, with recent reports of likely autosomal recessive heritance.
- Osteoclastic resorption of mandibular bone occurs, followed by production of woven bone on both the periosteal and endosteal surfaces of the bone. Cyclic episodes of bone resorption and proliferation result in the formation of mature fibrous bone that may remain permanently.

Clinical Signs

- Disease onset occurs at 4 to 10 months of age. Both sexes are affected equally.
- Presenting clinical signs include pain on manipulation or opening of the mouth, mandibular swelling, ptyalism, inability to open the mouth, intermittent fever, and lethargy.

Diagnosis

Physical Examination

Signs of pain are elicited during direct palpation of the swelling or attempts to open the mouth. In advanced cases, the clinician may be unable to open the mouth more than 1 or 2 cm. Dogs may be febrile during the period of bone proliferation. Lymphadenopathy or temporal muscle atrophy may be present.

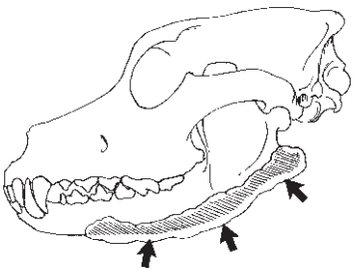

Figure 117-3. Bony proliferation *(arrows)* on the ventral mandible of a dog with craniomandibular osteopathy.

Radiography

Diagnosis of CMO is confirmed by radiographic evidence of the bony proliferative lesions.

- Obtain survey radiographs of the skull and mandible, including oblique, dorsoventral, and lateral views, to assess the extent of the disease.
- A non-neoplastic, bilaterally symmetric bony proliferation is seen projecting from the periosteal surfaces of the mandible or other bones of the cranium (Fig. 117-3).
- Angular processes of the mandible and bullae may fuse and obstruct jaw motion. Lesions may also involve the occipital bone, parietal bone, frontal bone, maxilla, and appendicular bones.
- The proliferation of new bone decreases as growth slows, and becomes radiographically static when the animal is approximately 1 year old. Partial or complete regression of bony lesions occurs, but moderate or severe cases result in permanent bone proliferation to varying degrees.
- The prognosis is poor for dogs with radiographic evidence of partial or complete bony ankylosis of the temporomandibular joints (TMJs).

Differential Diagnoses

- Lesions of CMO in the appendicular skeleton may appear radiographically similar to HOD, but CMO lacks the metaphyseal radiolucent line of HOD.
- Radiographic appearance differentiates CMO from bony neoplasia and osteomyelitis.

Treatment

- There is no specific therapy for CMO.
- Administer nonsteroidal anti-inflammatory analgesic therapy at manufacturer recommended dosage as needed (see Chapter 6).
- Nutritional support by gastrostomy or enterostomy tube or parenteral supplementation may be necessary (see Chapter 3). As the condition stabilizes, most animals have impaired mouth function but are capable of maintaining normal nutritional status.

- Surgical intervention to reduce new bone mass and increase TMJ range of motion has met with limited success.

MULTIPLE CARTILAGINOUS EXOSTOSIS

Multiple cartilaginous exostosis (MCE) is a disease of dogs and cats in which multiple ossified protuberances arise from the bone in metaphyseal regions. Vertebrae, ribs, and long bones commonly are affected. The exostosis ceases to grow when the physis nearest the exostosis ossifies.

Etiology

- MCE probably is heritable in dogs, horses, and humans.
- The accepted pathogenesis is that the exostosis is derived from displaced chondrocytes that separate from the physis during development.

Clinical Signs

- The animal often is presented with a firm, distinct swelling on the involved bone.
- Lameness or limb dysfunction develops only when adjacent structures such as the tendons or nerves are compressed or mechanically distorted by the exostoses.
- Other clinical signs, including pain, lameness, mechanical dysfunction, and neurologic deficits, depend on the structure affected.

Diagnosis

Physical Examination

- A smooth, immovable bony swelling is visible and palpable near a metaphysis.
- Pain may be elicited on palpation of the mass or surrounding soft tissues.

Radiography

- Obtain skeletal survey radiographs of animals with suspected cartilaginous exostosis.
- Radiographic lesions are juxtacortical masses at or adjacent to the metaphysis.
- Large, scattered radiolucent areas of hyaline cartilage may be present within the exostosis. The exostotic growths may involve any bone except the skull.
- Surgical biopsy of the lesion confirms the diagnosis.

Treatment

▼ ***Key Point*** Removal of the exostosis relieves associated pain, mechanical dysfunction, and neurologic deficits.

- Removal of MCE sometimes is requested to improve cosmetic appearance.
- Malignant transformation of exostoses to chondrosarcomas or osteosarcomas has been reported. Continued growth of the exostosis after the animal is mature suggests malignant transformation.
- In general, the prognosis is good after removal of uncomplicated MCE.

BONE CYSTS

Bone cysts are smooth radiolucent cavities found rarely in the long bones of dogs. Flat bones (e.g., mandible, ribs) also may be affected. Four types of bone cysts have been described in dogs:

- Monostotic (affecting one bone)
- Polyostotic (affecting more than one bone)
- Aneurysmal
- Subchondral

Aneurysmal bone cysts are extremely rare in dogs and are locally aggressive. Bone cysts found in young, large-breed dogs usually do not produce clinical signs until they attain a large size.

Etiology

- The etiology of monostotic, polyostotic, and aneurysmal bone cysts is unknown.
- Subchondral bone cysts often are not primary lesions and may be the result of chronic osteoarthritis or diseases leading to osteoarthritis (e.g., rheumatoid arthritis, systemic lupus erythematosus).

Clinical Signs

Signalment

- The age of affected animals ranges from 4 to 30 months, but most animals are less than 1 year of age.
- Breeds reported to develop bone cysts include the German shepherd, Weimaraner, Irish wolfhound, Afghan, saluki, Great Dane, and Doberman pinscher.

Presentation

- Pain, swelling, and stiffness of the nearest joint may be present.
- Acute lameness or swelling may occur at the site of the cyst owing to a pathologic fracture.

Diagnosis

Radiography

- Survey radiographs establish a diagnosis of bone cysts. A benign, expansive, radiolucent area in the metaphysis is characteristic.

- The metaphyseal cortex may be thinned by expanding cysts.
- Pathologic fractures may be evident radiographically.

Histopathology

- The cyst is lined by fibrous connective tissue.
- Aneurysmal bone cysts are filled with blood, and the blood spaces are lined by connective tissue trabeculae. Multinucleate giant cells and mature bone may be present in these cysts.
- Monostotic and polyostotic cysts may fill with blood after pathologic fracture.

Differential Diagnoses

- Differentiate bone cysts from more aggressive lesions such as chondrosarcoma, osteosarcoma, and giant cell tumors.

Treatment

- Curettage of the walls and filling of the defect with cancellous bone is the definitive treatment in most animals.
- Treat pathologic fractures through cysts by debridement of the cyst wall, cancellous graft, and fracture fixation.
- Consider cyst resection if the lesion is located in flat bones (e.g., rib resection or mandibulectomy).

RETAINED ENCHONDRAL CARTILAGINOUS CORES

Retained enchondral cartilaginous cores occur in the distal ulnar metaphysis of young, large-breed dogs. Radiographically, the retained enchondral cartilage is seen as a central, longitudinal radiolucent cone in the distal ulnar metaphysis and usually is an incidental finding of no clinical significance. These lesions, however, may interfere with normal growth of the ulna, resulting in forelimb deformities.

Etiology

- The etiology is unknown.

Clinical Signs

- Signs may include valgus deviation, external rotation of the carpus, and cranial bowing of the radius.

Diagnosis

- Survey radiographs establish the diagnosis in animals with appropriate forelimb deformities.
- The lesion also may be an incidental finding unrelated to clinical lameness if normal growth of the ulna is apparent.

Treatment

- No treatment is necessary for animals without forelimb deformity.
- Immature animals with forelimb deformities may benefit from distal ulnectomy, which may allow spontaneous correction of radial and ulnar deformities during continued growth (see Chapter 105).
- Mature animals require ulnar and radial osteotomies to correct forelimb deformity (see Chapter 105).

LABRADOR RETREIVER SKELETAL DYSPLASIA

Skeletal dysplasia is a heritable disease of Labrador retrievers characterized by forelimb achondroplasia and ocular effects. It demonstrates autosomal recessive transmission of skeletal effects and is linked with an incomplete dominant heritable ocular dysplasia in these dogs.

Etiology

- The skeletal defects are heritable via autosomal recessive transmission.
- Linked ocular defects are heritable via incomplete dominant transmission.
- The disease is only recognized in Labrador retrievers.

Clinical Signs

- The forelimbs of affected immature Labs appear shorter and exhibit achondroplastic conformation. The disease is often first noted during rapid growth phases from 8 to 16 weeks of age.
- Abnormal conformation of the coxofemoral joints also occurs and is visible radiographically.
- Ocular changes include cataracts, retinal dysplasia, and rhegmatogenous retinal detachments. Dogs are often visually impaired at presentation.

Diagnosis

▼ ***Key Point*** The combination of forelimb achondroplasia associated with the linked ocular diseases of cataracts, dysplasia, or retinal detachment in immature animals leads to the diagnosis.

- The history or presence of other full siblings with similar signs is indicative of the heritable condition.
- Radiograph the forelimb to demonstrate the achondroplastic changes of the disease and demonstrate asynchronous growth of the radius and ulna. Comparison of radial length with heterozygote siblings is diagnostic.

Differential Diagnosis

- Differentiate the skeletal lesions from traumatic shortening of the radius and ulna due to previous

damage to the distal radial or ulnar growth plates. In the latter, the radiographic changes will most likely be unilateral and visible evidence of early closure of the growth plates may be evident.

Treatment

- There is no treatment for individual animals affected by the disease.
- Monitor breeding lines of Labrador retrievers for evidence of the disease. Remove probable carriers of the trait from breeding stock.

Chapter

118 Osteochondrosis

Michael P. Kowaleski

Osteochondrosis refers to a group of diseases that are characterized by aberrant development of the epiphyseal or physeal cartilage in growing animals. The cause of osteochondrosis appears to be multi-factorial; some of the factors that have been implicated include nutrition (overnutrition, excess dietary calcium, excess protein), genetics, exercise, environmental factors, and trauma (excessive mechanical loading), as the lesions frequently occur at the point of greatest loading of the joint.

ETIOLOGY

▼ ***Key Point*** Osteochondrosis is a failure of endochondral ossification, and this term refers to the disease in general. Osteochondritis dissecans (OCD) refers to the combination of dissecting lesions of articular cartilage, communication of synovial fluid into the subchondral bone, and the resulting synovitis. Most commonly large- or giant-breed dogs are affected.

- Osteochondrosis at the physeal growth plate begins as an abnormal accumulation of viable hypertrophic chondrocytes that subsequently fail to undergo matrix mineralization, causing a slowing of growth, not complete cessation. In the dog, this primarily occurs at the distal ulnar physis (retained cartilage core or radius curvus), leading to the characteristic antebrachial deformities seen with asynchronous growth of the radius and ulna, namely shortening of the ulna, cranial bowing of the radius, valgus angulation, external rotation, shortening of the radius, and variable amounts of elbow and carpal incongruity.
- Elbow dysplasia is a collection of diseases presumed to be a result of osteochondrosis, including ununited anconeal process (UAP), OCD of the medial portion of the humeral condyle, and fragmented medial coronoid process (FMCP) (Fig. 118-1).

OSTEOCHONDRITIS DESSICANS OF THE SHOULDER, HOCK, AND STIFLE

In dogs, OCD lesions can occur in the shoulder on the caudal humeral head, in the hock on the trochlear ridges of the talus (medial more commonly than lateral), and in the stifle on the femoral condyle (lateral more commonly than medial).

Anatomy

- See the respective chapters on shoulder, hock, and stifle disorders (Chapters 102, 112, and 110).

Pathophysiology

- A defect in endochondral ossification results in a focal area of abnormal subchondral bone formation.
- The overlying cartilage fails to undergo endochondral ossification resulting in focal retention of cartilage instead of conversion to bone.
- This thickened region of cartilage becomes necrotic and weak, resulting in cartilage breakdown under normal loading conditions or secondary to trauma.
- Early in the disease process, the lesions of osteochondrosis affect only the epiphyseal cartilage, and the animal is asymptomatic.
- Once a fissure occurs in the thickened cartilage, it extends through the necrotic cartilage into the subchondral bone, allowing access of the synovial fluid to the subchondral bone.
  - This stage seems to correspond to the onset of clinical signs, at which time it is called osteochondritis dissecans.
- OCD results in two distinct joint abnormalities: joint incongruity secondary to malformation of cartilage and subchondral bone, and joint mouse formation.
- Cartilage flaps that remain attached may ossify, and the resulting bone remains viable as long as the flap is attached.
  - Detached cartilage flaps may survive in the joint fluid and grow in size.

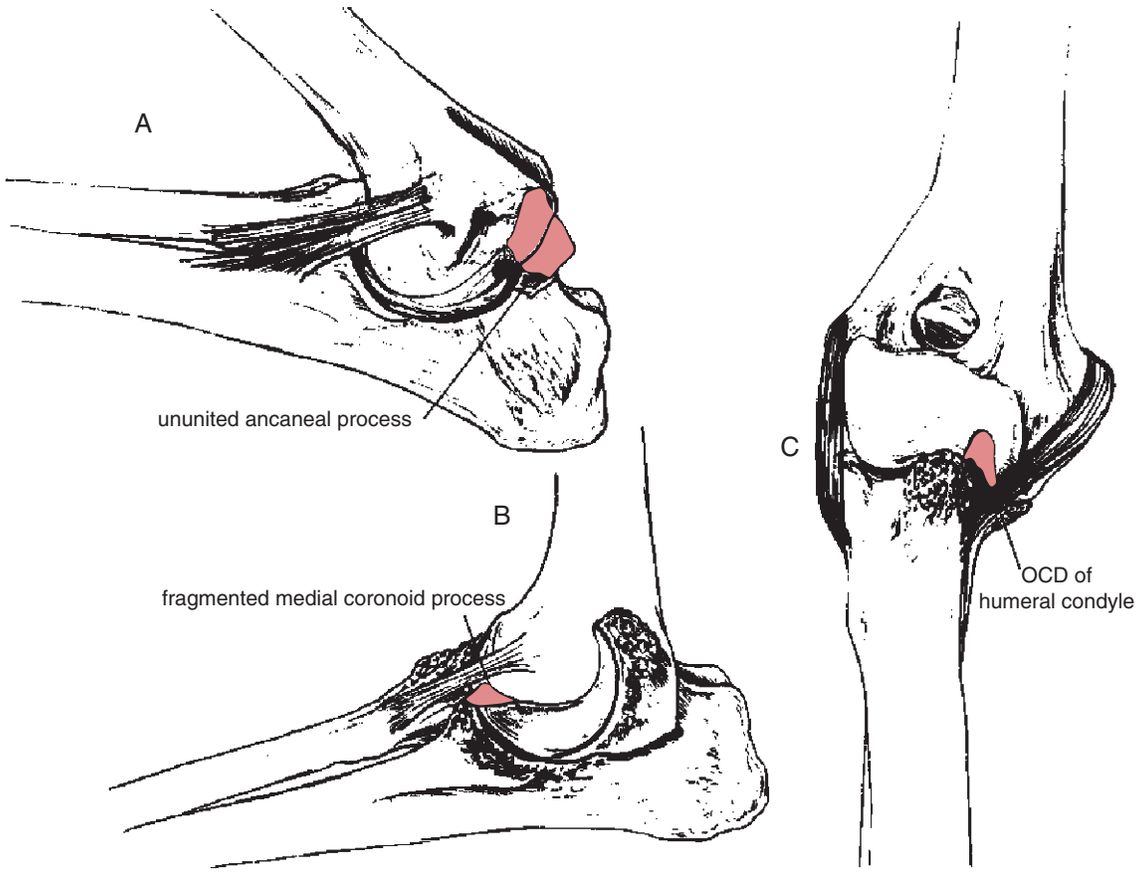

Figure 118-1. The various manifestations of elbow dysplasia include *(A)* ununited anconeal process, *(B)* fragmentation of the medial portion of the coronoid process of the ulna, and *(C)* OCD of the medial portion of the humeral condyle.

- If these cartilage flaps attach to the joint capsule, they may become mineralized or ossified.
- Curettage of the chondral and subchondral lesion stimulates neochondrogenesis; however, the resultant fibrocartilage does not have the same material properties as the original hyaline cartilage, and is not as durable.
- The new cartilage rarely attains the height or density required to reestablish joint congruity.

Clinical Signs

Shoulder

- Large-breed dogs, 4 to 8 months of age, 2:1 to 3:1 male/female ratio.
- Bilateral in 27% to 68% of cases; many are clinically affected in only one limb.
- Lameness is initially noted after exercise or after rest preceded by exercise.
- Pain with shoulder extension, crepitus, deltoid and spinatus muscle atrophy.

Hock

- Large-breed dogs, 5 to 8 months of age, commonly Rottweiler, Labrador retriever, and bullmastiff.
- Lateral trochlear ridge OCD is seen most commonly in the Rottweiler.
- Hind limb lameness characterized by a shortened stride and hyperextension of the tarso-crural joint.
- Thickening of the tarsus especially if the medial trochlear ridge of the talus is involved.

Stifle

- Large-breed dogs, 5 to 7 months of age.
- Lameness varies from mild to severe.
- Joint effusion, muscle atrophy, and crepitus may be evident.

Diagnosis

- The radiographic signs of osteochondrosis are well characterized and easily recognized in most cases;

high-quality, well-positioned radiographs are necessary for an accurate diagnosis (see Chapter 4).
- Normal cartilage is not visible radiographically unless significant dystrophic calcification has occurred.
- Since OCD lesions consist of areas of relatively thicker cartilage than the surrounding cartilage and a failure of endochondral ossification of the underlying bone, the lesion is observed as a flattened or saucer-like "divot" in the subchondral bone.

Shoulder

- Radiographs reveal a flattening of the humeral head in a properly positioned lateral view.
- An arthrogram may be needed of the lesion is not evident or a cartilage has migrated into the biceps tendon sheath.

Hock

- Radiographic identification of the lesion may be difficult due to the location of the lesion on the trochlear ridge.
- Extended dorsoplantar projection may reveal a defect in the trochlear ridge.
- A dorsolateral-plantaromedial 45-degree oblique projection in full extension outlines the medial trochlear ridge of the talus.
- A skyline view of the talus may identify a lesion on the center of the trochlear ridge of the talus.

Stifle

- Slight flattening and sclerosis of the subchondral bone of the femoral condyle is evident in a caudocranial view of the stifle.
- Avoid confusing the extensor fossa for an OCD lesion.

Preoperative Considerations

- As the relative size of the osteochondral defect to the total joint surface area increases, the resulting joint incongruity also increases. Thus, a small defect in a large joint (shoulder) has less of an impact than in a small (hock) or complex (elbow or stifle) joint.

▼ ***Key Point*** Surgical treatment of OCD lesions can result in normal or near-normal function in large joints with relatively small lesions (shoulder); however, function is improved but clinical signs are not always alleviated in complex or small joints (elbow, hock, and stifle).

- The degree of osteoarthritis in the joint prior to surgery has an impact on long-term function; as the degree of osteoarthritis increases, function is diminished.
- Patients with small lesions and minimal osteoarthritis will have the best surgical result; conversely, patients with large lesions and severe osteoarthritis are less likely to benefit from surgery.
- Dogs with OCD of the hock may fare as well with or without surgery; this is likely due the relatively large size of the typical lesion in the hock, as well as the tendency for osteoarthritis to be significant in this joint preoperatively.

Surgical Procedures

Objectives

- The goals of surgery are to debride the osteochondral defect with minimal damage to the joint during the surgical approach and procedure.

Equipment

- Same as for OCD of the humerus, discussed later in this chapter.

Technique

- An arthrotomy or arthroscopy can be employed.
- See respective chapters on shoulder, hock, and stifle disorders for a description of surgical approaches (see Chapters 102, 112, and 110).
- Debride the lesion to the level of subchondral bleeding bone utilizing a curette, a hand bur, or a motorized shaver.
- Debride the edges of the lesion peripherally to normal cartilage, and perpendicular to the subchondral bed.
- Microfracture can be utilized to create vascular access channels from the lesion to the underlying subchondral bone.

Postoperative Care and Complications

- Apply a soft padded bandage for 3 to 5 days from the digits to the mid-diaphysis proximal to the incision to minimize postoperative swelling.
- Remove skin sutures in 10 to 14 days.
- Confine the dog to leash walks only for 6 weeks to allow neochondrogenesis to occur. Allow gradual return to normal activity over the next 6 weeks to allow cartilage remodeling to occur.

Prognosis

▼ ***Key Point*** The prognosis for return to normal function in dogs with OCD of the shoulder is good to excellent; over 95% of patients are sound at 4 to 8 weeks.

- Early treatment of OCD of the hock (4–6 months of age) is indicated; otherwise the prognosis is poor due to a tendency for progressive degenerative joint disease (DJD) to develop.

- OCD of the stifle carries a more guarded prognosis than that of the shoulder OCD; 75% will be normal if treated early.

CANINE ELBOW DYSPLASIA

Elbow dysplasia is a collection of diseases, which were initially presumed to be a result of osteochondrosis. Recently, asynchronous growth or uneven joint loading has been implicated in the pathogenesis of this disorder.

Pathophysiology

- Canine elbow dysplasia (CED) is a collection of developmental diseases of the canine elbow, which is believed to be caused by a primary incongruity between the humerus, radius, and ulna.
- Manifestations include fragmented medial coronoid process (FMCP) of the ulna, ununited anconeal process (UAP) of the ulna, and osteochondritis dissecans (OCD) of the medial portion of the humeral condyle.
- Classically, a decreased radius of curvature of the ulnar trochlear notch was suggested as the cause.
- A second theory is that elbow incongruity in CED is caused by asynchronous growth between the radius and ulna.
- Lagging radial growth and a relatively long ulna may stress the medial coronoid process and humeral condyle, resulting in FMCP and OCD, respectively.
- In an experimental study, surgical shortening of the radius in normal dogs resulted in altered intra-articular contact potentially stressing the medial coronoid process.
- Dogs with unilateral UAP have been shown to have a slightly longer radius on the affected side.

Ununited Anconeal Process

Anatomy

- Ununited anconeal process (UAP) is a failure of the ossification center of the anconeal process to fuse with the proximal ulna by 20 to 24 weeks of age. Thus, a diagnosis of UAP prior to 24 weeks of age may be premature.
- The blood supply to the anconeal process is via the dorsal joint capsule attachment; therefore the bone remains viable and capable of endochondral ossification unless these attachments are disrupted.
- Physeal closure of the anconeal process initially occurs distally, and then progresses proximally along the physis.
- The anconeal process is an important stabilizer of the canine elbow, particularly in extension during the stance phase of the gait. Instability or detachment of the process leads to synovitis and eventually osteoarthritis.

Pathophysiology

- UAP may be secondary to abnormal loading of the elbow joint secondary to elbow incongruity or an abnormal size or shape of the trochlear notch; it has not been definitively proven to be secondary to OCD.
- Physeal closure of the anconeal process initially occurs distally, and then progresses proximally along the physis.
- Incomplete endochondral ossification along the physis can result in foci of retained cartilage within a closed physis mimicking UAP.

▼ ***Key Point*** The anconeal process is an important stabilizer of the canine elbow, particularly in extension during the stance phase of the gait. Instability or detachment of the process leads to synovitis and eventually osteoarthritis.

- In chondrodystrophic breeds, UAP may result from premature closure of the distal ulnar physis and asynchronous growth of the radius and ulna.

Clinical Signs

- Large-breed dogs, especially the German shepherd, basset hound, and St. Bernard, are affected.
- Signs including forelimb lameness, elbow abduction, and external rotation of the foot become apparent at 5 to 8 months of age.
- Crepitus, joint effusion, and peri-articular thickening of the elbow may be noted.

Diagnosis

- Clinical signs, age, and breed form the basis for a provisional diagnosis.
- A flexed lateral radiographic view reveals an irregular radiolucent line between the anconeal process and the olecranon.
- Radiographs of the contralateral elbow may be useful for comparison; bilateral UAP occurs in about 30% of cases.

Preoperative Considerations

- Removal of the anconeal process is an acceptable method of treatment. However, the anconeal process is an important stabilizer of the elbow, and its removal may lead to elbow instability and osteoarthritis.
- Surgical reconstruction, such as procedures that enhance fusion of the anconeal process, may be the preferred method of management, since these procedures preserve the function of this intra-articular stabilizing structure.
- A dynamic proximal ulnar osteotomy alone may be sufficient to allow fusion of the anconeal process in young (6–12 months) dogs, while a dynamic proximal ulnar osteotomy and lag screw fixation may be required in older (over 1 year) dogs, or in dogs

with loose attachment of the anconeal process to the olecranon.

- Four categories of UAP have been defined, and the type of union may be used to guide treatment.
  - *Cartilage retention nest.* In this lesion (usually an incidental finding) the anconeal process is united; however, an area of cartilage remains along part of the fusion site. This lesion is not likely to be a cause of lameness.
  - *Delayed union.* A normal union may occur in young dogs (5–6 months) if cage rest and exercise restriction are employed. If union fails to occur after 4 to 6 weeks of conservative treatment, surgical treatment is indicated.
  - *Non-displaced nonunion.* The anconeal process is apposed to the proximal ulna by fibrous or fibrocartilaginous tissue. Such fragments can be successfully reconstructed if the fragment size, bone density (screw holding power), viability of the tissue interface and fragment, and degree of interfragmentary compression achieved are adequate.
  - *Displaced nonunion.* The anconeal process is physiologically (due to lack of blood supply or viable interface tissue) or anatomically separated from the proximal ulna. These loose fragments act as foreign bodies and interfere with normal joint function, and should be removed.

Surgical Procedures

Objectives

- Remove or reconstruct the anconeal process.
- Identify and treat concurrent conditions such as OCD/FMCP.

Equipment

- Standard surgical pack and suture
- Gelpi self-retaining retractors
- Suction and cautery
- Periosteal elevator
- Drill, drill bits, taps, depth gauge, screws, and screwdriver
- Small bone curette
- Small osteotome and mallet, gigli wire or oscillating bone saw

Technique

The anconeal process may be removed via a caudo-lateral arthrotomy.

1. Place the patient in lateral recumbency, with the affected limb up; prepare for aseptic surgery using the hanging limb technique.
2. Perform a caudo-lateral approach to the elbow, placing the incision in the anconeus muscle at its insertion on the ulna, and elevate the muscle using the periosteal elevator.
3. Retract the anconeus muscle and lateral head of the triceps with the gelpi retractor.
4. Externally rotate the antebrachium and slightly flex the elbow to gain adequate exposure of the anconeal process.
5. Remove the anconeal process and close.

The quality of attachment of the anconeal process can be evaluated with arthroscopy or following an arthrotomy. If the anconeal process is firmly attached, perform a dynamic proximal ulnar osteotomy to normalize loading within the joint; this may allow the anconeal process to fuse spontaneously. If the anconeal process is loosely attached, perform interfragmentary compression with lag screw fixation, and a dynamic proximal ulnar osteotomy can be performed to normalize loading within the joint.

1. Explore the joint and the quality of attachment of the anconeal process with arthroscopy or following an arthrotomy.
2. If the anconeal process is loosely attached, attempt lag screw fixation of the UAP.
   a. Drill a thread hole either freehand from the apex of the anconeal process to the caudal ulna, or from the caudal ulna to the apex of the anconeal process (the latter is facilitated by using an aiming device).
   b. Drill a glide hole in the caudal ulna by overdrilling the thread hole.
   c. Measure the screw length.
   d. Tap the thread hole in the anconeal process.
   e. Insert the screw from caudal to cranial observing the degree of compression (Fig. 118-2).
   f. Do not allow the screw tip to protrude beyond the apex of the anconeal process.
3. Perform a caudo-lateral approach to the ulnar diaphysis by elevating the extensor carpi ulnaris and abductor pollicis longus from the lateral aspect of the ulna, and the flexor carpi ulnaris and deep digital flexor from the medial aspect.
4. Perform an ulnar osteotomy just distal to the level of the radial head, oriented cranio-distal to caudo-proximal 30 to 40 degrees (Fig. 118-3). The angle of the osteotomy prevents caudal tipping of the proximal segment due to the pull of the triceps muscle.
5. An intramedullary pin placed from the olecranon to the distal ulnar diaphysis can be used to increase stability of the proximal segment (see Fig. 118-3).
6. Do not hesitate to remove the anconeal process if
   a. Technical difficulties prevent successful internal fixation.
   b. Bone quality is poor resulting in poor screw purchase or compression.
   c. The shape of the anconeal process results in poor joint congruency following internal fixation.

Postoperative Care and Complications

- Apply a soft padded bandage for 3 to 5 days from the digits to the mid-diaphysis proximal to the incision to minimize postoperative swelling.

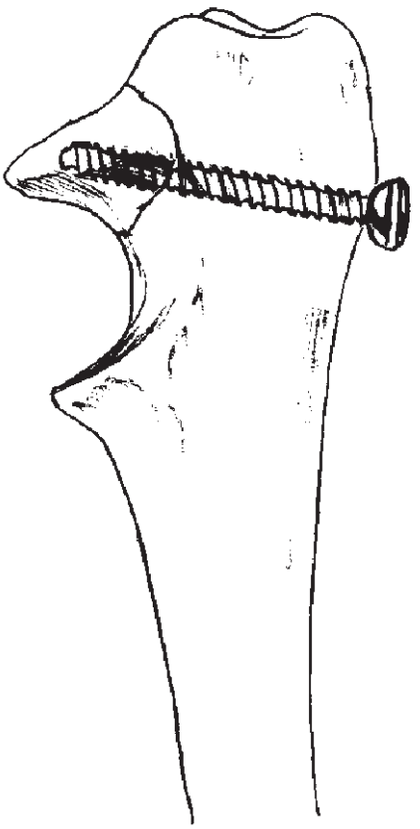

Figure 118-2. Rigid internal fixation of the anconeal process utilizing a screw placed in lag fashion.

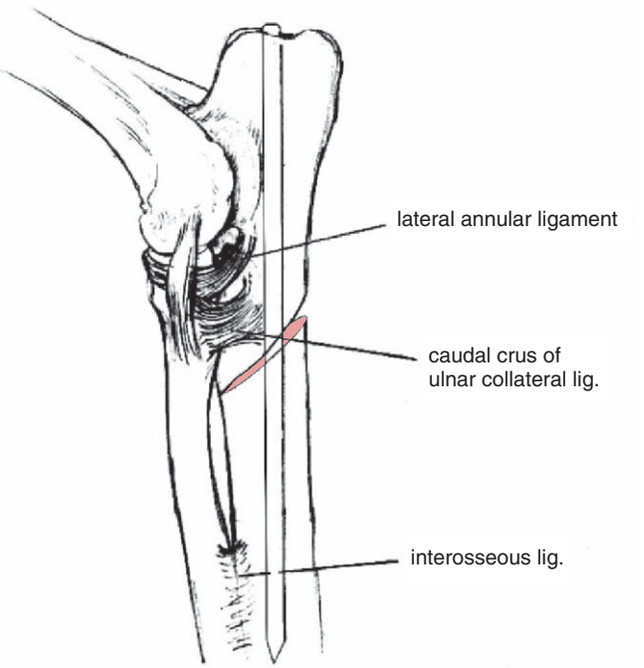

Figure 118-3. An oblique osteotomy of the ulna can be performed to equalize forces within the elbow joint. The placement of an intramedullary pin in the ulna is optional. Perform this technique if internal fixation of the anconeal process is utilized, in order to decrease the likelihood of implant failure due to cyclical stress.

- Remove skin sutures in 10 to 14 days.
- Confine the dog to leash walks only for 6 weeks to allow neochondrogenesis to occur at the site of removal, or anconeal process fusion to occur, depending on the technique that has been performed.
- Repeat radiographs in 4 to 6 weeks to assess fusion of the anconeal process and healing of the ulnar osteotomy if performed.
- Allow gradual return to normal activity over the next 6 weeks to allow cartilage remodeling to occur.

Prognosis

- Good results were obtained with dynamic proximal ulnar osteotomy in a group of young dogs 6 to 12 months old; less favorable results were obtained in a group of dogs 1 to 2 years old.
- In animals with anconeal process removal the prognosis is good to fair; resolution of lameness occurs postoperatively. However, most animals begin to be lame at 6 to 7 years of age secondary to osteoarthritis.
- The prognosis is good to excellent if the anconeal process fuses following surgical reconstruction.

OCD OF THE MEDIAL PORTION OF THE HUMERAL CONDYLE AND FRAGMENTATION OF THE MEDIAL PORTION OF THE CORONOID PROCESS (FMCP) OF THE ULNA

OCD and FMCP affect the distal humerus in the same dog populations that are affected by OCD of the shoulder, and may be bilateral. OCD and FMCP coexist in as many as 37% of cases.

Anatomy

- FMCP is separation of the medial coronoid process from the ulna; the etiology is unknown.
- OCD usually occurs on the medial portion of the humeral condyle.

Pathophysiology

FMCP

- OCD of the medial coronoid may play a role; a defect in endochondral ossification may lead to degeneration of the process and fissure formation.
- Developmental elbow incongruity has also been implicated; a relatively long ulna and short radius may result in an increase of weight-bearing forces on

the medial coronoid process, which may precipitate fragmentation.
- Fragmentation of the coronoid results in a separate piece of cartilage and trabecular bone, which is attached to the annular ligament with fibrous tissue.
- Separation occurs through calcified trabeculae that are then covered, in part, with fibrous connective tissue.
- The end result is joint instability and development of DJD.
- Cartilage on the opposing medial humeral condyle may be eroded by the loose coronoid fragment (kissing lesion).
- Peri-articular osteophytes and soft-tissue fibrosis develop progressively over time.

OCD

- A failure of endochondral ossification results in an OCD lesion in the medial portion of the humeral condyle.

Clinical Signs

- Forelimb lameness, initially evident at 5 to 8 months of age, is seen in retrievers, Bernese mountain dogs, and Rottweilers.
- Clinical signs usually become apparent at 5 to 7 months of age; however, the dog may not be presented until 1 to 2 years of age after development of DJD.
- Lameness is worse after exercise, and joint effusion and peri-articular fibrosis may be palpable.
- Lameness is usually unilateral even if both joints are affected; a stiff or stilted gait may be observed if bilateral forelimb lameness is present due to shortened stride.
- Pain with flexion and extension of the joint is evident, especially with supination or pronation; discomfort may be noted with palpation of the medial coronoid process.
- Avoid shoulder motion during manipulation to avoid mistaking shoulder pain for elbow pain.

Diagnosis

FMCP

- The radiographic findings of FMCP are nonspecific.
- Evaluate both elbows radiographically, as the disease is commonly bilateral.
- A presumptive diagnosis is made based on typical history and clinical signs.

▼ ***Key Point*** The FMCP cannot always be observed, and the diagnosis may be made by inference due to the presence of osteoarthritis.

- Osteophytosis and superimposition of the radial head on the coronoid process make identification of the FMCP difficult.

Radiographs

- Obtain lateral and cranio-caudal views, and a flexed lateral exposed anconeal process to assess for osteophytosis.
- A craniolateral-caudomedial 15-degree oblique with 30 degrees flexion may help visualize the medial coronoid.
- A mediodistal-lateroproximal oblique (MEDLAP) view has recently been shown to enhance visualization of the medial coronoid process.
- Blunting of the coronoid, visible fragments, and osteophytes associated with the coronoid process, anconeal process, or radial head may be visible.
- The earliest radiographic sign is commonly the presence of osteophytes on the anconeal process.
- Later signs include subchondral bone sclerosis, articular and peri-articular osteophytosis, joint space narrowing, joint effusion, and peri-articular soft-tissue thickening indicating secondary DJD.
- Definitive diagnosis can be made with arthroscopy, computed tomography, magnetic resonance imaging, or arthrotomy.

OCD

- Radiographically a triangular subchondral bone defect is evident in the medial portion of the humeral condyle in the cranio-caudal projection.

Differential Diagnosis

- Other conditions affecting the elbows of young dogs produce similar signs, and can be differentiated radiographically.
- Consider UAP, combinations with OCD/FMCP and UAP, and subluxation resulting from premature physeal closure.
- Other diseases of the forelimb in young dogs should be considered such as OCD of the shoulder and panosteitis.

Treatment

Medical Management

- Asymptomatic dogs or those with severe DJD may be treated medically; all surgically treated dogs are also treated with lifelong medical management, as surgical treatment does not halt the progression of DJD.
- Weight loss, exercise moderation, nonsteroidal anti-inflammatory drugs (NSAIDs), and chondroprotective agents are the cornerstones of treatment.
- Rest (2–3 weeks) and NSAIDs are utilized to treat episodes of lameness, followed by return to moderate regular exercise.

Preoperative Considerations

Persistent lameness and mild DJD are indications for surgery; however, some dogs with moderate or severe

DJD may benefit from loose fragment removal. It is important to note that surgical treatment does not halt the progression of DJD.

Surgical Procedure

Objectives

- The goals of surgery are to remove the FMCP and to debride the osteochondral defect with minimal damage to the joint during the surgical approach and procedure.
- An arthrotomy or arthroscopy can be employed.
  - Elbow arthroscopy via medial portals allows identification and removal of the FMCP with graspers or a shaver. Arthroscopy improves intra-articular identification with recognition of cartilage defects, and allows eburnated cartilage to be treated by abrasion arthroplasty and/or microfracture. The ability to treat bilaterally, as well as identify and manage coexistent cartilage defects, supports arthroscopic management.
- See respective chapters on elbow disorders for a description of surgical approaches (see Chapter 105).

Equipment

- Arthroscopy tower, arthroscope and camera, hand instrumentation, and motorized shaver if arthroscopy is to be performed
- Standard surgical pack and suture if arthrotomy is to be performed
- Gelpi self-retaining retractors
- Suction and cautery
- Small bone curette

Technique

- Perform either arthroscopy via the medial portals, or an open approach.
  - If arthroscopy is performed, both elbows may be treated in a single session.
  - If an arthrotomy is performed, operate on the more symptomatic elbow first, followed by the second in 4 to 6 weeks.
- Several open approaches are suitable, including the muscle splitting approach (Fig. 118-4), and osteotomy of the medial epicondyle of the humerus.
- In FMCP, remove the fragment(s) and debride the fragment's bed to the level of subchondral bleeding

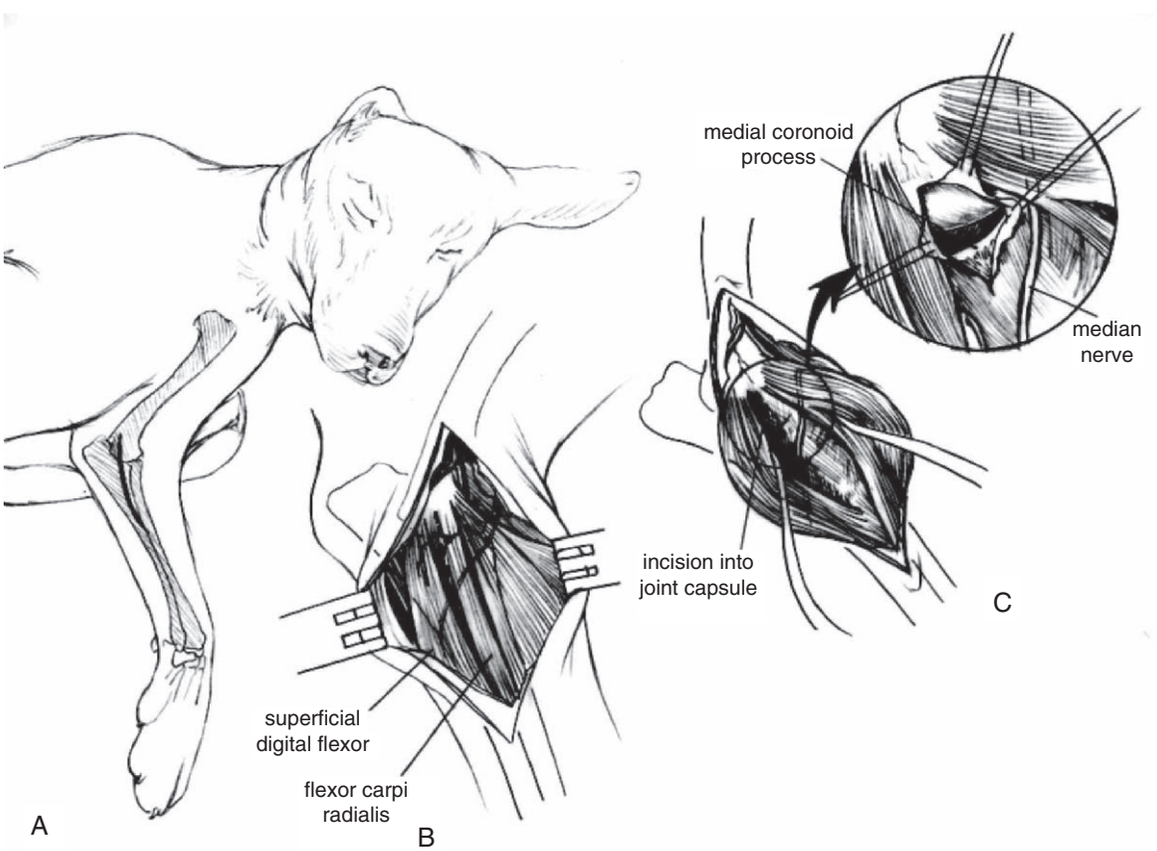

Figure 118-4. Medial approach to the elbow joint by an intermuscular incision. Incise the intermuscular septum between the flexor carpi radialis and deep digital flexor muscles or the flexor carpi radialis and the pronator teres muscles. Retraction of the muscles allows exposure and incision of the joint capsule parallel to the muscles. Note the proximity of the ulnar and median nerves.

bone utilizing a curette, a hand bur, or a motorized shaver.
- In OCD, debride the lesion to the level of subchondral bleeding bone utilizing a curette, a hand bur, or a motorized shaver, ensuring that the edges of the lesion are debrided peripherally to normal cartilage, and are perpendicular to the subchondral bed. Microfracture can be utilized to create vascular access channels from the lesion to the underlying subchondral bone.
- If arthroscopy is performed, identify and treat concurrent conditions such as cartilage eburnation or kissing lesions with microfracture or abrasion arthroplasty.
  - Perform microfracture with specially designed chondropicks. Place the pick within the lesion, and gently tap it into the surface using a mallet. Treat the entire lesion in a grid-like pattern; space the holes 2 to 3 mm apart and 1 to 2 mm deep.
  - Perform abrasion arthroplasty as for an OCD lesion; debride the lesion to the level of subchondral bleeding bone utilizing a curette, a hand bur, or a motorized shaver, ensuring that the edges of the lesion are debrided peripherally to normal cartilage, and are perpendicular to the subchondral bed.

Postoperative Care and Complications

- Arthroscopy:
  - Apply a soft padded bandage for 24 hours.
  - Institute strict exercise restriction for 4 to 6 weeks, followed by gradual return to normal activity.
  - Long-term medical management of osteoarthritis should be employed.
- Arthrotomy:
  - Obtain postoperative and 6-week follow-up radiographs if implants are used (osteotomy of the epicondyle).
  - Apply a soft padded bandage for 5 to 7 days.
  - Institute strict exercise restriction for 4 to 6 weeks, followed by gradual return to normal activity.
  - Administer long-term medical management of osteoarthritis.

Prognosis

- The prognosis for full function is guarded because of progressive DJD regardless of the treatment method.
- Most dogs are functional pets with intermittent lameness.
- Osteoarthritis is usually present and requires lifelong medical management.
- In a recent study of surgical management of 429 dogs, approximately 50% had a resolution of lameness, 30% had a diminished severity of lameness, and in 20% severity of lameness was not affected by surgery.

Chapter

119 Pediatric Fractures

Matthew Palmisano

Fractures occurring in immature animals (<1 year of age) are commonly seen in small animal practice. Immature bone is relatively weaker when compared to the surrounding soft tissues and ligaments, so it is more susceptible to injury. The most common site of fracture in the pediatric patient is in the metaphyseal region of the bone, with 30% of all fractures involving the metaphyseal growth plate (or physis). Fractures may also involve the diaphysis. Special consideration must be made when dealing with these types of fractures in order to ensure a successful outcome.

ANATOMY

- Immature long bone consists of a compact shaft (diaphysis), an intermediate zone (metaphysis), and a terminal portion (epiphysis). Structurally, the metaphysis is weaker than the diaphysis, epiphysis, or its supporting ligaments. The physis lies between the epiphysis and metaphysis, and is responsible for the longitudinal growth of long bones.
- There are two major differences in blood supply in immature and mature bone. First, blood vessels do not cross the actively growing physis, which means that the epiphysis and metaphysis have separate blood flow. Second, the periosteum of young bone requires an extensive blood supply that is not necessary in the mature patient.

Histology of the Physis

The physis is a cartilage that is composed of five developmental zones that are crucial to the longitudinal length of long bones. The zones are, from epiphysis to metaphysis, the reserve zone, the proliferative zone, the hypertrophic zone, the ossification zone, and the metaphyseal zone.

- The *reserve zone* has several layers of randomly arranged chondrocytes. This zone is important in storing nutrients and housing germinal cells.
- The *proliferative zone* is the growth zone of the physis. The germinal chondrocytes are rapidly dividing and forming palisades. Longitudinal growth results from active cell division and matrix production by these chondrocytes.
- In the *hypertrophic zone*, chondrocytes enlarge by accumulation of fluid and calcium.
- In the *ossification zone*, chondrocytes begin degenerating, depositing calcium into the matrix. Metaphyseal capillaries invade the hypertrophic zone and promote mineralization of the matrix and formation of primary and secondary spongiosa in the ossification zone.
- The *metaphyseal zone* is characterized by remodeling of the primary and secondary spongiosa.

CLASSIFICATION OF PHYSEAL FRACTURES

The classification of physeal fractures in young animals is adapted from the human Salter-Harris classification system (Fig. 119-1).

- Type I fractures are characterized by separation of the epiphysis from the metaphysis through the physis.
- Type II fractures occur through portions of the physis and metaphysis.
- Type III fractures occur through portions of the physis and the epiphysis. Therefore, these fractures have an intra-articular component.
- Type IV fractures occur through the metaphysis and the epiphysis. These fractures also have an intra-articular component.
- Type V fractures are crushing injuries, involving all zones of the physis. These fractures are often difficult to see radiographically.
- Type VI fractures are not part of the original classification system. In this type of fracture, the physis is injured resulting in a peripheral closure of one side of the physis.

Early research suggested that the hypertrophic zone is structurally the weakest zone and most susceptible to fracture due to increased cell size and less support matrix. Also, a stress concentration effect may occur in this zone as the tissues of the physis change from softer cartilage to bone. Recent research suggests that the other zones of the physis may be involved with naturally occurring fractures. When the proliferative zone is

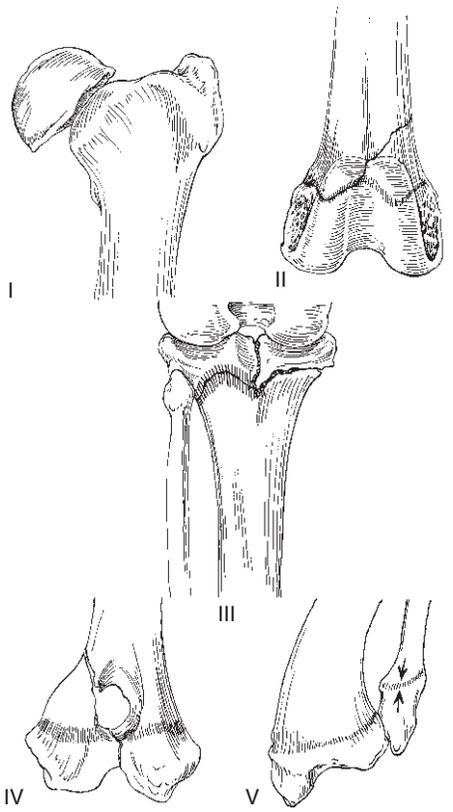

Figure 119-1. Five different types of growth plate fractures. See text for explanation.

involved, the incidence of premature closure of the physis, limb shortening, or angular limb deformity with resultant joint subluxation or luxation is increased. Most growth plates are closed by 12 months of age; physeal injuries are therefore rare in animals >1 year of age.

▼ ***Key Point*** The prognosis for continued growth of the physis with Salter-Harris type I through III fractures may be more favorable than type IV through VI due to preservation of the growing zones of the physis. However, warn owners of the possibility of premature physeal closure with limb shortening or angular limb deformity with any fracture of the long bones involving the physis.

PREOPERATIVE CONSIDERATIONS

- High-quality, orthogonal radiographic views of the fractured bone are a must when characterizing the type of fracture and determining method of repair.
- Consider external coaptation, either by splinting or casting, in fractures that are simple, transverse, minimally displaced, easily reduced, and distal to the stifle or elbow. Some Salter-Harris I and II physeal fractures can be reduced and are amenable to external coaptation.

▼ ***Key Point*** All intra-articular fractures require surgical repair.

- Pediatric bone heals very quickly due to rapid bone turnover and deposition associated with growth. External coaptation has the advantage of preserving blood supply with minimal soft tissue disruption, which will allow a bony union by 3 to 4 weeks.
- Consider open reduction and internal fixation (bone plates, pins, or screws) of fractures with unstable fractures, intra-articular fractures, or fractures >48 hours old.
- Immature bone is very soft and easily fractured with aggressive manipulation. Particular care should be taken with the growth plate. The proliferative zone of cartilage is usually with the epiphyseal segment, so particular care should be taken with this segment so as not to cause premature physeal closure.
- Gentle tissue handling and preservation of blood supply are important. A balance should be made between rigid stabilization of implants and maintenance of the soft tissues.

SURGICAL PROCEDURES

Operative Considerations

- In most physeal fractures, use the smallest Kirschner wires, pins, or screws that will provide sufficient stabilization, while causing the least amount of physeal trauma.
- Refer to the following chapters for specific fixation techniques of commonly seen physeal fractures:
  - Salter-Harris IV distal humeral fracture: Chapter 104.
  - Salter-Harris I or II capital femoral physeal fracture: Chapter 109.
  - Salter-Harris I proximal humeral fracture: Chapter 104.
  - Salter-Harris I or II distal femoral fracture: Chapter 109.
  - Salter-Harris I or II proximal tibial fracture: Chapter 111.

POSTOPERATIVE CARE AND CONSIDERATIONS

Postoperative Care

- Elimination of high-impact activity is a must, since immature bone is soft and implants used in fixation are relatively small and susceptible to bending and loosening.

- If postoperative immobilization is required using a bandage or cast, reevaluate the coaptation weekly. A cast may need to be changed every 2 weeks in young, large- or giant-breed dogs, because they may quickly outgrow the cast.
- Obtain radiographs of the repair every 2 weeks in order to assess healing. Radiograph the contralateral limb for comparison.
- Exuberant callus formation with muscle and tendon entrapment, muscle atrophy, and joint contracture may be minimized using postoperative physical therapy (see Chapter 95).
- In some cases, remove the implants in 4 weeks in order to minimize the potential for premature physeal closure.

Complications

- Exuberant bony callus is a problem in younger patients and is seen in unstable fixations or external coaptation of distal femoral fractures. Bony callus can entrap muscle and tendon.
- Bony callus can also cause fusion between bones. If this occurs between the radius and ulna, asynchronous growth and resultant angular limb deformity can occur.
- Angular limb deformity caused by premature physeal closure should be identified and addressed early. Corrective osteotomies are often required in order to correct the angular limb deformity (see Chapter 105).
- Limb shortening caused by premature physeal closure may alter limb gait, but limb length discrepancies of 25% or less are often well tolerated in dogs and cats due to their relatively flexed stance.

Chapter

120 Open Fractures

Charles E. DeCamp

An open fracture is one that has been exposed to the environment and contaminated by or infected with bacteria. The soft tissue injury that accompanies an open fracture may be a simple puncture wound or a complex injury with vascular compromise and tissue necrosis. Successful management of open fractures depends on proper treatment of soft tissue wounds and fracture fixation. If soft tissue wounds are properly managed, the morbidity of wound infection is reduced and fracture healing can proceed at a normal rate.

CLASSIFICATION OF OPEN FRACTURES

Open fractures are classified as type I, II, or III, based on the mechanism and severity of soft tissue injury (Fig. 120-1). The purpose of classification is to determine the likelihood of serious infection. The type of wound management and the choice of fracture fixation partly depend on the classification.

- Type I develops when a fracture fragment penetrates the skin, exposing the fracture to bacterial contamination. Soft tissue injury is minor, and wound infection is unlikely with proper care.
- Type II develops when an external object forcefully penetrates the skin and soft tissues, creating a fracture and contaminating the wound. Fracture severity is highly variable, but soft tissue injury is relatively minimal and usually is not complicated by vascular compromise and tissue necrosis. Bacterial contamination generally is more extensive than for type I injuries.
- Type III develops when an external object forcefully penetrates the skin and soft tissues, creating a fracture, contaminating the wound, and severely damaging the soft tissues. The ability of the body to combat soft tissue infection commonly is complicated by vascular compromise and necrosis. The risk of bacterial infection is very high.
- Some authors describe an additional class of open fracture, type IV, where the trauma has caused amputation or near amputation of the limb.

▼ ***Key Point*** Type I open fractures are least likely to develop wound infections; type III open fractures almost always have some level of infection.

- In all fracture types, if the wound has been neglected and infection develops, manage the injury as though it were a type III injury.

PREOPERATIVE CONSIDERATIONS

- Perform a complete physical examination to rule out injury to other organs.
- The diagnosis of an open fracture may be made by direct inspection, palpation, and radiography.
- If skin penetration, laceration, or avulsion is present, assume that the fracture is open and contaminated until proven otherwise.
- Cover all open wounds with a sterile dressing.
- Obtain radiographs after dressing placement.
  - Radiographic signs of air within the soft tissues adjacent to a fracture are diagnostic of an open fracture.
- Use aseptic technique when manipulating the wound.

▼ ***Key Point*** Violating the rules of strict asepsis during early wound management increases the probability of nosocomial infection.

- If preparation of the wound cannot proceed immediately, use external coaptation for temporary stabilization of the fracture. Apply a reinforced Robert Jones bandage for injuries below the stifle or elbow. Use a spica splint for open fractures of the femur or humerus.
- To prepare the wound, remove the sterile bandage and carefully clip surrounding hair to avoid contamination. If necessary, cover the wound with sterile gauze sponges moistened with sterile saline or sterile water soluble lubricant gel to prevent introduction of the clipped hair into the wound.

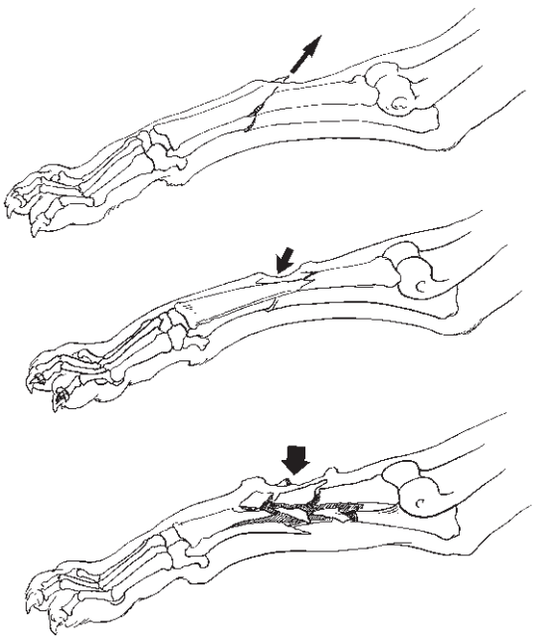

Figure 120-1. Types of open fractures. Type I *(top):* Fracture fragment penetrates skin. Type II *(center):* Penetrating object causes minor injury to soft tissue. Type III *(bottom):* Penetrating object causes extensive damage to soft tissue.

- Lavage the wound with copious amounts of sterile saline or lactated Ringer's solution to remove small particulate matter from the wound interstices (see Chapter 56).
- Betadine and alcohol may be used on the skin surrounding the wound; however, avoid contact of detergents or alcohol with the open wound.
- Remove a sample of fluid from the fracture site for laboratory tests, using a swab if the size and type of wound permit its introduction. Base definitive antibiotic treatment on culture and sensitivity tests. A Gram stain may reveal the organism type and aid the initial choice of antibiotics.
- Consider giving broad-spectrum systemic antibiotics while waiting for results of culture and sensitivity.

▼ ***Key Point*** Systemic antibiotics are less important than proper wound care for prevention and treatment of wound infection.

SURGICAL DEBRIDEMENT, FRACTURE FIXATION, AND SOFT TISSUE RECONSTRUCTION

Objectives

- Improve wound environment to reduce the risk of infection.
- Reconstruct soft tissue to cover bone and provide limb function. It may be necessary to defer this aspect if a large tissue defect or necrosis is present.
- Provide temporary or definitive fracture fixation.

Equipment

- Two standard general orthopedic packs and suture material
- Bone curette and brush
- Sterile saline or lactated Ringer's solution
- Fracture fixation equipment:
  - Materials for external coaptation
  - External skeletal fixation pins and clamps
  - Power drills
  - Bone plating equipment

Surgical Debridement

Techniques

Type I Open Fracture

1. Little or no surgical debridement is required.
2. If the bone is not visibly exposed and the wound is small, copiously lavage the wound with sterile lactated Ringer's solution.
3. Sharply excise necrotic tissue, if present, from the wound before fracture fixation.

Type II Open Fracture

1. Surgical debridement generally is not extensive; however, be careful to remove all non-viable tissue.
2. Copiously lavage the wound with sterile lactated Ringer's solution before fracture fixation.

Type III Open Fracture (Extensive Debridement and Lavage)

1. Prepare the limb and wound for aseptic surgery. If a surgical approach to a bone is anticipated, extend the skin preparation to the appropriate anatomic field.
2. Drape the limb using standard aseptic technique and water-impermeable drapes.
3. Sharply excise necrotic skin, fat, fascia, and muscle from the wound.
4. Remove any loose, dirty, small fragments of bone.
5. To preserve the blood supply and prevent development of bone sequestra, maintain tissue attachments to bone fragments.

▼ ***Key Point*** Clean *large,* attached bone fragments with a bone curette or brush if necessary. *Do not remove them.*

6. Clean, but do not debride, tendons, ligaments, intact blood vessels, and nerves unless they are necrotic.
7. If necessary, extend access to the bone by a surgical approach for fracture fixation. If severe contamina-

tion or infection is present, apply external skeletal fixation with minimal or no surgical approach (see Chapter 111).

Fracture Fixation

- Do not carry out fracture fixation until initial wound management is complete (as described previously).
- If the fracture is stable and non-articular and involves a bone distal to the stifle or elbow joint, external coaptation may be effective. Most other fractures require surgically applied orthopedic fixation.

Techniques

If a surgical approach is made, obtain samples of fluid from the fracture site and submit for culture and sensitivity.

▼ ***Key Point*** To avoid bacterial contamination from debrided tissues, use a new, sterile pack for the surgical approach and fracture fixation.

Type I Open Fracture

1. Repair with the appropriate method of external or internal fixation.
2. If a surgical approach is made to the bone, avoid contact with the traumatic wound to prevent bacterial contamination. Skin drapes may be used.
3. After fracture fixation, close the wound routinely. Penrose drains or delayed wound closure techniques usually are not necessary.

Type II Open Fracture

1. Repair with the appropriate method of external or internal fixation.
2. If a surgical approach is made to the bone, avoid contact with the traumatic wound. Skin drapes may be used.
3. Because bacterial contamination of the wound can be more severe than for type I fractures, provide proper drainage of exudates.
4. If the surgical wound is closed, place Penrose drains to exit the wound at a site ventral to the surgical incision. Alternatively, in medium to large dogs, consider placement of closed suction drains.
5. If bacterial contamination is severe, perform delayed or partial wound closure to ensure proper drainage (see Chapters 55 and 56).

Type III Open Fracture

▼ ***Key Point*** Treatment of most type III open fractures proceed in the following order: wound care, fracture fixation, and skin reconstruction.

1. Carefully choose a method that reduces the risk and severity of wound infection.
2. In general, do not use metallic implants at the fracture site unless adequate wound drainage is assured. Do not use intramedullary pins because of the difficulty in providing surgical drainage from the medullary canal.
3. Bone plates may be used in conjunction with delayed or secondary wound closure techniques, unless severe infection is present.
4. If possible, use external skeletal fixation (see Chapter 111) because a fixator may be constructed that avoids placement of metallic implants directly in the fracture site. However, anatomic considerations may contraindicate their use.

▼ ***Key Point*** Regardless of the type of orthopedic implant, rigid fixation is mandatory for definitive treatment of the fracture.

5. If an external fixator cannot be used, a type I external fixator, transarticular external fixator, or external coaptation may be used as temporary fixation so that local wound care and resolution of infection may proceed. When the wound environment has improved, other methods of internal fixation such as bone plates and lag screws may be applied with less risk of infection.

Reconstructive Soft Tissue Surgery

- Primary, delayed primary, or secondary closure techniques (see Chapters 55 and 56) may be used to treat traumatic wounds in open fractures.
- Wounds may be allowed to heal by second intention.
- Some wounds may not heal because of their large size or because they are located at a site of active motion or a pressure point (e.g., elbow). In these cases, reconstruct the skin wound with a skin flap or graft (see Chapter 57).
- Skin flaps or grafts may be constructed at the time of fracture fixation but often are delayed until a healthy bed of granulation tissue indicates that wound infection is resolved.
- If arthrodesis is the primary method of orthopedic fixation for the carpus or tarsus, perform skin reconstruction 1 month before arthrodesis. This allows full resolution of soft tissue infection and good soft tissue cover over the proposed arthrodesis site.

POSTOPERATIVE CARE

- Administer postoperative analgesics as necessary (see Chapter 6).
- Continue appropriate postoperative wound care to prevent and control infection.
- Keep open wounds bandaged, and replace the bandage daily to prevent accumulation of exudates at the wound site.

- Lavage open wounds daily with sterile saline or lactated Ringer's solution until healthy granulation tissue indicates resolution of infection.
- Restrict activity, depending on the fracture type and method of fixation.
- Use an Elizabethan collar, if necessary, to prevent the animal from licking its wounds or removing the bandages.
- Stage implant removal to provide optimal bone healing and to minimize risk of long-term wound or bone infection.
- Perform a physical examination and obtain radiographs at appropriate intervals to evaluate proper bone healing and resolution of infection.
- Administer postoperative physical therapy as needed to restore function in the affected limb (see Chapter 95).

COMPLICATIONS

- Continued infection suggests the presence of necrotic soft tissue or bone, an unstable fracture site, or unstable orthopedic implants.
- Delayed healing of a fracture may develop from prolonged infection at the fracture site, poor reduction, unstable fixation, or bone loss due to trauma or infection (see Chapters 121 and 122).

▼ ***Key Point*** Most complications can be avoided with proper wound management, orthopedic fixation, and postoperative care. Serial examinations to assess progress are essential to avoid development of major problems.

Chapter

121 Osteomyelitis

Callum W. Hay

Osteomyelitis is caused by infection of bone and associated structures (soft tissue, periosteum, and endosteum). Osteomyelitis is invariably caused by an infectious agent such as bacteria or fungi. Acute onset osteomyelitis is rare and generally does not show detectable radiographic changes until 5 to 10 days after bone inoculation. Chronic osteomyelitis is seen as a complication from orthopedic surgery, extension of tooth infection into bone (with periodontal disease), or from nail bed infections. Osteomyelitis can mimic other diseases such as panosteitis, hypertrophic osteodystrophy, and neoplasia and should be differentiated from these.

ETIOLOGY

Bacteria

- The common routes of bacterial infection are outlined in Table 121-1.

▼ ***Key Point*** Chronic bacterial osteomyelitis is the most common form seen in veterinary medicine.

- Orthopedic surgical procedures allow introduction of bacteria from the patient's skin or from implants placed in the wound (bone plates, suture). Direct inoculation from the surgeon's skin or apparel is also possible.
- Chronic periodontal disease with extension of infection into the mandible or maxilla can lead to chronic osteomyelitis and bone weakening. The mandible of small dogs can be susceptible to iatrogenic fracture during tooth extraction, if significant osteomyelitis is present.
- Nail bed infections acquired from trauma and the environment can extend into phalanges and digits (see Chapter 63).

▼ ***Key Point*** Osteomyelitis is often propagated by local tissue environmental factor(s), which overwhelm the body's own natural defense mechanisms. These include poor vascularity, necrotic bone or soft tissue, foreign material such as metallic orthopedic implants or methyl methacrylate, and especially fracture instability.

- Beta-lactamase–producing *Staphylococcus aureus* bacteria cause a large majority of infections. Other common bacteria are *Pseudomonas aeroginosa; Escherichia coli;* and *Streptococcus, Bacteroides, Actinomyces,* and *Clostridium* species.
- Bacteria produce a mucopolysaccharide coating called glycocalyx, which protects bacteria from phagocytes, antibiotics, and antibodies. Bacterial colonization of orthopedic implants or necrotic bone allows reinfection once antibiotic therapy is stopped.

Fungi

Fungal entry into the respiratory tract can lead to osteomyelitis from hematogenous spread. Direct contamination through an open wound is possible, but rare. Most infections will occur in the vertebral bodies/disks or in the bones of the skull.

Coccidioides, Blastomyces, Histoplasma, Cryptococcus, and Aspergillus spp. can all cause fungal osteomyelitis.

DIAGNOSIS

History

- Osteomyelitis can be preceded by orthopedic surgery, penetrating trauma, chronic dental disease, injury to the toes/foot pads, or possibly known travel to an endemic fungal region.

Physical Examination

- The patient may have evidence of lameness, inappetence, malaise, elevated body temperature, muscle atrophy, and pain on direct palpation of affected area(s).
- Patients who have had orthopedic surgery may have obvious instability at the fracture site or exterior migration of pins. A draining tract may develop distal

Table 121-1. ROUTES OF INFECTION IN OSTEOMYELITIS

Open reduction and internal fixation of fractures; other orthopedic intervention
Open fractures
Extension from soft tissue infection (periodontal disease, rhinitis, otitis media)
Traumatic injuries and bite wounds
Penetrating foreign bodies, including sticks and grass awns
Gunshot injury
Hematogenous
Prosthetic joint replacement surgery

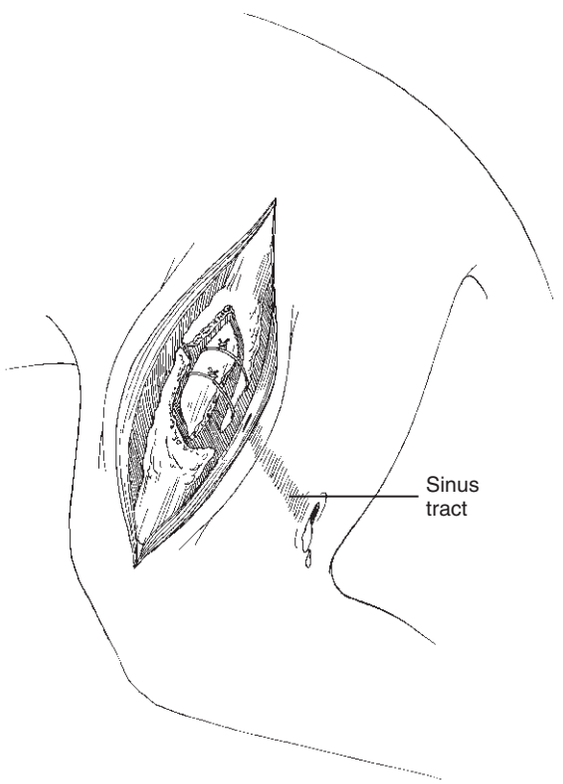

Figure 121-1. Chronic osteomyelitis with sequestrum, loose unstable implants, and involucrum walling off the focus of infection. These conditions favor chronic bacterial infection, and purulent exudate drains through a dependent sinus.

to the surgical site (Fig. 121-1). Exudate from a tract is not necessarily copious and can appear minimal, especially if the patient is frequently licking the site.

- Small-breed dogs with severe dental disease with mandibular involvement may be very painful on oral manipulation. Pathologic fractures (either precipitated iatrogenically from tooth extraction or from trauma) are easily palpable under general anesthesia.
- Swelling, heat, pain, and possibly a draining tract may be seen in patients with digital osteomyelitis.
- Mucopurulent nasal discharge, coughing, or pulmonary crackles/wheezes may be observed in patients with disseminated fungal infections (see Chapter 20).

Hematology

- Acute systemic infection may cause a neutrophilic leukocytosis; however, chronic osteomyelitis may not cause significant hematologic abnormalities.

Diagnostic Imaging

Survey Radiography

- Acute osteomyelitis will not be readily apparent for 10 to 14 days after initial inoculation.
- Focal bone lucencies and aggressive periosteal proliferation may be seen.
- Bone sequestra are diagnostic of chronic osteomyelitis.
- Evidence may be seen of implant migration/failure.
- It can be difficult to differentiate hypertrophic nonunion from chronic osteomyelitis with survey radiographs (also see Chapter 122). Both processes can be associated with an aggressive periosteal response with apparent lucent areas. In the case of mild fracture instability, both can be present simultaneously.
- Fungal osteomyelitis generally involves flat bones and the metaphyses of long bones and may have multiple lytic and proliferative lesions.
- Acute osteomyelitis can be difficult to distinguish from acute postoperative infection because radiographic changes are minimal.

Contrast Radiography

- It may be useful to inject soluble iodinated contrast media (e.g., iohexal) into a draining tract to determine the location and extent of chronic osteomyelitis. This can be especially useful in trying to differentiate the location of necrotic bone encased in more vascular periosteal bone formation.
- Perform the fistulogram by injection of contrast media into the draining tract. Use an appropriate-size rubber feeding catheter, or Foley catheter, and place in the tract under aseptic conditions. Occlusion of the exterior of the tract with digital pressure or using an atraumatic instrument may be necessary to allow proper contrast flow. Try not to allow significant outward leakage, which could hinder the ability to interpret radiographic abnormalities.

Laboratory Evaluation

Cytology

- Smears of aspirates or swabs can be useful for diagnosing fungal infections. They are probably of limited use for presumed bacterial causes since the sensitivity and specificity of cytology is likely to vary widely between cases of osteomyelitis.

Bacteriology

- Obtain samples using appropriate asepsis (clipping, disinfecting skin, and using sterile gloves) with appropriate restraint (heavy sedation or general anesthesia). Submit aspirates of affected tissue for aerobic and possibly anaerobic culture and sensitivity.
- Obtain surgical samples from bone, implants, or tissue; these should be taken preferably before perioperative antibiotic prophylaxis has been administered.
- Obtain samples for fungal cultures. However, these may take weeks to yield results.

Histopathology

- Histopathology is likely to be useful if neoplasia is suspected.
- Specialized fungal stains can be requested on pathology samples submitted to any laboratory.

TREATMENT

The treatment goals in osteomyelitis are to provide a suitable local environment that is conducive to granulation tissue formation, soft callus formation, and ultimately new bone regeneration. Chronic bacterial osteomyelitis is much more common than acute osteomyelitis and fungal osteomyelitis. However, open fractures, acute postoperative orthopedic infection, and deep bite wounds should be considered predisposing factors to acute osteomyelitis, which if inappropriately treated could lead to chronic osteomyelitis.

Surgical Procedures

Objectives

- Identify pathogenic organisms.
- Determine antibiotic sensitivity.
- Drain infected tissue.
- Remove avascular bone (sequestrectomy).
- Stabilize the fracture.
- Implant a bone graft to aid osseous union of fractures.

Equipment

- Standard orthopedic instrument pack and suture.
- Rongeurs to debride bone.
- Fracture repair instruments and equipment (e.g., plates, screws, external fixator, and possibly interlocking nails).
- Orthopedic power equipment.
- Curettes for bone graft collection and debridement.
- Retractors: hand-held or self-retaining, such as gelpi retractors.

Acute Osteomyelitis

▼ ***Key Point*** Open fractures, especially in the upper limbs or with extensive soft tissue loss and bone exposure in any bone, are considered surgical emergencies. Appropriate equipment and experience are necessary to minimize complications. Consider expedient referral to a specialist if these resources are not readily available.

Preoperative Considerations

Antibiotic Prophylaxis

- Administer antibiotics after appropriate samples have been obtained.
- Parenteral use: consider using ampicillin (20 mg/kg q6–8hr IV) with either amikacin (15 mg/kg q24hr IV) or enrofloxacin (5–10 mg/kg q24hr SC). Use metronidazole (15 mg/kg q12hr IV) for suspected anaerobes; however, ampicillin will be effective against most anaerobic organisms. Cefazolin, while effective against *S. aureus*, is generally not effective against *Enterococcus*, which is likely to be present in a wound contaminated from the environment.
- Oral use: consider amoxicillin/clavulanate (20 mg/kg q12hr PO) and/or enrofloxacin (5–10 mg/kg q24hr PO).

Analgesia

- Patients with acute osteomyelitis are extremely painful. Consider using injectable narcotics such as morphine, butorphanol, buprenorphine, or other similar drugs. If not contraindicated, ketoprofen, meloxicam, carprofen, or flunixin can be given parenterally. Consider epidural administration of morphine and/or bupivacaine for hind limbs where there is no involvement of tissue over the lumbosacral junction (see Chapter 6 for discussion of pain management).

Technique

1. Administer general anesthesia and then clip and aseptically prepare the surgical site.
2. While good exposure is necessary, avoid unnecessary disruption of blood supply or soft tissue attachments to bone.
3. Debride necrotic and infected tissue and remove any foreign material involved in the infection.
4. Lavage the wound thoroughly with sterile saline under pressure from a 20- to 60-cc syringe with an 18-gauge needle.

▼ ***Key Point*** Pulsatile pressure with a syringe and needle is more effective at removing bacteria from a wound than simple low-pressure lavage.

5. Replace loose implants and provide rigid fracture fixation.
6. External fixation is useful for temporary and definitive stabilization of open fractures, especially on the tibia, radius/ulna, and mandible. It may be preferable to stabilize the femur and humerus with plates/screws or interlocking nails depending on the surgeon's preferences.
7. Consider leaving wounds on the distal limbs open if there is severe loss of skin, muscle, or bone. With appropriate care these wounds will form granulation tissue and can possibly be closed in a delayed manner.

Postoperative Care and Complications

- If the wound is left open, cover it with sterile petrolatum-impregnated gauze with sterile sponges. Use cast padding, stretch gauze, and a stretch bandage to cover the wound (see Chapter 56 for open wound management).
- Irrigate daily (sterile saline) for 3 to 10 days until there is healthy granulation tissue present.
- Continue with antibiotics, based on the results of culture, for 4 to 6 weeks.
- Obtain radiographs at 3- to 6-week intervals to determine the progression of healing.

Chronic Osteomyelitis

Preoperative Considerations

▼ ***Key Point*** Chronic antibiotic therapy alone will fail unless the other underlying causes are identified and corrected.

Consider amputation of the affected limb if treatment carries a poor prognosis, especially if there is considerable muscle contracture, neurologic damage, soft tissue loss, and financial constraints from the owner. Treat phalangeal osteomyelitis by digital amputation (see Chapter 114). Chronic mandibular or maxillary osteomyelitis can pose a therapeutic challenge due to the lack of bone present in these cases. Obviously infected or necrotic bone should be removed (see Chapter 99); however, iatrogenic fractures created during tooth extraction will generally heal with debridement and antibiotic therapy and will not require stabilization.

▼ ***Key Point*** Bone will heal in an infected environment with internal fixation as long as there is adequate stability.

Technique

1. Expose the fracture site and identify non-viable bone and remove it using rongeurs.
2. Remove and replace implants with either internal fixation (plate/screws or interlocking nail) or external fixation.
3. Irrigate the wound with sterile saline using pulsatile lavage through a 30- to 60-cc syringe and 18-gauge needle.
4. Harvest a cancellous bone graft from the proximal humerus and pack into the bone defect. Larger defects can be filled with a mixture of cancellous bone and cortical/cancellous bone from a rib or ilium.
5. If the wound is to be left open, delay bone graft application until granulation tissue has formed (3–10 days). Manage the wound as outlined in acute osteomyelitis (also see Chapter 56).
6. Highly resistant infections (such as *Pseudomonas aeroginosa* or *E. coli*) can be treated with antibiotic-impregnated methylmethacrylate beads; these can be impregnated with amikacin, gentamycin, or tobramycin and left temporarily in the wound for 7 to 14 days.

Postoperative Care

- Select antibiotics on the basis of microbiologic culture and continue for 4 to 6 weeks.
- Obtain radiographs at 3- to 6-week intervals to assess the progression of healing.
- Consider physiotherapy and swimming to maintain range of motion in joints and to promote controlled use of the limb (see Chapter 95).
- If continued poor healing is present, assess fracture stability, look for sequestra, and reevaluate microbiologic sensitivities. If none of these factors are present, the fracture may be biologically inactive. Place a bone graft in the bone defect to accelerate healing.

Chapter

122 Delayed Union, Nonunion, and Malunion

Randy J. Boudrieau

DELAYED UNION AND NONUNION

Healing times for similar fractures in any single group of patients are fairly uniform; however, a small number of fractures have longer than normal healing times, or may fail to heal at all. The particular type of fracture (comminuted or simple), the bone involved and its location (e.g., distal radius/ulna in small-breed dogs), the age of the animal, and the type of fixation use all influence normal healing times.

- Classification:
  - When the fracture requires longer than normal time to heal but shows definitive signs of progression in healing, it is classified as a *delayed union*.
  - A fracture that does not heal over a similar period and that has no tendency toward further healing is classified as a *nonunion* (Table 122-1).

Other classifications are based on fracture site, fragment displacement, and presence or absence of infection, but are not routinely used.

Definitions

Delayed Union

Radiographic evaluation of the fracture site will reveal callus formation and progressive bone healing, but complete healing has yet to occur over a longer than expected time frame. Delayed union usually needs no other therapy than continuation of ongoing treatment of the fracture. Continued immobilization (assuming stable fixation) allows healing to occur in the majority of cases. A delayed union may, however, be preliminary to a nonunion.

Nonunion

Radiographic evaluation of the fracture site reveals a lack of progression of fracture healing (i.e., bone healing has stopped). Variable amounts of callus may be present depending upon a further subclassification of viable (biologically active) or non-viable (biologically inactive) nonunion (Table 122-2). These nonunions can be classified into two groups: those with callus formation (the hypertrophic viable nonunions) and those without callus formation (both viable oligotrophic and non-viable nonunions).

Most fractures unite within a reasonable time despite systemic factors such as malnutrition, generalized metabolic or endocrine abnormalities, and acute or chronic generalized disease states.

▼ ***Key Point*** Nonunion results from local factors at the fracture site.

Most commonly these local factors can be identified as inadequate fracture fixation, resulting in instability (Table 122-3). Motion within a fracture site creates interfragmentary strain at the site, and if this strain exceeds tissue tolerance, the tissue will not form within the gap. For example, essential fragile capillaries will not be able to cross the fracture gap within the early granulation tissue formation, or later, with the subsequent stages of tissue differentiation (cartilage and bone).

- This concept has mistakenly been thought to be a greater problem in highly comminuted fractures as opposed to simple fractures. The problem has greater significance in a two-piece fracture. This situation most often occurs in transverse fractures, where greater difficulty is encountered in attaining appropriate stability. This is important in fracture fixation and the achieving of stability when anatomically reconstructing a fracture.
- A two-piece fracture has the interfragmentary strain concentrated at the single fracture site.
- A comminuted fracture has this same amount of interfragmentary strain distributed throughout the many fracture sites (or less strain at each individual site).
- The result is that in a single fracture there is high strain, whereas in a comminuted fracture there is low strain at each fracture site.
- Resultant motion in a two-piece fracture will have potentially greater adverse effects on bone healing than in a more comminuted fracture.

Table 122-1. EXPECTED APPROXIMATE HEALING TIMES OF UNCOMPLICATED DIAPHYSEAL FRACTURES WITH MINIMAL LOSS OF CORTICAL BONE

Age of Animal	External Skeletal and Intramedullary Pin Fixation	Bone Plate Fixation*
<3 mo	2–3 wk	4 wk
3–6 mo	4–6 wk	2–3 mo
6–12 mo	5–8 wk	3–4 mo
>1 yr	7–12 wk	5–8 mo

*Fractures stabilized by this method may not be considered clinically healed (have sufficient strength) as early as fractures stabilized by other means of fixation, because direct cortical union (primary bone healing by Haversian remodeling) is not supported by periosteal callus. This is of primary importance when considering timing of implant removal. Clinical function is not adversely affected by this method of fixation because plates provide rigid fixation.

Table 122-2. VIABLE AND NON-VIABLE NONUNION

Viable Nonunion (Biologically Active)
Hypertrophic ("elephant foot," or abundant callus)
Moderately hypertrophic ("horse's hoof," or moderate callus)
Oligotrophic (little or no callus)
Non-viable Nonunion (Biologically Inactive)
Dystrophic (poor vascularity of one or both sides of the fracture)
Necrotic (avascular areas, or bone fragments, within the fracture, i.e., sequestra)
Defect (large bone defect at the fracture)
Atrophic (defect at the fracture with resorption of the adjacent bone)

Table 122-3. FACTORS ASSOCIATED WITH DELAYED UNION AND NONUNION

Local Factors*
Fracture location
Fracture gap
Soft tissue interposition
Bone loss secondary to trauma
Soft tissue trauma
Loss of blood supply as a result of initial trauma
Contamination, infection
Neoplasia
Treatment Factors†
Malposition (inadequate reduction)
Fracture gap
Soft tissue interposition
Distraction (by implants or external fixation devices)
Bone loss due to intraoperative removal
Soft tissue trauma
Loss of blood supply due to surgical trauma
Inadequate Fixation (Internal or External)‡
Instability
Postoperative infection

*Related to the fracture.
†Related to the reduction and fixation.
‡Most common factor.

The most common local factor is a fracture gap (with or without interposition of soft tissues) that exceeds the regenerative capacity of the bone. There is a critical distance over which bone will not form within a gap, resulting in a nonunion.

▼ ***Key Point*** Soft tissue trauma also is an important local factor for bone healing, as damage to the vascular supply will impede healing.

This may occur at the time of fracture, but also at the time of surgery. The importance of the surrounding soft tissues cannot be overemphasized as it is these tissues that are the source for the early revascularization of the bone (transient extraosseous circulation). Therefore, the surgical approaches must be anatomic and atraumatic in nature in order to best preserve this surrounding soft tissue envelope.

Finally, a very common local factor identified in the etiology of nonunions is in miniature or toy breed dogs, where there is a limited vascular supply to the distal radius. Fractures of this bone in these breeds of dogs have a high propensity for developing into a nonunion. Therefore, obtain rigid fixation using bone plates and place cancellous bone grafts.

▼ ***Key Point*** Regardless of the etiology of the nonunion, it requires some form of surgical intervention in order for healing to progress.

Problems Related to Non-healing Fractures

Patients with non-healing fractures may have additional problems related to function, such as disuse muscle atrophy, decreased range of joint motion and stiffness related to scar tissue contraction, neurovascular dysfunction, and limb angulation and/or shortening. These functional deficiencies will be the ultimate determinant of the success or failure of treatment, not whether the bone eventually can be made to unite.

Bone Healing

- Bone heals by either primary (Haversian remodeling) or secondary (periosteal callus) union.
- Secondary bone healing, with formation of visible periosteal callus, begins with connective tissue formation that progresses to form fibrocartilage and finally bone.

- Primary bone healing occurs without formation of connective tissue; bone disposition occurs directly (direct Haversian remodeling, or by gap healing, with fracture gaps <0.8 mm) without any visible callus. Familiarity with these concepts allows accurate sequential evaluation of the healing process.

Histology

- The most notable histologic feature of a delayed union or nonunion is increased periosteal cartilage in the callus in lieu of bone formation.
- Persistent fracture gaps at the bone ends (sometimes greater than that present at the time of the original fracture) are filled with fibrous tissue or fibrocartilage callus.
- The characteristics of a nonunion include chondroid tissue, areas of degeneration with necrosis, and fibrous connective tissue.
- Sclerosis of the bone ends at the fracture site also may occur, effectively sealing the medullary cavity (and access to the medullary circulation).

Clinical Signs

- The patient is usually lame on the affected limb, and may be non–weight bearing.
- Muscle atrophy and joint stiffness are likely sequelae to limb disuse.
- Pain may or may not be present at the level of the fracture.
- Movement (instability) of the fracture may or may not be detected clinically.
- Signs of infection and resultant pain may be present.
- Palpable enlargement of the fracture area may be present.

Diagnosis

Diagnostic Imaging

- Radiographic signs vary, depending on the extent of healing (delayed union versus nonunion); classification of these events is the basis for treatment.
- Radiography allows sequential evaluation of healing.
  - *Delayed union:* There is continued healing, albeit slow, as indicated by progressive callus formation and resorption of dead bone. A persistent fracture line with evidence of some non-bridging callus is characteristic. The marrow cavity remains open without evidence of significant sclerosis of the bone ends.
  - *Nonunion:* There is no evidence of progression of fracture healing (i.e., little or no change on sequential radiographic evaluation over a 3-month evaluation period). Smooth fracture surfaces are typical (no periosteal "irritation"), with evidence of sclerosis at the bone ends and sealed marrow cavities. Sequestra or avascular bone fragments may be observed.
- Radiography may reveal the etiology of the problem.
  - Evaluate the "treatment factors" (see Table 122-3) that may be contributing to the delayed union or nonunion.
  - The fracture fixation is the most common source of the problem, with visible evidence of instability and implant loosening. For example, a small, radiolucent halo around any of the implants (screws, wires, etc.) indicates a loose device. A change in the position of the implants on serial radiographs also indicates implant instability.

Scintigraphic Evaluation

- Scintigraphy may allow for determination between a viable and non-viable nonunion where an absence of callus is present.

Preoperative Considerations

- Always prepare for at least one autogenous cancellous graft donor site.
- Obtain tissue (preferably bone) from the fracture site for aerobic and anaerobic bacterial culture and sensitivity testing.
- Administer perioperative antibiotics (cefazolin, 22 mg/kg IV *after* cultures have been obtained; continue IV administration q2h during the surgical procedure). Continue the antibiotics (cephalexin, 22 mg/kg q8h PO) until culture results and sensitivity testing become available. Further antibiotic therapy depends upon the culture results.
- Decide whether to increase the stability of the fixation without disturbing the fracture site and callus that is present (delayed union, or hypertrophic nonunion) or to debride the fracture site in cases where minimal callus is present (oligotrophic [viable] nonunion or non-viable nonunion).
- Add an autogenous cancellous bone graft in addition to increasing the stability of, or changing, the fixation.
- Note: Treat oligotrophic nonunions (viable nonunion) in the same manner as non-viable nonunions.

▼ ***Key Point*** If in doubt as to the necessary treatment, improve fixation stability and place an autogenous cancellous graft.

- Rigid stability is best achieved with screw and plate fixation. Place the plate under tension in order to compress the fracture fragments and thus use the frictional forces generated at the point of bone fragment contact to increase stability.
- If grossly apparent infection is present (see Chapter 121), consider open wound management (and secondary wound closure with an autogenous cancellous bone graft at a later date) (see Chapter 56).
- If primary closure is performed, consider closed suction drainage of the fracture site.

- Consider options for treatment of soft tissue complications (e.g., joint stiffness, contracture). Use physical therapy to restore functional use (see Chapter 95).

Surgical Procedure

Objectives

- Increase the stability of the fracture site by increasing or changing the fixation (compression plate fixation).
- Debride the fracture site as necessary to provide restimulation for fracture healing.
- Perform autogenous cancellous bone grafting, if gaps are present, to provide further stimulation for bone formation and promote osseous union.
- Restore satisfactory function of the affected limb (*aggressive* physical therapy).

Equipment

- Standard orthopedic pack and suture material
- Implants, usually screws and plates (occasionally may necessitate a separate tension device in order to obtain greater compression at the fracture site)
- Oscillating saw (for making osteotomy cuts)
- Bur set or rongeurs (for debriding fragment ends)
- Appropriate bacterial transport media for tissue cultures
- Curettes for procurement of cancellous grafts
- Closed suction drainage system

Technique

1. Prepare the affected limb for aseptic surgery. Aseptically prepare a separate suitable donor site for harvest of autogenous cancellous bone. Usually the wing of the ilium or the proximal humerus yields a large amount of bone graft.
   a. Plan to procure the graft using a separate set of surgical instrumentation in order to avoid cross-contamination of the donor site and possible infection at the delayed/nonunion site.
2. Make a standard anatomic approach to the affected bone, preserving all soft tissue structures. A large amount of fibrous connective tissue probably is adherent to the overlying muscle bellies; identification of the various tissue planes generally is difficult and requires *sharp* dissection. Exercise caution when approaching sites adjacent to major neurovascular structures.
3. Obtain samples of bone for aerobic and anaerobic bacterial culture and sensitivity testing of the fracture site.
4. *Delayed union, or viable nonunion (with hypertrophic callus formation):* Increase the stability of the fixation with implants such as additional intramedullary pins or an external skeletal fixator (see Chapter 111), or change the implant device (e.g., external skeletal fixator or bone plate placed under tension).

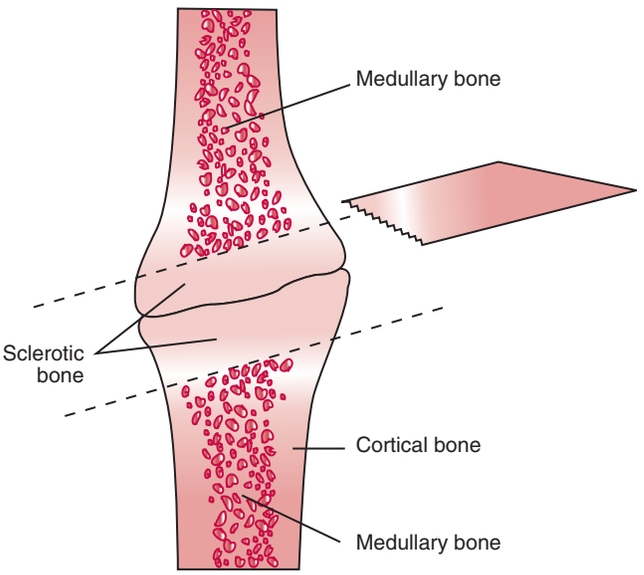

Figure 122-1. Diagrammatic representation of a nonunion with a sealed medullary cavity (sclerotic bone at the fracture margin). Dashed lines indicate level of the osteotomy cut to remove 1 to 2 cm of bone, thus removing the entire nonunion site.

5. *Non-viable nonunion or oligotrophic (viable) nonunion (with minimal callus formation):*
   a. Debride the fracture site. Remove any loose metal, dead bone (sequestra), and infected tissue.
   b. Remove the fibrous connective tissue in the fragment gap by local debridement (bur or rongeurs) or transverse ostectomy (1–2 cm) of the entire nonunion site (Fig. 122-1). *Note:* The latter technique creates a small amount of limb shortening, but this generally is not a functional problem in animals, owing to their flexed joint stance.
   c. Reestablish medullary continuity (and therefore the medullary circulation) by drilling the sclerotic bone ends (Fig. 122-2).
   d. Place an autogenous cancellous bone graft around the debrided fracture site. Ensure a separate sterile operative field and procurement process to prevent possible iatrogenic contamination of the donor site. Bone grafts may not be necessary in cases in which the nonunion site does not have a gap, such as in the osteotomy technique (circumferential fragment contact is ensured under stable, compression plate fixation). Add a cancellous graft if any doubt concerning healing exists.
      - Banked bone may be used, either as an extender for an autogenous cancellous graft or by itself. Banked bone has similar properties to autogenous bone, and is available (Osteo-Allograft, Veterinary Transplant Services, Inc., Kent, WA) as demineralized bone matrix powder, cancellous bone chips (fine or coarse), or a mix of the two.

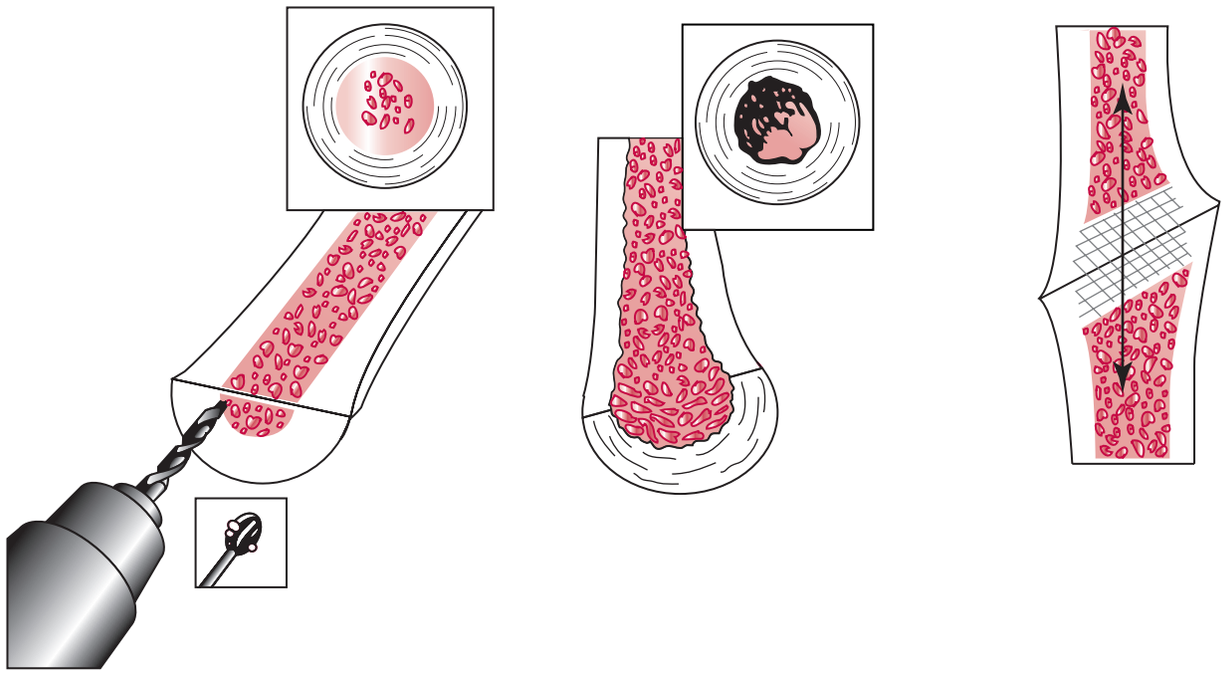

Figure 122-2. After an osteotomy (or local debridement) of the fracture site, the medullary canal may remain sealed by the remaining sclerotic bone at this level. *Left,* Medullary continuity is reestablished by drilling or burring from the fracture site into the medullary canal. *Center,* The medullary canal access has been reestablished. *Right,* Both fracture fragments are reapposed (and compression plate fixation applied), with medullary continuity now reestablished *(arrow). Insets* show cross sections of bone; *hatched area* depicts previous site of sclerotic bone.

- A newer modality is recombinant human bone morphogenetic protein (rhBMP-2) (InFuse Bone Graft, Medtronic Sofomor Danek, Memphis, TN). These substances have had limited clinical use in veterinary medicine as they only recently have become commercially available and are very expensive.

e. When using plate fixation, a separate tension device may be required in order to achieve adequate fragment compression if greater than 4.0 mm of compression is desired. This usually is not necessary, and has not been used with the osteotomy technique.

6. If the tissues grossly appear healthy, routinely close the incision. Place closed suction drains if any question of contamination/infection exists, or if dead space with continued diffuse bleeding is present.
7. Use open wound management if tissues appear grossly infected. Perform delayed primary closure and autogenous cancellous bone grafting at a later date after a healthy granulation tissue bed has developed.
8. Healing *will proceed* in the presence of infection *provided* the fixation is stable.

Postoperative Care and Complications

Physical Therapy (also see Chapter 95)

▼ ***Key Point*** Physical therapy is a key element in successful rehabilitation of these patients.

- Perform passive range of motion of joints adjacent to the surgical site *immediately* after surgery (30–50 flexions-extensions 3–4 times daily). Additional analgesics may be required in the first 2 to 4 days postoperatively. The degree of stability obtained with plate fixation allows this level of activity without major patient discomfort.
- Perform or encourage active range-of-motion exercises (e.g., controlled activity such as short walks and swimming).
- Encourage controlled weight bearing. Limb use favors improved circulation and exercise of the musculature, which in turn improves the local fracture environment.

Open Wound Management

- Change bandage(s) at least once daily and pack the entire wound with wet-to-dry gauze (see Chapter 56). Keep the soft tissues and bone moist. The goal is establishment of a healthy granulation tissue bed to cover both the bone and the implant(s).
- Perform delayed primary closure, usually with the addition of an autogenous cancellous bone graft. Consider using closed suction drains if dead space is present.
- Following successful open wound management of infected wounds, persistent drainage and local or diffuse incisional dehiscence (usually over the implant) may occur. Continued wound management is then required during fracture healing. The

implants are left in position to maintain stability. Subsequent implant removal may be necessary to finally eliminate the infection.

- Note: Metallic foreign bodies (implants) decrease the number of bacteria necessary to establish an infection. Bacterial adherence to the implants with biofilm formation (i.e., glycocalyx) may remain as the nidus for continuing infection.

Prognosis

The prognosis generally is excellent for bone healing. The prognosis is, however, ultimately dependent upon the degree of functional compromise, existing fracture disease, and compromise of joint function due to scar tissue contraction, neurovascular dysfunction, and limb angulation and/or shortening that is present at the time the altered healing is addressed.

MALUNION

Many fractures heal with some degree of deformity without significant effect on function or appearance. Although these technically are malunions, they are not considered true malunions from a practical or clinical standpoint. Clinically, a malunion implies a union with deformity sufficient to cause a functional and/or cosmetic defect. A malunion can occur as a result of untreated or improperly treated fractures.

Malunion may result in angular and rotational deformities, limb shortening, and soft tissue adhesions. These problems may directly affect adjacent joint function by alteration of the articular surfaces and/or supporting ligamentous structures. They also may affect the adjacent joints indirectly through changes in the functional angles placed on the joint and the abnormal stresses thus placed on the ligaments and joint capsule. Joint involvement, either direct or indirect, may result in decreased range of joint motion and degenerative joint disease (see Chapter 123). Correction of the malunion is accomplished by osteotomy through the area of greatest deformity, followed by realignment with stable skeletal fixation.

Precise fracture management can prevent malunion. Serial radiographic evaluation of the fracture throughout the healing period is essential to ensure continued appropriate fragment apposition and alignment. If a deformity is identified early, immediate corrective measures may prevent further complications.

Diagnosis

- Carefully evaluate the entire limb for bone and joint problems. Define the area of the long bone with the greatest amount of deformity: bowing of the bone in the craniocaudal aspect, varus/valgus angulation, or rotational abnormalities along the axis of the bone. For example, a distal radial malunion resulting from premature distal ulnar physeal growth arrest (see Chapter 105) results in cranial bowing, carpal valgus, and external rotation of the distal radius.
- Define the orientation of the adjacent joints. All axes of joint rotation should be parallel to the weight-bearing surface. In the example cited above of a distal radial malunion, the antebrachiocarpal joint surface angles cranially and medially. Depending on the duration of the deformity, severe derangements of the intercarpal joints may be present.
- Assess adjacent structures to the malunion for abnormalities of orientation and function (e.g., degenerative joint disease, joint contraction, altered range of joint motion).

Preoperative Considerations

- Determine the amount of angulation present in the awake, weight-bearing animal and compare with that of the opposite normal limb.
- Determine the amount of angulation observed on radiographic evaluation of the involved limb and compare with radiographs of the opposite normal limb. Carefully determine joint axis orientation. Be aware that radiographs may not reveal the true extent of the deformity, as the stresses of weight bearing are no longer present.
- Compare and collate the information derived from the physical examination and the radiographic evaluation to determine the amount of correction (angle) of osteotomy required.

Preoperative Planning

- Using a duplicate radiograph of the involved limb, draw the limb and joint axes and plot the angle of the correction at the area of greatest deformity.
- Cut the radiograph along the pre-drawn lines and place in the corrected position to evaluate the planned osteotomy cut and the expected result, making adjustments as necessary.
- This two-dimensional radiograph allows correction to be planned in only two planes: craniocaudal and mediolateral. Determine the remaining rotational deformity by observation at the time of surgery. (See Chapter 105 for more information about growth deformities of the radius and ulna.)
- Guide wire technique. In this method all corrections of angulation, rotation, and bending are performed using guide wires placed adjacent to the area of maximal deformity and parallel to the center of motion of the corresponding joint surfaces. Using this orientation, joint surfaces are parallel to the ground and oriented in the transverse plane, to make the respective osteotomy cuts. Although this technique is described for correction of radial ulnar growth deformities, it can be successfully used for any limb deformity.

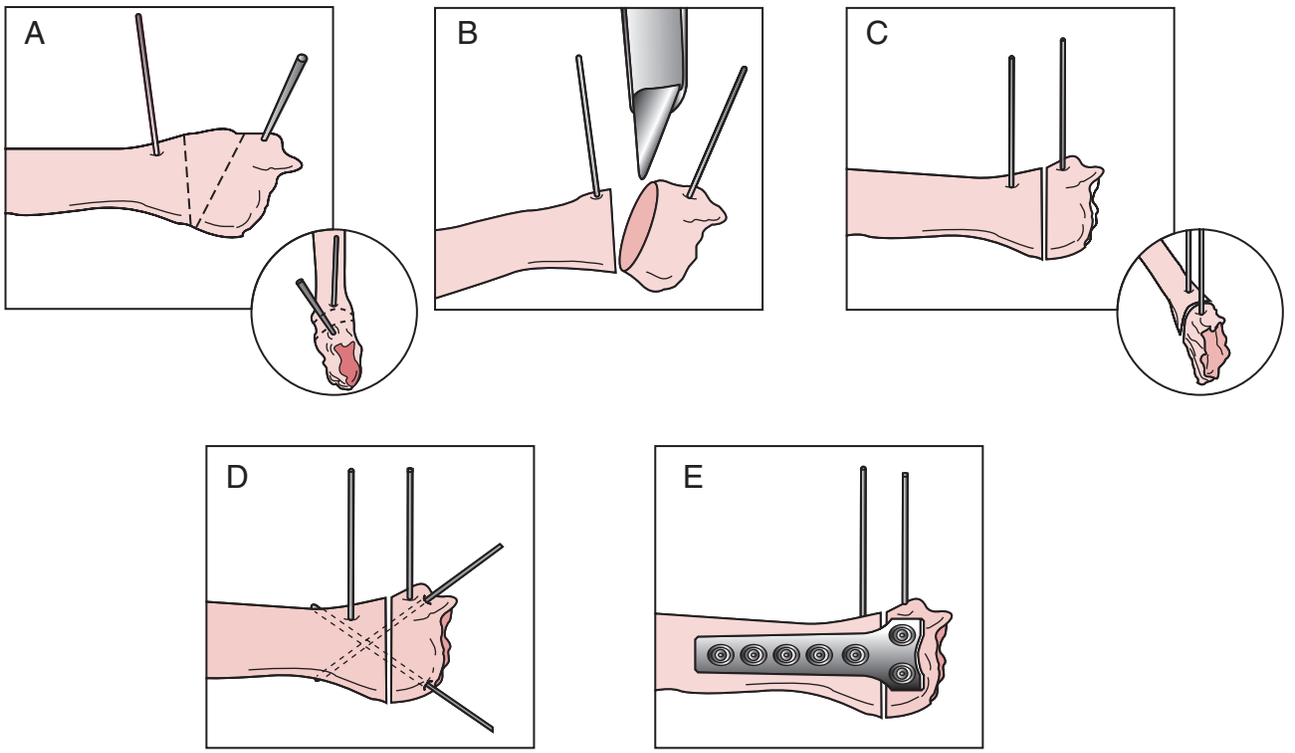

Figure 122-3. Craniocaudal and end-on illustrations demonstrating the guide wire surgical technique for a closing wedge osteotomy (example of right distal radius). (A) Place guide K-wires medial to lateral immediately adjacent to and on either side of the maximal radial deformity. Place proximal K-wire parallel to the elbow joint and its center of rotation. Place distal K-wire parallel to the antebrachiocarpal joint and its center of rotation. The *dashed lines* indicate the angle and placement of the planned osteotomy cuts. These wires address the angulation (varus/valgus) and the rotation of the distal fragment. (B) The osteotomy completed through the distal radius. Orient the cuneiform osteotomy according to the preplaced guide K-wires. Orient the proximal cut parallel to the proximal K-wire and perpendicular to the radial diaphysis. Orient the distal saw cut parallel to the distal K-wire and parallel to the distal radial joint surface. Perform the latter to address the bowing (cranial/caudal) of the distal radius. (C) Reduce the cut ends of the radius so that the K-wires are brought parallel to each other and into the same plane. At this point, correct realignment of the limb has been obtained (the carpal and elbow joints are now all parallel, and the valgus deformity, external rotation, and cranial bowing of the distal radius has been eliminated). (D) Achieve temporary reduction of the cuneiform osteotomy with two cross pins (K-wires). (E) Apply a T-plate to the cranial surface of the radius. Use either 2.7- or 3.5-mm cortical screws with the veterinary T-plate. Achieve compression across the osteotomy site using a compression guide for the eccentric placement of one or two screws in the proximal fragment. Remove the crossed K-wires. (Reproduced with permission from Balfour RJ, Boudrieau RJ, Gores BR: Vet Surg 29:207–217, 2000.)

Surgical Procedure

Objectives

- Straighten the limb by corrective osteotomy.
  - The closing wedge osteotomy is the most versatile and easy to use technique. The loss of bone length is approximately equal to the width of wedge removed.
  - Other osteotomy techniques (reverse wedge, oblique, and dome) are more difficult to perform and/or less precise in the correction of the malunion; furthermore, healing has been shown to occur with a greater number of complications.
  - A technique using distraction osteogenesis with an external skeletal fixator, most often a circular external fixation device, may be used to gradually correct the deformity after a single osteotomy cut. This technique also allows limb length to be maintained as it simultaneously allows bone lengthening.
  - This is a complex technique that requires a great deal of preplanning and expertise/experience. Consider referral to a specialist.
- Provide stable fixation.
  - Apply a plate with bone fragments placed under tension for maximal stability.
  - Alternatively, apply an external skeletal fixator (see Chapter 111).

Equipment

- Standard orthopedic pack and suture material
- Implants (preferably screws and plates, external skeletal fixator, K-wires)
- Oscillating saw
- Goniometer (for measuring and confirming angles of correction intraoperatively)

Technique (Closing Wedge Osteotomy) (Fig. 122-3)

1. Determine the angle of correction, based on the previously evaluated radiographs and physical examination; alternatively, use the guide wire technique (described here).
2. Prepare the affected limb for aseptic surgery; include within the operative field the joints above and below the proposed osteotomy site.
   a. Consider aseptic preparation and full draping of the opposite normal limb within the operative field for use as a comparison. This is especially important with chondrodystrophic-breed dogs.
3. Perform a standard surgical exposure to the bone at the level of greatest deformity.
4. Place guide wires parallel to the center of rotation of the respective joints. These wires are placed adjacent to, and on either side of, the maximal deformity.
5. Perform a closing wedge osteotomy of the affected bone to correct the deformity.
6. Reduce both bone fragments with full contact with both osteotomy surfaces. Use the guide wires to realign the bone fragments, and temporarily secure the fracture with two small cross-pins (K-wires). Make any necessary further adjustments at this time by removing the cross-pins and shaving additional bone as necessary. Draping of the surgical field to include the entire affected limb facilitates this evaluation.
7. Apply plate fixation to both bone fragments under tension. Use standard Association for the Study of Internal Fixation (ASIF) technique, including prestressing of the implant. Then remove cross-pins.
8. Close the surgical wound routinely.

Postoperative Care and Complications

- A soft padded bandage may be applied for the first 24 to 48 hours to control postoperative swelling.
- Provide standard postoperative care as for any fracture fixation, including exercise restriction and physical therapy. Evaluate the postoperative conformation and gait.
- Persistent, mild cosmetic disfiguration requires no further therapy.
- Continued functional problems require further, more precise surgical correction.
- Complications include the following:
  - Undercorrection or overcorrection of the deformity.
  - Continued functional problems due to other previously unrecognized abnormalities (e.g., degenerative joint disease, abnormal range of joint motion).
  - Slightly decreased range of joint motion is to be expected when the fixation device is placed immediately adjacent to the joint. Generally this is not a functional limitation.
  - Slight limb shortening. This generally is not a functional limitation.
  - Infection.
  - Delayed union or nonunion.

Prognosis

- The prognosis generally is good with proper case selection.

Chapter

123 Osteoarthritis

Callum W. Hay / Paul A. Manley

Osteoarthritis (OA) is the term commonly used in describing the pathologic process of cartilage degeneration in mammalian diarthrodial joints. The term *osteoarthrosis* is preferred by those who wish to stress the non-inflammatory nature of this disease. *Degenerative joint disease* (DJD) is a term used to encompass all changes seen in OA. For practical purposes, the terms can be used interchangeably. Even though aging results in articular cartilage changes of reduced tensile strength, OA is not recognized frequently as a result. The purpose of this chapter is to discuss the etiology, diagnosis, and treatment of small animal OA.

▼ ***Key Point*** Osteoarthritis is diagnosed in dogs far more frequently than cats.

ANATOMY AND PHYSIOLOGY

- Diarthrodial joints consist of articular cartilage lubricated by synovial fluid that is secreted by the synovial membrane lining. The synovial membrane secretes synovial fluid, provides a boundary to the joints, and contains pain receptors. Articular cartilage is aneural and receives nourishment by diffusion from the joint fluid.
- Eighty percent of articular cartilage is composed of water, with most of the remainder composed of type II collagen and proteoglycan matrix, which is synthesized by chondrocytes (Fig. 123-1).

▼ ***Key Point*** In normal articular cartilage, chondrocytes continually synthesize and degrade proteoglycan. Type II collagen is degraded only during disease processes, and then type I collagen is synthesized.

- Proteoglycan consists of many repeating chains of glycosaminoglycans (mainly chondroitin sulfate and keratin sulfate). Glycosaminoglycans are bound to a protein core, which in turn is bound to hyaluronate by a link protein, to form a macromolecular structure called aggrecan (see Fig. 123-1).
- Glycosaminoglycans are negatively charged, causing them to repel one another and maintain the aggrecan in an expanded state. The negative charges bind water and cations, while the expanded state imparts stiffness to the cartilage matrix.

▼ ***Key Point*** As compressive loads move the glycosaminoglycan chains together, displacing water, the negative charge resists further compression. In this way, cartilage is viscoelastic and is able to deform and re-form with normal repetitive loading.

ETIOLOGY

- OA can be caused by primary or secondary disorders. Primary causes are rarely recognized in clinical practice. Secondary causes due to altered joint biomechanics account for most cases of OA in veterinary patients.
- Secondary causes of OA include developmental disorders, such as osteochondritis dissecans or hip dysplasia, and acquired causes, such as cranial cruciate ligament injury, patellar luxation, joint instability due to ligament sprain, and malunion of intra-articular fractures.

PATHOPHYSIOLOGY

▼ ***Key Point*** In dogs and cats OA usually results from a disruption of normal joint homeostasis by an overriding biomechanical force.

- Cartilage derangements observed in OA include increased synthesis and degradation of proteoglycan, increased cartilage hydration, loss of collagen integrity, loss of tensile strength, fibrillation, and eburnation.
- Synovial membrane derangements observed in OA include synovitis, mainly from mononuclear cell infiltration, which releases inflammatory mediators into synovial fluid.

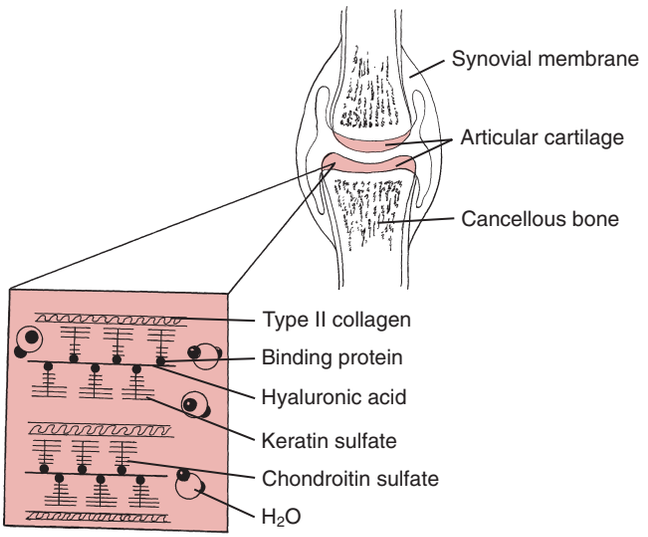

Figure 123-1. Schematic representation of cartilage structure.

▼ ***Key Point*** The release of degradative cartilage enzymes (metalloproteinases) is pivotal in the pathology of OA and results in irreversible cartilage damage. Metalloproteinases can arise from both chondrocytes and synovial membrane.

- Cytokines such as interleukin-1 (IL-1) and tumor necrosis factor-α (TNF-α) cause catabolic cartilage changes by promoting degradative cartilage enzyme production. Other mediators such as insulin-like growth factor (IGF), transforming growth factor-α (TGF-α), and interleukin-6 (IL-6) are associated with increased proteoglycan synthesis.
- The sources of inflammatory mediators include chondrocytes, synovium, and mononuclear inflammatory cells.

▼ ***Key Point*** Although there is increased proteoglycan synthesis in OA, there is increased destruction and a net loss of proteoglycan from matrix, leading to loss of structure and function.

CLINICAL SIGNS

- Morning stiffness, which improves with gentle exercise (animal "warms" out of it).
- Lameness worsens after heavy exercise.
- Lameness in one or more legs, with occasional or persistent non–weight bearing.

DIAGNOSIS

A suspicion of OA will be present after history and physical examination. Radiographs and rarely joint fluid analysis confirm the diagnosis. It is rare to confuse OA with polyarthropathy due to non-infectious or infectious causes.

History and Physical Examination

- Any age, breed, or sex of dog or cat can be affected with OA. Younger animals tend to have developmental disease. Adolescents and older dogs tend to have acquired conditions.
- A history of previous trauma that might lead to joint instability or disturbance of the articular surface is important.
- While the animal is standing, palpate for joint effusion especially in the knees, hocks, elbows, and carpi. Muscle atrophy around the thighs and over the spine of the scapula can also be better appreciated in standing animals.
- Complete the rest of the examination with the animal on its side.

▼ ***Key Point*** Gentle restraint in lateral recumbency works best with sedation, depending on the animal's temperament.

▼ ***Key Point*** Reduced range of motion and joint effusion are good indicators of a joint problem.

- Palpate for pain and crepitus (a grinding feeling when joints are flexed and extended).
- Palpate for joint laxity, which may be especially prevalent in the hip and knee.

Radiographic Examination

▼ ***Key Point*** Good-quality radiographs with correct exposure for bone and joint evaluation and proper developing technique are essential in detecting subtle evidence of OA (see Chapter 4). Radiographic abnormalities include joint effusion, osteophytes at the site of capsular attachment, subchondral bone sclerosis, and bone remodeling.

Joint Fluid Analysis

- Rarely needed in diagnosing OA.
- In most cases of OA, joint fluid yields a noninflammatory, mononuclear cell population.
- See Chapter 124 for a discussion of joint fluid analysis.

TREATMENT

OA is a progressive disease, cannot be reversed, and is generally not arrested by medical therapy. Decide if a particular patient needs to be treated surgically or medically. Many cases of OA can be managed surgically with a good prognosis for improvement in function.

Medical Treatment

There are two general groups of small animal patients that may be treated medically.

Group 1. Dogs with OA in which surgery will not help because OA is advanced or surgery is risky due to concurrent medical problems or those dogs in which surgery is declined by the owners for financial or emotional reasons. (These patients usually have advanced OA in the hips, knees, or elbows.)

Group 2. Dogs in which surgery may be part of the treatment.

▼ ***Key Point*** Often weight loss (in overweight animals) and lifestyle modifications are the only treatments necessary for an animal with OA.

- Gentle exercise is beneficial for maintaining joint mobility. Swimming and controlled leash walks work best. Generally, avoid heavy activity. Counsel owners to identify activities that exacerbate their pet's problem. Such activities are Frisbee catching, rigorous hunting, or excessive agility exercises.
- Supporting joints with external coaptation (i.e., for OA in the carpus or tarsus) may have a short-term benefit for dogs with acute exacerbations. Soft padded bandages or a support splint could be used.

Non-Steroidal Anti-Inflammatory Drugs

- Non-steroidal anti-inflammatory drugs (NSAIDs) are the mainstay of managing OA.
- Some of the pain in OA comes from prostaglandin release. By inhibiting cyclooxygenase, NSAIDs reduce prostaglandin production, alleviating pain and inflammation. Some NSAIDs (e.g., acetaminophen) have anti-inflammatory and analgesic action not attributable to cyclooxygenase inhibition; little is known about these mechanisms. It is likely that some of the NSAIDs used in small animal practice also have analgesic actions not attributable to cyclooxygenase activity.

▼ ***Key Point*** Most NSAIDs used in small animal practice inhibit proteoglycan synthesis and worsen the pathology of OA. Many NSAIDs have undesirable gastric and renal side effects. Management of OA with NSAIDs is a tradeoff between pain relief and deleterious cartilage effects and/or gastric or renal toxicity. Pain relief does not necessarily equate with chondroprotection.

- It is increasingly apparent that at least two categories of cyclooxygenase enzymes exist. Cyclooxygenase 1 (cox 1) is present in vascular tissue and is responsible for normal vascular homeostasis. Cyclooxygenase 2 (cox 2) is induced by cytokines and may have a role in OA.

▼ ***Key Point*** Inhibition of cox 1 leads to gastric ulceration and nephrotoxicity. Different classes of NSAIDs have varying abilities to inhibit cox enzymes, which dictates their efficacy and side effects. The ideal NSAID is one that inhibits cox 2 preferentially and has no deleterious effect on proteoglycan synthesis. Newer NSAIDs have been developed with these principles in mind.

- Use the lowest possible dose of NSAIDs to minimize gastric and renal side effects and minimize cartilage damage.

NSAIDs for Use in All Dogs (Groups 1 and 2)

▼ ***Key Point*** Managing OA in dogs is a balance among effective pain relief, minimal side effects, and owner satisfaction with treatment. Proper owner education about NSAIDs is essential to the harmony of this process.

▼ ***Key Point*** Choosing an NSAID for an individual patient is dictated by factors such as personal experience, relative safety of the product, patient history with NSAID use, and cost.

Buffered Aspirin

- Analgesic dose is 10 to 25 mg/kg q8–12h PO; anti-inflammatory dose is 20 to 40 mg/kg q8–12h PO in dogs.
- Buffered aspirin works better than non-buffered products. Absorption of enteric-coated aspirin can be erratic and may give variable results.
- Inhibits cox 1 more than cox 2, so gastrointestinal (GI) side effects (ulceration) may occur.
- If aspirin is not tolerated due to vomiting, the gastric side effects can be alleviated with misoprostol (a prostaglandin E_2 analog) at 2 to 5 µg/kg q8h PO. Alternatively, change to a less ulcerogenic NSAID.
- Although human buffered aspirin products are not licensed products for animals, we prescribe them commonly. Several preparations marketed for small animals are available.
- Use aspirin with extreme caution in cats. A dose of 10 mg/kg q52h PO is suggested.

Carprofen

- Carprofen may be used as a first choice over aspirin because of its proven effectiveness in pain relief, and less chance of gastric side effects.
- Dose is 2.2 mg/kg q12h PO.
- Carprofen is a carboxylic acid related to ibuprofen, but it inhibits cox 1 less relative to cox 2, so GI side effects are less than aspirin and its relative, ibuprofen.

- Carprofen is licensed for use in dogs but not in cats.
- Rare and reversible hepatic toxicity has been associated with carprofen administration in dogs.

Deracoxib

- Dose is 1 to 2 mg/kg q24h PO.
- Deracoxib has selective cox 2 activity.
- Deracoxib is licensed for use in dogs only, and rare side effects such as vomiting, anorexia, melena, and hepatic enzyme elevation are noted.

Etodolac

- Etodolac is a pyranocarboxylic acid that has selective cox 2 inhibition and possibly direct cellular anti-inflammatory activity.
- Etodolac undergoes extensive enterohepatic recirculation, so administer once daily at 10 to 15 mg/kg PO.

Meloxicam

- Dose is 0.1 mg/kg q24h PO.
- Meloxicam is supplied in an oral liquid and in an injectable form and has selective cox 2 activity.
- Meloxicam is licensed for use in dogs only, and rare side effects such as vomiting, diarrhea, and soft stool have been reported.

Phenylbutazone

- Dose is 10 to 15 mg/kg q8h PO (maximum dose is 800 mg/day regardless of body size).
- Side effects such as GI irritation and bone marrow suppression can occur. Try to taper to lowest possible dose.
- It is licensed for small animal use.
- Do not use in cats, due to adverse side effects.

NSAIDs for Use in Group 1 Dogs

These drugs carry higher risks of GI side effects, but they provide good pain relief and may be necessary for long-term use in patients in which surgery is not an option.

Piroxicam

- Is generally very effective for pain relief.
- Dose is 0.3 mg/kg q24–48h PO. It comes in capsule form, so in smaller patients breakage and division of the capsule contents is necessary to prevent overdosing.
- May not depress proteoglycan synthesis as much as other NSAIDs, based on in vitro studies.
- Gastric ulceration may occur.
- Not licensed for small animal use.

Meclofenamic Acid

- Is generally effective for pain relief.
- Dose is 1.1 mg/kg q24h PO for 4 to 7 days, then 0.5 mg/kg q24h PO.
- Watch for GI side effects.
- Is licensed for dogs.

Ibuprofen

▼ ***Key Point*** Do not use ibuprofen due to potential side effects (such as gastric or colonic perforation) and the availability of suitable licensed alternatives.

Other NSAIDs

- Flunixin and ketoprofen are licensed for small animal use in other countries but were not currently licensed in the United States at the time of publication. The recommended dose of flunixin is 0.5 to 2.2 mg/kg q24h IM or IV or 1 to 2 mg/kg q24h PO for a maximum of 3 days. Do not use in cats or for long-term therapy in dogs due to potential GI or renal side effects.

Other Drugs for Group 1 Dogs

Corticosteroids

- Unlike NSAIDs, corticosteroids severely depress synthesis of proteoglycan, even in normal articular cartilage.
- Use corticosteroids judiciously at the lowest possible dose. Corticosteroids should be used for very short-term (weeks) therapy *only*.
- Combination preparations with aspirin are available, although it is best to administer each drug separately so the dose of steroid can be reduced individually.
- Steroids tend to cause significant pain relief due to their potency; however, this does not equate with long-term benefit to the patient. It also makes it difficult to wean patients with OA off steroids because of the apparent improvement in their condition.
- Steroid therapy in surgical patients (group 2) is not advisable, since steroids may hamper any beneficial outcome of surgery.

Chondroprotective Agents

- The precise mechanism(s) of action of these drugs is still under investigation. They reportedly promote cartilage preservation through stimulation of proteoglycan synthesis and inhibition of degradation.

Polysulfated Glycosaminoglycans

- These have been shown to provide improvement in pain and function in dogs with OA, especially hip dysplasia.
- If needed in group 2 patients, surgery is the best option.
- Dose is 5 to 7 mg/kg IM once every 4 days for 7 injections. Then repeat 1 to 2 times monthly as needed.
- Initially, intra-articular use was recommended but is rarely done now because of the effectiveness of intramuscular administration and the increased

risk of joint infection associated with intra-articular injection.

Glucosamines (Nutraceuticals)

- The hypothesis for their use is that incorporation of glucosamine into glycosaminoglycan is a rate-limited step in OA, and thus by supplementation with glucosamine, more proteoglycan will be produced.
- Most compounds are oral supplements.
- Their use is currently being evaluated and may be beneficial in some cases.
- Be aware that they are licensed as nutritional supplements and not pharmacologic agents.

Shark Cartilage and Fish Cartilage Supplements

- These are marketed similarly to nutraceuticals.
- Many over-the-counter preparations are available.
- Anecdotally, they help some animals and have minimal side effects.

Vitamin C

- This is often used as a treatment for many orthopedic disorders.
- The benefit in OA is questionable, but it appears to do no harm.

Tramadol

- Tramadol is a centrally acting synthetic opioid analgesic. It is supplied in oral form (50-mg tablets) and is licensed for human use.
- The primary author of this chapter has used tramadol in patients with chronic orthopedic pain with very good results. It can be used with or without NSAIDs. The empirical dosage used is 1 mg/kg PO q12h.

Surgical Treatment

- Surgical management of certain cases of secondary OA should be considered. These include osteochondritis dissecans (shoulder, elbow, tarsus, stifle), cranial cruciate ligament disease, patellar luxation, and hip dysplasia. (See respective chapters for more information on these disorders.)
- Surgery can be expected to slow down the progression of OA and improve lameness.
- Salvage surgical procedures, such as total hip replacement and carpal arthrodesis, can provide excellent results.
- Salvage arthrodesis procedures for other joints give variable results.

Chapter

124 Immune-Mediated Arthritis

Callum W. Hay / Paul A. Manley

Immune-mediated arthropathies are inflammatory, non-infectious, and considered either non-erosive or erosive, depending on the effect on articular cartilage. The arthropathies are characterized by synovitis and articular cartilage damage. Erosive arthritis is characterized by articular cartilage loss, and nonerosive arthritis is not. Nonerosive forms are more common in small animal practice. These conditions are not curable but can be treated to improve quality of life.

ETIOLOGY

▼ ***Key Point*** The initial site for the pathology of immune-mediated arthritis is in the synovium, rather than in the articular cartilage as in osteoarthritis (OA).

- The etiology of immune-mediated arthritis is often unknown.
- Little investigation of cytokines has been done in immune arthropathies in dogs and cats. It is well established that interleukin-1 (IL-1) and tumor necrosis factor-α (TNF-α) activate metalloproteinases and cause cartilage degeneration. These cytokines diffuse from synovial membrane to articular cartilage (and vice versa). Studies in humans have shown higher levels of IL-1 and TNF-α in inflammatory arthropathies compared to osteoarthritis. Future investigation in small animals will probably show that these cytokines are involved in the pathology of both nonerosive and erosive inflammatory arthritis.

Nonerosive Forms

- The nonerosive arthropathies are characterized by antigen-antibody deposition in the synovium.
- Antigen-antibody complexes (type III hypersensitivity reaction) are potent stimuli for inflammatory mediator release, through complement fixation and subsequent infiltration of synovium by inflammatory cells. This inflammatory process releases cartilage-degrading enzymes (metalloproteinases) and leads to a self-perpetuating process of synovial inflammation and cartilage degradation. When such complexes involve antinuclear antibodies, this disease is termed systemic lupus erythematosus (SLE).

Erosive Forms

In rheumatoid arthritis, host IgG becomes antigenic, with rheumatoid factor (IgM antibody) being formed in response. The binding of IgM with IgG triggers inflammatory mediator release, similar to the pathology of the nonerosive forms. It is ill-defined, however, which factor is responsible for the development of articular cartilage erosion.

▼ ***Key Point*** A polyarthropathy is swelling of six or more joints. Swelling of more than one and less than six joints is termed pauciarthropathy.

CLINICAL SIGNS

Canine Nonerosive Arthritis

- This form usually affects larger-breed dogs with an average age of 5 to 6 years.
- The signs may be acute onset of lameness, fever, lethargy, and swelling, especially of the distal joints.
- Initially, the range of motion in the joints may be decreased due to swelling, and later the joints may become unstable due to ligamentous damage.

▼ ***Key Point*** The nonerosive arthropathies are more commonly seen in veterinary patients and have been classified into four groups.

- Type I—These have idiopathic causes and account for 50% of small animal cases.
- Type II—These are associated with remote infection from sites other than joints, for example, bacterial endocarditis or any other focus of infection that could act as a source of antigens. The joints are usually not infected; rather, immune complexes between host antibody and bacterial components cause the problem. Type II accounts for 25% of small animal cases.
- Type III—These are associated with chronic gastrointestinal disease and are also called enteropathic

arthritis. They account for 15% of small animal cases.
- Type IV—These are associated with neoplasia remote to joints and account for the remaining 10% of small animal cases.

Nonerosive Arthritis Syndromes

Several disease syndromes that do not fit in the above classification include:

Systemic Lupus Erythematosus

- Characterized by autoimmunity to body tissues and immune complex disease. Clinical problems include thrombocytopenia, hemolytic anemia, neutropenia, dermatitis, glomerulonephritis, and polyarthritis.

Juvenile-Onset Polyarthritis Syndrome in Akitas

- Affects Akitas less than 1 year of age. Clinical signs include cyclic pain, fever, lymphadenopathy, and occasionally non-septic meningitis. A heritable component is suspected.

Inflammatory Arthritis of Chinese Shar-Peis

- Affects Shar-Peis of any age. The arthropathy is characterized by episodic fever and swelling, mainly of the hocks. It is usually associated with renal amyloidosis and is also known as Shar-Pei fever.

Polyarthritis/Polymyositis

- Affects spaniel breeds. Clinical signs include muscle pain, atrophy, and contracture along with pyrexia and polyarthropathy. High levels of creatine phosphokinase may be seen, due to muscle involvement.

Polyarthritis/Meningitis

- Affects Bernese mountain dogs, beagles, boxers, German shorthaired pointers, and Weimaraners. Clinical signs include cyclic fever and neck pain lasting 3 to 7 days. Joint swelling may be seen but is not the primary feature of the disease.

Idiopathic Drug-Induced Polyarthritis

- Most commonly seen secondary to administration of antibiotics such as sulfonamide drugs and less commonly erythromycin, lincomycin, cephalosporins, and penicillins. Doberman pinschers have been identified as being particularly susceptible to the effects of sulfonamide drugs. The mechanisms of drug-induced polyarthritis could include a hapten reaction or direct immune complexes of host-produced antibody with the drug.

Canine Erosive Arthritis

Rheumatoid Arthritis

- Most commonly recognized canine erosive arthropathy, but is rarer than nonerosive arthropathies.
- This form affects smaller-breed dogs of any age.
- The signs may be more insidious than in the nonerosive forms and may be associated with fever, lethargy, swollen joints, and shifting leg lameness.
- Angular deformities may occur especially in the carpi as a result of ligamentous destruction around the joints.

Greyhound Polyarthritis

- Affects young greyhounds and has been described in Australia and the United States. The cause is unknown, but *Mycoplasma spumans* has been suspected.
- The disease may have an insidious or acute onset characterized by joint swelling, pyrexia, weight loss, pneumonia, and diarrhea. The articular cartilage pathology observed includes erosion and pannus.

Inflammatory Arthropathies of Cats

▼ ***Key Point*** Inflammatory arthropathies in cats are recognized less frequently than in dogs.

Nonerosive Forms

- The Type I to IV classification described in dogs also holds true for cats.
- With polyarthropathy in cats, bone marrow neoplasia (Type IV) should be suspected, with lymphoma or multiple myeloma being the cause.

Feline Progressive Polyarthritis

- This is described in both nonerosive and erosive forms. The nonerosive form, also known as the periosteal proliferative form, is most common.
- The nonerosive form occurs almost exclusively in male cats. Clinical signs include stiffness, pyrexia, and lymphadenopathy. Commonly, the tarsi and/or carpi are affected.
- Feline syncytia-forming virus and feline leukemia virus have been implicated as the causal agent.

Erosive Forms

- This is the less common form of feline progressive polyarthritis.
- Chronic onset of stiffness involving the carpi and/or tarsi may be seen.
- The disease often progresses to subluxation and luxation of the carpi, tarsi, and phalanges.

DIAGNOSIS

Unfortunately, no one diagnostic test is specific for a certain type of immune-mediated polyarthropathy. Extensive diagnostic testing may yield confusing results. Infectious agents such as rickettsiae, *Borrelia burgdorferi,* mycoplasma, bacteria, and fungi can cause polyarthropathy. They may be ruled in or out with a variety of serologic tests and/or cultures.

History/Physical Examination

- Signalment and history help determine if breed-specific causes may be present.
- A thorough physical examination is necessary because of the wide range of causes of polyarthritis.
- Joint swelling and reduced range of motion or laxity, especially of the carpi and tarsi, may be appreciated on physical examination.
- Peripheral lymphadenopathy and splenomegaly may be present.
- About 30% of dogs with the nonerosive form have dermatitis, or focal alopecia.
- Elevated rectal temperature can be present.

Radiography

Nonerosive Forms

- Early-stage nonerosive arthropathies may show joint swelling and minimal radiographic signs of osteophytes. Osteophytes may be present later in the disease.

Erosive Forms

- Erosive arthropathies show small or large lytic areas of subchondral bone and osteophytosis.

▼ ***Key Point*** It may be difficult to radiographically distinguish long-standing nonerosive disease (with secondary joint destruction) from erosive disease.

Laboratory Evaluation

- Obtain a complete blood count, serum chemistry profile, and urinalysis. In conjunction with history and physical examination, prioritize the rule-out list and identify concurrent diseases.
- The presence of an inflammatory leukogram and hyperglobulinemia suggests inflammation.
- Over 50% of patients with nonerosive polyarthropathies are proteinuric, so hypoalbuminemia may be seen as a result of renal damage.
- Consider a rheumatoid factor (RF) test. Dogs with rheumatoid arthritis may periodically have positive or negative RF tests and dogs without rheumatoid arthritis may have a positive RF test.
- Antinuclear antibody (ANA) is helpful in supporting a diagnosis of SLE. A lupus erythematosus (LE) preparation is an in vitro test used to identify polymorphonuclear cells that have phagocytosed nuclear material. This test may be considered when the ANA test is positive and the diagnosis of SLE is elusive.

▼ ***Key Point*** In diagnosing rheumatoid arthritis, the most reliable criteria include the following combination of clinical findings: erosive changes on radiographs, a positive RF test (present in up to 75% of cases), and inflammatory synovial fluid (see Table 124-1). A biopsy to identify histologic synovial membrane changes consistent with canine rheumatoid arthritis may be helpful in elusive cases.

Joint Fluid Analysis

- Aseptic percutaneous needle arthrocentesis under heavy sedation or, preferably, anesthesia is necessary to evaluate joint fluid.
- Clip the hair around the joint and prepare with a disinfectant scrub.
- Use a 20- or 18-gauge needle and 5-cc or 12-cc syringe and aspirate gently. The relevant landmarks for commonly aspirated joints are shown in Figures 124-1 to 124-5.
- Remove the syringe before withdrawing the needle. This prevents iatrogenic blood contamination of the sample from the subcutaneous tissue due to negative pressure in the syringe as the needle is removed.
- Submit synovial fluid (in order of priority) for cytology, total cell count, protein levels, and mucin clot. Save some synovial fluid for aerobic culture. Before submitting to a laboratory by mail, make two slides

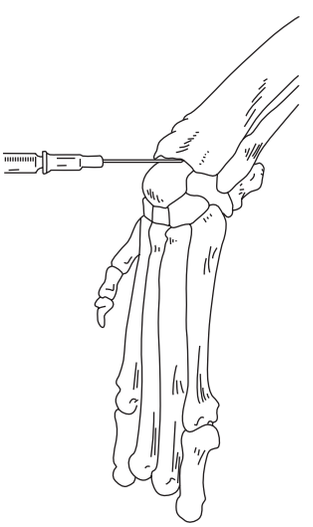

Figure 124-1. Arthrocentesis of the carpal joint. The joint lies on the same level as the base of the accessory carpal bone. With the joint flexed, the needle is introduced at the midline of the joint. (From Piermattei DL, Flo GL: Brinker, Piermattei, and Flo's Handbook of Small Animal Orthopedics and Fracture Repair, 3rd ed. Philadelphia: WB Saunders, 1997.)

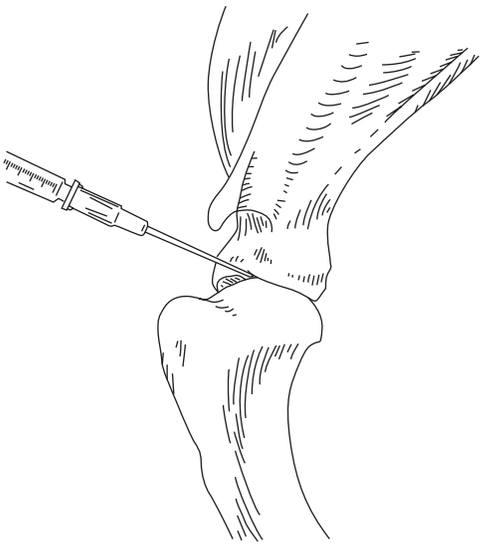

Figure 124-2. Arthrocentesis of the scapulohumeral joint. The needle is introduced about 1 cm distal to the acromion process of the scapula. If no fluid is obtained, an assistant may gently pull the forearm distally to "open" the joint space. (From Piermattei DL, Flo GL: Brinker, Piermattei, and Flo's Handbook of Small Animal Orthopedics and Fracture Repair, 3rd ed. Philadelphia: WB Saunders, 1997.)

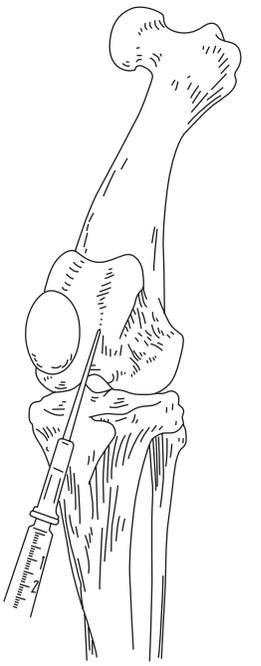

Figure 124-4. Arthrocentesis of the stifle joint. With the knee flexed, the needle is introduced just medial or lateral to the midportion of the straight patellar ligament. (From Piermattei DL, Flo GL: Brinker, Piermattei, and Flo's Handbook of Small Animal Orthopedics and Fracture Repair, 3rd ed. Philadelphia: WB Saunders, 1997.)

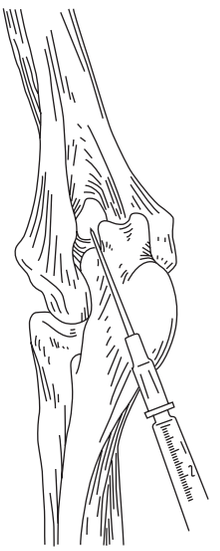

Figure 124-3. Arthrocentesis of the elbow joint. With the elbow in extension, the needle is introduced just lateral to the olecranon. (From Piermattei DL, Flo GL: Brinker, Piermattei, and Flo's Handbook of Small Animal Orthopedics and Fracture Repair, 3rd ed. Philadelphia: WB Saunders, 1997.)

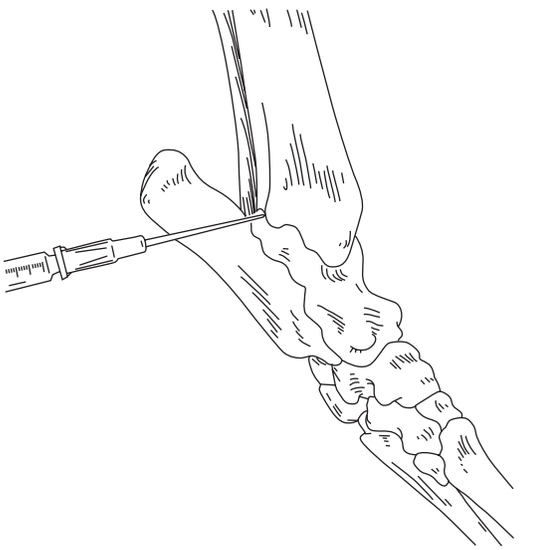

Figure 124-5. Arthrocentesis of the tarsocrural joint. With the hock held in extension, the needle is introduced lateral to the fibular tarsal bone and aimed toward the middle of the joint. (From Piermattei DL, Flo GL: Brinker, Piermattei, and Flo's Handbook of Small Animal Orthopedics and Fracture Repair, 3rd ed. Philadelphia: WB Saunders, 1997.)

Table 124-1. JOINT FLUID ANALYSIS IN DIFFERENT CLASSES OF JOINT DISEASE*

Disease	Mucin Clot	Appearance	WBC Count (mm^3)
Normal	+	Clear	0–2900
Osteoarthritis	+	Clear	<3000
Immune-mediated	±	Turbid	>5000; neutrophils are well preserved
Septic arthritis	–	Very turbid	Usually >60,000; degenerate neutrophils

*Isolation or observation of significant numbers of any microorganism from joint fluid is highly supportive of an infectious or septic etiology, regardless of cell count. Cell counts in immune-mediated and septic joints may be similar in many cases.
WBC, white blood cell; +, positive; ±, can be positive or negative; –, negative.

(one for cytology, one for a Gram stain) and place some synovial fluid in a blood culture bottle to enrich small numbers of bacteria that may be present if sepsis is suspected. Then place the rest of the synovial fluid in a blood tube with ethylenediaminetetraacetic acid (EDTA) shaken out (frequently the synovial fluid volume is small, so there is a relative excess of EDTA). EDTA interferes with the mucin clot test, making interpretation difficult.

- The predominant cell type seen on cytology in immune arthropathy is usually non-degenerate neutrophils, but mononuclear cells can sometimes be predominant.
- See Table 124-1 for comparison of joint fluid analysis in various arthropathies.

Synovial Biopsy

- May be indicated in diagnostically challenging cases of immune-mediated joint disease.
- Requires open biopsy using strict aseptic technique.
- Harvest synovium at the cartilage-bone margin.
- Histology shows plasma cell and lymphocyte infiltration.

TREATMENT

A dilemma in the treatment of polyarthropathy is whether the process is infectious or non-infectious. The treatment for a non-infectious problem (i.e., immunosuppression) exacerbates an infectious cause of polyarthropathy. If intracellular bacteria are seen on synovial fluid analysis or if bacterial culture is positive, the process is likely septic. However, in endemic areas for Lyme disease and ehrlichiosis it can be difficult to distinguish these from immune-mediated joint disease. Some prefer to initially treat with tetracyclines (e.g., for 1 week) and change to corticosteroids if no response is seen, or after results of diagnostic testing are available. The cyclic nature of many of the immune-mediated diseases, however, makes interpreting a response to treatment difficult.

Nonerosive Forms

▼ ***Key Point*** The initial treatment for all nonerosive immune-mediated arthropathies is similar. Use either nonsteroidal anti-inflammatory drugs (NSAIDs) or corticosteroids.

- The lowest dose of drugs to control signs should be used.
- Recurrences are possible after cessation of therapy.

Initial Therapy (2 to 4 Weeks of Therapy)

- Buffered aspirin at the higher (anti-inflammatory) dose range (25–40 mg/kg q8h PO) could be tried. Carprofen (2 mg/kg q12h PO) could be administered as an alternative because of its lower risk of gastrointestinal side effects.
- If sepsis has been ruled out, prednisone at 1 to 3 mg/kg q12h PO may be given.
- It is best to use either NSAIDs or steroids, but not both. The higher doses of these drugs together may potentiate each other's side effects. It is feasible to use prednisone on alternate days with NSAIDs, at low doses.
- Besides clinical signs, repeat aspiration of joint fluid may allow monitoring of the effectiveness of therapy. A cell count of less than $4000/mm^3$ is ideal. In cases in which the cell count does not decrease and the clinical signs are present, other immunosuppressive drugs may be needed (Table 124-2).

Long-Term Therapy (Months to Years)

- Preferably, the patient should be weaned off therapy after 2 to 4 months of treatment.
- If signs reappear after several attempts to discontinue therapy, the patient will likely require long-term corticosteroid therapy at the lowest possible dose. Base the decision to proceed with long-term therapy on the severity of the problem. Cases nonresponsive to glucocorticoids may require more aggressive immunosuppression as outlined in the next section.

Table 124-2. DRUG REGIMENS USED FOR CONTROL OF IMMUNE-MEDIATED ARTHRITIS

Drug	Dose	Action	Comments
Acetylsalicylic acid (aspirin)	25–40 mg/kg q8h PO	Analgesic; anti-inflammatory	Generally more effective for degenerative joint disease
Glucocorticoids (prednisone, prednisolone)	1–3 mg/kg q12h PO until remission achieved; then decrease to lowest effective maintenance dose	Anti-inflammatory; immunosuppressive	First choice for nonerosive forms; can be used alone or in combination with other drugs
Cyclophosphamide* (Cytoxan, Mead Johnson)	1.5–2.5 mg/kg PO q24h 4 days/week	Immunosuppressive	Monitor WBC count; watch for hemorrhagic cystitis
Azathioprine† (Imuran, Burroughs Wellcome)	*Dogs:* 2 mg/kg q48h PO	Immunosuppressive	Monitor WBC count; relatively toxic in cats
Gold sodium thiomalate (Solganal, Schering)	0.5–1 mg/kg IM once weekly	Unknown	Used in erosive forms; limited clinical experience

*Glucocorticoids are commonly administered concurrently with this drug.
†Glucocorticoids are commonly administered on alternating days with this drug.
WBC, white blood cell.

Erosive Forms

▼ ***Key Point*** Canine rheumatoid arthritis usually requires immunosuppression in addition to prednisone for a response.

- Cyclophosphamide is often used along with prednisone in treating rheumatoid arthritis.
- The side effect of hemorrhagic cystitis associated with cyclophosphamide can be devastating to the patient. Discontinuing cyclophosphamide after 4 months of therapy minimizes the chances of hemorrhagic cystitis.
- Note that cyclophosphamide is used for 4 days during each week of therapy.
- Gold sodium thiomalate can be used to maintain remission after cessation of cyclophosphamide. Gold salt is a slow-acting antirheumatic drug and is unsuitable for inducing remission.
- Azathioprine can be used instead of cyclophosphamide to induce remission in dogs only, since it is toxic to cats.
- Additional treatment information is in Table 124-2.

Surgery

- Surgery has a limited role in managing immune-mediated arthropathies.
- Pancarpal arthrodesis could be considered in some patients with localized disease to the carpi (see Chapter 106).
- Surgery for cranial cruciate ligament rupture in immune-mediated polyarthropathies should be considered with a very guarded prognosis due to ongoing joint destruction.

Supportive Care

- As in osteoarthritis, lifestyle modification, weight reduction, and exercise restriction aid in managing immune-mediated arthropathies.

PROGNOSIS

Nonerosive Forms

The prognosis for Type I to III forms is favorable; it is guarded for Type IV due to the presence of neoplasia. The breed-specific diseases differ in prognosis. The arthritis of Akitas and Shar-Peis has a poor prognosis. SLE patients may frequently relapse. The polyarthritis-myositis syndrome of spaniels has a guarded to good prognosis, and the polyarthritis-meningitis syndrome in other dogs has a good prognosis. Drug-induced polyarthropathies usually respond to cessation of drug therapy. The nonerosive form of feline progressive polyarthritis has a guarded prognosis.

Erosive Forms

Canine rheumatoid arthritis can be difficult to treat successfully and may be expensive, especially if gold salt therapy is needed. Greyhound polyarthritis and the erosive forms of feline progressive polyarthritis have poor prognoses.

Section

9 Nervous System

Philip A. March

Chapter

125 Diagnostic Approach to Neurologic Disease

William R. Fenner / Philip A. March

PRINCIPLES OF NEUROLOGIC EXAMINATION

Objectives

- Confirm that neurologic disease is present.
- Localize the site of any lesion(s).
- Determine the extent to which the nervous system is involved.
- Guide the choice of diagnostic aids.
- Determine the prognosis.

Approach

- Perform the examination in a logical, methodical, and consistent manner.
- Develop a consistent sequence and follow it with all patients.
- Begin with the general and advance to the specific.
- Perform painful portions of the examination last.

PROCEDURES FOR THE NEUROLOGIC EXAMINATION

General Observations

Mental Status

Mental status is regulated by the brain stem and cerebrum and consists of level and content of consciousness.

- Begin by evaluating the level of consciousness. A normal animal is alert; an abnormal animal is depressed, stuporous, or comatose, depending on the severity of the mental depression. Abnormal levels of consciousness may result from lesions of the brain stem or diffuse cerebral disease.
- In addition to the level of consciousness, evaluate the patient for mentational disorders. Behavior of a normal animal is described as appropriate; an animal with abnormal behavior is considered demented.
  - A demented animal is unaware and unconcerned with its surroundings. It may head-press, walk off tables, and in other ways show a complete disregard for its own safety and well-being.
  - Dementia is a sign of a cerebral disorder.

Head Posture

Head posture is regulated by the vestibular system and the strength of neck muscles.

- A normal animal holds its head in a plane parallel to the ground.
- If an animal holds one ear closer to the ground than the other ear, it is described as having a head tilt, which suggests a vestibular injury.
- In some animals, the chin is tucked under or pulled tightly toward the sternum; this postural abnormality (ventroflexion) may be seen in cats with polymyopathies (e.g., hypokalemia) or thiamine

deficiency and in dogs with cervical vertebral malformations.

Coordination of Head Movement

This is regulated primarily by the cerebellum. Disturbances of head coordination appear as head tremors.

Circling

Circling is a nonspecific finding in animals with brain disease.

- A lesion in any part of the brain may cause circling; the animal usually circles toward the diseased side.
- Circling in brain stem and cerebellar injury usually is a result of a vestibular dysfunction; therefore, circling is accompanied by a head tilt.
- Animals with cerebral injury circle, but they rarely have head tilts.

Gait and Stance

Gait

A normal gait requires integration of almost the entire nervous system; therefore, abnormal gaits may result from injury to almost any part of the nervous system.

- Sensory disturbances, such as loss of proprioception, usually result in ataxia or loss of coordination of limb movements. Signs of loss of coordination of the limbs include swaying, veering, crossing over of the limbs, and scuffing of the toes.

▼ ***Key Point*** Ataxia may be seen with disease or injury of the cerebellum, brain stem, spinal cord, and injuries to cranial nerve 8 (vestibular nerve). Cerebral and peripheral nerve lesions rarely cause ataxia.

- Cerebellar lesions cause ataxia in most patients.
- Cerebral lesions may produce mild weakness characterized by intermittent stumbling, tripping, and reluctance to initiate or sustain activity. More obvious signs of weakness may be caused by an injury to the brain stem, spinal cord, or peripheral spinal nerves. When classifying the weakness, also consider the resting muscle tone in the limbs.
  - Spasticity is an increase in muscle tone resulting in decreased flexion of the limbs during movement. The resultant gait is rigid and choppy.
  - Spasticity may be seen with injuries to the cerebrum, the brain stem, and some levels of the spinal cord.

Stance

Normal animals stand with their limbs at about shoulder or hip width, with the weight equally distributed on all four limbs.

- Abnormal posture may be caused by diminished position sense (proprioception), weakness, or pain.
- Many animals present with abnormal posture as a result of pain from orthopedic disorders rather than neurologic disturbances.

Tests of Postural Reactions

Attitudinal and postural (A-P) reactions test the integrity of the interconnecting pathways that regulate posture and movement as an extension of the evaluation of gait and stance. These tests evaluate the proprioceptive fibers of peripheral nerve, spinal cord, brain stem, cerebrum, and cerebellum. Some tests also evaluate special proprioception. The upper motor neurons and their connections to lower motor neurons are also evaluated.

Because so many portions of the nervous system are evaluated, A-P reactions are good screening tools for detecting nervous system disorders but are not very helpful with specific localization.

- With lesions of the cerebrum, the postural deficit normally is seen in the limbs on the opposite side of the body (contralateral) from the diseased hemisphere.
- With brain stem lesions, the clinical signs usually are bilateral but are worse on the same side (ipsilateral) as the brain stem injury.
- With lesions of the cerebellum, spinal cord, and peripheral nerves, the clinical signs are almost always on the same side of the body as the nervous system injury.
- With cerebellar injuries, A-P reactions usually are present but are ataxic.
- With peripheral vestibular injuries, A-P reactions are preserved, but the animal tends to lean, fall, and roll to the diseased side when the maneuvers are performed. Hemihopping may be slightly delayed on the same side as the vestibular lesion.

Proprioceptive Positioning

Abnormally abduct or adduct a limb, or turn the paw so that the animal bears weight on the dorsal surface of its paw (stands knuckled over). If A-P reactions are intact, the animal briskly brings the limb back to a normal resting position.

Hemihopping

Hold the limbs on one side off the ground while the patient is hopped sideways on its other two limbs. A normal animal has no trouble initiating a brisk hopping response without buckling or collapsing on the limb if conscious proprioception and strength are normal in that limb. Hemistanding the animal on one or two limbs can also be used to assess limb strength.

Wheelbarrowing

Hold the thoracic or pelvic limbs off the ground while the patient is walked forward and then backward on its other two limbs. A normal animal has no trouble maintaining itself and walking normally during this test.

Other Attitudinal and Postural Reactions

Additional A-P reactions include the extensor postural thrust reaction, the righting reaction, visual placing reactions, tactile placing reactions, and tonic neck reactions. All these tests evaluate the same basic pathways, although each may test one portion of the nervous system more completely than another. These tests are well described in standard neurology texts.

Cranial Nerve Examination

The cranial nerve (CN) examination tests the function of each CN. Often a CN deficit confirms the presence of a lesion above the foramen magnum. The CN examination allows precise localization of intracranial diseases in many cases. Because many CNs supply only the motor or the sensory component of a CN reflex, the testing of a CN reflex generally involves testing more than one nerve. This is unlike spinal reflexes in which generally the sensory and the motor components of a reflex are carried by the same nerve.

Many of the CN reflexes also are under higher control. Therefore, a CN reflex evaluates the following:

- Two peripheral CNs (one motor and one sensory)
- A central connection (usually the brain stem)
- A higher regulatory center (usually the cerebrum)

A lesion in any one of these sites may cause loss or depression of the reflex being tested. For a more complete review of the neuroanatomy of CNs, consult a neuroanatomy textbook.

Menace Response (see also Chapter 141)

The menace response tests CN2 (sensory) and CN7 (motor) and their central connections in the cerebrum, brain stem, and cerebellum. The test is performed by making a menacing gesture toward an animal. The normal response is an avoidance response (e.g., an eye blink or turning of the head).

- Loss of the menace response normally indicates a lesion in one of the following sites: retina (ipsilateral), optic nerve (ipsilateral), optic tract (contralateral), cerebrum (contralateral), brain stem (ipsilateral), cerebellum (ipsilateral), or facial nerve (CN7) (ipsilateral).
- False-positive menace responses also occur, most commonly when the movement of the hand produces air currents that stimulate the corneal reflex.
- Sounds and other distractions may make the menace response difficult to evaluate. Animals (especially cats) in a stressful environment may have an absent menace (false-negative finding).

Pupillary Light Reflex (see also Chapter 141)

This tests the reflex portion of the optic nerve (CN2) and the autonomic function of the oculomotor nerves (CN3). The test is performed by illuminating the eye with a bright light source. The normal response is rapid constriction of both pupils.

The pupillary constriction in the eye being illuminated is called the *direct pupillary response*. The constriction in the opposite pupil (the one being illuminated indirectly) is called the *consensual response*. Failure of one or both pupils to constrict is an abnormal pupillary light reflex (PLR).

- A lesion of CN2 produces loss of constriction in both pupils when the affected eye is illuminated; however, when the normal eye is illuminated, both pupils constrict.
- If the lesion is in CN3 or the brain stem, the affected pupil fails to constrict regardless of which eye is being illuminated, but the unaffected eye constricts normally when each eye is illuminated.
- Because ophthalmic diseases such as posterior synechia or severe iris atrophy may also produce loss of pupillary responsiveness, a thorough eye examination is essential in any patient with abnormal pupils.
- Other causes of a misleading PLR are increased sympathetic tone and a weak light source, both of which will slow the PLR.

Pupillary Symmetry

In this test the eyes are observed for equal pupil size.

- If CN3 and the sympathetic nerve to the eye are normal, the two pupils will be equal in size.
- If the pupils are unequal (anisocoria), this indicates possible damage to one of these two nerves.
  - If CN3 is abnormal, the large pupil is denervated and the PLR will be absent in that eye.
  - If the sympathetic nerve is abnormal, the small pupil is abnormal and the PLR will be normal in both eyes.
- Cats may have mild physiologic anisocoria if one eye is receiving more light than the other. For this reason, ensure that both eyes receive equal illumination when evaluating for anisocoria.
- A number of ophthalmic disorders may produce anisocoria, including glaucoma, iritis, uveitis, and synechia. Because of this, perform a complete ophthalmic examination on all patients with anisocoria.

Pupillary Size

The size of the pupil is determined by the amount of ambient light (CN2) and the integrity of the innervation of the pupillary muscles (CN3 and sympathetic nerve).

- Abnormally large pupils may be caused by excitement (sympathetic stimulation), bilateral optic nerve injury, CN3 paralysis, or ophthalmic disease.
- Abnormally small pupils may be associated with loss of sympathetic tone, excess parasympathetic tone, or ophthalmic disease.

Ocular Position

In normal dogs and cats, both eyes look in the same direction at any given time (normally straight ahead). This normal resting position is determined by the influence of the cerebrum and CN8 on the extraocular muscles (CN3, CN4, and CN6). If one of these portions of the nervous system is not functioning, deviation of one or both of the eyeballs may occur.

Strabismus is deviation of only one globe.

- Medial strabismus may result from an injury to CN6 (abducens nerve).
- Ventrolateral strabismus may result from injury to CN3 or CN8 (vestibulocochlear nerve).
- A lesion to CN4 (trochlear nerve) results in intorsion (a form of rotation) of the eye, which can be recognized only in animals with oval pupils or on ophthalmic examination.
- Passive deviation of both eyes in the same direction (gaze paresis) is sometimes seen in cerebral injuries.

Ocular Motility

Voluntary Eye Movement

Voluntary eye movement is initiated by cerebral stimulation of CN3, CN4, and CN6. As the animal looks around the examination room, observe to see if it appears unable to move the eyes in one or more directions.

- With a cerebral lesion, both eyes are involved, and there is a tendency for the eyes to look toward the diseased cerebral hemisphere.
- With a lesion of the CNs, only one eye is usually involved. The involved eye will tend to have strabismus at rest and lack the ability to move.

Involuntary Eye Movements: Nystagmus

Involuntary rhythmic oscillations of the eyes, termed *nystagmus,* can be induced by turning the head. This maneuver stimulates CN8, which in turn stimulates CN3, CN4, and CN6, which innervate the extraocular muscles. This involuntary eye movement is called *physiologic nystagmus.*

Physiologic Nystagmus

Physiologic nystagmus is characterized by a "slow phase," in which the eyes move slowly away from the direction in which the head is turning, followed by a "fast phase," in which the eyes rapidly move in the direction of the head turn. This recurring slow-fast, slow-fast oscillation continues as long as the head is moving.

- A lesion of CN8 or its central connections may result in loss of the ability to initiate physiologic nystagmus so that neither eye will move when the head is turned toward the side of the vestibular lesion.
- A lesion of one or more of the CNs that innervate the extraocular muscles (CN3, CN4, or CN6) paralyzes only that eye, resulting in loss of physiologic nystagmus in the paralyzed eye.

Pathologic Nystagmus

When a normal animal's head is not moving, it does not display any involuntary eye movements. If nystagmus is present when the head is at rest, this is a sign of nervous system disease and is called *pathologic nystagmus.* This usually is the result of an imbalance in the special proprioceptive system, which includes CN8, the brain stem, and the cerebellum. A lesion of any of these structures can cause pathologic nystagmus. Features of pathologic nystagmus that may help localize its origin include the *direction, method of induction,* and *persistence* of the nystagmus.

- Direction of nystagmus:
  - In *horizontal nystagmus,* the eyes move in a plane parallel to the head (i.e., the eyes move from side to side).

▼ ***Key Point*** Horizontal nystagmus is most commonly seen in peripheral vestibular disease but can occur in central vestibular disease (see Chapter 61). The fast component of the nystagmus usually is away from the diseased side.

  - In *vertical nystagmus,* the eyes move in a plane perpendicular to the head (e.g., the eyes move up and down).

▼ ***Key Point*** Vertical nystagmus is most commonly seen in central vestibular disease. The fast component of the nystagmus is usually away from the diseased side; therefore, brain stem disease causes up-going nystagmus, and cerebellar disease causes down-going nystagmus.

  - In *rotatory nystagmus,* the eyes rotate in a clockwise or counterclockwise direction in the orbit, with components of both horizontal and vertical movement. This type of nystagmus may occur with a peripheral or central vestibular lesion.
- Method of induction of nystagmus:
  - *Resting nystagmus* occurs when the head is at rest and in a normal position. This type of nystagmus is most characteristic of peripheral vestibular disease but can be seen with central vestibular disease.

  - *Positional or induced nystagmus* occurs when the head is still but is in an abnormal position (e.g., on its side or upside down). Positional nystagmus is most characteristic of central vestibular dysfunction (e.g., brain stem and cerebellar lesions). It is also seen during the recovery phase of peripheral vestibular diseases.
- Persistence of nystagmus:
  - *Permanent nystagmus* persists over time. It may have any direction and method of induction, but it is consistently present. Permanent nystagmus is characteristic of most brain stem diseases and of progressive peripheral vestibular and cerebellar diseases.
  - *Resolving nystagmus* disappears over a period of time (days to weeks). It does not recur unless there is new damage to the vestibular system. Resolving nystagmus is characteristic of nonprogressive peripheral vestibular and cerebellar diseases. In the recovery period of these diseases, nystagmus may become positional.

Facial Symmetry

Facial weakness (CN7) may result from injury to the contralateral cerebrum, ipsilateral brain stem, and ipsilateral peripheral nerve.

- Clinical signs include drooping of the lip, deviation of the nasal philtrum, increases in palpebral fissure size (pseudoptosis), and in some animals, drooping of the eyelid (true ptosis).
- Confirm the diminished muscle function by testing the palpebral and/or corneal reflexes.

Palpebral Reflex

This reflex tests CN5 and its brain stem connection to CN7.

- Initiate the reflex by touching the palpebral margins, which produces an eye blink. Loss of the eye blink reflex is usually complete if there is an injury to CN5 or CN7.
- In some animals with contralateral cerebral disease or myasthenia gravis, lagophthalmos or incomplete closure of the palpebral margins is observed.

Corneal Reflex

Like the palpebral reflex, this reflex tests CN5 and its brain stem connection to CN7.

- Initiate the reflex by lightly touching the cornea, which produces an eye blink.

Retractor Oculi Reflex

This reflex tests CN5 and its brain stem connection to CN6 (abducens nerve).

- Initiate the reflex by lightly touching the cornea, which produces retraction of the eye into the orbit.
- Lack of the reflex usually is a sign of neurologic dysfunction of CN5 or CN6.
- In some animals with loss of the retrobulbar fat pad, the eye may be enophthalmic and incapable of retraction, whereas in others, a retrobulbar mass may prevent retraction.

Facial Sensory Examination

This tests CN5 and its cerebral connections.

- Lightly stimulate the nasal mucosa, which should produce an avoidance response such as head turning or withdrawal.
- The nasal mucosa is a more reliable site for stimulation than the lips, which are relatively insensitive in some animals.

Gag Reflex

The gag reflex, which is easier to test in dogs than in cats, tests CN9 (glossopharyngeal nerve) and CN10 (vagus nerve) and their brain stem connections.

- To initiate the test, lightly stimulate the oropharynx, which should produce a swallowing reflex. Loss or depression of the reflex usually indicates brain stem or peripheral nerve dysfunction.
- Examine the pharynx for evidence of paralysis of the soft palate, and look at the larynx for evidence of laryngeal paralysis (may be difficult in an awake animal). Either condition may result from brain stem injuries or peripheral nerve injuries to CN9 or CN10.

Tongue Examination

- Look for atrophy of the tongue, which can be produced by brain stem or peripheral nerve injury to CN12.
- Also look for deviation of the tongue, which can be caused by cerebral injuries, as well as brain stem and peripheral nerve injuries. The tongue will deviate toward the side of the lesion.

Spinal Reflex Examination

The spinal segmental reflexes directly test the reflex arcs of the spinal cord. They also indirectly test the higher centers in the brain that regulate the spinal reflexes.

▼ ***Key Point*** If an injury occurs within the reflex arc, it will cause loss or depression of the reflex. Such a reflex loss allows precise localization of a nervous system injury. Because a lesion in the lower motor neuron (LMN) is involved, loss of reflexes is called an *LMN sign* or an *LMN reflex change.*

▼ ***Key Point*** If a lesion occurs cranial to a reflex arc, it disconnects the reflex from its higher (brain) regulation. This regulation tends to be inhibitory over specific proprioceptive reflexes such as the patellar and triceps reflexes. Loss of regulation results in exaggeration of these reflexes, especially the patellar reflex. Because this exaggeration reflects a lesion in the central nervous system (CNS) involving upper motor neuron (UMN) pathways, these reflex changes are called *UMN signs* or *UMN reflexes.*

UMN changes are not as precisely localizing as LMN reflexes. Spinal reflexes are classified into three groups:

- Proprioceptive reflexes
- Nociceptive reflexes
- Special (released) reflexes

This division is based on the type of sensory stimulation required to elicit the first two reflexes and on the special conditions required to elicit the third reflex.

Proprioceptive Reflexes

These myotatic reflexes are initiated by stretch of tendons or muscle spindles. The patellar reflex is strongly influenced by UMN pathways and, therefore, may be exaggerated with UMN lesions. Other proprioceptive reflexes either are not influenced or are weakly influenced by the UMN system. Increases and decreases in the force of reflex activity are both components of proprioceptive reflexes; thus, be sure to grade the strength of these reflexes. A standard grading scale is as follows:

0 = Absent reflex
1 = Diminished reflex
2 = Normal reflex
3 = Increased reflex
4 = Increased reflex with clonus

Thoracic Limb Proprioceptive Reflexes

Triceps Reflex

This tests the radial nerve that arises from spinal cord segments C7 to T2.

- Elicit by striking the tendon of insertion of the triceps muscle. A normal response is a slight extension of the elbow.
- This reflex is difficult to obtain in a normal animal. A reflex may be present if a UMN lesion is present.

Extensor Carpi Radialis Reflex

Like the triceps reflex, this tests the radial nerve and spinal cord segments C7 to T2.

- Elicit by striking the muscle belly of the extensor carpi radialis muscle. The normal response is extension of the carpus.
- This reflex is easier to elicit than the triceps reflex, but its significance is often uncertain since it can often be elicited even with lesions of the LMN pathways.

Biceps Reflex

This reflex evaluates the musculocutaneous nerve, which arises from spinal cord segments C6 to C7.

- Initiate by striking the tendon of insertion of the biceps tendon, causing a slight flexion of the elbow.
- This reflex is more difficult to obtain than the triceps reflex and is difficult to interpret.

Pelvic Limb Proprioceptive Reflexes

Patellar Reflex

This reflex tests the femoral nerve and its spinal cord segments (L4–L6).

- Elicit by striking the patellar tendon. This action produces extension of the stifle.
- This reflex is very obtainable and reliable in all animals.
- An exaggerated reflex may be present if a UMN lesion is present.
- When testing this reflex, a phenomenon known as a *false localizing sign* sometimes occurs if a sciatic nerve or L6 to S2 injury is present. Paralysis of the sciatic nerve results in a hyperactive patellar reflex. This may be due to functional loss of the antagonist muscles that oppose the extensor muscles of the stifle.

Cranial Tibialis Reflex

This reflex tests the peroneal branch of the sciatic nerve, which originates from spinal cord segments L6 to S2.

- Initiate by striking the belly of the cranial tibial muscle. The normal response is flexion of the tarsus. This reflex is readily obtainable in most animals.

Gastrocnemius Reflex

This reflex tests the tibial branch of the sciatic nerve, which originates from spinal cord segments L6 to S2.

- Elicit by striking the belly of the gastrocnemius muscle or its tendon of insertion. The expected normal response is extension of the tarsus.
- This reflex is very difficult to obtain in dogs and cats and is considered unreliable.

Nociceptive Spinal Reflexes

The nociceptive reflexes are initiated by nociceptive (painful) stimuli, such as pinching, compression, and pin pricks. These nociceptive stimuli induce withdrawal of the limb or some other reflex action. These reflexes only test the integrity of the spinal reflex arc.

▼ ***Key Point*** The fact that a reflex withdrawal reflex is present tells nothing about the health of the nociceptive pathways traveling cranially to the brain. Loss of a nociceptive reflex indicates an LMN lesion.

These reflexes do not have a large UMN influence; therefore, they do not become exaggerated with UMN lesions.

Thoracic Limb Flexor Reflex

This reflex utilizes all the peripheral nerves of the thoracic limb and tests spinal cord segments C6 to T2.

- Elicit by digital compression. The normal response is withdrawal of the limb from the source of the stimulus.
- Loss of the reflex indicates a lesion in the reflex arc.

Pelvic Limb Flexor Reflex

This reflex tests the sciatic nerve and the L6 to S2 spinal cord segments and nerve roots.

- Initiate by digital compression. The normal response is withdrawal of the limb from the source of the stimulus.
- Loss of this reflex indicates a lesion in the reflex arc.

Perineal Reflex

The perineal reflex tests the pudendal nerve, spinal cord segments S1 to S3, and the cauda equina.

- Initiate by lightly pricking or stroking the perianal skin or perineum area. The expected response is constriction of the anal sphincter and flexion of the tail.
- If mild weakness is suspected, it is best to test the reflex during a digital rectal examination to estimate the strength of contracture of the sphincter.

Special (Released) Reflexes

These are reflexes that are suppressed by the UMN in normal animals. When disconnection between the reflex arc and the UMN occurs, these reflexes become released or uninhibited. Thus, the presence of these reflexes indicates loss of UMN inhibition to a reflex arc.

Babinski Reflex

This occurs only in the pelvic limbs.

- Elicit by lightly stroking the plantar aspect of the metatarsus. In a normal animal, the toes either are unaffected or flex slightly.
- In the presence of UMN disease, the toes may spread apart and elevate (dorsiflex), which is known as a positive Babinski reflex.
- This reflex is often absent even with UMN lesions.

Crossed Extensor Reflex

This abnormal reflex may be seen in any limb.

- Initiate by eliciting a flexor reflex in an animal in lateral recumbency. In a normal animal, the limb being stimulated flexes and the contralateral, paired limb is unaffected.
- In UMN disease, when the stimulated limb flexes, the contralateral limb will involuntarily extend.

▼ ***Key Point*** When present, the crossed extensor reflex is a sign of UMN dysfunction.

Nociceptive Evaluation

Nociceptive evaluation (testing pain responses) tests for cerebral recognition of pain perception after digital compression. Cerebral recognition must be in the form of a purposeful directed response to the stimulus (turning, vocalizing, biting, struggling).

Decreased Pain Perception

A mild loss in pain perception is called *hypalgesia* or *hypoesthesia*. If the loss is total, it is referred to as *analgesia* or *anesthesia*.

- Loss of pain perception is tested by producing enough pain so that cerebral recognition occurs and a reaction is produced.
- To elicit a reaction, compress the digits vigorously. The expected response is turning of the head and/or vocalization.

This evaluation tests peripheral nerves, spinal cord, brain stem, and cerebrum. The cerebellum is not involved in the nociceptive pathways.

▼ ***Key Point*** Peripheral nerve lesions usually cause focal sensory loss, confined to the distribution of the involved nerve(s). Severe spinal cord lesions cause a bilateral, symmetrical sensory loss proceeding caudally from the approximate level of the injury.

- Brain stem lesions rarely produce detectable analgesia, because a lesion of that severity would result in the death of the animal.
- Cerebral lesions produce only hypalgesia.
- The sensory deficit with a cerebral lesion is usually contralateral to the diseased hemisphere.

Increased Sensitivity or Exaggerated Response to Pain

Hyperesthesia refers to increased sensitivity; *hyperpathia* is an exaggerated response to pain. In veterinary medicine these two terms are used interchangeably.

Exaggerated responsiveness to pain is tested by digital manipulation of the dorsal spinous processes

and paraspinal muscles. Alternatively, the paraspinal region can be stimulated with a hemostat or safety pin.

- The objective is to produce a recognizable stimulus that is not normally bothersome to the patient.
- The stimulus is applied up and down the spine, looking for an area where the patient shows an unusually acute response to the stimulus.
- An exaggerated response usually is an indication of an extradural, nerve root, or meningeal lesion (e.g., herniated disc or meningitis).

▼ ***Key Point*** Paraspinal stimulation is valuable for localizing spinal cord lesions because a hyperpathic response indicates that the problem is extramedullary and establishes the location of the lesion.

INTERPRETATION OF THE NEUROLOGIC EXAMINATION

The neurologic examination will usually demonstrate neurologic abnormalities if the patient has neurologic disease. Listing the neurologic abnormalities and then answering the following questions will aid lesion localization (Fig. 125-1).

- Is the disease in the CNS or peripheral nervous system (PNS)?
  - If conscious and unconscious proprioceptive deficits (knuckling, ataxia) are present, the lesion is probably in the CNS.
  - If UMN signs are present (paresis with UMN reflex changes), the lesion is probably in the CNS.
  - If there are lateralizing signs of paresis or proprioceptive loss, the lesion is probably in the CNS.
  - If diffuse weakness and diminished reflexes in all four limbs are present (usually without postural deficits), the lesion is probably in the PNS. (See Chapters 129 and 130 for localization of PNS lesions.)
  - If the animal has CN deficits and limb signs (postural deficits, weakness, ataxia), the lesion is usually in the CNS.
  - If the animal has CN deficits and no other signs, the lesion is probably in the PNS portion of those CNs.
  - If the animal has a history of seizures, a depressed level of consciousness, and/or a head intention tremor, the lesion is probably in the CNS.
- Is the disease above or below the foramen magnum?
  - If the animal has a CN abnormality, a history of seizures, an abnormal head posture, abnormal head coordination, or an abnormal level of consciousness, the lesion is likely to be above the foramen magnum. (See Chapter 126 for localization of brain lesions.)
  - If the lesion involves the limbs alone, the lesion is most likely below the foramen. (See Chapter 128 for localization of spinal cord lesions.)
- After you have localized the lesion (above or below the foramen; CNS or PNS), try to localize the lesion more precisely.
  - Use CN deficits, cerebellar signs, cerebral signs, spinal reflex changes, and areas of spinal hyperpathia to determine a more specific localization (see Chapters 126 and 128).
  - Make every effort to attribute all neurologic abnormalities to one focal lesion. If this is not possible, the lesion is probably multifocal or diffuse.
- Information gained by localizing the lesion includes the following:
  - Ability to rule out etiologies that would not cause lesions at the site of your localization.
  - Improved ability to select appropriate diagnostic tests based on your localization. For example, myelography is appropriate if the lesion localization is in the spinal cord. A cerebrospinal fluid (CSF) analysis would be appropriate if the lesion localization was multifocal since the primary cause of multifocal CNS disease is inflammatory disease.
  - Prognostic information for the animal's likely outcome. For example, UMN tetraplegia with no deep pain sensation after severe trauma has a very guarded to poor prognosis.

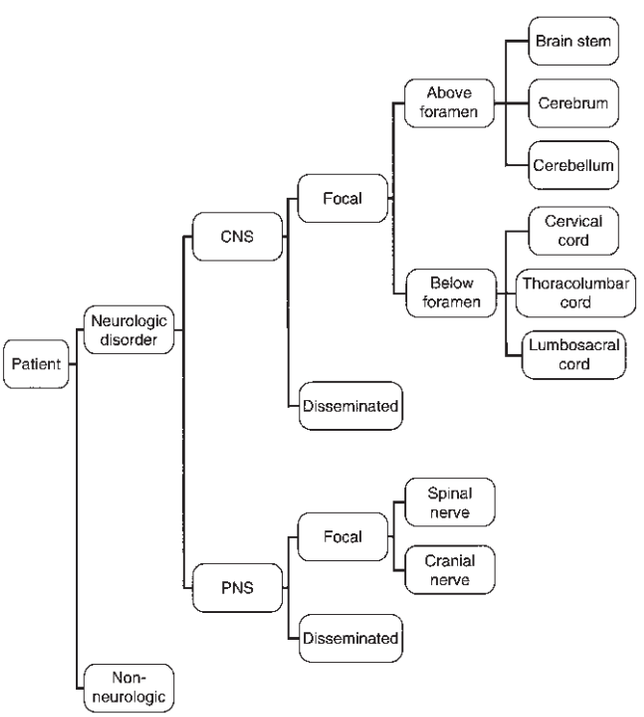

Figure 125-1. Localization flow chart. (CNS, central nervous system; PNS, peripheral nervous system.)

SELECTION OF DIAGNOSTIC AIDS

Diagnostic aids are laboratory tests and procedures that help determine which differential diagnosis is the most likely cause of the patient's signs. The primary purpose of a diagnostic aid is to provide etiologic information. As a consequence of establishing a diagnosis, these tests may also provide prognostic information. In addition, some tests provide anatomic information, allowing "fine-tuning" of the results of the neurologic examination.

Diagnostic aids used in evaluation of the nervous system include general screening tests such as routine serum biochemistries and complete blood counts that identify metabolic and toxic injuries to the nervous system. More specific tests that aid in lesion localization and diagnosis include neuroimaging, CSF analysis, and electrodiagnostic tests. Electrodiagnostic tests will also more specifically localize lesions causing neurologic dysfunction.

To select the most appropriate diagnostic aids, combine historical information with neurologic examination findings. After interpreting results of the diagnostic aids, the diagnosis should be evident.

GENERAL SCREENING TESTS

Hematology

In the majority of patients with nervous system disease, there are minimal hematologic changes. There are exceptions, such as some forms of infectious encephalitis and toxic diseases that secondarily affect the nervous system (e.g., lead poisoning).

White Blood Cell Changes

Elevation of white blood cell (WBC) numbers often indicates an inflammatory disease process; however, a low WBC count may be seen in viral infections.

Red Blood Cell Changes

Anemia, if profound, may result in hypoxia and cerebral signs. An abnormally high red blood cell (RBC) count (polycythemia) with increased serum viscosity can cause diminished blood flow to muscles and produce a myasthenia-like syndrome. It also may result in sludging of CNS blood flow with subsequent CNS infarction.

Biochemical Tests

These tests help evaluate animals with metabolic illness. Because the cerebrum has very high metabolic demands, it is affected by many generalized metabolic disorders. The motor unit also appears susceptible to a wide variety of generalized metabolic insults. Examples of biochemical abnormalities that have an impact on the nervous system include hypoglycemia and hyperglycemia, hypocalcemia and hypercalcemia, hypokalemia and hyperkalemia, hyponatremia and hypernatremia, acidosis and alkalosis, uremia, hyperammonemia, hyperlipidemia, and hyperviscosity from dysproteinemia.

Urinalysis and Urine Culture and Sensitivity

Many metabolic diseases that may affect the nervous system (diabetes mellitus, diabetes insipidus, renal disease, liver disease) produce changes in the urine. An increased urine protein-to-creatinine ratio due to protein-losing nephropathy could predispose the patient to CNS thromboembolic events secondary to hypercoagulability. In addition, some CNS infections (discospondylitis, etc.) are associated with concurrent urinary tract infections; therefore, evaluation of urinalysis and urine culture and sensitivity may be helpful in CNS infections. Urine and blood cultures are recommended if discospondylitis is present.

Ophthalmologic Examination

An ophthalmologic examination is indicated in patients with inflammatory neurologic disease. Many CNS infectious diseases can cause a concurrent anterior uveitis and chorioretinitis. A retinal exam may also be a useful screening test for hypertension (detached retinas and retinal hemorrhage) and raised intracranial pressure (papilledema). (See Chapter 138.)

Blood Pressure Measurement

Hypertension can be associated with hypothyroidism, hyperthyroidism, hyperadrenocorticism, renal insufficiency, hepatic insufficiency, and pheochromocytoma. Hypertension can also be idiopathic (essential hypertension). An elevated blood pressure can predispose the patient to CNS vascular disease. If hypertension is present, appropriate blood tests, especially for underlying endocrine or renal disease, should be performed. (See Chapter 153 for more information on hypertension.)

Thoracic Radiographs and Abdominal Ultrasound

Thoracic radiographs and abdominal ultrasound are often indicated if either neoplastic or infectious conditions of the nervous system are suspected. They may also be indicated if an underlying endocrine or renal disorder exists. Transcranial ultrasonography in young toy breeds with open fontanelles is a useful screening test for hydrocephalus.

Fecal Analysis

Severe parasitism has been reported as a cause of CNS disease in young animals.

Serology

Viral (distemper, feline infectious peritonitis), fungal (cryptococcosis, blastomycosis, histoplasmosis, coccidioidomycosis), protozoal (toxoplasmosis, neosporosis), and rickettsial (Rocky Mountain spotted fever and ehrlichiosis) infections of the nervous system result in the development of antibodies. These antibodies may be assayed in the patient's serum. CSF serology is more reliable than serum antibody assays for some of these infectious disease agents. (See the CSF serology section, Chapter 126, and Section 2 for more specific information.)

Immunofluorescence

Some viral infections that affect the nervous system may be diagnosed by using immunofluorescent techniques to detect antigen in CSF or nervous tissue (the latter is reserved for postmortem examination).

Toxicology

Blood can be assayed for many toxins known to affect the nervous system (e.g., lead poisoning).

NEURORADIOGRAPHY AND SPECIAL IMAGING

Radiography and special imaging can be used to evaluate the supporting structures of the nervous system and in some cases the nervous system itself. These studies provide information about CNS anatomy and can reveal structural abnormalities but generally do not provide information about neurologic function. (See Chapter 4 for additional information about neuroradiography and appropriate radiographic techniques.)

Plain Radiography of the Spine

- Plain radiographs can be very helpful in identifying bony lesions of the spine. Disorders that can cause changes in the vertebrae include vertebral body tumors, osteomyelitis, degenerative joint disease, fractures and luxations, soft tissue tumors that cause secondary bony lysis or pressure necrosis, mucopolysaccharidosis, hypervitaminosis A, and congenital vertebral body disorders (spina bifida, hemivertebrae, atlantoaxial malformation, etc.). Changes in the intervertebral disc space (collapse, calcification, foraminal opacification, discospondylitis) can also be identified (see Chapter 128).
- The major disadvantage of plain radiographs is the inability to image the spinal cord itself and soft tissues that may be impinging on the spinal cord. For this reason, plain radiographs provide minimal information regarding actual spinal cord compression.

Myelography

- For myelography of the spine, positive (radiopaque) contrast material is delivered into the subarachnoid space to outline the spinal cord and radiographs are taken (see Chapter 4).
- Myelography is very useful for imaging extradural or intradural/extramedullary lesions that are causing secondary spinal cord compression. Myelography can be used to localize areas of intervertebral disc herniation, spinal tumors, and other compressive lesions. It is also extremely effective in identifying areas of dynamic spinal cord compression. Post-myelogram computed tomography aids in determining the extent of lesion lateralization in the spinal canal.
- Myelography requires lengthy anesthetic times, provides marginal to no information about intramedullary diseases, is contraindicated in the presence of meningomyelitis, and is contraindicated in the presence of elevated intracranial pressure. Epidural leakage of contrast material can diminish the diagnostic information obtained.
- See Chapter 4 for proper myelographic technique and interpretation.

Skull Radiography

- Skull radiography provides very limited information about potential intracranial lesions. Bony structures of the cranial vault are visualized, but the brain itself is not.
- Loss of convolutional markings (gyral and sulcal markings) on the inside of the skull may be seen with hydrocephalus.
- Foramen magnum occipital dysplasia or "keyhole malformation" can be diagnosed using special rostrocaudal and caudorostral views of the foramen magnum.
- Bony or intranasal tumors and infections may be characterized by focal areas of bony lysis and/or proliferation.
- Occasionally, focal areas of the calvarium will show either hyperostosis (bony thickening) or lysis adjacent to a slowly expanding meningioma.
- Fractures of the skull can usually be identified with the appropriate views.
- Soft tissue or fluid densities within the tympanic bullae, bulla wall thickening and lysis, or a combination of both is usually evidence of chronic otitis media.
- See Chapter 4 for more details of the positioning techniques, imaging procedures, and image interpretation for skull radiography.

Computed Tomography

- Computed tomography (CT) provides adequate imaging of forebrain structures and large space-occupying lesions.
- CT provides excellent imaging of bony lesions such as skull fractures, skull and vertebral tumors, bulla osteitis secondary to otitis media, and discospondylitis. Intraparenchymal brain hemorrhage in the acute stages can also be identified.
- Post-myelogram CT of the spinal cord is very useful for defining axial locations of spinal cord lesions (see Chapter 128).
- Disadvantages of CT include poor resolution of brain stem, cerebellar, and spinal cord parenchyma and limited abilities to image CNS structures in more than one plane. Axial images can be reformatted to provide a limited series of low-resolution images in different planes.
- See Chapter 4 for more details on CT.

Magnetic Resonance Imaging

- Magnetic resonance imaging (MRI) provides superior imaging of brain and spinal cord parenchyma but poor imaging of bony structures. For brain lesions, MRI provides more precise lesion localization than CT (see Chapter 126). Brain edema is also more clearly identified using MRI than using CT. MRI sequences can be manipulated to give more information regarding primary lesions and CSF characteristics. Magnetic resonance images can easily be obtained in three planes to provide additional information about lesion size and extent.
- Extra-axial versus intra-axial location and pattern of contrast enhancement often aid in establishing a tentative diagnosis of brain tumors.
- The precise neuroanatomic information provided by MRI facilitates surgical planning for either biopsy or resection and radiation therapy planning.
- MRI also provides excellent resolution of intramedullary inflammatory, vascular, and congenital lesions. Some neurodegenerative conditions including cerebellar abiotrophy and lysosomal storage diseases may have characteristic MRI features. Syringohydromyelia and caudal occipital malformation syndrome in toy breeds and Cavalier King Charles spaniels are readily identified using MRI (see Chapter 128).
- MRI is less invasive than myelography and is an alternative imaging technique for intervertebral disc herniation and spinal cord tumors. MRI is the imaging modality of choice for peripheral nerve sheath tumors because it enables simultaneous visualization of the peripheral and central (spinal cord) components of the tumor (see Chapters 128 and 129).
- See Chapter 4 for more details on MRI.

CEREBROSPINAL FLUID COLLECTION AND ANALYSIS

Indications

- CSF collection and analysis are indicated if an inflammatory (infectious or non-infectious) CNS condition is suspected. Signs of inflammatory meningoencephalomyelitis may include rapidly progressive focal or multifocal neurologic deficits, recurrent seizures, neck or multifocal spinal pain, and chronic or recurrent "fevers of unknown origin."
- CSF analysis is less useful for non-inflammatory CNS conditions. CSF abnormalities in non-inflammatory conditions are often mild and nonspecific.

Contraindications

CSF collection is contraindicated in the presence of elevated intracranial pressure. Increased intracranial pressure can usually be recognized in the unanesthetized patient as a declining or depressed level of consciousness. In a patient with these signs, MRI is indicated prior to the CSF tap in order to assess the extent of brain swelling and early signs of brain herniation. (See Chapter 126 for a more detailed discussion of signs of brain herniation.) A cisternal or lumber CSF tap in a patient with elevated intracranial pressure can lead to severe brain herniation and death.

Technique

- Perform CSF collection under general anesthesia in dogs and cats. For brain disorders, collect CSF at the cerebellomedullary cistern. For spinal cord disorders, collect CSF at the L4 to L5 or L5 to L6 site. The lumbar space, however, can be more difficult to enter, yields smaller amounts of CSF, and has a higher rate of blood contamination in very small animals.
- The average distance between the skin and the cerebellomedullary cistern varies with the size of the patient. Reported distances for dogs and cats are $^1/_2$ inch for cats and dogs < 4.5 kg, $^3/_4$ inch for dogs 4.5 to 9.1 kg, 1 inch for dogs 9.1 to 22.7 kg, $1^1/_2$ inches for dogs 22.7 to 50.9 kg, and 2 inches for dogs > 50.9 kg.

Cerebrospinal Fluid Analysis

CSF analysis includes gross visual examination, cytologic analysis, biochemical analysis, and culture. In addition, serologic procedures may be indicated. There are slightly different normal values for fluid collected from cerebellomedullary and lumbar spaces; thus, note the

collection site. Fluid from the cerebellomedullary cistern tends to have slightly more cells and lower protein than fluid from the lumbar space.

Gross Examination

Normal CSF is clear and colorless. With inflammation, CSF generally becomes turbid and assumes an off-white to grayish color. Pink discoloration is usually caused by blood contamination. Yellow-orange–colored CSF (xanthochromic) generally indicates either breakdown of hemoglobin from previous hemorrhage or severe elevations of CSF protein (>100 mg/dl).

Cytology

- Cytologic evaluation consists of a total cell count on unconcentrated CSF and preparation of a slide from a concentrated CSF sample for evaluation of cell types and differential numbers.

▼ ***Key Point*** Perform the total cell count quickly (within 1 hour or less of the tap) because cells from CSF begin to degenerate rapidly following collection.

- The type and number of cells may reflect the cause of the inflammation and thus provide etiologic information. Normally there are <5 WBCs per microliter and the WBCs are a mixture of lymphocytes and monocytes.
  - A finding of 5 to 50 WBCs per microliter suggests a mild inflammatory process as seen with viral diseases and some forms of trauma, acute intervertebral disc herniation, vascular disease, and neoplasia; >5 WBCs per microliter are definitively abnormal if no RBCs are present.
  - A finding of 50 to 200 WBCs per microliter suggests a moderate inflammation, as seen with fungal, protozoal, and immune diseases, but this number may also be seen with meningiomas.
  - More than 200 WBCs per microliter indicates a marked inflammatory process, as seen with bacterial meningitis and some immune diseases.

Cerebrospinal Fluid Cytologic Interpretation

Suppurative Meningitis

Suppurative meningitis is diagnosed if the number of cells in the CSF is increased and the cells are predominantly neutrophils. Suppurative meningitis is the most common pathologic response to idiopathic meningitis or vasculitis in young dogs, bacterial encephalitis, feline infectious peritonitis, and some tumors (e.g., meningiomas). Mild increases in CSF neutrophils may be seen following CNS trauma, acute intervertebral disc herniation, fibrocartilaginous embolic myelopathy, and other acute vascular insults.

Mixed Inflammation

Mixed inflammation is diagnosed when the increased number of cells in the CSF are composed of multiple cell types, including macrophages, lymphocytes, neutrophils, and sometimes plasma cells. Although a mixed cytology is generally the result of fungal, protozoal, and idiopathic encephalitis, this cytologic change may also be seen in chronic bacterial infections that are being inadequately treated. Idiopathic granulomatous meningoencephalitis (GME) is typically characterized by granulomatous inflammation (lymphocytes, monocytes, macrophages), but neutrophils may sometimes be present in the acute stages.

Nonsuppurative Inflammation

Nonsuppurative inflammation is diagnosed when the number of cells in the spinal fluid is increased and it is composed primarily of mononuclear cells, especially lymphocytes. It is most characteristic of idiopathic immune-mediated forms of encephalitis, rickettsial infections, and some viral infections. Although this type of CSF abnormality is least likely to be due to an acute bacterial infection of the nervous system, it may occur. Chronic compressive spinal cord lesions may cause a mild elevation of lymphocytes and monocytes.

Eosinophilic Inflammation

Increased eosinophils in CSF may be observed secondary to immune-mediated eosinophilic meningoencephalitis, fungal infections, protozoal infections, and aberrant parasite migrations.

Red Blood Cell Pleocytosis

Increased RBC numbers are usually due to iatrogenic blood cell contamination during the CSF tap procedure. RBCs may also be increased due to previous hemorrhage due to trauma, coagulopathy, or inflammation. Erythrophagocytosis and xanthochromia may be observed if there has been previous hemorrhage.

Tumor Cells, Infectious Agents, and Intracellular Inclusions

Tumor cells are rarely identified in CSF with the exception of neoplastic lymphocytes in some forms of CNS lymphoma. Cryptococcal and other fungal organisms may occasionally be identified (see Chapter 20). Rarely, intracellular rickettsial organisms, distemper inclusions, and bacteria may be observed. Absence of intracellular bacteria and degenerative changes in neutrophils do not rule out a bacterial CNS infection. Some lysosomal storage diseases are characterized by intracellular storage bodies within WBCs. (See Chapters 126 and 128 for further discussion of CSF abnormalities in brain and spinal cord diseases.)

Cerebrospinal Fluid Biochemical Evaluation

When evaluating the chemical composition of the CSF, remember that CSF is produced both by active transport and by ultrafiltration. As a result, CSF contains essentially the same constituents as plasma, but they are present in different concentrations. Generally, the levels of CSF constituents are lower than the serum levels. The two constituents measured most commonly for diagnostic purposes are *protein* and *glucose*.

Protein Levels

The concentration of protein is quite low in CSF compared to plasma. In dogs and cats, protein from a cerebellomedullary cisternal tap is usually less than 25 mg/dl, whereas that from a lumbar puncture may be as high as 45 mg/dl. This difference may be the result of an increase in the permeability of the blood-brain barrier, production of immunoglobulins in the intrathecal space, or a combination of both. Conditions known to elevate CSF protein include encephalitis, meningitis, neoplasms, CNS infarctions, chronic neurodegenerative conditions, and trauma. CSF protein can be analyzed qualitatively and quantitatively by electrophoresis or immunoelectrophoresis. In normal CSF, albumin composes about 75% of the protein, and most of the remainder is globulin. An increase in CSF globulin without a parallel increase in albumin suggests local immunoglobulin production and encephalitis.

Glucose Levels

Normal CSF glucose levels are about 60% to 80% of those in blood. In humans with CNS bacterial infections, the CSF glucose is decreased. There does not appear to be a similar relationship between bacterial encephalitis and decreased CSF glucose in dogs. Plasma glucose can decrease dramatically in the presence of septicemia and bacteremia. A meningitic patient that is also bacteremic will likely have a drop in CSF glucose.

Cerebrospinal Fluid Serologic Examination

The CSF may be tested serologically for antibodies against infectious agents. Cryptococcal antigen can also be measured in CSF. Detection of CSF antibodies may be especially helpful in the diagnosis of canine distemper, feline infectious peritonitis, and toxoplasmosis. Paired or single serum titers are usually sufficient for diagnosis of neosporosis, rickettsial diseases, and some fungal disorders.

- The presence of CSF antibody usually indicates an active CNS infection and production of intrathecal antibody.
- False-positive CSF antibody titers can occur due to either iatrogenic blood contamination or blood-CSF barrier breakdown secondary to inflammation. CSF titer correction formulas are available and can be performed by some diagnostic testing laboratories if both CSF and serum are submitted (see Chapter 126).
- False-negative CSF antibody titers can occur with feline infectious peritonitis and cryptococcosis.

ELECTROENCEPHALOGRAPHY

Electroencephalography (EEG) is the graphic recording of shifts in resting membrane potential of the dendritic network in the cerebral cortex. This network is influenced and modulated by the activity of subcortical nuclear centers such as the reticular formation. Changes in EEG wave frequency and amplitude and occurrence of paroxysmal epileptiform complexes (spikes, sharp waves, and spike-slow wave complexes) are abnormalities that indicate a corticocerebral disturbance.

Indications

- EEG can be a useful screening test for any corticocerebral lesion. The procedure is noninvasive, relatively inexpensive, and can occasionally be performed without chemical restraint in the dog. Sedation or anesthesia is often required to minimize patient movement and to maintain a constant level of consciousness. In the awake state, normal variations in wakefulness can change EEG waveform frequency and amplitude.
- A montage (specific arrangement) of scalp electrodes allows patterns of abnormal activity to be localized to specific cortical areas. Focal slowing and paroxysmal activity suggests a focal neoplastic, infectious, traumatic, or vascular lesion. Diffuse slowing and changes in amplitude are suggestive of diffuse cerebral injury or metabolic disorders.
- EEG can be useful for confirming seizure activity in patients with atypical or subclinical seizures.

Disadvantages

- Disadvantages include recording artifacts due to patient movement, muscle activity, equipment malfunction, electrical interference, and drugs used to sedate or anesthetize the patient. These artifacts can obscure EEG recording and make it difficult to interpret.
- EEG provides little definitive information concerning the etiology of the underlying cerebral lesion. Neuroimaging with CT or MRI provides more definitive information about what is causing the cerebral dysfunction (see Chapter 126).

BRAIN STEM AUDITORY EVOKED RESPONSE

The brain stem auditory evoked response (BAER) tests the nervous system pathways for hearing. A normal

Table 125-1. INTERPRETATION OF ABNORMAL ELECTRODIAGNOSTIC EXAMINATION

Procedure	Abnormal Finding	Interpretation
Electromyography	Increased insertional activity	Neuropathies Myopathies Myotonia Cramp Electrolyte disorders
	Spontaneous activity	Myopathies Neuropathies (axon or cell body) Electrolyte disorders
Motor unit action potentials	Diminished size	Myopathies Acute denervation
	Increased size	Reinnervation Myopathies
Nerve conduction studies	Decreased velocity	Neuropathies (myelinopathies or combined axonopathy and myelinopathy)
Repetitive nerve stimulation	Incremental or decremental response	Junctionopathies

BAER depends on normal function of hearing receptors (cochlear receptors), CN8 (cochlear branch), the cochlear nucleus, and other "relay" nuclei for auditory signal transmission in the brain stem. An audible click produced by headphones or inserts in the ear triggers electrical activity in the structures above. The sequential neural activity is detected by scalp electrodes after each click stimulus. Several hundred amplified responses are "signal averaged," and the averaged waveform is displayed as a consecutive series of four to five waveforms. Wave I is generated by the cochlear receptors and cochlear nerve. Waves II through V are generated by relay nuclei in the brainstem.

Interpretation

- In congenital "sensorineural" deafness, the cochlear receptors degenerate perinatally. The resulting BAER is a "flat line" tracing.
- Injury to the cochlear receptors in the inner ear by otitis interna, neoplastic processes, or ototoxic drugs can also result in sensorineural deafness and an absent BAER.
- Middle ear effusions or soft tissue masses may inhibit normal sound transmission to the inner ear. This can result in lower amplitude, delayed BAER waveforms, or if severe, complete absence of the BAER. This form of hearing loss is called *conductive hearing loss.*
- A brain stem lesion affecting the auditory relay nuclei may decrease amplitudes and delay onset latencies (time to onset of wave) of waves II to V.
- Since the vestibular receptors and vestibular branch of CN8 are close to the cochlear system, the BAER may provide indirect localizing information in patients with vestibular disease secondary to otitis or neoplasia. In idiopathic geriatric vestibular syndrome, the auditory pathways and BAER are not affected.

ELECTRODIAGNOSTIC EXAMINATION OF THE MOTOR UNIT

The electrodiagnostic examination of the motor unit consists of three parts:

- Needle electromyography
- Nerve conduction studies
- Repetitive nerve stimulation

Each test evaluates different aspects of the motor unit. Interpretation of abnormal electrodiagnostic findings is summarized in Table 125-1.

Needle Electromyography

- Electromyography (EMG) provides information about the functional status of motor unit innervation and muscle membrane ion conductance. A recording needle is inserted into a muscle and spontaneous muscle potentials are recorded and evaluated. Electrical activity is "audible," and the sound of the potentials can be amplified to produce characteristic sounds from a loudspeaker. Persistent spontaneous activity in a resting muscle under anesthesia is abnormal. Normal muscle is "electrically silent" in the resting state with the exception of very low–amplitude miniature endplate potentials.
- In veterinary patients, general anesthesia is usually necessary to avoid patient discomfort and minimize patient movement. In humans and in extremely cooperative animal patients, awake studies may be performed to assess motor unit action potentials (MUAPs) normally generated during a voluntary muscle contraction. During sustained contractions, patterns of "recruitment" of these potentials can be observed to determine if they are normal or abnormal. Individual MUAP waveform characteristics

(amplitude, duration, number of phases) can also be altered in neuropathies and myopathies. Neuromuscular junction disorders may cause a reduction in MUAP amplitude.

Interpretation

- Fibrillation potentials, positive sharp waves, and complex repetitive discharges are examples of abnormal spontaneous activity. Fibrillation potentials and positive sharp waves are brief isolated potentials that range from 40 to 1000 μV in amplitude. The presence of any of these potentials indicates a neuropathy or myopathy but does not distinguish between them. Both neuropathies and myopathies cause functional denervation of the myofiber. Myopathic injury and necrosis disrupt normal muscle membrane integrity and the membrane receptors that are post-synaptic to nerve axon terminals.
- Complex repetitive discharges are several-second bursts of high-amplitude potentials (500–1000 μV) that may increment, decrement, or remain consistent in amplitude over time. These potentials may be observed in chronic neuropathies, myopathies, and in congenital myotonia. In congenital myotonia, the high-frequency repetitive discharges that wax and wane in frequency and amplitude are called *myotonic discharges* and may cause a characteristic "dive-bomber" sound.
- Spontaneous activity in neuromuscular junction disorders is rare but can occur sporadically with tick paralysis and botulism.
- In most polyneuropathies and polymyopathies, EMG activity is generalized and can be observed in most muscle groups. With focal nerve or muscle injuries, EMG can be very useful in localizing the distribution and extent of nerve and/or muscle injury.
- Occasionally, the resting EMG will be normal (no spontaneous activity) in peracute neuropathies and in some chronic neuropathies and myopathies. Nerve conduction tests and repetitive nerve stimulation should still be performed in these cases. If nerve conduction studies are abnormal or if clinical signs are suggestive of a neuropathy or myopathy, muscle and nerve biopsies should also be performed.

Nerve Conduction Studies

- Motor nerve conduction studies measure the velocity of action potential conduction between two points along a motor nerve. Conduction velocity is calculated as the difference in distance divided by the difference in conduction latency of the action potential between these two points. Latency is the amount of time that elapses between the stimulus and the onset of the electrical response in the innervated muscle.
- Electrical stimulation of a normal motor nerve proximally results in electrical activation and contraction of the innervated muscle distally. The distal muscle contraction produces a signal called a *compound muscle action potential* (CMAP) that can be recorded with a recording needle placed in the muscle. The CMAP is typically biphasic and approximately 25 mV in amplitude if the nerve is stimulated supramaximally. The CMAP is also called the *M wave*. Amplitude, duration, and number of phases of the CMAP can be altered in different neuromuscular diseases and should be measured and evaluated in all nerve conduction studies.

Interpretation

- The speed of conduction primarily evaluates the health of the myelin sheath. Myelin injury results in slowed conduction velocity and, often, a lower amplitude and polyphasic CMAP due to temporal dispersion. *Temporal dispersion* refers to the prolonged duration of the CMAP due to the presence of nerve fibers that conduct at widely different velocities as a result of varying degrees of demyelination. Conduction block (no conduction) can occur if myelin injury is severe. The amplitude of the CMAP is also affected by the number of healthy motor units (nerve fibers with their respective neuromuscular junctions and myofibers). The greater the number of normal motor units activated, the greater the amplitude of the CMAP.
- With axonal injury that spares the myelin sheath, nerve conduction may be normal or mildly decreased. There is a reduction in the number of available motor units; this reduction leads to the reduced size of the CMAP. As the neurogenic lesion becomes chronic, there is axon sprouting of the terminal branches of surviving neurons. These axon sprouts reinnervate some of the denervated muscle fibers. The evoked potential will then have a prolonged duration (temporal dispersion) and may become polyphasic. This occurs because the axon sprouts conduct more slowly than the normal fibers, so the muscle fibers receive their impulses at different times. In addition, because the motor unit now has more fibers, the evoked potential will be increased in amplitude.
- In most acute and chronic neuropathies, a *combined* axon and myelin injury is the general rule. Furthermore, axonal degeneration will inevitably lead to myelin degeneration over time. For this reason, most neuropathies are characterized by slowed conduction velocity, reduced amplitude of the CMAP, and increased duration and number of phases of the CMAP.
- Myopathic conditions reduce the number of healthy myofibers in the motor unit and thus will result in reduced amplitude of the CMAP. Nerve conduction velocity is normal.
- Neuromuscular junction disorders in which acetylcholine release is reduced (tick paralysis and botu-

lism) are characterized by normal conduction velocity but severely reduced amplitude of the CMAP.
- Sensory nerve conduction is similar to motor nerve conduction testing, except that the stimuli are applied to the nerve distally and the recordings are made directly from the nerve proximal to the site of stimulation.

Repetitive Nerve Stimulation

Repetitive nerve stimulation (RNS) refers to nerve stimulation by 5 or 10 consecutive supramaximal stimuli with concurrent recordings made of the consecutive CMAPs produced by these stimuli. The amplitudes of each CMAP are then compared with the amplitude of the first CMAP. A normal patient will show no changes in the amplitudes of the successive CMAPs in the series. Neuromuscular junction diseases often cause a progressive change in the amplitudes during the first five stimuli. An increase in amplitude is called an *incremental response;* a decrease in amplitude is called a *decremental response.* RNS should be performed at a stimulation rate of <5 stimuli per second.

Interpretation

- An incremental response suggests a presynaptic disease such as botulism, tick paralysis, or hypocalcemia. Most of the disorders that result in incremental responses are characterized by a defect in the release of acetylcholine at the neuromuscular junction.
- A decremental response suggests a postsynaptic disease, especially myasthenia gravis.

OTHER MOTOR UNIT TESTS

Tensilon Test

Edrophonium chloride or Tensilon is a short-acting anticholinesterase drug that will transiently alleviate signs of myasthenia gravis in most affected dogs and cats. Intravenous administration of Tensilon will usually result in a marked improvement in strength in animals with myasthenia gravis. The response to Tensilon is brief (usually about 5 minutes). Other neuromuscular disorders may show a partial response to Tensilon, but obvious signs of exercise-induced weakness are still present (see Chapter 130).

Muscle Enzymes and Metabolic Tests

- Any disease process that results in necrosis of the muscle cell membrane releases muscle enzymes into the systemic circulation. The most significant of these conditions is polymyositis. Because many incidental conditions (e.g., muscle trauma from an intramuscular injection) also release these enzymes, this must be taken into account when interpreting elevated serum levels of muscle enzymes.
- Some metabolic myopathies will cause abnormalities in pre-exercise and post-exercise lactic acid and pyruvic acid plasma concentrations. Specific types of myopathies can alter concentrations of urinary organic acids.

Serologic Tests for Autoantibodies

- Serologic testing for antibodies against acetylcholine receptors is the diagnostic test of choice for acquired myasthenia gravis.
- Serologic testing is also available for autoimmune masticatory muscle myositis. A diagnosis of masticatory myositis can be confirmed by finding increased circulating antibodies against type 2M muscle fiber antigen (see Chapter 130).
- Immune mediated polymyositis may be accompanied by a positive antinuclear antibody titer.

Muscle and Nerve Biopsy

Inflammatory and degenerative diseases of nerve and muscle are best diagnosed by biopsy (also see Chapters 129 and 130). These procedures can be done safely with minimal complications. The tissues require special handling and processing; therefore, arrangements should be made with the laboratory prior to collection of the samples. Analysis by a laboratory that is experienced in handling these biopsies will avoid erroneous results (see Chapter 130).

Chapter

126 Diseases of the Brain and Cranial Nerves

Philip A. March

The brain may be anatomically and functionally divided into three major compartments, the brain stem, cerebellum, and cerebrum. Cranial nerves have their cell bodies within the brain, but most of their nerve fibers course outside the brain. Diseases of the brain and cranial nerves may be neoplastic, infectious, idiopathic, vascular, traumatic, metabolic, toxic, congenital, or degenerative in origin. These disorders may result in dysfunction of a focal, regionally specific brain area or may produce more diffuse or multifocal deficits. Because many different diseases can affect similar areas causing very similar clinical signs, the first portion of this chapter discusses clinical signs of lesions in each brain region. The remainder of the chapter discusses important brain diseases within each etiologic category. Diagnosis of neurologic disease is discussed in Chapter 125, and management of seizures is discussed in Chapter 127.

CLINICAL SIGNS AND NEUROLOCALIZATION

Refer also to Chapter 125.

Brain Stem Lesions

- The brain stem contains the midbrain, pons, and medulla in the caudal fossa (below the tentorium cerebelli or infratentorial) and diencephalon in the more rostral middle fossa (above the tentorium cerebelli or supratentorial). Signs associated with lesions in the infratentorial brain stem are discussed below. Signs associated with the diencephalic (thalamic and hypothalamic) lesions are similar to those associated with cerebral lesions and so are discussed in the cerebral lesion section.
- Cranial nerve dysfunction is a common sign of brain stem disease. The brain stem contains cranial nerve 3 through cranial nerve 12 (CN3–CN12). Multiple or single cranial nerves may be involved in a disease process; signs are typically asymmetrical. CN5 through CN12 in the pons and medulla are more commonly affected than CN3 and CN4 in the midbrain.

▼ ***Key Point*** Central vestibular signs are usually present in diseases of the brain stem.

- Head tilt, circling, falling, disequilibrium, and nystagmus indicate damage to vestibular nuclei of CN8. Head tilts usually occur toward the side of the lesion. Paradoxical vestibular syndrome is characterized by a head tilt opposite the side of the lesion.
- Dysfunction of muscles of facial expression (CN7) and mastication (CN5) are common. Disorders of swallowing (CN9 and CN10), laryngeal function (CN9 and CN10), and tongue mobility (CN12) can occur but are less common.
- Oculomotor weakness, strabismus, and resting pupillary changes occur with CN3, CN4, and CN6 involvement.
- Injury to ascending white matter tracts in the brain stem results in ipsilateral conscious proprioceptive deficits and other abnormalities in postural reactions. Occasionally, ataxia, dysmetria, and exaggerated postural reactions may be seen.
- Injury to descending upper motor neuron (UMN) nuclei and their tracts in the brain stem causes tetraparesis or paralysis characterized by increased extensor muscle tone and exaggerated reflexes. The weakness or paresis is usually more severe in limbs on the same side as the lesion.
- Severe brain stem lesions can result in disruption of the ascending reticular activating system. Clinical signs of progressively decreasing levels of consciousness (depression, obtundation, stupor, coma) correlate with the severity of the injury.
- Severe brain stem lesions can also affect cardiovascular and respiratory regulation. Altered heart rate (bradycardia, supraventricular arrhythmias) and respiratory patterns (hyperventilation, ataxic respirations, apnea) are evident.

Cerebellar Lesions

- *Ataxia of gait:* Cerebellar lesions produce pronounced limb incoordination during voluntary movements. Exaggerated range and force of limb movement is

common. Hypermetria and limb circumduction can be seen. Strength and conscious proprioception (CP) are preserved. Postural reactions often are preserved but exaggerated.

- *Truncal ataxia:* Truncal swaying and a wide-based stance are typical of cerebellar disease. Affected patients may fall to one side. Dysmetric head bobbing with overshooting and undershooting occurs. Forward and backward movements of the trunk (titubation) may be seen.
- *Intention tremor:* A fine oscillating tremor of the head and sometimes the body is seen during highly controlled movements, such as eating or visually fixating on an object.
- *Menace deficit:* The menace response is lost ipsilateral to the cerebellar lesion. Vision and facial nerve function are intact.
- *Anisocoria:* Mild mydriasis may be seen ipsilateral to the cerebellar lesion.
- *Vestibular signs:* The cerebellum contains the flocculonodular lobe, which is considered part of the vestibular system. Lesions in this area of the cerebellum may produce pathologic (and often positional) nystagmus, head tilt, and circling. Occasionally, a pendular nystagmus (rhythmic but rapid horizontal oscillation of the eyes) is seen with cerebellar disease.
- *Opisthotonus* (extension of the head and neck) and thoracic limb extensor rigidity may be seen with severe cerebellar disease or with cerebellar herniation.
- *Mental status* is normal in patients with isolated cerebellar injury.

Forebrain Lesions

- Forebrain diseases can affect the cerebrum or diencephalon either bilaterally (diffusely) or unilaterally (focally). Both diffuse and focal forebrain disorders can cause the following:
  - Seizures (generalized or partial)
  - Behavior or personality change
  - Dullness, agitation, or otherwise inappropriate responses to environmental stimuli (abnormal mentation or "dementia")
  - Contralateral visual deficits (loss of menace) with intact pupillary light reflexes
- Diffuse diseases of the cerebrum or diencephalon can also cause the following:
  - Generalized conscious proprioceptive deficits (all four limbs)
  - Stupor or coma with decreased to absent responses to painful stimuli
  - Generalized ataxia if an acute injury
  - Bilateral miosis with an intact pupillary light reflex
- Focal diseases of the cerebrum or diencephalon can cause the following:
  - Circling toward the side of the lesion
  - Contralateral conscious proprioceptive deficits and slow postural reactions
  - Contralateral facial sensory deficits (especially nares sensation)
  - Contralateral mild facial weakness
  - Hemi-inattention to stimuli on the side of the body opposite the lesion
- Focal diencephalic lesions may cause lethargy; inappetence; altered mentation and behavior; circling, listing, and/or head turn toward the side of the lesion; and hemi-inattention. These deficits may occur in the absence of proprioceptive, visual, or facial sensory and motor deficits.
- Structural intracranial lesions can produce referred head and neck pain.

▼ ***Key Point*** Cerebral and diencephalic diseases do not cause significant abnormalities of limb strength or weight bearing.

Manifestations of Systemic Metabolic Alterations

The above description of generalized and focal cerebral diseases applies to intracranial or structural disorders. Extracranial diseases (toxic, metabolic, and some nutritional disorders) may not produce actual structural lesions but may alter cerebral function enough to produce cerebral signs. Usually signs are diffuse in nature and mental status is altered. Seizures may be seen and may be either generalized or focal. Between seizures, lateralizing neurologic deficits are not found. Other body systems are often affected concurrently by systemic extracranial disorders.

Herniation from Space-Occupying Brain Lesions

- Space-occupying lesions in the forebrain and cerebellum may grow rapidly, may be accompanied by extensive edema, or may result in acute hemorrhage or infarction due to invasion of local blood vessels. Intracranial tissue and fluid compartments (parenchyma, blood, cerebrospinal fluid [CSF]) can compensate for space-occupying lesions up to a point. Beyond this critical threshold, brain shift or herniation occurs. Sudden changes in clinical signs not referable to the original neurolocalization suggest brain herniation and warrant emergency treatment.
- The two most common types of herniation are caudal transtentorial herniation due to an expanding forebrain mass and foramen magnum herniation due to an expanding cerebellar lesion.
  - Clinical signs of *transtentorial herniation* include extensor rigidity in all four limbs and cervical musculature (decerebrate rigidity), pupillary constriction followed by dilatation or fixed, midrange pupils, loss of the vestibulo-ocular reflex (doll's eye reflex), and a stuporous or comatose state.
  - Clinical signs of *foramen magnum herniation* include opisthotonus (extended head and neck), thoracic limb rigidity (usually without rigidity of the pelvic

limbs), pupillary changes (usually miosis), and either severely irregular respirations or apnea.
- Appearance of these clinical signs indicates a severe brain injury and a need for immediate medical attention.

NEOPLASIA

Primary and secondary brain tumors most commonly affect middle-aged and older dogs and cats and can be located anywhere in the brain. Direct mechanical compression and necrosis of surrounding brain parenchyma, peritumoral edema, and blood vessel invasion with hemorrhage may all contribute to signs of a space-occupying mass. Clinical signs reflect location of the tumor in a specific brain area. As discussed above, when brain compensatory mechanisms are exhausted, brain herniation occurs and rapid clinical deterioration ensues.

Brain tumors can be *extra-axial,* arising from more superficial areas of the brain and compressing or invading the underlying parenchyma, or *intra-axial,* arising deep within the brain parenchyma and invading neural tissue surrounding them. Extra-axial masses tend to have a gradual onset and slow progression of signs. Intra-axial tumors tend to have a more rapid onset and progression.

Etiology

Primary Brain Tumors in the Canine

Primary tumors of the canine brain arise spontaneously and may grow slowly or rapidly.

▼ ***Key Point*** The two most common primary brain tumors in the dog are meningioma and glioma.

Etiologic factors are not well understood. The glioma group includes astrocytomas, glioblastomas, oligodendrogliomas, ependymomas, and choroid plexus papillomas or carcinomas. Meningiomas arise from arachnoid cells of the meninges, whereas gliomas arise from neuroectodermal supporting cells.

Meningiomas tend to occur in dolichocephalic breeds, whereas gliomas tend to occur in brachycephalic breeds. Any dog, however, may develop either tumor. Meningiomas in the dog are often located in the olfactory or frontal lobe or over the convexities of the cerebrum, but they can occur on the floor of the intracranial vault (rostral, middle, or caudal fossae). They often appear to be well-circumscribed masses but invade the underlying neural parenchyma. They may have a cystic component. Astrocytomas and oligodendrogliomas arise mostly from deep intra-axial locations in the brain (usually cerebrum or diencephalon). Ependymomas are relatively uncommon and arise from cells lining any of the ventricular compartments. The lateral ventricles of the cerebrum are the most common sites for ependymoma formation. Choroid plexus papillomas and carcinomas develop in areas of the brain where choroid plexus is present. The most common sites for a choroid plexus papilloma are the fourth ventricle-lateral aperture area and the third ventricle. Obstruction of the third ventricle by a choroid plexus papilloma results in secondary hydrocephalus and intracranial hypertension. Choroid plexus carcinomas, ependymomas, and, occasionally, oligodendrogliomas may metastasize to other central nervous system (CNS) areas using CSF pathways.

Primary Brain Tumors in the Feline

▼ ***Key Point*** The most common brain tumor of aged cats is the meningioma.

Most feline meningiomas are cerebrally located, extra-axial, and well encapsulated. They are frequently multiple and may occur anywhere along the falx, along the tentorium cerebelli, and in the tela choroidea of the third ventricle. Gliomas in the cat are uncommon but do occur. Primary CNS lymphoma may arise from brain structures, but it most commonly arises in thoracolumbar spinal cord locations.

Secondary Brain Tumors in the Canine and Feline

Secondary tumors are either solitary or multiple. The two most common mechanisms of brain invasion are by hematogenous routes and by extension from surrounding tissues. Hemangiosarcoma, malignant melanoma, mammary adenocarcinoma, and pulmonary adenocarcinoma use the hematogenous route to metastasize to the brain. The most frequent metastatic location is the cerebrum. Secondary CNS lymphoma in dogs is usually associated with the multicentric form of lymphoma. Brain, cranial nerve, and spinal cord lesions can occur with concurrent leptomeningeal involvement. Multicentric malignant histiocytosis can secondarily invade the CNS in dogs (especially Bernese mountain dogs, rottweilers, golden retrievers). Forebrain, brain stem, spinal cord, and vertebral body invasion has been reported. Tumors that invade the brain by local extension include nasal adenocarcinoma, pituitary macroadenoma and carcinoma, and bony tumors of the skull including multilobular osteochondroma, osteosarcoma, and chondrosarcoma. Peripheral nerve sheath tumors of CN3 and CN5 also tend to grow up their respective nerve trunks and invade the brain stem. Ganglioneuromas in young dogs behave similarly.

Many of the same tumors that secondarily invade the canine brain also occur in the feline. These include metastatic carcinomas, nasal carcinomas, and pituitary carcinomas. Squamous cell carcinomas can extend into the brain from middle ear locations.

Clinical Signs

- The onset and progression of clinical signs depend on the type of tumor and its location. Extra-axial meningiomas grow slowly and clinical signs are gradual in onset and progression. Intra-axial gliomas grow rapidly and cause a more rapid clinical deterioration. Secondary tumors also tend to progress rapidly. An exception to this is the trigeminal neurofibroma, which exhibits very slow growth (months to years).
- Early clinical signs of forebrain tumors may be vague and include increased irritability, behavior change, pacing, head and neck pain, and increased lethargy. Head pain or headache in dogs can be recognized by gently applying bilateral pressure across the temporal aspects of the head and skull.
- Some forebrain tumors may be clinically "silent" or may only cause seizures. These tumors can be located in the olfactory, temporal, or occipital cerebral lobes.

▼ ***Key Point*** Signs of asymmetrical cerebral involvement include circling and contralateral conscious proprioceptive, visual field, and facial sensorimotor deficits.

- Diffuse cerebral signs may occur secondary to a tumor obstructing CSF flow. This results in fluid accumulation in the lateral ventricles of the cerebrum and secondary hydrocephalus.
- Herniation syndromes may occur with tumors of the forebrain or cerebellum (see under "Herniation from Space-Occupying Brain Lesions").
- Brain stem tumors usually occur in the pontomedullary area and typically cause central vestibular and other cranial nerve and long tract (e.g., limb proprioception and paresis) deficits.
- *Cerebellopontomedullary angle tumors* (choroid plexus papillomas, ependymomas, neurofibromas, meningiomas, and other tumor types) may invade the flocculonodular lobe of the cerebellum or the cerebellar peduncles. If this occurs, a "paradoxical vestibular syndrome" is seen. Signs are head tilt with possible circling and ataxia (rolling, falling, stumbling) *away* from the side of the lesion. The fast phase of nystagmus is often toward the side of the lesion. Long tract signs (e.g., limb proprioception and paresis), however, are ipsilateral to the lesion. If other cranial nerves are involved (e.g., CN5 and CN7), those deficits will be on the same side as the lesion.
- *Cavernous sinus syndrome* is a sporadic syndrome due to a lesion in the cavernous sinus along the floor of the rostral fossa (beneath the forebrain and just caudal to the orbital fissure). Neoplastic masses occupying this area will compress CN3, CN4, CN6, the ophthalmic branch of CN5, and the sympathetic nerve going to the eye. The result is an ipsilateral fixed pupil, absent corneal and eyelid sensation, and ocular immobility.

Diagnosis

Laboratory Testing

- Perform a complete blood count (CBC), chemistry profile, and urinalysis to rule out extracranial causes of brain dysfunction prior to pursuing tests for intracranial disease.
- Because most patients with brain tumors are older, run a geriatric screen of liver and kidney function.
- Perform an adrenocorticotropic hormone (ACTH) stimulation test and a low-dose dexamethasone suppression test if a pituitary mass is suspected.

Ophthalmologic Exam

Perform a complete ophthalmologic examination to check for papilledema (a sign of increased intracranial pressure [ICP]), uveitis, retinal hemorrhage, and other abnormalities.

Electrodiagnostic Testing

- An electroencephalogram (EEG) may detect asymmetries in brain activity or actual epileptiform complexes if a seizure focus is present. See Chapter 125 for a more thorough description of the EEG and its uses.
- A brain stem auditory evoked response (BAER) may aid in localizing a brain stem lesion. See Chapter 125 for additional information.

Radiography

- Perform thoracic radiographs to screen for metastatic disease.
- Skull radiographs are usually not helpful in the diagnosis of a brain tumor.
- Skull radiographs may reveal a nasal or bony tumor with secondary brain invasion.
- An area of bone sclerosis or lysis may be visible in the skull immediately adjacent to a feline meningioma.
- Some feline meningiomas may have an area of dystrophic mineralization that is visible on skull radiographs.

Computed Tomography and Magnetic Resonance Imaging

- Tumor margins and neuroanatomic location can be more precisely defined with computed tomography (CT) or magnetic resonance imaging (MRI). Peritumoral edema is also visible. Parenchyma definition, especially in brain stem areas, is best identified with MRI.
- Intravenous contrast agents (meglumine iothalamate for CT and gadolinium diethylenetriamine pentaacetic acid for MRI) highlight areas of blood-brain barrier disruption. Patterns of enhancement are not pathognomonic for tumor type but aid in making a tentative diagnosis.

- Inflammatory or other non-neoplastic lesions may mimic a neoplastic lesion on both CT and MRI. A CSF tap and biopsy of the mass are sometimes needed to confirm the underlying process.

▼ ***Key Point*** CT and MRI provide the precise neuroanatomic information needed for accurate biopsy, surgical, and/or radiation procedures. (See Chapter 4 for more information on these imaging modalities.)

Cerebrospinal Fluid Analysis

For CSF tap technique and normal values, see Chapter 125.

- CSF analysis may be useful in distinguishing inflammatory from neoplastic processes (see also "Inflammatory Brain Diseases").
- The majority of brain tumors are characterized by no cytologic abnormalities (normal cell count and differential) on CSF analysis. CSF pleocytosis may be seen if the tumor is necrotic and has a secondary inflammatory component. Neoplastic lymphocytes in CSF are typically seen in dogs with CNS lymphoma.
- Protein levels are usually elevated for all tumor types. Elevated protein with a normal cell count is called *albuminocytologic dissociation*.

▼ ***Key Point*** The CSF tap procedure is contraindicated in patients with elevated ICP.

- If clinical signs and/or CT or MRI suggest elevated ICP, the use of mannitol, furosemide, and hyperventilation may lessen the risks of brain herniation.

Brain Biopsy

Brain biopsy can be performed either by open craniotomy or by using stereotactic CT guidance. Cytologic preparations of the biopsy can be examined intraoperatively and may be diagnostic.

Treatment

Corticosteroids

- Corticosteroids primarily help in resolving vasogenic edema and often benefit patients with peritumoral edema. Administer prednisone at a dosage of 0.25 to 0.5 mg/kg every 12 hours as maintenance therapy for peritumoral edema.
- Meningiomas in cats may show a partial clinical response to corticosteroids in the short term (several weeks or months).
- If there is a rapid progression of signs due to a significant edema component, administer methylprednisolone sodium succinate (Solu-Medrol) at 30 mg/kg IV once followed by 15 mg/kg IV every 6 hours for 24 to 48 hours *or* dexamethasone at 1 mg/kg IV every 12 hours for 24 hours.

Hyperosmotic Solutions and Diuretics

- Mannitol therapy is reserved for those patients with signs of increased ICP and/or herniation.
- In the euvolemic patient, mannitol at 1 g/kg IV over 20 minutes will draw fluid out of more normal areas of brain and temporarily lower ICP.
- Furosemide given 20 minutes after mannitol at a dose of 1 to 2 mg/kg IV will help prolong the effects of mannitol. Furosemide may also decrease CSF production.

Anticonvulsant Therapy

Phenobarbital at a dosage of 2.2 to 2.5 mg/kg PO every 12 hours is indicated if seizures are part of the clinical picture (see Chapter 127). Potassium bromide is often required as an additional anticonvulsant if seizures are recurrent.

Specific Chemotherapy

- Controlled clinical trials in dogs and cats have not been done to assess the true efficacy of different chemotherapeutic agents in the treatment of brain tumors.
- Nitrosoureas (lomustine, carmustine) appear to be beneficial in the treatment of some canine gliomas and meningiomas. Longer survival and even temporary tumor regression have been reported. Lomustine is also frequently effective against CNS lymphoma and malignant histiocytosis. Nitrosoureas are unique in that they cross the blood-brain barrier, the limiting factor for most chemotherapeutic agents. Give 50 to 80 mg/m^2 of body surface area every 4 to 6 weeks. For conversion of body weight to surface area (m^2), see Table 26-4 in Chapter 26.
- Cytosine arabinoside reaches therapeutic CSF concentrations after large intravenous doses in normal dogs. Intrathecal and IV infusions of cytosine arabinoside have been used in dogs with CNS lymphoma. A dosage of 300 to 400 mg/m^2 of body surface area intravenously over 4 to 12 hours is recommended.
- Tumor cell heterogeneity with respect to relative phase in the cell cycle diminishes the likelihood of a uniform tumor response to chemotherapeutic agents.

Surgery

- Craniotomy or craniectomy with tumor excision is a treatment option for extra-axial tumors involving the cerebrum or cerebellum. Refer the patient to a neurosurgical specialist.

▼ ***Key Point*** Survival rates are generally good to excellent when feline meningiomas over the cerebral convexities are removed surgically.

- It is usually years before clinically significant regrowth occurs after meningioma excision in cats. Survival periods of 6 months to 1 year are reported following meningioma excision in dogs. Postoperative radiation therapy extends the survival period in the canine (1–2 years).
- Tumors in more intra-axial and brain stem locations cannot be resected completely. Biopsy and radiation therapy (see below) can be performed.

Radiation Therapy

▼ ***Key Point*** External beam megavoltage radiation therapy for brain tumors appears to prolong survival more consistently than other modes of therapy. A well-tolerated treatment protocol appears to be 45 to 48 Gy in 12 to 18 fractions over 3 to 4 weeks.

- Longest survival times for dogs with meningiomas are obtained when radiation therapy is combined with surgery.
- Canine pituitary tumors are radiation sensitive. Long remission times have been achieved.
- Brain metastases may respond to radiation therapy.
- Clinical signs of neurologic dysfunction often improve rapidly (within 2–8 weeks) following radiation therapy. Tumor shrinkage is delayed (>4 months) and is not associated with early clinical improvement.
- Complications of radiation therapy include ocular (conjunctivitis, keratoconjunctivitis sicca, cataracts) and dermatologic (erythema, alopecia, otitis) changes. A potential late, delayed reaction may occur 9 to 24 months after radiation and is characterized by white matter necrosis.

Stereotactic Radiosurgery

- Stereotactic radiosurgery is the application of a single high dose of radiation delivered to a stereotactically defined target volume.
- The procedure utilizes multiple, non-coplanar beams originating from a radiation source that rotates in an arc around the patient's tumor. All beams are focused on the target in non-intersecting planes using a stereotactic image-based system.
- This radiation procedure reduces radiation exposure of normal brain tissue and so avoids adverse effects associated with conventional radiation therapy.
- Delivery of the entire radiation treatment as a single dose minimizes anesthetic events and reduces costly repeat visits associated with conventional radiation therapy.

INFLAMMATORY BRAIN DISEASES

Inflammation of brain parenchyma and its meninges (meningoencephalitis) occurs secondary to infectious or idiopathic insults.

▼ ***Key Point*** Idiopathic inflammatory conditions are more common than infectious conditions in dogs, but the reverse is true in cats.

Idiopathic disorders frequently have an immune-mediated component. Most infectious agents reach the brain hematogenously. Local extension from extraneural sites, usually due to erosion through bone, is a mechanism used by some fungal and bacterial organisms. Other sources of infection include foreign body migration, previous trauma, and iatrogenic contamination during neurosurgery. An unusual but important mode of entry into CNS is that used by rabies and pseudorabies viruses and by *Listeria* bacteria. These agents are inoculated into a peripheral site, enter peripheral nerve axons, and then undergo retrograde axonal transport into the CNS.

The cascade of inflammatory changes that occurs after brain injury leads to a self-perpetuating process of brain tissue ischemia, necrosis, and edema. Inflammatory brain disorders are usually associated with multifocal clinical signs and lesions are often disseminated throughout the CNS. Clinical signs, however, may indicate a focal neurolocalization for the most prominent lesion. Some inflammatory disorders have a predilection for the cerebral cortex, whereas many others have a predilection for brain stem sites and frequently cause central vestibular signs. The onset and progression of clinical signs is usually rapid (days to weeks) but can be prolonged. Infectious diseases may be accompanied by systemic signs, but idiopathic brain conditions are usually characterized by signs referable to the CNS only. As in the case of neoplastic conditions, inflammatory diseases can lead to the formation of large, space-occupying lesions, increased ICP, and herniation of brain structures.

Infectious Meningoencephalitis

Etiology

- Infectious diseases are a common cause of acute to subacute, rapidly progressive neurologic dysfunction in dogs and cats and tend to occur in young adults.
- Major etiologic categories include viral, fungal, rickettsial, and protozoal agents. Bacterial diseases of the CNS can also occur but are less common. *Klebsiella, Escherichia coli, Streptococcus, Enterococcus, Staphylococcus, Pasteurella, Actinomyces, Nocardia,* and various

Table 126-1. INFLAMMATORY BRAIN DISEASE CAUSED BY INFECTIOUS AGENTS IN THE CAT

Disease/Agent	Typical Age of Onset	Onset/ Progression	Typical Neurologic Signs	Typical CSF Characteristics	Serology/CSF Titers	Treatment*
FIP (coronavirus)	Young (<2 yrs)	Rapid or intermediate	Brain stem, cerebral, or spinal cord (may be multifocal)	Suppurative or mixed; very high protein	CSF coronavirus IgG antibody coefficient (some false negatives)	Palliative only (corticosteroids, chlorambucil, cyclophosphamide, melphalan)
Cryptococcosis *(Cryptococcus neoformans)*	Any age	Intermediate to slow	Brain stem (may be multifocal)	Mononuclear or mixed; moderate protein	CSF or serum antigen titer (CSF preferred)	Fluconazole
Toxoplasmosis *(Toxoplasma gondii)*	Adult	Rapid to intermediate	Multifocal or focal brain stem, cerebral, cerebellar, spinal cord, or nerve root signs	Mild to moderate mononuclear; rare eosinophils; moderate protein	CSF antibody coefficient preferred (if serum, need positive IgM or fourfold rise in IgG titer)	Trimethoprim-sulfadiazine +/− pyrimethamine; clindamycin
FIV (lentivirus)	Adult	Slow	Cerebral (behavior change, dementia, roaming)	Mild lymphocytic; normal protein	Positive serum FIV antibody titer	Experimental only (alpha-interferon, PMEA, AZT)
Rabies (rhabdovirus)	Any age	Rapid	Cerebral (behavior change, irritable, seizures) (may be multifocal)	Normal or mild lymphocytic; normal or mild protein	NA (IFA testing of brain tissue most reliable)	None

*Preferred treatment(s) are listed first; other available drugs are listed in parentheses.
CSF, cerebrospinal fluid; FIP, feline infectious peritonitis; FIV, feline immunodeficiency virus; IFA, immunofluorescent antibody; IgG, immunoglobulin G; IgM, immunoglobulin M; NA; not available.

anaerobic species are the most common bacterial isolates. Some of the more important causes of infectious meningoencephalitis and their clinical and clinicopathologic features in the dog and cat are listed in Tables 126-1 and 126-2.

Diagnosis

- Due to frequent multisystemic involvement seen with many infectious brain disorders, diagnostic testing should include ophthalmic exam, CBC, chemistry profile, urinalysis, thoracic radiographs, and sometimes abdominal ultrasound or echocardiography, and ophthalmologic examination. Both anterior uveitis and chorioretinitis are common with toxoplasmosis, rickettsial, and feline infectious peritonitis (FIP) infections. Chorioretinitis and optic neuritis may also be observed with cryptococcal and distemper infections.
- Cytologic evaluation of skin lesions, nasal exudates, liver and splenic aspirates, lymph node and bone marrow aspirates, joint fluid, and CSF can sometimes identify the offending pathogen. Histopathologic evaluation of skin and muscle biopsies may also be useful to diagnose fungal and protozoal infections.
- CSF analysis in CNS infectious diseases frequently reveals a moderate to severe pleocytosis and elevated protein. Bacterial meningoencephalitis typically produces a neutrophilic pleocytosis with or without toxic changes in the neutrophils. Intracellular organisms are rarely observed. Blood, urine, and CSF cultures are indicated when bacterial infections are suspected even though CSF cultures are usually falsely negative. CSF characteristics of other CNS infections are described in Tables 126-1 and 126-2.
- CSF titers are preferred for diagnosis of distemper, cryptococcosis, and toxoplasmosis. An immunoglobulin G (IgG) ratio or intrathecal antibody coefficient for canine distemper virus (CDV) and toxoplasmosis can be determined using CSF and serum samples from affected animals. These methods correct for possible blood-CSF barrier breakdown by comparing CSF-to-serum ratios of pathogen-specific antibodies

Table 126-2. INFLAMMATORY BRAIN DISEASE CAUSED BY INFECTIOUS AGENTS IN THE DOG

Disease/Agent	Typical Age of Onset	Onset/ Progression	Typical Neurologic Signs	Typical CSF Characteristics	Serology/CSF Titers	Treatment*
CDV (paramyxovirus)	Young (<1 yr)	Rapid or intermediate	Cerebral, brain stem, cerebellum, or spinal cord (may be multifocal)	Normal to moderate lymphocytic; mild protein	Positive CSF CDV antibody or antibody coefficient; RT-PCR on CSF	No specific treatment; prednisone in chronic form; AEDs if seizures
Cryptococcosis *(Cryptococcus neoformans)*	Any age; often young (<1 yr)	Intermediate to slow	Brain stem (often multifocal brain stem signs)	Mixed (predominantly mononuclear or eosinophilic); high protein; may see organism rarely	CSF or serum antigen titer (CSF preferred)	Fluconazole
Coccidioidomycosis *(Coccidioides immitis)*	Adult	Intermediate to slow	Cerebrum or brainstem	Mixed; mild to moderate protein	Serum CF titer ≥1:8	Fluconazole
RMSF *(Rickettsia rickettsii)*	Adult	Rapid	Diffuse or multifocal; often central vestibular component; neck pain	Mixed or suppurative; moderate protein	Rising IFA serum antibody titer (paired); PCR if negative titer in acute phase	Doxycycline, (chloramphenicol, enrofloxacin)
Ehrlichiosis *(Ehrlichia canis)*	Adult	Rapid or intermediate	As for RMSF	Mixed or non-suppurative; moderate protein	Positive IFA serum antibody titer at >1:20; PCR	Doxycycline
Neosporosis *(Neospora caninum)*	Young (<1 yr); rarely adults up to 7 years	Rapid	Caudal paresis, arthrogryposis, or tetraparesis (spinal cord); More generalized signs including brainstem and cerebral signs in adults	Non-suppurative; moderate protein	Positive IFA serum antibody (often ≥1:800)	Clindamycin; trimethoprim-sulfadiazine +/− pyrimethamine
Rabies (rhabdovirus)	Adult	Rapid	Spinal cord, brainstem, and/ or cerebral signs (may be multifocal)	Normal or mild mononuclear; normal or mild protein	NA (IFA testing of brain tissue most reliable)	None
Pseudorabies (herpesvirus)	Any age	Rapid	Hyperesthesia; spinal cord and brain stem signs (often multifocal)	Mild mononuclear; mild protein		None

*Preferred treatment(s) are listed first; other available drugs are listed in parentheses.
AEDs, antiepileptic drugs; CDV, canine distemper virus; CF, complement fixation antibody; CSF, cerebrospinal fluid; IFA, immunofluorescent antibody; NA; not available; PCR, polymerase chain reaction; RMSF, Rocky Mountain spotted fever; RT-PCR, reverse transcriptase polymerase chain reaction.

against ratios of vaccine-associated (usually adenovirus or calicivirus) antibodies. Non-paired serum titers for toxoplasmosis are unreliable in the dog and cat due to persistence of high antibody titers long after exposure. The antibody coefficient calculation may also be useful to diagnose CNS FIP, although false-negative cases of CNS FIP have been reported. Cryptococcal antigen-specific titers can be run on serum, but CSF titers provide a more definitive diagnosis of CNS involvement. Cryptococcal antibody titers may be falsely negative due to an inadequate humoral immunologic response to the encapsulated organism. Serum titers are useful for diagnosis of neosporosis and rickettsial diseases. *Neospora caninum* serum antibody titers are usually very high (>1:800) in infected dogs and do not crossreact with toxoplasmosis titers. Dogs exposed to the organism but without clinical signs of infection may also have high titers.

- MRI features of CNS infectious diseases include patchy edema and focal to multifocal contrast-enhancing lesions of the parenchyma. Some fungal and protozoal granulomas and bacterial abscesses can ring enhance. Edema can be severe with bacterial encephalitis. Meningeal enhancement is common, especially with bacterial meningoencephalitis. FIP is

Table 126-3. ANTIMICROBIAL DRUGS FOR CENTRAL NERVOUS SYSTEM INFECTIONS

Drug	BBB Penetration	Bacteriocidal vs. Bacteriostatic	Dose (mg/kg)	Route	Frequency (hrs)	Antimicrobial Spectrum
Amphotericin B	Poor	Static	0.15–0.50	IV	48	Fungi (crypto)
Ampicillin	Intermediate	Cidal	10–20	IV	6	Broad (except BLRSE)
Cefotaxime	Good	Cidal	20–50	IV	6	Broad (except *Salmonella*)
Cefepime	Good	Cidal	40–50	IV	6	Broad (except *Bacteroides, Clostridium, Enterobacter*)
Ceftazidime	Good	Cidal	15–30	IV	6–8	Broad (except *Enterococcus*)
Ceftiofur	Poor to intermediate	Cidal	2.2–4.4	SQ	12	Broad (except *Pseudomonas, Enterococcus, Bacteroides, Bordetella*)
Ceftriaxone	Good	Cidal	15–50	IV, IM, SQ	12	Broad (except *Enterococcus, Salmonella*)

Cefuroxime	Good	Cidal	30	IV	8	Broad (except BLRSE)
Cephalexin	Poor	Cidal	20–30	PO	8	Gm+ (except BLRSE)
Chloramphenicol	Good	Static	25–50	PO	6–8	Gm– (except *Pseudomonas, Klebsiella*), some Gm+
Clavamox	Poor	Cidal	10–20	PO	8–12	Broad (except *Pseudomonas, Enterococcus*)
Clindamycin	Poor	Static/cidal	12.5–20.0	PO, IM	12	Gm+, anaerobes, protozoa
Doxycycline	Intermediate	Static	5	PO	12	Rickettsial
Enrofloxacin	Intermediate	Cidal	5–10	IV, SQ, PO	12	Gm–
Florfenicol	Good	Static	25–50	IM, SQ	8	Broad
Fluconazole	Good	Static	5–10	PO	12–24	Fungi (crypto)
Flucytosine	Intermediate	Static	50	PO	6	Fungi (crypto)
Gentamicin	Poor	Cidal	2–4	IV, IM	8–12	Gm–
Itraconazole	Poor	Static	5	PO	12–24	Fungi (crypto)
Ketoconazole	Poor	Static	10–20	PO	12–24	Fungi (crypto)
Metronidazole	Good	Cidal	10–15	PO	8	Anaerobes
Penicillin G	Poor to intermediate	Cidal	20,000–40,000 U/kg	IV	6	Broad (except BLRSE)
Pyrimethamine	Good	Cidal	1 (cats: 0.25–1.00)	PO	24	Protozoa
Rifampin	Good	Cidal	10–20	IV	24	Gm+, *Chlamydia*
Tetracycline	Intermediate	Static	22	PO	8	Rickettsial
Trimethoprim-sulfadiazine	Good	Cidal	15–30	PO, SQ	12	Broad (except *Pseudomonas*, anaerobes), protozoa
Vancomycin	Poor to intermediate	Cidal	15	IV	6	Gm+, BLRSE (except Gm–)

BBB, blood-brain barrier; BLRSE, beta-lactamase–resistant *Staphylococcus* and *Enterococcus* species; Broad, broad spectrum including Gm+, Gm–, and anaerobic bacteria; IM, intramuscularly; IV, intravenously; PO, per os; SQ, subcutaneously.

often characterized by periventricular and meningeal contrast enhancement and ventricular dilatation due to secondary hydrocephalus. Fungal granulomas and bacterial abscesses may resemble intracranial tumors due to their patterns of enhancement and perilesional edema.

- Occasionally, a brain biopsy may be needed to make a definitive diagnosis.

Treatment

- Medical therapy for infectious brain diseases is presented in Table 126-3. Protozoal and fungal infections frequently require prolonged therapy. The recommended treatment duration for CNS cryptococcal and coccidioidal infections with fluconazole is 9 to 12 months. In dogs, treatment of cryptococcal infections is stopped after two consecutive negative titers are obtained at least 4 weeks apart. Relapses are common if fluconazole therapy is stopped too early.
- Initial treatment of bacterial meningoencephalitis is most effective if parenteral antibiotics are administered. Parenteral (usually intravenous) administration allows rapid therapeutic CNS and CSF drug concentrations to be achieved. Penicillin or ampicillin in combination with third-generation cephalosporins have a broad antimicrobial spectrum and are bactericidal (see Table 126-3). Many third-generation cephalosporins also cross the blood-CSF and blood-brain barrier in both the presence and the absence of inflammation. Concurrent low-dose dexamethasone therapy (0.15 mg/kg IV every 6–8 hours for 4 days) has been shown to be beneficial in human bacterial meningoencephalitis. After 3 to 5 days of parenteral

therapy, inflammation resolves and the barrier to the entry of many antibiotics is restored. Extended therapy is then instituted with broad-spectrum oral antibiotics that penetrate non-inflamed meninges. These drugs include trimethoprim-sulfonamide, chloramphenicol, florfenicol, and fluoroquinolones. Metronidazole is often added if an anaerobic component to the infection is suspected.

▼ ***Key Point*** Treatment failures usually relate either to delays in antibiotic administration or to selection of antibiotics with an inadequate spectrum, poor CNS penetrating abilities, or lack of bactericidal properties.

IDIOPATHIC INFLAMMATORY BRAIN DISORDERS

Most of these conditions have an immune-mediated pathogenesis with clinical signs limited to the CNS.

Granulomatous Meningoencephalomyelitis

Etiology

Granulomatous meningoencephalomyelitis (GME) is an idiopathic, immune-mediated condition in dogs characterized by pronounced inflammatory changes in the CNS. These changes tend to predominate in white matter areas of the brain and spinal cord. Perivascular accumulations of lymphocytes, plasma cells, and histiocytic-like cells are the hallmark of GME. Some perivascular cell aggregates may coalesce to form a space-occupying mass in the brain. GME should be distinguished from neoplastic reticulosis and from B cell lymphoma in which homogeneous populations of neoplastic cells predominate. Whether inflammatory cells in GME eventually undergo neoplastic transformation to these cancerous phenotypes is still unknown. At present, the mixed granulomatous cell response is believed to represent a chronic immune response to a suspected but unconfirmed antigen.

Three forms of GME have been described. The *disseminated form* is characterized pathologically by multifocal perivascular cuffs throughout the brain and spinal cord and clinically by multifocal neurologic signs. The *focal form* is characterized by a focal neurolocalization due to the presence of a granulomatous mass in the brain stem, the cerebrum, or more rarely, the spinal cord. The focal form, however, is probably a variant of the disseminated form since histologic lesions can usually be identified postmortem all throughout the neuraxis. A rare *optic form* with dense optic nerve infiltration by inflammatory cells is also recognized.

Clinical Signs

- GME is primarily a disease of toy and small breeds between 1 and 8 years of age. Large-breed dogs may occasionally be affected (e.g., Airedale terriers).
- Onset and progression of clinical signs may be more rapid (several days) in the disseminated form compared with the focal form (1–3 weeks).
- Initially, mild fever, lethargy, and intermittent anorexia may be the only clinical signs seen.

▼ ***Key Point*** Neurologic signs of GME often indicate a focal brain stem or cerebral lesion.

- Central vestibular signs are common and may be paradoxical (see "Neoplasia"). Long tract signs (proprioceptive deficits and paresis) and other cranial nerve deficits (CN5 and CN7) may be present.
- Neck pain is often present and indicates meningeal involvement.
- Focal or multifocal areas of intramedullary spinal cord inflammation (myelitis) may cause tetraparesis or caudal paresis.
- The optic form is characterized by a sudden onset of bilateral or unilateral blindness.

Diagnosis

- A marked mononuclear pleocytosis consisting of lymphocytes, plasma cells, monocytes, macrophages, and multinucleated giant cells is usually evident on CSF analysis. Neutrophils may be present. Rarely, CSF cytology is normal. Protein is usually elevated.
- CSF titers, cultures, and virus isolation studies are negative for any infectious etiology.
- CT or MRI may reveal focal or multifocal contrast-enhancing lesions (homogeneous or heterogeneous) with edema in white matter adjacent to the lesions.
- GME is a diagnosis of exclusion. A predominant mononuclear CSF pleocytosis and negative tests for infectious agents (rickettsial, fungal, bacterial, protozoal, viral) suggest a diagnosis of GME. If the CSF is normal and a focal lesion is present, a brain biopsy is necessary to rule out neoplasia.

Treatment

- Prednisone at 2 mg/kg every 12 hours for 2 weeks, then 1 mg/kg every 12 hours for 1 to 2 months fol-

lowed by a gradual taper over several months, will usually result in temporary remission of clinical signs in the focal form. The disseminated form has a less favorable response to therapy. The optic form, if treated in the early stages, can result in recovery of vision.
- Other therapies for GME include lomustine, azathioprine, cytosine arabinoside, procarbazine, cyclophosphamide, and cyclosporine. I prefer lomustine as maintenance therapy. The dosage is 60 mg/m^2 of body surface area every 4 to 6 weeks for 12 to 24 months. Lomustine therapy can be initiated early in the course of corticosteroid therapy.
- Radiation therapy for the focal form of GME may be of benefit as adjunctive therapy.

Prognosis

Relapses are common and may occur weeks to months (up to 48 months) following onset of therapy. Upon relapse, patients are often refractory to a second course of chemotherapy.

Necrotizing Encephalitis

Etiology

Necrotizing encephalitis is a brain disease of toy breeds (pugs, Maltese terriers, and Yorkshire terriers). The acute disease bears many similarities to GME and may have an immune-mediated component. Lymphocytes and histiocytes form large perivascular cuffs in cerebrum. Neuronal necrosis and malacia in both gray and white matter are more severe in necrotizing encephalitis than in GME. Multifocal, necrotic, cavitating lesions are commonly observed in the chronic stages. A familial predisposition is probable, but this disorder is considered idiopathic.

Clinical Signs

- Age of onset of clinical signs is 9 months to 5 years of age.
- Seizures, dementia, blindness, neck pain, and ataxia are seen in the acute form. Over 1 to 2 weeks, signs may or may not progress to coma and/or status epilepticus.
- In the chronic form, partial or generalized seizures are initially seen but the interictal neurologic examination is normal. Other forebrain signs and progressive seizure activity develop over the subsequent 4 to 12 months.
- Brain stem and cerebellar signs are also reported.

Diagnosis

- A diagnosis of necrotizing encephalitis is supported by clinical signs and a CSF mononuclear pleocytosis. Small lymphocytes predominate in the majority of affected dogs. More pronounced pleocytosis is seen in the acute form or in the early stages of the chronic form. Protein levels are increased.
- MRI in the acute form shows asymmetrical cerebral edema that affects white and gray matter. Patchy or scant contrast enhancement may be seen acutely. In chronic cases, MRI changes include asymmetrical cortical cavitation, ventriculomegaly, and atrophy. Cavitated, cystic lesions are frequently periventricular. Chronic lesions fail to contrast enhance. Concurrent thalamic, midbrain, and cervical lesions have also been identified in selected cases.
- The primary differential diagnoses are GME, infectious disease, and neoplasia. An additional differential diagnosis for the chronic form is cerebrovascular disease.

Treatment

Use immunosuppressive therapy as for GME and anticonvulsant therapy.

Prognosis

The prognosis is guarded to poor.

Generalized Idiopathic Tremors (Little White Shaker Syndrome) of Adult Dogs

Etiology

An acute onset of tremor in toy- to small-breed dogs with white coat color (Maltese terrier, West Highland white terrier, poodle, Bichon frisé, Samoyed) is recognized. Other breeds with other coat colors (beagle, miniature schnauzer, spitz, Yorkshire terrier, etc.) can also be affected. This syndrome was originally described by some authors as a "non-suppurative encephalitis" or "cerebellitis" due to the occasional finding of a non-suppurative meningoencephalitis involving the cerebellum and other brain areas. A demyelinating disorder, a neurotransmitter defect, and various other mechanisms have been hypothesized but not proven.

Clinical Signs

- Young adult dogs (less than 6 years of age) are affected.
- The onset is acute to peracute.
- Clinical signs are a severe coarse head and body tremor that worsens with stress, exercise, or handling. At rest or during sleep, the tremor diminishes. Continuous shaking makes ambulation difficult, but strength and motor abilities are preserved. The excessive muscle activity may cause hyperthermia.
- Disconjugate, jerky eye movements may be seen (opsoclonus).
- Dogs are alert and responsive and rarely have other neurologic deficits.

Diagnosis

- Differential diagnoses include neurotoxin exposure ("moldy cheese" toxicity, metronidazole toxicity), other inflammatory CNS diseases, and generalized seizures. Generalized tremors in the absence of other signs of neurologic or systemic illness suggest a diagnosis of shaker syndrome.
- CSF may be normal or a mild lymphocytic pleocytosis may be seen.

Treatment

- Cool the patient if hyperthermic.
- Diazepam, 0.5 to 1.0 mg/kg PO every 8 hours, will help alleviate signs in the short term.
- Prednisone, 1 mg/kg every 12 hours for 4 weeks followed by a gradual taper over the next 8 weeks, appears to be the most effective treatment. Some dogs may recover without therapy.

Prognosis

- The prognosis is good for recovery. Relapses may occur.

VASCULAR DISEASES

Vascular Encephalopathies Secondary to Systemic Disorders

Etiology

Vascular encephalopathies can affect the forebrain, cerebellum, or brain stem of dogs and cats. Affected animals are usually older. Signs are peracute and rarely progressive. Focal ischemia or infarction ("stroke") usually occurs due to thrombosis of a brain blood vessel secondary to hypercoagulable states, hyperviscosity syndromes, atherosclerosis, vasospasm (from hypertension), local vasculitis, tumor emboli, or tumor invasion of regional blood vessels. A primary cause may not be found in many cases. Spontaneous hemorrhage in the CNS can occur due to thrombocytopenia, coagulopathies, vasculitis (immune-mediated or infectious), neoplastic invasion of blood vessels (especially from hemangiosarcomas), traumatic or ischemic damage to vessels, or arteriovenous malformations or aneurysms. Traumatic injuries to the brain and its vessels are discussed under "Brain Trauma." Other common causes of vascular disease in small animals are discussed in subsequent sections.

Clinical Signs

- Common zones of ischemia in the dog and cat include those brain areas supplied by the middle cerebral artery (forebrain) and rostral cerebellar artery (cerebellum).
- Signs of focal ischemia are almost always asymmetrical and reflect the areas of the CNS involved. Signs of unilateral forebrain disease (seizures, circling, dementia, aggression, contralateral blindness, and CP deficits) and signs of cerebellovestibular disease (ataxia, head tilt, nystagmus, hypermetria, torticollis) may be seen. Some dogs with cerebellar infarcts may show paradoxical vestibular signs.

Diagnosis

- Hypercoagulable states can occur due to renal disease with protein-losing nephropathy, Cushing's disease, and septicemia. A CBC, chemistry profile, urinalysis, urine protein-to-creatinine ratio, ACTH stimulation test, thoracic radiographs, and abdominal ultrasound are necessary to rule out these disorders.
- Atherosclerosis can occur due to hypothyroidism and is also recognized in miniature schnauzers with hyperlipoproteinemia. A thyroid panel, fasting triglycerides, and a lipid/cholesterol panel are recommended.
- Hypertension in dogs and cats may be associated with hypothyroidism, hyperthyroidism, Cushing's disease, diabetes mellitus, renal insufficiency, hepatic insufficiency, pheochromocytoma, and phenylpropanolamine administration. Idiopathic or essential hypertension is also being recognized with greater regularity. Serial blood pressure monitoring, retinal examination, and appropriate testing to rule out the above disorders are warranted if hypertension is present (see Chapter 153).
- Hyperviscosity syndromes can occur secondary to gammopathies, polycythemia vera, and hyperfibrinogenemia. Protein electrophoresis and coagulation profiles may be indicated.
- MRI is very important in determining the extent of the ischemia or hemorrhage and potential local concurrent conditions (tumor, inflammation, arteriovenous malformation) that could have produced it. Pure areas of ischemia are primarily hypointense on T1-weighted images and hyperintense on T2-weighted and fluid-attenuated inversion recovery images. Secondary edema, especially during reperfusion, can cause a transient mass effect with signs of acute brain swelling, but this is not common and usually no mass effect is evident. Contrast enhancement is minimal to absent in most cases, although a peripheral rim enhancement of the lesion can be seen starting 1 week after onset. Chronically, large areas of infarction "collapse" due to atrophy and loss of parenchymal volume. A paradoxical "mass effect" could be incorrectly diagnosed due to a contralateral shift of the brain midline and ventricles toward the side of the infarction.
- CSF analysis can be normal or show a mild increase in cells and protein. If acute, cells may be predominantly neutrophils.

Treatment

- Treatment for brain ischemia depends on the severity of the event and the correction of an existing underlying cause.
- Severe infarction can cause secondary brain edema that could require mannitol therapy (0.5–1.0 g/kg IV over 20 minutes). Careful but adequate fluid therapy to maintain a euvolemic state is essential.
- Anticonvulsants may be necessary if seizures occur. Anticonvulsant drugs that have fewer sedative properties (felbamate, zonisamide, gabapentin, levetiracetam) will permit better assessment of neurologic recovery.
- Hypertension can usually safely be treated with angiotensin-converting enzyme inhibitors (enalapril) or vasodilators (amlodipine, prazosin). Heparin, warfarin, and aspirin are used routinely in humans after a stroke if atherosclerosis is suspected. Treatment of any predisposing causes of vascular disease is essential.

Prognosis

▼ ***Key Point*** Vascular encephalopathies can cause severe signs initially, but many of the signs improve steadily with time (over 2–3 months) and generally have a good prognosis.

Feline Ischemic Encephalopathy

Etiology

This is an idiopathic syndrome of young to middle-aged cats characterized by a peracute onset of unilateral cerebral infarction due to vasospasm of the middle cerebral artery. The pathogenesis of this disease is not well understood. It is usually *not* associated with thromboembolic disease secondary to feline hypertrophic cardiomyopathy or any other etiology. An association between aberrant *Cuterebra* species migration in brain and possible middle cerebral artery vasospasm has been suggested because of the occasional finding of this parasite in the cranial vault. There is a higher incidence of this syndrome in late summer.

Clinical Signs

- Affected cats often exhibit peracute signs of unilateral cerebral dysfunction. Altered mentation, behavior change, circling, visual field deficits, contralateral postural deficits, seizures, or a combination of these signs may be observed.
- Seizures may be the only clinical sign observed.
- Signs may worsen slightly over 24 to 48 hours but then stabilize.
- If the injury is not fatal, signs may steadily improve over days to months.
- Seizures and altered personality may be long-term sequelae.

Diagnosis

- Rule out other causes of unilateral cerebral dysfunction and peracute vascular disease (cardiomyopathy-associated thromboemboli, hypertension, hypercoagulable states, infectious vasculitis, neoplasia, trauma).
- CSF analysis may reveal a pleocytosis and elevated protein due to inflammatory changes induced by necrotic tissue.
- MRI in acute stages demonstrates cerebral edema, usually without significant mass effect. Chronically, asymmetrical atrophy of cortical regions supplied by the middle cerebral artery will be seen.
- The peracute onset of signs in an otherwise healthy cat aids in making a tentative diagnosis.

Treatment

- There is no specific treatment.
- Corticosteroids do not alter the clinical course.
- Start anticonvulsant therapy (diazepam or phenobarbital) if seizures occur (see Chapter 127).

Prognosis

The prognosis for survival is fair to good. The prognosis for complete recovery is guarded.

Necrotizing Vasculitis of the Beagle, Bernese Mountain Dog, and German Shorthaired Pointer

Etiology

A necrotizing vasculitis of young adult beagles, Bernese mountain dogs, and German shorthaired pointers is frequently associated with neurologic signs. This is an idiopathic condition, but a genetic predisposition is suspected. The typical lesion is a fibrinoid necrosis and thrombosis of small- and medium-sized meningeal vessels with subsequent meningeal fibrosis. A marked inflammatory component to the lesion suggests an immune-mediated basis for the disease. Meningeal artery damage may lead to hemorrhage or to thrombosis or infarction of adjacent neural parenchyma.

Clinical Signs

- Age of onset is 3 to 18 months of age.
- Signs of meningitis (neck pain and stiffness, stiff, stilted gait, fever) are common. "Painful" episodes may wax and wane. Clinical signs of meningitis are very similar to sterile suppurative meningitis of young, large-breed dogs.
- Secondary parenchymal involvement may result in conscious proprioceptive deficits and paresis. Rarely, cranial deficits occur.
- Blindness and seizures are seen secondary to an associated encephalitis in Bernese mountain dogs.
- Beagles may have neutrophilic polyarthritis and coronary arteritis associated with the neurologic disease.

Diagnosis

- CSF analysis is characterized by a marked neutrophilic pleocytosis and elevated protein levels. No infectious agents can be isolated, and titers for infectious causes of meningitis (rickettsial, viral, bacterial, fungal, protozoal) are negative.
- GME can be ruled out based on the CSF findings.
- Intervertebral disc disease is ruled out by the demonstration of no compressive lesions on cervical myelography.
- Antinuclear antibody titers are negative, and there is no evidence of neoplasia or a drug reaction.

Treatment

- Immunosuppressive dosages of corticosteroids (2 mg/kg PO every 12 hours for 2 weeks with a very slow taper over 3–6 months) often result in a clinical response.
- Occasionally patients are nonresponsive and may require other immunosuppressive agents.

Prognosis

The prognosis is fair to guarded. Some patients do not respond to therapy. Relapses can occur.

Infectious Causes of Vasculitis

Etiology

Many of the infectious causes of vasculitis have previously been discussed in "Inflammatory Brain Diseases" (see Tables 126-1 and 126-2). Various fungal, protozoal, and viral agents may create secondary blood vessel inflammation with edema, hemorrhage, or infarction. Rickettsial disorders may produce an immune-mediated vasculitis and direct damage to endothelial cells due to intracellular replication. Bacterial vasculitis occurs most commonly as a sequela to sepsis. Bacterial toxins and inflammatory mediators released by neutrophils increase vascular permeability and cause edema and hemorrhage. Septic thromboemboli lead to multiple areas of infarction.

Clinical Signs

- Diffuse or multifocal vasogenic edema can result in brain swelling and diffuse cerebral signs of dullness, dementia, head pressing, and pacing. Signs of brain herniation may be evident.
- Head and neck pain are common due to accompanying meningitis.
- Multifocal cranial nerve deficits and long tract signs reflect multifocal involvement of the brain stem and spinal cord. Rickettsial diseases are often associated with central vestibular signs.
- Focal or generalized motor seizures and other focal cerebral signs may be seen.
- Systemic signs of fever, lymphadenopathy, polyarthritis, uveitis, and peripheral edema are sometimes present.

Diagnosis

- CSF characteristics will depend on the inciting cause (see "Inflammatory Brain Diseases" and Tables 126-1 and 126-2). The degree of pleocytosis is often determined by the degree of meningitis. Bacterial vasculitis is characterized by normal or neutrophilic pleocytosis and high protein levels.
- Xanthochromia, free blood, and erythrophagocytosis by neutrophils or macrophages are typical CSF findings in patients with previous hemorrhage.
- Gram stains and other special stains may demonstrate organisms.
- Appropriate CSF titers and cultures will often reveal the underlying pathogen.
- A CBC, a chemistry profile, and other blood tests will frequently uncover abnormalities in other organ systems.

Treatment

- Treatment is directed at the underlying etiologic agent.
- See "Inflammatory Brain Diseases" and Table 126-3 for properties of specific antimicrobial agents.

Prognosis

The prognosis will vary depending on the underlying pathogen, its sensitivity to chemotherapies, and the state of disease progression. Aggressive medical therapy is necessary to prevent irreversible brain injury.

BRAIN TRAUMA

Pathophysiology

Severe head trauma can result in acute brain injury. Primary mechanical injury to cell membranes and fiber tracts results in irreversible necrosis. This can take the form of a blunt contusion or a laceration. Secondary events are due to biochemical changes at the cellular level and increased ICP. Excitotoxins, free radicals, prostaglandins, and inflammatory cytokines fuel a self-perpetuating cycle of ischemia and necrosis in the traumatized brain. Intracranial edema and hemorrhage combine to raise ICP, exhaust compensatory mechanisms, and create conditions favorable for brain herniation. Elevated ICP may also lead to bradycardia, systemic hypertension, and neurogenic pulmonary edema. A final immediate or delayed consequence of brain trauma is epilepsy. Seizures can be seen months following head trauma.

Clinical Signs

- The signs of brain trauma will depend upon whether the lesion remains localized or progresses to involve other brain structures. If progression occurs, it will occur within the first 24 to 48 hours after an injury. For this reason, it is critical to perform serial neurologic examinations every few hours in traumatized patients.
- Focal signs may originate from injury to the cerebrum, cerebellum, or brain stem and will reflect dysfunction of the region involved.
- Signs of increased ICP, transtentorial herniation, and foramen magnum herniation are discussed in the first section of this chapter, under "Herniation from Space-Occupying Brain Lesions." An orderly progression of signs due to increased ICP can be graded from mild to severe.
  - Motor activity tends to progress from normal ambulatory status to recumbency with progressive extensor rigidity.
  - Pupils initially appear miotic but soon become mydriatic or midrange and nonresponsive to light.
  - The oculovestibular reflex (doll's eye) is lost in the late stages of transtentorial herniation and is a poor prognostic sign.
  - Level of consciousness deteriorates from the alert state to depression, stupor, and coma. These states are defined by the patient's responsiveness to stimuli, including deep pain.
  - Hyperventilation may be seen with midbrain compression, whereas either an ataxic (irregular) respiratory pattern or apnea may be seen with medullary compression.

Diagnosis

- Clinical signs usually reflect the severity of the injury.
- Use an EEG and BAER can be used to localize areas of brain damage (see Chapter 125). The EEG can also be used to detect seizure foci.
- Consider CT and MRI in those patients with progressive neurologic dysfunction despite medical therapy or if unstable skull fractures are present. Progression of clinical signs may occur secondary to a space-occupying epidural or subdural hematoma or secondary to compression and/or laceration of brain parenchyma by a depressed or displaced skull fracture. CT is often preferred over MRI due to its sensitivity to bony changes and intracranial hemorrhage and also the shorter examination time required compared with MRI.
- A CSF tap is rarely necessary. It is contraindicated in the patient with increased ICP.

Treatment

- Correct hypovolemic shock, pneumothorax, cardiac arrhythmias, and other life-threatening non-neural injuries. When correcting for shock, do not overhydrate the patient.
- Elevating the head will facilitate venous return to the heart, enhance CSF resorption, and help maintain cerebral blood flow. Avoid jugular vein compression when elevating the head.
- Hypercarbia will act to cause cerebral vasodilation and increased ICP. Intubation and hyperventilation will lower blood and brain carbon dioxide concentrations and stimulate vasoconstriction. Vasoconstriction of cerebral vessels will decrease intracranial blood volume, lower ICP, and raise cerebral perfusion pressure.
- Methylprednisolone sodium succinate (Solu-Medrol) may be of some benefit if administered at the time of or immediately following the trauma (within 1 to 2 hours). Administer methylprednisolone sodium succinate at 30 mg/kg as an intravenous bolus, then give repeat boluses of 15 mg/kg IV at 2 hours and then every 6 hours for 1 to 2 days. After this, discontinue the steroids.
- Mannitol and furosemide are administered if signs of impending herniation are present. Administer a single (1 g/kg) IV bolus of mannitol as a 20% solution at a rate of 2 ml/kg/min. Administer 0.7 mg/kg of furosemide IV 15 minutes after mannitol. Furosemide will prolong the effects of mannitol and decrease CSF production.
- Use hypertonic saline (7.5% as a 4 ml/kg IV bolus) with hydroxyethyl starch (20 ml/kg IV) in a patient that presents with both hypovolemic shock and head trauma or cerebral edema. Hypertonic saline will lower ICP as long as there is no bleeding from a major vessel. Hydroxyethyl starch will prolong the effects of the hypertonic saline. Follow these boluses with lactated Ringer's solution at a dosage of 40 to 50 ml/kg/hour. If there is significant bleeding, administer whole blood or plasma at 25 ml/kg over 1 hour (do not use hypertonic saline or mannitol). Follow with lactated Ringer's solution at a dosage 40 to 50 ml/kg/hour. Fluid therapy is discussed in Chapter 5 and management of shock is described in Chapter 156.
- Administer intravenous diazepam to control seizures. Intravenous phenobarbital and other anticonvulsants may be needed in some cases (see Chapter 127). Initiate oral anticonvulsant (phenobarbital) therapy and do not taper or discontinue treatment unless the patient remains seizure free for a minimum of 6 months.
- Monitor supportive fluid therapy to prevent overhydration or dehydration (see Chapter 5). Patients should be turned and kept on padded bedding. Intermittent bladder expressions or catheterizations may be necessary. Initiate parenteral or enteral nutritional support as needed (see Chapter 3).

METABOLIC ENCEPHALOPATHIES

The brain relies on the body's various homeostatic mechanisms to control extracellular osmolality, electrolyte concentrations, acid-base balance, oxygenation, and glucose levels. Potentially neurotoxic metabolites are continuously removed from the body by fully functional hepatic and renal systems. If homeostatic mechanisms are disrupted, normal brain function may be impacted and physical brain injury may occur. The cerebrum is often the major brain region affected by metabolic encephalopathies. Altered behavior, depressed mentation, and seizures are common manifestations of diffuse cerebral dysfunction. Table 126-4 lists important metabolic causes of brain disease, specific regional vulnerabilities, clinical signs, and treatment. Etiologies, pathogenic mechanisms, diagnosis, and further descriptions of each disorder are discussed in detail in other sections of this text and the following chapters:

- Osmotic and ionic imbalances—Chapter 5
- Acid-base imbalances—Chapter 5
- Hypoglycemia—Chapters 34 and 35
- Hypoxia
- Renal failure and uremia—Chapter 77
- Hepatic encephalopathy and liver failure—Chapter 71

THIAMINE (VITAMIN B_1) DEFICIENCY

Etiology

Thiamine is a water-soluble B vitamin that is an essential dietary nutrient. Depleted body stores of thiamine may be a result of deficient thiamine in the diet, a prolonged period of anorexia, or chronic ingestion of all-fish diets containing thiaminase. Thiamine deficiency results in altered energy metabolism, decreased adenosine triphosphate (ATP) formation, and eventual cell death. Neurons in brain stem nuclei are most vulnera-

Table 126-4. IMPORTANT METABOLIC ENCEPHALOPATHIES IN SMALL ANIMALS

Condition	Causes	Brain Region Affected	Clinical Signs	Treatment
Global hypoxia/ischemia	Pulmonary disease, anemia, carbon monoxide, cyanide, shock, cardiac disease or arrest	Cerebrum (occipital region), cerebellum, hippocampus	Blindness, seizures, ataxia, memory loss, coma	Correct underlying cause; give fluids, oxygen, mannitol and furosemide for edema
Hypoglycemia	Juvenile hypoglycemia, insulinoma, sepsis, severe liver disease, Addison's disease	Cerebrum, cerebellum, hippocampus	Ataxia, weakness, collapse, pupillary changes, depressed mentation, seizures, focal facial twitches	Correct underlying cause
Hypocalcemia	Eclampsia, hypoparathyroidism, renal failure, others	Cerebrum (neuromuscular junction)	Muscle tremors, spastic tetraparesis/tetany, behavior change, seizures, myoclonus	0.5–1.5 ml/kg, up to 10 ml total of 10% calcium gluconate, slow IV
Hypernatremia	Diabetes insipidus, severe dehydration, adipsia, primary hyperaldosteronism	Cerebrum	Ataxia, weakness, tremors depression, seizures, coma	Slow correction with normal saline then half-strength saline
Hyponatremia	Diuretics, Addison's disease, inappropriate adh secretion, water intoxication	Cerebrum	Depression, stupor, coma	Slow correction with normal saline then hypertonic saline; will induce pontine or thalamic myelinolysis if corrected too fast
Uremia	ARF, CRF	Cerebrum	*For ARF:* Seizures, tremors, myoclonus, non-fixed muscle twitches *For CRF:* Dementia, depression, coma	Correct underlying cause; use anticonvulsants if seizures, oral phosphate binders, cimetidine
Hepatic encephalopathy	Portocaval shunt, acquired liver disease	Cerebrum	Episodic dementia, head pressing, pacing, ataxia, visual deficits, seizures, ptyalism	IV fluids with potassium, colon evacuation, lactulose or dilute providone enemas, metronidozole PO; low-protein, high-carbohydrate diet; surgery for shunt ligation

ARF, acute renal failure; CRF, chronic renal failure.

ble to this energy deficit. Cats are much more frequently affected than dogs, presumably because of lower body stores of the vitamin.

Clinical Signs

- Signs may be intermittent initially but are rapidly progressive once present. Affected cats are often thin or on a poor diet.
- Head and neck ventroflexion and ataxia may progress to recumbency, extensor rigidity, opisthotonus, and coma.
- Ocular changes include mydriasis, sluggish to no pupillary light reflexes, blindness, and absence of the oculovestibular reflex.
- Positional vertical nystagmus is common. Seizures may be present.
- Sudden death can occur 24 to 48 hours after onset of signs.

Diagnosis

- Rule out other causes of acute brain stem or central vestibular signs in the cat, including FIP, cryptococcosis, toxoplasmosis, and vascular disorders.
- CSF may show a slight pleocytosis and protein elevation and/or xanthochromia due to ongoing necrosis and hemorrhage.
- Erythrocyte transketolase activity may be decreased and blood pyruvate and lactate levels may be increased.
- Blood thiamine levels may be normal or decreased.
- Response to therapy is the usual method of diagnosis.

Treatment

- Give parenteral thiamine at a dosage of 25 to 50 mg per cat intramuscularly or subcutaneously every 12 hours until signs resolve.
- Institute a balanced diet and supplement with B vitamins for at least 2 weeks.
- A dramatic response to thiamine is usually seen in 24 to 48 hours.

Prognosis

The prognosis is good with prompt therapy. If pretreatment signs are severe, the response may be incomplete. The condition is fatal if no treatment is instituted.

NEUROTOXINS

A variety of toxins can affect the CNS in dogs and cats. Multisystemic signs may or may not be present. Any region of the neuraxis can be affected. Those neurotoxins that result in signs of brain dysfunction are discussed below.

For most ingested toxins, general treatment guidelines include the following:

- Induction of vomiting with 2 ml/kg of 3% hydrogen peroxide (except in comatose or obtunded patients or in the case of petroleum distillate or alkali ingestion) if it has been less than 2 hours since ingestion.
- Gastric lavage under anesthesia if it has been less than 2 hours since ingestion. Use 5 to 10 ml/kg of water for each lavage and lavage several times. Leave activated charcoal in the stomach after the final lavage.
- Administration of activated charcoal 2 g/kg orally by stomach tube.
- Administration of a cathartic (usually magnesium sulfate) at the same time as or 30 minutes following activated charcoal administration.
- Colonic lavage and enemas (especially for heavy metals).

Lead Poisoning

Etiology

Lead poisoning is a sporadic problem caused by ingestion of lead-containing paint chips, plaster board and sheetrock, grease, crankcase oil, linoleum, battery parts, solder, putty and caulking material, roofing material, and occasionally lead-contaminated soil. Younger animals are more frequently affected than older animals due to chewing tendencies, increased gastrointestinal absorption, and increased blood-brain barrier permeability. Acute toxicity is generally seen, but chronic exposure to low levels of lead may lead to a cumulative toxicity. Within the CNS, lead causes endothelial cell damage, edema, hemorrhage, and cerebrocortical laminar necrosis.

Clinical Signs

- Acute systemic signs of vomiting, diarrhea, anorexia, and abdominal pain may be seen. A rare finding is megaesophagus.
- Neurologic signs include hysteria, behavior change, pica, vocalization, and blindness.
- Either generalized or focal motor seizures may be present. “Chewing gum” seizures and myoclonus may be observed.

Diagnosis

- A blood lead level greater than 40 µg/dl is suggestive of lead poisoning. A level greater than 60 µg/dl is diagnostic for lead poisoning.
- Urinary lead levels will be elevated approximately 24 hours after the start of chelation therapy.
- Abdominal radiographs may reveal radiopaque material in the gastrointestinal tract.
- Nucleated red blood cells and basophilic stippling are often evident on stained blood smears.

Treatment

- If lead is visible in the gastrointestinal tract, administer cathartics and enemas.

- Use any one of the following chelating drugs:
  - Calcium disodium ethylenediaminetetraacetic acid at 25 mg/kg SC every 6 hours for 5 days. Prepare a 1% solution in 5% dextrose in water. Side effects are anorexia, diarrhea, and nephrotoxicity.
  - D-penicillamine at 110 mg/kg/day PO divided into three or four doses every 6 to 8 hours for 2 weeks. Gastrointestinal side effects are common.
  - 2,3-Dimercaptosuccinic acid at 10 mg/kg/day PO for 10 days. Side effects are rare.
- Administer anticonvulsants for seizures (diazepam, phenobarbital) (see Chapter 127).
- Treat suspected cerebral edema with mannitol and corticosteroids.

Prognosis

The prognosis is fair to good if neurologic debilitation is not severe. Residual neurologic deficits and seizures may be long-term sequelae.

Metaldehyde Poisoning

Etiology

Metaldehyde is a molluscide that can produce signs of neurotoxicity after oral ingestion. Metaldehyde produces a severe metabolic acidosis. Levels of the CNS neurotransmitters gamma-aminobutyric acid (GABA), norepinephrine, and serotonin are decreased in affected animals. The exact mechanism of neurotoxicity is unknown.

Clinical Signs

- Seizures, tremors, depression, salivation, tachycardia, hyperesthesia, hyperthermia, vomiting, and diarrhea are seen peracutely. Cats may also have nystagmus and ataxia. Respiratory failure may develop within 24 hours.
- If animals survive the initial toxic insult, hepatic failure occurs 3 to 4 days after ingestion.

Diagnosis

- Compatible signs, acidosis, and a history of exposure are suggestive of metaldehyde intoxication.
- A definitive diagnosis can be made by chemical analysis of stomach contents, urine, or liver tissue.

Treatment

- Perform gastric lavage and administer activated charcoal if it is within 2 hours of ingestion.
- Use sodium bicarbonate to treat the acidosis.
- Anticonvulsants are indicated for seizure control (see Chapter 127).

Prognosis

The prognosis for recovery is poor.

Methylxanthine Toxicosis (Caffeine, Theobromine, etc.)

Etiology

Ingestion of stimulants containing caffeine, theophylline, aminophylline, or theobromine may produce signs of methylxanthine toxicosis. Chocolate contains both caffeine and theobromine. Ingestion of 1 ounce of baker's chocolate per kilogram of body weight can be lethal in the dog. Although it is known that methylxanthines inhibit phosphodiesterases, increase calcium influx into cells, and enhance catecholamine release, the mechanism of its neurotoxicity is unknown.

Clinical Signs

- Tachycardia, cardiac arrhythmias, vomiting, polyuria and polydipsia, hyperthermia, respiratory paralysis, and cyanosis.
- Acute signs occur within several hours of ingestion and include seizures, hyperactivity, muscle tremors, ataxia, and coma.

Diagnosis

- Drug or chocolate exposure and clinical signs allow a tentative diagnosis of methylxanthine toxicosis.
- Serum, stomach contents, and urine can be analyzed for methylxanthine levels.

Treatment

- Administer activated charcoal and promote diuresis with aggressive fluid therapy.
- Treat cardiac arrhythmias with antiarrhythmic agents (see Chapters 145 and 146).
- Use diazepam for muscle tremors and seizures.

Prognosis

The prognosis is fair to good if treatment is instituted early.

Organophosphate and Carbamate Poisoning

Etiology

Both organophosphates and carbamates inhibit acetylcholinesterase, the enzyme that breaks down acetylcholine at muscarinic and nicotinic sites of the autonomic and somatic nervous systems. Usually signs of parasympathetic stimulation predominate, but signs of somatic, sympathetic, and CNS overstimulation may also be present. Delayed organophosphate neurotoxicity can cause an irreversible central-peripheral axonal degeneration. Chlorpyrifos, dichlorvos, fenthion, carbaril, methonyl, aldicarb, and carbofuran are just a few of the insecticides that can be toxic after dermal application or following oral ingestion. Many of these insecticides are found in dips and sprays, flea collars, and wormers.

Clinical Signs

- Muscarinic signs include salivation, vomiting, diarrhea, bronchial secretion, miosis, and bradycardia.
- Nicotinic signs may be delayed in onset and include muscle tremors, neuromuscular weakness, exercise intolerance, and respiratory paralysis.
- CNS stimulation results in hyperactivity and seizures.
- Organophosphate toxicity in cats is characterized by pronounced muscle weakness, mydriasis, twitching, and anorexia, which may last for weeks.

Diagnosis

Exposure history, clinical signs, and low whole-blood cholinesterase activity (less than 25% of normal) suggest toxicosis.

Treatment

- Induce vomiting if ingestion has occurred within 2 hours of presentation and the patient is asymptomatic. Provide a meal prior to giving an emetic. Follow with activated charcoal and a cathartic (may need to repeat every 8 hours).
- Bathe the animal in dishwashing detergent and water if exposure was by skin contact.
- Start anticonvulsants (IV diazepam, phenobarbital) if seizures occur (see Chapter 127).
- Administer 0.2 mg/kg atropine (0.05 mg/kg IV, 0.15 mg/kg SC); repeat as necessary for bradycardia, bronchoconstriction, respiratory depression, and other muscarinic signs.
- Use pralidoxime chloride (10–15 mg/kg IM or SC) for muscle tremors and nicotinic signs.
- Intravenous fluids, nutritional support, frequent turns, and padded bedding are recommended.

Prognosis

The prognosis is good with early treatment.

Ivermectin Toxicity

Etiology

Ivermectin is an avermectin used as an anthelmintic in large and small animals. The blood-brain barrier of normal animals normally prevents ivermectin entry into CNS tissues. A P-glycoprotein pump in brain endothelial cells transports any ivermectin that enters the CNS back into the systemic circulation. A subpopulation of collies, Shetland sheepdogs, Australian shepherds, and Old English sheepdogs are homozygous recessive for a specific P-glycoprotein gene mutation that results in a nonfunctional P-glycoprotein molecule. Ivermectin and other P-glycoprotein substrates are able to freely enter the brain of these affected individuals. Single oral doses of 100 to 500 µg/kg of ivermectin can be neurotoxic in these breeds.

Clinical Signs

- Ivermectin has inhibitory actions in the brain similar to GABA.
- Signs of neurotoxicity include ataxia, muscle tremors, symmetrical or asymmetrical tetraparesis, dullness, and sometimes coma.
- The more rapid the onset and progression of clinical signs, the more likely that signs will progress to coma.
- Mydriasis and apparent blindness have also been reported.

Diagnosis

Ivermectin exposure and compatible clinical signs in a breed with known sensitivity to ivermectin is strongly suggestive of ivermectin neurotoxicosis.

Treatment

Treatment is supportive only (there is no definitive way to remove the neurotoxin). Use fluid therapy, parenteral or enteral nutrition, turns, bladder and fecal management, and other supportive care for the recumbent, nonresponsive patient.

Prognosis

The prognosis is good with appropriate supportive care, but recovery can take several weeks.

Metronidazole Toxicity

Etiology

Metronidazole (Flagyl) toxicosis is seen in the dog and cat following oral dosages of 66 mg/kg/day for more than 7 days. The mechanism of toxicity is unknown. Lesions of the vestibular nuclei and Purkinje cells of the cerebellum are recognized.

Clinical Signs

- Severe ataxia, positional vertical or rotary nystagmus, opisthotonus, seizures, asymmetrical upper motor neuron tetraparesis, and spastic muscle tremors may be seen acutely.
- Affected animals may exhibit a crouched posture in the pelvic limbs that is accentuated during ambulation.
- Many animals are weakened and disoriented to the point that they are recumbent, non-ambulatory, and anorexic.

Diagnosis

Drug exposure and compatible clinical signs are suggestive of the diagnosis. Tests for inflammatory, neoplastic, or other causes of multifocal CNS disease are negative.

Treatment

Discontinuing the drug will result in gradual resolution of clinical signs over 1 to 2 weeks. Provide supportive care as necessary.

▼ ***Key Point*** Diazepam (0.5 mg/kg IV or PO every 8 hours) reduces mean recovery time to less than 24 hours in most cases of metronidazole toxicity.

Prognosis

The prognosis is good if the drug is withdrawn.

Bromethalin Poisoning

Etiology

Bromethalin is a pelleted anticoagulant rodenticide that uncouples oxidative phosphorylation in CNS mitochondria. This results in a cellular ATP deficit, a sodium-potassium pump failure, and mild cerebral and spinal cord edema. Cats are more susceptible than dogs to the neurotoxic effects. Histopathologic lesions are mild, indicating a functional deficit at the cellular level.

Clinical Signs

- Acute hyperexcitability, muscle tremors, hyperthermia, running fits, and focal or generalized seizures may be seen in dogs. Thoracic limb rigidity, nystagmus, anisocoria, and depressed levels of consciousness are also part of the acute syndrome in dogs. Death occurs within 10 hours if the amount of bromethalin ingested is >5 mg/kg of body weight.
- Chronic signs (1–4 days after ingestion) in dogs include depression, pelvic limb ataxia, paresis, and hyperreflexia. This progresses to paraplegia and loss of deep pain. Cats exhibit very similar clinical signs 3 to 7 days after ingestion.

Diagnosis

- Exposure history and appropriate clinical signs suggest bromethalin toxicity.
- Tissue chemical analysis is definitive but not widely available.

Treatment

- Induce vomiting, perform gastric lavage, and administer activated charcoal if it is less than 2 hours after ingestion. Activated charcoal and a cathartic are recommended every 4 to 8 hours for at least four doses.
- Mannitol and dexamethasone do not appear to alleviate clinical signs.
- Control seizures with IV diazepam or phenobarbital (see Chapter 127).
- Provide supportive care; avoid overhydrating the patient with IV fluids.
- Monitor for 48 hours to evaluate for continued absorption or delayed onset signs.

Prognosis

The prognosis is poor once neurologic signs are seen.

Ethylene Glycol Poisoning

Ethylene glycol is a potent neurotoxin that can cause marked CNS depression. See Chapter 77 for additional information.

CONGENITAL MALFORMATIONS AND ANOMALIES

Most developmental defects of the brain affect either the cerebrum or the cerebellum. Clinical signs are usually present at birth and are nonprogressive. Congenital hydrocephalus can worsen postnatally with a gradual or sudden exacerbation of clinical signs. Although the majority of congenital malformations have a suspected genetic basis, a small number of disorders are due to in utero viral or toxic insults.

Hydrocephalus

Etiology

Primary hydrocephalus is a congenital disorder characterized by a pathologic accumulation of CSF within the ventricular system of the brain. Congenital hydrocephalus is recognized in the Maltese terrier, Yorkshire terrier, Chihuahua, Manchester terrier, Pomeranian, toy poodle, Cairn terrier, Shih Tzu, English bulldog, Boston terrier, Pekinese, Lhasa apso, and other breeds. Decreased CSF absorption at arachnoid villi and occlusion of the mesencephalic aqueduct are potential causes, but frequently an underlying structural abnormality cannot be identified. Congenital hydrocephalus may also be associated with other nervous system anomalies, including caudal occipital malformation syndrome, cerebellar hypoplasia, and meningomyelocele.

Clinical Signs

- Signs are usually seen in dogs less than 1 year of age, but trauma may precipitate signs in older dogs.
- Altered consciousness, head pressing, dementia, behavior changes, seizures, visual deficits, and ataxia are observed.
- Acute intraventricular hemorrhage can cause a sudden deterioration in neurologic status.
- Affected animals are frequently stunted, unthrifty, and poor doers.
- Associated signs are an open fontanelle, a thinned and domed calvarium, and a bilateral ventrolateral strabismus (“setting sun sign”).

Diagnosis

- Differential diagnoses include hepatic encephalopathy due to a portosystemic shunt, encephalitis due to

infectious or idiopathic causes, and toxin exposure (lead).
- Skull radiographs may demonstrate a large, thinned calvarium with loss of gyral markings.
- Ultrasonography through an open fontanelle allows visualization of dilated ventricles.
- Optimal visualization of ventricular dilatation and subcortical white matter atrophy is obtained by CT or MRI. There may be mild to moderate asymmetry in ventricular size.

▼ ***Key Point*** The presence of acute to subacute forebrain signs in conjunction with marked ventricular dilatation is strongly suggestive of hydrocephalus.

- Affected animals have normal (normotensive) or elevated (hypertensive) CSF pressures.

Treatment

- Provide therapy only if the patient has clinical signs of cerebral dysfunction. Many animals with ventriculomegaly are clinically normal and do not require therapy.
- Corticosteroids with or without furosemide benefit many patients in the short term.
- Mannitol is helpful if patients are exhibiting signs of acute ICP elevation.
- Anticonvulsant therapy is used for seizures (see Chapter 127).

Ventriculoperitoneal or ventriculovenous shunts can be placed to promote drainage of CSF. This procedure has alleviated clinical signs in some cases; however, referral to a neurosurgery specialist is required.

Prognosis

The prognosis is fair with early diagnosis and treatment.

Lissencephaly

Etiology

Lissencephaly is a migration defect of neural cell precursors in the telencephalon characterized by an absence of cerebrocortical convolutions, thickened cortical gray matter, and thinned cortical white matter. It is presumed to be an inherited defect in the Lhasa apso, wirehaired fox terrier, and Irish setter. Affected wirehaired fox terriers and Irish setters often have concurrent cerebellar hypoplasia.

Clinical Signs

- Neurologic signs are usually present at birth or within the first year of life.
- Behavioral changes, visual deficits, dementia, and seizures are seen.

Diagnosis

- Differential diagnoses are the same as for hydrocephalus (see above).
- CT or MRI reveals absence of gyri and sulci, thickening of the gray matter, and thinning of the white matter. Ventricular size is usually normal.

Treatment

- There is no specific treatment for this condition.
- Treat seizures symptomatically with anticonvulsants (see Chapter 127).

Prognosis

The prognosis is fair to poor. Seizures may be refractory to therapy.

Congenital Arachnoid Cysts

Etiology

- Congenital arachnoid cysts, also called subarachnoid cysts, are developmental anomalies characterized by cystic accumulation of fluid in the subarachnoid space. The cyst wall is composed of several layers of arachnoid cells.
- Arachnoid cysts can occur at any location along the neuraxis including the brain. Intracranial arachnoid cysts most frequently form between the cerebellum and the tentorium cerebelli and often are associated with the quadrigeminal cistern.
- Over time, the cyst can slowly enlarge to compress adjacent neural tissue.

Clinical Signs

- Signs are usually seen in young adults.
- Seizures, paresis, abnormal behavior, and cranial nerve deficits may be observed. If the cyst is causing secondary hydrocephalus, diffuse forebrain signs may be evident.
- Arachnoid cysts may be incidental findings associated with no clinical signs.

Diagnosis

- MRI or CT will reveal a well-circumscribed cystic structure compressing underlying brain tissue.
- Secondary hydrocephalus may be present if the cyst is compressing CSF outflow pathways.

Treatment

Surgical fenestration of the cyst wall and partial excision will result in decompression of underlying neural tissues and prevent further damage to these tissues. Medical therapy with glucocorticoids and diuretics can be attempted but is usually only effective in the short term.

Prognosis

The prognosis is good if surgery is performed before significant irreversible brain atrophy has occurred.

Cerebellar Hypoplasia in Cats

Etiology

Cerebellar hypoplasia refers to a defect in cerebellar development leading to decreased neuronal numbers with or without a gross reduction in size. This condition in kittens is usually due to an in utero or early postnatal panleukopenia viral infection (see Chapter 14). Vaccination of pregnant queens with modified live panleukopenia virus vaccine may also produce this syndrome. Rapidly dividing cells in the developing cerebellum are killed by the virus.

Clinical Signs

▼ ***Key Point*** Severe ataxia, falling, hypermetria, head intention tremor, head bobbing, and loss of menace response are usually seen at 3 to 4 weeks of age when kittens begin to ambulate.

- Signs are nonprogressive.
- There may be fewer clinical signs with lesser degrees of cerebellar damage.
- Littermates may or may not be affected.

Diagnosis

- Differential diagnoses are other infectious causes of cerebellar disease, cerebellar abiotrophy, or lysosomal storage disease.
- Clinical signs of a nonprogressive, purely cerebellar disorder in kittens are strongly suggestive of a diagnosis of cerebellar hypoplasia.
- CT or MRI will often reveal a small cerebellum.

Treatment

No treatment is available.

Prognosis

The prognosis is poor for clinical improvement. Many cats with cerebellar hypoplasia make functional pets.

Cerebellar Hypoplasia in Dogs

Etiology

Most of the canine forms of cerebellar hypoplasia have a genetic basis. An exception to this is cerebellar hypoplasia secondary to postnatal herpesvirus infection. Breeds affected include the chow chow, Airedale, Irish setter, wirehaired fox terrier, Boston terrier, bull terrier, Weimaraner, dachshund, and Labrador retriever. The Irish setter and wirehaired fox terrier have concomitant lissencephaly. Selective involvement of the cerebellar vermis (vermian hypoplasia) is observed in the Boston terrier and bull terrier.

Clinical Signs

- Nonprogressive cerebellar signs are obvious at the time of ambulation, but subtle deficits can be detected from birth.
- Truncal ataxia, disequilibrium, dysmetria, falling, intention tremor, and an absent menace response are seen to varying degrees.

Treatment

No treatment is available.

Prognosis

Strength, CP, and personality are maintained. If coordination is not incapacitating, affected dogs can make acceptable pets.

DEGENERATIVE BRAIN DISEASE

Inborn errors of metabolism can lead to neural cell degeneration after normal differentiation and maturation. Neuronal or glial cell degeneration is termed *abiotrophy*. A metabolic defect has not been identified in the vast majority of abiotrophies in animals. Neurodegenerative changes may occur within either the cell body or its processes. Although most abiotrophies affect the cerebellum, others may affect neurons in multiple brain regions. Neurodegenerative changes also occur with aging in some dogs and cats. Neuronal and glial changes are most severe in the cerebrum of older animals with this disorder.

Lysosomal storage diseases are autosomal recessive neurodegenerative disorders in which the cellular defect has been identified in most cases. Homozygous recessive individuals often exhibit a specific lysosomal hydrolase defect that leads to a cascade of structural and biochemical changes at the cellular level. The most obvious change is the accumulation of undegraded material within lysosomes, giving neurons a foamy, vacuolated, and swollen appearance. Other abnormalities include neuroaxonal dystrophy (axonal swellings), changes in synaptic connections, neurotransmitter and calcium imbalances, and occasionally cell death. Neuronal ceroid lipofuscinosis is unique in that massive neuronal cell loss and atrophy occurs in both the cerebrum and the cerebellum. Other lysosomal storage diseases do not share this feature.

▼ ***Key Point*** Animals affected with lysosomal storage disorders are normal at birth and weaning, but at a few months of age they develop a slowly progressive neurologic disease with multifocal cerebellar, brain stem, and spinal cord signs.

For reasons poorly understood, the cerebellum is especially vulnerable and will often show the most severe pathologic changes early in the disease course. Consequently, early clinical signs in the majority of lysosomal storage diseases are predominantly cerebellar in origin. Differential diagnoses for cerebellar signs in young cats and dogs include infectious diseases (FIP, cryptococcosis, toxoplasmosis, CDV, etc.), cerebellar hypoplasia, or cerebellar abiotrophy. With the exception of globoid cell leukodystrophy, lysosomal storage diseases are also characterized by visceral storage of undegraded material. Storage in liver, pancreas, spleen, kidney, bone marrow, adrenal glands, ocular structures, and lymph nodes is commonly found but rarely causes organ dysfunction. Globoid cell leukodystrophy results in storage within cells of the nervous system only and eventually produces central and peripheral demyelination.

Cerebellar Abiotrophies

Etiology

Cerebellar abiotrophies have been identified in many canine breeds and in the cat. Breeds affected include the beagle, Samoyed, Irish setter, Kerry blue terrier, Gordon setter, American Staffordshire terrier, rough-coated collie, Airedale, Finnish harrier, Bern running dog, Bernese mountain dog, Labrador and golden retrievers, cocker spaniel, Cairn terrier, Great Dane, Australian kelpie, Brittany spaniel, English springer spaniel, bull terrier, and German shepherd. Normal cerebellar formation is followed by premature degeneration and cell death. Cerebellar Purkinje and granule cell loss usually occurs. Pathogenic mechanisms are largely unknown. An autosomal recessive mode of inheritance is proven in some breeds.

Clinical Signs

- Age of onset is usually between 4 and 10 weeks, but some breeds show an earlier or later onset. Most dogs are normal at birth.
- Progression may be slow or rapid.
- Cerebellar signs of intention tremor and progressive ataxia and dysmetria are characteristic.

Diagnosis

- Other causes of progressive cerebellar disease in young dogs (infectious diseases, lysosomal storage disease, myelin disorder, medulloblastoma) should be ruled out.
- CT or MRI may reveal a smaller-than-normal cerebellum, but usually the cerebellum is normal in size.

Treatment

No treatment is available.

Prognosis

The prognosis is guarded to poor due to the progressive, debilitating nature of these disorders.

Multisystem Neuronal Abiotrophies

Etiology

Multisystem neuronal abiotrophies are characterized by overt cell loss or chromatolytic change in multiple brain compartments. Breeds affected include the Kerry blue terrier, rough-coated collie, miniature poodle, cocker spaniel, and Cairn terrier. The primary lesion in Kerry blue terriers, rough-coated collies, and miniature poodles is cerebellar abiotrophy, but multiple brain stem nuclei, spinal cord neurons, and cerebrocortical neurons also degenerate. Affected cocker spaniels have cell loss in multiple regions and neuroaxonal dystrophy in cerebellar and cerebral white matter. Multisystem chromatolytic degeneration in Cairn terriers is characterized by chromatolysis of neurons in spinal cord, brain stem, and cerebellum. An autosomal recessive mode of inheritance has been demonstrated in some breeds.

Clinical Signs

- Onset of signs is between 4 and 16 weeks of age, and clinical progression may be rapid (over weeks) or slow (over months).
- Kerry blue terriers and rough-coated collies exhibit primarily cerebellar signs.
- Miniature poodles have early cerebellovestibular signs from 3 to 4 weeks of age followed by upper motor neuron tetraplegia at 4 months of age.
- Cocker spaniels show both cerebellar and cerebral signs at 1 year of age.
- Signs in Cairn terriers include cerebellar ataxia, paresis, and cataplexy.

Diagnosis

- Differential diagnoses include lysosomal storage disease and inflammatory CNS disease.
- A tentative diagnosis is based on signalment, clinical signs, and progression.
- A definitive diagnosis can only be made postmortem.

Treatment

No treatments are available.

Prognosis

The prognosis is poor.

Multisystem Neuroaxonal Dystrophy

Etiology

Primary neuroaxonal dystrophy refers to an inherited error of metabolism resulting in swellings or spheroids along any region of the axon. The distal axon and axon

terminal are the most common cellular sites affected by this neurodegenerative disease. Any region of the CNS may be affected, including the cerebellum, cerebrum, and brain stem. Neuroaxonal dystrophy has been reported in the rottweiler, Jack Russell terrier, Chihuahua, collie-sheepdog mixed breed, bullmastiff, Labrador retriever, and domestic shorthaired cat. An autosomal recessive mode of inheritance is known or suspected in these breeds.

Clinical Signs

- Clinical signs are primarily cerebellar in origin in the majority of affected breeds.
- Cerebral signs are seen in the Labrador retriever.

Diagnosis

- Differential diagnoses include inflammatory, metabolic, toxic, and other congenital causes of cerebellar or cerebral disease.
- No specific diagnostic tests are available.

Treatment

No treatment is available.

Lysosomal Storage Disorders

See Table 126-5 for information about the more important lysosomal storage disorders.

Neurodegenerative Changes Associated with Aging and Cognitive Dysfunction

Etiology

- Canine cognitive dysfunction is a neurodegenerative disease of the forebrain characterized by a very gradual onset and progression of cognitive decline in dogs greater than 11 years of age.
- The cause of cognitive dysfunction is not fully understood, but certain morphologic and functional changes are recognized in association with this syndrome.
- Cortical atrophy due to neuronal loss (apoptotic cell death), amyloid plaques and perivascular amyloid, myelin degeneration with perivascular macrophage infiltration and gliosis, and intraneuronal lipofuscin accumulation are commonly observed. Changes in the frontal and temporal lobes are most severe. The density of amyloid plaques shows a correlation with the severity of cognitive decline.
- Functional changes hypothesized to occur include decreased levels of norepinephrine and dopamine in frontal cortex, increased monoamine oxidase activity with increased norepinephrine and dopamine breakdown (with free radical formation), alterations in post-synaptic receptor numbers and function, and decreased mitochondrial energy production.

Clinical Signs

▼ ***Key Point*** The clinical course of canine cognitive dysfunction is often 18 to 24 months or longer. Behavior problems are "newly emergent" and should not resemble previous behavior patterns in the pet.

Behavior changes include decreased spatial orientation (staring, wandering, getting lost, resisting confinement), decreased responsiveness and social interaction (no seeking of affection, loss of owner recognition, resistance to handling), loss of house training, and altered sleep-wake cycles (active at night and sleeping during the day).

Diagnosis

- A tentative diagnosis can be made based on a compatible history and clinical signs and by ruling out disorders that may mimic the signs of cognitive dysfunction.
- The neurologic examination is normal with the exception of abnormalities of mentation that include resisting restraint, agitation, increased startle, blank stare or shifting eye movements, and aimless pacing and wandering. Lateralizing deficits and seizures are not observed.
- Affected dogs should be screened for concurrent disorders such as vision and/or hearing loss and for metabolic and endocrine imbalances that may impact normal brain function.
- MRI or CT will rule out a brain tumor or vascular lesion as the cause of the dementia. Corticocerebral atrophy with secondary ventriculomegaly is a common finding.

Treatment

- Cognitive dysfunction secondary to neurodegeneration is not a traditional behavior disorder. Since manifestations of dementia are due to a neurodegenerative process, behavior modification strategies are usually not effective.
- Steps that modify the pet's environment, such as providing adequate space and footing, building ramps, and fencing outdoor areas, are useful. Frequent attention, close monitoring of nutrition, and "timed" feeding and exercising are also advised.
- Medical therapy that has been approved for use with this disorder is selegiline. Improved sleep-wake cycles, activity levels, and house training have been reported after administration of 0.5 to 1.0 mg/kg PO every 24 hours (given in the morning). Selegiline inhibits the breakdown of several monoamines, including dopamine, norepinephrine, and 2-phenylethylamine, and facilitates dopaminergic transmission and activity.

Table 126-5. LYSOSOMAL STORAGE DISEASES IN DOGS AND CATS

Disease	Enzyme Defect	Breeds	Age of Onset	Clinical Signs	Diagnosis	Treatment
GM1 gangliosidosis	Beta-galactosidase deficiency	Portuguese water dog, English springer spaniel, Siamese cat, DSH	2–4 months	Early cerebellar signs, UMN tetraparesis, dementia, seizures, cranial nerve deficits, visual deficits +/− hepatomegaly, skeletal deformities, corneal opacities	Enzyme assays on WBC, plasma, other tissues; vacuolated WBCs	BMT with limited effect
GM2 gangliosidosis	Beta-hexosaminidase deficiency	Japanese spaniel, mixed-breed dog, DSH, Korat cat	2–4 months (18 months in dogs)	Cerebellar signs, UMN tetraparesis, blindness, seizures, dementia +/− skeletal deformities, corneal opacities	WBC, plasma, tissue assays; WBCs with heterochromatic granules	BMT with no clinical effect
Niemann-Pick disease type A	Sphingomyelinase deficiency	Balinese cat, Siamese cat, miniature poodle	4–5 months	Cerebellar signs, LMN tetraparesis +/− hepatomegaly	WBC, plasma, tissue assays	Not attempted
Niemann-Pick disease type C	Cholesterol transport defect	DSH, boxer	2–4 months	Cerebellar signs, UMN tetraparesis, mentation changes +/− hepatomegaly	Cholesterol esterification assays on cultured fibroblasts	BMT with limited effect
Mucopolysaccharidosis I	Alpha-L-iduronidase deficiency	DSH, Plott hound	3–6 months	No neurologic signs, skeletal deformities, stunted growth, corneal changes	WBC, other tissue assays; urine screening test	BMT with moderate to marked effect
Mucopolysaccharidosis VI	Arylsulfatase B deficiency	DSH, Siamese cat, miniature pinscher	2–6 months	See MPS-I; paraparesis due to cord compression	WBC, other tissue assays; urine screening test	BMT with moderate to marked effect
Alpha-mannosidosis	Alpha-mannosidase deficiency	DSH, DLH, Persian	2–7 months	Cerebellar signs +/− cataracts, hepatomegaly, limb deformities	WBC, other tissue assays	BMT with marked clinical effect
Fucosidosis	Alpha-fucosidase deficiency	English springer spaniel	6–12 months	Behavior change, cerebellar signs, dementia, visual deficits, jaw chomping	WBC, plasma, CSF, or tissue assays	BMT with moderate effect
Neuronal ceroid lipofuscinosis	Defect unknown (mitochondrial subunit accumulates)	English setter, dalmation, border collie, Australian cattle dog, others	1–2 years	Behavior change, dementia, visual seizures +/− cerebellar signs	Brain biopsy or not attempted deficits,	BMT not effective in many breeds
Globoid cell leukodystrophy	Galactocerebrosidase deficiency	West Highland white terrier, Cairn terrier, miniature poodle, bluetick hound, beagle, others	2–4 months	Cerebellar signs, paraparesis to tetraparesis	WBC, tissue assays; peripheral nerve biopsy	BMT not attempted in dogs (moderate success in mice)

BMT, bone marrow transplantation (allogeneic); DLH, domestic longhaired cat; DSH, domestic shorthaired cat; MPS, mucopolysaccharidosis; LMN, lower motor neuron; UMN, upper motor neuron; WBC, white blood cell.

Prognosis

This condition can be managed but not cured. Response to medical therapy is variable. Neurodegenerative changes will continue, and response to therapy is often transient at best.

CRANIAL NERVE DISORDERS

Disorders of the peripheral portions of cranial nerves may occur secondary to neoplastic, inflammatory, idiopathic, congenital, and endocrine diseases. The most common cranial neuropathies affecting CN5, CN7, or CN8 are discussed below. Horner's syndrome is discussed in Chapter 141. Laryngeal paralysis is covered in Chapter 161. Megaesophagus is discussed in Chapter 65.

Idiopathic Disorders

Trigeminal Neuritis (Idiopathic Trigeminal Neuropathy, Dropped Jaw Syndrome)

Etiology

The etiology is unknown. A bilateral, nonsuppurative neuritis of CN5 and its ganglia is seen histologically. There is no breed predilection. Most dogs are middle aged.

Clinical Signs

- An acute to peracute onset of a dropped jaw and inability to close the mouth are seen. The signs are nonprogressive and muscle atrophy rarely occurs.
- Animals have difficulty prehending and chewing food. Food and water fall out the sides of the mouth. Swallowing abilities are usually maintained if food is placed in the back of the mouth.
- A unilateral or bilateral Horner's syndrome may be seen in association with trigeminal neuritis.
- Sensation to the face is usually normal, and there are no long tract signs or changes in mentation.
- Pain may be elicited upon palpation around the jaw.

Diagnosis

- Acute, severe mandibular paralysis in the absence of other neurologic deficits is usually pathognomonic for this disease.
- Lymphoma and other myelomonocytic leukemias with nerve root involvement may rarely produce similar signs.

Treatment

- Therapy is strictly supportive. Maintaining hydration and nutrition is critical.
- Corticosteroid therapy is of no benefit.

Prognosis

▼ ***Key Point*** Idiopathic trigeminal neuritis is a self-limiting disorder with recovery taking place within 2 to 4 weeks after the onset of signs. The prognosis is excellent with adequate nutritional support.

Idiopathic Facial Paralysis or Palsy

Etiology

An idiopathic paralysis of the facial nerve occurs in dogs. There may be unilateral or bilateral involvement. Histologically, there is axonal degeneration with secondary demyelination of the facial nerve. There appears to be a high incidence in cocker spaniels.

Clinical Signs

- Signs are acute in onset and nonprogressive.
- Complete paralysis of the facial nerve results in a unilateral facial droop (lips, ears, etc.) and an inability to blink the eye. The palpebral fissure may be wider than normal.
- Food, water, and saliva tend to fall out the side of the mouth that is paralyzed.
- In the acute stage, the nasal philtrum is deviated slightly toward the unaffected side due to unopposed nasal muscles.
- Denervation of the lacrimal gland may lead to decreased tear production.
- Facial contracture (lip retraction, deviation of the lip and nose toward the affected side) can be seen chronically.
- No other neurologic signs are usually present, but involvement of the opposite facial nerve is not uncommon.

Diagnosis

Differential diagnoses include otitis media or interna (see Chapter 61), hypothyroid neuropathy (see this section and Chapter 31), a neuropathy associated with pituitary lesions, lead poisoning, neoplasia, and trauma.

Treatment

There is no treatment. Artificial tears may be needed to prevent corneal lesions (see Chapter 139).

Prognosis

The prognosis for recovery of function is guarded to fair. Many dogs may recover partial function only.

Canine Idiopathic Vestibular Disease (Old Dog Vestibular Syndrome)

Etiology

This is a disease of older dogs (average age of 12–13 years) of any breed. The pathogenesis is unknown. This condition can also occur in the cat at any age, but it usually occurs in young adult cats.

Clinical Signs

- Signs of vestibular imbalance are peracute and include head tilt, ataxia, circling, falling, rolling, and nystagmus (usually rotary) with a fast phase away from the side of the head tilt.
- Affected dogs are disoriented and frequently agitated.
- Postural reactions and strength are preserved, and there are no other cranial nerve deficits.
- Anorexia with or without vomiting is common.
- Signs are most severe at the onset and gradually improve over days to weeks.

Diagnosis

- Otitis media or interna, hypothyroidism, trauma, vascular disease, and neoplasia are differential diagnoses.
- Otic examination, bulla radiographs or CT, thyroid testing, blood pressure measurement, and other screening tests for vascular disease may be performed to exclude the above differential diagnoses.

Treatment

- There is no specific treatment.
- Steroid therapy is not beneficial.

- Nutritional and fluid support may be necessary if persistent nausea and anorexia are present.
- A padded, confined area may be needed to prevent self-injury.

Prognosis

▼ ***Key Point*** The prognosis is good to excellent for recovery in dogs with idiopathic vestibular disease. Improvement is usually seen over the first 2 to 3 days after onset, and resolution of the majority of signs is observed 10 to 14 days after onset. Recurrences can occur but are uncommon.

Endocrine Diseases

Hypothyroidism

Etiology

Thyroid hormone deficiency can cause an unusual combination of peripheral and central vestibular signs. Other cranial nerves may be affected, especially CN7 and CN10 and the sensory branches of CN5.

Clinical Signs

- Middle-aged to older dogs of any breed may be affected, and there may be no other signs of hypothyroidism.
- The onset may be rapid or chronic and the clinical course may be static or progressive.
- Vestibular signs are usually unilateral (head tilt, etc.) but signs can be bilateral. The character of the nystagmus is vertical, horizontal, rotary, or direction changing. Vestibular ataxia is usually present with listing and falling toward one side.

Diagnosis

- Differential diagnoses include otitis interna, idiopathic vestibular disease, vascular disease, infectious disease, or neoplasia.
- Otoscopic exam, CSF analysis, and imaging studies (CT or MRI) are typically normal.
- A complete thyroid panel is necessary to distinguish non-thyroidal illness from true hypothyroidism (see Chapter 31).

Treatment

Treatment is thyroid supplementation (see Chapter 31). Resolution of signs can occur but is gradual over 1 to 4 months.

Prognosis

The prognosis is good for eventual return of vestibular function.

Neoplasia

Trigeminal Neurofibroma (Schwannoma, Nerve Sheath Tumor)

Etiology

The most common tumor that may involve CN5 is the neurofibroma or schwannoma. Lymphoma and meningioma may involve the trigeminal nerve less commonly. Trigeminal neurofibromas are invariably unilateral and usually originate peripherally with eventual encroachment on brain stem structures in the region of the cerebellopontomedullary angle. Nuclei of CN7 and CN8 may secondarily be affected. This neoplastic disease occurs in middle-aged to old dogs.

Clinical Signs

- The onset and progression of signs are slow (over months).
- Marked unilateral temporalis and masseter muscle atrophy is seen initially.
- Jaw weakness is not clinically apparent.
- Muscle atrophy is followed by facial sensory loss.
- Brain stem involvement is indicated by the onset of ipsilateral vestibular signs, facial muscle weakness, and occasionally long tract signs with ipsilateral hemiparesis and conscious proprioceptive deficits.

Diagnosis

- The main differential diagnosis is trauma to CN5. The progressive course of this disorder helps rule out trauma.
- Electromyography and temporal muscle biopsies reveal signs of denervation.
- Contrast-enhanced MRI scanning is most sensitive in detecting the tumor location and extent.

Treatment

- Surgical excision is the treatment of choice, but the surgery is technically demanding and rarely achieves complete excision.
- Radiation therapy appears to slow progression of the tumor, but further clinical studies are needed to confirm this observation.
- MRI aids surgical and radiation planning and may improve outcome.

Prognosis

The prognosis is guarded to poor, especially if brain stem involvement has occurred.

Primary and Secondary Neoplasia Involving Cranial Nerve 8

Etiology

Primary neurofibromas of CN8 are rare. Meningiomas in the caudal fossa may affect the extradural, intra-

cranial portion of CN8. Secondary tumors affecting CN8 usually originate in the temporal bone or bullae and invade the nerve or its peripheral receptors by local extension. Squamous cell carcinoma, ceruminous gland adenocarcinoma, osteosarcoma, and chondrosarcoma are tumors in this category and do occur in the dog and cat. Middle ear polyps in cats may also secondarily involve vestibular and cochlear structures in the inner ear (see Chapters 61 and 62).

Clinical Signs

- Slowly or rapidly progressive vestibular signs are observed.
- Horner's syndrome and other cranial neuropathies (especially of the facial nerve) may be seen concurrently.

Diagnosis

- Rule out otitis media and interna (see Chapter 61), idiopathic conditions, and endocrine-related neuropathy.
- Otic examination and biopsy may reveal a neoplastic process.
- Bullae radiographs detect soft tissue opacities or bony lysis.
- CT is useful in identifying both bony and neural parenchyma involvement.
- MRI is the imaging modality of choice for determining the extent of neural parenchymal involvement.

Treatment

Total surgical resection is usually not possible, except in the case of a benign inflammatory polyp.

Prognosis

The prognosis is usually poor.

Congenital Degenerative Disorders

Congenital Sensorineural Deafness

Etiology

Postnatal cochlear hair cell and spiral ganglion degeneration occurs in many breeds, including dalmatians, English setters, bull terriers, Old English sheepdogs, English bulldogs, Australian heelers, border collies, collies, Australian shepherds, Australian cattle dogs, Catahoulas, Norwegian dunkerhounds, pointers, rottweilers, and white cats with blue irises. Cochlear structures develop normally, but degeneration of the stria vascularis is soon followed by loss of cochlear hair cells. The pathogenesis is unknown. The method of genetic transmission is also poorly understood in most breeds.

Clinical Signs

- Owners may not recognize a deaf puppy for several months.
- Poor response to verbal commands and loud noises often indicates bilateral deafness.
- Unilaterally deaf pups may not orient to sounds properly or may appear completely normal.

Diagnosis

- Clinical signs may or may not be definitive.
- The BAER will accurately detect unilaterally and bilaterally deaf animals.

Treatment

There is no treatment for this degenerative disorder.

Prognosis

The prognosis is poor for recovery of hearing. Special behavioral training is often necessary for dogs with bilateral deafness.

Chapter

127 Seizures

Michael Podell

Any animal may be prone to having a seizure, often with little indication of when, why, or how often the seizures will occur. Moreover, the veterinarian never observes most clinical signs of the disease. This unpredictability and lack of direct connection with the disease is challenging to veterinarians trying to determine the appropriate diagnostic and therapeutic plan. The purpose of this chapter is to provide a perspective on how to identify and treat dogs and cats with a seizure disorder.

TERMINOLOGY

Classification of seizures and epilepsy into a universally accepted, coherent, and relevant scheme for clinicians has been an ongoing dynamic process in human epilepsy over the past 2 decades. The standardized classification scheme for seizures and epilepsy, established by the International League against Epilepsy (ILAE) in the 1980s, provided the first basis for a taxonomic foundation to an analytic approach in the diagnosis and treatment of epilepsy. This classification scheme, however, is restricted by the following limitations: (1) the reliance on the clinician's ability to classify seizure types based on the presence of "impaired consciousness"; (2) the reliance on electroencephalographic features to classify seizure type; and (3) the difficulty in distinguishing between an *idiopathic* disorder of confirmed undetermined etiology and a *cryptogenic* cause of highly suspect morphologic disease of the brain. Considering these limitations and that, as veterinarians, we may not always have the opportunity to perform a complete battery of neurodiagnostic tests (including brain imaging), it is no wonder that confusion arises when we try to describe, classify, and categorize seizures and epilepsy in our patient population.

My goal is to piece together a rationale categorization for use in small animal epileptic patients adapted from the recent recommendations of the ILAE Task Force on Classification and Terminology. The purpose is to establish a common mode of communication to allow diagnostic and therapeutic data to be tabulated for clinical outcome measures. The proposed new diagnostic scheme consists of five levels, or axes, as proposed by Engel (Table 127-1; for review see Engel, 2001 and Podell, 2004).

Axis 1: Ictal Phenomenology

- A *seizure* can be defined as a nonspecific, paroxysmal, abnormal event of the body.
- An *epileptic seizure* is the clinical manifestation of excessive and/or hypersynchronous abnormal neuronal activity in the cerebral cortex. Thus, an epileptic seizure has a specific neural origin.
- *Epilepsy* is present if the animal has a chronic brain disorder characterized by recurrent epileptic seizures. Note that neither the term seizure nor the term epilepsy connotes the underlying etiology of the disorder.
- *Non-epileptic episodes* are paroxysmal events with severe consequences to the body but without any epileptic electroencephalographic activity (e.g., syncope).
- *Status epilepticus* can be defined as a state of continuous seizure activity lasting 30 minutes or longer or repeated seizures with failure to return to normalcy within 30 minutes. *Epilepsia partialis continua* is a continuous focal seizure involving the motor cortex. Although not well documented by electroencephalography in animals, the typical manifestations include facial muscle movements with "chewing gum" activity, repetitive eye or lip twitching, or myoclonic jerking of limb muscles.

Clinical Stages of Epileptic Seizures

- The *prodrome* is the time period prior to the onset of seizure activity. Owners report that they can "predict" the onset of their pet's seizures by behaviors exhibited during this time, such as increased anxiety-related behaviors (attention seeking, whining, etc.), reluctance to do normal activity patterns, or increased hiding (in cats).
- The *aura* is the initial manifestation of a seizure. During this time period, which can last from minutes to hours, animals can exhibit stereotypic sensory or motor behavior (e.g., pacing and licking), autonomic patterns (e.g., salivating, urinating, and vomiting), or even unusual psychic events (e.g.,

Table 127-1. PROPOSED DIAGNOSTIC SCHEME FOR DOGS AND CATS WITH EPILEPTIC SEIZURES

Axis 1: Ictal Phenomenology

excessive barking and increased or decreased attention seeking).

- The *ictal* period is the actual seizure event manifested by involuntary muscle tone or movement and/or abnormal sensations or behavior lasting usually from seconds to minutes.
- The *postictal* period is the time immediately following the ictal phase and can last from minutes to days. During this time, an animal can exhibit unusual behavior, disorientation, inappropriate bowel or bladder activity, excessive or depressed thirst and appetite, and/or actual neurologic deficits of weakness, blindness, and sensory and motor disturbances. The latter problems are known as Todd's paralysis and are often an indicator of a contralateral cortical epileptic focus. Often owners only observe the postictal period as evidence that their pet has had a seizure. Thus, careful questioning is needed by the clinician to decide if an animal did experience a seizure.

Axis 2: Epileptic Seizure Types

Self-limiting: Isolated (Single Event Only) Seizures

- *Focal seizures* are the manifestation of a discrete, epileptogenic event in the cerebral cortex. The focal nature of this seizure type is associated with a higher incidence of focal intracranial pathology.
- *Focal elementary motor seizures* are either commonly seen as facial muscle twitching or manifested by more abnormal behavioral disorders. Progressive involvement of the facial, neck/shoulder, and/or limb muscles is known as a *Jacksonian march seizure event.*
- *Automatism, or automotor seizures,* were previously termed complex partial or psychomotor seizures (Engel, 2001). Animals may show "fly-biting" behavior patterns, become aggressive without provocation, howl incessantly, become restless, or exhibit a variety of motor disturbances. Cats may show a variety of abnormal behaviors and/or motor signs, including drooling, hippus, excessive vocalizations, or random, rapid running behaviors in the house.

▼ ***Key Point*** Whenever a focal seizure is suspected, the clinician should be suspicious of a focal cerebral disturbance and plan the diagnostic workup accordingly.

- *Generalized convulsive seizures* are the most common seizure type seen in veterinary medicine. These seizures are characterized by impaired consciousness coupled with bilateral motor signs of a tonic-clonic, tonic, or myoclonic nature.
- *Generalized non-convulsive seizures* are less common and are either atonic (complete loss of voluntary movement with collapse) or absent (ability to stand or pose but without the ability to perceive or respond). These terms replace the previously used terms convulsive *(grand mal)* and non-convulsive *(petit mal)* seizures.
- Generalized seizures originate from both cerebral hemispheres from the start or progress secondarily from focal seizures. Unlike focal seizures, generalized seizures are not necessarily associated with focal cerebrocortical disease.

Clustered or Continuous Focal Seizures

Clustered seizures are two or more seizures within a 24-hour period.

- Motor: Epilepsia pars continua
- Sensory: Aura continuous
- Generalized: Status epilepticus

Axis 3: Syndrome

- Epilepsy syndromes are not well defined in veterinary medicine, although familial epilepsies are now being identified with segregation analysis.
- A number of purebred dogs have been identified with either proven or highly suspect familial epilepsy: Belgian Tervuren, keeshonds, retrievers, Shetland sheepdogs, and a variety of other breeds.
- The vast majority of epileptic syndromes in dogs will be idiopathic in nature.

Axis 4: Etiology

Epilepsy represents a heterogeneous disease consisting of diverse etiologies, electrophysiologic and behavioral seizure patterns, and responses to therapy. Genetically determined "seizure susceptibility factors" play a crucial role in the brain's response to triggering or precipitating factors. Seizures in these individuals may be activated from unrecognized changes in neuronal activity, by intrinsic neurochemical transmission, or by environmental stimuli that do not cause seizures in the normal brain.

▼ ***Key Point*** A basic mechanism of epilepsy is an imbalance in excitatory and inhibitory neurotransmission.

- A seizure develops when the balance shifts toward excessive excitation. Recruitment of a critical number of areas in the brain with synchronized depolarization will lead to a seizure. Reasons for the progressive nature of epilepsy include the following:
  - Conditions leading to excessive excitation or loss of inhibition result in depolarization of neurons without normal regulatory feedback mechanisms.
  - The number of cells with an intrinsic pattern of high spontaneous firing activity (pacemaker cells) increases in the epileptic focus.
  - A mirror focus of actively firing epileptogenic neurons may develop in a similar region on the opposite hemisphere. This enables the number of epileptic foci to multiply rapidly. As an animal continues to have seizures, an increased number of areas of the brain are randomly and spontaneously able to initiate a seizure.
- Refer to Chapter 126 for information regarding specific diseases of the brain.
- The differential diagnosis of epileptic seizures due to underlying brain disease can be divided into three main etiologic categories: Idiopathic, symptomatic, and probably symptomatic (previously termed cryptogenic) epileptic seizures.
  - *Idiopathic epilepsy* implies that no underlying structural brain lesion is present, and the epilepsy is presumed to be genetic in origin.
  - *Symptomatic, or secondary, epilepsy* is the result of an identifiable structural lesion of the brain.
  - *Probably symptomatic, or cryptogenic, epilepsy* is believed to be the result of a structural lesion of the brain that is not identified. While this sounds like a nebulous disease category, it has particular implications when understanding why certain animals may be refractory to therapy. Examples of cases that may fit into this category would be prior head trauma in patients with normal imaging, postencephalitic seizures developing at a later date, undetected hypoxic or vascular events of the brain after anesthesia, and birth trauma.
- Reactive epileptic seizures are due to metabolic disease and therefore are not classified as an etiology for epilepsy, as the brain returns to normal once the underlying inciting change in metabolism is corrected. The differential diagnoses for these categories are presented below.

Axis 5: Impairment from Epilepsy

Inclusion of signs that are associated with epilepsy allows veterinarians to evaluate for persistence of functional and/or structural neurologic changes with associated seizures. The majority of signs in cats and dogs are transient, including disorientation, visual impairment, salivation, incontinence, and altered behaviors. Dogs have been found to demonstrate transient structural changes with cerebral edema of the temporal lobe on magnetic resonance imaging (MRI) scans of the brain, along with altered cerebral metabolism with proton magnetic resonance spectroscopy after seizures. Symptomatic temporal lobe epilepsy with associated hippocampal neuronal loss, however, appears not to be present in idiopathic epileptic dogs. More permanent neuropathologic deficits can occur, especially in dogs or cats with very prolonged seizure activity.

CLINICAL SIGNS

A thorough and accurate history is essential for diagnosis of seizure patients.

▼ ***Key Point*** Suspicion of an epileptic seizure should be made with any event that has a sudden onset with a finite period of abnormal behavior and/or motor activity followed by some change in behavior or orientation.

- Obtain historical information concerning pedigree information, vaccination status, travel, trauma and toxin exposure potential, previous medical and surgical problems, and drug history.
- Organize information about the actual seizure episode(s) by stage into the prodrome, aura, ictal, postictal, and interictal periods.
- Record dates, times, duration, and description of each abnormality to assess progression and allow a comparison if medication is started.

▼ ***Key Point*** Evaluate the status of the pet's cerebrocortical function between seizures (after the postictal period) by asking questions concerning the animal's behavior, vision, gait, and sleep-wake patterns.

- Take a thorough neurologic history. For example, question if the dog is more withdrawn or attention seeking, shows any unusual episodes of aggression or

irritability, or fails to follow simple commands. These would suggest a structural cerebral problem. Likewise, determine the presence of subtle gait abnormalities (stumbling up and/or down the stairs), visual disturbances (occasionally bumping into objects on one side), and restless sleep patterns that may indicate cerebral problems.
- Classify seizure type as focal or generalized (see "Axis 2: Epileptic Seizure Types" and Table 127-1).
- Subcategorize focal seizures into elementary or automatisms.
- Subcategorize generalized seizures into convulsive and non-convulsive seizures.
- Characterize postictal abnormalities.
- Characterize as either isolated (one per 24 hours) or clustered (two or more in 24 hours). As a consequence of severe or prolonged seizure events, animals can develop detectable neurologic deficits during the immediate and extended postictal period. More severe immediate postictal abnormalities include vision loss, circling, paresis, profound disorientation, aggressive personality changes, and other dementing behaviors. Some of these changes may last several days to weeks, a condition known as Todd's paralysis when sensorimotor localizing deficits are found. Fortunately, practically all of these abnormalities are reversible.
- Characterize seizure-related interictal abnormalities.
- With chronic seizure activity, changes in cellular physiology of the brain can lead to actual changes in neurologic function, especially persistent behavior disturbances. Dogs with recurrent epileptic seizures may also exhibit changes in personality. Lack of obedience, withdrawal activity, changes in socialization with other animals or people in the household, and unprovoked aggressive behavior can all occur as interictal manifestations of a chronic epileptic condition in the dog. Attributing these changes to the disease or the treatment can be difficult to discern.

DIAGNOSIS

Differential Diagnosis

Dogs

▼ ***Key Point*** Carefully evaluate for an underlying identifiable etiology for seizures when dogs present from <1 or >5 years of age, have an initial interictal interval of <4 weeks, or have a focal seizure as the first observed seizure.

When approaching a differential diagnoses list (Table 127-2), consider the signalment, history, physical and neurologic examination changes, and laboratory abnormalities.

- For dogs <1 year of age, seizures are most commonly secondary, in particular, caused by developmental, metabolic, and inflammatory diseases (see Table 127-2). Specific diseases to include are hydrocephalus, portosystemic shunts, and canine distemper encephalitis, respectively. Specific breeds prone to congenital hydrocephalus are Maltese dogs, Chihuahuas, Yorkshire terriers, and the brachycephalic breeds. Any breed of dog, however, may suffer from this disease.
- For dogs between 1 and 5 years of age, the most common cause of seizures is idiopathic epilepsy. However, a proportion of dogs in this age category may suffer from a congenital brain anomaly that may be progressive in nature.
- For dogs >5 years of age that start to experience seizures, consider specific structural (symptomatic) and metabolic diseases (e.g., reactive). In particular, dogs are more prone to primary brain tumors and cerebrovascular disease as they age.

Cats

▼ ***Key Point*** Idiopathic epilepsy is rare in the cat.

The diverse genetic background of cats has fortunately made idiopathic epilepsy an uncommon diagnosis. Practically all cats have an underlying etiology for their seizure disorder. The differential diagnoses of seizure etiology for cats are listed in Table 127-2.

Diagnostic Approach

Refer to Chapter 125 for information on diagnostic evaluation of the patient with neurologic disease, and Chapter 126 for diagnostic parameters of specific diseases of the brain.

▼ ***Key Point*** The decision to pursue diagnostic testing should not be based on the number or severity of prior seizures. Rather, the decision should be based on the signalment, history, and initial neurologic examination.

Dogs

The goals of a diagnostic evaluation in a patient with seizures are to determine the underlying etiology, evaluate the prognosis for recurrence, and establish if antiepileptic medications are necessary for treatment. Most dogs have already suffered from more than one seizure by the time they are presented to a veterinarian. Furthermore, many dogs appear normal when examined during interictal periods. In a dog with a history of seizures, try to determine if the seizure will recur and whether a more serious underlying disease exists.

Table 127-2. DIFFERENTIAL DIAGNOSES OF SEIZURES IN THE DOG AND CAT

Idiopathic
Channelopathies
Other genetic diseases

Symptomatic (or Secondary)

Developmental anomaly
Hydrocephalus
Cortical dysplasia
Lissencephaly

Inflammatory Diseases (Encephalitis)
Infectious
- Viral
- Fungal
- Bacterial
- Parasitic

Immune-mediated
- Granulomatous meningoencephalitis
- Eosinophilic meningoencephalitis
- Breed-specific meningoencephalitis
- Other corticosteroid-responsive inflammatory diseases

Vascular
Ischemic
- Thromboembolic
- Idiopathic feline ischemic encephalopathy

Hemorrhagic
- Hypertension-related
- Coagulopathy

Neoplasm
Extra-axial: Meningioma, bone tumors
Intra-axial: Glial tumors, metastasis
Intraventricular: Ependymoma, choroids plexus tumors

Traumatic
Toxicity

Probably Symptomatic (or Cryptogenic)
Prior head trauma in patients with normal imaging
Postencephalitic seizures developing months to years later
Undetected hypoxic or vascular events of the brain after anesthesia
In utero or birth trauma

Reactive Epileptic Seizures
Organ failure
- Hepatic
- Renal

Electrolyte imbalance
- Hyponatremia or hypernatremia
- Hypocalcemia

Energy deprivation
- Hypoglycemia
- Thiamine deficiency

- A diagnosis of idiopathic epilepsy is more likely when the following are true:
  - The dog is between 1 and 5 years of age at the first seizure.
  - The dog is a large breed (>15 kg).
  - The interval between the first and the second seizure events is long (>4 weeks).
- A diagnosis of secondary epilepsy is more likely when the following are true:
  - A dog is <1 or >7 years old at the first seizure.
  - The first seizure is a focal seizure.
  - The interval between the first and the second seizure events (an event being all seizures within a 24-hour period) is brief (<4 weeks).
  - The neurologic examination is abnormal.
- A diagnosis of reactive epileptic seizures (metabolic etiology) is more likely when the following are true:
  - The interval between the first and the second seizure events is brief (<4 weeks).
  - The animal is showing signs of systemic illness.

Diagnostic Testing

Dogs

- Evaluate a minimum database consisting of noninvasive blood pressure, complete blood count (CBC), serum chemistry profile, urinalysis, and thoracic radiographs to rule out possible metabolic causes. In younger dogs, a serum bile acid study is recommended to rule out a portosystemic shunt. Unfortunately, these tests have a very low yield of positive findings in most seizure patients.
- If symptomatic epileptic seizures are suspected, consider MRI of the brain. This test offers the best opportunity to diagnose either an intracranial anomaly or a primary neoplasia, which are the prevalent causes of seizures in dogs <1 or >7 years of age, respectively. If negative scan results are found, then cerebrospinal fluid (CSF) should be collected for analysis.
- Collect CSF first if a multifocal disease or meningeal inflammatory process is suspected after the neurologic examination.
- Perform additional diagnostic testing in any dog with persistent interictal neurologic abnormalities. Select tests according to the history and clinical suspicions—for example, serum bile acids to evaluate liver function, serial fasting blood glucose paired with insulin levels to diagnose hyperinsulinemia, plasma lead concentration, and specific serum antibody titers for infectious diseases.

Cats

▼ ***Key Point*** Always consider that an underlying cause for seizures is present in cats, until proved otherwise.

Consider the following diagnostic tests in cats:

- Evaluate a minimum database consisting of noninvasive blood pressure, complete blood count, serum chemistry profile, urinalysis, baseline thyroid level, retrovirus testing, *Toxoplasma* antibody titers, and thoracic radiographs to rule out possible metabolic or infectious causes. Serum feline infectious peritonitis (FIP) antibody titers are poorly correlated with the central nervous system form of infection.

- Collect CSF first if a multifocal disease or meningeal inflammatory process is suspected.
- Perform MRI brain scanning in all cats >7 years of age and/or in those cats with an abnormal neurologic exam. The combination of MRI scanning and CSF analysis is often the most direct approach to a definitive diagnosis in any age cat with normal laboratory testing.
- Also consider specific serologic tests for infectious diseases (e.g., fungal) and serum bile acids to evaluate liver function.

TREATMENT

This section describes seizure control therapy. Refer to Chapter 126 for treatment of specific diseases of the brain.

Goals of Therapy

Prior to starting antiepileptic drug (AED) treatment, owners and veterinarians should have a realistic expectation of what to expect over the course of therapy.

- Foremost, seizure control does not equal elimination.
- Realistic goals are a decrease in the number and severity of seizures, fewer post-ictal complications, and an increase in the interictal period.
- Inform clients that this may be a lifetime, daily treatment regimen; there will be frequent reevaluations; there is a potential for emergency situations to arise; and there are inherent risks from the drugs.
- Single-drug therapy for treating epilepsy is preferred because it reduces possible drug–drug interactions and adverse effects.

▼ ***Key Point*** The ultimate goal of antiepileptic therapy is to maintain a seizure-free status with acceptable or no adverse effects.

Limitations of Antiepileptic Drugs

Unfortunately, several limitations exist in the selection of AEDs for use in veterinary medicine:

- *Toxicity*—Drugs with hepatic metabolism have the potential for hepatotoxic effects.
- *Tolerance*—This can be metabolic in origin in that progressively more drug is needed over time to maintain the same therapeutic serum concentration, or it can be functional in that cellular adaptations occur that prevent full efficacy of the drug.
- *Inappropriate pharmacokinetics*—Certain AEDs are metabolized too rapidly to allow a steady-state concentration to be achieved with normal-interval dosing (2 to 3 times per day).
- *Expense*—Lifetime drug administration and monitoring can be prohibitively expensive for some owners.

Deciding When to Start Treatment

▼ ***Key Point*** Instruct the owner to document seizures and other problems in a written log. This record provides the basis for initiating and adjusting AED therapy and for determining the benefits of therapy.

Base the decision to initiate AED therapy on the underlying etiology, seizure type and frequency, and diagnostic evaluation. Initiate phenobarbital therapy in the following situations:

- An identifiable intracranial disease process is present.
- Status epilepticus has occurred.
- Two or more isolated seizures have occurred within a 6-month period.
- Two or more cluster seizure episodes have occurred within a 12-month period.
- The first seizure was within 1 week of trauma.
- Severe or prolonged post-ictal effects are present (e.g., prolonged blindness and aggressive behavior).

Phenobarbital Administration

Phenobarbital is the initial AED of choice because it is a relatively inexpensive, well-tolerated drug that effectively prevents seizures in animals when administered 2 to 3 times per day.

Phenobarbital in Dogs

▼ ***Key Point*** In the dog, give phenobarbital initially at least every 12 hours at a dose of 2.5 mg/kg PO with subsequent increases in dose most likely within 30 days to maintain a trough therapeutic serum concentration.

- In the dog, phenobarbital has a high bioavailability (between 86% and 96%). The drug is rapidly absorbed within 2 hours with a maximal plasma concentration obtained within 4 to 8 hours after oral administration. Almost one-half of the drug is protein bound. The majority of phenobarbital is metabolized by the liver, with approximately one-third excreted unchanged in the urine. Phenobarbital is an autoinducer of hepatic microsomal enzymes (P450 system), which can progressively reduce the elimination half-life with chronic dosing. Elimination half-lives have been reported to range from 42 to 89 hours, with a significantly shorter half-life in beagles (32 hours). Thus, initial steady-state serum phenobarbital concentrations (Css) are achieved within a maximum of 18 days in dogs with the longest elimination half-life (five elimination half-lives). At 5.5 mg/kg/day, Css and total body clearance are stable by 30 days.

Phenobarbital in Cats

▼ ***Key Point*** In the cat, give phenobarbital initially every night at a dose of 2.5 mg/kg with subsequent increases in the dose or frequency most likely within 30 days to maintain a trough therapeutic serum concentration.

- As in the dog, phenobarbital has a high bioavailability with rapid gastrointestinal absorption in the cat. Unlike the dog, the cat does not have significant autoinduction of the p-450 system with phenobarbital treatment. Thus, the elimination half-life of 40 to 60 hours does not appear to change significantly over time. This long half-life makes it possible to start once-a-day therapy. However, a wider fluctuation between the peak and the trough daily serum concentrations with once-a-day dosages may not provide adequate seizure control, necessitating dosages to be given in twice-daily intervals in some cats.

Intravenous Phenobarbital Loading

▼ ***Key Point*** Phenobarbital has the dual advantage of achieving high serum concentrations and reducing the cerebral metabolic rate following intravenous (IV) dosing.

- The advantage of IV administration is the ability to achieve a therapeutic concentration in the brain very rapidly (see "Hospital Emergency Treatment for Seizures"). IV phenobarbital is rapidly distributed within 10 minutes in the dog and the cat; therefore, it provides a rapid, high drug concentration to stop seizures while serving as a cerebral protectant.
- To achieve a serum concentration of 20 µg/ml in the dog:

$$\text{Total IV loading dose (mg)} = (\text{Body weight [kg]}) \times (0.8\ \text{L/kg}) \times (20\ \mu\text{g/ml})$$

- To achieve a serum concentration of 15 µg/ml in the cat:

$$\text{Total IV loading dose (mg)} = (\text{Body weight [kg]}) \times (0.9\ \text{L/kg}) \times (15\ \mu\text{g/ml})$$

- Give the total dose at a rate of <100 mg/min.

Serum Monitoring of Phenobarbital

▼ ***Key Point*** Monitor trough serum concentrations of phenobarbital to determine if a therapeutic level is maintained when the lowest serum concentration is present (i.e., immediately before the next dose). Animals will be most susceptible to seizure at this time.

Overall, phenobarbital is well tolerated at therapeutic serum concentrations in the dog and cat. My recommended trough therapeutic concentration range of phenobarbital is between 20 and 40 µg/ml in the dog and between 10 and 20 µg/ml in the cat.

- The goal of any AED therapy is to achieve serum concentrations within the established therapeutic range for that drug. The major advantage of monitoring serial serum trough phenobarbital concentrations is to individualize treatment by documenting that an adequate amount of drug is being given while minimizing the potential for toxic effects.
- The lower limit of the therapeutic range is the minimal concentration at which 50% of animals will have any therapeutic benefit. Conversely, the upper limit is the maximal concentration at which 50% of animals will not have toxic adverse effects. Monitor the serum concentrations only after steady-state levels are reached. Furthermore, wide variations in serum concentration can occur in dogs and cats on similar oral doses of phenobarbital.

▼ ***Key Point*** Optimal seizure control with minimal toxicity can be obtained by maintaining the trough serum concentration of phenobarbital between 20 and 30 µg/ml in dogs and between 10 and 20 µg/ml in cats.

- Measure trough serum concentrations of phenobarbital according to the following guidelines:
  - At 14, 45, 90, 180, and 360 days after the initiation of treatment
  - At 6-month intervals thereafter
  - Any time the pet has more than two seizure events between these times
  - Any time cluster seizures or status epilepticus occur
- Adjustments of the trough concentration can be calculated with the following formula:

$$\text{mg of phenobarbital per day} = \frac{\text{Desired concentration}}{\text{Actual concentration}} \times \text{Total mg of phenobarbital PO per day}$$

  - This new value can then be divided either twice daily or 3 times daily. The only advantage of administration 3 times a day is less fluctuation between the peak and the trough serum concentrations, which may be important in animals requiring tighter therapeutic windows. Note that no adjustment is made according to weight and no upper-limit dosage is present. Each animal is treated as an individual with allowances for individual variations in metabolism.
- If concern arises about toxicity, obtain peak levels by measuring the concentration 4 to 6 hours after pill ingestion with once-daily or twice-daily administra-

tion and 4 hours after pill ingestion with 3-times-a-day dosages.
- Evaluate complete blood counts and serum chemistry profiles at 3 months and at 6-month intervals thereafter for evidence of toxicity.

Adverse Effects of Phenobarbital

▼ ***Key Point*** Do not lower the initial phenobarbital dose if signs of sedation or behavior changes are seen after starting treatment. These signs are transient adverse effects that typically disappear in 10 to 14 days.

Adverse effects of any AED can be broadly categorized into predictable and unpredictable (idiosyncratic) complications. Further subclassification can be based on transient versus chronic or progressive problems. Despite the long historical use of phenobarbital in veterinary medicine, few reports exist documenting the adverse effects of the drug in dogs and cats. Lack of reportable information may be due to overall safety of the drug, difficulty in accurately documenting clinical adverse reactions, delay in detection of problems after onset of therapy, or a combination of these.

Idiosyncratic Drug Reactions

Idiosyncratic drug reactions to phenobarbital are usually associated with unusual behavioral changes after starting the drug. Hyperexcitability and restlessness are infrequent problems that do not appear to be dose related. Acute toxic hepatopathy is infrequently associated with phenobarbital administration in the dog and cat.

Transient and Mild Effects

More predictable, dose-related, transient adverse effects of a non–life-threatening nature can be categorized as follows:

- *Behavior changes*—Owners may complain that their pet is acting more sedate and lethargic after starting phenobarbital therapy. This change often dissipates after 1 to 2 weeks of treatment. Other potential transient complaints are polydipsia, polyuria, and polyphagia. On physical and neurologic examination, animals may demonstrate excessive somnolence, ataxia, and disorientation. Higher oral and IV doses can produce more profound behavioral changes. Polydipsia and polyphagia can also occur. Dogs may develop psychogenic polydipsia with associated polyuria. The polyphagia can lead to intense scavenging and begging behavior. This can lead to dietary indiscretion with subsequent serious problems of gastroenteritis, pancreatitis, or foreign body obstruction. Some owners also complain that their dog "just isn't the same pet" after phenobarbital therapy.
- *Physical examination changes*—The most common change with chronic phenobarbital therapy is weight gain. Most likely this is the result of increased appetite (with an increased food supply) coupled with a more sedentary lifestyle. Some dogs may develop splenomegaly and/or hepatomegaly. Persistent neurologic deficits without underlying intracranial pathology are extremely uncommon.
- *Clinical laboratory changes*—Transient clinical laboratory changes are minimal. Urine specific gravity may decrease. The most common clinical laboratory change associated with chronic phenobarbital therapy is elevation of serum alkaline phosphatase (ALP) in the dog. This can occur as quickly as 2 weeks after therapy. Neither endogenous adrenocorticotropic hormone (ACTH) nor exogenous response to ACTH is altered by phenobarbital. Moreover, phenobarbital does not interfere with a low-dose dexamethasone suppression test regardless of dose or treatment time. However, baseline serum thyroxine concentration is depressed in 60% to 70% of dogs on phenobarbital. These dogs have a normal response to thyroid-stimulating hormone (TSH). Thus, use TSH response to diagnose hypothyroidism in dogs on phenobarbital.

Life-Threatening Complications

Three serious and potentially life-threatening complications can occur with long-term phenobarbital therapy:

- *Physical dependence*—Such dependence on the drug develops over time. Withdrawal seizures can develop as serum phenobarbital concentration declines, especially during precipitous drops below 20 µg/ml (dog) or 10 µg/ml (cat).
- *Functional tolerance*—The loss of drug efficacy despite adequate serum concentration can develop as the result of altered transport of the drug through the blood-brain barrier, down-regulation of receptors in the brain, and progression of epilepsy resulting in multiple seizure foci or changes in neurotransmission. The degree of functional tolerance to phenobarbital in the dog is not clear. In my experience, phenobarbital is less in dogs with predominant focal epileptic seizure types.
- *Drug-induced toxicity*—Chronic phenobarbital therapy can also lead to hepatotoxicity, especially if serum trough levels are maintained at or above 35 µg/ml. Hepatotoxicity to primidone (which is metabolized predominantly to phenobarbital), either alone or in combination with other AEDs, occurs in dogs. A more serious idiosyncratic reaction is development of immune-mediated neutropenia, anemia, and thrombocytopenia in dogs. Typically, this reversible blood dyscrasia will occur within the first 6 months of dosing.

Treatment of Refractory Epilepsy in Dogs

Approximately 20% to 50% of dogs treated for epilepsy at referral veterinary institutions are reported to be poorly controlled with medical management and thus become classified as refractory epileptics.

Criteria for Refractory Epilepsy

My criteria for classifying idiopathic canine epileptics as refractory are as follows:

- An etiology of seizures has not been identified.
- Phenobarbital has been administered for at least 3 months with all serum trough concentrations between 20 and 40 µg/ml and a trough steady-state concentration between 25 and 30 µg/ml without a subsequent change in dosage for at least 1 month.
- Seizure number and severity have not improved or have worsened for at least 3 months despite phenobarbital and/or other AED treatment.
- Status epilepticus has occurred.
- Hepatotoxicity is present.

▼ ***Key Point*** Consider adding a second AED for dogs whose seizures continue despite persistent trough serum phenobarbital concentrations > 30 µg/ml for 1 to 2 months.

Bromide Therapy

The recommended add-on AED of choice in the dog is bromide (Table 127-3). Concomitant bromide and phenobarbital decreased seizure numbers and severity in the majority of dogs in two studies, with seizure-free status ranging from 21% to 72% of all treated dogs. In general, many canine refractory idiopathic epileptics may benefit from bromide despite prior seizure history onset or duration. By allowing a reduction of the use of drugs metabolized by the liver, bromide therapy may also reduce the incidence of hepatotoxicity.

Table 127-3. SUMMARY OF ANTIEPILEPTIC DRUG THERAPY IN THE DOG

ANTIEPILEPTIC DRUG	CLINICAL PHARMACOLOGY $T_{1/2}$ (hour)	Tss (days)	Vd (L/kg)	Prot Bd (%)	THERAPEUTIC RANGE	INITIAL DOSAGE	EFFICACY	MAJOR POSSIBLE ADVERSE EFFECTS
Phenobarbital*	40–24	10–14	0.80	40	20–40 µg/ml	2.5 mg/kg q12h	Generalized seizures	Sedation, polydipsia, liver disease; induces P450 system
Bromide*	15–20 days	100–200	0.40	0	Monotherapy: 2000–3000 µg/ml With phenobarbital: 1500–2500 µg/ml	40 mg/kg q24h	Generalized seizures	Sedation, weakness, polydipsia, polyphagia
Felbamate*	5–6	1–2	1.00	25	25–100 µg/ml	20 mg/kg q8h	Partial seizures	Blood dyscrasia, liver disease; induces P450 system
Gabapentin*	2–4	1	0.20	0	4–16 µg/ml	30–60 mg/kg/day[t] (divide bid or tid)	Generalized and partial seizures	Sedation
Clorazepate*	5–6	1–2	1.60	85	20–75 µg/L (nordiazepam)	2–4 mg/kg/day (divide bid)	Add on: Generalized and partial seizures	Sedation, withdrawal seizures
Topiramate	20–30	3–5	0.65	15	2–25 µg/ml	2–10 mg/kg q12h[t]	Add on: Generalized and partial seizures	Gastrointestinal upset, irritability
Zonisamide*	15–20	3–4	1.50	50	10–40 µg/ml	5–10 mg/kg/day (divide bid or tid)	Add on: Generalized and partial seizures	Sedation, ataxia, loss of appetite
Levetiracetam*	4–6	1–2	0.50	<10	10–37 µg/ml	500–4000 mg/day[t] (divide bid or tid)	Add on: Generalized and partial seizures	Sedation, inappetence

*Clinical pharmacology data presented for dogs.
Prot Bd, protein binding; t, gradual incremental dosing recommended; $T_{1/2}$, elimination half-life; Tss, approximate time to steady state; Vd, volume of distribution.

Although its exact mechanism of action is not completely understood, bromide appears to have a competitive interaction with chloride to hyperpolarize neuronal membranes in the brain. Thus, bromide is expected to have a synergistic effect with drugs that enhance chloride conductance, such as phenobarbital.

Bromide is administered as the inorganic salt, potassium bromide, typically as a 200- to 250-mg/ml solution dissolved in doubled distilled water. Bromide is a known mucosal irritant, and while capsular formulation is available, this dosing method may result in gastric irritation due to the direct contact of a concentrated amount of bromide with the gastric lining.

At a starting dosage of 40 mg/kg/day, bromide is slowly metabolized in the dog, with a median elimination half-life of 15.2 days resulting in achievement of median steady-state concentrations of 2450 mg/L. Apparent total body clearance was 16.4 ml/day/kg and volume of distribution was 0.40 L/kg. Steady-state concentrations fluctuate among dogs, most likely due to individual differences in clearance and bioavailability. Dietary factors also alter serum bromide concentrations, with high chloride diets resulting in excessive bromide renal secretion and lower serum concentrations.

The protocol for potassium bromide administration and monitoring is as follows:

- *Preparation*—Dissolve analytic-grade potassium bromide in double distilled water as a 200-mg/ml solution.
- *Administration*—The initial dosage is 30 mg/kg/day PO in food (with concurrent phenobarbital administration) or 40 mg/kg/day as monotherapy. The solution can be placed directly on the dog's food. Give the drug once per day or divided every 12 hours. Dividing the dose allows better adaptation to the sedative effects of the drug.
- *Monitoring*—Obtain trough serum concentrations of bromide at 30 days, 90 days, and every 6 months after initiation. The therapeutic range is 150 to 200 mg/dl (1.5–2.0 mg/ml) with concurrent phenobarbital administration (maintaining trough serum phenobarbital concentration from 20–30 µg/ml). Decrease the phenobarbital if hepatotoxicity occurs or if the dog is seizure free for >6 months.
- *Dosage adjustments*—The dosage is adjusted according to the following formula:
  - For concomitant phenobarbital- and bromide-treated patients, the new maintenance dose can be calculated with the following formula:

(Target Css – Actual Css) × (Clearance/Bioavailability) =
(2000 mg/L – Actual Css) × 0.02 =
added mg/kg/day to existing dose

  - Here, Css is the steady-state concentration at day 75 after treatment.
- Bromide is indicated as a single-agent AED in the following situations:
  - Underlying liver disease (e.g., hepatotoxicity or portosystemic shunting), which prevents the use of phenobarbital
  - Prolonged seizure-free status (>1 year) on combined phenobarbital and bromide therapy
  - Unacceptable quality of life on combined phenobarbital and bromide therapy with a seizure-free status period of >3 months
  - Infrequent initial seizures (<4 per year)
- *Dosing and monitoring*—The oral monotherapy starting dosage is 40 mg/kg/day. Oral loading dosing can be accomplished with a dose of 900 mg/kg divided into equal doses every 4 hours over 1 day, but this may result in gastric upset. The IV loading dose is described under emergency treatment of seizures (see below). Dogs treated with subsequent monotherapy bromide should have bromide concentrations at or above 2500 mg/L for optimal seizure control. Gradual increases in the dose allow better adaptation to the drug. Doses are adjusted according to the following formula:
  - For monotherapy bromide-treated patients, the new maintenance dose can be calculated with the following formula:

(Target Css – Actual Css) × (Clearance/Bioavailability) =
(2500 mg/L – Actual Css) × 0.02 =
added mg/kg/day to the existing dose

  - Again, Css is the steady-state concentration.
- *Adverse effects*—Bromide is generally well tolerated in the dog. The most common adverse effects seen with combination bromide and phenobarbital therapy are polydipsia, polyphagia, increased lethargy, and mild ataxia with increasing serum concentration. Pancreatitis and gastrointestinal intolerance have also been reported. Bromide intoxication to the point of stupor is rare, but pelvic limb ataxia, weakness, and altered behavior are more likely with serum concentrations >3000 mg/L. Caution should be used in treating dogs with underlying renal insufficiency, due to reduced renal elimination of bromide. Therapy of bromide intoxication consists of IV normal saline administration to enhance bromide renal excretion. Careful monitoring is advised as dogs may become more susceptible to seizure activity with lowering of the serum concentration.

New Antiepileptic Drugs with Potential for Use in Dogs

Several AEDs that have recently been approved for use in people offer exciting potential for use in dogs. Unfortunately, complete information is unavailable on the pharmacokinetic or therapeutic properties of these

drugs in controlled studies in dogs. Most of these medications are still quite expensive. The drugs are listed in alphabetical order and not in preference of use.

Felbamate (Felbatol)

Felbamate is a dicarbamate with proven ability to block seizures induced by a variety of methods. Felbamate is believed to increase seizure threshold and prevent seizure spreading by reducing excitatory neurotransmission in the brain. Neuroprotective effects have also been shown through this ability to alter excitatory neurotransmission. In clinical trials in people, felbamate has been shown to be most useful as monotherapy in the treatment of uncontrolled partial epilepsy. The drug is metabolized by the hepatic microsomal P450 enzymes and with increased clearance in younger dogs. In dogs, the drug has a high bioavailability and protein-binding capability.

- Effective control of focal seizure activity with documented therapeutic serum concentrations has been shown with felbamate therapy in dogs.
- The recommended dosage in dogs is 20 mg/kg q8h PO initially; increase as necessary up to a maximum of 3000 mg/day.
- Felbamate is a non-sedating drug but has been reported with a higher incidence of aplastic anemia and liver toxicity in people. These adverse effects have not been documented in dogs.
- Avoid concurrent use of felbamate and phenobarbital due to the possibility of increased hepatotoxicity and alteration of serum phenobarbital concentrations (felbamate increases serum phenobarbital concentration by 25%).
- Serial monitoring of the complete blood count and chemistry panel is recommended at 1 month and then every 3 months during treatment for the first year and then every 6 months thereafter.
- Trough serum drug concentration is typically done 1 to 2 weeks after initiation of treatment, with a therapeutic range between 25 and 100 mg/L.

Gabapentin (Neurontin)

Gabapentin is a novel AED whose mechanism of action is still not fully understood. Initially designed to mimic gamma-aminobutyric acid (GABA) in the brain, gabapentin can readily pass through the blood-brain barrier. Once in the brain, however, gabapentin does not mimic the pharmacologic properties of GABA, nor does it bind to GABA receptors. In preclinical studies, gabapentin effectively blocked seizures induced by a variety of proconvulsant methods. New evidence suggests that gabapentin may facilitate the extracellular transport of GABA out of cells to act on the GABA-alpha receptor. The dog is the only known species to partially biotransform the drug to N-methyl-gabapentin.

▼ ***Key Point*** A major benefit of gabapentin is that there is minimal hepatic metabolism thus it will not induce drug–drug interactions with other AEDs with hepatic metabolism (e.g., phenobarbital).

- Dosage: 30 to 60 mg/kg/day (divided every 8–12 hours). Gradual increase in dose over 1 to 2 weeks is recommended to allow adaptation to the sedating effects. Reduced doses may be needed in patients with renal insufficiency.
- Serum monitoring is not recommended, as the drug has a very high therapeutic index and little drug–drug interactions.
- Gabapentin is particularly useful in epileptic dogs with underlying hepatic disease.

Levetiracetam (Keppra)

Levetiracetam is the S-enantiomer of the ethyl analogue of piracetam that has broad-ranging, unique, and not completely known mechanisms of action against seizures. The drug is well absorbed but is more rapidly metabolized in people as compared with other drugs. The pharmacodynamic effect (i.e., the effect of the drug at the target organ) is believed to outlive the known half-life of the drug. Levetiracetam was the best tolerated of all new AEDs currently in human clinical trials, with adverse reactions equal to that of the placebo. Overall, this drug is proven to be an effective adjunctive therapy to control partial seizures previously refractory in treatment in people.

- Initial dosage: 500 to 1500 mg/day divided every 8 to 12 hours with gradual incremental dose titration.
- In my experience, the best response to this drug has been in dogs exhibiting automatisms and generalized seizures as an add-on medication to phenobarbital and/or bromide.
- The serum trough therapeutic range in epileptic people is reported to be 3 to 37 µg/ml.

Topiramate (Topamax)

Topiramate is a sulphamate-substituted monosaccharide with a mechanism of action of blockade of seizure spread by rapidly potentiated GABA activity in the brain. In people, topiramate is well absorbed and is primarily renal excreted as an unchanged drug. With a relatively long half-life of 20 to 30 hours, twice daily dosing is recommended. With a relatively broad-spectrum activity against many seizure types and minimal adverse effects, topiramate is approved for use in both adult and pediatric human patients. The dosage range is between 25 and 50 mg/kg/day, but gradual dose titration is better tolerated.

- Initial dosage: 2 to 10 mg/kg q12h with gradual incremental dose titration.
- I have used topiramate most successfully in dogs with partial and generalized seizures unresponsive to phenobarbital and bromide therapy.
- The serum therapeutic range is unknown in dogs but is between 2 and 25 mg/L in people.

Zonisamide (Zonegran)

Zonisamide is a substituted 1,2-benzisoxazole derivative that works by both blocking the propagation of epileptic discharges and suppressing focal epileptogenic activity. Pharmacokinetic information on the dog is limited to a very small population of normal beagles. In general, zonisamide is well absorbed, has a relatively long half-life, and has high protein-binding affinity. The drug is highly concentrated in red blood cells due to high binding to carbonic anhydrase and other red cell protein components. Zonisamide is hepatic metabolized and thus is influenced by concurrent administration of similarly metabolized drugs. Broad-spectrum antiepileptic activity has been reported against a variety of seizure types, with particular improvement in the treatment of adult myoclonus epilepsy. Major adverse effects in people include a higher incidence of renal calculi formation, sedation, and gastrointestinal disorders.

- Initial dosage: 5 to 10 mg/kg/day divided every 8 to 12 hours with gradual incremental dose titration.
- In my experience, zonisamide can be an efficacious and well-tolerated drug in the dog with recurrent generalized seizures refractory to phenobarbital and/or bromide therapy. The major adverse effects include sedation, ataxia, and inappetence. Phenobarbital dosages should be reduced by 25% at the time of starting zonisamide.
- The serum trough therapeutic range is reported from 10 to 40 µg/ml.

Drugs with Increased Risk or Inappropriate Pharmacokinetics in the Dog

▼ ***Key Point*** Since both primidone and phenytoin have been proved not to provide effective seizure control and are potentially hepatotoxic in the dog, do not use these drugs to treat seizures in the dog.

Lamotrigine (Lamictal)

The drug is converted to a cardiotoxic 2-N methyl metabolite in dogs, which is not found in people.

Phenytoin (Dilantin)

- There is a high risk of hepatotoxicity with this drug.
- It is difficult to maintain adequate steady-state serum concentrations due to the very rapid elimination half-life (approximately 2 hours).

Diazepam (Valium)

- Functional tolerance develops very quickly to diazepam, which results in inability to use diazepam as an effective emergency drug to stop cluster seizures or status epilepticus.
- There is potential for causing physical dependence and withdrawal seizures.
- It is difficult to maintain adequate steady-state serum concentrations.

Gamma-vinyl-gamma-aminobutyric acid (Vigabatrin)

- Potential for causing hemolytic anemia
- Potential for causing central nervous system vacuolation with chronic use
- Ineffective for stopping seizures

Carbamazepine (Tegretol)

It is difficult to maintain adequate steady-state serum concentrations due to the very rapid elimination half-life (approximately 2 hours).

Benzodiazepines

Benzodiazepines are a class of AEDs that interact with specific central nervous system benzodiazepine receptors, which activate the GABA-alpha chloride channel to hyperpolarize neuronal membranes.

- Diazepam is the most widely used benzodiazepine in veterinary medicine and is best used for the treatment of emergency seizures by IV and per rectal administration (see below).

▼ ***Key Point*** Chronic oral administration of diazepam is not recommended in the dog due to lack of effectiveness to stop seizures, very short half-life, potential for increased hepatic enzyme inhibition, physical dependence, and cross-tolerance to prevent effective use of IV diazepam to stop emergency seizures.

- A long-acting benzodiazepine, clorazepate, is a diazepam prodrug with more suitable pharmacokinetic properties for chronic use in the dog. However, similar problems may arise as with chronic oral diazepam, especially the potential for severe withdrawal seizure activity.

Treatment of Refractory Epilepsy in Cats

Since cats have an extremely high prevalence of symptomatic epileptic seizures, epileptic cats may not respond to phenobarbital alone. Moreover, the often focal nature of the underlying pathologic condition (e.g., meningioma or cerebrovascular accident) may predispose cats to focal seizure activity, which can be difficult to control with phenobarbital, in my experience. Unfortunately, cats are quite sensitive to the sedative

effects of many of the AEDs. Therefore, most combination therapies require a delicate balance of drug dosing. The following drugs may be tried in addition to or as replacement of phenobarbital therapy in cats.

▼ ***Key Point*** Adding a second AED or changing to a different therapy should be considered in cats whose seizures continue despite persistent trough serum phenobarbital concentrations above 20 μg/ml.

Benzodiazepines

Diazepam

- Cats appear to be resistant to developing functional tolerance to diazepam.
- Initial dosage: 0.5 mg/kg PO divided every 8 to 12 hours.
- Serum concentrations of nordiazepam can be monitored, but a therapeutic range has not been determined for the cat.

Clorazepate

Clorazepate is a long-acting benzodiazepine, similar in action to diazepam.

- Initial dosage: 2 to 3.75 mg total dose per cat q12–24h PO. Start at a low dose (1–2 mg per cat) and gradually increase over time.
- Serum concentrations of nordiazepam can be monitored, but a therapeutic range has not been determined for the cat.

Clonazepam

Clonazepam is a long-acting benzodiazepine, similar in action to diazepam.

- Initial dosage: 0.5 mg total dose once to twice daily.

Gabapentin (Neurontin)

Gabapentin is a useful AED in the cat due to its predominant renal excretion, similar to the dog. Cats, however, may exhibit increased sedation and will benefit by a gradual increment in dosing over 1 to 2 weeks.

- Initial dosage: 5 to 10 mg/kg daily for 3 to 5 days, then increase to every 12 hours. Further increases are dependent on response to therapy.
- Both solution (250 mg/5 ml) and capsular formulations of the drug are available. The drug can be used as both a monotherapy and an add-on medication.

Topiramate (Topamax)

In my experience, a number of cats with focal seizures, exclusive or with secondary generalization of seizures, will improve with the addition of topiramate to phenobarbital therapy. The key to success is gradual adaptation and eventual lowering of the phenobarbital dosage. The latter should be performed to acquire a trough level of approximately 10 μg/ml.

- Initial dosage: 12.5 mg total dose per cat per day, with incremental dosing up to 25 mg every 12 hours.
- Both breakable tablet (25 mg) and sprinkle (15 mg) formulations are available.
- Metabolic acidosis has been associated with chronic dosing in people. Periodic venous blood gas monitoring is recommended in addition to routine evaluation of complete blood counts and serum chemistry panels.

Drugs with Increased Risk or Inappropriate Pharmacokinetics in the Cat

Benzodiazepines

Fatal, acute idiosyncratic hepatotoxicity after diazepam administration has been reported in the cat. Thus, obtain a liver chemistry panel in all cats 3, 7, and 14 days and then every 3 to 6 months after initiation of therapy.

Bromide

Bromide therapy in cats is not recommended as a standard therapy due to the relatively high prevalence of adverse respiratory problems. Cats can develop cough and more severe respiratory signs suggestive of an allergic asthmatic disease. I no longer recommend the use of bromide in cats.

Hospital Emergency Treatment for Seizures

▼ ***Key Point*** A reliable protocol for rapid treatment is necessary for the emergency management of seizuring patients.

The physiologic sequelae of clustered or continuous seizure activity (status epilepticus) leading to increased intracranial pressure and neuronal necrosis include systemic arterial hypertension, loss of cerebrovascular regulation, disruption of the blood-brain barrier, and cerebral edema. If not treated appropriately, the seizuring patient may develop serious neurologic complications due to these events.

Guidelines for When to Administer Emergency Therapy for Seizures

- A single seizure that persists >5 minutes from the time the seizure is identified
- Status epilepticus
- More than one seizure per hour, regardless of seizure length
- Three or more seizures per day, regardless of seizure length

Protocol for Emergency Management of Seizures

A protocol for the emergency treatment of seizures in the dog and cat is outlined in Table 127-4. Two main

Table 127-4. PROTOCOL OF THE MEDICAL MANAGEMENT OF STATUS EPILEPTICUS AND CLUSTER SEIZURES IN THE DOG AND CAT

Phase 1

The goals of this initial phase are to stabilize the patient, institute short-acting AEDs with minimal adverse effects to immediately control active seizures, and to rapidly establish serum concentrations of a maintenance AED to preserve seizure control.

1. ABC: Establish a patent airway, maintain adequate breathing, and provide circulatory support.
2. Start a continuous IV infusion of 0.9% saline at a dosage of 5 to 10 ml/kg/hour.
3. Evaluate STAT blood glucose, PCV/TP, BUN, and AED serum concentration (if appropriate). Treat for hypoglycemia only if the blood glucose is ≤60 mg/dl.
4. Administer a bolus dose of DZ 0.5 mg/kg IV if a seizure episode lasts ≤1 minute, there have been at least two seizures (regardless of duration), or an intracranial etiology is suspected (regardless of duration).
   a. Alternate treatment: DZ per rectal injection (5 mg/ml of parenteral DZ)
      (1) No prior PB therapy: 1 mg/kg
      (2) Prior PB therapy: 2 mg/kg
5. Administer PB after DZ to provide a sustained antiepileptic effect as serum levels of DZ decline.
   a. Drug-naïve patients:
      (1) Give a loading dose of PB to rapidly establish therapeutic drug levels. Use this formula: **Loading dose (total mg) = Desired serum level (µg/ml) × Body weight (kg) × 0.8 L/kg.** Use an IV injection at a rate of ≤100 mg/min.
      (2) Desired serum concentration: Dogs = 20 µg/ml, cats = 10 µg/ml.
   b. PB-treated patients:
      (1) Give 1 mg/kg IV for each microgram per milliliter of desired increase in patient serum level.
      (2) Dogs: Raise serum concentration at increments of 5 µg/ml up to 30 µg/ml.
      (3) Cats: Raise serum concentration at increments of 3 µg/ml up to 20 µg/ml.
6. Alternative treatment with BR after DZ in dogs only:
   a. Drug-naïve patients:
      (1) Oral loading (NaBr or KBr): 200-mg/ml solution
      Target Css × Vd = Total dose administered = 2000 mg/L × 0.45 L/kg = 900 mg/kg/day divided into equal doses every 4 hours for 24 hours
      (2) IV loading (NaBR): 3% NaBR in sterile water
      Target Css × Vd = Total dose administered by continuous rate infusion in a central vein = 2500 mg/L × 0.45 L/kg = 900 mg/kg every 24 hours
   b. BR-treated patients:
      (1) New added oral dose over 24 hours: (Target Css − Actual Css) × Vd L/kg = (Target Css − Actual Css) × 0.45 L/kg = mg/kg doses in 4 equal doses every 6 hours
      (2) Target Css: Monotherapy BR treatment = 2000 mg/L; BR plus PB = 1500 mg/L

Phase 2

The goals of this phase are to institute maintenance AED therapy and monitor for further seizures activity.

1. Institute maintenance PB either PO or IM.
   a. Drug-naïve patients: After IV loading dose, initiate oral therapy at 2.5 mg/kg q12h starting in 12 hours.
   b. Established epileptic patients: Increase dose to an amount higher than that being administered on admission.
      (1) New total mg/day = (Desired concentration/Established concentration) × Total mg current dose
   c. Dogs: Increase the desired concentration in the maintenance dose formula at increments of 5 µg/ml up to 30 µg/ml.
   d. Cats: Increase the desired concentration in the maintenance dose formula at increments of 3 µg/ml up to 25 µg/ml.
2. BR therapy (dogs only) if BR is to be used as *monotherapy:*
   a. Drug-naïve patients:
      (1) Maintenance dose: Target Css × (Clearance/Bioavailability) = mg/kg/day = 2000 mg/L × 0.02 = 40 mg/kg/day divided bid
   b. Previous BR-treated patients:
      (1) New maintenance dose: (Target Css − Actual Css) × (Clearance/Bioavailability) = mg/kg/day = (2500 mg/L − Actual Css) × 0.02 = added mg/kg/day
3. BR therapy (dogs only) if BR is to be used as *combined therapy with PB:*
   a. Drug-naïve patients:
      (1) Maintenance dose: Target Css × (Clearance/Bioavailability) = mg/kg/day = 1500 mg/L × 0.02 = 30 mg/kg/day given daily or divided BID
   b. Previous BR-treated patients:
      (1) New maintenance dose: (Target Css − Actual Css) × (Clearance/Bioavailability) = mg/kg/day = (2000 mg/L − Actual Css) × 0.02 = added mg/kg/day
4. If seizures continue:
   a. At a rate of less than one per 3 hours: Use DZ 0.5 mg/kg IV bolus up to three doses and then proceed to phase 3.
   b. At a rate of more than one per hour: Proceed to phase 3.

Table 127-4. PROTOCOL OF THE MEDICAL MANAGEMENT OF STATUS EPILEPTICUS AND CLUSTER SEIZURES IN THE DOG AND CAT—cont'd

Phase 3

The goal of this phase is to treat recurrent seizures in patients that fail to respond to an initial course of IV bolus doses of DZ and PB.

1. Begin continuous rate IV infusion of DZ at an initial rate of 0.25 mg/kg/hour in a 0.9% NaCl (or 0.45% NaCl/2.5% dextrose if on BR) at a maintenance fluid rate.
2. If seizures continue (less than three total), increase the rate up to 0.5 mg/kg/hour.
3. If a total of three or more seizures occur while on the DZ infusion, administer one of the following for 6 hours:
   a. For pentobarbital: Initial bolus to induce general anesthesia at 2 mg/kg IV slowly to effect (if patient has been on PB prior to admission, a higher dose may be needed due to induction of the hepatic P450 system). Continuous infusion of approximately 5 mg/kg/hour to effect.
   b. For propofol: Initial slow infusion of 4 to 8 mg/kg IV to effect, followed by continuous infusion to maintain general anesthesia (8 to 12 mg/kg/hour).
      (1) Advantages: Primarily renal excreted (safer to use in dogs with liver disease), rapidly metabolized to allow rapid recovery, and does not induce biochemical changes.
      (2) Disadvantages: Can induce apnea, cause hypovolemia, and is relatively expensive for prolonged use.
4. Maintenance PB therapy should be administered IM throughout the anesthesia to provide sustained therapeutic serum concentration upon emergence from anesthesia.
5. Appropriate supportive care and monitoring should be provided for general anesthesia.
6. After 4 to 6 hours, if any further seizures occur, proceed to phase 4.

Phase 4

The goal of this phase is induction of prolonged general anesthesia.

1. Barbiturate
   a. Maintain general anesthesia as established in phase 3 for an additional 12 hours, followed by a tapering of anesthesia every 2 to 4 hours.
2. Gas anesthesia
   a. Indications: Refractory seizures to above steps or contraindication to use of benzodiazepine or barbiturate drugs (hepatotoxicity or hepatic encephalopathy).
   b. Isoflurane offers the following advantages: Rapid induction and adjustable anesthetic depth with smooth emergence from anesthesia, no hepatotoxicity, less perfusion problems, and less effect on elevation of intracranial pressure than halothane.
   c. Obtain arterial blood gases every 4 to 8 hours to ensure adequate oxygenation.

AED, antiepileptic drug; BR, bromide; BUN, blood urea nitrogen; Css, steady-state concentration; DZ, diazepam; PB, phenobarbital; PCV/TP, packed cell volume and total protein; Vd, volume of distribution.

components are listed in this protocol: restoring homeostatic conditions and providing specific seizure treatment. Many drugs used to control seizures have the potential to cause serious adverse effects, including death. Specific seizure treatment is divided into four successive phases.

- Phases 1 and 2 involve using a short-acting AED to stop immediate seizure activity and a long-acting AED to prevent further seizures. Diazepam is currently the drug of choice in treating prolonged seizures, including status epilepticus and cluster seizures.
- Phases 3 and 4 outline steps to follow if a dog continues to seizure despite prior treatment.
- To implement this protocol, be sure to have injectable diazepam, phenobarbital, pentobarbital, propofol, and a 24-hour monitoring facility.

At-Home Emergency Treatment for Seizures Using Diazepam per Rectum

Financial and emotional constraints of recurrent emergency therapy are often the limiting factor in an owner's decision to continue treating an animal. Per rectal administration of diazepam is a safe, affordable home treatment for cluster seizures that can reduce owner cost, decrease patient morbidity, and contribute positively to the overall AED therapy.

Per rectum administration of the IV formulation of diazepam allows rapid absorption of active drug into the bloodstream through the rectal mucosa in <15 minutes. Antiepileptic plasma concentrations are maintained for several hours after administration. In comparison, an intramuscular injection of diazepam results in an erratic absorption of the drug and may take up to 30 minutes for peak concentrations to appear in the blood. Use rectal administration of diazepam for the emergency treatment of seizures in the dog according to the following recommendations. No information is available for the cat.

- *Indications:* History of generalized cluster epileptic seizures, status epilepticus, and underlying cerebral disease.
- *Administration:* Use a syringe through a plastic application tip ($1^1/_3$ inch J-12 teat infusion cannula) lubricated with a water-soluble jelly.
- *Dosage:*
  - If not on phenobarbital: rectally administer 1 mg/kg of diazepam parenteral solution (5 mg/ml).
  - If on phenobarbital: rectally administer 2 mg/kg of diazepam parenteral solution (5 mg/ml).

- Do not exceed a maximum dose of 100 mg.
- Administer at the onset of a seizure up to 3 times in 24 hours but no closer than 15 minutes apart.

- *Toxicity:* Increased sedation and rectal mucosal irritation.

NON-EPILEPTIC SEIZURES DUE TO NARCOLEPSY AND CATAPLEXY

Non-epileptic seizures or episodes can be categorized into non-neurogenic and neurogenic causes. Many events may mimic epileptic seizures. Distinguishing non-epileptic seizures or episodes is important, because failure to do so could lead to failure to identify another serious medical condition, administration of unnecessary medication to the animal, and undue emotional and financial strain on the owner. This section discusses the non-epileptic seizures associated with sleep disorders: narcolepsy and cataplexy.

Etiology

- *Cataplexy* is a brief, sudden episode of muscle weakness without loss of consciousness. The signs are due to motor inhibition only.
- *Narcolepsy* is a disorder of daytime somnolence characterized by excessive sleeping episodes. Narcolepsy and cataplexy can occur together.

Pathophysiology

- A deficient hypocretin or orexin system is the underlying mechanism in narcolepsy.
  - Hypocretin or orexin neurons are restricted to the tuberal region of the hypothalamus, with extensive cortical projections that function to enhance brain excitation for arousal control.
  - Loss of hypocretin or orexin output results in a failure to regulate critical sleep-wave pathways.
  - Breeds documented to have an autosomal inheritance are the Doberman pinscher, Labrador retriever, miniature poodle, and dachshund.
  - The genetic mutation is due to the *canarc-1* deletion mutation of the hypocretin or orexin receptor-2 gene, resulting in a nonfunctional receptor.
  - The *canarc-1* gene is transmitted as an autosomal recessive trait with full penetrance that is not associated with the dog leukocyte antigen system.
- Several other breeds reported with narcolepsy or cataplexy include the Airedale, Afghan, Irish setter, malamute, Saint Bernard, rottweiler, English springer spaniel, Welsh corgi, and giant schnauzer.
- Autoimmune destruction of hypocretin-containing cells in the hypothalamus has been proposed as another common cause of narcolepsy in humans with the adult-onset form of the disease.
- The characteristic finding in this acquired form of the disease is low concentrations of hypocretin in CSF.
- Hypocretin-deficient narcolepsy or cataplexy has recently been described in a 3-year-old Weimaraner.
- This disease is rare in cats.

Clinical Signs

In practically all instances, dogs with non-epileptic seizures do not exhibit postictal effects. Possible exceptions are dogs that exhibit autonomic release phenomena (e.g., urination) after a syncopal episode and dogs with vestibular disease that continue to appear disoriented from their vertigo. The typical history and clinical signs of narcolepsy-cataplexy consist of the following:

- Onset usually by 6 months of age
- Sudden, paroxysmal generalized muscle atonia lasting seconds to 10 to 20 minutes
- Episodes often precipitated by excitement
- Intact respirations and cough and swallow reflexes
- Possibly aroused by external stimuli
- Possible signs of rapid eye movement (REM) sleep with ocular motility, facial or eye muscle twitching, and whining

Diagnosis

Differential Diagnoses

Non-neurogenic Episodes

- Syncope of cardiac origin (see Chapter 148)
- Arrhythmias (see Chapter 145)
- Right-to-left shunts (reverse patent ductus arteriosus, tetralogy of Fallot) (see Chapter 154)
- Cardiomyopathy (see Chapter 150)
- Metabolic disturbances
- Polycythemia (see Chapter 22)
- Hypoglycemia (see Chapter 35)
- Hypoadrenocorticism (Addison disease)
- Pheochromocytoma

Neurogenic Episodes

- Narcolepsy and cataplexy
- Vestibular disease (see Chapter 126)
- Myasthenia gravis (see Chapter 130)

Diagnostic Testing

Food-Elicited Test

The purpose of this test is to create an environment of excitement to induce an attack.

- *Protocol:* Place 10 pieces of palatable food approximately 1 cm^3 in size in a row about 1 ft apart from each other. Record the time required to eat all pieces and the number, type, and duration of the attacks.
- *Interpretation:* The normal dog will eat the food in <1 minute and have no attacks.
- *Abnormal responses:*

- The dog will take >2 minutes to eat the food and have two or more attacks.
- The animal drops to the ground with flaccid paralysis (complete attack).
- Thoracic and/or pelvic limbs drop to the ground but the head does not (partial attack).

Pharmacologic Testing

The purpose of these tests is to induce or reduce attacks with various central-acting drugs.

- *Yohimbine response test:* Give a 50-µg/kg IV bolus of yohimbine. A positive response is a 75% reduction in the number or severity (time reduction) of attacks. Response occurs within 30 minutes and may last up to 4 hours.
- *Physostigmine challenge test:* Give 0.025 mg/kg of physostigmine salicylate as an IV bolus. Follow each injection with a food-elicited test in 10 minutes. Repeat the test with additional 0.025-mg/kg increments up to 0.100 mg/kg. In affected animals, signs increase in severity and frequency in a dose-dependent manner. The total effect of each dose will last 15 to 45 minutes.

Electrophysiologic Testing

The purpose of these tests is to confirm loss of muscle activity during an attack and absence of epileptic activity in the brain.

- Electroencephalographic recordings are consistent with acute onset of REM sleep during an attack without epileptiform activity.
- Concurrent electromyographic recordings from appendicular muscles show complete loss of activity during an attack.

Genetic Analysis

Genetic analysis in dogs has been performed at the Center for Narcolepsy, Department of Psychiatry, Stanford University, School of Medicine, Stanford, CA 94305.

Treatment

- Modafinil is the drug of choice for narcolepsy and cataplexy.
  - Novel wake-promoting agent
  - Dosage: 1 to 5 mg/kg/day
  - Adverse effects: Excessive stimulation and wakefulness, decreased appetite, tachycardia, and hypertension
- Methylphenidate (Ritalin)
  - Dosage: 0.25 mg/kg q24h or q12h PO
  - Adverse effects: Potentially inappetence, irritability, or altered sleep patterns

Prognosis

Overall, the prognosis for a good life is fair to good. Dogs may improve as they age. Alterations of lifestyle may be necessary to avoid precipitating events, such as reducing excitement or stressful events as much as possible.

Chapter

128 Disorders of the Spinal Cord

Patricia J. Luttgen / Paul A. Cuddon

The term *spinal cord disorders* (see Table 128-1 for classification and examples) broadly refers to all diseases affecting the spinal cord. Clinically, spinal cord disorders may cause dysfunction in one or more limbs. Urinary and fecal incontinence and tail dysfunction may also be seen.

▼ ***Key Point*** Disorders of the spinal cord do not cause signs referable to diseases above the foramen magnum, such as mentation changes, cranial nerve deficits, and vestibular ataxia.

ETIOLOGY

Spinal cord disorders can arise from numerous insults and may be associated with particular signalments (breed, age, sex) and neuroanatomic localizations. Many of these disorders cause relatively predictable patterns of onset (acute versus chronic) and clinical signs (progressive versus nonprogressive).

Anomalies

Anomalies of the spinal cord usually are first recognized when ambulation begins and are nonprogressive. Examples include spinal dysraphism in Weimaraners and sacrocaudal dysgenesis with spina bifida in English bulldogs and Manx cats.

- For some anomalies, traumatically induced "decompensation" may be required for minor lesions to be recognized clinically. An example is atlantoaxial subluxation of toy breeds in which ligamentous and dens malformations create C1-C2 instability and an increased risk of C1-C2 luxation.
- Some anomalies slowly worsen over the life of the animal to cause progressive worsening of signs. Dogs with congenital arachnoid cysts show slowly progressive spinal cord signs as the cavitating lesion expands in size. In dogs with caudal occipital malformation syndrome (COMS), progressive foramen magnum compression causes disruption of cerebrospinal fluid (CSF) flow and syringohydromyelia formation. Signs of slowly progressive spinal cord dysfunction can be seen at almost any age.
- Vertebral anomalies that compromise the stability of the vertebral column or the canal size may cause spinal cord dysfunction secondary to compression. For example, hemivertebra may lead to vertebral body luxation, and malarticulation/malformation of articular facets may lead to spinal canal stenosis.

Degenerative Disorders

Degenerative conditions are usually insidious in onset and chronically progressive.

- Many of these conditions are inherited and are seen in young animals. Examples include lysosomal storage disorders such as globoid cell leukodystrophy and Niemann-Pick disease, spinal muscular atrophy of Brittany spaniels, and hereditary ataxia of Jack Russell and smooth-haired fox terriers.
- Other neurodegenerative disorders are age-related and may be familial. Examples include degenerative myelopathy seen in older, large-breed dogs, particularly the German shepherd. In this disorder, white matter degeneration is most severe in the T3-L3 region.
- Some age-related degenerative disorders affect bony and soft tissues surrounding the spinal cord and result in spinal cord compression. Examples include cervical spondylomyelopathy in Doberman pinschers, intervertebral disc disease (discussed under spinal cord trauma below), lumbosacral spondylopathy/stenosis of German shepherd dogs, and mucopolysaccharidosis in cats.

Trauma

- Trauma can arise from external sources (e.g., being hit by a car or a bullet) or from internal sources (e.g., disc herniation or a pathologically collapsed vertebra).
- Clinical signs are usually acute and nonprogressive. However, progressive signs may be seen.
- Pathologic vertebral body fractures can occur secondary to vertebral body neoplasia or osteomyelitis.

Table 128-1. CLASSIFICATION AND EXAMPLES OF SPINAL CORD DISORDERS

Category	Examples
Degenerative	Globoid cell leukodystrophy
	Degenerative myelopathy of German shepherds
	Hereditary spinal muscular atrophy of Brittany spaniels
	Hereditary ataxia of smooth-haired and Jack Russell terriers
	Caudal cervical spondylomyelopathy
Anomalous	Spinal dysraphism
	Spina bifida
	Myelodysplasia
	Atlantoaxial subluxation
	Hemivertebrae
	Spinal arachnoid cysts
	Caudal occipital malformation syndrome with syringohydromyelia
Neoplastic	Intramedullary ependymoma
	Intramedullary astrocytoma
	Intramedullary oligodendroglioma
	Extramedullary intradural meningioma
	Extramedullary peripheral nerve sheath tumor
	Lymphoma
	Extradural vertebral osteosarcoma
Infectious	Feline infectious peritonitis
	Canine distemper myelitis
	Rabies
	Cryptococcosis
	Rickettsial diseases
	Neosporosis
	Toxoplasmosis
	Discospondylitis
Immune-mediated	Granulomatous meningoencephalitis
	Steroid-responsive meningitis/vasculitis
Toxic	Tetanus
	Strychnine
Traumatic	Intervertebral disc herniation
	Fracture/luxation of spinal column
Vascular	Fibrocartilaginous embolization
	Progressive hemorrhagic myelomalacia
	Caudal aortic embolization

Intervertebral Disc Disease

- *Type I intervertebral disc disease* is characterized by sudden disc extrusion. Signs of spinal cord compression are usually acute and may progress over a few hours or days.
- *Type II intervertebral disc disease* is characterized by slow protrusion of a slowly degenerating disc. Signs are usually gradual in onset and progression.

Inflammation/Infection

Numerous infectious agents can affect the spinal cord and surrounding structures of animals of all breeds and ages. Clinical signs vary depending on the inciting agent, the location of the lesion, and the degree of spinal cord involvement. Signs are usually rapid in onset and progression. Often inflammatory disease of the central nervous system (CNS) is not confined to the spinal cord, and clinical signs of brain involvement will also be present (see Chapter 126).

Bacterial

- Primary bacterial meningitis or meningomyelitis is infrequently diagnosed in dogs and cats. Bacterial infection is most commonly introduced secondary to infection of surrounding tissues or to trauma.
  - For example, bacterial discospondylitis causes discomfort from disc and vertebral body infection and may cause neurologic deficits if secondary compression of the spinal cord occurs.

Viral

Viral myelitis is a relatively common problem in dogs and cats. Clinical presentation and neuroanatomic localization vary.

- Typically, encephalitic signs are associated with rabies infection, but this virus may also cause signs of myelitis (see Chapter 15).
- All ages of dogs are susceptible to canine distemper virus (CDV; see Chapter 13). Previous vaccination does not preclude "breaks" in immunocompetency due to other illnesses or disease states. Signs of spinal cord disorder without associated encephalitic signs may occur.
- In cats, coronavirus (feline infectious peritonitis) and retrovirus (feline leukemia virus and feline immunodeficiency virus) infections may cause signs of spinal cord dysfunction with or without signs of brain involvement (see Chapters 8, 9, and 10).

Fungal

- Fungal myelitis has been reported in patients with cryptococcosis, blastomycosis, histoplasmosis, and coccidioidomycosis.
- Multiple levels of the nervous system usually are involved simultaneously (e.g., eyes, brain, spinal cord); however, signs are limited to the spinal cord in some patients.
- Systemic mycoses are discussed in Chapter 20.

Rickettsial

- In addition to other clinical signs, tickborne rickettsial diseases such as ehrlichiosis and Rocky Mountain spotted fever may cause myelitis, meningitis, and encephalitis (see Chapter 17).

Protozoal

- *Neospora caninum* may cause pelvic limb rigidity followed by a rapid ascending tetraparesis/tetraplegia due to a severe myelitis (see Chapter 21).

- Toxoplasmosis can also cause spinal cord myelitis and radiculitis, especially in cats (see Chapter 21). Encephalitis, ocular involvement, and myositis may also be present.
- We recommend testing for both organisms if protozoal myelitis is suspected.

Granulomatous Meningoencephalomyelitis (GME)

- This is believed to be an immune-mediated disorder of the brain and spinal cord.
- Signs of spinal cord myelitis and meningitis may predominate. The cervical area seems to be the preferred site of involvement in the spinal cord.
- GME primarily affects the white matter of the CNS and consists of perivascular accumulations of lymphocytes, plasma cells, and reticuloendothelial cells. Perivascular cuffs can coalesce to produce granulomas.
- The disease is invariably progressive in nature (see Chapter 126).

Immune-Mediated Disorders

- Immune-mediated steroid-responsive meningitis and/or meningeal-vasculitis have been reported in young dogs of many breeds. Boxers are commonly affected with this disorder. A more severe form of this syndrome (necrotizing vasculitis) has been reported in beagles, Bernese Mountain dogs, and German short-haired pointers.
- Clinical signs are typical of spinal meningitis including neck stiffness, hyperesthesia, and fever.

Toxins

- Strychnine and tetanus directly affect the spinal cord in dogs and cats. These toxins act in a similar manner.
- Tetanus toxin decreases the release of the inhibitory neurotransmitters, γ-aminobutyric acid and glycine in the spinal cord, whereas strychnine competitively blocks the inhibitory effect of glycine.
- Clinical onset is usually acute, and the disease progresses to a state of severe tetany.

Vascular Disorders

- Vascular conditions resulting in ischemia of the spinal cord most often cause peracute to acute nonprogressive spinal cord dysfunction. Intramedullary spinal cord lesions are nonpainful.
- The lesion may affect any area of the spinal cord.

▼ ***Key Point*** In adult large-breed dogs, fibrocartilaginous embolization is the most common cause of vascular injury to the spinal cord. Lesions are often asymmetrical and may affect several spinal cord segments in a continuous or discontinuous distribution.

- In cats, caudal aortic embolization secondary to cardiomyopathy is a common cause of spinal cord vascular injury.

Neoplasia

- Neoplasia of the spinal cord can affect animals of all ages and breeds. Initial clinical signs vary, depending on the type and location of the tumor. Signs usually are progressive over weeks to months. Two major types of tumors affect the spinal cord: intramedullary and extramedullary.
  - Intramedullary tumors such as astrocytoma and ependymoma arise from the spinal cord itself, causing damage by derangement of the normal anatomy. Hemangiosarcoma, lymphoma, and other tumors may metastasize to intramedullary sites in the spinal cord.
  - Extramedullary tumors arise from tissues surrounding the spinal cord and cause damage by compression. Extramedullary tumors can be located intradurally (e.g., meningiomas and nerve root tumors) or extradurally (e.g., vertebral osteosarcomas and multiple myeloma). Extradural lymphoma is a common cause of caudal paresis in cats.
- See Chapter 101 for discussion of neoplasia of the axial skeleton.

CLINICAL SIGNS

Characteristic clinical signs of spinal cord injury include spinal pain or hyperpathia, proprioceptive deficits, paresis or plegia, and nociceptive (pain) loss.

Hyperpathia

- Involvement of nerve roots, dura, and other extradural structures adjacent to the spinal cord will result in hyperpathia (exaggerated response to a painful stimulus).
- Spinal hyperpathia can be assessed by observing for pain on spinal palpation, neck guarding or stiffness, or signs of a root signature (holding/favoring the limb at rest).
- Extradural and extramedullary lesions are often painful. This can be helpful in lesion localization.

Postural Deficits and Ataxia (Proprioceptive Dysfunction)

- Ascending sensory tracts in cord white matter convey proprioceptive information from the limbs to the brain.
- Conscious proprioceptive (CP) tracts convey signals concerning limb position at rest to the cerebral cortex.
- Unconscious proprioception (UP) tracts convey signals concerning limb position during locomotion to the cerebellum.

- Injury to CP tracts causes knuckling and slow postural reactions (as during the hopping test).
- Injury to UP tracts causes ataxia ("drunken" gait with crossing over, wide-based posture, truncal sway, circumduction, and, occasionally, hypermetria). Ataxia is usually observed in the limbs caudal to the lesion.

▼ ***Key Point*** Ascending proprioceptive fibers in the spinal cord are the most sensitive to compressive lesions. Therefore, CP deficits and incoordination (sensory ataxia) of one or more limbs is commonly the initial sign of spinal cord disease.

Paresis and Plegia

- Descending upper motor neuron (UMN) tracts in cord white matter originate in brain and terminate in the spinal cord. The UMN system modulates functions of the thoracic and pelvic limb lower motor neurons (LMNs) located in the gray matter of cord segments C6-T2 and L4-S2, respectively.
  - UMN inputs facilitate limb strength and motor abilities and inhibit some spinal reflexes and limb extensor muscle tone.
  - LMNs also facilitate strength, relay locomotor signals from the UMN system, are part of the reflex arc for spinal reflexes, and provide trophic support to limb muscles.
- Injury to either UMN or LMN pathways will cause varying degrees of *paresis* (weakness) or *plegia* (weakness with loss of locomotor abilities) of the limbs.

▼ ***Key Point*** UMN injury results in paresis to limbs caudal to the level of the lesion, and LMN injury results in paresis to limbs at the level of the lesion.

- Injury to UMN pathways results in retention of spinal reflexes and increased extensor muscle tone when animals are recumbent.
- Injury to LMN pathways results in depression of spinal reflexes, decreased muscle tone, and muscle atrophy.

Affected Spinal Segment

- *C1-C5 injuries* can potentially cause signs of UMN tetraparesis or tetraplegia if damage to UMN pathways occurs.
- *C6-T2 injuries* can cause signs of LMN paresis in the thoracic limbs and signs of UMN paresis in the pelvic limbs.
- *T3-L3 injuries* can cause signs of UMN paresis in the pelvic limbs.
- *L4-S3 lesions* can cause signs of LMN paresis in the pelvic limbs, incontinence due to urinary bladder, urethral sphincter, and anal sphincter dysfunction.

Nociceptive (Pain) Loss

- Ascending nociceptive tracts in the spinal cord white matter convey nociceptive (pain) signals from the limbs to the cerebral cortex.
- Injury to these tracts results in depressed or absent detection of noxious stimuli.
- Nociceptive perception is usually assessed by testing the digits for superficial and deep pain sensation.
- Nociceptive tracts in cord white matter are very resistant to injury and are affected by only very severe spinal cord injuries.

▼ ***Key Point*** The ascending spinal cord pain fibers are the most resistant to compressive lesions. Therefore, lack of deep pain perception as demonstrated by no visible response to a noxious stimulus (i.e., the animal does not appear to be consciously aware of the pain) applied to a limb or tail caudal to a compressive lesion indicates severe damage to the spinal cord.

Other Features of Spinal Cord Lesions

- As compressive (extradural or extramedullary) lesions worsen, CP, UP, UMN (limbs and then bladder/sphincter), and then nociceptive functions are lost in that order. Examples include intervertebral disc disease, discospondylitis, vertebral body tumors, and vertebral malformations. Predictable and sequential signs of CP deficits, sensory ataxia, and then paresis are observed.
- Neurologic deficits are ipsilateral to the lesion.
- Extramedullary lesions that "lateralize" cause asymmetrical signs.
- Intramedullary lesions such as some spinal cord tumors, degenerative conditions, myelitis, and some spinal cord anomalies tend to cause symmetrical neurologic deficits (exception is asymmetrical fibrocartilagenous infarction) that may progress in a less predictable fashion.
- Intramedullary lesions without concurrent extramedullary involvement are nonpainful.
- Intramedullary cervical cord lesions may lead to cervical torticollis (lateral deviation of the neck).
- The ratio of spinal canal to spinal cord diameter is much greater in the cervical region than in the thoracolumbar region. For this reason, extramedullary lesions in the cervical region can be quite large without causing severe neurologic deficits. Conversely, smaller extramedullary lesions in the thoracolumbar area can be associated with severe neurologic deficits due to the small amount of space around the spinal cord.

DIAGNOSIS

History

- In spinal cord disorders, key aspects of the history are signalment, nature of onset, and progression of clinical signs. Knowledge of breed, age, and progression of signs can usually aid in narrowing down the list of most likely differential diagnoses.
  - For example, chronic progressive disease in an older German shepherd suggests degenerative myelopathy, neoplasia, or chronic type II disc herniation.
  - Acute nonprogressive disease in a young dog suggests trauma, acute type I disc herniation, or fibrocartilaginous embolization.

Lesion Localization (Neurologic Examination)

- The neurologic examination establishes the presence or absence of neurologic dysfunction (see Chapter 125).
- See previous discussion under "Clinical Signs" for localizing lesions in animals with paresis and/or plegia.
- Many of the diseases described above (myelitis, tumors, fibrocartilagenous infarction, degenerative disorders) can affect any segment of the spinal cord.
- Other diseases target specific areas of the spinal cord. Examples include atlantoaxial subluxation (C1-C2), hemivertebrae (thoracic spinal cord), degenerative myelopathy (T3-L3), spina bifida (lumbosacral area), and cervical spondylomyelopathy (C5-C7). Knowledge of these predilection sites can aid in choosing appropriate diagnostic tests to perform.
- As discussed above, spinal hyperpathia usually suggests an extramedullary lesion while absence of hyperpathia suggests an intramedullary lesion. This information may influence choice of imaging modality (magnetic resonance imaging [MRI] versus myelography).

Minimum Database

- Establishing a minimum database (MDB) is essential for assessment of the animal's overall health prior to general anesthesia for neurologic testing. The MDB also aids in ruling out systemic inflammatory, metabolic, and endocrine disorders that may be contributing to the neurologic state.

▼ ***Key Point*** The MDB for neurologic patients consists of a complete physical examination (including neurologic, otic, and ophthalmic evaluation), complete blood count (CBC), serum biochemical analysis, urinalysis, fecal analysis, thyroid panel (T4, free T4, thyroid-stimulating hormone) and electrocardiogram. Routinely test for heartworm in endemic areas.

Specialized Laboratory Examinations

- Specialized tests may be indicated, based on physical examination findings and/or MDB results.
- Examples include endocrine function tests, fine-needle aspiration cytology of enlarged lymph nodes, tests for infectious diseases (e.g., feline leukemia, feline immunodeficiency, feline infectious peritonitis, canine distemper, toxoplasmosis, neosporosis, rickettsial disease, and fungal infections; see appropriate chapters in Section 2, Infectious Diseases).
- Urine and blood cultures are recommended if discospondylitis is present.

Electrodiagnostic Tests

- Electrodiagnostic tests useful in the diagnosis of spinal cord disease include electromyography (EMG), motor and sensory nerve conduction velocity studies (MNCV and SNCV, respectively), dorsal and ventral nerve root studies (cord dorsum potentials [CDPs] and F waves, respectively), spinal cord evoked potentials (SCEPs), and somatosensory evoked potentials (SSEPs). These evaluations generally require specialized equipment and referral to a veterinary neurologist.
- Epaxial and limb EMG is useful for localizing areas of denervation secondary to a lower motor neuron lesion (see Chapter 125).
- MNCV and SNCV studies of peripheral nerves, and nerve root evaluation (CDPs and F waves), help to rule out peripheral nerve, nerve root, and muscle diseases that present with many of the same clinical signs as spinal cord disease (see Chapters 129 and 130 for discussion of peripheral nerve and muscle disorders, respectively).
- SCEPs and SSEPs evaluate the integrity of the ascending spinal cord tracts to determine the extent of functional damage.

Imaging Techniques

Plain Spinal Radiography

- Plain radiography is often sufficient to diagnose problems such as atlantoaxial subluxation, vertebral fracture/luxation, vertebral neoplasia, vertebral anomalies such as spina bifida and hemivertebrae, and discospondylitis.
- Discospondylitis is characterized by lytic, irregular end plates with sclerosis of adjacent vertebral bone. Avoid causing further injury to the animal during these procedures.
- Refer to Chapter 4 for positioning and technique.
- When plain radiographs are inconclusive, use specialized procedures.

Myelography

- Myelography remains a useful diagnostic procedure in small animals (see Chapter 4).

- Disadvantages compared to MRI include greater invasiveness (intrathecal contrast injection), longer anesthetic times, lack of imaging of intramedullary lesions, and inability to image in the axial plane.
- Myelography has certain advantages for imaging extradural lesions, especially those involving bony structures or those that may dynamically compress the spinal cord. Post-myelogram computed tomography allows excellent imaging of the axial spinal canal and bony structures and provides accurate information concerning localization of lateralized lesions.
- Myelography is contraindicated in the presence of CNS inflammation (encephalitis, myelitis, meningitis) or if increased intracranial pressure is suspected.

Magnetic Resonance Imaging (MRI)

- MRI is a very useful and effective technique to image the spinal cord (see Chapter 4).
- MRI provides excellent soft tissue resolution and is the imaging modality of choice for characterizing intramedullary spinal cord lesions, nerve sheath tumors, and lumbosacral spondylopathy in the German shepherd.
- MRI has increased our awareness of the prevalence of syringohydromyelia in certain breeds. It also provides imaging in the sagittal, axial, and horizontal planes for improved lesion localization.

Computed Tomography (CT)

- If the goal is to evaluate a suspected bony lesion, CT is the preferred imaging modality (see Chapter 4).

Cerebrospinal Fluid (CSF) Analysis

▼ ***Key Point*** CSF analysis is the test of choice for establishing an inflammatory cause of spinal cord disease; furthermore, it provides nonspecific information that is helpful in the diagnosis of degenerative, neoplastic, and vascular conditions, including the following:

- Degenerative, neoplastic, and occasionally vascular problems may cause increased protein levels in the presence of normal cell counts in CSF.
- Inflammatory conditions of the spinal cord cause increases in CSF protein and variable increases in cell numbers and type, depending on the specific etiologic agent causing the insult.
- Sterile suppurative or steroid responsive meningitis is characterized by a predominance of neutrophils in CSF.
- GME is characterized by increased numbers of lymphocytes, monocytes, and macrophages in CSF.
- Etiologic agents (e.g., bacteria, rickettsiae, protozoa, fungi) are sometimes identified in CSF by culture (bacteria) or cytology.
- Comparative titers on simultaneously collected CSF and serum are also helpful for identifying active CNS infection by canine distemper virus and toxoplasmosis.
- Neoplastic cells are rarely seen in the CSF of patients with CNS neoplasia. However, globoid cells may be identified in cases of globoid cell leukodystrophy.
- For further details concerning CSF collection technique and abnormalities in specific infectious and inflammatory conditions of the CNS, see Chapters 125 and 126.

TREATMENT

The management of spinal cord disorders depends on the etiology and the severity of the spinal cord injury. Medical treatment, surgery, radiation therapy, or a combination of these treatment modalities may be indicated.

Medical Therapy

Degenerative Disorders

- Glucocorticosteroids at anti-inflammatory doses are recommended for degenerative conditions that cause secondary compression of the spinal cord. These disorders include cervical spondylomyelopathy, type II intervertebral disc disease, and lumbosacral spondylopathy. In each of these disorders, avoid long-term corticosteroid therapy. Surgical intervention is usually indicated due to the progressive nature of these conditions.
- For most of the neurodegenerative diseases, no specific therapy is available and only supportive treatment can be provided. Various treatments have been attempted in degenerative myelopathy, all without proven effect. Bone marrow transplantation has shown some efficacy is some lysosomal storage diseases (see Chapter 126).

Spinal Cord Trauma

- Medical therapy to combat the effects of acute spinal cord trauma (e.g., edema, ischemia) is based on the use of glucocorticosteroids.

Glucocorticosteroids

- Best results in spinal cord trauma are obtained when large doses of corticosteroids are administered immediately after injury, followed by rapid dosage tapering.
- Base the total dosage and tapering of dosage on the patient's response to therapy. Evaluate the patient's neurologic function at least every 8 hours to determine if another dose is necessary.
- The maximum amount of time that glucocorticosteroids are beneficial following spinal cord injury

appears to be 2 to 3 days; longer administration is of little benefit and enhances the likelihood of gastric ulcers, gastroenteritis, and pancreatitis. Use a concurrent H_2-blocker and sucralfate therapy to reduce the potential for gastric ulceration (see Chapter 67 for dosages).

▼ ***Key Point*** The most beneficial glucocorticosteroid for acute spinal cord trauma, including that from acute intervertebral disc herniation, is methylprednisolone sodium succinate (MPSS or Solu-Medrol, Upjohn).

- In experimental studies, MPSS administered intravenously during the first 8 hours following injury has shown remarkable sparing action on the spinal cord compared with dexamethasone, mannitol, dimethyl sulfoxide (DMSO), naloxone, and thyrotropin-releasing hormone.
  - Give an initial dose of 30 mg/kg IV followed by dosages of 15 mg/kg IV at 2 hours and then every 6 hours for a minimum of 24 hours. Alternatively, give the initial 30 mg/kg dose followed by a continuous infusion of 5.4 mg/kg/hr IV for 24 to 48 hours. The above protocols have been shown to be effective in human and experimental animal models of spinal cord injury if provided within 1 to 6 hours of the injury. Controlled clinical trials in veterinary medicine have not been performed.
- If additional glucocorticosteroid therapy is necessary, substitute with dexamethasone, prednisolone, or prednisone.

Hyperosmotic Solutions

- Hyperosmotic solutions, such as mannitol, have been widely used to combat post-traumatic brain edema, but their use in cases of spinal cord trauma is ineffective.

Other Drugs

- Other investigated drugs for adjunctive therapy of spinal cord trauma, such as antioxidants, calcium channel blockers, and vasodilators, are not routinely recommended at this time.

Infection

Antimicrobial Drugs

- Antimicrobial drugs may be indicated if specific infectious agents are identified or suspected. Treatment of systemic mycoses, protozoal, and rickettsial infections are discussed in detail in Chapters 20, 21, and 17, respectively. Also, see Chapter 126 for treatment of CNS infections.

Spinal Meningitis and Myelitis

- In cases of meningitis or myelitis, select antimicrobials that are known to cross the blood-brain barrier readily (i.e., highly lipid soluble in the non-ionized state, such as trimethoprim-sulfonamide combinations, rifampin, metronidazole, chloramphenicol, and certain imidazoles such as fluconazole).
- Drugs with intermediate penetrating abilities in the normal CNS may have improved penetrating abilities when the CNS is inflamed. These include the penicillin family (e.g., amoxicillin, carbenicillin), quinolones (e.g., enrofloxacin), the newer-generation tetracyclines (e.g., doxycycline, minocycline), clindamycin, and certain cephalosporins.
- Avoid drugs that penetrate poorly such as the aminoglycosides, amphotericin B, and ketoconazole.

Discospondylitis

- Treatment of discospondylitis presents a unique challenge because of the difficulty of presenting sufficient antimicrobial concentrations to the affected disc space and vertebral bodies.
- *Staphylococcus* is the organism most frequently reported. *Brucella canis, Nocardia, Streptococcus canis, Corynebacterium diphtheroides,* and various fungi also have been isolated.
- If possible, base selection of antimicrobial drugs on positive culture results (blood, urine, or the affected disc space) or a positive *Brucella* agglutination test. Otherwise, assume that the causative organism is coagulase-positive *Staphylococcus* and administer beta-lactamase–resistant antibiotics that reach sufficient therapeutic levels in bone and purulent exudates.
- Clinical signs may improve within a few days, but long-term therapy of several months is usually required to prevent relapses.
- In some cases, antimicrobials alone are not effective, and surgical intervention is required. When surgery is required, remove the infected vertebral end plates and associated disc structures. Use a vertebral body bone plate to stabilize the area and fill in the defect with cancellous bone. (See Chapter 100 for more information on spinal surgery.) Administer intralesional antibiotics.

Immune-Mediated Disorders

- Both GME and immune-mediated meningitis syndromes are treated via immunosuppression. Initially give prednisone (1.0–2.0 mg/kg q12h) and consider using it in combination with other immunosuppressive agents (cytosine arabinoside, azathioprine, procarbazine, lomustine). With combination therapy, the prednisone dosage often can be decreased to once daily or every other day therapy. In some dogs, prednisone therapy can be eliminated over time.

- Radiation therapy has been shown to have a beneficial effect on encephalitis caused by GME.

Toxicities

Tetanus

- For tetanus, initially administer penicillin G (20,000–100,000 IU/kg q6–12h IV or IM). Tetracycline (22 mg/kg q8h PO or IV) is recommended as an alternative because of the variable effect of penicillins on vegetative forms of the organism. Metronidazole (dog, 15 mg/kg q8h PO; cat, 250 mg total, q12–24h, PO) has shown excellent efficacy. It is bactericidal against most anaerobes and reaches effective levels in necrotic tissues.
- Equine tetanus antitoxin (100–1000 IU/kg IV, usually administered only once) may combat the neurotoxin if given early enough. However, anaphylactic reactions are common, necessitating an initial test dose (0.1–0.2 ml) given SC or intradermally (ID) 15 to 30 minutes prior to IV dosing.
- Chlorpromazine (0.5–2.0 mg/kg q8–12h, given IM, IV, or PO) is effective against the hyperexcitability sometimes observed.
- Diazepam (dog, 5–10 mg total, q2–4h, given PO, IV, or IM; cat, 2.5–5 mg total, q2–4h, PO) blocks the effect of the toxin on the spinal cord but has a very short duration of action.
- Barbiturates also may be used to combat the tetany. Phenobarbital (16–18 mg/kg, IV) can be given to immediately control seizure activity and generalized body stiffness, followed by oral maintenance therapy (2–4 mg/kg q12h PO). Pentobarbital therapy may be needed if muscle spasms are severe and nonresponsive to diazepam, methocarbamol, and phenobarbital therapy.

Strychnine

- For strychnine intoxication, chlorpromazine, diazepam, and barbiturates are used as for tetanus above. In order to block further gastrointestinal absorption, perform gastric lavage followed by oral administration of binding agents, such as activated charcoal.

Neoplasia

- Most antineoplastic drugs do not cross the blood-brain and blood-CSF barrier.
- Lomustine does penetrate CNS tissues and, in conjunction with prednisone, can be useful for treatment of CNS lymphoma. Cytosine arabinoside penetrates into the CNS when given intravenously at high concentrations (up to 400 mg/m^2). Use of cytosine arabinoside at induction followed by long-term lomustine therapy can be used in conjunction with traditional chemotherapy protocols for multicentric lymphoma with CNS involvement (see Chapter 27).
- Lomustine and glucocorticoid therapy can also be used effectively for malignant histiocytosis in the CNS.
- Radiation therapy has been beneficial in the treatment of some types of neoplasia. Remission times of 1 to 2 years for tumors such as meningiomas, nerve sheath tumors, and lymphoma must be weighed against the significant risk of radiation-induced spinal cord injury.

Surgical Treatment

Principles

- The primary goals of neurosurgical intervention are to decompress the spinal cord and nerve roots and to stabilize the vertebral column. Surgical intervention is most frequently effective in cases of compressive extramedullary spinal cord disease such as intervertebral disc herniation. It is possible to debulk some intramedullary tumors, but surgery has no application in the majority of intramedullary diseases (i.e., degenerative, anomalous, and infectious disorders; traumatic lacerations; vascular accidents).

Criteria for Surgery

- The decision for neurosurgical intervention is based on the historical progression of spinal cord signs, the localization and extent of neurologic deficits, and the likelihood that decompression and/or stabilization will be effective for the disorder diagnosed.

Timing of Surgery

- When indicated, surgical intervention is most valuable in the early stages of a problem, especially in acute compressive conditions such as acute type I disc herniation in which the functional outcome often parallels the speed with which surgical decompression is performed.
- Prompt surgical decompression for acute compressive lesions is indicated if neurologic deficits are progressive over 24 hours or if the patient is plegic or has lost deep pain. See "Prognosis" (next page) for prognostic indicators of outcome.
- In chronic progressive conditions, such as caudal cervical spondylomyelopathy and type II intervertebral disc disease, surgery performed in the early stages of disease is far more rewarding than surgery performed after significant dysfunction has been allowed to develop. Chronic compression causes irreversible damage to the spinal cord that surgery cannot correct and may even worsen by decompensating a chronically compensated condition.

▼ ***Key Point*** When recommending spinal cord surgery for a paralyzed animal, warn the owner that

extensive postoperative physiotherapy and nursing care may be necessary.

Surgical Techniques

- Cervical cord decompression for disc herniation usually is performed via a ventral slot procedure (through the vertebral body). Dorsal decompression of the cervical cord is used less frequently for cases of stenosis, malformation, malarticulation, dorsal ligamentous hypertrophy, and lateralized disc extrusion.
- Surgical decompression of the thoracolumbar or lumbosacral spinal cord usually is performed via hemilaminectomy, foramenotomy, or dorsal laminectomy, depending on the site of the lesion.
- Disc fenestration is routinely performed by some neurosurgeons as a prophylactic procedure to prevent recurrence of disc herniation. Disc fenestration does not decompress the spinal cord.
- For COMS, a subtotal occipital craniectomy with durotomy decompresses the foramen magnum and has been shown to improve CSF flow in humans.
- See Chapter 100 for details on treatment of spinal fractures and luxation.
- Spinal cord surgery requires advanced skills and equipment, and can cause significant harm to the animal if improperly performed. Refer the patient to a surgical specialist.

Physiotherapy and Nursing Care

▼ ***Key Point*** Regardless of the nature of the spinal cord disorder, physiotherapy and good nursing care are extremely important to avoid secondary problems and to hasten return to a functional state.

Physiotherapy (also see Chapter 95)

- Thermal applications—cold and hot packs
- Soft tissue mobilization—muscle massage
- Joint mobilization—limb manipulations
- Functional exercise training—towel walking, sit-to-stand
- Electrical stimulation of muscles
- Hydrotherapy—swimming

Nursing Care

- Perform frequent evacuation of the bladder (q4–6h) to prevent urinary tract infections and secondary bladder dyssynergia.
- Use clean padded bedding or pet waterbed to prevent decubital ulceration.
- Give daily baths to prevent secondary dermatitis.

PROGNOSIS

- In general, the more severe the neurologic deficits, the more guarded the prognosis.
- As discussed under Clinical Signs, severe clinical signs of compressive spinal cord lesions include plegia and loss of deep pain. Loss of deep pain for greater than 24 hours indicates a poor prognosis for recovery of normal function. If deep pain is still present and surgery is done immediately, the prognosis is fair to good.

▼ ***Key Point*** Accurately assess for deep pain sensation prior to recommending surgery on paralyzed animals. The animal must exhibit conscious perception of pain, not just a withdrawal reflex.

Based on Clinical Signs

- The presence of conscious proprioceptive deficits and sensory ataxia only in animals with non-neoplastic extramedullary compression is a favorable prognostic sign because it indicates compression affecting only the proprioceptive fibers.
- In general, the longer the duration of spinal cord injury, the more guarded the prognosis. The spinal cord undergoes irreversible degenerative changes if compressed or inflamed for a long period of time.

Based on Etiology

Anomalies

- Anomalous conditions usually have a nonprogressive course and thus their prognosis depends on the extent of spinal cord injury.
- Anomalous conditions that either decompensate after minor trauma (atlantoaxial subluxation) or gradually worsen over time (COMS) may benefit from surgical decompressive procedures.

Degenerative Disorders

- Neurodegenerative conditions often progress to severe disability and have a guarded to poor prognosis.

Trauma

Intervertebral Disc Disease

- The prognosis for intervertebral disc disease and trauma will depend on the conditions outlined above for compressive lesions.
- In general, extramedullary compressive lesions have a better prognosis than intramedullary destructive lesions.

Spinal Fractures

- In an animal with spinal fractures, if radiographs indicate severe vertebral displacement, it is likely that the neurologic deficit is irreversible; therefore, advise the owner that surgical intervention probably will not be beneficial. However, in cases in which MRI, or other imaging modalities, indicates that the spinal cord

may be intact, a significant percentage will improve if surgery, combined with aggressive medical therapy, is performed within a few hours of injury.

Infection

- Infectious myelitis has a guarded prognosis unless a specific causative agent can be identified and/or response to antimicrobial therapy occurs. Spinal cord infections for which no treatments are available (canine distemper, rabies, and feline infectious peritonitis) have a poor prognosis.
- Discospondylitis has a fair to good prognosis if antimicrobial therapy is instituted before the onset of paresis or more severe neurologic deficits. If plegia is present, the prognosis is poor.

Meningitis and Myelitis

- Immune-mediated meningitis generally has a good prognosis with appropriate immunosuppressive therapy.
- Myelitis due to GME has a guarded prognosis, especially if immunosuppressive therapy is not started promptly. GME can progress rapidly resulting in irreversible cord damage. GME is treatable but is rarely curable. Remission times will vary depending on the severity of the CNS involvement (see Chapter 126).

Vascular Disorder

- The prognosis for fibrocartilagenous embolic myelopathy will depend on the severity of the neurologic deficit (see preceding page). For any vascular disorder of the spinal cord, it is advisable to monitor affected animals for at least 48 hours for signs of improvement. Early signs of recovery may change the long-term prognosis.

Neoplasia

- The prognosis for intramedullary tumors is usually poor because surgical removal is not possible and radiation therapy is often not effective. Glucocorticosteroids may slow progression but do not effect a cure.
- The prognosis for extramedullary nerve sheath tumors is variable depending on their location and extent of involvement. The prognosis is poor when multiple nerve roots are involved, but can be good if only one nerve root is involved and surgical removal can be performed. Radiation therapy can increase remission times for nerve sheath tumors. Even in these cases, however, the tumor will eventually regrow and invade the spinal cord.
- *Extramedullary meningiomas* can often be surgically debulked. They are also radiation sensitive. Survival times with combined therapy may be as long as 2 years.
- *Extradural lymphoma* can be treated with chemotherapy and/or radiation therapy but recurrence usually occurs within 1 year.
- *Vertebral osteosarcomas* are difficult to resect and often result in pathologic fractures (see Chapter 101). Multiple myeloma is chemotherapy responsive and has a fair to good prognosis if therapy is instituted before bony destruction has become severe.

Chapter

129 Peripheral Nerve Disorders

Linda G. Shell*

ANATOMY AND PHYSIOLOGY

The peripheral nervous system (PNS) is composed of 12 pairs of cranial nerves (see Chapters 125 and 126) and 36 pairs of spinal nerves that arise from the spinal cord. Spinal nerve fibers give rise to the peripheral nerves, which usually are composed of both sensory and motor fibers. Sensory nerve fibers are activated by peripheral receptors (Fig. 129-1). Impulses are transmitted up the peripheral nerve to the spinal cord. Some disorders affect only the sensory nerve fibers or ganglia, causing clinical signs such as hyperesthesia and analgesia, proprioceptive deficits, and self-mutilation (Table 129-1). In many cases sensory losses may be difficult to detect.

Motor or efferent nerve fibers arise from nerve cell bodies in the gray matter of the spinal cord. They carry information from the central nervous system (CNS) to the striated muscles (see Fig. 129-1). Motor deficits, characterized by limb weakness, muscle atrophy, and reduced spinal reflexes, occur with injury to any of the following: lower motor neuron in the gray matter of the spinal cord, ventral nerve root, spinal nerve, peripheral motor nerves, neuromuscular junction, and muscle (see Fig. 129-1). Disorders of the neuromuscular junction and muscle are discussed in Chapter 130.

Neuropathy is a general term denoting pathologic changes and/or functional disturbances in the PNS. *Polyneuropathy* refers to involvement of several nerves, usually resulting in bilaterally symmetrical signs.

CLINICAL SIGNS

Motor nerve disorders generally cause weakness and muscle atrophy. Sensory nerve disorders cause hyperesthesia or anesthesia, self-mutilation, and other abnormalities (see Table 129-1). The clinical signs of motor nerve disorders are similar to those of muscle disorders and can be distinguished using muscle enzyme determinations and muscle and nerve biopsies (see Chapter 130).

▼ ***Key Point*** Many common peripheral nerve disorders are manifested as one of the following clinical problems: acute flaccid tetraplegia, chronic progressive tetraparesis, monoparesis or monoplegia, and sensory disturbances (Table 129-2).

PRINCIPLES OF DIAGNOSIS

History and Physical Examination

- The *history* allows classification of the disease process as acute or chronic and progressive or nonprogressive.
- Perform a careful *physical examination* to detect signs of involvement of other systems (e.g., endocrine disorders) that may influence the peripheral nerves.
- Perform a *neurologic examination* (see Chapter 125) to localize the process to the PNS if reduced muscle mass and tone and reduced spinal reflexes are found on the physical examination.

Laboratory Evaluation

- Initial studies usually consist of a hemogram, blood chemistry profile, and urinalysis to evaluate for metabolic, endocrine, and neoplastic disorders.
- Elevated serum concentrations of muscle enzymes (creatine kinase, aldolase, lactate dehydrogenase [LDH], and aspartate aminotransferase [AST]) suggest a muscle disorder.
- Low cholinesterase levels in whole blood or serum may indicate exposure to organophosphates.
- Blood and tissue samples can be analyzed for heavy metal levels.
- Thoracic radiographs are often indicated in neuropathic disorders to evaluate for evidence of megaesophagus. If a paraneoplastic neuropathy is suspected, thoracic radiographs and abdominal ultrasound are indicated to screen for neoplastic disease.

*The author acknowledges the contributions of Karen Dyer Inzana in the previous edition.

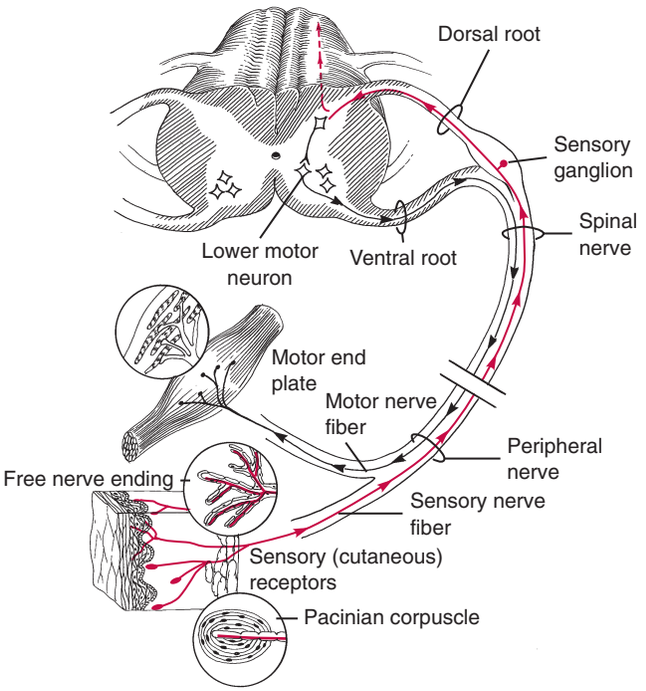

Figure 129-1 Impulse pathways in peripheral and spinal nerves.

Table 129-1. CLINICAL SIGNS OF MOTOR AND SENSORY NERVE DEFICITS

Motor Nerve Deficits	*Sensory Nerve Deficits*
Weakness/paralysis	Hyperesthesia/anesthesia
Muscle atrophy	Self-mutilation
Reduced reflexes	Loss of proprioception
Reduced muscle tone	Dysmetria
	Reduced reflexes

Table 129-2. DIFFERENTIAL DIAGNOSIS BASED ON CLINICAL SIGNS OF NEUROPATHY

Problem	Differential Diagnosis
Monoparesis or Monoplegia	
Acute onset	Trauma to nerve root or peripheral nerve
	Fibrocartilaginous infarct
	Intervertebral disc herniation to lateral side
Chronic onset	Tumor of nerve root or peripheral nerve
	Intervertebral disc herniation to lateral side
	Joint disease
Acute Flaccid Tetraplegia	
	Acute polyradiculoneuritis (coonhound paralysis)
	Tick paralysis (see Chapter 130)
	Botulism (see Chapter 130)
	Myasthenia gravis crisis (see Chapter 130)
	Post-vaccinal polyneuropathy
	Acute idiopathic polyneuropathy
	Protozoal neuritis/myositis
Chronic Progressive Tetraparesis	
Immature	Globoid cell leukodystrophy
	Giant axonal neuropathy (German shepherds)
	Progressive axonopathy (boxers)
	Hypertrophic neuropathy (Tibetan mastiffs)
	Motor neuron diseases (Brittany spaniels, pointers, rottweilers)
Mature	Chronic relapsing polyradiculoneuritis
	Distal denervating disease
	Distal polyneuropathy (Doberman pinschers)
	Distal symmetrical polyneuropathy
	Metabolic neuropathy
	Neoplastic and paraneoplastic neuropathy
	Toxic neuropathy
	Nutritional neuropathy
	Various myopathies
Sensory Disturbances	
Immature	Acral mutilation in pointers
	Sensory neuropathy (longhaired dachshunds)
Mature	Sensory neuropathy (ganglioradiculoneuritis)

Electrodiagnostics

- Use *needle electromyography (EMG) studies* to record electrical activity in skeletal muscle (see Chapter 125).
  - Needle EMG studies are used to confirm the presence and distribution of peripheral nerve and muscle disorders and can be performed on a cooperative awake patient or an anesthetized patient.
  - Spontaneous abnormal activity, such as fibrillations and positive sharp waves (denervation potentials), are found in many neuropathies.
- Use *nerve stimulation studies* to determine the location and nature of peripheral nerve abnormalities (see Chapter 125).
  - Reduction of the conduction velocity or a change in amplitude, duration, or waveform of the evoked action potential suggests pathologic conditions.
  - Nerve conduction studies are recorded using specialized electrodiagnostic equipment (usually by a specialist at a referral center) under general anesthesia. Both motor and sensory nerves can be evaluated.

Muscle and Nerve Biopsy

- *Muscle biopsy* specimens not only distinguish different muscle disorders but can also differentiate nerve from muscle disorders if histochemical staining is used (see Chapter 130).
- Sensory and motor nerve biopsies involve removing a fascicle of the nerve several centimeters in length, leaving the rest of the nerve intact. Because special handling and processing are required, these biopsies are probably best performed by a specialist at a referral center.

Cerebrospinal Fluid Analysis

- Spinal fluid analysis occasionally is beneficial in diagnosis of disorders of the nerve roots such as acute polyradiculoneuritis and protozoal diseases.

PRINCIPLES OF TREATMENT

▼ ***Key Point*** The key to treatment is to find the cause. Unfortunately, a specific cause of many of the acquired peripheral neuropathies may not be obvious even after extensive diagnostic evaluation.

Treatment often must rely on supportive care. In all peripheral nerve disorders that cause decreased mobility and muscle wasting, the following measures are important:

- Use waterbeds or heavily padded surfaces for bedding, to prevent decubital ulcer formation.
- Flex and extend the joints several times a day to prevent tendon and muscle contraction (see Chapter 95 on physical therapy).
- Maintain proper nutritional intake.
- Ensure frequent and complete urinary bladder evacuation.
- Use corticosteroids only for those neuropathies associated with immune-mediated diseases such as systemic lupus erythematosus.

SPECIFIC PERIPHERAL NERVE DISORDERS

A wide range of disease processes, varying from simple trauma to more complex inherited disorders, can affect the peripheral nerves. For the purpose of this discussion, peripheral nerve disorders are categorized according to their etiology, as anomalous/inherited/congenital, metabolic, nutritional, neoplastic, inflammatory/immunologic, idiopathic, traumatic, and toxic.

Anomalous, Inherited, and Congenital Disorders

Anomalous causes of peripheral nerve disease usually are noticed before 1 year of age. For each of the following anomalies, signalment and clinical signs are keys to a presumptive diagnosis, and thus only additional procedures are described under Diagnosis.

▼ ***Key Point*** Many anomalous causes of neuropathies are breed-specific and are not treatable.

Globoid Cell Leukodystrophy

This storage disease is caused by an inherited (autosomal recessive) deficiency of the enzyme beta-galactocerebrosidase that results in damaged oligodendrocytes and Schwann cells in the CNS and PNS, respectively.

- *Signalment:* West Highland white and Cairn terriers, beagles, poodles, Pomeranians, basset hounds, and cats <1 year of age.
- *Clinical signs:* Pelvic limb ataxia progressing to tetraparesis, hyporeflexia, hypermetria, and head tremors. Nystagmus, blindness, and anorexia may develop prior to death.
- *Diagnosis:* Nerve biopsy demonstrating segmental demyelination, axonal degeneration, and endoneural globoid cell accumulation; biochemical evaluation of beta-galactocerebrosidase enzyme activity in leukocytes, brain, and spinal cord.

Glycogen Storage Disease in Norwegian Forest Cats

This metabolic defect is a deficiency of a glycogen branching enzyme and is believed to be inherited as an autosomal recessive trait.

- *Signalment:* Norwegian Forest cats 5 months of age.
- *Clinical signs:* Hyperthermia, movement associated whole body tremors, muscle atrophy, and ataxia that progresses to tetraparesis with decreased spinal reflexes, cranial nerve signs, seizures, and death.
- *Diagnosis:* Transient elevations in creatine kinase; spontaneous needle EMG activity; decreased amplitude of evoked action potential and normal to slightly reduced motor nerve conduction velocities on nerve stimulation; PAS-positive material in central and peripheral nervous system (as well as multiple organs) that results in neuronal loss and axonal degeneration.

Other Storage Diseases Affecting Peripheral Nerves

- *Niemann-Pick disease* usually presents with cerebral or cerebellar signs in 2- to 5-month-old Siamese cats, but some cats have signs of tetraparesis, reduced spinal reflexes, and hypotonia. Spontaneous needle EMG activity and reduced motor and sensory nerve conduction velocities are present. Peripheral nerves show demyelination and remyelination with vacuolated macrophages surrounding affected nerve fibers.
- *GM_2 gangliosidosis* in dogs and cats usually presents as cerebellar signs, but isolated cases of peripheral nerve signs have been described. Peripheral nerve histopathology shows Wallerian degeneration of peripheral axons and accumulation of lamellar inclusions in Schwann cells.
- *Alpha-L-fucosidosis* is an autosomal recessive storage disease in English springer spaniels that produces behavioral changes and ataxia beginning at 12 to 14 months of age. Signs progress until dogs become incapacitated at around 4 years of age. Spinal reflexes become depressed and peripheral nerves may be palpably thickened. Nerve enlargement is caused by infiltration of foamy macrophages and loose fibroedematous endoneurial tissue.

- *Hyperchylomicronemia* is an inherited disorder of lipoprotein metabolism resulting in fasting hypertriglyceridemia and hyperchylomicronemia and subsequent deposition of excessive lipids around peripheral nerves. Clinical signs are due to compression of nerves from the lipid accumulations and are reversible if plasma triglyceride concentrations can be controlled with diet and drugs. The radial and tibial nerves appear to be most commonly affected.

See Chapter 126 for a discussion of other lysosomal storage diseases affecting the nervous system.

Hyperoxaluria Type 2 in Domestic Shorthaired Cats

This metabolic defect is believed to be inherited as an autosomal recessive trait. While the predominant feature is acute renal failure due to deposition of calcium oxalate in the kidneys, some cats have lower motor neuron weakness due to Wallerian degeneration of peripheral nerves.

- *Signalment:* Domestic shorthaired cats <1 year of age.
- *Clinical signs:* Crouching, cow-hocked stance with weakness, hyporeflexia, and diminished pain perception.
- *Diagnosis:* Chemistry changes compatible with acute renal failure; increased concentrations of oxalate and L-glycerate in urine; axonal swellings with neurofilament accumulations in proximal axons in spinal ventral horn cells, ventral roots, and intramuscular nerves.

Giant Axonal Neuropathy in German Shepherds (Alsatians)

This is an inherited (probably autosomal recessive) neuropathy characterized primarily by distal axonal swellings filled with tightly packed, whorled neurofilaments in the PNS and CNS. Based on the spatial-temporal spread of lesions, it is considered a central peripheral distal dying back neuropathy.

- *Signalment:* German shepherds 1 to 2 years of age.
- *Clinical signs:* Progressive symmetrical paraparesis followed by loss of patellar reflexes, distal muscle atrophy, hypalgesia in the pelvic limbs, fecal incontinence, weak bark, vomiting, regurgitation from megaesophagus, and aspiration pneumonia. Some dogs have a curly coat.
- *Diagnosis:* Spontaneous needle EMG activity in distal muscle groups; decreased amplitude of evoked action potential and reduced motor and sensory nerve conduction velocities on nerve stimulation; giant axonal swellings found on nerve histopathology.

Hypertrophic Neuropathy in Tibetan Mastiffs

This inherited (autosomal recessive trait) chronic demyelinating disease of the PNS is most likely due to an inability of the Schwann cells to form and maintain a myelin sheath during rapid growth periods. Remyelination can occur and some dogs may regain some strength within 4 to 6 weeks but do not usually have normal strength.

- *Signalment:* Tibetan mastiffs 7 to 12 weeks of age.
- *Clinical signs:* Pelvic limb weakness that rapidly progresses to generalized weakness, hyporeflexia, hypotonia, recumbency, and dysphonia. Some dogs may regain the ability to stand but remain weak.
- *Diagnosis:* Occasional spontaneous needle EMG activity that may diminish as the affected dog ages; slowed motor and sensory nerve conduction velocities; Schwann cell proliferation and relatively little axonal degeneration on nerve histopathology.

Progressive Axonopathy of Boxers

Progressive axonopathy is an inherited (probably autosomal recessive) neuropathy characterized by axonal degeneration and demyelination and remyelination in the PNS and CNS. Impaired transport of neurofilaments may be involved in the pathogenesis.

- *Signalment:* Boxer dogs <1 year of age.
- *Clinical signs:* Slowly progressive pelvic limb ataxia with a swaying hypermetric gait; hypotonia; loss of patellar reflex and conscious proprioception; and mild muscle atrophy. Thoracic limb involvement and mild cerebellar signs may occur late in the disease. Signs may stabilize by 12 to 18 months.
- *Diagnosis:* Normal or slightly reduced motor and sensory nerve conduction velocities; small or absent evoked muscle action potential; axonal swellings and degeneration on nerve biopsy and spinal cord histopathology; axonal spheroids with disorganized neurofilaments on brain histopathology.

Acral Mutilation and Nociceptive Loss in Pointers

This is a suspected inherited (probably autosomal recessive) nociceptive defect in English and shorthaired pointers resulting in reduced number of primary sensory neurons and a reduction of myelinated and unmyelinated fibers.

- *Signalment:* Pointers 3 to 4 months to 1 year of age.
- *Clinical signs:* Biting and licking at paws progressing to mutilation of paws and possibly autoamputation; normal gait, posture, and spinal reflexes, with loss of pain sensation in digits of the pelvic limbs.
- *Diagnosis:* Normal EMG activity and sensory and motor nerve conduction velocities; pathologic changes of the primary sensory neurons include degeneration of nerve fibers in the dorsal roots and peripheral nerves and reduced number of cell bodies in spinal ganglia, with the remaining cell bodies appearing smaller than normal.

Sensory Neuropathy in Longhaired Dachshunds

This is a familial disorder (possibly autosomal recessive trait) characterized by degeneration of large and small, myelinated and unmyelinated, sensory and autonomic nerve fibers. A similar neuropathy has been reported in a Jack Russell terrier.

- *Signalment:* Young longhaired dachshunds 2 to 3 months of age.
- *Clinical signs:* Slowly progressive pelvic limb ataxia, urinary and fecal incontinence, loss of conscious proprioception, and decreased pain perception over the entire body; normal patellar reflexes but absent flexor reflexes.
- *Diagnosis:* Reduced sensory nerve conduction and normal motor nerve conduction; normal EMG activity; loss of large myelinated and unmyelinated fibers in sensory nerves on nerve histopathology.

Motor Neuron Diseases in Brittany Spaniels, English Pointers, and Rottweilers

These disorders are characterized by progressive degeneration and eventual loss of the motor neurons in the gray matter of the spinal cord and the motor nuclei of the brain stem. An autosomal dominant mode of inheritance with variable penetrance occurs in Brittany spaniels while an autosomal recessive mode of inheritance is suspected in English pointers.

- *Signalment:* Young Brittany spaniels, pointers, and rottweilers.
- *Clinical signs:* Progressive weakness, muscle atrophy, and hyporeflexia.
  - Megaesophagus and head tremors have been observed in some affected rottweilers while some Brittany spaniels will have respiratory muscle weakness and difficulty prehending and swallowing food.
  - Three variants exist in Brittany spaniels: the accelerated form, with signs at 6 to 8 weeks of age; the intermediate form, with signs at 6 to 12 months of age; and the chronic form, with milder signs at >1 year of age.
- *Diagnosis:* Neuronal chromatolysis and axonal swellings with neurofilament accumulations on histopathology of the spinal cord and brain.

Inherited Axonal Polyneuropathy in Leonberger Dogs

This distal symmetrical polyneuropathy has been documented in a large multigenerational family of Leonberger dogs and is suspected to involve an X-linked inheritance.

- *Signalment:* Leonbergers 1 to 9 years of age.
- *Clinical signs:* Exercise intolerance, weakness, atrophy of distal limb muscles, change in or loss of bark, dyspnea, and hyporeflexia of both spinal and cranial nerves.
- *Diagnosis:* Spontaneous needle EMG activity; slowed motor nerve conduction velocities, loss or marked attenuation of compound muscle action potentials; neurogenic muscle atrophy on muscle biopsy; axonal loss, decreased myelinated fiber density, and smaller-sized axons on nerve histopathology.

Hereditary Polyneuropathy in Alaskan Malamutes

This autosomal recessive disorder was last reported in Norway in 1982 and was characterized by degeneration of myelinated axons in peripheral nerves and nerve roots.

- *Signalment:* Alaskan malamutes 7 to 18 months of age.
- *Clinical signs:* Progressive posterior ataxia, exercise intolerance, megaesophagus, atrophy of shoulder and thigh muscles, and hyporeflexia. The disease is progressive but can be remitting and relapsing.
- *Diagnosis:* Spontaneous EMG activity; slowed motor nerve conduction velocities; axonal degeneration and demyelination on peripheral nerve and nerve root histopathology.

Idiopathic Polyneuropathy in Alaskan Malamutes

This appears to be a familial disorder different than the hereditary polyneuropathy (described above) based on the course and the neuropathology. The disease is progressive and not remitting or relapsing. It may be a type of distal axonopathy.

- *Signalment:* Alaskan malamutes 10 to 18 months of age.
- *Clinical signs:* Progressive paraparesis, exercise intolerance, generalized hyperesthesia, and hyporeflexia. No megaesophagus has been reported.
- *Diagnosis:* Spontaneous EMG activity; slowed motor nerve conduction velocities; reduced amplitude of evoked muscle action potential; axonal degeneration of myelinated and unmyelinated fibers on peripheral nerve histopathology.

Polyneuropathy in Rottweilers

This distal sensorimotor polyneuropathy is suspected to have a genetic etiology.

- *Signalment:* Rottweilers 1 to 4 years of age.
- *Clinical signs:* Paraparesis that progresses to tetraparesis within a year, hyporeflexia, hypotonia, and muscle atrophy most prominent in the distal limb muscles. The disease may be remitting and relapsing and may relapse with corticosteroid treatment.
- *Diagnosis:* Spontaneous EMG activity in distal limb muscles; slowed motor and sensory nerve conduction velocities; axonal degeneration of myelinated and unmyelinated fibers in distal nerve segments on nerve histopathology; demyelination secondary to axonal loss.

Laryngeal Paralysis-Polyneuropathy Complex in Dalmatians

This generalized polyneuropathy is suspected to be inherited in an autosomal recessive manner. The disease is progressive, and affected dogs usually die from aspiration pneumonia within months of beginning clinical signs.

- *Signalment:* Dalmatians 2 to 6 months of age.
- *Clinical signs:* Megaesophagus, generalized weakness, hyporeflexia, hypotonia, muscle atrophy, and weak facial and lingual muscles. Acute respiratory distress due to laryngeal paralysis is a prominent presenting sign.
- *Diagnosis:* Spontaneous EMG activity in distal limb muscles; normal to slowed motor and sensory nerve conduction velocities; axonal degeneration and loss of large- and medium-diameter myelinated fibers in distal nerve segments on nerve histopathology.

Neuropathy in Birman Cats

This is a central peripheral distal axonopathy that is likely of genetic origin.

- *Signalment:* Birman cats 8 to 10 weeks of age.
- *Clinical signs:* Progressive plantigrade gait, pelvic limb ataxia, and hypermetria of limbs.
- *Diagnosis:* Distal loss of myelinated fibers in sciatic nerves and cerebral and cerebellar white matter.

Peripheral Neuropathy in Aged German Shepherds

Three 9-year-old German shepherd littermates raised in different households developed progressive lower motor neuron signs. The pathogenesis is unknown but a genetic basis is suspected.

- *Signalment:* Older German shepherds.
- *Clinical signs:* Paraparesis that progresses to tetraparesis, reduced spinal reflexes, and muscle atrophy.
- *Diagnosis:* Endoneurial fibrosis of peripheral nerves, Wallerian degeneration, secondary demyelination, and regenerating axons on peripheral nerve histopathology.

Hypomyelinating Neuropathy in Golden Retrievers

Two littermates had a marked absence of peripheral nerve myelin resulting in mild weakness of the pelvic limbs. Clinical signs were not progressive and stabilized. The pathogenesis is unknown but an autosomal recessive condition is suspected.

- *Signalment:* Golden retrievers 5 to 7 weeks of age.
- *Clinical signs:* Mild paraparesis, reduced spinal reflexes, and muscle atrophy.
- *Diagnosis*: Rare EMG changes; marked slowing of motor nerve conduction velocities; hypomyelination of peripheral nerves without evidence of demyelination or remyelination or inflammation or degeneration.

Metabolic/Endocrine Disorders

Most metabolic and endocrine disorders do not produce a clinically evident peripheral neuropathy. Diabetes mellitus and hypothyroidism are the most commonly recognized endocrine diseases that may affect peripheral nerves and/or muscles (see Chapter 130 on hyperadrenocorticism-induced myopathy).

▼ ***Key Point*** Evaluate all animals with signs of a chronic neuropathy for an underlying endocrine or metabolic abnormality.

Diabetes Mellitus

Diabetes mellitus can cause both a sensory and motor neuropathy in pelvic and thoracic limbs in cats. Although the exact pathophysiology is not fully understood, an increase of fructose in peripheral nerves without sorbitol accumulation suggests an increase in sorbitol dehydrogenase, which may mean that the pathogenesis involves the flux in the polyol pathway rather than an accumulation of sorbitol.

- *Clinical signs:* The pelvic limbs are more affected than thoracic limbs. Weakness (especially of the pelvic limbs), muscle atrophy, and a plantigrade stance are commonly found.
- *Diagnosis:* Laboratory evidence of diabetes mellitus (see Chapter 34), needle EMG, denervation potentials, decreased motor and sensory nerve conduction velocities, and finding demyelination, Schwann cell injury, and distal axonal loss on nerve histopathology.
- *Treatment:* Weakness usually improves over weeks to months with proper control of the diabetes mellitus (see Chapter 34).

Hypothyroidism

Hypothyroidism (see Chapter 31 for detailed description) occasionally is associated with polyneuropathies, but the pathophysiology is not understood. Most likely there is a relationship between thyroid hormone activities and neuronal metabolism.

- *Clinical signs:* Variable onset and progression of weakness, muscle wasting, normal or reduced spinal reflexes, and cranial nerve disturbances. Facial, vestibulocochlear, and trigeminal nerves are most commonly affected although megaesophagus and laryngeal paralysis have also been reported. Other clinical signs of hypothyroidism, such as obesity, mental depression, and dermatologic lesions, are not always present.
- *Diagnosis:* Needle EMG changes and decreased motor nerve conduction velocities; thyroid function testing (as described in Chapter 31).

- *Treatment*: Replacement hormone therapy can result in gradual improvement in neurologic signs over 1 to 3 months (see Chapter 31).

Nutritional Disorders

Nutritionally induced neuropathies are uncommon in veterinary medicine; however, consider vitamin B deficiency, because of an inadequate diet or impaired intestinal absorption (e.g., malabsorption or small intestinal bacterial overgrowth), especially in idiopathic cases.

Neoplastic Disorders

Neoplasia can affect the peripheral nerves directly via the development of nerve sheath tumors, indirectly by metastasis or compression of nerves from adjacent tumors, and indirectly by having remote or paraneoplastic effects.

Nerve Sheath Tumors

These are the most common primary tumors affecting the PNS. Schwannomas (malignant transformation of Schwann cells) are the most common type; tumors arising from endoneural and epineural fibroblasts (neurofibromas, neurofibrosarcomas) also occur.

- *Signalment:* Mature dogs and cats.
- *Clinical signs:* Signs vary with tumor location. Spinal nerve roots of the brachial plexus are most susceptible. Nerve root tumors at C8 to T2 often cause ipsilateral Horner's syndrome and ipsilateral loss of the cutaneous trunci reflex. Neoplastic cells invade adjacent spinal nerve roots, causing dysfunction of multiple peripheral nerves. Proliferation of neoplastic cells within the spinal canal can result in a compressive myelopathy.

▼ ***Key Point*** Vague lameness progressing to weakness and muscle atrophy of the affected limb is the most common sign of a nerve sheath tumor.

- *Diagnosis:* Needle EMG denervation potentials; histopathology. If spinal nerve roots are involved, survey spinal radiographs may show an enlarged intervertebral foramen or myelography may show an intradural-extramedullary mass. Computed tomography (CT) or magnetic resonance imaging (MRI) scans may identify enlarged or thickened nerve roots or peripheral nerves.
- *Treatment:* Surgical excision of the tumor and/or amputation of the affected limb (see Chapter 116). Recurrence is common. Radiation therapy may delay recurrence by 1 to 2 years.

Lymphoma

Lymphoma is the most common tumor of non-neural origin affecting the PNS. Neoplastic cells can infiltrate nerve and nerve roots and produce signs of a mono- or polyneuropathy.

- *Signalment:* Mature dogs and cats.
- *Clinical signs:* Signs may be very similar to peripheral nerve sheath tumors but there may be more than one limb affected. Signs of multicentric lymphoma are usually present.
- *Diagnosis:* Electrodiagnostic testing and imaging as for peripheral nerve sheath tumors above. Cerebrospinal fluid analysis will often reveal neoplastic lymphocytes due to concurrent involvement of the CNS meningeal layers.
- *Treatment* consists of chemotherapy (see Chapters 27 and 126). Peripheral nerve damage may be permanent.

Paraneoplastic Neuropathies

Cancer patients may have clinical or subclinical neuropathies for which the pathogenesis is poorly understood. An immune-mediated mechanism for the neuropathy is suspected; autoantibodies may be produced against antigens shared by the tumor and the nervous system. Most cases with clinically significant neuropathies have been associated with pancreatic islet cell tumors and hyperinsulinism (see Chapter 35). However, signs of a neuropathy in any middle-aged to older patient could potentially be associated with any neoplasia.

- *Clinical signs:* Weakness (especially in the pelvic limbs), decreased muscle tone, and reduced spinal reflexes.
- *Diagnosis:* Identification of a primary neoplasm and the elimination of other causes. Decreased sensory and motor nerve conduction velocities also may be seen. Demyelination, remyelination, and axonal necrosis and atrophy may be observed on nerve histopathology.
- *Treatment:* Remove the underlying neoplasm if possible. (See Chapter 35 for removal of pancreatic islet cell tumors.)

Inflammatory and Immune-Mediated Disorders

These disorders can affect the neuromuscular junction, peripheral nerves, spinal nerves and roots, and ventral horn cells in the gray matter of the spinal cord.

Protozoal Neuritis/Myositis

Organisms such as *Toxoplasma gondii* and *Neospora caninum* can cause inflammatory and degenerative changes in peripheral nerves and dorsal and ventral nerve roots, as well as muscle. Dogs less than 4 months of age are frequently presented for hindlimb hyperextension, but others may be presented for acute or progressive flaccid weakness. (See Chapter 21 for diagnosis and treatment of protozoal infections.)

Acute Polyradiculoneuritis (Coonhound Paralysis)

This is one of the most common peripheral nerve disorders in dogs. It is characterized by a mild lymphocytic radiculitis with demyelination of the ventral (and occasionally the dorsal) spinal roots and axonal degeneration. Immune-mediated destruction of the myelin is suspected.

- *Signalment:* Adult dogs of any age, breed, or sex; frequently observed in hunting dogs 7 to 14 days after contact with a raccoon; occasionally reported in cats.
- *Clinical signs:* Pelvic limb weakness progressing to hyporeflexic or areflexic tetraparesis or tetraplegia within 1 to 2 days; and rapid muscle atrophy. Voluntary tail movement is often unaffected. Thoracic limb weakness occasionally develops first. Responses to mild pain stimuli often are exaggerated. Some dogs develop facial paralysis, change in bark, and dysphagia. Respiratory muscle paralysis occurs occasionally, requiring the use of mechanical ventilation. Many affected dogs retain voluntary control of urination/defecation.
- *Diagnosis:* Needle EMG denervation potentials; normal or slowed motor nerve conduction velocities; dispersed and low amplitude action potential suggesting demyelination and axonal injury; delayed or absent F waves reflecting ventral nerve root injury; increased spinal fluid protein from lumbar subarachnoid space but not from cisterna magna.

▼ ***Key Point*** Differential diagnoses for coonhound paralysis include botulism, tick paralysis, fulminant myasthenia gravis, and protozoal infection of nerve and muscle.

- *Treatment:* Supportive care: physical therapy (see Chapter 95) and urinary bladder evacuation. Spontaneous remission usually occurs but may take weeks or months and recovery may not be complete. Complications include cystitis, aspiration pneumonia, tendon contracture, decubital ulcers, respiratory paralysis, and death.

Brachial Plexus Neuritis

This is a rare weakness of the thoracic limbs that has been compared to serum neuritis in humans. In one case, a newly instituted horse meat diet was incriminated as the cause of the allergic neuritis. Flexor reflexes in the thoracic limbs are reduced or absent and muscle atrophy is present. Pelvic limb function is normal. Spontaneous recovery may take weeks to 4 months.

Post-vaccinal Polyneuropathy

This disorder is rare and occurs 7 to 10 days after rabies vaccination. Clinical signs are similar in appearance to those of acute polyradiculoneuritis. Spontaneous recovery usually occurs over a period of weeks to months.

Idiopathic Disorders

The causes of many acquired peripheral nerve disorders often are unknown. There are many single case reports but very few series of cases for the majority of these disorders. To consolidate these disorders, they are grouped here according to the predominant site of pathology. Many of the cases described under a single heading actually may have multiple, but as yet unknown, causes.

Idiopathic Neuropathies Affecting the Neuronal Cell Body

Lower Motor Neuron Disease

This progressive disorder is characterized by an acute loss of ventral horn cells within the spinal cord and has been reported in nine dogs in New Zealand.

- *Clinical signs:* Acute onset of paraparesis or tetraparesis progresses over 2 to 4 weeks until euthanasia is performed. Sensory and autonomic functions are preserved.
- *Diagnosis:* The diagnosis is based on spinal cord histopathology.

Sensory Neuropathy Ganglioradiculitis

This has been reported in several adult dogs with progressive ataxia, decreased patellar reflexes, and normal muscle tone and limb strength.

- *Clinical signs:* Variable degrees of facial hypalgesia, dysphagia, and prehension difficulty may occur.
- *Diagnosis:* Few to no needle EMG changes, normal to slightly reduced motor nerve evoked action potentials, and reduced sensory nerve evoked action potentials and conduction velocity are found in affected dogs. Histopathology shows degeneration of sensory neurons within dorsal root and cranial nerve ganglia.

Dysautonomia

Dysautonomia is characterized histopathologically by a loss of neurons in all autonomic ganglia, some cranial nerve ganglia, and occasionally ventral horn cells. It was common in cats in the United Kingdom in the 1980s, but incidence has since declined. Isolated cases have been observed in other countries. A disorder with similar features has been reported in dogs in the United Kingdom and midwestern United States.

- *Clinical signs:* Signs develop over 2 to 3 days and consist of lethargy, anorexia, regurgitation or vomiting, constipation or diarrhea, dysuria, and dysphagia. Mydriasis, megaesophagus, dry mucous membranes, bradycardia, and protrusion of the nictitating membrane are often found on physical examination.

- *Diagnosis:* Electrodiagnostic testing is usually normal except for occasional spontaneous EMG activity. Pupillary pharmacologic testing shows increased sensitivity to direct-acting parasympathomimetics or sympathomimetics.
- *Treatment:* The survival rate in cats is around 25% with prolonged (months to years) and dedicated nursing care. Survival rate in dogs is 10% to 30% after months to a year of very slow recovery.

Idiopathic Neuropathies Affecting the Proximal Axon

Acute Idiopathic Polyneuropathy

- *Clinical signs:* This has been reported in 14 dogs that had an acute onset of generalized flaccid paralysis, similar to that described for acute polyradiculoneuritis (coonhound paralysis) except that there was no known exposure to raccoons or other neurotoxins.
- *Treatment:* Most dogs recovered spontaneously. Those that died had mononuclear inflammation of the nerve roots and extensive peripheral nerve demyelination.

Chronic Relapsing Neuropathy

This generalized neuropathy in both dogs and cats has a remitting and relapsing clinical course.

- *Clinical signs:* Signs consist of an insidious or acute onset of weakness in one or more limbs, muscle atrophy, and hyporeflexia.
- *Diagnosis:* The diagnosis is based on needle EMG changes, reduced motor and sensory nerve conduction velocities, and nerve histopathology showing demyelination and remyelination and variable degrees of mononuclear cell infiltrates in peripheral nerves and nerve roots.
- *Treatment:* Immune-suppressive doses of prednisone may reverse clinical signs and may be necessary for many months.

Idiopathic Neuropathies Affecting the Distal Axon

Distal Denervating Disease

This disorder has been reported in dogs in the United Kingdom.

- *Clinical signs:* Dogs present with variable onset of tetraparesis, loss of bark, diffuse muscle atrophy, and areflexia.
- *Diagnosis:* Spontaneous needle EMG changes, normal to reduced motor nerve velocity, and a small dispersed action potential are compatible with primary axonal loss. Histologically, pathological changes are restricted to the distal motor axon.
- *Treatment:* A majority of dogs recover spontaneously in 1 to 5 months.

Distal Polyneuropathy in Doberman Pinschers (Dancing Doberman Disease)

This is a chronic, progressive distal axonopathy.

- *Clinical signs:* Signs begin with persistent rear limb flexion when the dog is standing. When both rear limbs are affected, the dog may appear to have bicycling motions in the rear legs or a shifting leg lameness. The pelvic limb reflexes may be exaggerated and the gastrocnemius muscles are often atrophied. Age of onset varies between 6 months and 7 years of age. Progression over months to years may produce generalized weakness, muscle atrophy, and proprioceptive deficits.
- *Diagnosis:* Needle EMG may show spontaneous activity; motor and sensory nerve conduction velocities are usually normal. Some dogs have histopathology changes compatible with a primary axonopathy, while others have muscle changes suggesting a form of myotonic myopathy.

Distal Symmetrical Polyneuropathy

This disorder has been reported in adult large-breed dogs.

- *Clinical signs:* Dogs have pelvic limb weakness that progresses to tetraparesis, and atrophy of distal limb and masticatory muscles.
- *Diagnosis:* Spontaneous EMG changes are present. Motor nerve conduction velocities are normal or slightly reduced, while evoked muscle action potentials are small and prolonged, suggesting axonal injury. Muscle and nerve histopathology confirm denervation and distal axonopathy, respectively. No effective treatment has been reported.

Traumatic Injury

Traumatic injuries to peripheral nerves are common causes of monoparesis or monoplegia.

Nerve Injuries

Nerve injury can occur from automobile trauma, intramuscular injections, fractures and repair of fractures, lacerations, and bite wounds. Tables 129-3 and 129-4 list the nerves that can be injured, their site of origin, and the clinical signs associated with each injury. Injuries are commonly classified as neurapraxia, axonotmesis, and neurotmesis.

Neurapraxia

Neurapraxia is a temporary loss of physiologic function without physical disruption of the nerve fibers. It results in weakness with intact pain perception. Motor function usually returns to normal within days to weeks.

Table 129-3. SIGNS OF NERVE INJURY IN THE THORACIC LIMB

Nerve	Origin	Clinical Signs of Dysfunction	Reflexes Affected
Suprascapular	C6–7	No gait changes; pronounced atrophy of supraspinatus and infraspinatus muscles	None
Radial	C6–T1	*Injury proximal to branches that supply triceps muscle:* Unable to support weight; limb collapses; may carry the limb if musculocutaneous nerve is functional; atrophy of triceps muscle *Injury distal to branches that supply triceps muscle:* Can support some weight, but knuckles on dorsum of paw	Reduced to absent triceps and extensor carpi radialis reflexes
Musculocutaneous	C6–C8	Gait may appear stiff and choppy; slight withdrawal and straightening of angle-to-elbow joint	Reduced biceps reflexes
Median and ulnar	C8–T2	Slight carpal extension ("dropped carpus")	Reduced carpal flexion on withdrawal reflex
Axillary	C6–C8	None	Reduced shoulder flexion on withdrawal reflex

Table 129-4. SIGNS OF NERVE INJURY IN THE PELVIC LIMB

Nerve	Origin	Clinical Signs of Dysfunction	Reflexes Affected
Femoral	L4–L6	Unable to support weight; limb collapses or may be carried; short stride; lack of pain perception on medial surface of thigh, stifle, leg, and paw; atrophy of quadriceps muscle	Reduced to absent patellar reflex
Sciatic	L6 to S1–S2	Supports weight on limb but knuckles on dorsum of paw; unable to flex or extend hock; atrophy of biceps femoris, semimembranosus, semitendinosus, cranial tibial, gastrocnemius, and other muscles; lack of pain perception on caudal and lateral sides of leg	Reduced to absent withdrawal reflex
Peroneal	L6–S1	Straightening of hock; knuckles on dorsum of paw and fetlock	Reduced to absent hock flexion on withdrawal reflex
Tibial	L6–S2	Increased flexion to hock ("dropped" hock)	None
Obturator	L4–L6	Abduction of limb on slippery surface	None

Axonotmesis

Axonotmesis is the interruption or severance of axons within a nerve but the supporting connective tissue sheath remains intact. Both motor and sensory deficits can be present. Following disruption of the axons, the distal axonal fragments degenerate. The proximal axonal segment must regrow along the intact connective tissue sheath at the rate of 1 to 3 mm/day or about 1 inch per month. Because the connective tissue sheath is intact, axonal regeneration may result in functional recovery, but this may take weeks to months, depending on the extent and the location of the injury. If the proximal axon segment is more than 12 inches from the muscle it innervates, it is unlikely that it will be able to make anatomic contact with the muscles because the connective tissue sheath shrinks and muscle fibers become fibrotic with time.

Neurotmesis

Neurotmesis is severance of both axons and their connective tissue sheath. Axonal regeneration is hampered because there is no scaffold of connective tissue to guide the direction of growth of the axons. Without surgical intervention to appose the two severed ends of the nerve, it is unlikely that any function will return.

▼ ***Key Point*** The closer the injured nerve is to the muscle it innervates, the better the prognosis.

Nerve Root or Brachial Plexus Avulsions

These avulsions are common sequelae of road traffic accidents or jumping from moving vehicles. It is more common for the nerve roots to be torn or avulsed from the spinal cord than for the brachial plexus to be severed (injured). Occasionally motor nerve roots (ventral nerve roots) are affected and sensory nerve roots (dorsal nerve roots) are spared.

- *Clinical signs:* Sudden onset of a combination of the nerve injuries to the forelimb as described in Table 129-3. Signs of radial nerve injury are almost always present.

Table 129-5. POSSIBLE CAUSES OF TOXIC NEUROPATHY IN HUMANS AND ANIMALS

Chemical Agents	*Heavy Metals*
Organophosphorus compounds	Arsenic
Parathion	Lead
Malathion	Gold
Tri-ortho-cresyl phosphate	Thallium
Di-isopropyl fluorophosphate	Mercury
Acrylamide	*Drugs*
Lindane	Vincristine
Polychlorinated biphenyls	Vinblastine
Carbon tetrachloride	Doxorubicin
Methylbutyl ketone	Chloramphenicol
Zinc pyridinethione	Ampicillin
Carbon disulfide	Erythromycin
N-hexane	Tetracycline
Chlorophenothane	Nitrofurantoin
	Diphenylhydantoin

- Damage to the T1–T3 ventral nerve roots may cause an ipsilateral Horner's syndrome.
- Damage to C8 and T1 nerve roots may result in loss of ipsilateral cutaneous trunci (panniculus) reflex.
- Damage to C5, C6, and C7 nerve roots may cause ipsilateral paralysis of the diaphragm.

- *Diagnosis:* History of trauma and clinical signs of monoparesis, needle EMG denervation potentials 5 days after injury; decreased motor nerve conduction velocity within 3 days of injury.
- *Treatment:*
  - Perform daily physical therapy to prevent tendon and muscle contraction (see Chapter 95).
  - Use a sock, boot, or bandage to prevent abrasions.
  - Regrowth of injured nerves (axonotmesis or neurotmesis) is slow and may take months. Perform monthly examinations.
  - Consider amputation if there is self-mutilation or unacceptable improvement in motor abilities after 6 to 8 months.

Toxic Neuropathies

Toxic neuropathies are diagnosed infrequently; however, the list of agents with the potential to cause neuropathies is quite extensive (Table 129-5). Nitrofurantoin, vincristine, vinblastine, and doxorubicin can have adverse effects on peripheral nerves; however, reports in veterinary literature are scant. Arsenic, lead, and mercury appear to be uncommon causes of neuropathies in animals. Certain organophosphorus compounds can cause a delayed neuropathy in sensitive species usually within 2 to 3 weeks of exposure. With chronic organophosphate toxicity, long, large-diameter axons in the peripheral nerves and the spinal cord undergo distal degeneration ("dying-back"), causing a mixture of lower motor neuron clinical signs (muscle atrophy, weakness, reduced spinal reflexes) and upper motor neuron signs (weakness, exaggerated spinal reflexes).

- *Treatment:* There is no specific treatment for the toxic neuropathies other than stopping or reducing the exposure potential.

▼ ***Key Point*** Suspect toxic causes when there is history of exposure or when there is no other reason for the clinical signs.

Chapter

130 Disorders of Muscle and Neuromuscular Junction

G. Diane Shelton

Neuromuscular disorders of dogs and cats are disorders of the motor unit. The motor unit is the morphologic and functional unit of skeletal muscle and includes the following:

- Motor neuron, consisting of the cell body and axon extending along a peripheral nerve
- Neuromuscular junction
- Myofibers innervated by the motor neuron

This chapter focuses on disorders of muscle and the neuromuscular junction. Disorders of peripheral nerves are discussed in Chapter 129.

ETIOLOGY

Underlying causes of disorders of muscle and neuromuscular transmission are listed in Table 130-1 and include hereditary or suspected hereditary disorders and acquired disorders with autoimmune, metabolic, endocrine, neoplastic or paraneoplastic, infectious, toxic or drug-induced, and ischemic etiologies.

Hereditary Disorders

Several neuromuscular diseases have a known or suspected genetic basis.

Canine Dystrophin-Deficient Muscular Dystrophy

- Canine X-linked muscular dystrophy has striking phenotypic and genotypic similarities to Duchenne muscular dystrophy (DMD) in humans. While this disorder occurs most commonly in males, females may be affected if a carrier female is bred to an affected male. Although this form of muscular dystrophy has been most extensively studied in the golden retriever, several breeds may be affected, including Irish terriers, Samoyeds, rottweilers, Japanese spitz, and Labrador retrievers. Onset is about 10 to 12 weeks of age. As in humans with DMD, affected dogs lack the Duchenne gene transcript and its protein product, dystrophin.
- Clinical signs include stunted growth, weakness, gait abnormalities, and muscle atrophy, with hypertrophy of selected muscles in some cases.
- Serum creatine kinase (CK) levels are dramatically elevated (>10,000 U/dL compared with normal levels of <100 U/dL).

Feline Dystrophin-Deficient Muscular Dystrophy

- A lethal muscle hypertrophy has been described in young male cats associated with dystrophin deficiency.
- Clinically the cats have generalized skeletal muscle hypertrophy, glossal hypertrophy and dysfunction, and excessive salivation. Progressive hypertrophy of the diaphragmatic muscles may result in occlusion of the esophagus.
- Serum CK levels are dramatically elevated and dystrophin is lacking in skeletal muscle.

Muscular Dystrophy with Merosin (Laminin Alpha-2) Deficiency in Dogs and Cats

- Congenital muscular dystrophies (CMDs) with deficiency of laminin alpha-2 make up a large group of autosomal recessive muscle diseases in humans. Recently, muscular dystrophy associated with absence of laminin alpha-2 was described in a young female Brittany-springer spaniel mixed-breed dog, and in domestic shorthaired, flame point Siamese, and Maine coon cats. Onset is less than 6 months of age.
- Clinical signs may vary from muscle weakness and atrophy to progressive spasticity and contractions.
- The serum CK levels are moderately elevated. Laminin alpha-2 is lacking in skeletal muscle.

Muscular Dystrophy with Sarcoglycan Deficiency

- The limb-girdle muscular dystrophies (LGMDs) make up a diverse group of myopathies in humans. Mutations of sarcoglycans (SGs), which span the muscle membrane, typically cause the most severe forms of LGMD. Recently, SG deficiencies have been

Table 130-1. CAUSES OF NEUROMUSCULAR DISEASES AND BREED PREDISPOSITION

Hereditary Disorders

Canine X-linked Muscular Dystrophy
Golden retriever
Irish terrier
Rottweiler
Several other breeds

Laminin Alpha-2 Deficiency
Domestic shorthaired cat
Flame point Siamese
Maine coon
Brittany spaniel/springer spaniel

Sarcoglycan Deficiency
Chihuahua
Boston terrier
Cocker spaniel

"Central Corelike" Myopathy
Great Dane

Nemaline Rod Myopathy
Domestic shorthaired cat
Border collie

Congenital Myasthenia Gravis
Jack Russell terrier
Springer spaniel
Smooth fox terrier

Familial Canine Dermatomyositis
Collie
Shetland sheepdog

Glycogen Storage Disorders (Glycogenoses)

Acid Maltase Deficiency (Glycogenosis Type II)
Lapland dogs

Branching Enzyme Deficiency (Glycogenosis Type IV)
Norwegian forest cat

Debranching Enzyme Deficiency (Glycogenosis Type III)
German shepherd

Phosphofructokinase Deficiency (Glycogenosis Type VII)
English springer spaniel

Hereditary Myopathy of Labrador Retrievers

Hereditary Myotonia
Chow Chow
Miniature schnauzer

Mitochondrial Myopathy
Clumber spaniel
Sussex spaniel
Old English sheepdog

Hypertonicity Syndromes
Cavalier King Charles spaniel
Springer spaniel
Wheaton terrier
Border terrier

Acquired Disorders

Autoimmune Disorders
Generalized myasthenia gravis
Focal myasthenia gravis
Masticatory muscle myositis
Polymyositis
Extraocular myositis

Metabolic Disorders
Abnormalities of glycogen metabolism
Abnormalities of lipid metabolism and oxidative phosphorylation
Electrolyte alterations
Hyperthermia (malignant and exercise-related)

Endocrine Disorders
Hypothyroidism
Hypoadrenocorticism and hyperadrenocorticism

Neoplastic and Paraneoplastic Infectious Disorders
Toxoplasma gondii
Neospora caninum
Hepatozoon canis
Ehrlichia canis
Feline immunodeficiency virus

Toxic or Drug-Induced Disorders
Tick paralysis
Botulism
Organophosphate toxicity
Drugs affecting neuromuscular transmission

Ischemia

identified in Chihuahua, Boston terrier, and Cocker Spaniel breeds.
- Serum CK levels are markedly elevated, and an absence of SG subunits can be demonstrated within skeletal muscle.

Hereditary Myopathy of Labrador Retrievers

- Although hereditary myopathy of Labrador retrievers (HMLR) is commonly referred to as "type II fiber deficiency" or "muscular dystrophy," the precise underlying abnormality is still unknown. A disorder in young Labrador dogs, clinically indistinguishable from HMLR and termed *centronuclear myopathy*, has recently been described in a French pedigree. Linkage analysis has shown that the gene for the disorder in the French pedigree is localized on canine chromosome 2.
- The mode of inheritance is autosomal recessive.
- Both disorders present clinically with progressive muscle weakness, exercise intolerance, and abnormalities of gait and posture. There is, however, a wide variation in clinical presentations and pathologic findings in HMLR.
- Within muscle biopsy specimens, variable morphologic features have been reported; some biopsies show changes typical of neuropathic disease, whereas others show myopathic changes. The fiber type proportions are also variable. To date, pathologic changes in the spinal cord and peripheral nerves

have not been found, even in cases in which histologic changes within the muscle biopsy suggest an underlying neuropathic disorder.

"Central Core-Like" Myopathy

- Myopathy with pathologic changes in the central region of muscle fibers has been reported in several young Great Danes from the United Kingdom showing clinical signs of progressive exercise intolerance, muscle atrophy, and tremors. Recently, an affected dog was confirmed from North America (Shelton, unpublished), suggesting that this myopathy may be more widespread. Excitement associated with feeding or exercise precipitates episodes of general body tremors and collapse. This condition is not pathologically analogous to the human disorder with this name.
- The precise biochemical defect requires further investigation.

Nemaline Rod Myopathy

- Five related cats were described with an early onset of mild weakness with progression to tremors, reluctance to move, and a crouched, hypermetric gait. Muscle atrophy was progressive. A similar myopathy has been seen in a young Border collie.
- Numerous nemaline rods were present within myofibers.

Familial Canine Dermatomyositis

- Familial canine dermatomyositis is well documented in young collies and less well characterized in Shetland sheepdogs. In collies, the inheritance pattern appears to be autosomal dominant with variable expression.
- Initially there is a variably severe dermatitis on the skin of the face, ears, distal extremities over bony prominences, and tail tip that may be followed by an inflammatory myopathy of the masticatory muscles and muscles distal to the elbow and stifle.
- There is evidence of an immunologic pathogenesis in dermatomyositis, but exact mechanisms are uncertain.

Glycogen Storage Disorders (Glycogenoses)

- Although rare in companion animals, disorders of lysosomal glycogenosis (acid maltase deficiency, an alpha-glucosidase that releases glucose from maltose, oligosaccharides, and glycogen) and non-lysosomal glycogenosis (branching enzyme deficiency, debranching enzyme deficiency, and phosphofructokinase (PFK) deficiency affecting glycogenolysis, glycolysis, or glycogen synthesis) have been described.
- In dogs, clinical presentations for the non-lysosomal glycogenoses are not usually specific to the neuromuscular system since glycolysis plays a relatively minor role in canine muscle energetics.
- In branching and debranching enzyme deficiencies, muscle involvement may be overshadowed by liver dysfunction, hypoglycemia, or cardiomyopathy. In PFK deficiency, chronic hemolytic anemia and episodic stress-related hemolytic crises without overt muscle weakness may predominate.

Myotonia Congenita

- An inherited myotonic myopathy has been described in the chow chow and miniature schnauzer breeds in which clinical signs of difficulty rising after a period of rest, muscle stiffness, and a stilted or bunny-hopping gait are visible when puppies are first able to walk. An autosomal recessive mode of inheritance is suspected in the chow chow and has been confirmed in the miniature schnauzer. A missense mutation in both alleles of the gene encoding the skeletal muscle voltage-dependent chloride channel C1C-1 has been identified in the miniature schnauzer.
- A DNA-based test capable of detecting the mutant allele in affected and carrier miniature schnauzers has been developed and is available at the Josephine Deubler Genetic Disease Testing Laboratory at the University of Pennsylvania (www.vet.upenn.edu/penngen).
- Myotonia congenita has also been described in domestic cats, although the mode of inheritance and the molecular defect have not been determined.

Mitochondrial Myopathy

- Although there has been an explosion of information related to mitochondrial-associated diseases in humans in the past 10 years, only a few case reports are in the veterinary literature regarding this potentially important group of disorders.
- Marked exercise intolerance associated with metabolic acidosis and excessive elevations in lactate and pyruvate support a mitochondrial myopathy. In Clumber and Sussex spaniels, a deficiency of pyruvate dehydrogenase has been described. A similar exertional lactic acidosis has been reported in Old English sheepdog littermates associated with altered cytochrome-*c* oxidase activity and reduced mitochondrial mRNA.
- Given the importance of oxidative metabolism in canine muscle energetics, additional reports of these disorders should be forthcoming.

Hypertonicity Syndromes

- Hypertonicity syndromes (paroxysmal movement disorders) are being identified in several breeds of dogs, including the cavalier King Charles spaniel (CKCS), springer spaniel, Wheaton terrier, and Border terrier. With the exception of the CKCS, these disorders are poorly characterized.

- In the CKCS, clinical signs are apparent between 3 and 7 months of age. Variable periods of exercise or excitement precipitate pelvic and thoracic limb hypertonicity that may result in complete incapacitation.
- Treatment with the benzodiazepine drug clonazepam can result in almost complete remission. Although not completely evaluated, resolution of clinical signs has been anecdotally reported, with the dogs asymptomatic and no longer requiring medication.

Congenital Myasthenia Gravis

A congenital familial form of myasthenia gravis (MG), inherited as an autosomal recessive trait, is described in Jack Russell terriers, springer spaniels, and smooth fox terriers. Failure of neuromuscular transmission results from a deficiency in muscle acetylcholine receptor (AChR) content, but unlike the acquired form of MG, it is not related to autoantibodies to AChR.

Acquired Neuromuscular Disorders

Autoimmune Disorders

Some of the most commonly occurring neuromuscular disorders of dogs are in this group. Included are acquired MG, masticatory muscle myositis (MMM), and polymyositis (PM). Although considered in the hereditary group, dermatomyositis in collies and shelties is also postulated to have an autoimmune basis.

Acquired Myasthenia Gravis

- Acquired MG is common in dogs and occasionally found in cats. Feline MG is associated with an increased incidence of thymoma. Acquired MG probably is the best defined of all the neuromuscular disorders with respect to mechanisms of injury and pathogenesis. It is now well documented that acquired MG is associated with autoantibodies directed against the nicotinic AChRs on the postsynaptic membrane of the neuromuscular junction. As a consequence of autoantibody binding, there is loss of AChRs resulting in impaired neuromuscular transmission and marked muscle weakness. AChR loss is a result of the following:
  - Increased endocytosis due to cross-linking of AChRs by antibody
  - Complement activation leading to focal lysis of the postsynaptic membrane
  - Direct inhibition of AChR function by bound antibodies

Masticatory Muscle Myositis

- MMM is a focal inflammatory myopathy that selectively affects the muscles of mastication. This selective distribution may be attributed to histochemical and biochemical differences between canine masticatory and limb muscles that provide the basis for a selective immune-mediated response.
- Although the role of autoantibodies is not yet determined, autoantibodies against cytoplasmic and sarcolemmal proteins of masticatory muscle type 2M proteins have been demonstrated by immunocytochemical methods both within muscle biopsy sections and indirectly in the serum in cases of MMM. Demonstration of these antibodies is a diagnostic marker for the disease.

Extraocular Muscle Myositis

- Another focal inflammatory myopathy is described in which the cellular infiltration is localized to canine extraocular muscles with lack of involvement of the masticatory and limb muscles.
- An immune-mediated condition is suggested by a marked lymphocytic cellular infiltrate within extraocular muscles and a rapid response to corticosteroid therapy alone. Although the specific immune mechanism is not known for this disorder, myofiber-specific antigens may play a role in the selective involvement of the extraocular muscles.

Polymyositis

- Not as common as MMM, PM is a generalized inflammatory myopathy in which muscle damage is the result of cell-mediated immunity. An association has been reported with systemic lupus erythematosus and with an immune-mediated arthritis/PM complex (see Chapter 24).
- PM also may be associated with malignancies; it has been reported as a paraneoplastic disorder associated with thymoma. Boxer dogs may have an increased incidence of preneoplastic myositis.

Metabolic Disorders

Enzyme Deficiencies

- Although neuromuscular disorders associated with defined enzyme deficiencies have an early onset and are associated with specific breeds, some abnormalities, in particular those associated with oxidative metabolism, may occur later in life. With further understanding, some of these disorders may need to be reclassified as heritable, while others may be the result of environmental influences, toxins, or drugs that affect oxidative pathways.
- Reversible mitochondrial myopathies are well described in the human literature secondary to azidothymidine therapy.
- I have evaluated several cases of lipid storage myopathy in various breeds of dogs having an older age of onset. Canine lipid storage myopathy has been associated with intramyofiber lipid droplets in muscle biopsy samples, elevated lactate and pyruvate, and secondary carnitine deficiency.

Malignant Hyperthermia Syndrome

- Malignant hyperthermia is a clinical syndrome classically characterized by skeletal muscle rigidity, tachypnea, rapid elevation of core body temperature, severe metabolic acidosis, hypercarbia, and cardiac arrhythmias, which invariably leads to death if left untreated.
- Administration of certain anesthetic agents, particularly halothane and quaternary amide muscle-relaxant drugs may induce hyperthermic episodes. Information on this syndrome can be obtained in a review by Brunson and Hogan (2004).

Electrolyte Imbalances

- Alterations in the levels of serum K^+ and Ca^{2+} due to underlying metabolic disorders can affect the excitability of neurons and muscle fibers, resulting in an increase or decrease in membrane excitability and resultant episodes of muscle weakness.
- A condition analogous to hyperkalemic periodic paralysis in humans has been described in a young American Staffordshire terrier.
- Studies in cats have shown that certain diet types (e.g., acidifying diets containing insufficient potassium) and diseases (especially renal disease) are associated with an increased occurrence of hypokalemia and clinically evident weakness that resolves following potassium administration.
- Alterations in the levels of serum phosphate and magnesium may also result in neuromuscular dysfunction, although they are poorly characterized.
- Electrolyte disorders and their therapy are discussed in Chapter 5.

Endocrine Disorders

Myopathies can be associated with endocrine disorders, especially hypothyroidism and glucocorticoid excess. In hypothyroidism (see Chapter 31), peripheral neuropathies and myopathies are reported to occur, whereas myopathy, myotonia, and rarely peripheral neuropathy are associated with hyperadrenocorticism (see Chapter 33). Muscle weakness, probably as a consequence of hyperkalemia, is frequently associated with hypoadrenocorticism (see Chapter 33).

Neoplastic and Paraneoplastic Disorders

- An association between neoplasia and neuromuscular disorders is suspected but not proven.
- Thymoma is sometimes associated with MG and PM. Thymoma may also be diagnosed after the diagnosis of MG is established, and it should be considered if AChR antibody titers remain elevated for long periods. Consider evaluating AChR antibody titers before surgery in all dogs with a suspected thymoma.
- Positive AChR antibody titers and clinical signs of MG have been reported in two cases of canine osteosarcoma and in single cases of cholangiocellular carcinoma and anal sac adenocarcinoma.
- Postulated mechanisms of paraneoplastic-associated muscle damage include the following:
  - Autoantibodies produced against tumor antigens that crossreact with muscle components
  - The release of myotoxic substances by the neoplasm
  - The possibility that the neoplasm and the underlying muscle disorder have a common pathogenesis

Parasitic Disorders

- A study by Evans and colleagues (2004) suggests that parasitic myositis, particularly that associated with the protozoan *Neospora caninum,* may be more common than once thought.
- While infectious agents may occasionally be identified within muscle biopsy specimens, an inflammatory myopathy secondary to an infectious agent should not be ruled out if organisms are not identified (further discussion of protozoa is found in Chapter 21).
- An association between PM and *Ehrlichia canis* infection in dogs has been reported.
- Other parasites, such as *Trichinella spiralis, Sarcocystis,* and *Hammondia,* elicit minimal inflammation and may be found incidentally in muscle biopsies.

Viral Disorders

- Some strains of feline calicivirus are associated with transient myalgia.
- A generalized lymphocytic myositis has been reported in adult cats infected with feline immunodeficiency virus.

Toxic or Drug-Induced Disorders

Neuromuscular blockade may be the result of various neurotoxins.

- Neurotoxins that inhibit the evoked release of acetylcholine (ACh) at the neuromuscular junction are secreted by ticks such as *Dermacentor* and *Ixodes* species, resulting in tick paralysis.
- Ingestion of the exotoxin of *Clostridium botulinum* results in clinical signs of botulism by a similar mechanism.
- Organophosphate insecticides containing long-acting anticholinesterases reversibly or irreversibly bind acetylcholinesterase, permitting continuous cholinergic stimulation with accumulation of ACh at central, muscarinic, and nicotinic cholinergic synapses. Myasthenia-like syndromes are reported with organophosphate intoxication.
- Several drugs have been shown to reduce the safety margin of neuromuscular transmission, including aminoglycoside antibiotics, antiarrhythmic agents, phenothiazines, methoxyflurane, and magnesium

given parenterally or in cathartics. These agents can potentiate neuromuscular blocking agents used during surgical procedures and may worsen or unmask preexisting disorders of neuromuscular transmission.
- PM may occur rarely in association with certain drug therapies. In human medicine, the drug most often implicated has been D-penicillamine. PM can occur as part of a generalized allergic drug reaction in Doberman pinschers following trimethoprim-sulfadiazine administration; however, this has not been confirmed by muscle biopsies or electromyographic studies.
- MG has been documented to occur in hyperthyroid cats on methimazole therapy. The mechanism may be similar to D-penicillamine–induced MG described in humans.

Ischemic Disorders

Ischemia as a result of thromboembolic disease and vascular occlusion is the most common cause of ischemic myopathy and neuromyopathy in dogs and cats. Circulation may be partly or completely compromised; the severity of clinical signs varies with the degree of occlusion.

CLINICAL SIGNS

▼ ***Key Point*** Muscular weakness is the clinical sign common to all neuromuscular disorders. Expression of muscular weakness may be limited to certain muscle groups or may be generalized. The clinical expression of muscular weakness may also vary in severity.

Generalized signs of motor system involvement include the following:

- Gait abnormalities
- Paresis or paralysis
- Exercise-related weakness

Other clinical signs that may occur concurrently with generalized weakness or in the absence of detectable weakness include the following:

- Masticatory dysfunction
- Dysphagia (pharyngeal dysfunction)
- Regurgitation (esophageal dysfunction)
- Dysphonia and dyspnea (laryngeal dysfunction) indicating involvement of selected motor units serving visceral functions

DIAGNOSIS

A thorough history and careful general physical and neurologic examinations are critical to the evaluation of neuromuscular disorders. Perform routine and special diagnostic testing procedures based on the differential diagnosis. Following the examination, it should be possible to tentatively localize the disorder to the motor unit.

History

Evaluate for the following:

- Time course of onset and progression of signs
- Exposure to an outdoor environment, ticks, and other animals
- Exposure to chemical agents
- Recent illnesses and recent medications
- Exposure to different geographic locations

Physical and Neurologic Examinations

Following a careful general physical examination, including a thorough evaluation of the cardiovascular system, perform a complete neurologic evaluation, as described in Chapter 125.

- Weakness (motor sign) is common to all motor unit abnormalities.
- Evaluate muscle strength by observing the animal's gait as it walks and, if necessary, after more strenuous exercise.
- Examine for stiffness of movement, seen in inflammatory myopathies, myotonias, and MG.
- General proprioception and pain sensation are usually intact in the majority of motor unit disorders. Rarely, the presence of ataxia (sensory sign) suggests an underlying neuropathic disorder with involvement of large, myelinated proprioceptive fibers or their cell bodies in sensory ganglia.
- Assess muscle tone and spinal reflexes.
- Note muscle atrophy or swelling.

Because the clinical expression of weakness varies considerably in severity and distribution, perform other tests such as wheelbarrowing, hopping, or hemiwalking.

Clinical signs such as dysphagia, regurgitation, dysphonia, and dyspnea may indicate selective involvement of motor units. These clinical signs may occur in the absence of generalized weakness and may indicate disorders of motor units originating in cranial nerves.

▼ ***Key Point*** Differentiate vomiting from regurgitation because a wrong assessment may lead to an inappropriate diagnosis.

Laboratory Tests

Perform a complete blood count (CBC), serum chemistry profile (including electrolytes and CK), and urinalysis in all cases to evaluate possible underlying metabolic abnormalities. Although not indicated in all instances, other laboratory assays may assist in obtaining a diagnosis.

Serum Creatine Kinase Assay

Serum CK levels are elevated in muscle disorders associated with damage to myofibers and membranes. Although CK is a sensitive indicator of the presence and severity of myonecrosis, it has not been reliable in the diagnosis of inflammation. Modest elevations in CK can occur in neuropathies.

▼ ***Key Point*** An elevation of serum CK is not diagnostic of myositis. Perform a muscle biopsy to confirm the diagnosis.

Resting and Postexercise Plasma Lactate and Pyruvate Assays

Evaluate plasma lactate and pyruvate levels at rest and following 10 minutes of strenuous exercise to diagnose disorders of oxidative metabolism. Perform these evaluations in any animal with exercise intolerance. Collect blood for lactate analysis in sodium fluoride-potassium oxalate tubes (gray top), centrifuge immediately, then separate the plasma. Special handling is required for pyruvate analysis.*

Thyroid and Adrenal Function Tests

Myopathies can occur secondary to disorders of both the thyroid and adrenal gland. Hypothyroidism can occur concurrently with autoimmune neuromuscular disorders such as acquired MG, and an optimal clinical response may rely on the treatment of both disorders.

Antinuclear Antibody Assay

A positive antinuclear antibody (ANA) titer in association with an inflammatory myopathy suggests an underlying systemic autoimmune disorder. A subset of canine patients with MG also has positive ANA titers.

Serologic Tests

- Serum *Toxoplasma gondii* and *Neospora caninum* titers, as described in Chapter 21, may be useful in the evaluation of inflammatory myopathies and peripheral neuropathies caused by protozoa. If found, demonstration of the organism in a muscle biopsy specimen is diagnostic.
- Serum *Ehrlichia* titers may be indicated in dogs, as described in Chapter 17.
- Evaluate cats suspected of feline immunodeficiency virus-associated myopathy with feline immunodeficiency virus serology, as described in Chapter 9.

*Assays are available from the Comparative Neuromuscular Laboratory, Basic Science Building, Room 2095, University of California–San Diego, La Jolla, CA 92093-0709 (telephone: 858-534-1537).

Plasma Cholinesterase Levels

Myasthenia-like syndromes and delayed neuropathies are associated with organophosphate toxicity.

Serum Antibodies against Masticatory Muscle Type 2M Fibers

The demonstration of autoantibodies against masticatory muscle type 2M fibers in fresh-frozen muscle sections by immunocytochemical and enzyme-linked immunosorbent assay methods is useful in the diagnosis of MMM. Direct methods for demonstrating the antibodies bound to myofibers within a muscle biopsy and indirect methods for demonstrating antibodies circulating within the patient's serum are available.*

Serum Antibodies against Nicotinic Acetylcholine Receptors

Demonstration of autoantibodies against muscle AChRs by immunoprecipitation radioimmunoassay is the diagnostic test of choice for acquired MG. This assay is sensitive and specific and demonstrates an immune response specifically against muscle AChRs. It is particularly valuable in cases of focal myasthenia in which muscle weakness is localized to pharyngeal or esophageal musculature in the absence of detectable generalized weakness. Serial serum antibody titers also are important in following clinical response to treatment because there is good correlation between serum titers and response to treatment.*

▼ ***Key Point*** Previous corticosteroid administration can lower serum antibody levels in assays for MMM and MG. Collect serum before corticosteroid therapy.

Edrophonium Chloride Challenge Test

A presumptive diagnosis of generalized MG in dogs and cats may be based on an increase in muscle strength following intravenous (IV) administration of edrophonium chloride (Tensilon, Roche) at a recommended dose of 0.1 to 0.2 mg/kg. The most dramatic response to edrophonium chloride is in MG; however, responses are variable: some patients with MG fail to respond, whereas some patients with other neuromuscular disorders may show a partial improvement in muscle strength.

▼ ***Key Point*** Do not eliminate a diagnosis of MG based on a negative response to edrophonium. Submit serum for AChR antibody titers to confirm the diagnosis.

- Perform an edrophonium challenge test in all cases of confirmed MG for determination of the correct treatment protocol. If there is a good response to edrophonium, there should be a good response to

anticholinesterase therapy. If the response to edrophonium is negative, then corticosteroids may be the treatment of choice.
- In cases of focal MG, if the palpebral reflex is absent or decreased, administration of the edrophonium chloride may result in an improved blink.
- During treatment of generalized MG with anticholinesterase drugs, edrophonium chloride may be useful in differentiating a myasthenic crisis (underdosing) from a cholinergic crisis (overdosing).
- In a myasthenic crisis, rapid improvement usually follows IV administration of edrophonium chloride. In cases of anticholinesterase drug overdose, IV administration of edrophonium chloride either will not improve or will worsen the clinical signs.

Electrodiagnostic Evaluation

- Electrodiagnostic testing is a valuable adjunct to the neurologic examination. It provides the following:
  - Information about the location of a lesion within the motor unit (e.g., axon, neuromuscular junction, or muscle)
  - Information about the distribution and severity of the disease process
  - Guidance to appropriate muscle groups and peripheral nerves for subsequent biopsy

  Electrodiagnostic testing includes the following:

  - Evaluation of muscles by electromyography
  - Evaluation of peripheral nerves by measurement of motor and sensory nerve conduction velocities and compound muscle and nerve action potentials (see Chapters 125 and 129)
- Measurement of evoked potentials following repetitive nerve stimulation is useful in the diagnosis of disorders of neuromuscular transmission if performed appropriately. In normal dogs, stimulus rates greater than 5 stimuli/second may result in decremental responses. Use of stimulus rates greater than 5 stimuli/second is not recommended because it can result in an inaccurate diagnosis of MG.
- Single-fiber electromyography studies may be of value in cases of seronegative MG or other disorders of neuromuscular transmission. The technique requires expertise and is only available at a few centers.

Muscle Biopsy

Muscle biopsy allows direct examination of portions of most motor unit components (e.g., intramuscular nerve branches, neuromuscular junction, and myofibers) and of supportive, connective, and vascular tissues. Using fresh-frozen sections, histologic and cytologic detail is preserved and many biochemical and immunochemical reactions within cells and tissues can be localized. Frozen sections also may be used in specific biochemical assays for enzymes and substrates.

▼ ***Key Point*** For maximum information from a muscle biopsy, specimens should be fresh-frozen in isopentane precooled in liquid nitrogen. Biopsy samples must be received cold for subsequent freezing at a laboratory specialized in processing muscle biopsies. Consult with the laboratory before taking a muscle biopsy. Place a second muscle biopsy in fixative for subsequent ultrastructural examination if required.

Appropriate sampling and transport methods are essential to the diagnostic value of the muscle specimen. Selection of the muscle(s) for biopsy is also important.

- Sample an involved muscle; however, avoid end-stage muscle because essential diagnostic features may no longer be present.
- The site of a localized disorder determines which muscle(s) should be sampled; however, in generalized disorders (e.g., polyneuropathy and PM), obtain samples from standard muscles (e.g., vastus lateralis in dogs and cats).
- Following collection, dip the muscle in saline, place it in a watertight container, and transport it on cold packs by a courier service to the laboratory.
- Delivery to the laboratory for processing within 24 hours is critical for optimal results.

Carnitine Quantification in Plasma, Urine, and Muscle

Lipid storage myopathies may result from primary or secondary abnormalities of carnitine. If excessive lipid droplets are present within a muscle biopsy section, carnitine should be quantified in plasma, urine, and muscle for formulation of a treatment plan.

Non-contrast and Contrast Radiographic Studies

Three-view, plain thoracic radiographs are indicated in neuromuscular disorders to rule out concurrent megaesophagus, aspiration pneumonia, thymoma, and other intrathoracic neoplastic processes. Because dysphagia as a result of oropharyngeal dysfunction and megaesophagus is a major problem in certain neuromuscular disorders, contrast studies that evaluate the dynamic swallowing process and motility throughout the esophagus may be indicated (see Chapter 4). Attempt contrast studies only if appropriate fluoroscopy and video recording equipment is available. (See Chapter 65 for discussion of diagnosis and management of esophageal disease.)

▼ ***Key Point*** If a large, air-filled pharynx or a megaesophagus is seen on plain radiographs, do not perform a barium swallow. If a contrast agent is absolutely necessary, use a small amount of dilute barium solution to minimize chances of barium aspiration (see Chapter 4).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) provides excellent soft tissue resolution and can distinguish among muscle, fat, and connective tissue. This technique may be of value in cases in which specific lesion localization is difficult, such as inflammatory myopathies involving the pharynx and larynx (see Chapter 4).

TREATMENT

Selective breeding and prevention comprise the treatment of choice for the hereditary neuromuscular disorders. New techniques in molecular genetics, available at selected research centers, allow the identification of some underlying genetic defects and carrier animals. Gene replacement therapies are currently in experimental testing stages and may be available in the future for treatment of some of these disorders. Acquired neuromuscular disorders in many instances are secondary to diverse underlying medical problems such as hypothyroidism (see Chapter 31), adrenal gland dysfunction (see Chapter 33), electrolyte disorders (see Chapter 5), and protozoal infection (see Chapter 21). Whenever possible, treat the primary problem. Specific treatment is available for some neuromuscular disorders. These are described below.

Generalized Myasthenia Gravis

Anticholinesterase Drugs

These drugs are the cornerstone of treatment for MG. They inhibit enzymatic hydrolysis of ACh at the neuromuscular junction, thereby increasing the effective concentration of ACh and the duration of its effect in the synaptic cleft and prolonging the interaction of released ACh with remaining AChRs.

- If there is a positive response to edrophonium chloride testing and the animal can tolerate oral medication, administer pyridostigmine bromide syrup (Mestinon, Roche) diluted 1:1 in water at a dosage of 0.5 to 3.0 mg/kg q8–12h PO beginning at the low end of the dosage scale and gradually increasing.
- In cases of focal MG without generalized weakness or a fatigable palpebral response, begin pyridostigmine bromide syrup at a dosage of 0.5 to 1.0 mg/kg q8–12h PO.
- If oral delivery of drugs is a problem owing to megaesophagus or pharyngeal dysfunction, give injectable neostigmine (Prostigmin, Roche) at a dosage of 0.04 mg/kg q6h IM until the animal is able to handle oral medication.
- In critical animals, constant rate infusion of pyridostigmine bromide (0.01–0.03 mg/kg/hour) may be used until oral feedings are resumed or a feeding tube is placed.
- Initiate concurrent treatment for aspiration pneumonia (see Chapter 163) as needed.

▼ ***Key Point*** In the treatment of MG, titrate dosages to fit each animal's needs; requirements may vary from day to day in response to activity levels and stress.

Corticosteroids

Do not use corticosteroids as initial therapy in MG unless there was a negative response to edrophonium chloride testing. Although it is true that MG is an autoimmune disease, clinical signs of weakness can be controlled in most cases with anticholinesterase drugs.

Contraindications

- Some dogs become weaker with immunosuppressive dosages of corticosteroids, possibly precipitating a myasthenic crisis.
- In many dogs with MG, there is spontaneous remission within variable periods of time; therefore, generalized immunosuppression may not be warranted, particularly in light of the side effects of these drugs in dogs.

Indications

- If muscle strength is not greatly improved following anticholinesterase treatment and aspiration pneumonia is not present, administer prednisone at 0.5 mg/kg q12h, gradually tapering to an alternate-day dosage.
- High-dose IV methylprednisolone therapy may be of benefit in severe cases of MG. One gram of methylprednisolone is suggested every 5 days.
- Other autoimmune disorders, for which a specific treatment for the underlying clinical signs is not available, may occur concurrently with MG. In these cases, immunosuppression with corticosteroids is warranted.

Other Immunosuppressive Treatments

Reserve agents such as azathioprine and cyclophosphamide for the rare refractory cases that do not respond to conventional therapy.

▼ ***Key Point*** Rare cases may present in myasthenic crisis with peracute onset of collapse and respiratory insufficiency. Anticholinesterase drugs may be of no benefit in these cases; thus, respiratory support and plasmapheresis may be necessary.

Management of Pharyngeal Dysphagia and Megaesophagus

▼ ***Key Point*** Early recognition of regurgitation due to megaesophagus is important in the successful management of MG; management includes alteration in methods of delivery of food and water.

- Administer anticholinesterase drugs 1 hour before feeding.
- Deliver food and water with the animal in an upright position (see Chapter 65).
- Ensure that the animal remains upright for at least 10 minutes following feeding.
- If upright feeding fails to control regurgitation, place a gastrostomy feeding tube, as described in Chapter 3, to bypass the dysfunctional pharynx and esophagus.

▼ ***Key Point*** In the absence of severe aspiration pneumonia and with appropriate management, the prognosis for complete remission of MG is fair to good. In many animals, the megaesophagus resolves and regurgitation is eliminated. Continue treatment until serum AChR antibody titers are normal.

Focal Myasthenia Gravis

Megaesophagus and pharyngeal dysfunction in the absence of detectable generalized weakness may occur in MG. The diagnosis in these cases is made by demonstration of positive serum AChR antibody titers.

- The single most important part of treatment is elevation of food and water (see Chapter 65).
- The value of anticholinesterase drugs in focal MG is not known; however, lower doses may be of some benefit in controlling regurgitation. In the absence of generalized weakness, monitoring drug response is difficult and overdosages may occur.
- In the absence of aspiration pneumonia and pharyngeal weakness, a large percentage of dogs with the focal form of MG go into spontaneous remission. Although it is not known whether the benefits of corticosteroids outweigh the risks, in focal MG as in generalized MG the presence of concurrent autoimmune disorders without a specific therapy warrants the use of corticosteroids.

Immune-Mediated Inflammatory Myopathies

Masticatory Muscle Myositis

- During the acute stages of MMM, masticatory muscle swelling and trismus (inability to open the jaw) usually resolve rapidly subsequent to immunosuppressive dosages of glucocorticoids (prednisone, 2–3 mg/kg q12h PO).
- Determine response to therapy by the ability to open the jaw and by serial determinations of serum CK levels.
- If the response is favorable, decrease the dosage after 1 to 2 weeks to 1.0 mg/kg q12h PO; then gradually decrease to the lowest effective alternate-day dosage. Maintain this alternate-day dosage for 4 to 6 months. In refractory cases, azathioprine can be used concurrently with prednisone to maintain complete clinical remission.
- If MMM is not treated appropriately, relapses are common.

▼ ***Key Point*** In acute MMM, glucocorticoids usually produce rapid resolution. In chronic MMM, glucocorticoid therapy may improve jaw mobility even though a significant proportion of muscle is replaced by fibrous connective tissue.

Polymyositis

- In the absence of aspiration pneumonia or an underlying infectious agent, treat dogs with PM with immunosuppressive doses of corticosteroids. Initiate a treatment regimen similar to that for MMM.
- In refractory cases, use corticosteroids and other immunosuppressive agents such as azathioprine or cyclophosphamide concurrently.

Lipid Storage Myopathy

- Large intramyofiber lipid droplets within a fresh-frozen muscle biopsy sample are an indication of an underlying metabolic abnormality. Evaluate lactate, pyruvate, and carnitine status.
- Treat orally with L-carnitine (50 mg/kg q12h), coenzyme Q10 (100 mg q24h) and a good-quality B vitamin for a minimum of 2 months for determination of response. The treatment may need to be continued indefinitely.

Chapter

131 Ophthalmic Equipment and Techniques

David A. Wilkie

OPHTHALMIC EQUIPMENT

The instruments and other equipment necessary for ophthalmic examination and surgery can be generally categorized as basic and advanced.

Diagnostic Equipment

Basic

- Penlight
- Direct ophthalmoscope with Finnoff transilluminator
- Indirect lens (20 diopter)
- Monocular biomicroscope
- Tonometer (Schiøtz) or Tonopen Vet (Mentor O&O)
- Miscellaneous
  - Schirmer tear test strips
  - Fluorescein stain
  - Nasolacrimal cannula (23 gauge)
  - Dilating agent (e.g., tropicamide)
  - Topical anesthetic (e.g., proparacaine)
  - Graefe forceps for third eyelid manipulation
  - Kimura spatula for cytology

Advanced

- Biomicroscope (slit lamp)
  - Monocular or binocular
- Indirect ophthalmoscope
- PanOptic ophthalmoscope
- Indirect lenses (15, 20, and 30 diopter)
- Applanation tonometer
- Gonioscopy lens
- Streak retinoscope
- Ultrasound (7.5, 10.0, and 20.0–50.0 MHz)
- Fundus camera
- Electroretinography

Surgical Equipment

Basic

- Magnifying loupes (4–6×)
- Colibri corneal forceps (0.3-mm teeth with tying platform)
- Bishop Harmon forceps (0.3- or 0.8-mm teeth)
- Barraquer needle holder (curved, without lock device; 9 mm × 0.85 mm jaws)
- Westcott tenotomy scissors
- Stevens tenotomy curved scissors
- Barraquer eyelid speculum
- Beaver blade handle
- Bard-Parker blade handle
- Desmarres chalazion clamp
- Strabismus hooks (two)
- Jamieson calipers
- Jaeger eyelid plate
- Irrigating cannula (23 gauge)

Advanced

- Operating microscope
- Right and left corneal section scissors

- Lens loop
- Angled tying forceps
- Carter sphere introducer
- Castroviejo cyclodialysis spatula
- Various intraocular forceps
- Diode or Nd : YAG laser
- Corneal trephines
- Phacoemulsification/irrigation-aspiration device
- Vitrector

Other

- Suture material
- 7-0 to 10-0 Vicryl or Dexon—ophthalmic spatula needle
- 9-0 nylon
- 6-0 monofilament—ophthalmic cutting needle (nylon, Surgilene, prolene)
- Blades
  - #64, #63, and #65 Beaver blades
  - #11 and #15 Bard-Parker blades
  - Diamond or sapphire knives
- Irrigating solutions
  - Ophthalmic balanced salt solution (BSS)
  - Lactated Ringer's
- Weck-cel surgical spears
- Prosthesis implants (18–19 mm)

OPHTHALMOLOGY TECHNIQUES

The general veterinarian in private practice should be able to perform the following routine ophthalmic procedures:

- Culture of the eye
- Schirmer tear test
- Tear breakup time
- Examination of the nictitating membrane (third eyelid)
- Direct ophthalmoscopy
- Indirect ophthalmoscopy
- Monocular biomicroscopy
- Fluorescein stain of the cornea
- Nasolacrimal irrigation
- Tonometry (Schiøtz, Tonopen)
- Conjunctival/corneal cytology

To properly evaluate and treat the patient with ocular disease, the clinician must have an accurate understanding of ophthalmic anatomy (Fig. 131-1).

In addition, based on the information obtained by these diagnostic tests, the clinician should be able to arrive at a diagnosis and formulate a plan for further diagnostic tests or treatment or, if indicated, referral.

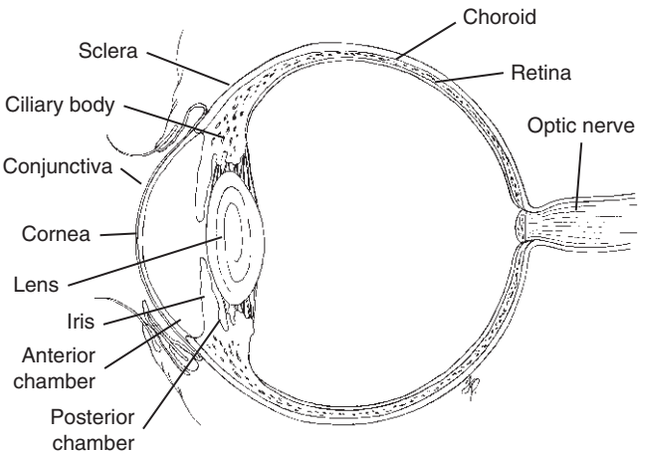

Figure 131-1 Normal ophthalmic anatomy.

Culture

Indications

- Chronic, nonresponsive corneal ulcer
- Acute, severe melting corneal ulcer
- Purulent ocular discharge
- Infectious blepharitis

Equipment

- A sterile, moist, synthetic culture swab is preferable, but a sterile cotton swab can be used.

Technique

The general principles and techniques for obtaining a culture from the eye are the same as for other organs.

1. Using a sterile swab moistened in transport media, obtain the sample in an aseptic manner from the area of concern; for example:
   a. If the lesion is a corneal ulcer, touch the swab to the ulcer (do not place in the conjunctival fornix).
2. Do not use a topical anesthetic for this procedure because it may interfere with the growth of organisms.
3. Label the sample and submit for aerobic and possibly fungal culture and sensitivity testing. It should be streaked onto nutrient agar as soon as possible.
4. Perform culture in combination with cytology or, if applicable, polymerase chain reaction (PCR) testing, when an infectious agent is suspected.

Schirmer Tear Test

Indications

- Assessment of normal aqueous tear production
- Chronic pigmentary keratitis
- Epiphora, including chronic mucoid epiphora

Equipment

- Commercially available Schirmer tear test (STT) strips

Technique

1. Place the notched end of the test strip in the lower conjunctival fornix. Do not touch this end.
2. Hold the eye closed and allow the strip to remain in place for exactly 1 minute. If convenient, both eyes may be tested at the same time.
3. Remove the strip and, using the standard measurement on the package, measure and record tear production. Normal dogs secrete 15 mm or more in 1 minute. While the normal value in the cat is reported to be similar to the dog, cats can have very low STT values without clinical signs. It is thought that stress may decrease the STT value in cats, and results must be interpreted along with clinical signs.
4. Do not use topical anesthetic for this test because the objective is to measure the response of the eye to an irritant. This requires the response of the ophthalmic branch of cranial nerve (CN) V as the afferent arm and the parasympathetic fibers in CN VII as the efferent arm.
5. In addition to the Schirmer tear test, evaluation of the tear breakup time to assess the mucin portion of the precorneal tear film and corneal staining with rose Bengal are also tools used in the assessment of the precorneal tear film and corneal surface health.

Tear Breakup Time (TBUT)

Indications

- Assessment of qualitative aqueous tear production
- Chronic pigmentary keratitis
- Epiphora, including chronic mucoid epiphora

Equipment

- Fluorescein stain
- Blue light and magnification (a slitlamp works best)
- Watch with a second hand

Technique

1. Place a drop of fluorescein stain on the cornea. Do not rinse it off.
2. Hold the eyelids closed and place the slitlamp to your eyes and the blue light on the eyelids.
3. Open the eyelids and, holding them open, begin timing while examining the green precorneal tear film. Continue to hold the eyelids open. The precorneal tear film should appear as a uniform, continuous film across the cornea. When the tears begin to separate into an oil and water pattern, stop timing.
4. Normal tears will remain stable for approximately 21 seconds. Failure to form a normal tear film or early breakup indicates a qualitative tear film abnormality. This is a result of a loss of goblet cells and tear film mucin.

Examination of the Nictitating Membrane

Indications

- Chronic conjunctivitis
- Suspicion of a foreign body
- Abnormalities of the gland or cartilage
- Mass lesion of the nictitating membrane (third eyelid)

Equipment

- Topical anesthetic
- Atraumatic forceps

Technique

1. Examine the palpebral surface of the third eyelid by gently retropulsing the globe and allowing the nictitating membrane to prolapse passively while the lower eyelid is retracted. This is useful for assessing the mobility of the third eyelid and for protecting the eye when obtaining a conjunctival scraping.
2. Examine the bulbar surface of the third eyelid. This requires topical anesthesia.
   a. The topical anesthetic of choice is proparacaine (Alcaine), which provides 10 to 15 minutes of anesthesia. Apply 2 drops of anesthetic and wait 2 to 3 minutes for the full effect.
   b. After anesthetizing the surface, gently grasp the leading edge of the third eyelid with small nontoothed forceps. Take care to avoid damaging the cornea.
   c. Gently pull the third eyelid up and out to allow examination of the posterior surface.
3. Examine all surfaces and the inner and outer fornices of the third eyelid for a foreign body and for lymphoid follicles, which indicate a chronic inflammatory process.

Biomicroscopy

This technique provides a magnified and 3-dimensional method to examine the globe from the eyelid surface back to the anterior third of the vitreous.

Indications

- Detailed examination of the anterior segment of the eye to examine the following:
  - Eyelids
  - Conjunctiva
  - Third eyelid
  - Cornea
  - Aqueous
  - Iris
  - Lens
  - Anterior vitreous

- Ability to examine for depth of lesion by providing an optical section (3-dimensional perspective)
- Detailed examination with higher magnification (5–20×) of specific areas such as the cornea, iris, and lens

Equipment

- Inexpensive monocular biomicroscope
  - Heine HSL-150
  - Eidolon 510L
- Expensive binocular biomicroscope
  - Kowa SL-14
  - Zeiss HSO-10

Technique

1. Turn on the slitlamp and use the rheostat to adjust the light intensity. If applicable, adjust the width of the slit beam.
2. A dilated pupil will facilitate examination of the structures posterior to the iris.
3. Darken the examination room.
4. Place the slitlamp to your eye and position the slitlamp 1 to 2 inches from the patient's cornea. Achieve focus by fine movements toward or away from the patient. The depth of focus is such that the cornea and the lens are not in focus simultaneously. Slowly sweep the beam of light from left to right and back to examine the entire eye from eyelids to anterior third of the vitreous. Work systematically from eyelids to vitreous focusing deeper with each pass of the light beam.
5. With a narrow slit beam it is possible to locate the depth of a lesion such as a corneal ulcer or cataract. In addition, the magnification provided aids in visualization of foreign bodies, aqueous flare, iris detail, and eyelid abnormalities such as distichia and ectopic cilia.

Direct Ophthalmoscopy

This technique provides an upright image of the fundus and associated structures and magnifies the image 15 to 18 times. In small animals, the field of view is narrow and therefore difficult to use for general screening of the eye.

Indications

- Examination of the ocular fundus
- Detailed examination with higher magnification of specific areas such as the optic nerve and blood vessels

Equipment

- Dilating agent (e.g., tropicamide)
- Charged, direct ophthalmoscope

Technique

1. Turn on the ophthalmoscope and use the rheostat to adjust the light intensity.
2. Turn the diopter wheel to the zero (0) setting. This usually is the proper setting to view the fundus.
3. Darken the examination room.
4. Place the ophthalmoscope to your eye, and from a distance of 12 to 24 inches obtain the tapetal reflection. While looking through the ophthalmoscope move toward the animal's eye, observing for any interference with the tapetal reflection, which may indicate opacity of the transmitting media, cornea, aqueous humor, lens, or vitreous. When you are 1 to 2 inches from the patient's cornea, the retina, optic nerve, retinal vessels, and tapetum will be clearly in focus.
5. Locate a blood vessel and follow it to the optic nerve. Evaluate the optic nerve and blood vessels and scan the fundus for abnormalities of color, clarity, size, and shape. Use the diopter wheel to adjust the focus, and to evaluate raised and depressed lesions (numbers in red indicate negative or deeper; those in black are positive or more superficial).
6. While higher magnification is achieved with direct as compared to indirect examination, opacities of the transmitting media will interfere with direct examination preventing visualization of the posterior segment with this technique.

Indirect Ophthalmoscopy

Although practice is required to become proficient in this technique, once it is mastered it is more useful than direct ophthalmoscopy for screening the fundus in small animals. Also, the equipment needed is less expensive unless a headset is used. Indirect ophthalmoscopy provides an inverted, reversed image magnified 3 to 5 times. This image, although of a lower magnification than with direct ophthalmoscopy, has a much larger field of view and is better for routine screening of the eye. In addition, indirect examination will allow identification of the posterior segment through mild opacities of the cornea, aqueous, lens, and vitreous.

Indications

- Examination of the ocular fundus

Equipment

- Dilating agent (e.g., tropicamide)
- Light source (e.g., penlight)
- Indirect, handheld 20-diopter lens
- Binocular headset for clinicians with advanced interest in ophthalmology

Technique

1. Dilate the patient's pupil with 1 or 2 drops of tropicamide (Mydriacyl). Allow 10 to 15 minutes for complete dilation (the effect will last 8 to 12 hours in dogs).
2. Begin the examination at arm's length from the patient, having an assistant restrain the patient and hold the eyelids open.
3. Darken the examination room.
4. With a focal light source (e.g., a penlight or direct ophthalmoscope with Finoff transilluminator) held at arm's length from the patient, obtain the tapetal reflection.
5. Holding the lens in the other hand, place the lens 1 to 2 inches in front of the patient's eye, in the path of the light. The fundus should appear as an upside down and reversed virtual image in front of the lens.
   a. Be sure to look at the image that is in front of the lens and not at the lens or the eye.
6. To view other areas of the fundus, you must move yourself, the light source, and the lens while keeping all of these in alignment. Remember that because the image is inverted you must move in the opposite direction to the image.
7. If the image is lost, move the lens out of the light beam and start again.
8. An indirect headset, while expensive, will greatly facilitate examination.
9. A alternative to an indirect headset is a monocular indirect ophthalmoscope, the Welch Allyn PanOptic ophthalmoscope.

Fluorescein Stain of the Cornea

Fluorescein is a hydrophilic drug that binds to the corneal stroma, but not to the epithelium or to Descemet's membrane.

Indications

- Red or painful eye
- An obvious corneal irregularity
- Ocular trauma or a foreign body
- Tear breakup assessment
- Suspected feline herpes keratitis
- Assessment of nasolacrimal duct function

Equipment

- Prepackaged fluorescein strips (commercially available)
- Sterile ocular collyria (eyewash solution)
- Cotton balls

Technique

1. Remove the fluorescein strip from the package, holding it by the green end. Fold the strip lengthwise to create a trough.
2. Place 2 or 3 drops of sterile eyewash solution on the strip and tilt it to allow the stain to drip onto the eye. Do not touch the eye with the strip because this may result in an iatrogenic area of stain retention.
3. With the eyewash solution, gently irrigate excess stain from the eye onto a cotton ball; examine the eye for stain uptake, using a penlight. Identification of the fluorescein uptake is improved by using a blue or Woods light, which excites the fluorescein molecules, making them fluoresce green. To assess TBUT, do not irrigate the flourescein from the cornea (see TBUT).

Assessment of Nasolacrimal Duct Function

1. To evaluate the patency of the nasolacrimal duct, perform the previously described steps, but do not rinse the fluorescein from the eye. The stain should appear at the nares within 5 minutes.
2. A positive test is definitive for a patent nasolacrimal duct but does not prove that both puncta are patent. A negative test suggests a problem, and irrigation of the duct is indicated.

Nasolacrimal Duct Irrigation

- This procedure can be performed on a minimally restrained dog, using only topical anesthesia.
- Sedation or general anesthesia usually is required for cats.

Indications

- Epiphora without an obvious etiology
- Failure of passage of fluorescein stain
- Mucopurulent ocular discharge

Equipment

- Topical anesthetic
- Syringe (3 or 6 ml)
- Nasolacrimal duct cannula (23 or 25 gauge)

Technique

1. Apply a topical anesthetic and connect a nasolacrimal duct cannula to a syringe filled with eyewash solution.
2. While an assistant restrains the animal's head, elevate and roll the upper eyelid in the medial canthus to expose the superior punctum.
3. Place the thumb or index finger on the plunger of the syringe, in preparation for injection. Hold the syringe loosely so that no injury will result if the patient should jerk its head. If possible, rest your hand on the patient's head in case the patient moves.
4. Gently insert the cannula in the punctum and, without forcing, allow it to seat itself in the duct. Apply gentle pressure to the plunger and observe fluid emerging from the inferior punctum.
5. Occlude the lower punctum, tip the nose down, and continue flushing. Fluid should now appear at the nostril.

▼ ***Key Point*** Do not use excessive force when placing the catheter or when irrigating.

6. If a patent duct cannot be established and the epiphora is severe, consider medical therapy such as topical antibiotics or anti-inflammatories and repeated irrigation, or examine under general anesthesia to further pursue the problem. Ultimately, skull radiographs and a contrast dacryocystorhinography can be used to further evaluate the nasolacrimal canaliculi, sac, and duct.

Tonometry

Be sure to have a functioning tonometer and be familiar with its use. There are two specific ways to determine intraocular pressure (IOP): indentation tonometry and applanation tonometry.

Indications

- Diffuse corneal edema
- Anisocoria
- Fixed and dilated pupils
- Episcleral congestion
- Blindness
- Buphthalmos
- Anterior uveitis
- Breeds predisposed to primary glaucoma—annual IOP determination
- Monitoring of medically or surgically controlled glaucoma
- Evaluation of the contralateral eye in animals with unilateral primary glaucoma

Schiøtz Indentation Tonometry

The Schiøtz tonometer is an indentation tonometer and measures the amount of corneal indentation that occurs when a given weight is placed on the cornea. The result is inversely proportional to the intraocular pressure. Obtain the actual pressure from a table of values. The Schiøtz tonometer requires assembly, disassembly, and cleaning in order to ensure its accuracy. The foot plate is large and the patient must be cooperative in order to place the foot plate on the cornea in a vertical position. If the animal is fractious or the eye painful, it is unlikely that accurate placement will be obtained and erroneous values will result. The result is that glaucoma is not diagnosed or monitored accurately and IOP determination is not performed at the frequency indicated by the breed or clinical signs.

Equipment

- Topical anesthetic
- Clean and calibrated Schiøtz tonometer
- Conversion chart

Technique

1. Anesthetize the cornea with topical proparacaine.
2. To assemble the tonometer, place the shaft in the housing and attach the 5.5-g weight. Hold the instrument vertically and check that the plunger slides freely within the hollow sleeve.
3. Use the metal calibration standard to test the accuracy of the tonometer. When the instrument is placed on the standard it should read zero (0) on the scale (i.e., the 5.5-g weight does not indent the metal standard).
4. While an assistant gently elevates the patient's nose, elevate the upper eyelid and place the tonometer foot plate on the cornea. Keep the tonometer vertical and on the center of the cornea. The tonometer should rest on the eye and does not need to be pushed down.
5. Take three readings and average them. Using the conversion chart, convert the averaged value to an approximation of the intraocular pressure, matching the weight used with the reading obtained.
6. Normal values for dogs are 15 to 25 mm Hg; the variation in both eyes should be no greater than 5 mm Hg.

Applanation Tonometry—Tonopen

Applanation tonometry determines IOP by evaluating the force required to applanate or flatten a given surface area of cornea. In recent years the Tonopen (Mentor O&O) has been evaluated and shown to be similar to other applanation tonometers in accuracy. It is lightweight, portable, accurate, and self-calibrating, and it averages several readings and gives a percentage error to ensure accuracy. In addition, the small foot plate allows this tonometer to be used on painful eyes in less cooperative patients because only a small area of cornea is required to obtain a reading, and the position of the patient's head is not related to obtaining the reading. This is the current accepted gold standard in veterinary ophthalmology. All small animal practices should have access to a functional Tonopen.

Equipment

- Topical anesthetic
- Calibrated Tonopen

Technique

1. Anesthetize the cornea with topical proparacaine.
2. Activate the Tonopen and gently tap the transducer tip, which is protected by a sleeve, against the cornea. A gentle bouncing motion of the transducer tip against the cornea works best. The device will give an audible tone as each reading is accepted and a longer tone when enough readings have been averaged.

3. Obtain the patient's IOP from the digital reading at the Tonopen display window. The standard error bar should be over the <5% error. If there is a greater percent error, repeat the procedure until a reliable measurement is obtained.

Cytology

Cytology is a simple, fast, and inexpensive method for characterizing the type of inflammatory process, and in many cases it is used to obtain a diagnosis.

Indications

- Obtain a sample for Gram stain
- Characterize the type of inflammation (i.e., neutrophilic, lymphocytic, eosinophilic)
- Aid in the diagnosis of feline conjunctivitis (e.g., for *Chlamydophila, Mycoplasma*)
- Obtain samples for PCR testing

Equipment

- Topical anesthetic
- Platinum spatula, cytology brush, or other instrument suitable for sample collection
- Microscope
- Microscope slides
- Stain

Technique

1. Place a topical anesthetic in the animal's conjunctival sac.
2. Gently retropulse the globe and retract the lower eyelid, thus exposing the third eyelid.
3. Using a spatula or other suitable instrument, scrape the palpebral surface of the third eyelid and the adjacent palpebral conjunctiva. Avoid damaging the surface, but use sufficient force to exfoliate cells. For ulcerative keratitis the sample must be obtained from

Table 131-1. OPHTHALMIC CLINICAL SIGNS ASSOCIATED WITH SYSTEMIC DISEASES

Ophthalmic Clinical Sign	Associated Systemic Disease
Keratitis sicca	Hypothyroidism Autoimmune Drug-induced (sulfonamides, edotodolac) Facial nerve paralysis Otitis media/interna Distemper
Anterior uveitis/chorioretinitis	Infectious (bacteria, rickettsia, mycoses, viruses) Traumatic Neoplastic Autoimmune
Glaucoma	Anterior uveitis Neoplasia Trauma Hyphema
Retinal detachment	Trauma Infectious (bacteria, rickettsia, mycoses, viruses) Neoplasia Autoimmune Systemic hypertension (renal disease, diabetes mellitus, pheochromocytoma, hyperthyroidism, idiopathic) Hyperviscosity
Blindness	Trauma Neoplasia Reticulosis Infectious (bacteria, rickettsia, mycoses, viruses) Autoimmune Other central nervous system diseases
Horner's syndrome	Thoracic mass Spinal cord trauma C1-T2 Neck trauma Otitis media/interna Orbital mass lesion
Hyphema	Coagulopathy Trauma Systemic hypertension (renal disease, diabetes mellitus, pheochromocytoma, hyperthyroidism, idiopathic) Infectious Neoplasia

the ulcer margin to accurately evaluate for potential pathogens.
4. Place the cells on a glass slide and streak them to form a monolayer.
5. Submit the slide for Gram staining (to characterize the type of bacteria); for Giemsa, Wright, or Diff-Quik staining (to examine for cell type, inclusion bodies, etc.); for fluorescent antibody testing (*Chlamydia,* herpesvirus); or for PCR testing (herpesvirus, mycotic keratitis).

Ocular Ultrasound

Ultrasound is a simple, fast, and inexpensive method for examination of the lens and posterior segment in eyes with opacities of the transmitting media. In addition, ultrasound can be used to evaluate the orbit, although computed tomography and magnetic resonance imaging are superior for orbital examination.

Indications

- All opacities of the transmitting media
  - Corneal edema
  - Hyphema
  - Cataract
- Evaluation of intraocular mass lesions
- Orbital disease indicated by exophthalmos

Equipment

- Topical anesthetic
- Sterile K-Y jelly as a coupling jel
- Ultrasound with a 5.0- to 10.0-MHz transducer probe
- Ultrasound biomicroscopy can be performed with dedicated 20.0- to 50.0-MHz ophthalmic ultrasound

Technique

1. Place a drop of topical anesthetic in the animal's conjunctival sac.
2. Place sterile ultrasound coupling gel or K-Y jelly on the transducer tip or on the corneal surface.
3. Place the transducer directly on the cornea, or the scan may be performed through closed eyelids or an offset device.
4. Image the globe in both the horizontal and vertical planes through the visual axis.
5. In general, ultrasonographic images are described as hyperechoic, hypoechoic, and anechoic. There are four major ocular acoustic echoes within a normal eye: anterior cornea, anterior lens capsule, posterior lens capsule, and retina/choroid/sclera. Additional echodensities may be generated by the iris, ciliary body, optic nerve, orbital fat, muscles, and other orbital structures.

OCULAR MANIFESTATIONS OF SYSTEMIC DISEASE

Ophthalmic clinical signs frequently are manifestations of systemic disease (Table 131-1). For many of these ophthalmic signs, specific ocular causes must be differentiated from the systemic ones provided in Table 131-1. For a more complete discussion of these diseases and their treatment, refer to appropriate chapters in this book.

Chapter

132 Diseases of the Eyelid

Susan E. Kirschner

Diseases of the eyelid result in a variety of clinical signs. Initially, the eyelids alone may be affected, but because of their close proximity to the cornea and conjunctiva, disease of these structures frequently results. Because corneal and conjunctival involvement is often more severe and more obvious, eyelid disease may be overlooked. Manage concurrent conjunctival and corneal disease as described in Chapters 133 and 134, respectively, in this section.

Diseases of the eyelid can be broadly categorized by their appropriate treatment (i.e., surgery or medical therapy), as listed in Table 132-1.

ANATOMY

- The eyelid functions to protect and moisten the cornea and to remove debris. The eyelid is covered by skin and lined internally by palpebral conjunctiva.
- The eyelid is closed by the orbicularis oculi muscle, which is innervated by the palpebral branch of the facial nerve. Paralysis of this nerve results in inability to close the eyelids. Spasm of the orbicularis oculi muscle results in spastic entropion.
- The eyelids are opened by the levator palpebrae and Mueller's muscle, which are innervated by the oculomotor nerve and by post-ganglionic sympathetic fibers, respectively. Paralysis of either of these nerves results in ptosis, or drooping of the eyelid.
- The meibomian glands line the conjunctival surface of the eyelid margin. They open onto the eyelid margin, where they secrete an oily fluid that helps prevent evaporation of the precorneal tear film. Distichia, ectopic cilia, and some tumors originate from the meibomian glands.

PRINCIPLES OF EYELID SURGERY

- The skin covering the eyelids is thin and easily traumatized. Perform clipping and aseptic preparation gently. A povidone-iodine solution diluted with saline solution to a 1:10 concentration is appropriate for preparing the eyelids for surgery.
- The eyelids have an extensive blood supply, and injured tissue heals well. Therefore, remove only clearly necrotic tissue. Removal of excess tissue can result in abnormal lid function.
- Close eyelid skin incisions with 4-0 to 6-0 monofilament nonabsorbable suture in a simple interrupted pattern. Close conjunctival wounds with 6-0 to 8-0 absorbable suture material. Remove nonabsorbable sutures 2 weeks following surgery.
- An Elizabethan-type collar may be necessary to prevent self-trauma.

▼ ***Key Point*** Accurate closure of the eyelid margin is the most important component of eyelid defect repair.

ANKYLOBLEPHARON

Ankyloblepharon is a condition seen in neonatal puppies in which the eyelids do not open properly.

- This condition may result in a subpalpebral infection called *ophthalmia neonatorum*.
  - If infection occurs, gently massage the eyelids to open a portion of the palpebral fissure. Occasionally, scissors or a scalpel blade is required to partially open the eyelids.
  - Lavage the subpalpebral area with a 1% povidone-iodine solution and apply a topical antibiotic solution or ointment (e.g., triple antibiotic, erythromycin, gentamicin) three to four times daily.
- If the infection is left unattended, the cornea may ulcerate or perforate.
- If the entire palpebral fissure is opened prematurely, corneal damage may result from exposure and desiccation.
  - To protect against corneal desiccation, use an artificial tear ointment four to six times daily.

Table 132-1. CLASSIFICATION OF EYELID DISEASES ACCORDING TO TYPE OF THERAPY

Surgery	*Medical Treatment*
Ankyloblepharon	Bacterial blepharitis
Coloboma	Chalazion/hordeolum
Entropion	Allergic blepharitis
Ectropion	Parasitic and fungal blepharitis
Distichiasis/ectopic cilia	
Lagophthalmos	
Neoplasia	

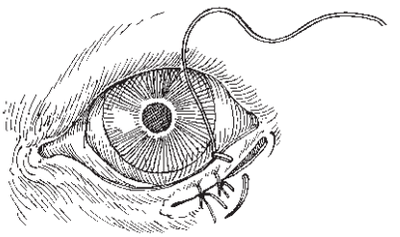

Figure 132-1. Correction of ventral entropion.

COLOBOMA

In this disorder, which affects kittens and occasionally puppies, a portion of the lid margin does not form.

- The major clinical signs are epiphora and blepharospasm.
- Coloboma may be confused with entropion because eyelid hairs often contact the cornea.
- Many cases can be corrected by everting the lid with entropion correction surgery, thus preventing corneal trauma by facial hairs.
- Extensive colobomas require reconstructive surgery performed by a veterinary ophthalmologist.

ENTROPION

Entropion often is observed in young dogs and is common in the chow, Shar-Pei, and hunting breeds. It can also occur in cats.

- Clinical signs vary from conjunctivitis with mild serous discharge to severe blepharospasm with corneal ulceration and purulent discharge.
- Diagnosis is made by examination of the eyelids. When the eyelid is rolled inward, facial hairs often directly contact the cornea.
- Correct neonatal entropion in the Shar-Pei with temporary everting sutures at 3 to 5 weeks of age. If this technique fails, perform permanent surgical correction.

Classification

▼ ***Key Point*** Entropion may be anatomic, anatomic with secondary eyelid spasm, or primarily spastic.

- Classification of entropion is made when the eyelids are relaxed. This may require topical anesthesia, palpebral nerve blocks, or general anesthesia.

Anatomic Entropion

- The eyelid rolls inward even when the eyelids are relaxed.
- This may be from a defect in the eyelids themselves, or in the case of certain breeds such as the Shar-Pei and the bloodhound, from forehead or brow folds, which force the eyelids inward.
- Surgical correction is indicated.

Anatomic Entropion with Secondary Spasm

- Blepharospasm exaggerates entropion such that a portion of the rolling is from an anatomic abnormality, with the remainder due to squinting.
- Surgically correct the anatomic portion of the entropion; additional temporary everting sutures may be required until the spasm cycle is broken.

Spastic Entropion

- Blepharospasm results in rolling inward of the eyelid margin. Under anesthesia or when the eyelids are relaxed, the entropion resolves.
- Correct with temporary everting sutures and treatment of the underlying cause of the spasm.

Surgical Techniques

Ventral or Dorsal Eyelid Entropion

1. Remove an ellipse of skin parallel to and 2 to 3 mm from the lid margin (Fig. 132-1). The amount of skin removed depends on the severity of the entropion. Remove more tissue for upper lid entropion than for lower lid entropion.
2. Remove the tissue with a scalpel or by crushing the selected tissue with a hemostat and then removing the crimped tissue with scissors.
3. Close the skin routinely with monofilament nylon sutures (e.g., 4-0) in a simple interrupted pattern.

Lateral Entropion

1. Remove a V-shaped area of skin (Fig. 132-2*A*) at the lateral canthus.
2. If the lateral canthus is extremely lax, dissect the underlying orbicularis oculi muscle free (Fig. 132-2*B*) and suture it to the lateral orbital rim with 4-0 or 5-0 nonabsorbable monofilament suture material (Fig. 132-2*C*).

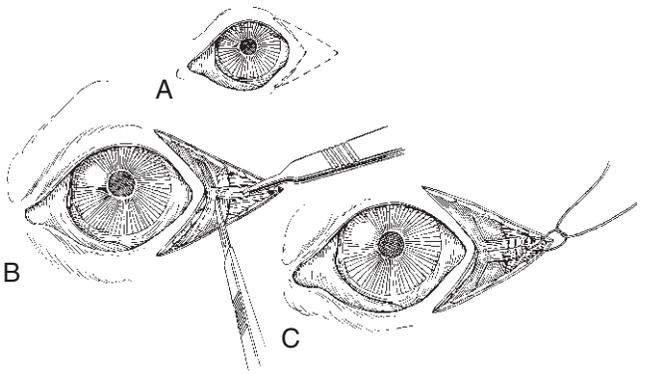

Figure 132-2. Correction of lateral entropion. *A,* Area of skin to be removed; *B,* orbicularis oculi dissected free; and *C,* orbicularis oculi sutured to the lateral orbital rim.

3. Close the skin with 4-0 or 5-0 nonabsorbable sutures in a simple interrupted pattern.

Medial Entropion

1. Evert the skin with an elliptical incision, as for ventral entropion.
2. Alternatively, perform a medial canthoplasty. Make a V-shaped incision along the eyelid margin that encompasses the caruncle (Fig. 132-3*A*). Take care not to injure the underlying lacrimal canaliculi. Transect the medial canthal ligament to release the medial canthus.
3. Close the incision by suturing the upper lid to the lower lid to create a horizontal closure (Fig. 132-3*B* and *C*). This has the effect of correcting the entropion and slightly shortening the palpebral fissure.

Temporary Everting Sutures for Spastic Entropion and for Neonatal Entropion in Shar-Peis

1. Use minimal anesthesia for very young puppies. Occasionally, light inhalation anesthesia via a mask is required (see Chapter 2).
2. In older dogs, inject a short-acting anesthetic (see Chapter 2).
3. Place one to two 4-0 to 5-0 nylon sutures in a mattress pattern in each eyelid. Sutures should be partial thickness only. Make the first bite 1 to 2 mm from the eyelid margin. Place the second bite at a sufficient distance to cause eversion of the eyelid margin when the suture is tied (Fig. 132-4).
4. Leave the sutures in place for 3 to 4 weeks. Premature suture removal may result in recurrence of the entropion.

Entropion Caused by Heavy Brow Folds

1. The skin of the forehead may be removed en bloc, or the folds may be elevated.

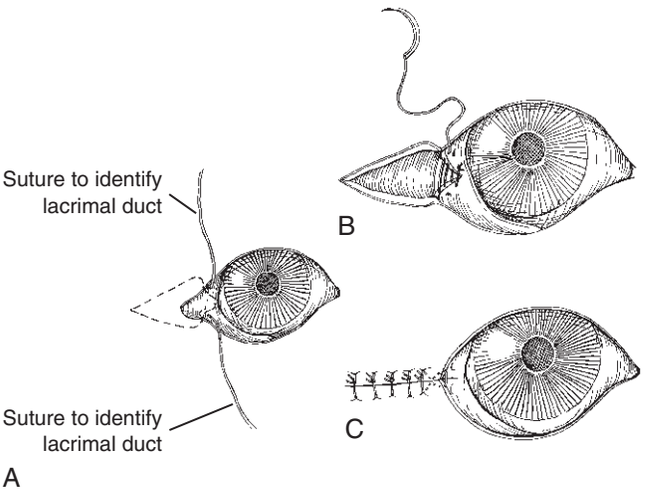

Figure 132-3. Correction of medial entropion by medial canthoplasty. *A,* Mark the lacrimal canaliculus with a suture—then make a V-shaped incision along the eyelid margin, encompassing the caruncle. *B and C,* Close the incision in two layers, creating horizontal closure.

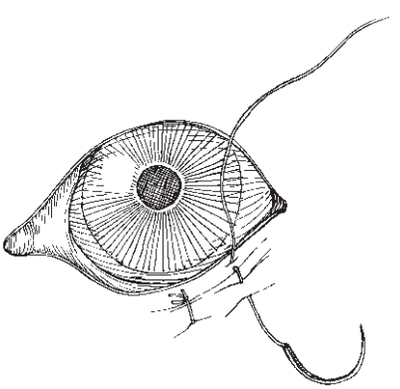

Figure 132-4. Temporary lid-everting sutures.

2. To elevate the folds, use surgical mesh, such as mersilene, cut into strips 3 to 4 mm wide and 10 to 15 cm long, and a straight surgical needle with an eye capable of receiving the end of the mesh strip.
3. Make a horizontal skin incision 1 to 2 cm above the lid margin, and a second one 8 to 12 cm higher on the brow.
4. Pass the mesh suture from the upper incision, beneath the skin to the lower incision, then horizontally through subcutaneous muscle, then beneath the skin back to the upper incision. Tighten to achieve the desired effect. Tie as one would with a typical suture.
5. Place two to six of these lifting sutures, as needed. Close the skin incisions with 3-0 to 4-0 nylon suture.

ECTROPION

- Ectropion may be caused by excessive eyelid length or by decreased tone of the eyelid muscles. This results in sagging of the lower eyelid, with exposure of conjunctiva. In addition, ectropion can result iatrogenically from overcorrection of entropion.
- Increased conjunctival exposure often results in chronic conjunctivitis or exposure keratitis. Poor lid-to-cornea fit may exacerbate keratoconjunctivitis sicca (KCS) because of abnormal tear distribution.
- Most cases of ectropion can be corrected by a full-thickness wedge resection of the affected portion of the eyelid (see under Neoplasia for procedure).
- Shortening of the palpebral fissure via a permanent lateral tarsorrhaphy is beneficial in many dogs (see description under Treatment of Lagophthalmos).

DISTICHIASIS

Distichiasis is a condition in which hairs that originate from the meibomian glands and emerge from their ducts contact the cornea and cause irritation. It is common in cocker spaniel, golden retriever, and Shih Tzu breeds and occasionally is seen in other breeds.

▼ ***Key Point*** Reserve surgical removal for animals in which epiphora, blepharospasm, or corneal disease is a significant clinical sign and when other ocular disease has been ruled out.

- The most common complication of distichiasis surgery is recurrence 3 to 5 months postoperatively.

Surgical Technique

Cryoepilation

1. Evert and stabilize the lid with a chalazion clamp and freeze a 3-mm band along the base of the meibomian glands, on the conjunctival surface of the eyelid, below each abnormal cilium. Freeze time varies, depending on whether nitrous oxide or liquid nitrogen is used. In general, the ice ball should extend to the lid margin, taking care not to freeze the full thickness of the lid.
2. A double freeze-thaw cycle is most effective.

Electroepilation

Reserve this time-consuming technique for cases in which only a few hairs are to be removed.

1. Insert an electrolysis stylet along the hair shaft into the base of the follicle.
2. Apply low amperage (2–4 mA) coagulating current until a small amount of meibomian gland material bubbles out of the duct opening.

CO_2 Laser Epilation

1. This is best used with the high magnification that a surgical microscope provides.
2. Use a focused beam to burn along the hair shaft down to the root.

ECTOPIC CILIA

- Ectopic cilia are hairs originating from the meibomian gland that emerge through the conjunctival surface of the eyelid.
- The most common clinical signs are blepharospasm and corneal ulceration.
- The most common location is the central upper eyelid, 2 to 4 mm from the eyelid margin.

Technique for Removal

1. Stabilize the eyelid during the procedure with a chalazion clamp.
2. Excise the hair and its root en bloc with a #11 scalpel blade, leaving the eyelid margin intact.
3. The conjunctival wound may be left open.

LAGOPHTHALMOS

- Lagophthalmos is a condition in which the eyelids cannot completely close. The most common cause is anatomic exophthalmos, seen in brachycephalic breeds. In these breeds, blink frequency often is decreased, exacerbating the problem.
- It also is associated with buphthalmos (progressive enlargement of the eye), palpebral nerve palsy, and ectropion.
- Corneal disease, including ulceration, pigmentation, neovascularization, and keratinization, may result.
- Treat surgically by permanent closure of a portion of the palpebral fissure.

Technique

1. Excise the eyelid margin of the ventral and dorsal lids at the lateral or medial canthus.
2. Close the eyelids in two layers, as described for wedge resection under Neoplasia.

NEOPLASIA

Etiology

- The most common eyelid tumor in the dog is meibomian gland adenoma. Other tumors seen in the eyelids include papilloma, meibomian gland adenocarcinoma, melanoma, histiocytoma, squamous cell carcinoma, and basal cell tumors.

- Meibomian gland tumors originate in the base of the gland but often emerge from the meibomian gland duct on the eyelid margin.
- Tumors occurring in the eyelids of cats include mast cell tumor, melanoma, fibrosarcoma, neurofibroma, and squamous and basal cell carcinoma.
- Squamous cell carcinomas usually are seen in white cats and appear as non-healing ulcerative lesions. They are locally aggressive and have a high recurrence rate.
- Melanomas of the eyelids have been known to metastasize in cats. Hydrocystomas are black cystic nodules on the lid that mimic melanomas.
- In dogs, most eyelid tumors are benign and are removed to prevent irritation or injury to the cornea or conjunctiva.
- In cats, most eyelid tumors are malignant and carry a guarded prognosis.
- For additional information on skin tumors in dogs and cats, see Chapter 30.

Preoperative Considerations

▼ ***Key Point*** One-fourth of the upper eyelid and one-third of the lower lid can be removed without severe distortion of the palpebral fissure.

- The most common cause of recurrence of meibomian gland adenoma is incomplete removal of the tumor. Keep in mind that even though the bulk of the tumor is at the eyelid margin, the tumor originates from the base of the meibomian gland.

Surgical Technique

- A full-thickness wedge resection of the eyelid is sufficient to remove most tumors.
- Cryosurgery also can be used to treat many eyelid tumors.
  - Although there is a higher recurrence rate with cryosurgery than with excision, it is a relatively safe, simple procedure that may be performed with local anesthesia combined with tranquilization.
- CO_2 lasers can be used for many eyelid tumors.
- Submit all excised tissues for histopathology.

Wedge Resection

1. Using a scalpel blade, incise the skin in a pie-shaped wedge with the base at the eyelid margin. Alternatively, crush along the incision line with hemostats and cut along the crimped line with scissors. Use a tenotomy or Metzenbaum scissors to complete the incision.
2. Close the incision in two layers:
   a. Close the subconjunctival tissue with 6-0 or 7-0 absorbable sutures, with the knots buried within the eyelid.
   b. Close the skin with 4-0 to 6-0 sutures beginning at the lid margin (Fig. 132-5).
3. Close the eyelid margin with a figure-of-eight 4-0 to 6-0 suture, and the remainder of the skin with sutures in a simple interrupted pattern. Alternatively, a horizontal mattress or simple continuous pattern can be used to close eyelid margins.

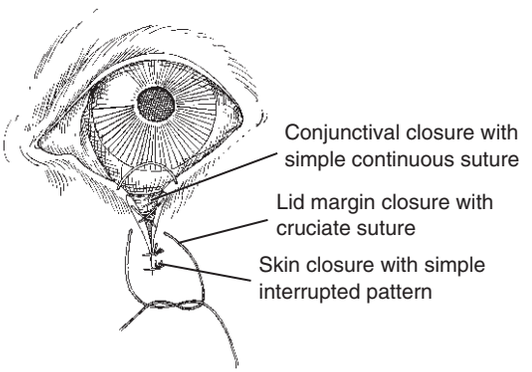

Figure 132-5. Closure for wedge resection of the eyelid. Close the subconjunctiva with 6-0 or 7-0 absorbable suture in a simple continuous pattern; the lid margin with a cruciate suture; and the remainder of the skin with 6-0 nonabsorbable suture, in a simple interrupted pattern.

Cryosurgery

1. Perform a double freeze-thaw cycle. Treat an area extending 3 to 5 mm beyond the tumor.
2. For meibomian gland tumors, place the probe on the conjunctival surface of the eyelid.

CO_2 Laser Surgery

1. For meibomian gland tumors use a focused beam perpendicular to the lid, from the lid margin down into the base of the gland.
2. For tumors on the skin of the eyelid that do not originate from within the lid use an unfocused beam.

INFLAMMATORY EYELID DISEASES

Bacterial Blepharitis

- In blepharitis, the eyelids and lashes are crusted with mucopurulent discharge and are erythematous and swollen. The conjunctiva usually is inflamed, and there may be an associated non-ulcerative keratitis.
- Blepharitis is often a manifestation of other inflammatory skin diseases (see the section on Skin and Ear Diseases), including atopy, food allergy dermatitis, pyoderma, dermatomycosis, demodicosis, and autoimmune diseases.

Treatment

- Apply a topical bactericidal ophthalmic solution or ointment (e.g., neomycin, bacitracin, polymyxin B) three to four times daily.
- Instruct the owner to clean the eyelids daily, using dilute baby shampoo.
- Give systemic antibiotics as described for pyoderma (see Chapter 38).
- If there is associated non-ulcerative keratitis, consider giving topical corticosteroids or cyclosporine ointment once or twice a day.
- If associated with pruritus or other signs of atopy, give systemic antihistamines as needed.
- If a satisfactory response to treatment is not seen within 2 weeks, swab the meibomian gland secretions or upper conjunctival cul-de-sac for culture and sensitivity testing, and perform thyroid function testing.

▼ ***Key Point*** Bacterial blepharitis can be difficult to cure. Inform the owner that some dogs require periodic eyelid scrubs and antibiotic therapy on a long-term basis, along with medications to control concurrent allergies.

Chalazion and Hordeolum

- *Chalazion* is a granuloma of the meibomian gland.
  - Treat with surgical curettage of the granuloma via the conjunctival surface of the eyelid.
- *Hordeolum* is an infection or abscess of a meibomium gland or of an eyelash that results in a focal swelling of the lid.
  - Treat with hot packs and systemic antibiotics.
  - To hasten resolution, apply a topical antibiotic/corticosteroid solution or ointment, such as dexamethasone 0.1%, neomycin, or polymyxin B, q6–8h.

Allergic Blepharitis

- The animal usually presents with erythema and swelling of the eyelids that may be pruritic but is rarely painful. There may be a serous to mucopurulent discharge.
- Chronic or recurrent allergic blepharitis may be a manifestation of atopy.
- Treat with systemic antihistamines such as diphenhydramine (Benadryl, 2 mg/kg q8–12h PO) or corticosteroids (prednisone, 0.5–1.0 mg/kg q12–24h PO) and with topical corticosteroids.
  - Cold compresses help to decrease pruritus.
- For further information on allergy testing and treatment for atopy, see Chapter 46.

Parasitic or Fungal Blepharitis

- The eyelids may be infected by cutaneous parasites such as *Demodex* and *Sarcoptes* or by dermatophytes (ringworm).
- In dogs in which periocular alopecia and skin lesions are present but in which the conjunctiva is relatively spared, perform skin scrapings, dermatophyte cultures, and skin biopsies (see Chapters 43, 42, and 37, respectively).

Granulomatous Blepharitis

- Dogs with this condition present with prominent multifocal firm swellings of the lid margins of both eyes, often associated with the meibomian glands. It is not usually painful. The skin in advanced cases may be ulcerated. Etiology is unknown.
- Mild cases may be treated with topical antibiotic-dexamethasone solution four to eight times a day and oral corticosteroids (e.g., prednisone 0.5–1.0 mg/kg q12–24h). Oral antibiotic therapy is occasionally helpful.
- Some cases are recurrent and require ongoing topical corticosteroids for control.

Chapter

133 Diseases of the Conjunctiva

Cecil P. Moore

ANATOMY AND PHYSIOLOGY

- Conjunctival mucosa covers the inner aspect of the eyelids, the front and back of the membrana nictitans, and the anterior sclera. Conjunctiva extends from the lacrimal caruncle nasally to the lateral canthus temporally.
- Normal conjunctiva is semitransparent and appears moist and glistening. Numerous small, branching blood vessels are visible within the conjunctiva.
- Sensory innervation to the conjunctiva is via ophthalmic and maxillary branches of the trigeminal nerve.
- The conjunctiva serves as a protective external physical, secretory, and immunologic barrier for the eye.
- Epithelial goblet cells within the conjunctiva produce mucus that contributes to the preocular tear film, harbors immunoglobulin, and traps foreign material and surface debris.

CONJUNCTIVITIS

The term *conjunctivitis* describes nonspecific inflammation of the ocular mucous membrane. Conjunctivitis is the most common cause of "red eye" in animals. To accurately assess the small animal patient presented with conjunctivitis, recognize inherent species differences in susceptibility and establish whether the disorder is primary or secondary. For example, feline conjunctivitis is generally caused by a primary ocular infection. Canine conjunctivitis, by contrast, usually is secondary to ocular surface irritants, tear film deficiencies, or foreign bodies.

Additional pertinent information regarding conjunctival disease is found in other chapters in this book. Conjunctival disease is often associated with viral infections, diseases of the cornea (see Chapter 134), diseases of the lacrimal apparatus (see Chapter 139), and diseases of the eyelids (see Chapter 132).

Etiology

Causes of conjunctivitis are numerous. Frequently, more than one etiologic factor plays a role in the clinical course of the disease.

▼ ***Key Point*** Regardless of the primary cause, bacterial infection is a common complicating factor in conjunctivitis.

Infectious Agents

- Infectious agents cause severe conjunctivitis in cats by infecting epithelial cells. Feline herpesvirus and *Chlamydophila felis* cause the most serious and common ocular infections in cats (see Chapter 11). *Mycoplasma felis, Staphylococci* species, *Streptococci* species, and coliform organisms are bacterial causes of usually less severe forms of feline conjunctivitis.
- Gram-positive aerobic bacteria are most commonly isolated from cases of canine conjunctivitis. Opportunistic bacterial infections are common in dogs following conjunctival irritation from other causes. Canine distemper virus (see Chapter 13) causes conjunctivitis and dacryoadenitis in dogs.

Tear Film Deficiency

- Tear film deficiency results in dehydration of the ocular surface with accompanying inflammation of the conjunctiva and cornea. Aqueous tear deficiency, or keratoconjunctivitis sicca, occurs more frequently in dogs than in cats (see Chapter 139).
- Although less common than aqueous deficiency, inadequacy of the lipid or mucous components may, when present, complicate the surface disease.
- Poor eyelid conformation, as with exophthalmos and/or lagophthalmos, potentiates exposure and drying, which may be further complicating factors.

Foreign Bodies

- Foreign bodies of the conjunctiva can include plant components, synthetic material, or metallic sub-

stances. Plant awns and weed seeds may become embedded in the fornices of the conjunctiva or migrate under the conjunctiva or behind the third eyelid. Embedded plant material is quite reactive and stimulates an intense pyogranulomatous inflammation.
- By contrast, synthetic material, such as glass or plastic, and certain metals, such as lead and stainless steel, are minimally reactive. Depending upon the location and rigidity of the material, conjunctival foreign bodies may cause direct frictional irritation and result in surface ulceration.

Trauma

- Trauma to the conjunctiva may be blunt, resulting in bruising of an intact membrane or penetrating with puncture or laceration.
- Conjunctival lacerations 5 mm in length or larger, or when the nictitans is involved, may require suturing.
- Otherwise, bruises, focal punctures, or smaller lacerations usually resolve uneventfully with symptomatic treatment.

▼ ***Key Point*** In cases of conjunctival trauma, examine the eye thoroughly for the presence of foreign bodies and intraocular lesions.

Chemical Irritants

- Chemical irritants that damage the conjunctiva include noxious gases, alkalis, and acids. Alkaline substances (e.g., lye, fresh lime, or ammonia) cause the most serious injuries.
- When chemical injury has occurred, flush the eye copiously with saline or tap water and evaluate for associated corneal and/or anterior uveal involvement.

Environmental Irritants

- Environmental irritants, such as dust, particles of sand or plant material, wind, and solar irradiation, are additional causes of conjunctivitis in small animals.
- These are particularly common causes in hunting dogs and outdoor working dogs.

Immune-Mediated Conjunctivitis

- Immune-mediated conjunctivitis results from acute allergic chemosis, atopy (see Chapter 46), follicular conjunctivitis, and conjunctivitis resulting from eosinophilic or plasmacytic infiltrates.
- An immune-mediated ulcerative conjunctivitis occurs in Doberman pinschers.

Proliferative Diseases

- Proliferative diseases are categorized as non-neoplastic or neoplastic.

Non-Neoplastic Disease

- Episcleritis and idiopathic granulomatous disease are the main non-neoplastic proliferative conjunctival disorders (see Chapter 134).
- Conjunctival epithelial hyperplasia, granulation tissue, and pigmentary infiltrates are additional examples of non-neoplastic proliferative conditions.

Neoplasia

- Conjunctival neoplasms may be primary or secondary.
- Papillomas, squamous cell carcinomas, and hemangiomas are the most common primary tumors. Less common primary neoplasms are hemangiosarcomas, mastocytomas, and melanomas.
- Adenomas, adenocarcinomas, fibromas, fibrosarcomas, lymphomas, transmissible venereal tumors (TVTs) and melanomas are tumors that may secondarily involve the conjunctiva.

Iatrogenically Induced Conjunctivitis

- Iatrogenically induced conjunctivitis results when topically administered therapeutic agents or surgical manipulations cause conjunctival inflammation.
- A number of drugs may cause conjunctivitis because of irritation from their active ingredients, vehicles, or preservatives. For example, neomycin hypersensitivity may manifest as severe conjunctivitis after topical administration of triple antibiotic combination.
- Surgical procedures result in conjunctivitis from direct insult (e.g., manipulation, dissection, thermal injury, or exposure during or following surgery).

Other Eye Diseases

- Other eye diseases, either ocular surface disorders or intraocular diseases, are frequently associated with conjunctival inflammation.
- Surface diseases in which conjunctivitis is prominent include episcleritis, keratitis, and eyelid disease (e.g., chalazia, entropion, ectropion, and cilia disorders).
- Conjunctival inflammation occurs with uveitis and glaucoma, although deeper episcleral injection is also present and is a hallmark of these intraocular diseases.

Clinical Signs

- ***Hyperemia*** resulting from vasodilation of conjunctival vessels causes the appearance of a red eye. The redness is intensified when conjunctival hemorrhage or episcleral vascular injection is also present.
- ***Ocular discharge*** is characteristic of conjunctivitis and is serous, mucoid (catarrhal), or mucopurulent. The type of discharge may change as conjunctivitis progresses—from serous (mild) to mucopurulent (severe).

- ***Chemosis*** is swelling or "puffiness" of the conjunctiva caused by edema of the mucosa and submucosal tissues.
- ***Pain*** with conjunctivitis varies with the severity of the ocular disease. Squinting and tearing are characteristic of most cases of conjunctivitis. Photophobia and marked blepharospasm generally occur only when other eye disease is present, such as ulcerative keratitis or uveitis.
- ***Tissue proliferation*** is a variable finding of subacute or chronic conjunctival disease. Conjunctival lymphoid follicular hyperplasia may develop in dogs as a nonspecific immune response to persistent antigenic stimulation. In cats, conjunctival follicles are associated with chlamydial conjunctivitis (see Chapter 11). Diffuse thickening of the conjunctiva may occur from epithelial hyperplasia or from chronic inflammatory cell infiltrates. Focal, acquired, proliferative lesions may be either granulomas or neoplastic.

Diagnosis

History

History pertinent to cases of conjunctivitis includes possible systemic illnesses, environment and habits, possible exposure to infectious or chemical agents, possible trauma, and previous ocular diseases, including notation of any medications administered.

Physical Examination

Perform physical examination to rule out multisystemic diseases (see Chapter 1).

Cultures

Culture and sensitivity testing is indicated for the definitive diagnosis and treatment of ocular infection. When culturing for fungi, *Mycoplasma, Chlamydophila,* or viral agents, consult with the diagnostic laboratory in advance regarding special requirements for submitting culture samples.

▼ ***Key Point*** When the need for cultures is anticipated, collect samples prior to applying topical agents or manipulating ocular surface tissues.

Ophthalmic Examination

Ophthalmic examination should be thorough and, in addition to confirming conjunctivitis, is aimed at identifying other forms of eye disease. Perform a complete ophthalmic examination.

- Inspect the external ocular surfaces and the anterior portion of the globe directly using a focal light source with magnification. The focused light is also used to check for pupil symmetry and light responses.
- Perform the intraocular examination with a focused light and an ophthalmoscope. Opacities of the normally clear ocular media (cornea, intraocular chambers, lens) are noted. Perform funduscopy to determine if abnormalities of the retina, choroid, or optic nerve are present.
- Measure aqueous tear production with Schirmer tear test strips as described in Chapters 131 and 139. Rule out aqueous tear deficiency because this is a common disorder in small animals, particularly in dogs, and results in chronic conjunctivitis with a tenacious mucopurulent ocular discharge.

▼ ***Key Point*** The Schirmer tear test strips measure reflex tear production. Evaluate prior to application of any local solutions, including topical anesthetic agents.

- Apply fluorescein stain to determine if surface ulceration is present. Establish nasolacrimal duct patency by allowing fluorescein stain to gravitate into the external nares.
- Following application of a topical anesthetic, examine for foreign bodies. Use blunt-tipped forceps to probe the conjunctiva fornices and to lift the third eyelid, allowing inspection of the posterior surface.
- Use tonometry to rule out other intraocular causes of red eye, for example, glaucoma (elevated pressure) and uveitis (low pressure). Applanation tonometry produces the most accurate intraocular pressure readings in small animal patients (see Chapters 131 and 137).

Cytology

- Cytology of conjunctival scrapings may provide a definitive diagnosis of inflammatory or neoplastic disease.
- Immunofluorescence testing of cytologic specimens can confirm viral or chlamydial infection.
- Fine-needle aspirates of masses can also provide the cytologic material for a definitive diagnosis.

Polymerase Chain Reaction

- Polymerase chain reaction (PCR) utilizes technology that allows detection of the DNA of ocular pathogens when present in very small quantities.
- In cases of feline conjunctivitis, the PCR procedure has been used successfully to diagnose feline herpesvirus-1 (FHV-1) infections. The sensitivity of PCR for FHV-1 diagnosis appears to be superior to other available methods.
- For the PCR test, place conjunctival swabs or scrapings in 1 ml of phosphate-buffered saline (PBS), frozen at −20°C, and submit for analysis.

Biopsy

- Biopsy the conjunctiva when cytology has not allowed the differentiation of inflammatory from neoplastic processes.

- Conjunctival biopsy is also needed to determine goblet cell density in suspected cases of preocular mucin deficiency.

Treatment

Objectives

- Correct or remove the underlying cause.
- Control secondary infection, which often complicates the primary process.
- Remove exudates and clean the eye and periocular area.
- Ensure a moist and well-hydrated ocular surface.
- Reduce inflammation and control discomfort.

Treat the Primary Cause

Because the primary causes of conjunctivitis in small animals are numerous, specific treatments vary considerably. Depending upon the circumstances, the following treatments may apply:

- Treat infection with a specific antimicrobial agent.
- Remove foreign materials.
- Surgically remove or correct for irritants (hairs or masses) that rub the eye.
- Remove offending allergens when possible.
- Treat for allergies (see Chapter 46).
- Treat tear deficiencies medically (see Chapter 139).

See Table 133-1 for more specific treatment recommendations.

▼ ***Key Point*** The following procedures are beneficial as symptomatic treatment and may be used as adjuncts when treating the primary disease, when awaiting results of diagnostic tests, or when treating empirically in nonspecific or undiagnosed cases of conjunctivitis.

Antimicrobial Therapy

- To control or prevent secondary pathogenic or opportunistic bacterial infections, apply broad-spectrum antibiotic ophthalmic drops or ointments topically.
- Avoid prolonged, indiscriminate application of topical antibacterial agents because this may encourage development of antibiotic-resistant bacterial strains or secondary fungal infections. The practice of continuous treatment can also predispose the animal to medication hypersensitivity.

Cleanse Discharges

- Use an eyewash solution (e.g., Dacriose, CooperVision) or physiologic saline solution to irrigate the ocular surface, remove exudates, and clean the eye and periocular area.
- Clip the periocular hairs.
- Use cotton swabs moistened with saline to soak and remove exudates.

Moisten or Hydrate the Eye

- Keep the conjunctival and corneal surfaces moist. If applied 3 to 4 times daily, antibacterial ointments have sufficient lubricating property to ensure continuous moistening of swollen or injured conjunctival tissues.
- When severe chemosis results in prolapse and exposure of swollen conjunctiva, place temporary tarsorrhaphy sutures until the acute swelling subsides (see Chapter 132).
- In cases in which the Schirmer tear test values are subnormal, apply artificial tear solutions topically 4 to 6 times daily. Lacrimostimulants may be indicated (see Chapter 139).

Anti-inflammatory Therapy

- Systemic anti-inflammatory drugs may be used in selected cases to minimize acute swelling, discomfort, and self-trauma. In cases of ocular trauma in dogs, systemic nonsteroidal anti-inflammatory drugs may be beneficial to reduce chemosis, hyperemia, and associated ocular pain.
- In dogs with normal renal function, flunixin meglumine (Banamine, Schering) may be given as a single dose IV of 0.5 to 1.0 mg/kg. This may be followed by oral aspirin at a dosage of 10 mg/kg q12h until signs of inflammation subside. Oral carprofen (2.2 mg/kg q12h) is also effective for controlling ocular inflammation. Monitor the animal closely for the side effects of gastritis and protect the stomach with an H_2 blocker, such as cimetidine (see Chapter 67). Flunixin, aspirin or other nonsteroidal anti-inflammatory drugs are not given to animals in which hemorrhage is the primary manifestation of the conjunctival disease.
- Short-term topical corticosteroids may reduce the swelling and hyperemia of an inflamed conjunctiva.

▼ ***Key Point*** Topical corticosteroids are contraindicated in cases of primary infectious conjunctivitis or corneal ulceration.

- Topical 5% sodium chloride may be applied to reduce chemosis; however, do not apply in eyes producing marginal amounts of aqueous tears because it will further dehydrate the ocular surface.

CONJUNCTIVAL SURGERY

Indications

- Trauma repair
- Diagnostic procedure (e.g., incisional biopsy)
- Focal lesion resection
- Repair of fibrosis/adhesions
- Grafting procedure

Table 133-1. TREATMENT OF SPECIFIC CAUSES OF CONJUNCTIVITIS

Causes	Treatments
Infectious Agents	
Bacterial	
Chlamydophila felis	Tetracycline ointment (q6–8h × 14–28d) (Terramycin, Pfizer; Achromycin, Lederle; Aureomycin, Lederle)
Mycoplasma felis	Tetracycline ointment (q6–8h × 10–14d) *or* Erythromycin ointment (q6–8h × 10–14d) (Erythromycin, Pharmafair) *or* Chloramphenicol ointment (q6–8h × 7d) (Chlorbiotic, Schering-Plough)
Streptococcus spp.	TA ointment (q6–8h × 10–14d) (Neobacimyx, Schering-Plough; TriOptic-P, SmithKline; or equivalent)
Staphylococcus spp.	TA or gentamicin (Gentocin, Schering-Plough) (as per TA above)
Gram-negative aerobes	TA, gentamicin, or ciprofloxacin (Ciloxan, Alcon) (as per TA above)
Viral	
Feline herpesvirus	Trifluridine or tacrolimus (see Chapters 11 and 134) Symptomatic therapy (see text)
Canine distemper virus	Symptomatic therapy (see text)
Keratoconjunctivitis Sicca	
Many causes	Treat cause if determined (see Chapter 139) Topical cyclosporine or tacrolimus (see Chapter 139) Topical antibiotics as needed Artificial tears (see Chapter 139) Lubricant ointments (see Chapter 139)
Foreign Bodies	Remove using magnification Irrigate eye Symptomatic therapy (see text) Complete eye examination
Trauma	
Bruise/focal puncture	Symptomatic therapy (see text)
Laceration	Symptomatic therapy (see text) ± Surgical repair
Chemical Irritants	Copious irrigation Symptomatic therapy (see text)
Environmental Irritants	Flush eyes Topical CS (q6–8h reduced to q12h as response is noted) only if fluorescein stain results are negative Lubricant ointment (q8h reduced to q24h as response is noted, then discontinue) ± Topical antibiotics Avoid reexposure
Immune-Mediated Disorders	
Acute chemosis	Topical and systemic CS
Atopy	Topical ± systemic CS, antihistamines, desensitization (see Chapter 46)
Follicular conjunctivitis	Topical ± intralesional CS, ± abrade follicles
Eosinophilic infiltrate	Topical ± intralesional CS (see Chapter 134)
Plasmacytic infiltrate	Topical ± intralesional CS (see Chapter 134)
Ulcerative conjunctivitis	Topical ± systemic CS, topical cyclosporine A (Optimmune, Schering-Plough)
Proliferative Diseases	
Inflammatory	Topical ± intralesional or systemic CS
Neoplastic	Surgery ± radiation, cryosurgery, or chemotherapy
Other Ocular Diseases	
Surface Diseases	
Eyelid disorders	Medical ± corrective surgery (see Chapter 132)
Keratitis	Medical ± surgery (see Chapter 134)
Episcleritis	Topical ± intralesional or systemic CS (see Chapter 134)
Intraocular Diseases	
Uveitis	Treat cause if determined (see Chapter 136) Topical CS and atropine Systemic anti-inflammatory agents
Glaucoma	Determine if primary or secondary (see Chapter 137) Topical hypotensive agents (see Chapter 137) Systemic hypotensive agents (see Chapter 137) Cycloablative or filtration surgery
Iatrogenic	
Topical agents	Discontinue use of irritating medications
Surgical procedures	Symptomatic treatment until surgical site heals

CS, corticosteroid; TA, Triple antibiotic.

Because the last category applies primarily to the treatment of ulcerative keratitis, refer to Chapter 134 for a discussion of conjunctival flaps and grafts.

Laceration Repair

Preoperative Considerations

- Examine the eye carefully for other damage (e.g., corneal, scleral, and intraocular lesions) and evaluate for retained ocular foreign bodies. Radiograph the head and orbit to check for radiopaque foreign bodies and to assess the extent of head trauma.

▼ ***Key Point*** If the traumatized eye is opaque, consider ultrasound imaging to determine the integrity of the globe and the extent of any intraocular damage.

- Because of the conjunctiva's rapid reparative characteristic, many punctures and small lacerations heal spontaneously without the need for suturing. Suture conjunctival lacerations 5 mm or greater or those associated with eyelid or nictitans lacerations.

Surgical Procedure

Objectives

- Cleanse and disinfect the wound.
- Remove surface foreign material and tissue debris.
- Explore the wound to determine if a foreign body was retained and to determine if deeper structures were damaged.
- Suture the conjunctival wound, if necessary, to restore mucous membrane integrity and function.
- Prevent secondary infection.

Equipment

- Eyelid retractors (e.g., Barraquer wire speculum)
- Small rat-tooth forceps (e.g., Bishop-Harmon forceps)
- Ophthalmic needle holders (Castroviejo)
- Conjunctival or Stevens tenotomy scissors
- Braided 6-0 or 7-0 absorbable suture material (e.g., Dexon, Vicryl) with microcutting needle

Technique

1. Following general anesthesia, insert eyelid retractors and flush the conjunctiva with 1:50 Betadine-to-saline solution; explore the wound for foreign bodies and for damage to deeper structures.
2. After assessing the extent of the conjunctival defect and confirming that surgical repair is needed, minimally debride the margins of the wound and gently undermine adjacent conjunctiva.
3. Close the conjunctival wound in a continuous pattern; space suture bites 1 to 2 mm apart.

Postoperative Care and Complications

- Apply topical antibiotic (e.g., neomycin, bacitracin, or polymyxin B) 3 to 4 times daily for 7 days.
- Administer systemic antibiotics for 1 week.
- If the eye is painful, apply fluorescein stain to identify corneal erosion or ulceration.

Biopsy

Preoperative Considerations

- Conjunctival biopsy and histopathology results should distinguish inflammatory from neoplastic diseases and can be used to determine goblet cell densities in suspected cases of preocular mucin deficiency.
- In tractable animals, conjunctival biopsy procedures can usually be performed following serial applications of topical anesthetic (e.g., 0.5% proparacaine).
- Subconjunctival or intralesional local anesthetic may be injected for deeper biopsies or for lesions of the palpebral, perilimbal, or third eyelid conjunctiva. Sedation and systemic analgesia may also be needed in such cases.

Surgical Procedure

Objectives

- Remove a representative sample of conjunctiva or subconjunctival tissue for histopathology.
- Minimize the resulting defect and avoid distorting the conjunctiva to the extent possible.

Equipment

- Small rat-tooth forceps
- Curved conjunctival or tenotomy scissors (e.g., Stevens, Westcott)
- Vial of 10% buffered formalin

Technique

1. Following local anesthesia, grasp the desired area of conjunctiva with small rat-tooth forceps and tent slightly.
2. Using small, curved scissors, excise a 3 mm × 4 mm specimen.
3. Gently spread the specimen onto a flat surface, such as a small Styrofoam pad or a section of a wooden tongue depressor.
4. Immediately fix the specimen in 10% buffered formalin.

Postoperative Care and Complications

- A small amount of hemorrhage is anticipated but is usually minimal, as fibrin quickly seals the wound.
- Defects resulting from biopsy that are less than 4 mm × 4 mm usually heal uneventfully with topical antibi-

otic treatment. Larger defects should be sutured as described in "Laceration Repair."
- Remove discharges and cleanse the eye as needed. This may be necessary 3 to 4 times the first day but is reduced over the following 5 days to once daily.
- Apply topical antibiotic ointment (e.g., neomycin, bacitracin, or polymyxin B) to the affected eye 3 times daily for 7 days.

Mass Removal

Preoperative Considerations

- Surgical excision alone may be curative for cysts, dermoids, ectopic hairs, focal granulomas, and some tumors involving the conjunctiva (e.g., papillomas and adenomas).
- Surgical excision is an important adjunct in the treatment of inflammatory pseudotumors and more aggressive neoplasms, such as squamous cell carcinomas or adenocarcinomas.
  - Chemotherapy, immunotherapy, cryosurgery, hyperthermia, or beta-irradiation may be needed to treat neoplastic diseases in addition to local excision.
  - Definitive therapy depends upon the specific histopathologic diagnosis.
- General anesthesia is usually required for effective removal of conjunctival masses.

Surgical Procedure

Objectives

- Surgically remove conjunctival masses that interfere with ocular function, threaten preservation of the globe, or pose a threat to survival of the animal.
- Debulk a mass to obtain diagnostic samples and to increase efficacy of adjunctive treatments (e.g., cryosurgery, radiation, immunotherapy, hyperthermia, and chemotherapy).

Equipment

- Same as that listed for "Laceration Repair"
- Vial of 10% buffered formalin

Technique

1. Incise the overlying conjunctiva. Grasp the mass with forceps and elevate. Undermine and excise with small, curved tissue scissors.
2. Small conjunctival wounds (i.e., up to 5 mm in diameter) generally do not require suturing and heal in 2 to 4 days.
3. Suture conjunctival wounds greater than 5 mm in diameter with 7-0 braided absorbable material (Vicryl) in a continuous pattern.
4. To allow primary closure for larger conjunctival wounds, undermining and sliding adjacent conjunctiva may be required.
5. Repair large defects by a pedicle graft of adjacent healthy conjunctiva similar to that of a rotating cutaneous pedicle flap.
6. For conjunctival mass lesions involving the cornea, see Figure 134-1 in Chapter 134.

Postoperative Care and Complications

- Remove discharges and cleanse the eye as needed.
- Apply topical antibiotic ointment (e.g., neomycin, bacitracin, or polymyxin B) to the affected eye 3 times daily for 7 days.
- Prevent self-trauma with a restraint collar.
- Administer systemic analgesic or anti-inflammatory agents as indicated to control discomfort.
- Large defects of the conjunctiva healing by second intention may result in extensive granulation and scarring, with possible symblepharon formation.

Symblepharon Repair

Preoperative Considerations

- Symblepharon results from the fibrosis of two apposing ulcerated epithelial surfaces.
- Neonatal conjunctivitis of kittens, caused by feline herpesvirus, is a common cause in cats (see Chapter 11).
- Postinflammatory adhesions may reduce or obliterate the conjunctival fornices resulting in immobility of the globe.
- Adhesions may result in abnormal tear dynamics and chronic epiphora.
- Corneal involvement results in scarring and opacification, which reduces vision.

Surgical Procedure

Objectives

- Remove scar tissue and free adhesions, thereby restoring normal anatomic relationships and functions of the ocular surface structures.
- Prevent readhesion and minimize postoperative scarring.

Equipment

- Colibri forceps
- Beaver blade (#64) with handle
- Instruments as listed for "Laceration Repair"
- Corneal-scleral conformer

Technique

1. When extensive corneal opacification is present, perform a lamellar keratectomy (see Fig. 134-1, Chapter 134).
2. Incise the perilimbal bulbar conjunctiva with a #64 Beaver blade, undermine and free adhesions with small curved scissors, and elevate the conjunctiva as a mobile circumlimbal flap.

3. Perform sufficient dissection and removal of subconjunctival scar tissue to reestablish the conjunctival fornices.
4. Free the third eyelid by dissecting amid the third eyelid, the globe, and the eyelids, if necessary.
5. Place a bandage soft contact lens over the corneal surface behind the third eyelid.
6. Apply a broad-spectrum antibiotic ophthalmic ointment into the conjunctival cul-de-sac.
7. Place a corneal-scleral conformer over the globe and the front side of the third eyelid.
   a. A conformer may be constructed using a commercially available corneal-scleral protector (Crouch corneal protector, Storz Instrument, St. Louis).
   b. The corneal protector may be reduced to an appropriate size by trimming the perimeter with utility scissors, smoothing the cut margins with a file or fine sandpaper, rinsing the plastic of sanded particles, and sterilizing with gas.
8. Secure the corneal protector with three temporary tarsorrhaphy mattress sutures.

Postoperative Care and Complications

- Place a restraint collar on the animal to prevent self-trauma.
- Immediately postoperatively, administer a mild sedative or analgesic.
- Remove discharges and cleanse the eye as needed.
- Tarsorrhaphy sutures prevent topical treatment of the eye; therefore, administer broad-spectrum systemic antibiotics (e.g., oral amoxicillin).
- Remove tarsorrhaphy sutures, the conformer, and the contact lens in 14 days.
- Following removal, irrigate the eye and initiate topical treatment with an antibiotic ointment 3 times daily for 1 week or until the ocular surface has a negative retention of fluorescein stain.
- Initiate a topical antibiotic or corticosteroid (e.g., neomycin, bacitracin, or dexamethasone) treatment 3 times daily *after* the surface has completely healed (i.e., negative results with fluorescein stain).
- Gradually reduce the frequency of topical treatments, and discontinue after 3 weeks.
- Additional corneal scarring and readhesion of conjunctival surfaces are the main complications with symblepharon surgery; however, the contact lens and corneal conformer minimize these complications and may result in substantial improvement in ocular function.

Conjunctival Grafts

See Chapter 134.

Chapter

134 Diseases of the Cornea and Sclera

Thomas J. Kern

Disorders of the cornea are common in veterinary practice. Acquired corneal disorders such as ulcerative keratitis, melanosis, and pannus are leading causes of preventable blindness in dogs and cats. The high frequency of corneal disorders should not lull practitioners into forgetting the importance of rigorous diagnosis and attentive management. Disorders of the sclera are less common. Their diagnosis may be more difficult than corneal disorders and they may be presented at a more advanced stage.

CONGENITAL DISORDERS

Dermoids

Dermoids are islands of skin embryologically misplaced on the cornea (especially the temporal cornea) and conjunctiva and occasionally malpositioned on the eyelids. They contain epidermis, dermis, fat, sebaceous glands, and hair follicles.

Etiology

- In Burmese cats, dermoids are an inherited condition that frequently involves the eyelids.
- Dermoids are considered a spontaneous nonheritable condition in dogs, although some breeds (e.g., German shepherd) appear to be afflicted at a higher frequency than others; thus a genetic basis cannot be completely ruled out.

Clinical Signs

Dermoids' surface irregularity promotes chronic blepharospasm and epiphora; the hairs cause corneal and conjunctival irritation.

Diagnosis

- On ocular examination, the typical appearance of skin on the cornea or conjunctiva is diagnostic.

Treatment

- Remove by keratectomy (surgical removal of corneal tissue). If removal is complete, corneal scarring is present but minimal.
- If the conjunctiva also must be resected, suture the edges of the conjunctiva to the limbus, using 7-0 Vicryl, to discourage postoperative adhesion of the conjunctiva to the cornea.

Microcornea

Etiology

Microcornea usually is associated with complicated *microphthalmos,* a condition with both genetic and environmental causes.

- Inherited microphthalmos syndromes have been characterized in the Australian shepherd, collie, Shetland sheepdog, Old English sheepdog, Akita, American cocker spaniel, miniature schnauzer, Doberman pinscher, Samoyed, Cavalier King Charles spaniel, and Lancashire heeler.
- Multiple heritable ocular defects associated with partial albinism and deafness occur in the Great Dane and collie. Teratogenic influences on the dam during early pregnancy (e.g., viral or other illnesses, live virus vaccines, drugs) may be responsible.
- Microphthalmos occurs less frequently in cats than in dogs; its causes are poorly characterized.

Clinical Signs

- The cornea appears abnormally small and often is misshapen.

Diagnosis

- Measure the horizontal and vertical diameters of the cornea and compare with those of the normal contralateral eye, if present, or with the eye of a normal animal of similar breed.

Treatment

- Treatment is neither available nor warranted. If the condition is associated with microphthalmos, vision may be impaired.

Corneal Opacities

Persistent Pupillary Membrane–Associated Opacities

Etiology

- An embryologic cleavage defect results in strands of iris attached to the endothelial surface of the cornea. Where attachment occurs, endothelium is absent and Descemet's membrane is abnormal, resulting in permanent nonprogressive opacity.
- The condition is inherited in basenjis and probably in other breeds; the mode of inheritance is uncertain (see Chapter 136).

Axial Geographic Subepithelial Opacities in Puppies

Etiology

- The cause(s) of these variably prominent, well-circumscribed corneal opacities is unknown.
- They are commonly noted during examination of certain breeds (collie, Shetland sheepdog, English springer spaniel) for inherited ocular disorders and thus have an uncertain genetic basis.

Clinical Signs

- Most obvious in the exposure strip of axial cornea, these superficial opacities are usually bilateral, relatively symmetric, painless, and irregular.
- Typical appearance is that of a non-ulcerated geographic axial corneal opacity of variable density.

Diagnosis

- A typical corneal opacity in a dog less than 1 year of age suggests the diagnosis.
- The absence of fluorescein dye retention rules out ulcerative keratitis and lack of corneal vascularization rules out an old corneal scar.

Treatment

- Do not treat. Most opacities substantially disappear by maturity.
- A residual faint opacity may remain near the nasal and temporal limbus.

Colobomatous Defects of the Sclera

Etiology

- Scleral defects occur as part of the spectrum of inherited ocular anomalies in collies, Shetland sheepdogs, and Australian shepherds.
  - The collie/Shetland sheepdog anomaly is said to be due to a simple recessive gene with variable expression; a different mode of inheritance has been postulated for the colobomas.
  - The Australian shepherd defect is inherited as an incompletely penetrant recessive trait.
- Optic disc and peripapillary colobomas occur in basenjis; inheritance may be autosomal dominant.
- Great Danes that are the progeny of two harlequin parents are afflicted with colobomatous microphthalmos similar to that in Australian shepherds.
- Posterior pole colobomas of the optic disc and surrounding sclera of unknown cause are seen occasionally in domestic short- and longhaired cats.

Clinical Signs

- In collies and Shetland sheepdogs, the only commonly visible external sign of the defect is relative or absolute microphthalmos. Choroidal hypoplasia, scleral ectasia, optic nerve coloboma, and retinal detachment may be present in the fundus. Blindness is present with retinal detachment and/or optic nerve coloboma.
- Affected Australian shepherds (and Great Danes) usually have mostly white coat color and unilateral or bilateral microphthalmos. In many microphthalmic eyes there are large equatorial staphylomas (i.e., areas of pitted and thinned sclera posterior to the ciliary body). Iris anomalies (heterochromia, corectopia, persistent pupillary membranes, pseudopolycoria) often are present, as are cataracts, retinal dysplasia, and retinal detachment.
- Basenjis with optic disc colobomas have abnormal vision and may have persistent pupillary membranes, although the two defects may not be related.
- Cats afflicted with posterior segment optic nerve coloboma and scleral ectasia are blind in the affected eye, the external appearance of which is normal except for tonic mydriasis.

Diagnosis

- Indirect ophthalmoscopy provides panoramic views of the ocular fundus and is the most sensitive and practical means of diagnosis.

Treatment

- Therapy for these defects is neither indicated nor available.
- Discourage breeding of affected animals.

CORNEAL DEGENERATIONS AND DYSTROPHIES

▼ ***Key Point*** Corneal dystrophy is a congenital or acquired, usually bilateral, corneal opacity typically

unassociated with neovascularization. Degenerations are often but not invariably unilateral abnormalities, frequently (but not necessarily) associated with neovascularization, which are secondary to other ocular or systemic disorders.

Corneal degenerations and dystrophies may affect epithelium, stroma, or endothelium (epithelial dystrophies are discussed under Corneal Ulceration). In some animals, differentiation between the two disorders is difficult.

Stromal Dystrophy

Etiology

- Stromal corneal dystrophy is a genetic disorder afflicting many breeds of dogs, including the collie, Siberian husky, Cavalier King Charles spaniel, beagle, Airedale terrier, cocker spaniel, Alaskan malamute, bearded collie, bichon frise, German shepherd, Lhasa apso, mastiff, miniature pinscher, Weimaraner, pointer, and Samoyed.
- One line of Manx cats was reported with an inherited bilateral stromal dystrophy.

Clinical Signs

- At least two forms of stromal dystrophy occur in dogs:
  - One form is a bilaterally symmetric oval axial or paraxial subepithelial/anterior stromal crystalline opacity.
  - The second form, in which a deeper stromal opacity involves more peripheral portions of the cornea, occurs in Siberian huskies and occasionally in other breeds.
  - Corneal neovascularization is absent in both forms. Age of onset varies according to breed and individual animals, from 6 months to old age.
- Affected Manx cats developed progressive stromal edema leading to bullous keratopathy and recurrent epithelial erosion.

Diagnosis

- *Dogs:* The typical crystalline, usually bilateral, corneal opacity (fluorescein dye negative) unassociated with corneal neovascularization or other corneal pathologic changes suggests stromal dystrophy.
  - Rule out causes of corneal degeneration, which may appear similar, including keratoconjunctivitis sicca (KCS), lagophthalmos, eyelid defects, and endocrinopathy (e.g., hypothyroidism).
- *Cats:* Progressive corneal edema in Manx cats suggests the diagnosis.

Treatment

- Treatment in dogs is rarely indicated or necessary. Keratectomy may remove superficial opacities, but recurrence is likely. Do not breed affected animals.

Stromal Degenerations

Etiology

Ocular causes of stromal degenerations include

- Ulcerative and non-ulcerative keratitis
- Corneal exposure
- Dryness secondary to KCS or lagophthalmos

▼ ***Key Point*** Systemic diseases suspected to cause degenerations include primary hyperlipidemia, secondary hyperlipidemia (especially associated with hypothyroidism), and hyperadrenocorticism (implicated in calcific degeneration or "band keratopathy").

Clinical Signs

- The central (axial) to paracentral opacities are often bilaterally symmetric and range from crystalline to dense yellow-white; they may be indistinguishable from primary corneal dystrophy.
- In calcific degeneration, the cornea feels "gritty" when touched with a cotton-tipped applicator.
- Neovascularization is often although not invariably present.

Diagnosis

- A typical lesion (with or without neovascularization) and/or a history of a previous condition (e.g., ulcer, other keratitis, lagophthalmos) suggests degeneration rather than dystrophy.

▼ ***Key Point*** Do not assume that concurrent primary or secondary hyperlipidemia or hyperadrenocorticism is the cause unless ocular causes of degeneration have been ruled out. Even then, a causal relationship may be uncertain.

- Clinical differentiation of these two conditions frequently is difficult.

Treatment

- Treatment is rarely indicated or necessary.
- Consider keratectomy for large, dense axial lesions that interfere with vision.
  - Prognosis is guarded, as recurrence is possible; in addition, postoperative corneal opacity may be significant.
- For calcific degeneration, consider keratectomy for superficial lesions. Topical application of 1% EDTA q4h may be helpful.

Endothelial Dystrophy

Etiology

- Endothelial dystrophy is a breed-related, acquired disease resulting in premature loss of corneal

endothelial cells to a level below that required to maintain normal corneal stromal deturgescence.

Clinical Signs

- *Dogs:* Progressive bilateral corneal edema may affect Boston terriers, Chihuahuas, dachshunds, and occasionally other breeds. It can begin focally or in a diffuse pattern and progress from the peripheral to the central cornea or vice versa.
  - Initially painless, the condition frequently results in recurrent corneal erosion when stromal and epithelial edema become extensive. Corneal neovascularization usually is absent.
- *Cats:* Endothelial dystrophy causing progressive bilateral corneal edema has been reported rarely in domestic shorthaired cats.

Diagnosis

- Endothelial dystrophy is presumptively diagnosed when bilateral corneal stromal edema is present unassociated with signs of uveitis or glaucoma.

▼ ***Key Point*** Determine intraocular pressure (IOP) to rule out uveitis (decreased IOP) or glaucoma (elevated IOP) (see Chapters 136 and 137).

- Corneal ulceration, if present, usually is superficial and insufficient to cause the degree of stromal edema observed.

Treatment

- For severe stromal and epithelial edema, consider treatment with topical 5% sodium chloride (Muro-128, Bausch and Lomb) q4–6h to discourage corneal erosion.
- When erosions occur, debride non-adherent epithelium and administer topical broad-spectrum antibiotics and 1% atropine.

Endothelial Degeneration

Etiology

- Intraocular inflammation or hemorrhage, primary and secondary glaucoma, anterior lens luxation, and corneal injury may cause endothelial degeneration.
- Natural infection with canine adenovirus-1 (infectious canine hepatitis) or vaccination with modified live vaccines containing adenovirus-1 or adenovirus-2 may result in immune-mediated anterior uveitis and endothelial destruction 7 to 10 days following exposure (see Chapter 16).
  - The proportion of dogs affected can be high (in natural infection, about 20%), low (adenovirus-1 vaccination), or very low (adenovirus-2 vaccination).

Clinical Signs

- Chronic focal or diffuse corneal edema (giving the cornea a ground-glass appearance) with or without superficial or deep corneal neovascularization characterizes endothelial degeneration. If the edema resolves, only transient endothelial dysfunction occurs.

▼ ***Key Point*** Corneal endothelial cells in many adult domestic animals have little to no regenerative capacity. Repair occurs by hypertrophy and migration of remaining endothelial cells.

- Most dogs with adenovirus-mediated uveitis present with generalized corneal edema after resolution of transient uveitis.
  - A small proportion of affected dogs, especially sight hounds and Arctic breeds, quickly develop intractable secondary glaucoma.

Diagnosis

- Diffuse, moderate to severe generalized corneal edema strongly suggests endothelial dysfunction.
- Perform a careful ocular examination to rule out antecedent causes (e.g., inflammation, glaucoma, hyphema, lens luxation).

Treatment

- Direct treatment toward prevention by effectively controlling the causative or attendant conditions (e.g., glaucoma, uveitis, hyphema) before irreversible endothelial degeneration occurs.

Prognosis

- Most dogs with adenovirus-related endotheliopathy recover endothelial function, and the corneal edema resolves within a few weeks.
- Corneal edema secondary to other causes has a variable prognosis for resolution.

CORNEAL ULCERATION

Loss of one or more corneal epithelial layers commonly is termed *corneal erosion* or *abrasion*. Full-thickness loss of epithelium with at least some stromal loss is termed *ulceration*.

- *Simple corneal ulceration* is that which heals uneventfully in a normal amount of time (3 days).
- *Complicated corneal ulceration* involves delayed healing associated with infection or other pathologic processes.
- *Progressive corneal ulceration* involves a deepening or enlarging area.

Etiology

Traumatic Injury

This is probably the most common cause of ulcerative keratitis in dogs and cats.

- Blunt trauma may cause focal or diffuse damage to any or all corneal layers. Corneal laceration may be partial or full thickness. Aqueous loss, anterior chamber collapse, and iris prolapse may ensue.
- Most traumatic corneal erosions and ulcers heal rapidly; however, some become persistent if epithelial basement membrane damage is severe or if a foreign body persists in the conjunctival fornix.
- Traumatic injury may begin a cascade of pathologic complications resulting in complicated ulceration.

Bacterial Infection

At least minor epithelial injury is required for colonization to occur; bacteria do not adhere to normal epithelial cell membranes.

- Pathogenic and normally nonpathogenic commensal organisms may infect the cornea. Staphylococci and streptococci are the ocular bacterial organisms most frequently isolated from normal eyes of dogs and cats.
- Topical antibiotic or corticosteroid therapy may result in overgrowth of pathogenic fungi, yeasts, and bacteria. However, infection of corneal ulcers by fungi is rare in dogs and cats.

Pseudomonas

- *Pseudomonas* infection commonly results in corneal melting, perforation, and loss of the eye.
- Proteolytic enzymes produced by the bacteria, inflammatory cells, and response to infection by the cornea itself cause stromal proteoglycan and collagen destruction, giving the affected cornea a mucoid appearance as melting occurs.

Feline Herpesvirus (FHV)

- FHV infection is an important cause of corneal ulceration in cats (see Chapter 11). Superficial ulcers may be small, punctate, or linear branching fern-like figures classically described as dendrites. Larger, geographic superficial to deep ulcers form from coalescence of smaller focal ulcers. Stromal ulcers, descemetoceles (i.e., a circular loss of stroma down to Descemet's membrane), and perforations may develop.

Epithelial Dystrophy (Erosion, Indolent Ulcer, Boxer Ulcer)

- An apparently inherited corneal epithelial basement membrane dystrophy has been recognized in boxers and probably occurs in other breeds. A different inherited epithelial dystrophy afflicts Shetland sheepdogs. Affected dogs are usually middle-aged or older.
- Trauma and chronic corneal inflammation may result in acquired epithelial basement membrane abnormalities.
- Endocrinopathies such as diabetes mellitus, hyperadrenocorticism, and hypothyroidism may be associated with fragile corneal epithelium that may be susceptible to injury and prone to delayed healing.

Neurotrophic Keratitis

This condition develops following denervation of the cornea's sensory nerve supply from the ophthalmic branch of the trigeminal nerve. Sensory nerves and the neurotransmitters and other substances involved have a beneficial influence on the maintenance of epithelial integrity.

Corneal Dryness

This condition occurs secondary to

- Aqueous tear deficiency (KCS; see Chapter 139).
- Qualitative tear film abnormalities (mucin deficiency).
- Exposure from lagophthalmos due to conformational abnormalities of eyelid closure or facial nerve palsy (see Chapter 139).

Endocrinopathies

Endocrinopathies such as diabetes mellitus, hypoadrenocorticism, and hypothyroidism have been associated with corneal ulceration in dogs; a causative role in the development of ulcers has not been established.

Idiopathic Corneal Ulceration

An idiopathic form is peculiar to the cat and is associated with corneal sequestrum formation (mummification).

- Following chronic, usually superficial, unilateral or bilateral corneal ulceration a brown or black discoloration of the stroma develops. The discolored plaques of degenerate cornea remain in place or slough away after weeks or months.
- A corneal sequestrum is associated with pain and corneal neovascularization.
- Concurrent herpesvirus infection has been demonstrated in some cats.

Clinical Signs

- *Blepharospasm, photophobia,* and *epiphora* are stimulated by painful sensations from damaged epithelium as well as from secondary ciliary muscle spasm.
- *Corneal opacity* results from stromal and epithelial edema and infiltration by inflammatory cells into the affected area.

- *Corneal surface depression* is present if stromal loss, including descemetoceles, has occurred.
- *Neovascularization* denotes complicated ulceration in which healing has been delayed by ocular factors (e.g., KCS, eyelid defects, infection) or non-ocular factors (e.g., self-trauma, inappropriate medical therapy).
  - Superficial neovascularization usually suggests a corneal or external complicating factor and appears as tree-like individual vessels infiltrating focal sectors of cornea.
  - Deep (ciliary) neovascularization denotes intraocular inflammation and appears as an advancing ring of fine vessels evenly infiltrating the peripheral cornea for its entire circumference.
- In *epithelial dystrophy*, the fluorescein dye–positive stained area is surrounded by a halo of poorly adherent or non-adherent epithelium that stains less brilliantly than the center, where epithelium is absent.
  - Corneal neovascularization is absent unless previous traumatic manipulation (e.g., chemical cauterization) has been performed. This is in contrast to chronic corneal ulceration due to traumatic, infectious, and other causes, which routinely incite neovascularization.
  - Blepharospasm and photophobia, if present, frequently are minimal.
- *Miosis* occurs as an axon reflex from stimulation of corneal, conjunctival, and periocular branches of the ophthalmic nerve (see Chapter 136).
- *Aqueous flare* (i.e., the presence of large amounts of serum proteins in the anterior chamber) indicates iridocyclitis (anterior uveitis) with breakdown of the blood-aqueous barrier (see Chapter 136).
- *Hypotony* (reduced intraocular pressure) usually accompanies moderate to severe anterior uveitis and results from reduced aqueous production and, possibly, increased aqueous outflow.

Diagnosis

History

Important aspects include

- Time and circumstances of onset.
- Presence and duration of discharge and blepharospasm.
- Change in the eye appearance between onset and presentation.
- Current and previously treated ocular disorders.

Ocular Examination and Accessory Diagnostic Tests

- Collect samples for corneal culture before instilling any diagnostic solutions.
- The hallmark of corneal ulceration is retention of fluorescein dye, which stains corneal stroma, tears, and aqueous humor.
  - To rule out KCS, perform a Schirmer tear test (Schering Plough) before fluorescein dye application.

▼ ***Key Point*** Descemetoceles demonstrate an annular pattern of dye retention along their walls, but exposed Descemet's membrane in the center does not stain.

- Before applying topical anesthesia, test corneal sensitivity with a cotton-tipped swab.
- Following topical anesthesia, obtain scrapings for cytology and Gram staining from ulcers showing rapid progression, soft edematous margins, or a yellow inflammatory cell infiltrate.
- Because sequestra have been noted in cats experimentally infected with FHV, submit diagnostic tests (viral isolation, polymerase chain reaction, or immunofluorescence testing of conjunctival scrapings; see Chapter 11) to rule out herpesvirus infection.
- The diagnosis of epithelial dystrophy is suggested by a chronic non-adherent epithelial margin with only mild discomfort.

Medical Treatment

▼ ***Key Point*** Topical corticosteroids and nonsteroidal anti-inflammatory drugs are contraindicated with corneal ulceration.

▼ ***Key Point*** Topical anesthetics for *diagnostic* purposes are safe; however, because they are toxic to corneal epithelium, their use in *treatment* is contraindicated.

Simple Erosions and Superficial Ulcers

- Instill topical broad-spectrum antibiotics (e.g., bacitracin, neomycin, polymyxin). Treat with ointments q6h or with aqueous solutions at least q4h.
- Instill topical 1% atropine ointment or solution, to effect, to maintain mydriasis and, presumably, ciliary muscle paralysis (e.g., q6–8h initially, followed by q12–24h, and then every other day).
- Schedule follow-up examinations every few days until epithelialization is complete.

Deep and/or Progressive Ulceration

Base the choice of topical and subconjunctival antibiotics on corneal cytologic findings (Table 134-1).

- Supplement topical 1% atropine therapy with
  - Topical fortified gentamicin or tobramycin drops (Tables 134-2 and 134-3) applied q1–2h.
  - Subconjunctival antibiotic injection (see Table 134-1).

Table 134-1. ANTIBIOTIC SELECTION BASED ON GRAM STAIN OF CORNEAL SCRAPINGS

Gram Stain Finding	Antibiotics*		
	Topical	Subconjunctival	Systemic
Gram-positive cocci	Bacitracin (Neosporin; Burroughs Wellcome) or cefazolin (Genera)	Methicillin (Staphcillin; Squibb), 100 mg, or gentamicin (Gentocin; Schering), 10–40 mg, or tobramycin (Tobrex; Alcon Labs), 10–30 mg	Ampicillin or gentamicin or cefazolin or tobramycin
Gram-negative rods	Gentamicin or tobramycin	Gentamicin, 10–40 mg, and/or carbenicillin, 250 mg, and/or tobramycin, 10–30 mg	Chloramphenicol or gentamicin or tobramycin
Mixed infections	Bacitracin and gentamicin	Methicillin, 100 mg, and gentamicin, 20 mg	Gentamicin or tobramycin

Modified from Kern TJ: Ulcerative keratitis. Vet Clin North Am (Small Anim Pract) 20(3):653, 1990.
*Product name and manufacturer are given in parentheses following the first mention of the generic drug.

Table 134-2. FORMULAS FOR FORTIFIED ANTIBIOTICS IN ARTIFICIAL TEARS

Drug	Form	Quantity of Antibiotic	Quantity of Artificial Tears (ml)	Final Volume (ml)	Final Concentration (mg/ml)
Gentamicin (Gentocin injectable; Schering)	100 mg/ml	2.5 ml (250 mg)	15	17.5	14
Gentamicin (Gentocin injectable; Schering)	50 mg/ml	5 ml (250 mg)	12.5	17.5	14
Tobramycin (Nebcin; Eli Lilly)	40 mg/ml	5.5 ml (220 mg)	15	20.5	11
Bacitracin (Bacitracin sterile USP; Quad Pharmaceuticals)	50,000 IU/vial	150,000 U (3 vials)	15	15.6	9600 IU/ml
Cefazolin (Genera)	1 g/vial	3 ml (1 vial)	15	18	50

Table 134-3. FORMULAS FOR FORTIFIED FORMS OF PROPRIETARY TOPICAL OPHTHALMIC ANTIBIOTICS

Drug	Bottle Concentration (mg/ml)	Bottle Volume (ml)	Parenteral Antibiotic Added	Final Concentration (mg/ml)
Gentamicin (Gentocin ophthalmic solution; Schering)	3	5	50 mg (1 ml of 50 mg/ml solution)	11
Tobramycin (Tobrex; Alcon)	3	5	10 mg or 40 mg/ml	4 or 9

Reprinted with permission from Kern TJ: Ulcerative keratitis. Vet Clin North Am (Small Anim Pract) 20(3):655, 1990.

- Consider treatment with acetylcysteine or sodium EDTA (0.15 M) q1–2h if corneal melting is apparent or suspected. Efficacy of these drugs is uncertain.

Surgical Treatment

- Consider surgical options for treatment of corneal ulcers that are deep and progressive.

Objectives

- Prevent ulcer progression.
- Repair perforation.
- Protect the corneal surface.
- Retard melting.

Protective Procedures

▼ ***Key Point*** Protective procedures do not provide blood supply or cells to aid in the healing of corneal ulceration. They do interfere with treatment and further evaluation of corneal ulceration.

- *Nictitans flap*—Indications include post-proptosis corneal coverage and, possibly, conservative treatment

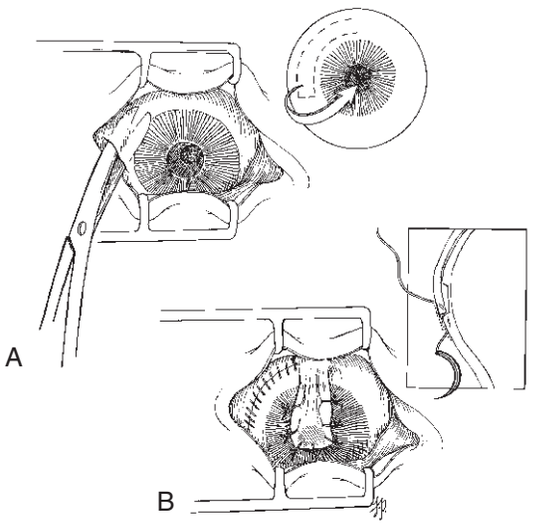

Figure 134-1. Pedicle graft. *A,* Using Stevens tenotomy scissors, elevate the bulbar conjunctiva, incise, and dissect free of the globe. Create and rotate a pedicle of conjunctiva, epithelial surface up, to cover the corneal defect. *B,* Suture the conjunctival pedicle to the cornea, covering the defect, using simple-interrupted sutures. Appose the epithelial margins of the conjunctival graft to the cornea (see inset and Fig. 134-3*B*).

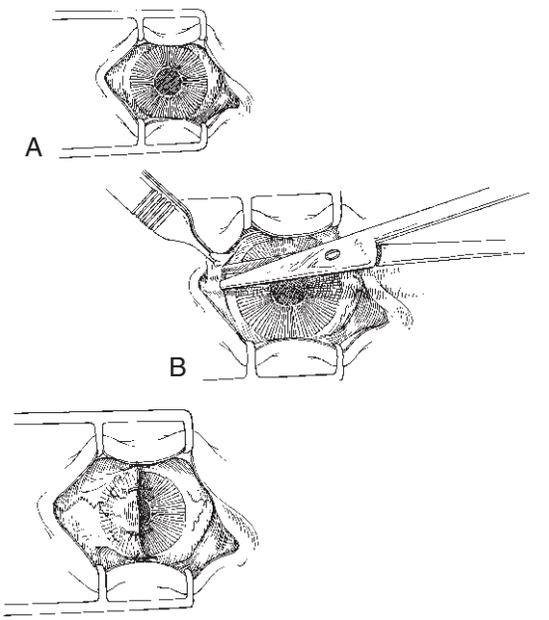

Figure 134-2. Fornix-based hood (180°) flap. *A,* A corneal ulcer is present and is to be repaired with a hood-graft from the adjacent bulbar conjunctiva. *B,* Elevate the bulbar conjunctiva adjacent to the corneal defect and use Stevens tenotomy scissors to incise and dissect free this portion of conjunctiva. *C,* Advance the conjunctiva over the defect and suture in place using simple interrupted sutures. Place sutures in the cornea to stabilize the graft over the corneal defect and in the limbus to relieve tension.

of recurrent superficial erosion following debridement; contraindications include deep or infected ulcers, descemetoceles, and uncorrected perforations.

- *Temporary tarsorrhaphy (closure of the eyelids)*—Indications and contraindications are the same as for nictitans flap.

Supportive Procedures

Supportive procedures include conjunctival flap surgery and cyanoacrylate tissue adhesive application.

Conjunctival Flap

Indications

Deep ulcers, infected ulcers following short-term intensive antibiotic therapy, descemetoceles, sutured corneal wounds that leak, and, rarely, recurrent epithelial erosions.

Type

Depending on the extent and location of the lesion, the flap may be a pedicle graft (Fig. 134-1), fornix-based hood (180 degrees) flap (Fig. 134-2), or circumferential (360 degrees) flap.

Technique

1. Carefully debride any necrotic or melting corneal stroma from the ulcer and its margin, using a #64 Beaver blade.
2. Form flaps by making a conjunctival incision at the limbus. Bluntly dissect the conjunctiva from the underlying connective tissue (episclera) using tenotomy scissors.
3. Free the conjunctival graft by cutting it from its limbal attachment.
4. Suture pedicle and hood grafts to the cornea, using 7-0 polyglactin (Vicryl) or smaller suture material. Attempt to achieve epithelial to epithelial apposition of the conjunctiva and cornea. To relieve tension, the graft can be sutured to the limbus with two sutures.
5. Suture complete 360 degree flaps in a horizontal mattress pattern, top half to the bottom half, along the center of the cornea but not directly to the cornea.
6. Remove sutures in 10 to 14 days.
7. Separate the graft from its blood supply and trim points of adhesion of the flap to the previous corneal defect with tenotomy or iris scissors under topical anesthesia 1 week after suture removal.

Cyanoacrylate Tissue Adhesive Application

Indications

Small partial- or full-thickness perforations, small descemetoceles, and deep stromal ulcers.

Technique

1. Sedate or anesthetize the animal as necessary.
2. Debride the lesion as necessary to remove necrotic tissue, non-adherent epithelium, and adherent mucus.
3. Instill a topical anesthetic (Ophthetic; Allergan Pharmaceuticals).
4. Insert an eyelid speculum.
5. Dry the corneal site of application with a cotton-tipped swab or cellulose sponge.
6. Apply a very thin layer of adhesive (Ophthalmic Nexaband, Abbott Laboratories) through a 30-gauge needle. Application of excessive amounts of adhesive can result in failure of the plug to adhere to the cornea.
7. Wait several minutes for the adhesive to polymerize before removing the speculum. Instill lubricant ointment until blinking returns.
8. Epithelialization occurs underneath the adhesive, which is extruded spontaneously by most animals within a few weeks. Excessive neovascularization may overgrow the plaque, necessitating manual removal under topical anesthesia.

Reconstructive Procedures

Indications

- Reconstructive procedures are indicated for descemetoceles and perforating corneal wounds. Commonly used types include sutures, pedicle flaps, and free conjunctival grafts.

Sutures

Technique

1. Suture perforating wounds and small descemetoceles directly with 7-0 to 9-0 absorbable (e.g., polyglactin 910-Vicryl, Ethicon) or nonabsorbable (monofilament nylon) sutures, using a horizontal mattress or simple interrupted pattern (Fig. 134-3).
2. Remove nonabsorbable sutures in 10 to 14 days.

Pedicle Flap

Technique

1. Raise a pedicle of bulbar conjunctiva, rotate, and then suture it to the edges of the deep corneal wound with absorbable suture material (e.g., polyglactin or polyglycolic acid-Dexon, David and Geck) (see Fig. 134-1).
2. After 2 to 4 weeks, trim the adhered flap connection to the limbus, leaving an island of conjunctiva to be incorporated into the scar.

Free Conjunctival Graft

Technique

1. Dissect an island of conjunctiva slightly larger than the corneal defect from the bulbar or palpebral conjunctiva, and suture it to the cornea directly over the defect.
2. The grafted conjunctiva will become incorporated as a translucent portion of the cornea.

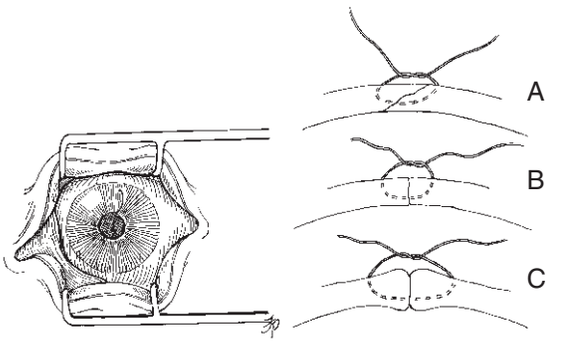

Figure 134-3. Repair of corneal laceration. Note that all sutures are placed to a depth of approximately two thirds of the corneal thickness. *A,* Closure of oblique edges of the laceration. *B,* Closure of vertical wound edges. *C,* Closure of edematous wound margins. Be sure the sutures extend beyond the edematous edge and into healthy cornea.

Referral Reconstructive Procedures

- *Corneoconjunctival transposition* and *autogenous corneal grafting* are forms of lamellar corneal graft requiring special instrumentation and expertise.
- *Penetrating keratoplasty (corneal transplant)* has few indications in veterinary medicine.

Treatment of Chronic Superficial Erosion

- After instilling a topical anesthetic, debride the non-adherent epithelium with a wet or dry cotton-tipped applicator back to the junction with normally adherent epithelium. Frequently, most of the corneal epithelium is removed in the process.

▼ ***Key Point*** Cauterants such as phenol, aqueous and tincture of iodine, trichloroacetic acid, and others are unnecessary and harmful. These agents incite excessive neovascularization that retards rather than accelerates epithelial healing.

- Instill topical broad-spectrum antibiotic drops (q3–4h) or ointments q6h, until healing is complete.
- To maintain mydriasis, administer topical 1% atropine drops or ointment to effect; apply q8h until dilatation occurs, followed by once daily to every other day.
- If the erosion has not healed, or nearly so, within 10 days, consider the following options:
  - Contact lenses.
  - Keratotomy.
  - Drugs.

Contact Lenses

Insertion of a soft contact lens (Hydroblues; Keragenix) following simple debridement frequently is effective.

Indication

- Chronic corneal (indolent) erosion.

Contraindications

- KCS; bacterial keratitis.

Technique

1. Following topical anesthesia, debride non-adherent epithelium with a cotton-tipped swab.
2. Insert soft contact lens (diameter, 15 mm; base curve, 8.4–8.8 mm). A partial temporary tarsorrhaphy is optional.
3. Administer a topical broad-spectrum antibiotic and 1% atropine solutions as described for simple erosions. Apply an Elizabethan collar.
4. Remove the contact lens weekly and stain with fluorescein to monitor ulcer healing. Reinsert the contact lens or insert a new one after cleaning and disinfection; repeat the process until the cornea is healed.

Superficial Punctate or Linear Keratotomy (Anterior Stromal Puncture)

The resultant small, visually insignificant scars are believed to secure the epithelium to the stroma.

Technique

1. Sedate the animal.
2. Instill a topical anesthetic to effect.
3. Debride non-adherent epithelium with a cotton-tipped swab.
4. Under magnification (Optivisor or similar device), make a series of shallow punctures or linear cuts with a sterile 25-gauge needle, spaced approximately 0.5 mm apart throughout the debrided area and extending 1 mm onto the surrounding epithelium.
5. Instill a topical broad-spectrum antibiotic and 1% atropine as described for simple erosions.

Superficial Keratectomy to Remove the Affected Area of Stroma, Epithelium, and Basement Membrane

Disadvantages include

- The need for general anesthesia.
- Proficiency in the surgical technique.
- Possible permanent corneal thinning.

Drugs

Drugs not yet commercially available but showing promise for medical management of chronic corneal erosions include epidermal and nerve growth factors, fibronectin, and substance P.

Surgical Management of Corneal Sequestra

- Perform keratectomy to remove sequestra that lie in the *superficial* half of the cornea; deeper keratectomy encourages iatrogenic corneal perforation.
- Sequestra may recur at the operated site or at other sites.
- For large or deep sequestra, consider performing a conjunctival pedicle graft to support and reconstruct the wound.

NON-ULCERATIVE CORNEAL DISORDERS

Chronic Superficial Keratitis (CSK)

Etiology

- The specific cause of CSK is unknown.
- Its predominance in a small spectrum of dog breeds (German shepherd, greyhound, occasionally others) and in mixed-breed dogs originating from these dog breeds, strongly implicates a genetic predisposition for immune-mediated disease.

Clinical Signs

- Superficial, bilaterally symmetric neovascularization, usually beginning inferotemporally, with or without melanosis, is a hallmark. Pain is not a common sign.
- Rarely, corneal ulceration develops.
- Corneal degeneration, manifested by oval crystalline opacities, may develop with chronicity.

Diagnosis

- Base diagnosis on typical corneal signs in a German shepherd, greyhound, or mixed-breed dog of their extraction, in the absence of other causes of chronic superficial keratitis (e.g., tear deficiency, eyelid abnormalities).

Treatment

- Administer corticosteroids topically (and, intermittently, subconjunctivally) to control this incurable condition.
  - For initial management administer a subconjunctival injection of 5 mg of methylprednisolone acetate (Depo-Medrol; Upjohn).
  - Supplement with a topical corticosteroid ointment or solution on a regimen of reducing frequency (e.g., q3–4h tapering to q8h over 4 weeks).
  - Long-term topical therapy is essential to maintain control; even short periods of owner noncompliance will result in relapse.
  - Only neovascularization responds to this therapy; melanosis and corneal degeneration do not.

- Consider instillation of 0.2% cyclosporine ointment (Optimmune; Schering Plough) or 1 drop of 2% cyclosporine in oil (see Chapter 139) q12h. Over many months, this may reduce corneal melanosis in many conditions, including CSK, by a poorly understood mechanism. CSK is believed to be a T-lymphocyte–mediated disease and has been reported to respond in some instances to cyclosporine therapy.
- Plesiotherapy with strontium-90–generated beta-radiation is an effective adjunctive treatment for neovascularization. However, this is only available through specialty practices and teaching institutions.

▼ ***Key Point*** Do not perform keratectomy for removal of corneal pigmentation. Complications include delayed epithelialization, recurrence of CSK, and corneal perforation.

Feline Eosinophilic Keratitis

Etiology

- The etiology is unknown; feline herpesvirus may play a role.

Clinical Signs

- Corneal neovascularization, which is frequently bilateral and symmetric, leads to formation of a pink-white plaque covered by a granular, crumbled cheese–like material. The superior temporal, inferior temporal, and inferior nasal quadrants are most frequently involved.
- This lesion is unique to the cat.
- Corneal ulceration is present rarely.

Diagnosis

Corneal scrapings contain combinations of eosinophils, mast cells, and mixed inflammatory cells.

▼ ***Key Point*** Identification of numerous eosinophils or mast cells in corneal scrapings is pathognomonic for feline eosinophilic keratitis.

Treatment

Corticosteroids

Intensive topical corticosteroid therapy frequently is successful.

- Give dexamethasone 0.1% (Decadron; Merck) or prednisolone 1% (PredForte; Allergan) as an ointment or solution, q3–4h. Monitor progress closely when epithelial erosion is present.
- If needed, combine topical corticosteroids with subconjunctival methylprednisolone (5 mg per eye). This combination controls the condition in most cats.
- Once the disease is in remission, reduce frequency of topical therapy to minimal levels; discontinue if remission is maintained.
- Some affected cats will have relapses, requiring chronic topical corticosteroid administration at a minimal effective frequency.

Megestrol Acetate

- Administer megestrol acetate (Ovaban; Schering) (0.5 mg/kg q24h until effect, and then 1.25 mg total dose once weekly) *only* to cats that have not responded to topical and subconjunctival corticosteroids.
- Side effects of oral megestrol acetate include weight gain, behavior changes, diabetes mellitus, and mammary gland hypertrophy and neoplasia.

Corneal Melanosis

Etiology

- Among domestic animals, only dogs commonly develop corneal pigmentation, which apparently develops through migration of limbal melanocytes into the basal epithelial layers and anterior stroma.

▼ ***Key Point*** Melanosis develops in dogs in response to chronic irritation from many causes, including KCS, eyelid deformities, lagophthalmos, and chronic superficial keratitis.

Clinical Signs

- Superficial corneal pigmentation develops focally or over large areas. Corneal neovascularization usually precedes or accompanies melanosis.

Diagnosis

- The typical appearance of a variably melanotic cornea is diagnostic.
- Rarely, melanosis must be distinguished from iris prolapse (anterior synechiae are also apparent) or, at the limbus, epibulbar melanoma.

Treatment

- Identify and treat the underlying causes of melanosis if possible (e.g., KCS) or definitively correct them (e.g., entropion, nasal fold trichiasis).
- Rarely, perform superficial keratectomy to improve corneal clarity when vision is reduced, but only after correcting the inciting cause.
- Consider long-term topical therapy for KCS with 2% cyclosporine drops or 0.2% cyclosporine ointment (Optimmune, Schering-Plough) (see Chapter 139), which may retard or reduce corneal melanosis (evidence of benefit is anecdotal).

SCLERAL INFLAMMATION AND TRAUMA

Fibrous Histiocytoma; Proliferative Keratoconjunctivitis of Collies; Nodular Granulomatous Episclerokeratitis

Etiology

- This condition probably is a genetic disorder of collies, but has been noted in other breeds. Clinical and pathologic features of both inflammation and neoplasia are present.

Clinical Signs

- Bilaterally symmetric scleral/episcleral nodules, especially at the temporal limbus, are hallmarks.
- The eyelids, planum nasale, and other mucocutaneous junctions (lips, anogenital areas) may be involved.
- If the cornea is invaded, corneal opacity develops, often with a leading edge of crystalline corneal degeneration.

Diagnosis

- Typical lesions in a collie are presumptive evidence.
- Obtain a biopsy of atypical lesions.
- The histologic appearance is that of fibroplasia with extensive histiocytic proliferation.
- Differential diagnosis includes lymphoma and other neoplasms.

Treatment

- Corticosteroids are the initial treatment of choice. For dogs with ocular lesions only, combine intensive topical corticosteroid therapy (dexamethasone 0.1% or prednisolone 1%) with subconjunctival injection of 3 to 6 mg per eye of triamcinolone, betamethasone, or methylprednisolone acetate.
  - Long-term topical steroid treatment at the minimally effective frequency reduces recurrence.
- For dogs with ocular and oral, nasal, and/or genital lesions, administer oral prednisone (1.1 mg/kg q12h); taper to the effective minimal dose and frequency.
  - Indefinite treatment may be required.
- For dogs with corticosteroid-unresponsive lesions, administer azathioprine (Imuran; Burroughs Wellcome) 2.2 mg/kg q24h PO for 14 days followed by 1 mg/kg every other day for 14 days; then give 1 mg/kg once weekly for 4 weeks and discontinue. Indefinite treatment at a low frequency may be required. Monitor leukocyte and platelet counts in animals on azathioprine therapy. Discontinue treatment if a significant reduction in either is observed.
- Discourage breeding of affected dogs.

Scleritis; Episcleritis; Ocular Nodular Fascitis

Etiology

- The cause is unknown; an immune-mediated etiology is suspected.

Clinical Signs

- Nodular, diffuse infiltrative, and necrotizing forms have been recognized.
  - Nodular lesions resemble fibrous histiocytomas, but often are unilateral and affect dogs other than collies.
  - Diffuse thickening and inflammation of the sclera may be associated with scleral necrosis and moderate to severe uveitis.

Diagnosis

- The diagnosis is based on clinical signs, histopathology, and response to therapy.
- Differential diagnosis includes lymphoma and other neoplasia.

Treatment

Treatment plan is similar to that for fibrous histiocytoma.

Scleral Wounds

Etiology

Blunt or perforating trauma may cause rupture of the globe through the sclera while the cornea is spared.

Clinical Signs

- Chemosis, conjunctival or external ocular hemorrhage, hyphema, and eyelid swelling in a traumatized animal suggest scleral perforation.

Treatment

- Surgical repair of small wounds may result in preservation of the globe as well as vision if the repair is performed promptly.
- Enucleation or evisceration with intraocular prosthesis implantation is indicated if the scleral laceration is large or if other ocular injuries prevent comfortable retention of the globe.

CORNEOSCLERAL NEOPLASIA

Primary Epibulbar Melanoma

Etiology

- These benign neoplasms probably arise from conjunctival or episcleral melanocytes.

- The German shepherd is a predisposed breed, but the disorder has been reported in numerous other breeds.

Clinical Signs

- A nonpainful, pigmented mass near the limbus, involving the sclera (and, later, adjacent cornea), slowly enlarges, expanding horizontally and vertically into the surrounding sclera.

Diagnosis

- The typical appearance suggests the diagnosis.
- Epibulbar melanomas should be distinguished (not always easily) from uveal melanomas, which are intraocular tumors that may expand through the sclera.

Treatment

- Small, superficial lesions may be resectable. Because scleral grafting may be necessary, consider referral to a specialist.
- Observe for a long period to assess the growth rate and characteristics of individual tumors.
  - In dogs, these normally benign neoplasms may be safely observed until/unless deeper extension causes uveitis or glaucoma, prompting enucleation.
  - Recommendations in cats are similar, although based on fewer reported cases.

Secondary Neoplastic Invasion of the Sclera

Etiology

- Primary or secondary intraocular neoplasms may extend through the sclera and into the orbit.
- Rarely, episcleral metastasis of a distant primary or multicentric neoplasm may occur.

Clinical Signs

- Masses may be obvious extensions of intraocular tumors. Episcleral masses may mimic episcleritis or fibrous histiocytoma.

Diagnosis

- Relationship to an intraocular tumor is presumptive evidence. Association of a scleral mass with a visible intraocular tumor suggests that the scleral mass is an extension of it.
- For histopathologic evaluation, completely excise solitary masses.

Treatment

- Consider palliative and diagnostic enucleation of a painful globe.

Chapter

135 Diseases of the Lens

David A. Wilkie

ANATOMY

The normal canine and feline lens is composed of an outer capsule, epithelial cells beneath the anterior capsule, and lens fibers formed by the migration of epithelial cells to the lens equator, where the cells elongate and create a regular arrangement of fibers. The regular arrangement of these fibers accounts for the transparency of the lens. The lens is posterior to the iris, anterior to the vitreous to which it is attached, and suspended by zonules, which arise from the ciliary body and attach to the lens capsule at the equator (see Fig. 131-1).

CONGENITAL ANOMALIES

Etiology

Lens development takes place early in embryogenesis and is complete in the dog by day 30 of gestation. Any genetic abnormality affecting lens development or any insult to the bitch or queen early in gestation, including infectious, nutritional, chemical, or drug related, can result in congenital lens anomalies. These abnormalities are often associated with other congenital ocular anomalies, including microphthalmia (small globe), persistent pupillary membranes, persistent hyaloid artery, retinal dysplasia, retinal detachment, posterior coloboma or staphyloma, and optic nerve hypoplasia.

Clinical Signs

Examples and features of congenital lens anomalies include the following:

- *Microphakia* (small lens)—With the pupil dilated, the equator of the lens and fine zonules, attaching at the equator and originating from elongated ciliary processes, are visible. The lens may also be luxated.
- *Coloboma* (notch defect)—With the pupil dilated, a notch defect may be visible in any quadrant of the equatorial zone, with or without zonular attachments.
- *Cataract*—See the cataract discussion in this chapter.
- *Lens luxation*—Often associated with microphakia (see discussion in this chapter).

Diagnosis

- Clinical signs (see previous section).
- Present at birth. Microphakia and coloboma are always congenital. Cataract and lens luxation, unless associated with microphakia, may not be congenital. An accurate history and early examination are helpful in differentiating congenital from acquired abnormalities.

Treatment

- Determine concomitant ocular anomalies and their significance to vision.
- Microphakia and coloboma alone require no treatment.
- Cataract, if impairing vision, may be amenable to surgical removal once the integrity of the retina and optic nerve has been ascertained by fundic examination, electroretinogram, ocular ultrasound, and visual-evoked potential.
- Remove a luxated lens if it is inciting uveitis and/or glaucoma, impairing vision, or interfering with corneal endothelial cell function.

Prevention

Congenital anomalies are not necessarily inherited anomalies. Careful inquiry into affected littermates and prevalence of problems in previous matings may raise the suspicion for an inherited defect. If the cause of the abnormality cannot be determined, discourage the use of this and related animals for breeding.

CATARACT

Etiology

Cataract is an opacity of the lens resulting from pathologic changes in lens protein composition or disruption of lens fiber arrangement.

Table 135-1. BREED LIST OF INHERITED OR FAMILIAL CATARACTS IN THE DOG

Afghan hound	French bulldog	Papillon
Alaskan malamute	German shepherd	Pembroke Welsh corgi
Beagle	German shorthaired pointer	Pointer
Bedlington terrier	Giant schnauzer	Pomeranian
Belgian Tervuren	Golden retriever	Poodle (toy, miniature, standard)
Bernese mountain dog	Great Dane	Puli
Bichon frisé	Ibizan hound	Rhodesian ridgeback
Border collie	Irish setter	Rottweiler
Border terrier	Irish water spaniel	Saint Bernard
Borzoi	Irish wolfhound	Samoyed
Boston terrier	Italian greyhound	Schipperke
Bouvier des Flandres	Keeshond	Scottish terrier
Cairn terrier	Kerry blue terrier	Siberian husky
Cavalier King Charles spaniel	Labrador retriever	Silky terrier
Chesapeake Bay retriever	Lakeland terrier	Staffordshire bull terrier
Cocker spaniel	Lhasa apso	Standard schnauzer
Collie	Manchester terrier	Tibetan terrier
Curly-coated retriever	Miniature pinscher	Welsh springer spaniel
Dachshund	Miniature schnauzer	Welsh terrier
English cocker spaniel	Norfolk terrier	West Highland white terrier
English springer spaniel	Norwegian elkhound	Whippet
English toy spaniel	Norwich terrier	Wirehaired fox terrier
Field spaniel	Old English sheepdog	Yorkshire terrier

Data from: Rubin LF: Inherited Eye Diseases in Purebred Dogs. Baltimore: Lippincott Williams & Wilkins, 1989.

▼ ***Key Point*** Cataract must be distinguished from nuclear sclerosis. Nuclear sclerosis is a normal aging change seen in all dogs and cats 6 years of age or older, produced by compression of central lens fibers.

Etiologies of cataract development include the following:

- ***Hereditary***—This is the most common cause of cataract in the dog (Table 135-1). Location, progression, and mode of inheritance of cataracts vary among breeds. The majority of inherited cataracts are bilateral but often asymmetrical in onset and progression.
- ***Inflammatory***—This is a common cause of cataract in the cat. Because the lens needs the aqueous and vitreous humors for nutrition and removal of metabolic wastes, intraocular inflammation can result in capsular and cortical opacities. Posterior synechia from anterior uveitis can result in anterior capsular cataracts.
- ***Metabolic***—Diabetes mellitus in dogs frequently results in rapid (days to weeks) onset of bilateral cataracts because of a shift in metabolic pathways, an accumulation of sorbitol causing an osmotic gradient, and a subsequent disruption of lens fibers. The cataracts are irreversible.
- ***Degenerative***—Cataracts may occur secondary to chronic retinal degeneration or chronic glaucoma.
- ***Traumatic***—Severe blunt trauma to the eye can result in cataract formation from concussive effects or can be secondary to inflammation and/or lens luxation. Penetrating injuries that puncture the anterior lens capsule (e.g., cat claw injuries) result in a focal or diffuse cataract, depending on the severity of the capsular tear. Uveitis may occur secondary to rupture of the lens capsule.
- ***Nutritional***—Puppies and kittens hand fed exclusively milk-replacement formula that is deficient in required amino acids, the most frequently cited being arginine, can develop bilateral cataracts.
- ***Toxic***—Electric shock, radiation therapy involving the ocular region, and certain drugs have been reported to cause cataracts.

Clinical Signs and Diagnosis

▼ ***Key Point*** For a thorough examination of the lens, mydriasis is mandatory because some of the most significant changes occur in the extreme periphery (equatorial zone) or posterior cortex of the lens. Topical tropicamide 1% (Mydriacyl, Alcon) results in mydriasis in 15 to 20 minutes and lasts 6 to 8 hours. An inexpensive, monocular biomicroscope will facilitate examination of the lens and aid determination of location and depth of lesion (see Chapter 131).

- Any *opacity,* anywhere in the lens or its capsule observed after dilation of the pupil, is a cataract.

- The degree of *visual impairment* is dependent on the extent of cataract development in one or both eyes. In addition, the use of the animal must be considered. Incipient and immature cataracts are more significant in hunting and working dogs with respect to vision impairment.
- Differentiate cataracts from nuclear sclerosis. *Nuclear sclerosis* is a bilaterally symmetrical, well-defined, homogeneous haze in the center of the lens observed in animals older than 6 years. Sclerosis is not a true opacity, and it does not obstruct a dilated examination of the fundus or cause clinically significant visual impairment. It may make direct ophthalmoscopy difficult.
- A *focal cataract* can be localized with respect to anterior or posterior by comparing the nasal or temporal direction of movement of the cataract with that of the eye. Anterior cataracts will move in the same direction as the globe; posterior cataracts will appear to move in the opposite direction of the globe. Thus, if the animal looks temporally, an anterior opacity will move temporally and a posterior opacity will move nasally. By localizing cataracts, the surgeon can help determine if they are inherited and predict progression. For example, nuclear cataracts are generally static, whereas equatorial cataracts, where new lens fibers are forming, are generally progressive.

Stages of Development

Incipient

Focal or multifocal opacities of the lens cause no clinical loss of vision and do not impair tapetal reflection or view of the fundus.

Immature

Significant lenticular opacity. Tapetal reflection remains, but an incomplete view of the fundus is present. Vision is affected depending on the extent of lens involvement.

Mature

Dense lenticular opacity with no tapetal reflection or fundus visible results in total vision loss in the affected eye.

Hypermature

As lens protein degenerates and liquefies, the lens can become smaller in the anterior-posterior axis, resulting in a wrinkled anterior capsule and deep anterior chamber.

Resorbing

As lens protein degenerates and liquefies, it can leak through the capsule. This is usually associated with hypermature cataracts but can occur in immature and mature cataracts. The process is faster in young dogs. A resorbing lens has varying amounts of clear, liquefied cortex with the remaining lens material often taking on a sparkling appearance. Although in some animals vision is regained by significant lens resorption, the process generally results in mild to severe lens-induced uveitis (LIU) because of the antigenicity of the leaking lens protein.

Lens-Induced Uveitis

Exposure of excessive amounts of lens protein can overwhelm the normal low-dose T cell tolerance resulting in both a humoral and cell-mediated immune response characterized by lymphocytes and plasma cells. This process is termed *phacolytic* or *lens-induced uveitis*. This may result in hypotony, miosis, flare, keratitic precipitates, synechia, retinal detachment, and glaucoma if allowed to persist (see Chapter 136). In addition, LIU may be associated with intraoperative complications during cataract surgery, a reduction in surgical success, and an increase in postoperative medication.

Phacoclastic uveitis is the result of rupture, spontaneous or traumatic, of the lens capsule. The resulting uveitis is much more severe than seen with lens-induced uveitis and results in secondary glaucoma, pupillary occlusion, and fibroplasia. The most common causes are diabetes mellitus with rapid intumescence or penetrating injury such as a cat claw. The treatment of choice is immediate lens extraction once a lens capsule rupture is observed.

Treatment

▼ ***Key Point*** There is no medical treatment to eliminate cataracts. Surgical removal of cataracts is a referral procedure; consult an ophthalmologist.

- Previously, because of the risks associated with cataract surgery, the cost to the owner, and the ability of a blind dog to acclimatize to their environment, cataract surgery was an elective procedure reserved for those animals with bilateral, mature cataracts. Recently, the improved success rate of phacoemulsification, the availability of intraocular lens implants, and the increased success associated with early surgical intervention have resulted in cataract surgery being offered in cases of unilateral and immature cataracts.
- Regardless, cataract surgery remains an expensive and elective procedure, the exception being a traumatic cataract with secondary lens capsule rupture and impending phacoclastic uveitis. Owners should be aware that not removing a cataract may result in its progression and secondary LIU and associated complications such as retinal detachment, lens luxation, and secondary glaucoma.

- Success rates for cataract surgery vary depending on preexisting uveitis, stage of the cataract, predisposition for glaucoma, surgical procedure used, and surgeon expertise. Success rates with phacoemulsification are reported to be 90% to 95% with little decline over time, while success of the open-sky extracapsular technique is approximately 80% with a steady decline in success over time following surgery to less than 50%.

Preoperative Considerations

- For owners expressing an interest in cataract surgery, refer them to a veterinary ophthalmologist early, while the fundus is still visible and before LIU develops.
- The animal should be healthy. If diabetic, the condition should be well regulated.
- The eyes are examined for concurrent uveitis, glaucoma, abnormal iridocorneal angle, keratitis, and retinal disease.
- If the fundus is not visible through the cataract, an electroretinogram is performed to evaluate for progressive retinal atrophy. An ocular ultrasound is carried out to evaluate for retinal detachment.

Surgical Procedures

Phacoemulsification

- The most common technique for cataract removal in veterinary ophthalmology is phacoemulsification. This uses ultrasonic energy to drive a needle that emulsifies the lens and, through irrigation-aspiration, removes the lens material from the lens capsule. This procedure requires a smaller incision, needs a reduced surgical time, and maintains the anterior chamber compared with the technique of open-sky extracapsular extraction. This results in improved success. The procedure requires a phacoemulsification device, an operating microscope, appropriate surgical equipment, and expertise. Therefore, it is a referral procedure.
- A 3-mm incision is made in the cornea at the limbus, the anterior chamber is inflated using a viscoelastic material, a continuous tear anterior capsulorrhexis is performed, and the lens is removed by phacoemulsification. Care is taken to avoid traumatizing the iris, cornea, and remaining lens capsule. Once the lens is removed and the remaining lens cortex is aspirated, some surgeons will remove a circular portion of the posterior lens capsule to ensure a clear visual axis and minimize postoperative lens capsule fibrosis.
- Currently, the most common lens for replacement in the canine eye is a single-piece lens constructed of polymethylmethacrylate with a 7-mm optical portion, 15- to 17-mm haptic-to-haptic dimension, and a power of 41.5 diopters (53 diopters in cats). If a polymethylmethacrylate lens is to be implanted, the corneal incision is then enlarged to allow insertion of an intraocular lens (IOL). This IOL is placed through the anterior capsule opening and into the remaining lens capsule, allowing the lens capsule to provide support and ensure position. The corneal incision is then closed. Newer-generation acrylic IOLs can be folded and implanted without having to enlarge the corneal incision. If the opposite eye also has a cataract, many surgeons will remove this lens and place an IOL at this time. The animal is then recovered. Failure to replace the cataractous lens with an IOL will leave the animal 14 diopters hyperopic (farsighted) and result in significant visual impairment.
- Certain breeds such as the bichon frisé and Shih Tzu are at increased risk for postoperative retinal detachment. In these and other at-risk eyes, transscleral laser retinopexy may be performed several weeks prior to cataract surgery to create chorioretinal scars and decrease the risk of postoperative retinal detachment.

Postoperative Care and Complications

Complications of cataract surgery can occur immediately to several years postoperatively. Evaluate patients frequently for several months following surgery. Maintain a long-term, 6-month reevaluation schedule for life.

- *Short-term postoperative complications* include anterior uveitis, glaucoma, luxation of the IOL, and retinal detachment.
- *Long-term complications* include chronic low-grade uveitis, glaucoma, corneal endothelial damage with associated corneal edema, fibrous metaplasia across the posterior capsule with opacification of the capsule, posterior synechia, production of new cortical material from remaining epithelial cells, IOL decentration, and retinal detachment.
- Reevaluation includes tonometry to determine intraocular pressure (IOP) and a dilated examination of the posterior capsule and fundus.

Prevention

- Incidence of inherited cataracts can be reduced by discouraging breeding of affected animals and carriers and by encouraging breeders to have yearly Canine Eye Registration Foundation (CERF) examinations.
- Inflammatory cataracts can often be prevented by prompt, appropriate treatment of uveitis (see Chapter 136).

LENS LUXATION

Etiology

- ***Primary zonular degeneration:*** This is an inherited trait in many terrier breeds and has familial tendencies in

Table 135-2. BREED LIST OF INHERITED OR FAMILIAL LENS LUXATION IN THE DOG

Australian cattle dog	Lakeland terrier	Sealyham terrier
Border collie	Manchester terrier	Siberian husky
Cairn terrier	Miniature schnauzer	Skye terrier
Cardigan Welsh corgi	Norfolk terrier	Smooth fox terrier
Chihuahua	Norwegian elkhound	Tibetan terrier
German shepherd	Norwich terrier	Welsh terrier
Greyhound	Pembroke Welsh corgi	West Highland white terrier
Irish setter	Poodle (toy)	Whippet
Jack Russell terrier	Scottish terrier	Wirehaired fox terrier

Data from: Rubin LF: Inherited Eye Diseases in Purebred Dogs. Baltimore: Lippincott Williams & Wilkins, 1989.

other breeds (Table 135-2). Lens luxation usually occurs at middle age with no predisposing ocular disease.

- ***Glaucoma:*** Chronic glaucoma results in a buphthalmic (enlarged) globe that can stretch and break the lenticular zonules, causing the lens to luxate.

▼ ***Key Point*** A primary lens luxation can also cause glaucoma, making it difficult to distinguish which occurred first in some cases.

- ***Uveitis:*** Chronic uveitis may weaken zonules owing to inflammatory cell infiltration.
- ***Cataracts:*** Advanced cataracts may cause degenerative changes in the zonules or zonular attachments.
- ***Trauma:*** Severe ocular trauma may cause lens luxation; however, it is not a common cause unless there is underlying zonule pathology.

Clinical Signs

- The clinical signs of lens luxation vary depending on whether the lens luxates anteriorly or posteriorly. Many times it is the secondary ocular changes that result in the clinical presentation, rather than the lens luxation itself.
- In many eyes with luxated lenses, the vitreous will liquefy and can be found in the anterior chamber. Vitreous appears as filmy white material suspended in the aqueous humor. Its presence, in the absence of lens luxation, may indicate early zonular breakdown and subluxation or an animal's predisposition to lens luxation.

Anterior Lens Luxation

- A penlight beam directed parallel to the iris will reveal the lens positioned in the anterior chamber, anterior to the iris and often blocking the pupil.
- Blue light (Wood's lamp) will cause a clear lens to fluoresce, simplifying the examination.
- A focal area of corneal edema may result from the lens touching the posterior cornea and damaging the corneal endothelium. This may be a permanent change.
- Secondary glaucoma can occur from pupillary occlusion by the lens or attached vitreous or from occlusion of the aqueous outflow through the iridocorneal angle.

Posterior Lens Luxation

- The edge of the lens may be seen through the pupil, resulting in an "aphakic crescent" between the pupil margin and the edge of the lens.
- The lens may fall into the vitreous where it can be seen on the floor of the chamber, trapped in the vitreous, or adhered to the retina.
- Without support of the lens, the iris may tremble with eye movement (iridodonesis). The anterior chamber will be deep.

Diagnosis

- Based on ophthalmic examination
- Tonometry to identify primary or secondary glaucoma
- Ocular ultrasound (if intraocular structures cannot be observed because of corneal or aqueous opacity)

Treatment

- Treatment for lens luxation is surgical. Refer the patient to an ophthalmologist.

▼ ***Key Point*** Anterior lens luxation is a potential emergency; posterior lens luxation is a more elective surgical procedure.

- If immediate referral for an anterior lens luxation is available, do not dilate the pupil. If referral is delayed, some ophthalmologists may prefer the pupil be dilated to minimize corneal endothelial trauma and the risk of pupillary-block glaucoma.
- Determine the intraocular pressure in all eyes with lens luxation.

Surgical Procedures

- Remove a luxated lens through a large limbal corneal incision, removing the lens and lens capsule intact, termed an *intracapsular lens extraction*. Minimize trauma to the vitreous and remove as little of it as possible.
- Removal of an anterior lens luxation is technically easier than removal of a posterior luxation. The latter requires vitrectomy to gain access to the lens, with an increased risk of intraoperative retinal detachment.
- Following intracapsular lens extraction, an IOL can be placed to restore emmetropia. Unlike traditional cataract surgery, in which the IOL can be placed in the lens capsule, the IOL in this instance must be sutured in position. Using two to three 10-0 nylon sutures attached to the IOL haptics, a needle is passed ab interno behind the iris, through the ciliary sulcus, and out the sclera. This is repeated for each suture attached to the haptic. Position the lens posterior to the iris, anterior to the vitreous, and in the ciliary sulcus.
- Close the corneal incision and reinflate the anterior chamber. Using the sutures attached to the haptics, the lens is manipulated into position in the pupillary opening and the 10-0 nylon sutures fixed to the sclera.
- Since the risk of postoperative retinal detachment is high with intracapsular lens extraction, transscleral laser retinopexy may be performed to create chorioretinal scars and decrease the risk of retinal detachment.

Postoperative Care and Complications

- Postoperative complications include retinal detachment, glaucoma, IOL decentration, dyscoria, uveitis, synechia, and vitreous entrapment in the corneal incision.
- If surgical removal is not possible, the lens is best kept in the vitreous chamber. Once there, topical miotics, such as 2% pilocarpine or 0.005% latanoprost, can be used in an effort to trap the lens behind the iris. Follow-up care should include periodic determination of intraocular pressure. Lenses that are luxated and not removed will become cataractous.
- Examine the contralateral eye in instances of primary lens luxation and if unstable, instruct the owner what to watch for as a sign of lens luxation. Alternately, some ophthalmic surgeons will offer to remove a lens due to instability, preferring to replace it with a sulcus-fixated IOL.
- If the lens luxation is secondary to buphthalmia and chronic glaucoma, therapy is directed toward the glaucoma (see Chapter 137).

Prevention

- Examine the contralateral eye carefully for evidence of lens subluxation, such as a deep or shallow anterior chamber, iris tremor, aphakic crescent, or vitreous in the anterior chamber.
- Advise owners to watch the animal's eye at risk for signs of lens luxation and to call immediately if noted.

Chapter

136 Diseases of the Uvea

David A. Wilkie

ANATOMY AND PHYSIOLOGY

The uvea is the middle or vascular tunic of the eye. It is covered externally by the fibrous tunic and provides much of the blood supply to the inner nervous tunic (retina) (see Chapter 131).

The uvea is composed of *three regions:* the iris, the ciliary body, and the choroid (see Chapter 138).

Iris

- The iris is the anterior most portion of the uvea. It forms an incomplete diaphragm between the anterior and the posterior chambers and regulates the amount of light entering the posterior portions of the eye.
- The color of the iris varies among species, within species, and even within the same animal. Heterochromia is a different color within or between irides.
- The iris contains a sphincter muscle controlled by parasympathetic fibers that travel from the Edinger-Westphal nucleus with the oculomotor nerve (cranial nerve 3) to the ciliary ganglion, where they synapse. The action of the sphincter muscle causes miosis. Intraocular inflammation will also result in contraction of the sphincter muscle. This results in the miosis and pain seen in anterior uveitis. The sphincter muscle can be paralyzed with parasympatholytic agents, causing dilation of the pupil. This is used clinically to better see the posterior portions of the eye and to treat anterior uveitis.

▼ ***Key Point*** The diagnostic parasympatholytic agent of choice is tropicamide (Mydriacyl), whereas the therapeutic parasympatholytic agent of choice is atropine 1%.

- The iris dilator muscle fibers are radially oriented and lie along the base of the posterior epithelium. The dilator muscle is under sympathetic control in mammals. The sympathetic fibers course along the spinal cord to T1 to T3, leave in the ventral roots, course through the anterior mediastinum, and run anteriorly with the internal carotid to the cranial cervical ganglion, where they synapse. They then travel to the eye in association with the ocular vascular supply (see Chapter 141). The action of the dilator muscle is to produce mydriasis.

Ciliary Body

The ciliary body is divided into the pars plicata and pars plana and is located posterior to the iris. The ciliary processes are folds of the ciliary epithelium with a vascular core and are the source of aqueous humor. The ciliary body is also the origin of the lenticular zonules, which serve to anchor the lens. Through these zonules and the ciliary musculature, accommodation occurs.

Choroid

The choroid is continuous anteriorly with the ciliary body and extends posteriorly to the optic nerve. The choroid lies external to the retina and supplies nutrition to the outer portions (rods and cones) of the retina in the dog and cat. The tapetum is located in the dorsal portion of the fundus and lies within the choroid (see Chapter 138).

CONGENITAL ABNORMALITIES

Persistent Pupillary Membranes

Etiology

These are persistent remnants of fetal blood vessels in the anterior chamber that originate from the collarette region of the anterior iris face. They may be seen alone or in association with other congenital abnormalities. Although persistent pupillary membranes (PPMs) are felt to have an inherited component (especially in basenjis), the mode of inheritance is not established in most affected breeds.

Clinical Signs

The clinical signs vary depending on where the PPM strands attach. In general, the color of the PPM will be

similar to that of the iris. PPMs that bridge iris to iris generally result in no clinical signs, whereas those attaching to the anterior lens capsule or corneal endothelium are associated with focal opacities of these structures. Differentiate PPMs from anterior and posterior synechiae when attaching to the cornea or lens, respectively.

Diagnosis

Base the diagnosis on the clinical signs and breed. Perform a complete ophthalmic examination to detect other congenital ocular abnormalities.

Treatment

There is no treatment required and the lesion is nonprogressive. Council breeders about possible inheritance and discourage breeding of affected basenjis and corgis.

Coloboma

Etiology

A coloboma is a developmental anomaly in which a portion of the tissue, in this case the uvea, is absent. Colobomas can affect all three portions of the uvea and are often associated with other congenital anomalies such as PPMs, lens coloboma, or retinal detachment. Colobomas can be inherited or the result of a toxic insult to the developing eye during gestation.

Clinical Signs

Depending on which portion of the uvea is affected, clinical signs will vary. Colobomas of the iris result in dyscoria and may be associated with PPMs or lenticular abnormalities. Colobomas of the ciliary body or choroid are generally not noted by the owner and are seen on a routine ophthalmic examination or are present as a result of other congenital abnormalities or from secondary changes such as retinal detachment. Posterior segment colobomas are seen as part of the collie eye anomaly (CEA) (see Chapter 138).

Diagnosis

Base the diagnosis on the clinical signs and breed. Perform a complete ophthalmic examination to detect other congenital ocular abnormalities.

Treatment

There is no treatment required and the lesion is nonprogressive. Council breeders about possible inheritance and discourage breeding of affected dogs.

Uveal Hypoplasia or Aniridia

A lack of complete development or absence of the affected portion of the uvea, iris hypoplasia, or aniridia is rare and usually associated with other congenital ocular abnormalities. Choroidal coloboma occurs in several breeds of dogs and is seen as part of CEA.

UVEAL CYST

Etiology

Uveal cysts arise from the posterior iris or ciliary body and can remain attached or break free and float in the anterior chamber. They arise as a primary disorder in certain breeds (golden retriever, Boston terrier) or can be secondary to anterior uveitis.

Clinical Signs

Uveal cysts are pigmented, attached to the posterior iris, or free floating in the anterior chamber. They can rupture, depositing on the ventral corneal endothelium or anterior lens capsule. In dogs, iris cysts will transilluminate, facilitating diagnosis. In cats, however, cysts are more densely pigmented, often remain attached, and may not transilluminate, making diagnosis more difficult.

Diagnosis

Base the diagnosis on the clinical signs and breed. A free-floating, pigmented mass that transilluminates is a cyst. If the mass remains attached or fails to transilluminate, it must be distinguished from a uveal melanoma. Use ocular ultrasound to demonstrate the hollow appearance of a cyst and distinguish between a cyst and a melanoma.

Treatment

If the cyst is not interfering with vision, no treatment is required. Large or multiple cysts may require treatment if vision becomes impaired. In addition, in cats, large cysts can be associated with an increase in intraocular pressure (IOP), requiring intervention. Treatment includes mechanical aspiration of the cyst from the anterior chamber or diode or Nd:YAG laser photoablation of the cyst, resulting in the rupture and/or resorption of the cyst.

IRIS ATROPHY

Etiology

Iris atrophy is seen most often in aged animals, especially toy-breed dogs and cats. Iris atrophy has been classified as primary, senile, and secondary. *Primary iris atrophy* is seen in Siamese cats, miniature schnauzers, poodles, and Chihuahuas. This is a slow progressive atrophy of the iris. *Senile iris atrophy* occurs in aged animals of all species and breeds. The distinction between these two forms of atrophy may not be significant. *Secondary iris atrophy* occurs as a sequela to chronic glaucoma, uveitis, or ocular trauma.

Clinical Signs

If the iris musculature is affected, the pupillary light response may be incomplete or absent and anisocoria may be noted. Atrophy of the pupil margin results in dyscoria. Thinning of the iris stroma appears as a focal color change or, if complete, as a hole in the iris.

Diagnosis

The diagnosis is made based on the clinical appearance and signalment. The differential diagnosis includes other internal or external causes of dyscoria, anisocoria, incomplete pupillary light response, or iris color changes. Measurement of IOP, a complete ophthalmic examination, and determination of afferent-versus-efferent pupil response abnormalities are all indicated with iris atrophy (see Chapter 141).

Treatment

No treatment is required. However, differentiate iris atrophy from other pupillary response abnormalities.

ANTERIOR UVEITIS

Uveitis is inflammation of the uvea and is divided into anterior (iris and ciliary body), posterior (choroid), and panuveitis (all three portions of the uvea). Posterior uveitis is often called chorioretinitis because of the intimate association between the choroid and the retina (see Chapter 138). Anterior uveitis is associated with pain and can be the result of both ocular and systemic factors. Because many etiologies of uveitis are systemic, it is essential to ascertain the reason for the inflammation when presented with an animal with anterior or posterior uveitis (Table 136-1).

Table 136-1. SYSTEMIC INFECTIOUS ETIOLOGIES OF ANTERIOR UVEITIS

Mycotic—blastomycosis, cryptococcosis, histoplasmosis, coccidioidomycosis, aspergillosis, other
Rickettsia—ehrlichiosis, Rocky Mountain spotted fever
Toxoplasmosis
Feline immunodeficiency virus, feline leukemia virus, feline infectious peritonitis
Lyme disease
Bacteremia/septicemia
Bartonellosis
Brucellosis
Aberrant parasitic migration—heartworm, roundworm, hookworm, etc.
Canine distemper
Infectious canine hepatitis
Protothecosis
Mycobacteriosis
Leptospirosis
Leishmaniasis

▼ ***Key Point*** If no primary ocular etiology of anterior uveitis can be ascertained, consider systemic disease. This approach applies whether the uveitis is unilateral or bilateral.

Etiology

Corneal Ulceration

Corneal ulceration often results in reflex anterior uveitis. Uveitis occurs due to stimulation of the ophthalmic branch of cranial nerve 5 (CN5) and does not indicate infectious keratitis.

Trauma

Trauma can result in anterior uveitis due to a direct penetration of the globe or a concussive effect. Uveitis may be associated with other ophthalmic abnormalities, such as corneal ulceration, hyphema, lens luxation, retinal detachment, proptosis, and globe rupture. See appropriate chapters for further discussion of these abnormalities.

Infection

Infectious causes of anterior uveitis are numerous and include bacteria, fungi, rickettsia, and protozoal organisms (see Table 136-1). These organisms result in anterior uveitis by direct infections of the eye, immune-mediated responses, or circulating endotoxins. Many of these infectious agents also cause posterior segment (retina, choroid) involvement (see Chapter 138). Direct infection of the eye can occur from penetrating trauma or blood-borne infection. Although anterior uveitis is commonly associated with infectious causes, the organism itself is generally not present within the anterior segment of the eye.

Lens-Induced Anterior Uveitis

Lens-induced anterior uveitis results from traumatic or spontaneous rupture of the lens capsule or from leakage of the lens material through an intact capsule as noted with a hypermature, resorbing cataract. Lens protein is antigenic and, if released, will result in mild to severe anterior uveitis. Cataracts are discussed in Chapter 135.

Autoimmune Anterior Uveitis

Autoimmune anterior uveitis, unassociated with lens protein leakage, is observed in the uveodermatologic syndrome (formerly Vogt-Koyanagi-Harada syndrome). This syndrome is observed in dogs and results in anterior and posterior uveitis, poliosis (depigmentation of the hair), and vitiligo (depigmentation of the skin). See Chapter 48 for discussion of the dermatologic manifestations. In addition, an immune-mediate chorioretinitis is seen in the golden retriever, resulting in bullous retinal detachment.

Table 136-2. CLINICAL SIGNS OF ANTERIOR UVEITIS

Discharge—serous, mucoid	Redness—conjunctiva, iris
Blepharospasm	Photophobia
Miosis	Hypotony
Corneal edema	Aqueous flare/fibrin
Keratitic precipitates	Hyphema
Hypopyon	Blindness

Pigmentary Uveitis

Pigmentary uveitis is seen in the golden retriever and can be unilateral initially but will become bilateral. The iris appears hyperpigmented with pigment deposition on the anterior lens capsule. Aqueous flare with pigment-containing cells in the anterior chamber is seen on biomicroscopy. Posterior synechiae, cataract, and secondary glaucoma are common sequelae. Uveal cysts may also be noted in this disease but should be differentiated from the cysts that are unassociated with uveitis (see under "Uveal Cyst").

Clinical Signs (Table 136-2)

- *Miosis* is a smaller than normal pupil due to contraction of the iris sphincter muscle. Spasm of the iris sphincter muscle, along with the ciliary body musculature, results in pain, noted clinically as photophobia (intolerance of light).
- *Flare* results from a breakdown in the blood-aqueous humor barrier and a subsequent leakage of plasma protein (with or without cells) into the eye. It is observed clinically as a haze in the anterior chamber (Fig. 136-1).
- *Hypotony* is a decrease in the IOP below the normal range of 15 to 25 mm Hg due to decrease in the production of aqueous humor.
- *Cells* are released into the anterior chamber in severe uveitis. The inflammatory cellular response can be neutrophilic or granulomatous. In addition, red blood cells (hyphema) or neoplastic cells can enter the anterior chamber. Cells can appear suspended in the aqueous humor, settled in the ventral anterior chamber (hypopyon), or as keratitic precipitates. Keratitic precipitates appear as focal deposits on the ventral corneal endothelium. They are associated with a granulomatous uveitis and are accumulations of protein, macrophages, and lymphocytes and plasma cells. In the dog they are most often seen in association with lens-induced uveitis or disseminated mycosis, and in cats they are in association with feline infectious peritonitis or toxoplasmosis.
- *Hyperemia* or redness may be seen on examination of the conjunctival, episcleral, and iris blood vessels in eyes with anterior uveitis.
- *Corneal edema,* associated with anterior uveitis, occurs from endothelial cell dysfunction or loss and is diffuse in nature. Diffuse corneal edema indicates intraocular disease and the need for measurement of IOP. If the edema is of a focal nature, the cornea should be stained with fluorescein to rule out a corneal ulcer with secondary anterior uveitis.

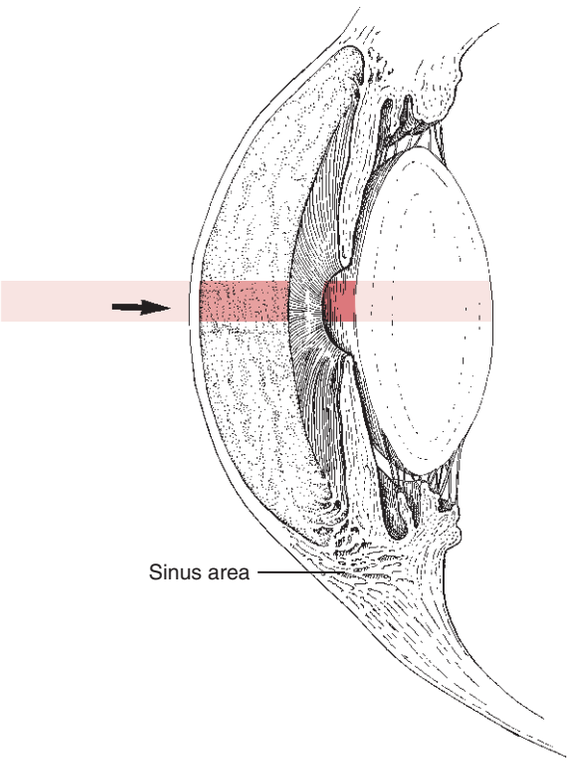

Figure 136-1. Using a bright, focused light source, aqueous flare is seen as a continuation of the light beam through the normally dark-appearing anterior chamber.

Diagnosis

History

A complete history is essential to detect previous or concurrent problems that may be associated with anterior uveitis. The history includes both ophthalmic and systemic problems.

Physical Examination

A complete physical examination is an essential part of the diagnostic evaluation of a patient with anterior uveitis. Palpate all external lymph nodes, auscultate the cardiopulmonary system, palpate the abdomen, and determine the body temperature.

Penlight Examination

A penlight examination is performed to evaluate pupil size, symmetry, and response to light. Assess the severity and character of the uveitis by the degree of aqueous flare and the cellular response. Assess the clarity of the clear media of the eye, cornea, aqueous humor, lens,

and vitreous. Evaluation of flare requires a bright focal light source, and a Finnoff transilluminator works well for this purpose. All abnormalities are described and diagramed in the medical record.

Tonometry

Tonometry is the determination of the IOP. Eyes with anterior uveitis have a decreased IOP (hypotony). A normal or elevated IOP indicates the potential for, or the presence of, glaucoma. While previous recommendations suggested the Schiøtz tonometer was the most cost-effective tonometer for private practice, the Tonopen (Dan Scott and Associates) is a more portable, accurate, and user-friendly tonometer and will result in more frequent and more accurate IOP readings. It is also easier to use on painful eyes (see Chapter 137).

▼ ***Key Point*** The clinical signs of anterior uveitis and glaucoma can be similar. Both diseases can be present together in the same eye. Determination of IOP is therefore essential.

Fundic Examination

Perform fundic examination, either by direct or indirect ophthalmoscopy, to determine the presence or absence of posterior segment involvement. Anterior uveitis in combination with posterior uveitis is termed *panuveitis* and is strongly suggestive of systemic disease, especially those infectious in nature (see Table 136-1). Posterior segment changes indicating active inflammation include retinal hemorrhage, retinal detachment, vasculitis, and infiltration by granulomatous or neoplastic cells. If the posterior lesions are chronic, they will appear as tapetal hyper-reflectivity, pigment clumping and depigmentation of the non-tapetal region, and atrophy of the retinal vasculature (see Chapter 138).

Fluorescein Stain of Cornea

Perform fluorescein stain to examine for a corneal ulcer. Corneal ulcers can result in a secondary anterior uveitis. If detected, the ulcer must be characterized with regards to depth, severity, and infection (see Chapter 134). In addition, determine the etiology and treat appropriately. Anterior uveitis, resulting from a corneal ulcer, resolves once the ulcer is healed.

Routine Laboratory Tests and Radiography

- Perform *biochemical profile, urinalysis,* and *complete blood count* on all patients with anterior uveitis of unknown cause and patients with concomitant systemic abnormalities.
- Perform *serology,* for the specific infectious diseases listed in Table 136-1, as indicated by the findings of the history, physical examination, ophthalmic examination, biochemical profile, urinalysis, and complete blood count.
- *Radiograph* the thorax and abdomen to evaluate for systemic mycosis, disseminated neoplasia, or other organ system involvement.

Cytology

- Cytology of intraocular or extraocular samples may be indicated in selected instances. Intraocular samples include both the aqueous and the vitreous humors. Of these, the vitreous humor sample is the most diagnostic but also the most traumatic to obtain. Anterior chamber samples are frequently not diagnostic. The indication for vitreocentesis is panuveitis in a blind eye for which the diagnosis cannot be obtained by alternate methods.
- Using general anesthesia, insert a 20-gauge needle 4 to 5 mm posterior to the corneal-scleral junction superior temporally.
- Direct the needle toward the center of the eye and aspirate 0.5 to 1.0 ml of fluid for culture and cytology.
- Extraocular cytology includes aspirates of regional lymph nodes or mass lesions.

Treatment

The treatment of anterior uveitis includes nonspecific approaches directed toward decreasing the inflammation and sequelae and specific ones directed toward eliminating the underlying etiology when one has been identified (Table 136-3).

Mydriatic-Cycloplegics

Use mydriatic-cycloplegics to paralyze the iris sphincter and ciliary body musculature. This effect will decrease the pain associated with anterior uveitis and the tendency toward formation of posterior synechia. The mydriatic-cycloplegic of choice is topical 1% atropine (parasympatholytic). Administer atropine to effect (pupil dilation), but do not exceed a treatment frequency of 4 times per day. This results in maximum drug effects with minimal side effects.

▼ ***Key Point*** Atropine is contraindicated in anterior uveitis when accompanied by secondary glaucoma.

Topical Anti-inflammatory Drugs

Topical anti-inflammatory drugs include both corticosteroids and nonsteroidal agents (see Table 136-3). Topical medication does not penetrate beyond the iris and ciliary body. Use only for problems of the anterior segment of the eye.

Corticosteroids

The topical corticosteroid of choice for the treatment of anterior uveitis is 1% prednisolone acetate ophthalmic suspension (Econopred). This agent achieves

Table 136-3. DOSAGES OF COMMONLY USED OCULAR ANTI-INFLAMMATORY AGENTS

Drugs	Trade Names	Dosages
Topical		
Corticosteroids		
1.00% Prednisolone acetate suspension	Econopred Plus	1–6×/d
0.10% Dexamethasone solution	Decadron	1–6×/d
0.05% Dexamethasone ointment	Decadron	1–6×/d
NSAIDs		
0.03% Flurbiprofen	Ocufen	4×/d
1.00% Suprofen	Profenal	4×/d
0.10% Diclofenac	Voltaren	4×/d
Atropine		
1.00% Atropine		1–4×/d
Systemic		
Corticosteroids		
Prednisolone/prednisone		Dog
	Immunosuppressive	1.0 mg/kg PO q12h × 7–14d, then taper
	Anti-inflammatory	0.5 mg/kg PO q12h × 3–5d, then taper
NSAIDs		
Flunixin meglumine	Banamine	Dog: 0.25–0.50 mg/kg IV single dose Cat: Do not use
Carprofen	Rimadyl	Dog: 2.0 mg/kg PO q12h
Etodolac	EtoGesic	Dog: 10–15 mg/kg PO q24h, monitor STT
Immunosuppressive		
Azathioprine	Imuran	Dog: 2.2 mg/kg PO q24h × 5d, then taper
Cyclophosphamide	Cytoxan	Dog: 50 mg/m^2 PO q24h × 4d/wk
Cyclosporine	Atopica, Neoral	Dog: 5–10 mg/kg PO q12–24h

NSAID, nonsteroidal anti-inflammatory drug; STT, Schirmertear test.

the highest intraocular level of the ophthalmic corticosteroids. If unavailable, 0.1% dexamethasone solution or 0.05% dexamethasone ointment can be applied. The frequency of treatment varies according to the severity of the uveitis, ranging from 1 to 6 times a day.

▼ ***Key Point*** Topical corticosteroids delay healing and potentiate infection and collagenase ulceration. Topical corticosteroids are contraindicated for anterior uveitis associated with corneal ulceration.

Topical corticosteroids are also absorbed systemically and alter adrenal and hepatic function.

Nonsteroidal Anti-inflammatory Drugs

The indications for topical nonsteroidal anti-inflammatory ophthalmic drugs are similar to those for topical corticosteroids. They are used as supplements to topical corticosteroids or as substitutes when topical corticosteroids are contraindicated (e.g., in diabetes mellitus). As with topical corticosteroids, nonsteroidal agents may delay the healing of a corneal ulcer. Administer 4 times a day.

Systemic Anti-inflammatory Drugs

Systemic anti-inflammatory drugs include corticosteroids, nonsteroidal agents, and immunosuppressive drugs (see Table 136-3).

Corticosteroids

Systemic corticosteroids are indicated in the management of non-infectious posterior uveitis and in severe anterior uveitis as a supplement to topical corticosteroids. The dosage is dependent on the underlying disease. An immunosuppressive dose is indicated for animals with uveodermatologic syndrome, and an anti-inflammatory dose is indicated for most other cases (see Table 136-3). The side effects of systemic corticosteroids include polyphagia, polyuria, or polydipsia; infection potentiation; altered carbohydrate metabolism; and adrenal suppression. Therapy with systemic corticosteroids begins at a high dose to achieve a response followed by a tapered dose to maintain effect and to decrease adverse side effects.

Nonsteroidal Anti-inflammatory Drugs

Systemic nonsteroidal anti-inflammatory drugs (NSAIDs) include aspirin, flunixin meglumine, carprofen, etodolac,

and others (see Table 136-3). They are indicated to decrease inflammation and facilitate pupil dilation. In small animal ophthalmology, flunixin meglumine is administered as a single dose (0.25–0.5 mg/kg IV) prior to ocular surgery to decrease post-surgical ocular inflammation. Side effects of NSAIDs include gastrointestinal ulceration and hemorrhage and acute renal papillary necrosis. Do not use systemic NSAIDs in combination with systemic corticosteroids. Use with caution in patients with questionable renal function. In addition, etodolac is associated with iatrogenic keratoconjunctivitis sicca.

Immunosuppressive Drugs

Systemic immunosuppressive therapy may be required when animals fail to respond to corticosteroids or NSAIDs or when the required levels of these drugs result in systemic toxicity.

Specific

Specific therapy is dependent on the etiology of the uveitis. See appropriate chapters for treatment of the systemic diseases that cause anterior uveitis.

Sequelae

- ***Secondary glaucoma*** results from the obstruction of the outflow pathway of the aqueous humor. This can occur at the pupil from posterior synechia, at the drainage angle from anterior synechia and preiridal fibrovascular membrane formation, or in the trabecular meshwork from deposits of inflammatory debris and fibrosis. Control of this type of secondary glaucoma through medical therapy is often extremely difficult to achieve (see Chapter 137).
- ***Synechiae*** are adhesions from the iris to adjacent structures, such as the cornea or lens. Synechiae can result in abnormal pupillary light response, misshapen pupil, glaucoma, pigmentation of the cornea or lens, and blindness.
- ***Cataracts*** can occur subsequent to anterior uveitis. The lens is dependent on the aqueous humor for nutrients and waste product removal. Anterior uveitis results in altered lens metabolism and a buildup of inflammatory by-products that may cause opacification of the lens and capsule (cataract) (see Chapter 135).
- ***Corneal edema*** occurs from the failure of the corneal endothelial cell pump or barrier. Corneal endothelial cells are responsible for the maintenance of corneal deturgescence, which is essential to corneal transparency. Endothelial cells need the aqueous humor for nutrients and waste product removal. Anterior uveitis may alter the function of these cells, resulting in diffuse corneal edema. Corneal endothelial cells in the adult dog and cat have little regenerative capabilities; thus damage may be permanent.
- ***Blindness*** secondary to severe anterior uveitis is common and results from secondary glaucoma, cataract formation, synechia, pigment migration, or posterior segment (retina, choroid) changes.
- ***Phthisis bulbi*** occurs as a result of atrophy of the ciliary body and a sustained decrease in aqueous humor production. Chronic hypotony (i.e., low IOP) results, and the eye decreases in size.

Prevention

Although prevention of anterior uveitis is usually not possible, the sequelae of anterior uveitis can be prevented by accurate diagnosis and appropriate and rapid treatment. Therapy directed toward the etiology not only will aid the management of the ocular disease but also may prevent the serious and life-threatening complications of the systemic disease.

UVEAL NEOPLASIA

Uveal neoplasms can be primary or secondary. Primary neoplasms include iris, ciliary body and choroidal melanomas, and ciliary body adenoma or adenocarcinoma. Secondary neoplasms include lymphoma and metastatic carcinomas (most common) or any disseminated neoplasm. Intraocular neoplasms result in damage to the eye through displacement of normal ocular structures, causing lens luxation, dyscoria, and retinal detachment. In addition to an intraocular mass lesion, glaucoma, uveitis, and hyphema are the most common presenting signs of intraocular neoplasia. In general, secondary neoplasms are more inflammatory and destructive as compared with primary neoplasms.

Primary Neoplasia

Of the primary neoplasms, anterior uveal melanoma is most common. Tumor behavior varies depending on the species.

Canine Melanoma

Canine anterior uveal melanomas are generally benign in nature with less than 5% metastatic potential. In addition, it appears that Labrador and golden retrievers and German shepherds may be predisposed to iridal melanomas. In these breeds, the neoplasm may arise in a juvenile dog, and a suggestion of inheritance has been proposed. Breeding of affected Labrador and golden retrievers should be discouraged. The best criterion for predicting malignancy of intraocular melanoma in the dog appears to be the mitotic index.

Feline Melanoma

In contrast to the dog, feline uveal melanoma has been reported to metastasize in 60% of affected cats. Pigmented lesions of the feline iris or ciliary body,

especially those that are raised, displacing adjacent structures or resulting in other intraocular damage, should be removed by enucleation. In addition, perform a complete systemic evaluation including thoracic and abdominal radiographs and palpation of regional lymph nodes. No information exists to suggest that enucleation of these affected eyes affects the rate of metastasis, favorably or unfavorably.

Feline Spindle Cell Sarcoma

Intraocular spindle cell sarcoma can occur in the feline eye as a sequela to ocular trauma or uveitis. The period following ocular trauma or uveitis to the time of diagnosis of intraocular spindle cell sarcoma varies from 5 months to 12 years. These tumors are locally invasive, extending transsclerally or traveling along the optic nerve, and have the potential for metastasis. Enucleation or possibly orbital exenteration is the treatment of choice. Consider enucleation of severely traumatized or chronically inflamed, blind feline eyes to avoid the possible development of an intraocular spindle cell sarcoma.

Other Tumors

In addition to primary intraocular melanoma, ciliary body adenoma and adenocarcinoma, hemangiosarcoma, and astrocytoma have been reported in the dog and cat. These are often slow to metastasize but can cause intraocular damage as they enlarge.

Treatment

The treatment of primary ocular neoplasms varies according to the species, location, and severity of the neoplasm, rate of progression, presence or absence of vision, IOP, and availability of treatment modalities. Enucleation, excisional biopsy with preservation of the globe and/or vision, and laser ablation are all used for primary intraocular neoplasms. Small masses with no associated secondary complications can be documented, followed, and then treated if found to be progressive. In addition, an en bloc excision in the form of a sector iridectomy or iridocyclectomy can be used to excise a mass, preserve vision, and obtain a biopsy. This is a referral procedure. Laser surgery is used most often for pigmented melanomas and uses a diode or Nd:YAG laser to achieve a thermal effect resulting in coagulation necrosis of the tumor mass.

Secondary Neoplasia

Lymphoma is the most common intraocular neoplasm in the dog and cat. In addition, adenocarcinoma, hemangiosarcoma, and several other neoplasms metastasize to the eye. The most common ocular abnormalities seen in association with secondary neoplasms include glaucoma, uveitis, hyphema, retinal detachment, and lens luxation. Treatment should be directed at finding the primary source of the neoplasia followed by systemic therapy, including chemotherapy, surgery, and radiation. Additional therapy might include topical ophthalmic anti-inflammatory drugs and atropine for uveitis or topical and systemic medications aimed at reducing the IOP if secondary glaucoma is present. Topical therapy is often unrewarding. Systemic treatment of the primary problem usually results in a greater ocular response. If the eye is painful, blind, or nonresponsive to systemic treatment, perform enucleation.

Chapter

137 Glaucoma

David A. Wilkie

Glaucoma is an increase in the intraocular pressure (IOP) beyond that compatible with maintenance of normal ocular physiology and function.

ANATOMY

See Chapter 131.

ETIOLOGY

Primary Glaucoma

Primary glaucoma is not associated with any other event or problem within the eye. It is usually breed related and often hereditary in nature. A partial list of predisposed breeds is given in Table 137-1.

▼ ***Key Point*** When glaucoma is primary, the opposite, unaffected eye may also develop glaucoma. Studies indicate an incidence of 50% involvement of the contralateral eye within 2 years following the diagnosis of glaucoma in the first eye.

Secondary Glaucoma

Secondary glaucoma is the result of an antecedent event within the eye. The etiologies of secondary glaucoma include anterior uveitis, anterior lens luxation, hyphema, intraocular neoplasia, chronic retinal detachment, pre-iridal fibrovascular membrane, and trauma.

- *Anterior uveitis* can cause glaucoma through obstruction of the flow of aqueous humor. This results from peripheral anterior or posterior synechiae, inflammatory debris in the iridocorneal angle, or the formation of a pre-iridal fibrovascular membrane. Anterior uveitis is discussed in Chapter 136.
- *Anterior lens luxation* can obstruct the flow of aqueous humor from the posterior to the anterior chamber or to the iridocorneal angle. The etiologies of anterior lens luxation include hereditary (in terriers), intraocular neoplasia, anterior uveitis, and trauma (see Chapter 135). Anterior lens luxation can also result from chronic glaucoma with enlargement of the globe (buphthalmos) and tearing of the lens zonules.
- *Intraocular* neoplasia, whether primary or secondary, can block the flow of aqueous humor through shedding of neoplastic cells into the iridocorneal angle or displacing of normal intraocular structures (see Chapter 136). In addition, intraocular neoplasia can result in the formation of a pre-iridal fibrovascular membrane.
- *Hyphema* can result from trauma, systemic hypertension, congenital ocular anomalies, vascular disorders, or bleeding disorders (see Chapter 136). Red blood cells can obstruct the trabecular meshwork of the iridocorneal angle resulting in ghost cell glaucoma.
- *Trauma* can result in anterior uveitis, anterior lens luxation, hyphema, or damage to the iridocorneal angle, all of which may lead to secondary glaucoma.
- *Retinal detachment,* when chronic, may be associated with proliferation of a pre-iridal fibrovascular membrane arising from the anterior iris stroma and resulting in anterior and posterior synechiae and iridocorneal angle obstruction. Chronic uveitis and intraocular neoplasia can result in a similar change.

CLINICAL SIGNS

- *Acute glaucoma* is a true medical and ultimately a surgical emergency. The diagnosis is made based on history and clinical signs (Table 137-2). If in doubt, err on the side of a diagnosis of acute rather than chronic glaucoma.
- *Chronic glaucoma* implies ophthalmic changes that cause the irreversible loss of vision (Table 137-3). The clinical changes most indicative of chronic glaucoma are retinal and optic nerve degeneration and buphthalmos.

DIAGNOSIS

▼ ***Key Point*** Although the history, breed, and clinical signs are all important in the diagnosis of glaucoma, definitive diagnosis can be made only through measurement of the IOP.

Table 137-1. BREEDS PREDISPOSED TO PRIMARY GLAUCOMA

American and English cocker spaniel	Malamute
English spinger spaniel	Chow Chow

Blepharospasm

Table 137-3. CLINICAL SIGNS OF CHRONIC GLAUCOMA

Episcleral hyperemia	Epiphora
Diffuse corneal edema	Blepharospasm
Corneal striae	Retinal degeneration
Dilated pupil	Optic nerve cupping
Absent pupillary light response	Buphthalmia
Absent menace response	

- IOP measurement requires a tonometer. Digital tonometry is an inaccurate and unreliable method of IOP determination. While previous recommendations suggested that the Schiøtz tonometer was the most cost-effective tonometer for private practice, the Tonopen (Mentor O&O, Inc.) is a more portable, accurate, and user-friendly tonometer and will result in more frequent and more accurate intraocular pressure readings. This in turn will improve the veterinarian's ability to make an early diagnosis and more accurately assess response to treatment (see Chapter 131). The Tonopen is lightweight, portable, accurate, and self-calibrating, and it averages several readings and gives a percentage error to ensure accuracy. In addition, the small foot plate allows this tonometer to be used on painful eyes in less cooperative patients because only a small area of cornea is required to obtain a reading, and the position of the patient's head is not related to obtaining the reading. Normal IOP in the dog and cat is 15 to 25 mm Hg, although most ophthalmologists are concerned with when IOP exceeds 20 mm Hg.
- Once the diagnosis of glaucoma is made based on IOP, establish the etiology (i.e., primary versus secondary) and the degree of ocular damage. Depending on the history and associated ocular changes, the glaucoma can be classified as either acute or chronic.

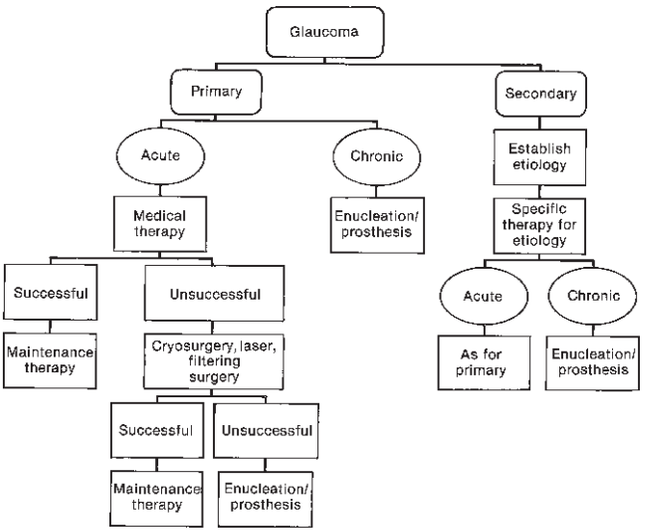

Figure 137-1. Treatment algorithm for glaucoma.

TREATMENT

▼ ***Key Point*** In order to treat glaucoma appropriately, answer two specific questions (Fig. 137-1). Is the glaucoma primary or secondary? Is the glaucoma acute or chronic?

- Treatment can be grouped into medical and surgical approaches. If the glaucoma is acute, a return of a portion of, or all of, the animal's vision is then possible. In acute glaucoma, immediate aggressive medical therapy is required to reduce the IOP to within normal range. Failure of medical therapy to lower and maintain IOP at a normal level indicates the need for surgical intervention and the possible referral to a veterinary ophthalmologist.
- The most appropriate treatment for chronic glaucoma is surgery, the goal of which is to reduce the IOP in order to relieve discomfort. Medical therapy of chronic glaucoma is neither effective nor cost-

Table 137-4. MEDICAL TREATMENT OF ACUTE GLAUCOMA

Drug/Concentration	Trade Name	Dose
Systemic		
Osmotic Drugs		
Mannitol		0.5–1.0 g/kg, IV
Carbonic Anhydrase Inhibitors		
Dichlorphenamide	Daranide	2–4 mg/kg, q8–12h, PO
Methazolamide	Neptazane	2–4 mg/kg, q8–12h, PO
Topical		
Carbonic Anhydrase Inhibitors		
Dorzolamide 2%	Trusopt	q8–12h
Dorzolamide 2% : timolol 0.5%	Cosopt	q8–12h
Parasympathomimetics		
Pilocarpine 2%	Isopto Carpine	q8–12h
Sympathomimetics		
Epinephrine 1%		q8–12h
Dipivefrin HCl 0.1%	Propine	q8–12h
Combination		
Pilocarpine 2% : epinephrine 1%	E-Pilo-2	q8–12h
Sympatholytics		
Timolol maleate 0.5%	Timoptic	q8–12h
Prostaglandins		
Latanoprost 0.005%	Xalatan	q12–24h

effective over time. The surgery of choice is either placement of an intraocular silicone prosthesis or an enucleation.

- Intravitreal injection of gentamicin or lidofovir (Vistide) designed to destroy the intraocular tissues is used by some to reduce intraocular pressure. This results in uveitis, cataract, and often phthisis bulbi and is cosmetically unappealing and unpredictable.

Medical

Medical therapy of acute glaucoma includes some, or possibly all, of the following agents (Table 137-4). The choice of medication varies according to the severity of the glaucoma, the etiology, and the response to the initial therapy.

Osmotic Drugs

- *Osmotic agents* act to dehydrate the vitreous and aqueous humors and thereby decrease the IOP. In order to be effective, they require an intact blood-eye barrier and therefore may not work well in eyes with uveitis or hyphema.

▼ ***Key Point*** One of the initial drugs of choice for rapidly decreasing IOP in the treatment of acute glaucoma is an osmotic agent. The osmotic agent of choice is 20% mannitol, administered intravenously (see Table 137-4).

- Withhold water from the animal for 3 to 4 hours following osmotic administration. The IOP begins decreasing within 20 minutes, with the maximum effect at 2 hours—the duration of effect is approximately 6 hours. An alternative osmotic agent is oral glycerin, but emesis is a frequent side effect.

Carbonic Anhydrase Inhibitors

- *Carbonic anhydrase inhibitors* (CAIs) work to decrease the IOP by blocking the enzyme responsible for the active production of aqueous humor. The systemic CAIs of choice, based on their efficacy and low frequency of side effects, are dichlorphenamide and methazolamide. Administer orally q8–12h (see Table 137-4).
- In addition to the eye, carbonic anhydrase can be found in the kidney, red blood cells, and lungs. Potential side effects of oral CAIs include metabolic acidosis and hypokalemia, manifested as panting, depression, vomiting, diarrhea, and collapse. If any of these side effects are noted, discontinue CAI therapy. Symptoms should resolve within 24 hours, and therapy can be reinstituted at a decreased dosage.
- A topical CAI, dorzolamide 2% (Trusopt, Merck & Co.) and dorzolamide 2%:timolol maleate 0.5% (Cosopt, Merck & Co), are also available. Administer q8–12h; this drug does not cause the systemic side effects seen with oral CAI administration. Topical CAIs are indicated for treatment of glaucoma and

have also become the drug of choice for prophylactic treatment of the contralateral eye.

Autonomic Drugs

- *Autonomic agents* include parasympathomimetics, sympathomimetics, and sympatholytics. Administer topically q8–12h (see Table 137-4). These drugs are synergistic and can, if needed, be applied to the same eye, provided their administration is 5 to 10 minutes apart. In my opinion, none of these is as efficacious in the dog as the newer glaucoma agents such as dorzolamide and latanoprost.

Parasympathomimetics

- *Parasympathomimetics* result in contraction of the iris sphincter and ciliary body musculature. Contraction of the longitudinal ciliary musculature increases the outflow of aqueous humor. In addition, parasympathomimetics result in vasodilation of the conjunctiva and increased aqueous humor protein and may reactivate or exacerbate iritis.
- The parasympathomimetic of choice is 2% pilocarpine (see Table 137-4). Transient topical irritation is often exhibited following administration but resolves 24 to 48 hours following initiation of therapy. An alternative parasympathomimetic is demecarium bromide (Humorsol), a potent and long-acting cholinesterase inhibitor. This has the advantage of once-daily administration.
- Parasympathomimetics are contraindicated in animals with active anterior uveitis that results in secondary glaucoma. Parasympathomimetics exacerbate the pain and symptoms of anterior uveitis.

Sympathomimetics

- *Sympathomimetics* increase the outflow of aqueous humor. Their mechanism of action differs from that of the parasympathomimetics and the two are synergistic.
- The sympathomimetic agent of choice is 0.1% dipivefrin HCl (Propine), a pro-drug of epinephrine (see Table 137-4). Alternatively, 1.0% epinephrine HCl can be administered either alone or in combination with 2% pilocarpine (E-Pilo-2).
- Side effects are minimal and include mild topical irritation, which is avoided with the use of 0.1% dipivefrin HCl. The long-term efficacy of these agents in lowering IOP in canine glaucoma is limited.

Sympatholytics

- *Sympatholytics* decrease the active production of aqueous humor.
- The sympatholytic agent of choice is a non-selective beta-blocking agent, 0.5% timolol maleate (Timoptic). Although disagreement exists over the efficacy of topical timolol maleate in small animal patients, information indicates that it has some IOP-lowering ability. Side effects have not been observed in small animals, but potentially systemic absorption could cause bronchoconstriction and bradycardia, both of which are side effects in humans.
- New topical alpha-2 adrenoreceptor agonists, apraclonidine 0.5% and brimonidine tartrate 0.2%, serve to lower IOP by reducing the formation of aqueous humor and in addition, in the case of brimonidine, increasing uveoscleral outflow. Apraclonidine may also result in mydriasis in the dog and miosis in the cat. Both of these drugs have been associated with side effects such as bradycardia, vomiting, and even death, especially in cats.

Prostaglandins

▼ ***Key Point*** Topical prostaglandins are the first drug of choice in acute, primary glaucoma. They will often lower the IOP to normal within 15 to 30 minutes and may avoid administration of systemic osmotic agents.

- Prostaglandins, administered topically in low concentration, have been found to lower IOP by increasing uveoscleral outflow. They are very species specific and while they have efficacy in dogs, their response is less in the cat. Side effects in humans include iris hyperpigmentation and conjunctival and facial irritation. Side effects are uncommon in the dog.
- Latanoprost 0.005% (Xalatan, Pharmacia) is the most commonly administered topical ophthalmic prostaglandin. In addition, isopropyl unoprostone 0.12% (Rescula, Novartis) is available.
- Administer topical prostaglandins every 12 to 24 hours. Miosis is a common side effect and owners can use this to monitor how frequently to administer the drug. If the pupil is returning to normal after 12 hours, administer the drug every 12 hours.
- These agents are contraindicated with concurrent anterior uveitis.

Plan of Action for Medical Treatment

- When presented with a patient with acute glaucoma, administer latanoprost first.
- If after 30 minutes no response is noted, administer intravenous mannitol.
- These are followed by maintenance therapy with an oral and topical CAI and topical latanoprost if initial response was noted. Topical pilocarpine or timolol can also be administered depending on clinician preference.
- Monitor IOP every 2 to 4 hours for the next 24 hours. If, following the initial reduction in IOP with mannitol, the IOP increases and exceeds 30 mm Hg, repeat mannitol therapy.
- Medical therapy can be increased to include all of the aforementioned topical medications. When adminis-

tering multiple topical medications, space each treatment 5 minutes apart.
- The failure of this aggressive, maximal therapy to lower and maintain IOP within the normal range indicates the need for surgical intervention (see following section). Most acute, primary glaucoma patients will require surgical intervention at initial presentation or shortly thereafter.
- In addition to therapy aimed at lowering IOP, attention is then focused on the resulting reperfusion injury that occurs to the retinal ganglion cells and axons of the optic nerve following rapid reduction of IOP. Newer therapies used in conjunction with pressure reduction are being examined and include calcium channel blocking agents, corticosteroids, and other potentially neuroprotective agents.

Surgical

Cyclocryosurgery

Cyclocryosurgery involves transscleral freezing of a portion of the ciliary body. This procedure selectively destroys an area of the ciliary processes, thereby decreasing the production of aqueous humor. It works best in conjunction with medical therapy and is indicated primarily in cases of acute glaucoma in which IOP is not effectively controlled with medical therapy alone. This is an older technique and has been largely replaced with laser cyclophotoablation.

Objectives

- Reduce the intraocular pressure to a level compatible with maintaining vision.
- Relieve the discomfort associated with glaucoma.

Equipment

- Liquid nitrogen *or* nitrous oxide cryogen unit with an ocular probe, 2.5 mm in diameter.

Technique

1. Place the anesthetized animal in lateral recumbency. Administer a single dose of systemic flunixin meglumine (Banamine) (0.25 mg/kg IV).
2. Use an eyelid speculum to obtain adequate exposure of the globe (Fig. 137-2).
3. Place the cryoprobe on the conjunctiva, 4 to 5 mm posterior to the limbus, in the superior or inferior temporal quadrant of the eye (see Fig. 137-2). Avoid the long posterior ciliary arteries found at the 3- and 9-o'clock positions.
4. Activate the cryoprobe and freeze the site. The actual freezing time varies according to the cryounit. Approximate freeze times and probe tip temperatures are for nitrous oxide, 2 minutes, –60° to –80° C, and for liquid nitrogen, until the ice ball extends 1 mm into the cornea (<30 seconds), –185° C.
5. Freeze multiple sites. The number of freeze sites varies according to the severity of the glaucoma and the cryoprobe. In general, freeze four to eight sites with liquid nitrogen, fewer than are done with nitrous oxide.

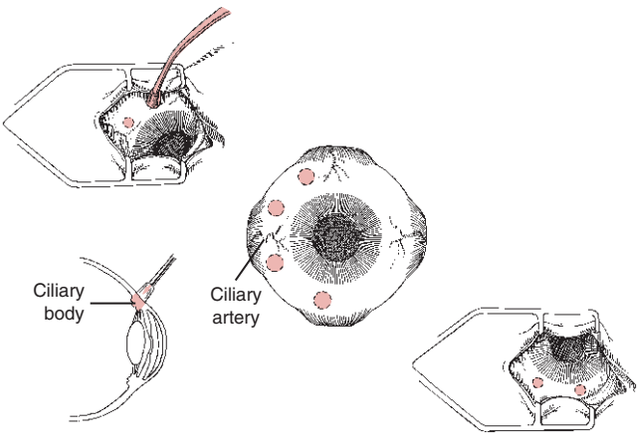

Figure 137-2. Cryosurgery or cyclophotocoagulation selectively destroys portions of the ciliary body (at areas indicated) and effects a decrease in the production of aqueous humor. Avoid damaging the long posterior ciliary arteries.

Following surgery, monitor the IOP. Prescribe medical therapy for glaucoma, based on the response of the IOP to cryosurgery. Treat postoperative discomfort with oral nonsteroidal anti-inflammatory drugs, such as carprofen (2.0 mg/kg PO q12h).

Transscleral Cyclophotocoagulation

▼ ***Key Point*** Diode laser transscleral cyclophotocoagulation is the most common surgical technique for acute, primary glaucoma. It is used in combination with emergency medical therapy.

- This technique uses a contact or non-contact neodymium:yttrium-aluminum-garnet (Nd:YAG) or diode laser to deliver energy that destroys a portion of the ciliary body and reduces aqueous humor formation (see Fig. 137-2).
- While the initial cost of these lasers is high, resulting in their being restricted to a referral-only procedure, the side effects are less than with cyclocryosurgery and the success is greater.
- The key to success appears to be early intervention, thus performing the cyclophotodestructive procedure prior to the development of acute congestive glaucoma. With the introduction of better prophylactic drugs and accurate IOP determination in practice using the Tonopen, early referral has become more common, with laser surgery performed at an

IOP between 20 and 35 mm Hg. The procedure works best in these eyes and has minimal side effects.
- Post-surgical uveitis and a transient ocular hypertension are the most common side effects.
- Treatment of eyes with IOP greater than 50 mm Hg appears to be less effective for achieving long-term control.
- Cyclophotocoagulation should be used in conjunction with, not as a replacement for, medical therapy.

Filtering Procedures

- These are designed to provide an alternate outflow pathway for the aqueous humor. The aqueous is usually redirected to the subconjunctival tissue space through either a filtering hole or an implantation of a filtering device.
- Although the initial success with this procedure may be high, many filtering procedures ultimately fail owing to fibrosis of the new outflow pathway. Filtering procedures work best in conjunction with medical and surgical therapies and for a short time only.
- Refer animals requiring a filtering procedure to an appropriate specialist.

Intraocular Prosthesis

Objectives

- Relieve pain associated with chronic glaucoma.
- Maintain cosmetic appearance of the eye.

▼ ***Key Point*** This procedure is indicated only for chronic glaucomatous eyes that are irreversibly blind. Intraocular prosthetic implants are contraindicated in cases of intraocular neoplasia, infectious panophthalmitis, and midstromal or deeper corneal ulceration.

Equipment

- Routine ocular surgical pack with a cyclodialysis spatula.
- Sterile intraocular silicone implant (Jardon Corp.). The implant is 2 mm larger than the horizontal dimension of the cornea of the normal eye. In the dog, an 18 to 19-mm prosthesis generally is satisfactory.
- Carter sphere introducer.

Technique

1. Place the anesthetized animal in lateral recumbency. Administer systemic flunixin meglumine as discussed in the cryosurgery section.
2. Use an eyelid speculum to obtain adequate exposure of the globe.
3. Make an incision in the superior conjunctiva, 4 to 5 mm posterior to the limbus (Fig. 137-3*A*). Continue the incision 120 degrees around the globe.

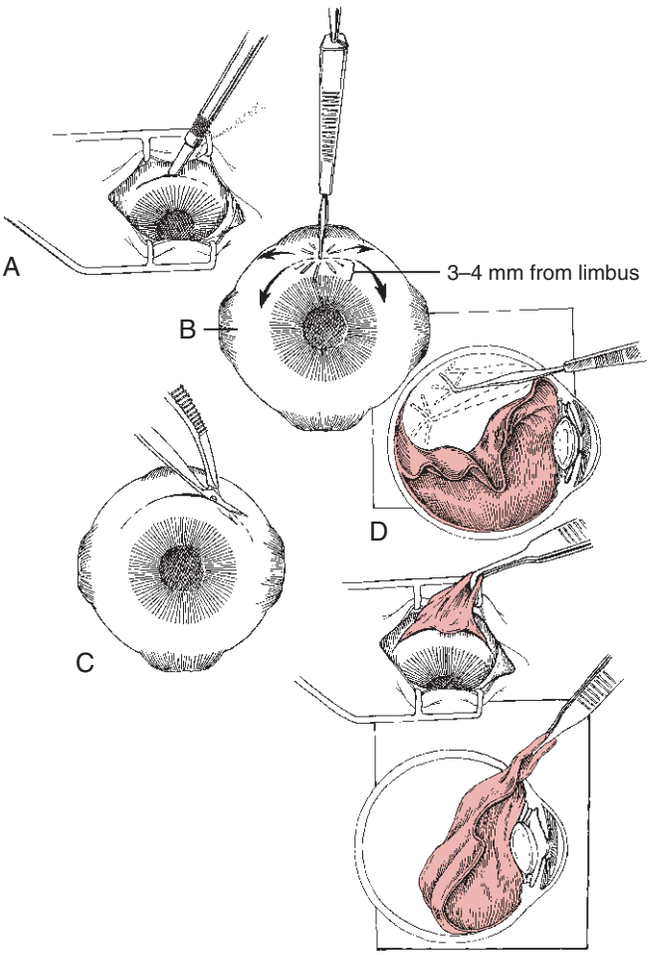

Figure 137-3. Preparation of globe for intraocular prosthesis. See text for details.

4. Dissect the conjunctival and episcleral tissues to the level of the sclera.
5. Make an incision in the superior sclera, 4 to 5 mm posterior to the limbus.
6. Introduce a cyclodialysis spatula into the globe between the fibrous and vascular tunics and gently separate these tunics. Avoid injury to the cornea (Fig. 137-3*B*).
7. Enlarge the scleral incision (Fig. 137-3*C*).
8. Remove the intraocular contents (Fig. 137-3*D*), leaving only the fibrous tunic (cornea and sclera).
9. Place the silicone implant within the globe.
10. Close the sclera and conjunctival tissues with 6-0 absorbable suture (e.g., Vicryl, Ethicon) in simple interrupted or simple continuous pattern.

Postoperative Care

- Administer topical, broad-spectrum antibiotic ointment q6h.
- Apply warm, moist compresses twice daily for 5 to 7 days.

- Administer systemic nonsteroidal anti-inflammatory agents as required (see Chapter 6).
- As the surgical procedure removes the aqueous humor (the primary source of corneal nutrition) the cornea will vascularize over the 2 to 4 weeks following surgery.
- Evaluate the eye 2 weeks after surgery. Note the progression of corneal vascularization and the absence of corneal ulceration. Determine the IOP in the contralateral eye of patients with primary glaucoma at this time.

Enucleation

Objective

- Relieve the pain associated with glaucoma.

▼ ***Key Point*** An enucleation is indicated in animals with chronic glaucoma, causing irreversible blindness, and in which an intraocular prosthetic implant is contraindicated.

Equipment

- Routine ocular surgical pack

Technique

1. Aseptically prepare and suture eyelids closed.
2. Incise the skin 5 to 6 mm away from the eyelid margin 360 degrees around the eyelids. Using sharp dissection, continue the incision to the level of the extraocular muscles.
3. Sever the extraocular muscles at their attachment to the sclera.
4. Clamp and sever the optic nerve and blood vessels. Ligate the pedicle with 3-0 to 4-0 absorbable sutures.
5. If desired, insert an intraorbital silicone prosthesis to minimize the post-surgical "sunken" appearance of the orbit. A 24- to 34-mm prosthesis is used, nearly filling the orbital space.
6. Close the extraocular muscles, periorbita, subcutaneous tissues, and skin in a routine manner. Close the orbital space and subcutaneous tissues utilizing continuous 4-0 absorbable sutures and the skin utilizing 5-0 or 6-0 non-absorbable sutures in an interrupted or continuous pattern.

Postoperative Care

- Administer postoperative analgesics as needed (see Chapter 6).
- Administer postoperative systemic antibiotics for eyes enucleated for infectious panophthalmitis or penetrating keratitis.
- Submit all enucleated eyes to a qualified veterinary pathologist for examination.
- Remove sutures 10 to 14 days following surgery.

Pharmacologic Ablation

In my opinion, this is an unacceptable method for the management of glaucoma. It involves the intravitreal injection of a substance toxic to the eye in the hope that this approach will result in the destruction of the ciliary body, thereby lowering the intraocular pressure. This is an irreversible, inaccurate, and sometimes painful procedure. In addition, the end result is usually a non-cosmetic phthisic globe that may require enucleation.

PREVENTION

- Evaluate IOP in all breeds predisposed to primary glaucoma, as part of the routine yearly physical examination. A sustained, gradual increase in IOP, even if still within normal limits, is sufficient cause to initiate preventive topical therapy.
- In an animal with primary glaucoma in one eye, determine the IOP in the opposite eye, every 2 to 4 months.
- In an animal with primary glaucoma in one eye, use preventive treatment in the opposite eye. This can consist of a systemic CAI administered to control the affected eye, which will also lower the IOP in the opposite eye. Alternatively, treat the unaffected eye topically, if systemic CAIs are not required for the affected eye.
- Measure IOP in all eyes with lens luxation or subluxation, anterior uveitis, or hyphema. If possible, the primary problem is eliminated in an effort to avoid secondary glaucoma.
- It is essential that owners understand that cure is not possible in most instances. Instead, *control, management,* and *prevention* are more appropriate terms to use when discussing glaucoma.

Chapter

138 Diseases of the Retina, Choroid, and Optic Nerve

Nicholas J. Millichamp / Joan Dziezyc

EVALUATION OF THE POSTERIOR SEGMENT

The posterior segment of the eye includes the vitreous humor; the retina and its vasculature; and the choroid, sclera, and optic nerve. The fundus is the portion of the posterior segment that can be seen with an ophthalmoscope. Considerable variation exists in the appearance of the normal fundus in the dog and cat. To fully appreciate subtle differences in normal fundi, consult available atlases detailing their appearance.

Generally, the fundus is divided into the brightly colored and reflective tapetal region, occupying the upper and more temporal area, and the darkly pigmented non-tapetal region, occupying the lower area and completely surrounding the tapetal area. Apart from these fundic regions, examine the retinal blood vessels and the optic nerve head (optic disc).

Ophthalmoscopy is the technique used to examine the fundus (see Chapter 131). The technique is ideally performed after dilating the pupil (except in an animal with ocular hypertension, glaucoma, or lens luxation) with a short-acting parasympatholytic drug such as tropicamide (Mydriacyl 0.5%, Alcon).

- Direct ophthalmoscopy with a hand-held ophthalmoscope is commonly used in practice. Unfortunately, this technique yields limited information about the fundic appearance even in the hands of experienced ophthalmologists. Small lesions and variations in contrast between normal and abnormal areas of the fundus are often overlooked when utilizing the direct technique.
- Indirect ophthalmoscopy, utilizing a 20D planoconvex lens held 2 to 3 inches from the animal's eye and illuminated with a penlight held at arm's length from the animal, is more useful as a diagnostic technique.

▼ ***Key Point*** Indirect ophthalmoscopy enables the examiner to quickly scan a large area of the fundus and to recognize obvious lesions.

- Ocular ultrasonography and color-flow Doppler ultrasonography are utilized to evaluate the structures of the posterior segment when opacities of the ocular media prevent an ophthalmoscopic examination.
- Electroretinography employs a light stimulus of varying intensity and frequency to elicit a retinal response from rod and/or cone photoreceptors. This test evaluates the functional integrity of the retina and is a procedure that requires referral to a specialist. Neuroophthalmology is discussed in Chapter 141.

DISEASES OF THE VITREOUS HUMOR

The vitreous is a gel composed mostly of water with lesser quantities of mucopolysaccharides and proteins. The normal adult vitreous is transparent and lacks blood vessels. The vitreous cannot itself become inflamed. However, products of inflammation or other abnormalities of adjacent tissues can result in exudate or hemorrhage that enters the vitreous and is seen by ophthalmoscopy.

Etiology

Retention of the Fetal Hyaloid Artery

- Retention of the fetal hyaloid artery or its remnants may be seen in an adult dog as a fine gray strand arising from the optic disc or inserting onto the posterior pole of the lens.

Persistent Hyperplastic Primary Vitreous (PHPV)/Persistent Tunica Vasculosa Lentis

- Persistent hyperplastic primary vitreous (PHPV)/persistent tunica vasculosa lentis is inherited in some breeds, notably the Doberman pinscher. The hyaloid artery is retained and is hyperplastic and associated with vessels that ramify over the posterior lens surface. Blood vessels and associated posterior lens capsular pigmentation and opacities (cataracts) or intralenticular hemorrhage is observed clinically. Color-flow Doppler ultrasonography may enable diagnosis and aid in predicting prognosis in cases of PHPV where the posterior segment cannot easily be seen by ophthalmoscopy. Surgical therapy yields poor results. Do not use these animals for breeding.

Asteroid Hyalosis

- Asteroid hyalosis is a unilateral or bilateral degenerative change associated with aging in dogs. Calcium-lipid complexes are deposited on the vitreous protein matrix. These appear as multiple white sparkles that oscillate slightly with eye movements. Asteroid hyalosis does not significantly impair vision in most dogs although advanced lenticular nuclear sclerosis and severe asteroid hyalosis in old dogs may reduce vision to some extent. No treatment is indicated.

Cholesterosis Bulbi

- Cholesterosis bulbi or synchysis scintillans is a far less common entity in which white cholesterol crystals are deposited in the vitreous secondary to intraocular inflammation. The vitreous often will become liquefied *(syneresis)* as a result of posterior segment inflammation. The cholesterol deposits sink to the bottom of the vitreous cavity. When the eye moves, the deposits swirl in the liquid vitreous before settling again under gravity. The initial cause of ocular inflammation and vitreous liquefaction may often have subsided by the time cholesterosis bulbi is detected. Vision is not affected by the cholesterosis bulbi per se, although it may be compromised by the underlying inflammatory disease.

Vitreous Hemorrhage

- Vitreous hemorrhage most commonly occurs in the dog and cat as a sequel to ocular trauma, intraocular surgery, retinal detachment, or systemic coagulopathy. If the hemorrhage is severe, blindness may result. Spontaneous resorption of vitreous hemorrhage may take several months.

Exudate and Cellular Infiltrate

- Exudate and cellular infiltrate appear as hazy, white, or gray material in the vitreous or on the posterior capsule of the lens. Pigment may also be deposited in the vitreous. Cellular infiltrate may become dense enough to obscure a view of the retina. Investigate for anterior uveitis or chorioretinitis (see later section).

Other

- Other possible vitreous opacities include posterior lens luxation; retinal detachment; foreign bodies; parasites *(Dirofilaria);* and neoplasms arising from the ciliary body, retina, choroid, or optic nerve.

Clinical Signs

▼ ***Key Point*** Opacities of this otherwise clear medium are the most commonly observed clinical findings that indicate disease of the vitreous.

- The effect on the animal's vision depends upon the severity and density of the opacities.

Diagnosis

- *Ophthalmoscopic examination* with a focal light source (penlight) or an ophthalmoscope will reveal the nature of the opacities (asteroid hyalosis, hemorrhage, pigment).
- *Submit blood for a clotting profile* when vitreous hemorrhage occurs unassociated with ocular trauma or intraocular surgery.
- *Perform physical examination, complete blood count, serum biochemistry,* and *serology evaluations* for infectious inflammatory disease (see Chorioretinitis) in cases in which vitreous exudate or cellular infiltrate is seen.
- *Perform ultrasonography* to rule out a diagnosis of coexisting retinal detachment, posterior segment neoplasia, or foreign bodies.

Treatment

- *Vitreous hemorrhage* resorbs slowly over the course of several weeks. Treat the coagulopathy systemically when possible.
- *Exudate and infiltrate* decrease by treating the underlying inflammatory disease with systemic antibacterial, antifungal, and nonsteroidal anti-inflammatory drugs (NSAIDs), as indicated. Corticosteroids can be used in dogs and cats once infectious etiologies are ruled out (prednisone or prednisolone, 1–2 mg/kg, q12–24h PO). NSAIDs (aspirin, 25 mg/kg q12h PO in dogs only) often improve ocular inflammatory disease.

CONGENITAL DISEASES OF CHORIORETINA AND OPTIC NERVE

Etiology

Many of these diseases occur most frequently in dogs and are inherited. Other possible congenital causes include inflammation and necrosis in the developing retina in utero due to infectious diseases, radiation, and teratogens.

Collie Eye Anomaly

- *Collie eye anomaly* (CEA) is a disorder that occurs commonly in rough and smooth collies and less often in Shetland sheepdogs and some other breeds (border collies, Australian shepherds, Lancashire heelers). CEA affects the retinal the choroid and retinal pigment epithelium and, in severe cases, the retina and optic nerve. The disease is usually asymmetric in the two eyes.
- The most characteristic lesion is choroidal hypoplasia (an area of thin, poorly vascularized choroid), which appears as a pale area of fundus temporal to

the optic nerve. The lesion is one of depigmentation of the retinal pigment epithelium and choroid and focal absence of tapetum exposing hypoplastic choroidal blood vessels overlying the sclera. Occasionally, hazy white corneal opacities accompany the chorioretinal lesions.

- In severe cases, colobomas (gaps or holes due to incomplete development) may occur in the optic nerve or choroid. These are often circular or oval lesions which may appear out of focus compared with the surrounding structures when seen by ophthalmoscopy. Retinal detachment or intraocular hemorrhage is found in the most severe cases.
- It has long been believed that the disease has a simple autosomal recessive means of inheritance, although recent studies of large numbers of dogs in Scandinavia have suggested that the inheritance is either polygenic or that choroidal hypoplasia and coloboma are inherited as separate traits. However, a gene for this disease has been located on canine chromosome number 37 and the recessive disease-causing mutation has been identified. Affected dogs are homozygous recessive—that is, both copies of the gene are mutant. All dogs that are homozygous recessive affected will show at least the mild form of the disease (choroidal hypoplasia) and may have more severe manifestations (coloboma, retinal detachment). Genetic linkage testing (from blood sample) can distinguish normal, carrier, and affected dogs (Optigen, LLC, Ithaca, NY; see www.optigen.com).
- Advise breeders to breed together genetically normal dogs (difficult in some breeds due to high incidence of affected animals) or carriers with subsequent testing to identify and eliminate affected dogs from the breeding program.

▼ ***Key Point*** The developmental abnormalities do not worsen after birth. Retinal detachment associated with optic nerve colobomas, however, may occur at any age.

Retinal or Vitreoretinal Dysplasia

- Retinal or vitreoretinal dysplasia occurs in cats and dogs. The disease may be inherited (often recessively) in the dog or may be a sequela to intrauterine infection (canine herpesvirus, feline panleukopenia).
- In the dog, inherited retinal dysplasia may be manifested as bilaterally asymmetric, small focal folds in the outer layers of the retina that do not result in retinal elevation. These folds are observed in the cocker spaniel and the Labrador retriever. The folds may appear as small dark dots, streaks, or circles in the tapetal fundus and gray or dark spots or streaks in the non-tapetal fundus. In some breeds (Sealyham and Bedlington terriers, Labrador retrievers, springer spaniel), the lesion is severe, and the dog is blinded by the retina lying unattached in abnormally formed vitreous.

Multiple Ocular Anomalies

- Multiple ocular anomalies are seen most commonly in Australian sheepdogs. Affected animals may have microphthalmia, iris colobomas, cataracts, retinal dysplasia or detachment, and uvea-lined defects (staphylomas) in the sclera.

Optic Nerve Hypoplasia

- *Optic nerve hypoplasia,* if bilateral, may be noted by breeders or owners in animals a few weeks old. The disease may be inherited in certain breeds, including the miniature poodle and dachshund. Affected eyes lack pupillary light reflexes and are blind. Ophthalmoscopy reveals a small optic nerve head with normal retinal vasculature.

Clinical Signs

Vision may be affected in dogs with severe congenital lesions. The pupillary light reflexes may also be variably affected, depending upon the severity of the lesions.

Diagnosis

Congenital abnormalities of the fundus are most readily diagnosed by the ophthalmoscopic appearance at 4 to 8 weeks of age. Some dogs have been seen to develop circular (or geographic) folds and dysplastic lesions at several months of age. Perform a second examination at 6 to 12 months of age in susceptible breeds. Genetic testing is available for dogs that might be affected with collie eye anomaly and can distinguish normal, carrier, and affected animals (Optigen, LLC, Ithaca, NY; see www.optigen.com).

Treatment and Prevention

The mode of transmission in the inherited diseases is often as an autosomal recessive trait (e.g., CEA and retinal dysplasia in most breeds). Prevent intrauterine infections by vaccination of breeding animals and by avoidance of infection and exposure of pregnant animals to ionizing radiation and teratogenic toxins.

▼ ***Key Point*** There is no treatment for congenital chorioretinal disease. Do not breed affected dogs.

ACQUIRED DISEASE OF THE CHORIORETINA AND OPTIC NERVE

Chorioretinal Degeneration

Etiology

Progressive Retinal Atrophy (PRA)

- Progressive retinal atrophy includes several genetic retinal diseases in which the ultimate outcome is degeneration and loss of retinal structure with

varying degrees of blindness. The different forms of PRA are all progressive and bilaterally symmetric. The disease occurs commonly in many purebred and mixed-breed dogs. The inheritance in most instances in the dog is autosomal recessive. Recessive sex-linked PRA is seen in the Siberian husky and Samoyed. PRA also occurs in various breeds of cat, although it has been best characterized in the Abyssinian.

- PRA may primarily affect the photoreceptors (rods/cones) or the adjacent layer of retinal pigment epithelium. Pigment epithelial dystrophy, or central PRA, is extremely rare in the United States and apparently on the decline in other parts of the world, including Europe. PRA affecting the rods or cones can be distinguished by the age of onset. In early-onset PRA (rod, rod-cone dysplasias), affected dogs show signs of night blindness during the first year of life.
- Affected breeds include the collie, Irish setter, miniature schnauzer, elkhound, and miniature dachshund. In late-onset PRA (progressive rod-cone degeneration), night blindness may be noticed at any age from 1 year on. Breeds affected include the miniature poodle, cocker spaniel, and Labrador retriever.
- The typical ophthalmoscopic appearance of diffuse retinal degeneration is an increased reflectance of light from the tapetal fundus (tapetal hyper-reflectivity). Retinal blood vessels are narrowed or lost, and depigmentation and patchy hyperpigmentation in the non-tapetal fundus may be seen. In advanced cases, atrophy of the optic nerve occurs.
- The various forms of PRA are gradually being identified at the molecular genetic level. In 2005 the DNA markers near the gene for late-onset progressive rod-cone degeneration (prcd-PRA) on chromosome 9 had been identified in a dozen canine breeds. Separate genes for early-onset rod-cone type dysplasia had been identified in a smaller number of breeds. Tests based on these genetic associations may either allow very accurate testing (gene mutation–based tests) or relatively accurate testing (linkage-based tests) of blood samples from dogs that are either normal, carriers, or affected with the disease (Optigen, LLC, Ithaca, NY; see www.optigen.com for details of interpretation of the various tests).

Sudden Acquired Retinal Degeneration (SARD)

- Sudden acquired retinal degeneration (SARD) is a degeneration of the retina that occurs in dogs. The defect that causes the degeneration is unknown.
- Dogs of any age that are otherwise normal may be affected. Obese, middle-aged dogs are most prone to the disorder.
- Some affected dogs may show signs or be clinically diagnosed with hyperadrenocorticism. The most characteristic feature of SARD is the rapid and complete loss of vision, often within a few days or at most weeks. The disease usually affects both eyes equally.

▼ ***Key Point*** In SARD, the photoreceptors are ultrastructurally abnormal at the time when blindness is first noted, although the fundus appears ophthalmoscopically normal.

- Ophthalmoscopic signs of retinal degeneration (tapetal hyper-reflectivity, vascular attenuation) appear over several months. The electroretinogram is extinguished at the time of presentation, which distinguishes the disease from optic neuritis, pituitary neoplasia, and central nervous system blindness.

Nutritional Deficiency

- Nutritional deficiency or taurine deficiency in the cat, especially in cats fed dog food that is deficient in taurine (an essential amino acid in the cat), results in feline central retinal degeneration (FCRD). The typical early lesion is a focal area of tapetal hyper-reflectivity in the temporal fundus. With progression of the lesion, a similar area appears nasally and the two patches join to form a horizontal band above the optic disc. Continued deficiency results in diffuse atrophy throughout the retina. Restoration of a taurine-rich diet halts the degeneration in the early stages, although the fundic lesion remains visible throughout the cat's life.
- Cats with taurine deficiency rarely show any evidence of blindness until the disease is advanced. For discussion of the cardiac effects of taurine deficiency in cats, see Chapter 150. FCRD also occurs in some cats on diets with adequate taurine. The cause in this situation is unknown. Since most cats are now fed diets with adequate taurine the incidence of FCRD appears to have decreased in recent years.

Enrofloxacin and Other Quinolone Antibacterial Drugs

- Enrofloxacin and other quinolone (orbifloxacin) antibacterial drugs have been associated with acute retinal degeneration in cats. Affected animals present with mydriasis and an acute onset of blindness (in older cats an important differential diagnosis would be hypertensive retinopathy). Examination of the fundus reveals tapetal hyper-reflectivity and attenuation of retinal blood vessels. Rust- or gold-colored foci may be seen in the tapetum at low illumination levels. The electroretinogram may be extinguished. The toxic effects on the feline retina appear to be idiosyncratic, varying with dose and length of time the drug is administered. Discontinuing use of the drug may not restore vision or avoid further progression of the degeneration.

▼ ***Key Point*** Never administer enrofloxacin at a total daily dose exceeding 5 mg/kg in cats due to the risk

of causing retinal degeneration. If possible use alternative antibacterial drugs in cats due to the idiosyncratic response of some animals to even low doses of the drug.

Chronic Glaucoma

- Chronic glaucoma results in diffuse retinal atrophy because of ischemia and pressure necrosis of initially the inner and later the outer retina (see Chapter 137).

Inflammation

- Inflammation that subsides or is successfully treated often results in focal lesions of chorioretinal degeneration in the affected areas. These lesions appear as focal hyper-reflective areas in the tapetal fundus or depigmented areas in the non-tapetum. Vision is affected to an extent commensurate with the area and region of the fundus involved (central versus peripheral retina).

Clinical Signs

- *Blindness* is a characteristic feature of retinal degeneration. Night blindness may be noted first in PRA that progresses to complete visual loss. Blindness may be sudden when caused by SARD and slowly progressive when caused by glaucoma.
- *Mydriasis* may be observed. Pupillary light reflexes may be incomplete and sluggish in advanced cases of PRA and can be absent in SARD.

Diagnosis

- *Ophthalmoscopy* identifies retinal degeneration when typical lesions are present.
- *Electroretinography (ERG)* may help one to make a diagnosis of PRA before typical ophthalmoscopic signs are seen and to confirm a diagnosis of SARD. ERG is a test of retinal function. Refer to a specialist.
- Genetic testing of blood samples is now available to diagnose PRA and in selected breeds. Refer to a specialist.

Treatment

No treatment is presently available for PRA or SARD. Chorioretinal degeneration due to glaucoma (see Chapter 137) or inflammation (see Chorioretinitis) can be limited by controlling the primary disease process. A deficiency of taurine in the diet can be corrected to halt progression of the disease (see Chapter 150).

Prevention

Progressive retinal atrophy in either dogs or cats can be prevented by selective breeding of unaffected dogs and of those dogs believed not to be carriers of the PRA gene. Recommend yearly evaluations of all breeding purebred dogs by a board-certified veterinary ophthalmologist, and register these animals through the Canine Eye Registry Foundation (CERF) as phenotypically normal. As genetic testing for PRA and other inherited ocular diseases becomes more available in different breeds this will significantly contribute to the elimination and prevention of the these eye diseases.

Chorioretinitis

Chorioretinitis is inflammation of the retina and choroid. Although inflammation may begin in either of the two layers, their proximity often results in spread and involvement of both. Clinically, the differentiation is of little importance. Choroiditis is also discussed in Chapter 136.

Etiology

Numerous causes of, or diseases associated with, chorioretinitis are recognized in the dog and cat. Chorioretinitis may develop as an extension of anterior uveitis (see Chapter 136) or as an isolated entity. Systemic diseases that can cause unilateral or bilateral chorioretinitis are listed in Tables 138-1 and 138-2. Refer also to the appropriate chapters elsewhere in this book for specifics on these diseases. For some potential etiologic agents (e.g., *Bartonella*) there is currently a suspected association with uveitis or chorioretinitis in dogs and cats, but more clinical data are needed to determine the exact role of these organisms in the disease process.

Table 138-1. DISEASES ASSOCIATED WITH CHORIORETINITIS IN DOGS

Viral	Distemper
Fungal	Blastomycosis
	Coccidioidomycosis
	Cryptococcosis
	Histoplasmosis
	Aspergillosis
	Geotrichosis
Bacterial	*Brucella canis*
	Borrelia burgdorferi
	Leptospirosis
	Bartonella spp. infection
Algal	Protothecosis
Rickettsial	Ehrlichiosis
	Rocky Mountain spotted fever
Parasitic	Toxoplasmosis
	Neosporum caninum
	Leishmaniasis
	Migrating fly larvae
	Toxocara canis larva migrans
Immune-mediated	Autoimmune chorioretinitis
	Uveodermatologic syndrome
Neoplastic	Lymphoma
	Multiple myeloma
	Metastatic neoplasia
Toxic	Miscellaneous toxins (often undiagnosed)

Table 138-2. DISEASES ASSOCIATED WITH CHORIORETINITIS IN CATS

Viral	Feline infectious peritonitis
	Feline leukemia virus
	Feline immunodeficiency virus
Bacterial	Tuberculosis
	Bartonella henselae infection
Fungal	Blastomycosis
	Cryptococcosis
	Histoplasmosis
Parasitic	Toxoplasmosis
	Migrating fly larvae
Immune-mediated	Autoimmune chorioretinitis
Neoplastic	Lymphoma
	Metastatic neoplasia
Toxic	Miscellaneous toxins (often undiagnosed)

Clinical Signs

- *Vision* may be affected in severe cases of chorioretinitis, especially with concurrent optic nerve inflammation. In mild cases of chorioretinitis, visual deficits may not be noticed.
- The *tapetal fundus* areas of chorioretinal exudate or edema appear as hazy gray areas that may have discrete borders and appear elevated. If cellular infiltrate is also present, the areas may appear darker and obscure the underlying tapetum.
- The *non-tapetal fundus* areas of exudate or cellular infiltrate appear gray or white. Perivascular cuffing appears as a hazy white border to retinal vessels.
- *Hemorrhages* may be seen at various depths in the retina.
- *Exudative retinal detachments* may occur.
- *Associated ocular disease* may include anterior uveitis (see Chapter 136) and exudate or hemorrhage in the vitreous.

Diagnosis

▼ ***Key Point*** Unilateral or bilateral chorioretinitis indicates a systemic disease until proven otherwise.

- *Physical examination*—look for any evidence of inflammatory or neoplastic disease elsewhere in the body.
- *Evaluate complete blood count, serum biochemistry profile,* and *urinalysis* for evidence of underlying systemic disease.
- *Evaluate thoracic* and *abdominal radiography* for evidence of systemic mycosis or neoplasia.
- *Evaluate serology* to rule out the various infectious causes of chorioretinitis as described in the chapters on viral diseases, bacterial infections, systemic mycoses, and toxoplasmosis.
- *Evaluate lymph node aspirate* and *skin biopsy samples* in animals with lymphadenopathies or cutaneous lesions.
- *Evaluate vitreous by paracentesis* for cytology and culture, but *only as a last resort* in cases in which all other less invasive systemic diagnostic techniques have been performed and the eye is irreversibly blind.

Treatment

The retina and choroid are inaccessible to most topical medications.

▼ ***Key Point*** To effectively treat chorioretinitis, drugs must be given systemically.

Underlying systemic disease is treated appropriately (as described in the relevant chapters in this book). If all evidence of infectious disease is ruled out, systemic corticosteroids or NSAIDs are given to control the inflammation. Additional therapy with immunosuppressive drugs such as azathioprine (Imuran) may be indicated in immune-mediated chorioretinitis (see Chapter 136).

After achieving an initial improvement in chorioretinitis with a systemic corticosteroid (prednisone) and/or immunosuppressive drug (azathioprine), these drugs may be combined at half of their regular dose for long-term therapy. This may avoid development of side effects from each drug and result in better control of posterior segment inflammation.

Retinovascular Disease

The retinal or choroidal vasculature may be affected in the aforementioned congenital chorioretinal diseases, retinal degenerations, and chorioretinitis. Vascular disease also may occur unrelated to these other entities.

Etiology

- *Coagulopathies,* including canine ehrlichiosis, warfarin and aspirin toxicity, von Willebrand disease, autoimmune hemolytic anemia, and immune-mediated thrombocytopenia in dogs, may cause retinal hemorrhage (see Chapters 22 and 23).
- *Systemic hypertension* in dogs and cats may result in retinal hemorrhage and transudative retinal detachment (see Chapter 153).
- *Congenital cardiac anomalies* may cause engorgement of retinal venules (see Chapter 154).
- *Hyperviscosity syndrome* due to macroglobulinemia in dogs with myeloma and polycythemia causes engorgement of the retinal blood vessels.
- *Anemia* in cats has been associated with retinal hemorrhage.
- *Hyperlipidemia* in cats and dogs results in pink-colored retinal blood vessels.

Clinical Signs

Retinal and vitreous hemorrhage and retinal detachment may result in acute blindness and loss of the pupillary light reflex.

Diagnosis

- *Ophthalmoscopy* reveals retinal hemorrhage, vessel engorgement, increased tortuosity, and color change.
- *Clotting profile* and *complete blood count* assess clotting time, clotting factor deficiencies, thrombocytopenia, and anemia. Coagulopathies are described in Chapter 23.
- *Blood pressure measurement* (see Chapter 153) is indicated in any older dog or cat with retinal hemorrhage or detachment. Rule out renal disease, cardiac disease, and hyperthyroidism in animals with hypertension (see appropriate chapters for each).

Treatment

Direct therapy in all acquired forms of retinovascular disease at the underlying cause. In most cases, retinal hemorrhage resorbs spontaneously, during a few days to weeks, once the disease is under control.

Retinal Detachment

Retinal detachment is separation of the neural retina from the retinal pigment epithelium (RPE). Unilateral detachments may exist undetected.

▼ ***Key Point*** Retinal detachments are often caused by systemic disease in dogs and cats.

Detachments may be partial or complete (infundibular) and arise near the periphery of the retina or adjacent to the optic nerve.

Etiology

- *Congenital developmental disease* includes both CEA and retinal dysplasia.
- *Inflammation* results in accumulations of serous fluid or cellular infiltrate or granulomas between the retina and RPE, causing detachment (non-rhegmatogenous detachments). The same causes of chorioretinitis apply to retinal detachment (see Tables 138-1 and 138-2).
- *Hypertension* (see Chapter 153) causes accumulation of transudate within and beneath the retina.

▼ ***Key Point*** Hypertension secondary to hyperthyroidism or chronic renal failure is the commonest cause of acute retinal detachment, mydriasis, and blindness in older cats. Blood pressure measurements should be measured in any cat with sudden blindness and every 6 months as part of regular geriatric workup in old cats.

- *Tears* in the retina associated with cataract formation, intraocular surgery, or liquefaction of the vitreous may allow vitreous to penetrate between the retina and RPE (rhegmatogenous detachments).
- *Traction* on the retina may result from fibrous tissue that forms in the retina or vitreous secondary to intraocular hemorrhage or chorioretinitis.
- *Neoplasia* or *granuloma* of the choroid or orbit may indent the sclera and detach the retina.
- *Ethylene glycol* toxicity in cats (see Chapter 77) may result in serous retinal folding and detachment.

Clinical Signs

- *Sudden blindness* occurs if bilateral; visual deficits occur if unilateral, depending upon the extent of the detachment.
- *The pupil is often dilated,* and the pupillary light reflexes are weak to absent.
- *A translucent, folded, gray or white sheet of tissue* with retinal blood vessels may be observed behind the lens.

Diagnosis

- *Ophthalmoscopy* reveals focal retinal detachment. Complete retinal detachment can usually be seen clearly with a focal light source.
- *Measure blood pressure* performed to diagnose hypertension (see Chapter 153).
- *Ultrasonography* may support the diagnosis of retinal detachment in cases of intraocular neoplasia or hemorrhage. It is also indicated to detect retinal detachment in eyes with opacities of otherwise clear ocular media (cornea, lens, vitreous).
- *Serology* is indicated if infectious disease is suspected.

Treatment

- *Appropriate therapy for a systemic disease* (hypertension) once diagnosed sometimes results in retinal reattachment, especially if the detachment is not chronic. This response may result in a return of vision and is more likely in dogs than in cats. A cat with bilateral blindness and retinal detachment and hemorrhage should be considered at a late stage of the disease. Serum biochemistries should assess thyroid and renal function. If renal function is reasonably normal treat cats with hypertension with the calcium channel blocker amlodipine besylate (Norvasc), 0.14 mg/kg q12–24h, usually 0.625 mg/cat q24h. Often this will result in rapid resolution of retinal detachment and some restoration of vision. Treatment of the underlying cause of the hypertension (where possible) should be started concurrently (see Chapter 153).
- *Systemic corticosteroids* are used after infectious disease and hypertension have been diagnostically ruled out (see Chapter 136).

- *Systemic NSAIDs* are indicated in retinal detachment, although avoided in cases associated with intraocular hemorrhage (see Chapter 136).
- *Retinal reattachment surgery* is indicated in recent detachments associated with small retinal tears. Laser retinopexy may halt further detachment. Scleral buckling with or without vitrectomy or other retinal tamponade and retinopexy methods may be effective for some detachments and maintain vision. These procedures are performed at some referral centers. In retinal detachments with 360-degree tears, surgery is not indicated.

ACQUIRED DISEASE OF THE OPTIC NERVE

The optic nerve may be involved in several chorioretinal diseases, including chorioretinitis and retinal degeneration.

Optic Neuritis

Optic neuritis is inflammation of the optic nerve. The condition may be recurrent in nature and often results in atrophy of the optic nerve and permanent blindness, regardless of therapy.

Etiology

- *Inflammatory and infectious etiologies* are similar to those causing central nervous system (CNS) disease (see Chapter 126) and chorioretinitis (see Tables 138-1 and 138-2).
- *Neoplasia* (canine granulomatous meningoencephalitis, feline lymphoma) affecting the CNS may cause optic neuritis (see Chapter 126).
- *Ocular trauma* (ocular proptosis) causes optic neuritis.
- *Orbital inflammatory disease* may, in severe cases, result in optic neuritis.
- *Immune-mediated optic neuritis* may be presumed in cases in which no underlying systemic cause can be identified.
- *Miscellaneous toxins* may potentially cause optic neuritis, although diagnosis is rarely possible.

Clinical Signs

- *Acute blindness* is present with bilateral optic nerve involvement, although no visual deficit may be noted if the neuritis is unilateral.
- *Mydriasis* and absence of the pupillary light reflex are evident.

Diagnosis

- *Ophthalmoscopy* allows the diagnosis of intraocular optic neuritis and helps differentiate optic neuritis from retinal detachment as a cause of sudden blindness.
- *The optic disc appears hazy, elevated, and edematous.* The edema often radiates into the peripapillary retina when the inflammation involves the intraocular portion of the nerve. Hemorrhages may be present at the disc or in the adjacent retina or vitreous. Vitreous exudate may obscure the optic disc.
- *Ophthalmoscopic signs may not be present* if the neuritis does not involve the optic disc.
- *Chorioretinitis* can be a concurrent finding.
- *Electroretinography* is indicated to rule out SARD in cases in which the optic nerve appears normal.
- *Ultrasonography* can detect nerve swelling when the retrobulbar nerve is involved.
- *Perform neurologic examination,* cerebrospinal fluid (CSF) analysis, and magnetic resonance imaging (MRI) to diagnose concomitant neurologic disease (see Chapter 125).
- *Evaluate the complete blood count and serology findings* for evidence of infectious etiologies.

Treatment

- Wherever possible, identify infectious etiologies and treat appropriately (see appropriate chapters).
- In cases in which infectious etiologies are ruled out, administer systemic corticosteroids (prednisone, 2 mg/kg q24h PO). Failure to limit the inflammation results in optic atrophy and vision loss. At initial presentation prior to diagnostic workup, it may be reasonable to administer corticosteroids during the first few days to control optic nerve inflammation while carrying out a diagnostic workup for the underlying cause. Continued use of corticosteroids should, however, be based on elimination of infectious causes of the inflammatory disease (especially bacterial and fungal infections).

Papilledema

Papilledema is the bilateral swelling of the optic nerve due to reduced blood and axoplasmic flow from the optic disc. The term is loosely applied in dogs and cats to any form of optic disc edema.

Etiology

- *Pressure applied to the optic nerve* by tumors or granulomas of the nerve or within the orbit can cause stasis of axoplasmic and optic nerve blood flow and can result in papilledema.
- *Neoplasia and inflammation of the CNS* can cause papilledema in dogs and cats by increasing CSF pressure and increasing pressure within and around the optic nerve.

Clinical Signs

- *Vision is usually unaffected.* However, blindness may occur in the absence of optic neuritis when inflam-

matory or neoplastic lesions significantly damage the central optic pathways, including the visual cortex (see Chapters 126 and 141).

Diagnosis

- Attempt to differentiate papilledema from optic neuritis.
- *Ophthalmoscopic appearance of a swollen optic disc, usually with normal vision,* is likely to indicate papilledema. This is unlike optic neuritis in which vision is affected.
- *The optic disc* protrudes into the vitreous. The retinal blood vessels leaving the optic disc appear to cascade over the edge of the disc. The margins of the optic disc appear hazy and indistinct. Hemorrhages may occasionally be observed in the adjacent retina.
- *Perform globe retropulsion* to determine whether a space-occupying lesion is present in the orbit.
- *Neurologic examination* can help localize CNS lesions.
- *Ultrasonography, radiology, and computed tomography (if available)* can be used to locate orbital space-occupying lesions (see Chapter 140).
- *Exploratory orbitotomy* is a difficult technique that can be employed to localize and diagnose any masses detected with the previous methods.

Treatment

- Because papilledema is often associated with CNS tumors, the prognosis is guarded to poor.
- Orbital tumors may occasionally be surgically removed during exploratory orbitotomy.
- *Perform exenteration of the eye and orbital contents* when a mass is localized near the globe.

Optic Nerve Atrophy

Atrophy of the optic nerve may occur as a sequela to other ocular diseases.

Etiology

- Advanced inherited retinal degenerations can occur.
- Glaucoma causes ischemia of the optic nerve at the scleral lamina cribrosa, resulting in atrophy and "cupping."
- Optic neuritis can be either severe or recurrent.
- Optic nerve trauma (traumatic ocular proptosis) can occur.
- Orbital inflammation or neoplasia may be noted.

Clinical Signs and Diagnosis

- Blindness is evident in the affected eye.
- The pupil is mydriatic, and the pupillary light reflexes are absent.
- Ophthalmoscopy confirms the diagnosis. The optic disc appears small and gray, with a loss of retinal blood vessels. The outline of the scleral lamina cribrosa may become visible, particularly in cats. In dogs, the margins of the disc may appear to spread from the disc owing to peripapillary gliosis (hypertrophy of neuronal supporting cells).

Treatment

No treatment is effective once the optic nerve undergoes atrophy.

NEOPLASIA OF THE POSTERIOR SEGMENT

Most tumors of the posterior segment in dogs and cats result from metastasis from other sites. The most common secondary tumor is malignant lymphoma. Primary tumors are rare but include malignant teratoid medulloepitheliomas, melanomas, and optic nerve meningiomas. Therapy entails enucleation (see Chapter 137) or exenteration of the orbit, depending upon the localization of the tumor to the globe.

Chapter

139 Diseases of the Lacrimal System

Carmen M. H. Colitz

The overall function of tears is to protect and nourish cornea, sweep debris into nasolacrimal canaliculi, and lubricate the eyelids. They also have a refractive function. An understanding of the anatomy and innervation of the lacrimal system, as well as the formation, composition, and function of the precorneal tear film, is important to the understanding of the physiology, pathogenesis, diagnosis, and treatment of its diseases.

ANATOMY AND PHYSIOLOGY OF THE LACRIMAL SYSTEM

- The secretory components of the lacrimal system include the main and accessory lacrimal glands, the gland of the nictitans (third eyelid), the meibomian glands, and the conjunctival goblet cells.
- The main lacrimal gland is a tubuloacinar gland located dorsolateral to the globe between the globe and the orbital ligament and the zygomatic process of the frontal bone. It produces between 50% and 70% of the aqueous tear layer.
- The gland of the nictitans is also a tubuloacinar gland and is located ventromedially at the base of the T-shaped cartilage that supports the nictitans. It produces between 30% and 50% of the aqueous tear layer.
- The accessory lacrimal glands (Krauss and Wolfring) are located in the conjunctival fornices.
- The meibomian (tarsal) glands are modified sebaceous glands located in the distal aspect of the tarsus that open onto the edge of both eyelids in a row of small openings. They number approximately 20 to 40 per eyelid and produce the lipid component of the preocular tear film. The innervation of the meibomian glands is parasympathetic in origin.
- The conjunctival goblet cells are heterogeneously dispersed in the dog; i.e., the highest numbers are located along the lower nasal and middle fornices and the lower tarsal portion of the palpebral conjunctiva. Their function is to produce the mucus component of the tear film.
- The accessory eyelid glands are the glands of Moll and Zeis. The glands of Moll are modified sweat glands, and the glands of Zeis are prominent sebaceous glands. Their function is unknown.
- The excretory components include the superior and inferior lacrimal puncta and their canaliculi, nasolacrimal sac, and ducts.
- The superior and inferior lacrimal puncta allow the exit of the tear film from the lacrimal lake to the canaliculi then to the nasolacrimal duct.

Precorneal Tear Film

- The precorneal tear film has three layers: the lipid layer, the aqueous layer, and the mucus layer.
  - The *lipid layer* is the outer layer that is produced by meibomian glands and functions to prevent evaporation of aqueous layer.
  - The *aqueous layer* is the middle layer that is produced by the main lacrimal gland and gland of the nictitating membrane. It flushes foreign material from the conjunctival sac; lubricates for the passage of the eyelids over the cornea; provides a medium for transferring oxygen, inflammatory cells, immunoglobulins, lysozyme, and lactoferrin to the cornea; and gives a smooth surface to the cornea for optimal optical efficiency.
  - The *mucus layer* is the innermost layer that is produced by goblet cells on the conjunctiva. It functions as a surfactant and stabilizer of the aqueous layer and spreads tears across the cornea, adhering to the microvilli of the corneal and conjunctival epithelium by charged polyanions enhancing the even spread of the tear film over the corneal surface. The mucin also filters trapped and foreign particles, forming mucus strands that are moved to the medial canthus for clearance from the eye.
- Tear drainage from the lacrimal lake is via the superior and inferior lacrimal puncta to the canaliculi, which meet at the lacrimal sac, then subsequently down the nasolacrimal duct and into the nose (or mouth in some).

Innervation of the Lacrimal System

- Both basal and reflex tear production are under the control of the autonomic nervous system.
- The trigeminal nerve plays an important role in the neurogenic control of lacrimation. The ophthalmic division of the trigeminal nerve, as well as the zygomatic nerve, a branch of the maxillary division of the

trigeminal nerve, provides afferent sensory information from the lacrimal gland, periocular structures, and globe. The cornea is directly innervated by free nerve endings of the trigeminal nerve that penetrate the limbus and enter the anterior corneal stroma. Stimulation of these nerve endings results in reflex tear formation.

- The parasympathetic nervous system innervates the efferent arm of lacrimation. The parasympathetic fibers originate in the facial nerve nucleus and are distributed to the lacrimal gland with the zygomatic nerve.

DISEASES OF THE LACRIMAL SYSTEM

Diseases of the lacrimal system can be divided into those that cause a decrease in any component of the preocular tear film or those that cause epiphora. Keratoconjunctivitis sicca is primarily caused by an immune-mediated disease against the lacrimal glands, resulting in a decrease in the aqueous component of the precorneal tear film. The other, less common causes will also be discussed. Diseases that cause epiphora, or excessive tearing, are usually secondary to a problem with tear drainage or irritation from periocular hairs contacting the corneal surface. These and their appropriate therapies will also be discussed.

Keratoconjunctivitis Sicca

- Keratoconjunctivitis sicca (KCS) can be due to qualitative and quantitative deficiencies of precorneal tear film.
- Congenital alacrima or congenital hypoplasia of the lacrimal acini occurs in miniature breeds (pug and Yorkshire terrier), is uncommon, and is characterized by complete lack of precorneal tear film production, resulting in severe dryness.
- Drug-related causes of KCS include systemic sulfonamide therapy, phenazopyridine, topical and general anesthesia, antihistamines, and etodolac.
- Other causes of KCS include supervoltage and megavoltage radiation therapy, excision of the gland of the nictitans, and neurologic abnormalities.

▼ ***Key Point*** The most common cause of KCS is immune-mediated lacrimal adenitis.

Keratoconjunctivitis Sicca Due to Quantitative Tear Deficiencies

Clinical Signs

- Clinical signs of KCS are dependent on the amount of time that the disease is present.
- Acute cases with severe dryness present with acute pain, blepharospasm, and axial corneal ulceration. Ocular discharge in these cases is often mucopurulent to suppurative, and corneal ulceration may progress to perforation if not treated quickly and aggressively.
- The more common presentation is one of chronic conjunctival hyperemia with intermittent mucoid discharge.
- Due to these nonspecific clinical signs, KCS is often misdiagnosed and treated inappropriately.
- With time, the ocular discharge will become mucopurulent due to imbalance of the bacterial flora, allowing abnormal microorganisms such as beta-hemolytic *Streptococcus,* coagulase-positive *Staphylococcus,* gram-negative coliforms, and *Pseudomonas* to grow while normal flora (*Staphylococcus* species) decrease.
- The goblet cells also become hypertrophied and overproduce mucus, adding to the abnormal discharge.
- The cornea becomes lackluster in appearance and irregular, and it can develop edema, pigmentation, vascularization, areas of fibrosis, and possibly ulceration.
- The periocular skin can also become inflamed due to accumulation of ocular discharge, resulting in persistent blepharospasm.

Histologic Changes

- The acute clinical signs of KCS are characterized histologically by epithelial degeneration with vacuolization and epithelial thinning of the cornea and conjunctiva. These changes are due to increased tear osmolarity and dehydration of the corneal and conjunctival surface. Since the cornea is not vascularized normally, these acute changes can result in loss of corneal stroma if an ulcer develops.
- With chronicity, the corneal epithelium thickens and becomes keratinized. Melanin granules are deposited throughout the corneal epithelium and anterior stroma and can become dense. The anterior stroma also becomes infiltrated with vascularization and lymphocytic-plasmacytic inflammation.

Diagnosis

- History, clinical signs, and results of the Schirmer tear test (STT) will establish the diagnosis of KCS in most cases of quantitative tear film deficiencies.
- The STT is a semiquantitative test that assesses aqueous tear production. The usual method is to perform the STT without topical anesthesia. This is the STT 1 and it measures basal and reflex tear production by stimulating the trigeminal nerve endings through local irritation. The STT 2 is less common and is performed following topical anesthesia to eliminate reflex lacrimation. It assesses only basal tear formation. (See Chapter 131 for STT technique.)
- Normal ranges for STT 1 are between 15 and 25 mm/minute. Values in the low-normal range should be reevaluated; if still low and clinical signs are present, then treat for KCS. Values between 10 and 15 mm/min

are considered to indicate early KCS. Initiate therapy and recheck values as described below. Values between 6 and 10 mm/min are diagnosed as mild to moderate KCS, and values below 6 mm/min are considered severe. Topical atropine therapy can influence the STT values, and STT should be reevaluated after therapy has ended.

▼ ***Key Point*** Most cases of KCS are bilateral.

- Unilateral KCS with crusting of the ipsilateral nostril is indicative of neurogenic KCS. The lateral nasal gland is innervated similarly to the lacrimal gland; therefore, aqueous nasal secretions are impaired, resulting in mucopurulent nasal discharge and crusting. STT results will be negligible in cases of neurogenic KCS.

Treatment

- Treatment of KCS due to decreased tear production should (1) stimulate tear production, (2) replace tears until production increases, (3) attempt to reestablish the normal bacterial flora, and (4) decrease inflammation.
- In recent years, two drugs have been used for the stimulation of tear production: cyclosporine and, most recently, tacrolimus. Both medications inhibit T lymphocyte proliferation by blocking interleukin-2 synthesis at the transcriptional level.
  - *Cyclosporine* (0.2%, 1%, or 2%) is a naturally produced immunosuppressant with some antibiotic properties, and it inhibits cytokine production. Under experimental conditions, it is also able to inhibit prostaglandin production. The mechanism by which cyclosporine stimulates tear production is not well understood but may be by its effects on cytokines. Most cases of KCS respond to cyclosporine after 14 to 16 days of therapy, but up to 2 months may be necessary in recalcitrant cases. Therefore, cyclosporine is an excellent drug for the treatment of KCS as it fulfills three of the four requirements of therapy.
  - *Tacrolimus* (0.02–0.03%) has similar immunologic activity as cyclosporine, but it is estimated to be 20 to 50 times more potent than cyclosporine. Difficult cases of KCS may respond to higher concentrations of cyclosporine or to tacrolimus.
- Cyclosporine and tacrolimus are to be used for the life of the animal in cases of immune-mediated KCS.
- *Tear replacement* options are numerous and are often subject to the clinician's preferences. The traditional artificial tear replacers include artificial tear solutions and ointments. The solutions provide moisture but must be applied every 20 to 60 minutes to adequately protect the cornea. Hypo-osmolar tear substitutes are recommended, as tears are hyperosmolar. Examples of artificial tear solutions include Hypotears and Tears Naturale. Artificial tear ointments also protect and sooth the cornea but have longer contact time and blur vision. Examples of artificial tear ointments include Duratears, Lacri-Lube, and AKWA-Tears. Newer viscous, preservative-free tear replacers are more commonly used in veterinary ophthalmology practices and are available over the counter. These are long-lasting preparations that enhance ocular surface moisture and have extended contact time with the ocular surface. Examples of the viscous tear replacers include Genteal gel and Celluvisc.

▼ ***Key Point*** Prolapse of the gland of the nictitans should be addressed surgically by replacing the gland using the imbrication technique. This will preserve the function of the gland.

- Neurogenic KCS is often not responsive to cyclosporine, and oral pilocarpine may be helpful. Pilocarpine is a direct parasympathomimetic that stimulates the lacrimal and lateral nasal glands. A suggested protocol is as follows: Begin at two drops of ophthalmic 2% pilocarpine PO q12h for 3 days, then increase it by one drop per instillation and use for 3 days. Continue this until the dog becomes physically ill (vomiting, diarrhea, hypersalivation) or tear and nasal secretions are produced. This can take many weeks to months, and it is possible that this is the time necessary for the innervation to return.
- Topical antibiotics can be used if bacterial overgrowth is seen on cytology or if there is a corneal ulcer present.
- Oral tetracycline (or doxycycline) in combination with niacinamide can be tried in cases of KCS that do not respond to cyclosporine or tacrolimus as they have immunomodulating effects, not for their antibiotic effects. The tetracycline and niacinamide dosage for smaller dogs (up to 15 kg) is 250 mg PO q8h and for larger dogs (greater than 15 kg) is 500 mg PO q8h. The results are often variable.
- Topical corticosteroids may be used in cases of severe conjunctivitis and blepharitis and if there is no corneal ulceration. Cyclosporine and tacrolimus are innately immunosuppressive and if these are used, corticosteroids are not usually needed.
- Some cases of KCS do not respond to medical therapy, especially the drug-induced (sulfa drugs and etodolac) KCS cases. These may benefit from surgical therapy, i.e., parotid duct transposition. Refer the patient to an ophthalmologist for this procedure.

Keratoconjunctivitis Sicca Due to Qualitative Tear Deficiencies

Etiology

- Abnormalities in the lipid or mucin components of the tear film result in this type of KCS.

- Diseased meibomian glands produce highly polar lipids that disrupt the non-polar lipid surface of the tear fluid, and the normal oily covering of the tear film is lost. This results in premature dispersion of the aqueous layer. In addition, these abnormal lipids may be directly toxic to the epithelial cells. Bacterial (*Staphylococcus* species) or yeast (*Candida* and *Malassezia* species) infections of the meibomian glands result in marginal blepharitis, blepharoconjunctivitis, and meibomianitis. Other causes include generalized seborrhea, lupus erythematosus, bullous pemphigoid, abnormal development of the meibomian glands, and cats with eyelid agenesis.
- Mucin deficiency also causes tear film instability that results in corneal desiccation. Specific causes of mucin deficiency are infectious or immune-mediated diseases resulting in destruction of goblet cells. Other causes include severe scarring, following ulcerative conjunctival disease, and vitamin A deficiency, which causes squamous metaplasia of the conjunctiva and subsequent loss of the goblet cells.

Clinical Signs

- Signs of meibomian gland disease can vary. Acute meibomianitis can cause swollen eyelid margins with obviously plugged meibomian glands. These chalazia can also irritate the corneal surface and cause further damage such as chronic keratitis or corneal ulceration.
- Goblet cell abnormalities and loss of the mucin layer of the tear film result in rapid tear breakup times (BUTs). The corneal surface is lackluster in appearance and obviously irregular or ulcerated.

Diagnosis

- Both mucin and lipid deficiencies will have an adequate aqueous component; therefore, STT will not be affected.
- Magnification is necessary to closely examine the eyelid margins and the meibomian glands.
- Swollen eyelid margins with hyperemia of the mucocutaneous junction and dry crusty exudates are indicative of meibomian gland disease. Chalazia are consistent with chronic meibomianitis with granulomatous infiltrate (see Chapter 132). Abnormal meibomian gland secretions are thick and opaque with a toothpaste-like consistency. Aerobic bacterial or yeast cultures are indicated for this condition.
- Mucin deficiency is best diagnosed with a tear BUT. The BUT evaluates the ability of the corneal surface to retain a homogeneous tear covering. One drop of fluorescein stain is dropped onto the corneal surface and the eyelids are held open. Record the time from the last eyelid blink to the appearance of the first dry spot. A cobalt-blue filter is helpful. Normal BUT is 20 seconds or longer. Shorter BUTs are indicative of a mucin tear deficiency and are often less than 5 seconds.
- A biopsy of the conjunctiva from the lower medial fornix between the third eyelid and the lower eyelid may further support a mucin deficiency by quantitating the number of goblet cells. This is the site of highest goblet cell density.

Treatment

- Treatment of meibomian gland disease is based on culture of microorganisms.
- Use appropriate antimicrobials both topically and systemically. Chronic cases may require intermittent intensive treatment or continuous low-level therapy.
- Expression of the inspissated material may be necessary periodically. Severe cases with granulomatous blepharitis secondary to ruptured meibomian glands may require systemic corticosteroids, warm moist compresses, and/or surgical curettage of the chalazia.
- Lipid substitutes including petrolatum, mineral oil, liquid lanolin, or a combination of these can be used, or an antibiotic or antibiotic-corticosteroid combination in ointment form can be used to replace lost lipid until meibomianitis is resolved.
- Mucin deficiency is more difficult to treat due to concurrent inflammation requiring corticosteroids and corneal ulcers in which corticosteroids are contraindicated. Therefore, treat the corneal ulceration if present, and use topical mucinomimetic tear replacers such as Adsorbobase, 2% methylcellulose (Celluvisc), and Genteal gel.
- Preliminary research has shown cyclosporine to increase mucus production; therefore, it may be useful in cases of mucin deficiency.

Diseases Causing Epiphora

Imperforate Nasolacrimal Duct

- In dogs, this is usually due to failure of the inferior marginal puncta to open. It is often evident beneath a thin layer of conjunctival epithelium, which can be excised. Flushing the nasolacrimal duct will ensure its patency (see Chapter 131 for technique); then treat with an antibiotic-steroid combination ophthalmic eye drop for 2 weeks.
- In cats, it is uncommon but associated with chronic herpesvirus infection causing cicatrisation of the duct opening.

Congenital Nasolacrimal Duct Obstructions

- Most commonly associated with dacryops and nasal cysts. Diagnosis is by dacryocystorhinostomy; treatment is surgical.

Dacryocystitis

- Dacryocystitis is caused by inflammation of the lacrimal sac and nasolacrimal duct.

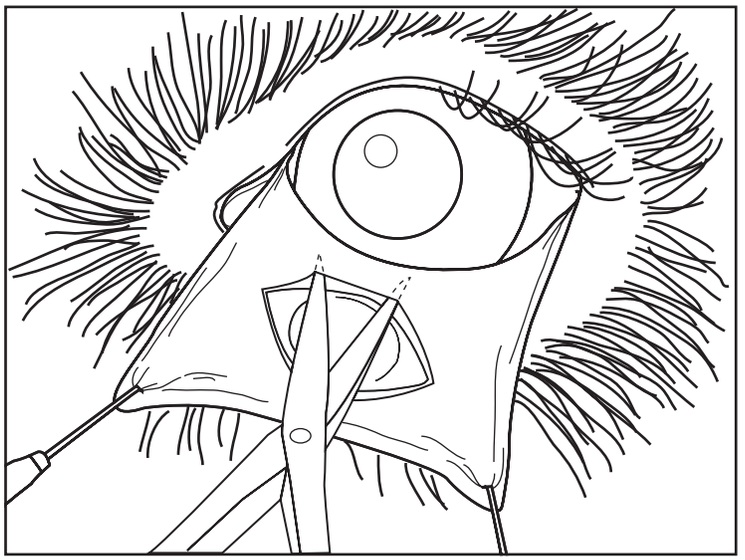

Figure 139-1. Make an elliptical incision in the conjunctiva of the third eyelid around the prolapsed gland, then undermine with ophthalmic scissors.

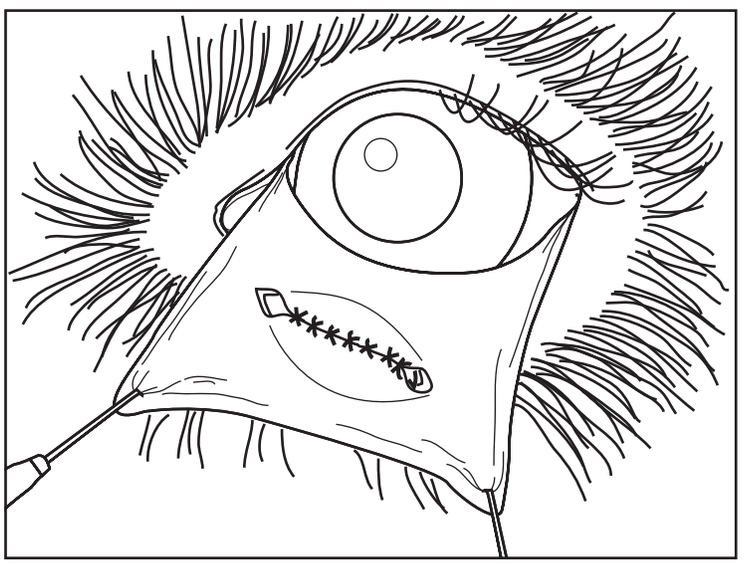

Figure 139-2. Close the conjunctiva over the gland with fine absorbable suture (5-0 or 6-0). Be sure to bury the knots to prevent abrasion of the cornea.

- Causes include foreign bodies that lodge in the nasolacrimal sac, periodontal disease, bacterial or fungal infection, or obstructions such as fractures, trauma, or sinusitis.
- The most common clinical sign is epiphora or mucopurulent ocular discharge.
- Diagnosis is by cytology and culture and sensitivity of the exudate. Dacryocystorhinography may be necessary to localize the lesion.
- Treatment includes removal of the obstruction if possible by irrigation of the nasolacrimal duct. Use appropriate antibiotic and anti-inflammatory therapy. If the disease is chronic and the nasolacrimal apparatus is not patent, dacryocystorhinostomy or dacryocystobuccostomy may be indicated.

Eyelid Abnormalities

- If the nasolacrimal anatomy and tear production are normal, assessment of the animal's periocular conformation should be performed (see Chapter 132).

- Entropion or excessively large nasal folds resulting in trichiasis can rub on the corneal surface, causing epiphora. Surgical correction of these abnormalities will resolve the epiphora (see Chapter 132).
- Distichiasis or ectopic cilia also manifest as epiphora. Cryotherapy (distichiasis) or en bloc excision (ectopic cilia) is indicated for these conditions.

PROLAPSED GLAND OF THE THIRD EYELID (CHERRY EYE)

- The ligament holding the gland of the nictitating membrane or third eyelid fails, allowing the gland to prolapse. This creates a mass like appearance at the ventromedial aspect of the medial canthus.
- With exposure, the gland becomes inflamed and swollen.
- Many breeds of dogs are predisposed to this condition supporting a genetic component. These include American cocker spaniel, Lhasa apso, beagle, and bulldog.
- Diagnosis is made on clinical appearance.
- Since the gland of the nictitating membrane produces up to 50% of the aqueous component of the tear film, it should be surgically repaired using the imbrication technique (Figs. 139-1 and 139-2). In some cases, it may reoccur and a second surgery is indicated.

▼ ***Key Point*** Never remove the gland of the third eyelid for treatment of Cherry Eye as it will predispose to KCS.

Chapter

140 Diseases of the Orbit

Mary B. Glaze

Disorders of the orbit are relatively uncommon in companion animals. Because the area cannot be directly visualized without sophisticated imaging devices or complicated surgical procedures, even the simplest of lesions can pose a diagnostic and therapeutic challenge.

ANATOMY

Orbital Cavity

- The orbit is a cone-shaped cavity that surrounds the eye and its supporting structures.
- Only the medial wall, part of the orbital roof in the dog, and the entire orbital roof in the cat are bony. The medial wall is a thin septum that separates the orbit from the nasal cavity. The floor of the orbit is muscular, with the exception of a small shelf of maxillary bone in the cat. A ligament that bridges the space between the frontal and the zygomatic bones completes the lateral aspect of the canine and feline orbit.
- Three prominent openings at the apex of the orbit permit the passage of its major vessels and nerves.
- The dorsal aspect of the ramus of the mandible moves rostrally when the mouth is opened, compressing the orbital contents.

Orbital Contents

- The contents of the orbit are enclosed by a fibrous membrane, the periorbita, that attaches to the orbital wall at the optic foramen and extends to the orbital rim. The periorbita contains sympathetically innervated smooth muscle fibers.
- The anterior limit of the orbit is formed by a sheet of connective tissue, the orbital septum, that extends from the periorbita at the orbital margin to blend with the tarsus of the lid.
- Of the seven extraocular muscles, six originate at the orbital apex. The inferior oblique arises from the anteromedial orbital wall.
- The orbital fat pad cushions the orbital contents and is found between the periorbita and the surrounding structures. Fat is also located within the periorbita between the extraocular muscles.
- In addition to numerous arteries, veins, and autonomic nerves, the second, third, fourth, and sixth cranial nerves and the ophthalmic branch of the trigeminal nerve traverse the orbit.
- The nictitans occupies the ventronasal portion of the orbit and moves passively in relation to globe movements in the dog. In addition, movement of the feline nictitans is sympathetically controlled.
- The lacrimal gland is contained within the periorbita near the superotemporal aspect of the globe.
- The zygomatic salivary gland occupies the lateral orbital floor, just behind the orbital margin and outside the periorbita.

Neighboring Structures

- Diseases of neighboring structures, including the oral and nasal cavities, teeth, tongue, muscles of mastication, and paranasal sinuses, must always be considered when evaluating orbital disease.
- The nasal cavity and paranasal sinuses are directly adjacent to the medial orbit.
- Tooth roots of the maxillary premolar and the first and second molars abut the orbital floor, separated from the soft tissues of the orbit by only a thin layer of alveolar bone.

ALTERATIONS IN THE GLOBE-ORBIT RELATIONSHIP

The position of the eye within the orbit depends upon the orbital dimensions, the relative globe size, and the volume of the other orbital contents. The normal brachycephalic dog or cat has a shallow orbit and prominent eye. Larger orbits and less prominent eyes are found in mesaticephalic and dolichocephalic breeds. As a general rule, the feline globe nearly fills the orbit and predisposes the animal to alterations in the globe-orbit relationship early in the course of orbital disease.

▼ ***Key Point*** The first clinical sign of orbital disease is often a change in the position or the direction of the globe relative to the orbital rim and to the other eye.

EXOPHTHALMOS

Exophthalmos refers to the abnormal protrusion of a normal-sized eye. Differentiate exophthalmos from buphthalmos, the enlarged eye that accompanies chronic glaucoma, by comparing the horizontal corneal diameter of the animal's affected eye with its normal eye. If the diameters differ, the problem is one of the globe rather than the orbit. Distinguish exophthalmos from (1) the contralateral enophthalmos, (2) the exaggerated palpebral fissures of macroblepharon and facial paralysis, and (3) the characteristically prominent globe of the brachycephalic dog and cat.

Causes of exophthalmos in dogs and cats encompass a spectrum of developmental disorders, inflammatory processes, neoplasias, traumatic lesions, cystic disorders, and skeletal diseases.

Developmental Disorders

Congenital Cysts

- Orbital cysts develop in association with other ocular anomalies, appearing as appendages of microphthalmic eyes or entirely supplanting a recognizable globe.
- These cysts are rare, non-heritable consequences of defective ocular organogenesis.
- If asymptomatic and cosmetically acceptable, no treatment is warranted. Excise large, exposed cysts to prevent secondary drying and irritation.

Craniofacial Deformities

- *Cyclopia* is a rare lethal anomaly in which the orbits and their contents are fused into a single structure. A single midline orbit and a dysplastic eye appearing as either a single or a bilobed sphere characterize the anomaly. The nose and maxilla are rudimentary. The defect has been reported in offspring of cats administered griseofulvin during the first half of gestation. There is no treatment for this anomaly.
- *Orbital malformation* and a subsequent divergence of the ocular axes accompany hydrocephalus.

Arteriovenous Malformations

Etiology

Rarely, fistulas may develop between orbital or periorbital vessels. The cause is unknown.

Clinical Signs

- Exophthalmos is associated with a pulsatile murmur auscultated over the orbit. The bruit diminishes when the carotid artery is compressed.
- The exophthalmos may exacerbate in response to postural changes, as when the animal lowers its head to eat.

Diagnosis

- Confirm the malformation in the anesthetized patient using orbital ultrasonography, color Doppler imaging, or contrast venography.
- For venography, inject 5 to 10 ml of contrast medium into the angularis oculi vein, using a 21-gauge needle or catheter, immediately before and during radiography. Perform a contrast study on the normal side for comparison.

Treatment

- The degree of postural exophthalmos may diminish as the animal and its orbit mature.
- Surgical attempts at ligation and resection are frequently unsatisfactory. One report described severe intraoperative hemorrhage and postoperative recurrence of the lesion in a dog.

Acquired Disorders

Acquired disorders are more common than congenital orbital diseases as causes of exophthalmos in dogs and cats. When clinical signs of orbital disease are present, an attempt should be made to classify the disease as inflammatory, neoplastic, or cystic. As a general rule, acute lesions associated with discomfort and swelling of conjunctiva and eyelids are inflammatory, whereas slowly progressive, nonpainful disorders are secondary to space-occupying masses.

▼ ***Key Point*** In instances of acquired exophthalmos, document the rapidity of onset and the presence or absence of pain, especially upon opening the mouth.

Inflammatory or Infectious Disorders

Orbital Cellulitis or Orbital Abscess

Orbital inflammatory disease is a common cause of *acute, painful,* unilateral exophthalmos.

Etiology

Orbital inflammation is usually the result of trauma, infection, or the extension of a disease from neighboring structures.

- *Trauma:* Trauma produces both septic and nonseptic inflammation. Infections follow breaching of the oral mucosa or eyelids by bite wounds or foreign objects, such as bones. Blunt trauma may damage the osseous and soft tissues of the orbit. Iatrogenic injury may occur as a consequence of aggressive or improper dental extraction techniques. Occasionally, a foreign body will be retained within the orbit, causing recurrent inflammation.
- *Infection:* Aerobic and anaerobic bacteria, fungi, and parasites infect the orbit primarily or extend from the paranasal sinuses and nasal cavity. Orbital fungal pyo-

granulomas can occur with blastomycosis, cryptococcosis, and coccidioidomycosis. In cats, *Aspergillus* and *Penicillium* have been implicated in orbital cellulitis secondary to sinusitis. Larvae of *Dirofilaria immitis* and *Ancylostoma* species, and *Toxocara canis* produce primary orbital cellulitis by invading canine orbital tissues. The nasal mite *Pneumonyssus caninum* is a documented cause of orbital cellulitis and sinusitis in a dog. Even *Cuterebra* larvae occasionally invade the orbit. Granulomatous nodules containing *Onchocerca* species Nematodes have been identified in the canine retrobulbar space.

- *Extension of disease:* Tooth root abscesses (particularly maxillary PM3, PM4, M1, and M2) are the most common cause of orbital cellulitis in dogs and cats. Disorders of the frontal or paranasal sinuses, nasolacrimal system, temporal and pterygoid muscles, or zygomatic salivary and lacrimal glands may also cause secondary orbital inflammation or infection. Inflammation of the posterior sclera may affect adjacent orbital tissues.
- *Rare proliferative inflammatory disorders:* Referred to as pseudotumors, these may mimic orbital neoplasms. Examples include fibrous histiocytoma, undifferentiated inflammatory pseudotumor, and eosinophilic granuloma. In cats, proliferation of spindle cells and fibrovascular tissue within and adjacent to the sclera decreases ocular motility and dictates enucleation for relief of progressive lagophthalmia and keratitis.

Clinical Signs

- Orbital inflammation is characterized by a relatively *acute* unilateral exophthalmos, with conjunctival hyperemia, chemosis, third eyelid protrusion, and pain on opening the mouth.
- The animal may be febrile and exhibit an inflammatory leukogram.
- Abscesses on rare occasion produce swelling or discoloration behind the last upper molar.

Diagnosis

- Diagnosis is based upon history and physical examination. Consider sedation in painful patients objecting to examination.
- Palpate the periocular and periorbital regions.
- Close the eyelids and retropulse (i.e., push) the globe into the orbit to rule out space-occupying masses.
- Thoroughly evaluate the oral cavity. If dental disease is not readily apparent, examine the caudal maxillary teeth with a dental explorer and periodontal probe.
- Hematology, cytology, and culture of orbital aspirates may be of benefit in some cases.
- Radiographically localize orbital foreign bodies with four views: lateral, ventrodorsal, oblique, and frontal. A wire ring positioned over the limbus may serve as a helpful point of reference. Dental radiography should also be performed.
- Orbital ultrasonography of diffuse cellulitis is characterized by a generalized loss of orbital tissue definition. The optic nerve and extraocular muscles are less easily visualized when compared with the normal eye. An abscess may appear as a hypoechoic area within a well-defined hyperechoic wall.

Treatment

- Administer a broad-spectrum systemic antibiotic such as amoxicillin clavulanate for at least 10 days. Response to antibiotic therapy is generally rapid, with resolution within 1 to 2 weeks.
- Protect the corneal surface with an antibiotic ophthalmic ointment in cases of extreme exophthalmos.
- Alleviate the acute swelling and discomfort with warm periocular compresses and a systemic nonsteroidal anti-inflammatory agent (aspirin at a dosage of 10–25 mg/kg q12h PO in dogs). Corticosteroid therapy is controversial because of the potential for sepsis in some patients.
- Establish ventral drainage through the mouth if no response is seen within 48 to 72 hours. Incise the mucous membrane behind the last upper molar with a #15 Bard-Parker scalpel blade. Carefully insert a hemostat through the pterygoid muscle and open gently in the retrobulbar space. Insert a sterile, open-ended tomcat catheter through the mucosal opening to obtain aspirates for cytology and culture.

▼ ***Key Point*** This orbital drainage procedure can damage the optic nerve, globe, or major orbital vasculature; perform carefully.

Masticatory Muscle Myositis (Eosinophilic Myositis)

Inflammation and swelling of the muscles of mastication may compromise the orbital space and push the globe forward.

Etiology

Cellular and humoral destruction of type 2M myofibers and myofibril-specific antibodies in affected dogs suggests an autoimmune disorder.

Clinical Signs

- Temporalis, masseter, and pterygoid muscle swelling is accompanied by fever, pain on opening the mouth, difficulty eating, and trismus (spasm of masticatory muscles).
- Ocular signs include exophthalmos, conjunctival hyperemia, eyelid edema, and third eyelid protrusion.
- The German shepherd appears most susceptible. Shetland sheepdogs, golden retrievers, and Weimaraners are also predisposed, but any canine breed may be affected. The mean age of onset is 3 years.
- The condition is more often bilateral than unilateral.

- Acute episodes may last 10 to 20 days. Recurrences lead to muscle atrophy and decreased prominence of the globe.
- Blindness is a rare complication.

Diagnosis

- Confirm the clinical diagnosis with temporalis muscle biopsy samples to demonstrate mononuclear and eosinophilic infiltrates and type 2M myofiber antigen-antibody complexes (see Chapter 130).
- Peripheral eosinophilia is inconsistent.
- If muscle biopsy is not possible, serum may yield evidence of type 2M myofiber antibodies (see Chapter 130).

Treatment

- Treatment must precede the onset of muscle atrophy to prevent recession of the globe into the orbit.
- Administer oral prednisone, beginning with a daily dosage of 2 mg/kg q12h for 3 weeks to reduce the likelihood of recrudescence. Reduce the dose gradually thereafter, continuing treatment for a total of 6 to 8 weeks.

Bilateral Extraocular Polymyositis

This unusual myositis targets the extrinsic muscles of the eye in primarily young, large-breed, female dogs.

Etiology

A mononuclear infiltrate composed predominantly of T lymphocytes and localized to the extraocular muscle bellies suggests an immune mechanism directed at specific extraocular myofibers. The disorder is reminiscent of euthyroid Graves' ophthalmopathy in humans.

Clinical Signs

- Affected dogs range in age from 5 to 72 months; 80% are between 7 and 10 months of age. Females are affected twice as often as males. Golden retrievers, Doberman pinschers, and springer spaniels are the most commonly affected breeds.
- Chemosis typically precedes the onset of bilateral, sometimes asymmetrical, nonpainful exophthalmos. The globes appear otherwise normal. Vision impairment occurs infrequently as a consequence of retinitis or compressive optic neuropathy. Third eyelid protrusion is rare.

Diagnosis

Document the extraocular muscle swelling with orbital echography, computed tomography, or magnetic resonance imaging. Confirm the clinical diagnosis with extraocular muscle biopsy to demonstrate the mononuclear cell infiltrate of CD3+ T lymphocytes and macrophages directed against fine extraocular myofibers (see Chapter 130). Complete blood counts and serum chemistry values are normal.

Treatment

Administer oral prednisone at 2 mg/kg every 12 hours. Although clinical response is often dramatic in 3 to 5 days, minimize recrudescence by continuing therapy for at least 21 days before tapering the dosage. After the initial 3-week treatment regimen, gradually taper the dosage over a 2-month period. Topical corticosteroid therapy is not effective.

Prognosis

Recurrences are likely and may be triggered by stressors including estrus, surgery, or boarding. Strabismus and enophthalmos are uncommon sequelae.

Neoplasia

▼ ***Key Point*** Most orbital neoplasms are aggressive, malignant tumors that are diagnosed in the advanced stages of development.

Etiology

- Both primary and secondary orbital tumors occur in dogs and cats.
  - Primary neoplasms arise from a variety of tissues within the orbit, including epithelium, bone, nerves, vessels, connective tissue, hemolymphatic tissue, and glandular tissues.
  - Secondary tumors extend from adjacent structures such as the nasal cavity or metastasize from distant sites.
- A retrospective study of 44 dogs identified 18 tumor types; most common were osteosarcoma, fibrosarcoma, and nasal adenocarcinoma. In dogs, 75% of orbital tumors are primary; 70% of feline tumors invade from adjacent tissues. In both species, approximately 90% of orbital tumors are malignant.

Clinical Signs

- *Gradual, painless exophthalmos* is accompanied by periocular swelling, third eyelid protrusion, and globe deviation. Secondary lagophthalmos may cause corneal drying.
- Compression of the globe can cause altered tapetal reflectivity, changes in the course of retinal vessels, or retinal detachment with subsequent abnormalities of the pupillary light response and blindness.
- On occasion, orbital lymphoma and mast cell sarcoma masquerade as inflammatory disease, with rapid onset of painful exophthalmos. Primary orbital neoplasia is typically unilateral. Metastatic disease may affect both orbits. The mean age of dogs with orbital neoplasia is 8 years, ranging from 18 months

to 15 years. Older cats (average 8.9 years) experience a similar risk, yet orbital lymphoma and multicentric fibrosarcoma occur in cats less than 2 years of age.

Diagnosis

- Perform a complete physical examination to evaluate for other neoplastic changes.
- Substantiate the clinical diagnosis and evaluate adjacent structures with radiography, orbital ultrasonography, computed tomography scan, and/or magnetic resonance imaging. Magnetic resonance imaging is recommended for patients in which surgery is proposed.
- Perform thoracic and abdominal radiography and/or ultrasonography to rule out metastatic disease.
- With the animal heavily sedated or anesthetized, obtain orbital aspirates for cytologic evaluation using a 1-inch, 22-gauge needle attached to a syringe.
  - The direction of deviation of the exophthalmic globe suggests the tumor's location and the site for needle entry. For example, lateral strabismus suggests a medial space-occupying mass.
  - To reach the medial mass, insert the needle medial to the third eyelid, penetrate the conjunctiva, and aspirate gently along the medial orbital wall. Other orbital quadrants may be sampled in a similar manner.
  - For masses directly behind the eye, surgically prepare the lateral aspect of the orbit and insert the needle just posterior to the angle formed by the lateral orbital ligament and the zygomatic arch.
  - If available, ultrasound-guided orbital aspiration helps minimize complications and ensure accurate needle placement. One study reported that cytologic examination was diagnostic for orbital neoplasia in 49% of retrobulbar aspirates.

Treatment

- Surgical resection of the neoplasm is the treatment of choice. Orbitotomy and tumor excision may be attempted in cases of circumscribed primary tumors. Surgical approaches to the orbit are described elsewhere. Refer patients requiring exploratory orbitotomy to a veterinary ophthalmologist or surgeon.
- If the extent of involvement precludes total excision of the tumor, orbital exenteration (removal of the globe, adnexa, and orbital contents) is recommended. While some tumors may respond to adjunct chemotherapy or radiation therapy, adverse radiation effects (chronic keratitis, diminished tear production, and cataract formation) should be taken into account before choosing this modality in lieu of exenteration.

Prognosis

Various studies document the poor survival rates associated with orbital neoplasia.

- In an early series of 23 patients, only 3 dogs with orbital neoplasia survived 3 years. The mean survival time after diagnosis in a series of 21 cats was only 1.9 months.
- A more recent study of 25 cases of retrobulbar neoplasia found dogs survived an average of 10 months while affected cats lived only 1 month following diagnosis.
- Of 44 dogs included in Hendrix and Gelatt's study (2000), 56% were euthanized or had died within 6 months of diagnosis.

Orbital Trauma

Traumatic Proptosis

Complete displacement of the globe from the orbit is a true, sight-threatening emergency. Tension on the optic nerve and vascular compromise secondary to tissue compression by the eyelids quickly damage ocular tissues beyond repair. Treatment begins as soon as the patient's systemic condition allows.

Etiology

- The depth of the orbit dictates the force necessary to displace the globe.

▼ ***Key Point*** Proptosis most commonly occurs in the brachycephalic dog because of its shallow orbit and exaggerated palpebral fissure. Excessive restraint alone may be sufficient to dislodge the globe in these breeds.

- In contrast, the eyes of cats and dolichocephalic dogs are rarely displaced from their well-proportioned orbits except in severe head trauma.

Clinical Signs

- The proptosed globe rests in front of the eyelids, its proximity to the orbit determined by the extent of the extraocular muscle damage, the integrity of the optic nerve, and the degree of retrobulbar hemorrhage.
- Chemosis and subconjunctival hemorrhage are often present.
- Prolonged exposure of the cornea leads to ulceration.
- The pupil may be dilated from oculomotor paralysis or constricted from an antidromic axonal reflex of contingent negative variation.
- Lateral strabismus is a common complication of proptosis due to rupture of the medial rectus muscle.

Diagnosis

- Perform a thorough physical examination to assess the other effects of head trauma.
- Examine the eye closely for intraocular damage. Palpate the orbital rim for fractures, and radiograph if indicated. Apply fluorescein dye to the cornea to document ulceration.

Treatment

- Apply a bland ophthalmic ointment to the eye to protect the exposed corneal surface. Since the corneal epithelium is typically compromised due to drying, avoid topical corticosteroids initially.
- Reposition the eye as soon as the animal's general condition stabilizes. If considerable delay is anticipated before surgery, consider a lateral canthotomy to relieve tissue compression and secondary vascular compromise by the eyelid "sphincter."
- Reserve enucleation for ruptured globes, for those with extensive extraocular muscle avulsion, or for those with severed optic nerves.

Surgical Procedure

Objectives

- To reestablish the normal position of the eyelids anterior to the globe
- To protect the cornea from exposure

Equipment

- Two strabismus hooks
- Ophthalmic forceps and needle holder
- 5-0 non-absorbable suture (e.g., nylon)
- Tubing or other material suitable for use as stents

Technique

1. Anesthetize the patient.
2. Irrigate the globe and surrounding tissues with sterile physiologic saline and dilute (1:50) the povidone-iodine solution.
3. Elevate the eyelid margins with either a blunt probe, such as a strabismus hook, or horizontal mattress sutures placed beforehand over stents. Sutures enter the eyelid 5 mm from the margin and exit through the meibomian gland openings along the lid margin to prevent corneal contact. The suture ends can be gathered together in a hemostat and lifted simultaneously as gentle counterpressure is applied against the cornea with a moistened cotton ball or the flat surface of a scalpel handle.
4. Tie the sutures firmly, bringing the eyelid margins into close apposition. Leave a slight separation at the medial canthus to facilitate topical therapy with a broad-spectrum antibiotic ointment 3 to 4 times daily. Miosis secondary to anterior uveitis may be modified by judicious application of topical atropine ointment. Overzealous atropine use can reduce tear production and complicate corneal recovery.
5. Administer an oral broad-spectrum antibiotic, such as ampicillin, for 7 days. Avoid systemic sulfonamides, which may reduce tear production.
6. Administer an initial injection of dexamethasone (0.2 mg/kg) followed by oral prednisone therapy (1 mg/kg) for 5 to 7 days to reduce orbital and optic nerve inflammation.

▼ ***Key Point*** Do not inject medication into the retrobulbar area. Do not aspirate orbital contents or the globe itself.

7. Remove the eyelid sutures when the orbital swelling resolves, usually in 3 weeks. Orbital swelling is evaluated by retropulsing the globe. Use the unaffected eye for comparison. Be patient! Premature suture removal will lead to exposure and secondary corneal ulceration.

Prognosis

- An animal with a minimal amount of extraocular muscle damage, an eye tightly positioned against the eyelids, a positive direct or consensual pupillary light reflex, a miotic pupil, and an absence of hyphema has the best prognosis for salvaging the globe.
- Conversely, unfavorable prognostic indicators include rupture of three or more extraocular muscles, lack of a consensual pupillary reaction, marked intraocular hemorrhage, or a hypotensive globe suggestive of scleral rupture.
- Prognosis for vision is guarded at best. In a study of 84 cases of ocular proptosis, only 27% of canine globes (18 of 66) remained visual after proptosis. All proptosed feline eyes in the study (18 of 18) were blind.
- Potential sequelae include lateral strabismus, chronic keratitis due to lagophthalmia and low tear production, phthisis bulbi, and blindness. Strabismus slowly improves over time in most cases. If exposure and secondary ulceration persist, a medial canthoplasty may be beneficial if the client will not consider enucleation.

Orbital Hemorrhage or Emphysema

Etiology

- Less severe orbital trauma may result in lagophthalmia due to retrobulbar and subconjunctival hemorrhage.
- Fractures of the sinus wall may cause air to collect beneath the conjunctiva.
- Orbital emphysema from entry of air through the nasolacrimal duct is a rare complication of routine enucleation.

Clinical Signs and Diagnosis

- Mild-to-moderate exophthalmos is associated with lagophthalmia, chemosis, subconjunctival hemorrhage, and lid swelling.

- Emphysema-related orbital distention is nonpainful and compressible; needle aspiration reveals only air.
- Perform radiography to rule out a sinus wall fracture in patients with post-traumatic emphysema.

Treatment

- Confine the patient to limit further hemorrhage.
- Use cold compresses to reduce acute swelling.
- Apply topical methylcellulose artificial tear ointments frequently (4–6 times daily) to protect the corneal surface from drying.
- Administer oral or parenteral corticosteroids as described for the proptosed globe (see previous section). Avoid nonsteroidal anti-inflammatory drugs that inhibit platelet function.
- Emphysema usually requires orbital exploration and ligation of the canaliculus.

Arteriovenous Fistula

Orbital vascular fistulas may develop secondary to trauma. Clinical signs and diagnostic procedures are similar to those described for developmental vascular anomalies.

Cystic Diseases

Acquired orbital cysts are uncommon consequences of trauma to orbital glands and incomplete excision of secretory tissues during enucleation.

Zygomatic Mucocele

Leakage of saliva from the zygomatic salivary gland or its duct is an uncommon cause of exophthalmos in the dog and cat.

Etiology

The condition may occur spontaneously or after orbital trauma.

Clinical Signs

A painless swelling beneath the inferior temporal or nasal conjunctival fornix is commonly associated with prominence of the third eyelid. The mucosa behind the last upper molar may protrude.

Diagnosis

- Aspirate fluid from the lesion. The mucocele contains a clear, straw-colored, or blood-tinged tenacious material.
- Perform a zygomatic sialogram to confirm the clinical and cytologic diagnosis.

Treatment

- The treatment is surgical; the location of the swelling dictates the approach for removal of the mucocele.
- Approach mucoceles beneath the inferior conjunctival cul-de-sac transconjunctivally, making an incision between the nictitans and the lower eyelid or through the eyelid surface.
- Lateral mucoceles require a limited orbitotomy, the details of which are described in surgical texts.

Mucocele Following Enucleation

Cystic swelling of the orbit may follow enucleation if mucus or tear-producing tissues are not completely excised.

Etiology

Retained conjunctival goblet cells or glandular tissue from the third eyelid may cause cystic swelling of the orbit.

Clinical Signs

As fluid accumulates within the orbit, the overlying skin distends. A fistula may develop, draining seromucoid fluid.

Diagnosis

- Clinical signs are suggestive.
- Perform aspiration cytology to rule out post-surgical infection.

Treatment

Explore the orbit to remove retained secretory tissue, approaching anteriorly through the eyelids.

Other Causes of Exophthalmos

Anecdotal reports attribute other causes of exophthalmos to the hormonal influences of estrus and to the edema caused by hypoproteinemia or systemic hypertension.

ENOPHTHALMOS

Enophthalmos refers to the recession of the eye within the orbit. Differentiate the condition from the relative enophthalmos that accompanies periorbital swelling or edema of the eyelids and conjunctiva.

Enophthalmos may be accompanied by mucoid-to-mucopurulent discharge because of the exaggerated conjunctival cul-de-sac and by ptosis and entropion because of loss of eyelid support by the underlying globe. With the exception of transient enophthalmos accompanying ocular pain, restoration of the globe's normal position within the orbit is seldom successful.

Causes of enophthalmos include developmental abnormalities, retraction of the globe due to pain, atrophy of orbital tissues following debilitating disease or trauma, and loss of smooth muscle tone in the periorbita.

Developmental Disorders

Microphthalmos or Anophthalmos

The microphthalmic globe fails to develop to normal size in dogs and occasionally in cats. Anophthalmos refers to a rare condition in which all ocular tissues are absent.

Etiology

Microphthalmos is inherited in several breeds of dog, including the Australian shepherd, miniature schnauzer, Old English sheepdog, Akita, cavalier King Charles spaniel, Samoyed, American cocker spaniel, Bedlington and Sealyham terriers, beagle, Labrador retriever, and Doberman pinscher. Multiple ocular defects, including microphthalmos, are associated with partial albinism and deafness in the Great Dane and collie. Teratogenic influences during early pregnancy may affect ocular development. Causes of microphthalmos in cats are poorly characterized.

Clinical Signs

- The anomaly is characterized by varying degrees of enophthalmos.
- Because orbital development is influenced by globe size during skeletal maturation, the orbit may also appear small and the palpebral fissure may appear narrowed.
- Accompanying ocular defects include persistent pupillary membranes, cataracts, colobomas, retinal dysplasias, and orbital cysts. Multiple ocular anomalies may render the globe sightless, but on occasion small globes may be structurally and functionally normal.

Diagnosis

- Diagnosis is based upon clinical signs.
  - Differentiate microphthalmos from phthisis bulbi, an acquired atrophy of the globe. Evidence of scarring, inflammation, and normal-sized orbit accompany atrophy.
  - Anophthalmos is diagnosed only after serial histologic examination of orbital tissue has excluded the possibility of microphthalmos.

Treatment

- There is no treatment for microphthalmos.
- Enucleate if chronic irritation and discharge accompany the condition.
- Eliminate affected animals from breeding programs.

Breed-Related Enophthalmos

Etiology

The large orbits and deeply set eyes inherited as conformational traits of dolichocephalic breeds, such as the Doberman pinscher, Irish setter, and golden retriever, may create a relative enophthalmos.

Clinical Signs and Diagnosis

- The globe appears normal but deeply set within the orbit.
- The nictitans may be prominent.
- Mucoid-to-mucopurulent discharge, ptosis, and entropion are common sequelae.

Treatment

- The condition is incurable.
- Manage secondary conjunctivitis with intermittent applications of topical antibiotic-corticosteroid ointment.
- Correct accompanying entropion.

Acquired Disorders

Acquired enophthalmos is common, particularly in response to ocular pain and as a consequence of severe or recurrent inflammation of the globe itself.

Ocular Pain

The retractor bulbi muscle pulls the eye into the orbit when pain is present. The phenomenon is more apparent in the dog than the cat.

Etiology

Any painful ocular disorder may cause enophthalmos, especially ulcerative keratitis, anterior uveitis, and acute glaucoma. These conditions are discussed in other chapters.

Clinical Signs

In addition to enophthalmos, the animal demonstrates other nonspecific signs of ocular pain: excessive tearing, eye rubbing, blepharospasm, photophobia, and nictitans protrusion.

Diagnosis

- Examine closely for ectopic cilia, foreign body, corneal ulcer, or intraocular disease.
- Pain associated with ocular surface disorders, such as ulcers, may decrease following topical application of 0.5% proparacaine.

Treatment

Treat the underlying ocular disease.

Changes in Orbital Volume

Reduction in retrobulbar tissue mass or damage to the bony or soft-tissue structures forming the walls of the orbit causes the globe to recede. Orbital neoplasia occasionally produces enophthalmos, especially in cats.

Dehydration or Cachexia

- Loss of retrobulbar fat causes a mechanical sinking of the globe into the orbit. Pronounced weight loss and dehydration secondary to vomiting, diarrhea, or other debilitating conditions decrease the retrobulbar fat pad.
- Reduced orbital tissue mass may also be a feature of aging.
- Correct dehydration if present. Enophthalmos secondary to cachexia and loss of retrobulbar fat may not be reversible.

Atrophy Following Inflammation or Trauma

Reduction of the orbital tissue mass effectively enlarges the orbit, resulting in enophthalmos.

Etiology

- Atrophy of the temporal, masseter, and pterygoid muscles is relatively common in dogs following myositis or as an idiopathic phenomenon.
- Brain stem infections or injuries may produce alterations in the trigeminal motor nucleus and result in atrophy of the muscles of mastication.
- Similar lesions may develop as a consequence of trauma to the trigeminal nerve at the base of the ear or fractures in the temporomandibular joint or skull at the oval foramen.
- Chronic or recurrent orbital inflammation may lead to atrophy of orbital contents; trauma or inflammation of the globe may lead to phthisis bulbi.

Clinical Signs and Diagnosis

- Atrophy of the masticatory muscles alters the facial appearance, exaggerating the skull's bony protuberances.
- The animal is unable to open the mouth widely and often has difficulty prehending food.
- Enophthalmos and passive nictitans prolapse may cause visual impairment.
- The phthisic globe is small and blind, with a thickened sclera, opaque cornea, and profound disorganization and scarring of the intraocular structures.

Treatment

- Consult a veterinary ophthalmologist regarding autogenous fat transplants or implantable beads (strictly a cosmetic procedure) to modify the degree of post-inflammatory or post-traumatic enophthalmos.
- There is no effective treatment for phthisis bulbi. Control secondary conjunctivitis with regular irrigation and intermittent topical antibiotic-corticosteroid ophthalmic preparations.
- Enucleate phthisic globes in cats because of the potential for post-traumatic ocular sarcoma.

Orbital Fat Prolapse

Enophthalmos and nonpainful subconjunctival swelling are reported in dogs with prolapse of orbital fat. Subconjunctival fine-needle aspirates are diagnostic. Surgical resection of the displaced fat is curative.

Sympathetic Denervation

Horner's syndrome and feline dysautonomia cause loss of sympathetic tone in the periorbita, with varying degrees of enophthalmos.

Neoplasia

Pathologic expansion of the orbit due to loss of the lateral and ventral periorbita may account for the enophthalmos that accompanies orbital neoplasia in the cat.

STRABISMUS

Involuntary deviation of the globe from its normal visual axis may occur as a developmental or acquired abnormality.

Developmental Disorders

Conformational Strabismus

Strabismus is common in brachycephalic and toy breeds of dogs. Exotropia or lateral deviation is most likely to occur in the Boston terrier, Pekingese, Shih Tzu, and pug.

Albinism

In Siamese and Himalayan cats, esotropia (crossed eyes) is attributed to effects of the albino gene. An increased number of optic nerve fibers originating in the temporal retina decussate at the optic chiasm in affected animals. The strabismus is thought to be a compensatory mechanism for the accompanying abnormal retinotopic projections to the lateral geniculate and occipital cortex. A fine pendular nystagmus may be associated with the strabismus.

Extraocular Muscle Hypoplasia

Congenital extraocular muscle aplasia and hypoplasia are rare causes of strabismus in the dog. A single report in a miniature poodle described dramatic upward rotation of one eye and esotropia of the opposite globe. Only the medial rectus and ventral oblique muscles were present. Position of the globe improved with resection of the medial rectus muscle.

Hydrocephalus

Expansion of the calvarium into the dorsomedial orbit is responsible for the lateral and ventral deviation of the globes in hydrocephalic puppies.

Acquired Disorders

Postproptosis Strabismus

Although deviation can occur in any direction, dorsolateral strabismus is a common sequela of proptosis due to avulsion of the ventral and medial rectus muscles. The strabismus usually improves over a period of weeks to months, although position of the globe seldom returns to normal. Severe, persisting deviation may be treated by anchoring sutures to realign the globe or by partial tarsorrhaphy to protect the cornea and improve the overall appearance.

Restrictive Extraocular Myositis

Restrictive myositis presents as a rapidly progressive ventral to ventromedial strabismus in young, adult, large-breed dogs, including the Irish wolfhound, Shar-Pei, Akita, golden retriever, and the dalmatian. Patients demonstrate unilateral or bilateral clinical signs, rapid onset ranging from 1 week to 4 months, and vision loss secondary to the severe globe deviation. Abnormalities are restricted to the extraocular muscles with no detectable abnormalities in the masticatory or limb muscles. Histopathology is characterized by muscle fibrosis, myonecrosis, and mononuclear inflammation. Limited serology for immune-mediated disease, infectious agents, antibodies against 2M fibers, and muscle enzymes have been normal.

Treatment

- Despite histopathologic evidence of mild lymphocytic-plasmacytic inflammation, medical treatment of restrictive myositis has been ineffective. Immunosuppressive systemic therapy with prednisone or prednisone and azathioprine has no effect on the muscle fibrosis and strabismus already present at initial examination.
- Surgical resection of the affected extraocular muscles alleviates the strabismus but has no appreciable effect on the accompanying enophthalmos. Some patients require repeated muscle resection.

Neoplasia

Strabismus secondary to space-occupying orbital disease has been previously described. External ophthalmoplegia with strabismus has also been reported secondary to intracranial masses. An intracranial meningioma affecting the oculomotor nerve caused ventrolateral strabismus and pupillary abnormalities in a 15-year-old Belgian sheepdog. Oculomotor lesions have also been reported in several cases of cavernous sinus syndrome in dogs.

Chapter

141 Neuro-ophthalmology

Randall H. Scagliotti

Clinical signs of ocular dysfunction may appear as disorders in the neuroanatomic pathways that allow normal vision. Vision is optimal when sufficiently protected eyes receive the proper amount of light while holding images steady on the retina. Many complex neurologic systems are involved in vision, including the visual sensory system (retina to visual cortex), the autonomic nervous system (pupillary function and lacrimation), the ocular motor system (neural control of eyeball, eyelid, and third eyelid position and movement), and the trigeminal somatic sensory system (pain sensation) of the eye and adnexa.

The diagnosis of abnormal neuro-ophthalmic signs is dependent upon acquiring a solid base of knowledge about the various neural substrates that enable normal vision. How these neural substrates interact determines the normal physical reflexes and responses that are observed during examination of each of the abovementioned neurologic systems. This chapter emphasizes the examination process for each system and the interpretation of normal and abnormal responses, and it discusses diagnostic tests that can aid lesion localization and diagnosis. Specific diseases of the eyes and nervous system that afflict each system are discussed in other chapters of this book.

NEURO-OPHTHALMIC ANATOMY

- The cranial nerves that enable normal vision are summarized in Table 141-1.
- The nerves of the petrous temporal bone are of two types: those in transit through the bone and destined for distant locations that subserve the eye or some of its supporting functions, like lacrimation, and those that mediate other functions, like hearing or taste. Those in transit to and destined for the eyeball or to protective and supporting structures for vision (e.g., the adnexa or the vestibular apparatus for head-eye coordination) include cranial nerve (CN) 5, 7, 8; postganglionic neurons of the sympathetic nervous system; and preganglionic and postganglionic fibers of the parasympathetic nervous system.
- The parasympathetic system (general visceral efferent [GVE] fibers) of the glossopharyngeal nerve (CN9) may be indirectly involved in ensuring ocular health and vision. The preganglionic parasympathetic fibers of CN9 form a synapse on a collection of cell bodies known as the *otic ganglion,* which lies within the ventrorostral petrous temporal bone. This ganglion is the source of postganglionic parasympathetic neurons that innervate the parotid and zygomatic salivary glands.
  - These glands may become denervated and dysfunctional (leading to xerostomia) by the same process and at the same time that lacrimation ceases or is diminished from the lacrimal gland (leading to keratoconjunctivitis sicca [KCS]). Be sure the parotid gland is normal before performing parotid duct transposition in cases of medically refractory KCS.
- Two neuroanatomic pathways modulate the pupillary light responses: the pupillary light reflex (PLR) pathway and the efferent sympathetic pathway (Fig. 141-1).
- The afferent arm of the PLR pathway from each eye is a three-neuron pathway. Each consists of a retinal chain neuron (photoreceptors and bipolar cells), optic nerve, and pretectal neuron that distribute information bilaterally (i.e., to both parasympathetic nuclei of the third nerve) as a result of the crossover that occurs at both the optic chiasm and the caudal commissure.
- *Note that the crossover of optic nerve fibers is unequal at the level of both the optic chiasm and the caudal commissure.*
- The afferent arms of the PLR are part of the central nervous system (CNS). Each efferent arm of the PLR is a two-neuron pathway from the autonomic nervous system (ANS) and consists of preganglionic and postganglionic parasympathetic neurons that are distributed as part of the oculomotor nerve (CN3). The efferent arms of the PLR do not cross to the opposite side en route to the iris sphincter muscles (for pupil constriction) and therefore do not distribute information to both eyes.
- The other pathway that controls the iris is the efferent sympathetic pathway. This pathway, which originates centrally in the posterolateral hypothalamus, remains unilateral throughout its course.
- The central neuron pathway (which may actually consist of several linked pathways leaving the brain stem) proceeds down the lateral cervical spinal cord

Table 141-1. SUMMARY OF NEUROANATOMY

Nerve	Nerve Type	Nerve Cell Body Location		Ganglion	Distribution	Function
		Gross	Micro			
Optic (CN2)	SSA	Retina	Ganglion cell Layer of retina	—	Lateral geniculate body	Vision
					Pretectal nucleus	Innervates parasympathetic nucleus of CN3 (miosis)
Oculomotor (CN3)	SE	Ventral mesencephalon	Motor nucleus of oculomotor nerve	—	Medial, dorsal, ventral recti, ventral oblique Levator palpebrae muscle	Ocular motility
	GVE	Ventral mesencephalon	Parasympathetic nucleus of CN3	Ciliary ganglion	Iris sphincter muscle Ciliary muscle	Miosis Regulates lens curvature
Trochlear (CN4)	SE	Dorsal mesencephalon	Motor nucleus of trochlear nerve	—	Dorsal oblique muscle	Ocular motility
Trigeminal (CN5)	SA	Cavum trigeminal of dura at apex of petrous temporal bone	Trigeminal ganglion (gasserian or semilunar)	—	Ophthalmic division—orbit Maxillary division—eyelids	Sensory to orbit, eyeball, and eyelid Sensory to eyelids
Abducens (CN6)	SE	Ventral metencephalon	Motor nucleus of abducens nerve	—	Lateral rectus muscle Retractor bulbi muscle	Ocular motility Globe retraction, third eyelid protrusion
Facial (CN7)	SVE	Ventral metencephalon	Motor nucleus of facial nerve	—	Orbicularis oculi Muscles of face	Eyelid closure Facial expression
	GVE	Ventral metencephalon	Parasympathetic nucleus of CN7	Pterygopalatine ganglion	Lacrimal gland	Tear secretion
Vestibulocochlear (CN8)	SP	Myelencephalon	Vestibular ganglion	—	Semicircular canals, utricle, sacculus	Coordinates eye with head movement
Glossopharyngeal (CN9)	GVE	Myelencephalon	Parasympathetic nucleus of CN9	Otic ganglion	Parotid salivary gland	Salivary secretion, used for PDT

CN, cranial nerve; SE, somatic efferents; GVE, general visceral efferents; SVE, special visceral efferents; PDT, parotid duct transposition; SA, somatic afferents; SSA, special somatic afferents; SP (SSA proprio.), special proprioception.

to synapse with preganglionic sympathetic fibers within the lateral-rostral thoracic spinal cord. After these fibers exit the vertebral column, they return to the head by ascending the neck in the vagosympathetic trunk, where they synapse on the cranial cervical ganglion medial to the tympanic bullae.

- The postganglionic sympathetic fibers course through the middle ear and base of the brain to reach the orbits from which they extend to the dilator muscle of the iris (for pupil dilation).

CLINICAL SIGNS OF NEURO-OPHTHALMIC IMPORTANCE

Absence of Reflex Blinking:

- Absence of reflex blinking is associated with eyelid closure abnormalities.

Ptosis or Blepharoptosis:

- Ptosis or blepharoptosis indicates insufficient opening of the eyelids. Differentiate from *pseudoptosis,* which occurs when the upper eyelid droops over an eye that is abnormal in size (microphthalmic), shape (keratoconus), or position (enophthalmic) (see Chapter 132).

Decreased Tear Production:

- A Schirmer tear test of less than 10 mm of wetting per minute may indicate a disorder of either the afferent arm (trigeminal nerve) or the efferent arm (parasympathetic neurons of the facial nerve) of the trigeminolacrimal reflex. Differentiate injury along the trigeminolacrimal reflex pathway from injury to the lacrimal gland proper (see Chapter 139).

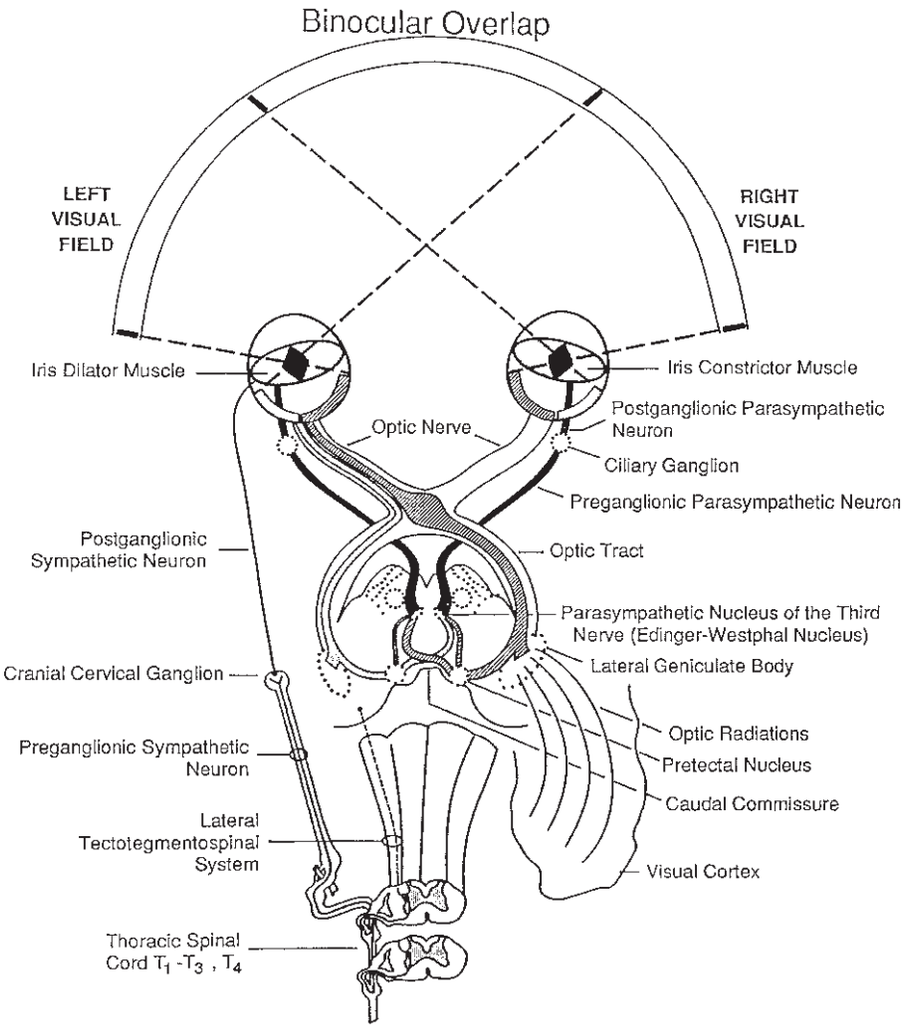

Figure 141-1. Pathways modulating the pupillary light response.

Decreased Parotid Salivary Gland Secretion:

- Decreased parotid salivary gland secretion can result from denervation of the parasympathetic fibers of the glossopharyngeal nerve (CN9). Parotid secretion must be adequate in the event that the parotid salivary duct is to be transpositioned to an eye for treatment of KCS (see Chapter 139).

Loss of Pain or Tactile Sensation to the Eye and Adnexa:

- Loss of pain or tactile sensation to the eye and adnexa occurs as a result of trigeminal sensory neuropathies. Differentiate ulcerative keratitis due to denervation of the trigeminal nerve (i.e., neuroparalytic keratitis) from other types of ulcerative keratitis.

Anisocoria:

- Anisocoria can result from developmental problems of the iris (e.g., aniridia) or acquired problems of the iris (e.g., posterior synechia). Differentiate from the anisocoria observed following neuropathology of the visual sensory system (CN2), PLR pathway, or efferent sympathetic pathway.

Strabismus:

- Strabismus indicates a problem with ocular alignment. This may occur due to a space-occupying mass in the orbit, mechanical restriction of extraocular muscles, extraocular muscle myopathy or junctionopathy, or neurologic dysfunction to the extraocular muscles.

Nystagmus:

- Nystagmus is an involuntary, repetitive, to-and-fro movement of one or both eyes that includes smooth sinusoidal oscillations (pendular nystagmus) and alternation of slow drift and corrective quick-phase oscillations (jerk nystagmus). Nystagmus occurs in any plane, can be permanent or transient, and may be either acquired (vestibular disease) or congenital (animals born congenitally blind).

Blindness:

- Blindness is a congenital or acquired condition in which there is complete loss of vision including all appreciation of or responses to light and dark. This may result from disorders of the eyes, visual pathways to the brain, or areas in the brain responsible for the sense of vision.

DIAGNOSIS

History

General History

- Obtain information about prior neurologic disturbances, systemic illness, head or neck disease, and drug use.
- Rubbing at the face or eyes with the paws or floor or furniture surfaces may indicate ocular pain. Orbital and ocular pain often lead to altered patterns of behavior. Most often patients with pain become secretive and reclusive; however, occasionally aggressive behavior is observed.

Ocular History

- Establish the specific nature of any ocular secretion; inflammation about the eye, eyelids, and orbit; and abnormalities in globe position and motility.
- When vision loss is incomplete, owners may characterize specific types of vision abnormalities. These descriptions include having difficulty observing stationary versus moving objects, seeing near versus far, or having loss of night or day vision.

General Physical Examination

Perform a complete physical examination including a thorough neurologic examination as described in Chapter 125, with particular emphasis on CN2 through CN9.

▼ ***Key Point*** Evaluate the ear, nose, mouth, pharynx, and paranasal sinuses, because they are intimately linked in disease to one another and to the eye. Disease involving any one these regions may directly or indirectly cause abnormal neuro-ophthalmic signs.

Visual Sensory System Evaluation

- Visual field testing, strictly speaking, cannot be performed in animals because their eyes will not hold a target (fixate) long enough to assess all visual fields. However, that should not preclude use of helpful clinical tests, albeit crude, to obtain information on vision quality or the integrity of the visual sensory system.
  - Although no one test should be relied upon to determine either aspect, use results from all the tests to make a good estimate of the type or degree of vision loss or the location of the lesion.

Ocular Examination

Use focal illumination and magnification to assess the anterior segment and direct or indirect ophthalmoscopy to examine the posterior segment.

Visual Placing Reaction

- This is a visually dependent postural reaction.
- Lift and support the patient under the abdomen and thorax while holding the head in a forward stationary position and advance toward a table edge. Present the table edge frontally (perpendicular to the long axis of the head and body) and then laterally (parallel to the long axis of the head and body). The normal response of a sighted patient is the forward advancement and placement of both feet on the table when the table edge is presented head-on and a lateral reaching movement with the leg nearest the table edge when it is seen by the *nasal hemiretina* (extreme lateral visual field).
- In lateral placing, have the nose extend beyond the corner of the table to ensure that only the most extreme portion of the nasal hemiretina (i.e., the most rostral portion of the nasal hemiretina referred to as the monocular crescent) is stimulated. When testing the visual fields, present the table edge from the front and side (laterally) under monocular and binocular test conditions.
- Visual placing requires an intact rostral portion of the striate cortex and foreleg region of the motor cortex.

Visual Cliff

- An indication of depth perception (stereopsis) ability can be obtained with a visual cliff.
- These are crudely created by using multiple variable height platforms or simply a table with variable height.
- A homogeneous texture and color has to cover all testing surfaces. Use a black-and-white checkered tablecloth.
- Normal dogs and cats will jump onto the lower platform (e.g., floor), whereas animals with poor depth perception will be unwilling to do so, will lower their bodies to the tabletop and slide off the table, or will

crash their chins into the floor as they miscalculate the depth of the jump.
- Monocular testing provides a reasonable control for determining whether monocular depth perception cues have been eliminated by the tablecloth. Most monocular patients are reluctant to jump, or they miscalculate the jump.

Visual Obstacle Course

- Use an obstacle course with a standardized layout based on the examiner's preference for most effective geometric design. This will result in more reliable deductions about the performance differences between sighted and non-sighted animals.
- Use five or six gray polyurethane foam cylinders, 2 feet tall and 4 inches in diameter, rather than the unprofessional and possibly injurious furniture objects customarily used, to ensure a safe, effective course.
- Run the course under monocular and binocular conditions using photopic (ambient room light) and scotopic (an incandescent red light bulb on a dimmer switch) illumination.
- Visually deficient animals will be reluctant to move in a strange environment under ambient light and/or scotopic light conditions or will move slowly through the course with their noses to the floor (i.e., "pick" their way). A few of the visually impaired will perform in a buoyantly bold manner yet run into many cylinders during each trial.
- Four or more trials through the obstacle course performed correctly under both photopic and scotopic illumination can be considered normal.

Dazzle Reflex

- This is a *subcortical reflex,* manifested as a bilateral partial eyelid blink in response to a bright light shined in one eye at a time.
- Use a powerful light source (halogen power with a Finoff transilluminator or, preferably, a fiberoptic light).
- It is present when the optic nerve is intact to the level of the midbrain. It also requires an intact facial nerve to elicit the blink.
- The closure is rapid and incomplete in the stimulated eye, and if present in the opposite eye, it is less extensive than in the stimulated eye.

Menace Response

- The menace response is a cortically mediated eyelid closure (i.e., cortical blink) and occasional head withdrawal originating in the cerebral cortex in response to a sudden threatening gesture in the near visual field. This response is complex and not totally understood.
- It requires intact peripheral and central visual pathways, including the cerebellum and facial nerves.
- Evaluation of the visual sensory system (CN2 and higher vision centers) requires isolating its function and integrity from the corneal blink reflex pathway (CN5 to CN7). If this is not achieved, a blink following a visual threat may elicit the corneal blink reflex afferently mediated by CN5, rather than the desired CN2-mediated menace response.
- Use a windshield (plastic shield or helmet visor) to block airwaves while still allowing the patient a view of the menacing threat.
- Menace the visual field of each eye (nasal and temporal hemiretina) after patching the other eye, which eliminates its participation in the response. Then evaluate the left and right binocular visual fields (i.e., the nasal hemiretina of one eye and the temporal hemiretina of fellow eye) by eliciting the menace response without patching.

Specialized Diagnostics

- *Electroretinography (ERG)* is a technique that differentiates retinal pathology from disorders of post-retinal anatomy (see Chapter 138).
- *Cerebrospinal fluid (CSF) pressure and analysis* is an invasive technique that assesses the status of the CNS when lesions are thought to be central in origin (see Chapter 125).

Autonomic Nervous System Evaluation

Pupillary Responses

Pupillary Light Reflexes

- This exam is best conducted in darkened conditions using a powerful light source (see Fig. 141-1). A halogen-powered light is minimally required to adequately evaluate the PLR, but a fiberoptic light source is best.
- The pupil under direct light stimulation (direct PLR) will constrict to a greater degree than the other eye. The constriction of the other eye is called the *indirect or consensual light reflex*. Thus, this pupil is said to react indirectly or consensually.
- Because the pupil receiving the direct light constricts to a greater degree than the other pupil (indirect pupil), an anisocoria exists during this active stimulation that is referred to as a *dynamic contraction anisocoria*. This is a normal physiologic response.
- Anisocoria is absent in ambient light unless there is heterochromia of the irides, iris disease, PLR pathway, or efferent sympathetic pupillary pathway pathology.

▼ ***Key Point*** Remember that iris muscle atrophy (as evidenced by light retroilluminating through holes in the iris) will weaken and, in some advanced cases, prevent the PLR.

Measurement of Pupil Size and Symmetry

- *Pupillary symmetry* is best obtained clinically using the direct ophthalmoscope as a crude pupillometer.
- Direct the light source at the interpupillary space on the bridge of the nose to observe the tapetal reflection of both eyes simultaneously.
- The overall size of the pupils and the existence of any inequality will be revealed quickly and accurately. Measure pupil size in ambient light using a hole sizing ruler or a caliper.

Swinging Flashlight Test

- This test measures the integrity of the retina and prechiasmal optic nerve.
- Perform in a darkened room because the PLR will be exaggerated.
- Immediately following direct light stimulation into one eye, swing the light source into the other eye, and then back again to the first eye directly stimulated. Repeat this procedure back and forth (thus the swinging flashlight) as often as necessary to be sure that both pupils constrict directly and indirectly.
- If a pupil dilates rather than constricts during direct stimulation immediately following its return from direct stimulation of the other eye, a unilateral retinal or prechiasmal optic nerve lesion exists. If dilatation of a pupil instead of pupil constriction occurs during the swinging flashlight test, this is referred to as positive for the dilating eye.

▼ ***Key Point*** A positive swinging flashlight test is pathognomonic for a unilateral retinal or prechiasmal optic nerve lesion.

Pharmacologic Testing

- Use topical drugs in cases of anisocoria to differentiate anatomic problems in the iris (e.g., synechia or iris atrophy) from neurologic problems. Also use topical drugs to localize the lesion to preganglionic or postganglionic fibers within each of the two efferent pathways (the efferent sympathetic pathway and the efferent parasympathetic pathway of the PLR).
- In an injured nerve whose terminals are allowed to degenerate, the structure supplied by it becomes supersensitive to the transmitter substance released by the terminals.
- Use pilocarpine (2%) and physostigmine (0.5%) to test the parasympathetic system and phenylephrine (10%) and hydroxyamphetamine (1–5%) to test the sympathetic system.

Lacrimation

Schirmer Tear Tests (Schirmer 1 and 2) (see Chapter 139)

- Use strips of Whatman paper to measure the autonomic innervation to the lacrimal gland (reflex tearing as measured by Schirmer 1 in the unanesthetized eye) and basal secretion from the lacrimal gland (by Schirmer 2 in the anesthetized eye). The contribution of the gland of the third eyelid is also figured into these measurements.

Trigeminolacrimal Reflex

- This reflex is responsible for reflex tearing as measured by Schirmer 1 values. The reflex-induced amount of tears is the difference between Schirmer 1 and 2 values. This difference is not as significant in the cat.
- The sensory nerve (CN5) of the eye conducts noxious stimuli centrally; the efferent arm of the reflex arises in the parasympathetic nucleus of CN7 in the ventral metencephalon (see Table 141-1) to course with branches of the facial nerve within the petrous temporal bone in route to the orbit. The pterygopalatine ganglion within the extraperiorbital sheath area of the orbit gives rise to postganglionic parasympathetic fibers that course with the zygomaticotemporal nerve (a branch of the maxillary division of the trigeminal nerve) to innervate the lacrimal gland with postganglionic parasympathetic fibers.
- It is assumed that the same reflex pathway is involved in the tear contribution made by the gland of the third eyelid.

▼ ***Key Point*** Lacrimation may be affected when the preganglionic parasympathetic fibers within the petrous temporal bone or the postganglionic parasympathetic fibers within the orbit are damaged during infectious or inflammatory disease in these regions.

Ocular Motor System Evaluation

Eyelid Position and Movement

Voluntary Eyelid Movement and Position

- Observing voluntary movement (blinks or eyelid elevation) in response to visual or auditory stimuli indicates much about normal eyelid closure and opening.
- Abnormal eyelid position is more easily observed because asymmetry of the palpebral fissures is more readily detected than eyelid movement. For instance, in facial paralysis, a lack of voluntary eyelid movement can be easily overlooked with certain head types (i.e., brachycephalic) that conceal the palpebral asymmetry associated with this disorder.

Eyelid Opening

- Motor neurons of the oculomotor nerve (CN3) innervate the levator palpebrae superioris muscle, the main muscle of upper eyelid elevation.
- In the dog, the levator anguli oculi medialis muscle (innervated by CN7) assists by elevating the medial portion of the upper eyelid and eyebrow. This muscle

action is readily assessed by leading the eyeball into a dorsal and medial position (intorsion) within the orbit. In order for an eye looking up and medially to maximize its visual field, the medial upper eyelid must be moved out of the way so that the eyebrow elevates during this eyeball movement. Evaluate both sides in a like manner.

Eyelid Closure

The facial nerve and the orbicularis oculi muscle mediate the final common neurologic pathway for all types of eyelid closure. The corneal blink reflex, dazzle reflex, and menace response all depend on a blink response and an intact facial nerve and afferent nerve supply. If any of the blinks are abnormal, determine whether it is an afferent or efferent arm problem.

- *Corneal blink reflex:* The corneal blink reflex is a subcortical reflex closure of the eyelids in response to a tactile or painful stimulus on the unanesthetized cornea. This reflex is afferently mediated by the trigeminal nerve (corneal sensory nerve) and efferently mediated by the facial nerve. Stimulation should come from outside the visual field to isolate this reflex from the menace response. A 3-ml syringe with a 27-gauge needle can provide a tight "air puff" stimulus across the corneal face outside the visual field.
- *Dazzle reflex:* See under "Visual Sensory System Evaluation."
- *Menace response:* See under "Visual Sensory System Evaluation."

▼ ***Key Point*** If all three types of blink responses are non-functional, it is most likely due to facial nerve paralysis.

Third Eyelid Position and Movement

- *Trigeminoabducent reflex and the third eyelid protrusion sign:* This reflex, in addition to protecting the eyeball by retraction (see trigeminoabducent reflex and the eyeball retraction response [ERR] below), is responsible for the active protrusion of the third eyelid through abducent nerve innervation of the lateral rectus muscle, which sends a slip of skeletal muscle to the third eyelid.
- *Passive protrusion of the third eyelid:* The third eyelid will passively protrude secondary to a variety of disorders, such as dehydration, atrophia bulbi, space-occupying mass, or displacement fractures of the bony orbit.
- *Active third eyelid retraction:* Sympathetic tone on the third eyelid retains the third eyelid in a retracted state in the ventral medial canthus. This is the normal position for the third eyelid.

▼ ***Key Point*** Protrusion of the third eyelid is indicative of pathology within the orbit, third eyelid, conjunctival surfaces, eyeball, or its innervation.

Eyeball Position and Movement

Duction Test

- The ability of one eye to rotate while it is viewing is referred to as a *duction.*
- Duction movements of an eye are evaluated by covering the other eye while the unpatched viewing eye is led through secondary and tertiary positions of gaze. Evaluate each eye in this manner for range of eye movement.

Version Test

- The ability of both eyes to move conjugately is referred to as *version movement.*
- Observe the eyes for conjugate movement and range of movement as they are led through the secondary and tertiary positions of gaze.

Forced Duction Tests

- These tests can be active or passive and are used in cases in which there is restricted range of eyeball movement.
- These tests help differentiate mechanical limitation of motion from paralysis of the extraocular muscles.
- In a passive forced duction test, grasp the anesthetized eye at the limbus with forceps on the side opposite to the direction in which the eye is to be moved and forcibly move the eye in the direction of gaze limitation. If no mechanical limitation is present, the eye can be moved fully into the direction of limitation. This indicates that the restricted movement of the eye is secondary to neurologic paralysis. If mechanical limitation is present, the eye will resist attempts to rotate it into the field of limitation.
- In the active forced duction test, grasp the anesthetized eye on the side of the gaze limitation. Hold the eye while the patient is coaxed into looking in the direction of gaze limitation. A tug on the grasped eye is felt if the nerve supply to the muscle is intact.

Trigeminoabducent Reflex and Eyeball Retraction Response

- This reflex is responsible for the protective eyeball retraction into the orbit from noxious stimulation of the eye and adnexa.
- This retraction can be sustained as long as needed because the motor neurons of the abducent nerve are stimulating retractor bulbi muscles, which are skeletal muscles.
- This reflex also causes active protrusion of the third eyelid. The enophthalmos created by active retraction also causes partial passive protrusion of the third eyelid (see the third eyelid position and movement discussion above).

Vestibulo-ocular Reflex

- This reflex maintains the eyes steady on a target during head rotation.
- This reflex is mediated through the vestibular apparatus, which compensates for the angular acceleration sensed by the semicircular canals. It is responsible for sustaining a clear visual image during head movement.
- It is often referred to as the doll's eye movement and is elicited by to-and-fro or up-and-down head rotation. One eyeball appears to move toward its medial canthus and the other eye simultaneously toward its lateral canthus during horizontal head rotation. During up-and-down movement of the head, both eyes will simultaneously move toward the center of the eyelids opposite the direction of the head movement.

Trigeminal Somatic Sensory System of the Eye and Orbit

- *Corneal blink reflex:* See eyelid position and movement above.
- *Corneal sensitivity:* The sensitivity of the cornea or the ability of the trigeminal nerve to feel and respond to discomfort is quantitatively measured with the Cochet-Bonnet aesthesiometer.

NEURO-OPHTHALMIC SYSTEM ABNORMALITIES

Abnormalities of the Visual Sensory System

Menace Response and Visual Fields

- Loss of a hemivisual field (homonymous hemianopia) and menace response in that visual field occur as a result of lesions that affect the ipsilateral nasal hemiretina and contralateral temporal hemiretina or higher in the CNS, a unilateral lesion in the contralateral striate cortex.
- Lesions of the rostral portion of the nasal hemiretina of one eye produce loss of the menace response and blindness in the ipsilateral monocular segment of the visual field.

Blindness

- Blindness broadly represents a loss of visual acuity and/or visual fields, and it may be complete or partial, unilateral or bilateral. Blindness can be categorized according to the location of the lesion. Lesions in the eye, brain stem, and cerebral cortex can result in blindness of neurologic origin.

Ocular Blindness

Ocular blindness is caused by any non-neurologic disorder that destroys the clarity of the ocular media (e.g., corneal scars or cataract) or any neurologic disorder (e.g., neuronal ceroid lipofuscinosis of the brain and retina) that interrupts the retinal processing of light. A lack of funduscopic abnormalities does not rule out the retina as the site of ocular blindness.

- Diseases of the retina can be divided into inherited and acquired. The inherited diseases are most frequently bilateral and may cause selective loss of vision (i.e., nyctalopia or hemeralopia) or progressive generalized loss of vision (i.e., generalized retinal atrophy and degeneration). Acquired retinal diseases (e.g., granulomatous meningoencephalitis [GME, reticulosis] of the ganglion cell layer and optic disc) may be unilateral or bilateral and can result in only partial or temporary loss of vision. Use electroretinography to assist in the differentiation of retinal diseases (see Chapter 138).
- The essential features of unilateral ocular blindness of retinal or prechiasmal optic nerve origin include loss of the dazzle reflex, menace response, direct PLR, and indirect PLR in the other eye. Static anisocoria (i.e., anisocoria present in steady ambient room light) and a positive swinging flashlight test are present in unilateral retinal disease, as well as in unilateral prechiasmal optic nerve disease. The above reactions (i.e., dazzle reflex, menace response, PLR, a positive swinging flashlight test) are lost in *advanced* bilateral retinal disease. In such advanced bilateral disease, the pupils are near maximum dilation and anisocoria may not be observed. In bilateral retinal disease at an *intermediate stage of progression,* the disease may be symmetrical or asymmetrical in its destruction of the retina; therefore, the reflexes will vary. The pupils will be larger than normal, with or without anisocoria (depending on the symmetry of retinal destruction), and the PLR can be absent, sluggish and incomplete, or paradoxical (see "Anisocoria in Optic Nerve Dysfunction" below). Ocular motility is normal in all positions of gaze.

Brain Stem Blindness

Blindness from acquired lesions in this region of the brain is the result of inflammation, infection, neoplasia, or vascular accidents. The areas of importance are those involved as vision relay centers (the dorsal lateral geniculate body) and visual pathways (the optic tracts or optic radiations [cerebral cortex]), and those responsible for visually guided behavior (rostral colliculi).

- The essential neuro-ophthalmic abnormalities will be variable depending on the lesion location and extent. The clinical features may include loss of visually guided behavior, blindness, anisocoria, loss of the dazzle reflex and menace response, and abnormal PLRs. Abnormal eye movement (gaze paresis) and eyeball position (strabismus) may be seen.
- Other neurologic signs referable to the brain stem may be present.

Cerebral Blindness

This is a generalized term describing the blindness caused by a disorder in any area of the cortex that plays a role in vision but that often results from a more rostral, cerebral cortical abnormality. In some cases cerebral blindness includes cortical blindness.

- The essential neuro-ophthalmic features may include complete loss of all visual sensation, including that for light and dark; a loss of the menace response and visual placing reactions; and the inability to detect a visual cliff. The eyes retain normal PLRs, dazzle reflexes, eye movements, and ocular alignment.

Cortical Blindness

This type of blindness indicates selective loss of the visual occipital cortex (striate cortex).

- The essential features include the loss of the menace response, problems with stereopsis, blindness in corresponding areas of the visual field, and abnormalities in the visual placing responses. The configuration of abnormalities is dependent upon the lesion site. The dazzle reflex (subcortical reflex) and PLR (subcortical reflex) remain normal. Ocular motility appears clinically normal, although ocular alignment may be abnormal, especially if the vision abnormality is congenital. For example, some Siamese cats have a congenital striate cortex abnormality that results in congenital bilateral esotropia with or without a pendular nystagmus. Although they do not have motion or visual field blindness, they are stereoblind (i.e., lack depth perception) (Table 141-2).

▼ ***Key Point*** Distinguish vision loss occurring from lesions in the striate cortex from that occurring from lesions in the motor cortex. Lesions of the motor cortex result in behavioral responses (e.g., falling off a visual cliff or running into objects) that are clinically used to indicate whether vision is present.

Table 141-2. LESION DIFFERENTIATION BASED ON BLINK REFLEX

Lesion	Optic Dazzle Reflex*	Tactile Corneal Reflex†	Menace Response	Vision
CN2 lesion	–	+	–	–
CN5 lesion	+	–	+	+
CN7 lesion	–	–	–	+
Visual cortex lesion	+	+	–	–
Large cerebellum lesion	+	+	–	+

*The dazzle and corneal reflexes are subcortical responses.
†The menace response requires an intact visual cortex.

- Unilateral lesions of the motor cortex in the regions for eyelid closure in response to a menace and in the region for visual placing in response to presentation of a table edge within the visual field result in the contralateral loss of the menace response and visual placing reaction. A loss of these responses usually is interpreted as a loss of vision. If the striate cortex is intact, both the menace and the table are seen in the contralateral visual field, but the lesion in the appropriate areas of the motor cortex prevents the appropriate behavioral response, a blink, and a placing reaction. For the same reason, a patient may fall off a visual cliff even if it is seen by the striate cortex. Thus, care must be taken in evaluating and defining the "blind" patient.

Abnormalities of the Autonomic Nervous System (Pupillary Light Reflexes and Lacrimation-Salivation)

Abnormalities of the Pupillary Light Reflexes

Lesions of the PLR pathways result in all or some of the following clinically detectable disturbances, depending upon the lesion site and extent: abnormalities in pupillary diameters and, in the cat, sometimes shape; abnormalities in response to dark adaptation; abnormalities in the PLR; and abnormalities in vision (Table 141-3).

Anisocoria in Ambient Light

- Unilateral pupillary pathway (i.e., afferent or efferent PLR pathway or efferent sympathetic pathway) lesions result in anisocoria of variable degrees. Some pupillary disorders that create anisocoria (e.g., feline spastic pupil syndrome and feline hemidilated pupil) also result in dyscoria.
- Unilateral lesions of the afferent arm of the PLR create subtle (i.e., the pupil size difference is very small) anisocorias and vision defects. The subtle anisocoria in Horner's syndrome is similar in appearance to those created by lesions in the afferent arm of the PLR. Differentiate on the basis of the associated clinical signs in Horner's syndrome (e.g., ptosis, reverse ptosis, enophthalmos, and protruded third eyelid). In addition, vision is not impaired in Horner's syndrome unless the extent of the third eyelid protrusion mechanically blocks vision. However, all lesions that occur in the afferent arm of the PLR result in complete to partial vision loss. Horner's anisocoria partially or completely disappears in bright light, while afferent PLR defects do not.
- Anisocoria with *large differences* in pupil size occurs with unilateral lesions of the efferent arm of the PLR.

Anisocoria in Darkness

- All unilateral and bilateral lesions of the afferent arm of the PLR dilate maximally and equally in darkness.

Table 141-3. NEUROPATHIC AND OTHER CAUSES OF ANISOCORIA: DIFFERENTIAL SIGNS AND TESTS

Diseases	Pupil Affected Side	PLR DI		SFT	Dazzle Reflex	Menace Response	DAD Test	Tonometry	PT	Diagnostic SLB	Funduscopy	Vision	Special Tests
Anterior uveitis	Miotic	±	±	–	+	±	Unequal	Hypo	No	+	–	Poor	–

Pharmacologic blockade (atrophine-induced mydriasis)	Dilated	–	+	–	+	+	Equal	Normo	Yes	–	–	Normal	PT
Postganglionic denervation	Dilated	–	+	–	+	+	Dog, unequal Cat, equal	Normo	Yes	–	–	Normal	PT
Preganglionic/ central denervation		–	+	–	+	+	Unequal	Normo	Yes	–	–	Normal	PT
Efferent sympathetic nerve lesions													
Preganglionic denervation	Miotic	+	+	–	+	+	Unequal	Normo	Yes	–	–	Normal	PT
Postganglionic denervation	Miotic	+	+	–	+	+	Unequal	Normo	Yes	–	–	Normal	PT
Polyneuropathy													
Spastic pupil syndrome	Variable	±	±		+	+	No	Normo	No	–	–	Normal	+FeLV

PLR, pupillary light reflexes; D, direct (in affected, stimulated eye) light reflex; I, indirect (in nonaffected, unstimulated opposite eye) light reflex; SFT, swinging flashlight test; DAD test, dark adaptation test; PT, pharmacologic test; SLB, slit lamp biomicroscopy; FeLV, feline leukemia virus; Hypo, <15 mm Hg; Hyper, 0.25 mm Hg; Normo, 15–25 mm Hg.

- In cats with lesions of the efferent arm (both preganglionic and postganglionic parasympathetic fibers) of the PLR, the pupils dilate maximally and equally in darkness. This occurs because the efferent arm, including the short ciliary nerves, consists of purely parasympathetic fibers up to the point of entering the sclera where they are joined by the long ciliary nerves (containing sensory trigeminal neurons and postganglionic sympathetics). Thus, injury to the short ciliary nerves rarely involves the sympathetic system in cats.

▼ ***Key Point*** Maximal and equal dilation in darkness distinguishes lesions of the afferent arm (dog and cat) of the PLR and efferent arm of the PLR (cats only) from all other pupillary abnormalities, including those caused by physical restriction of iris movement (synechia).

- In dogs with ciliary ganglion or short ciliary nerve injury, anisocoria persists in darkness because the short ciliary nerves in the dog are mixed nerves containing both sympathetic and parasympathetic postganglionic fibers in addition to sensory nerves. The smaller pupil is ipsilateral to lesions in the ciliary ganglion or short ciliary nerves.
- The anisocoria of Horner's syndrome becomes more pronounced in darkness because the intact innervation to the dilator muscle opens the normal eye in darkness but not the Horner's pupil.
- Cats with feline spastic pupil syndrome will retain their anisocoria and dilate minimally or not at all in darkness.

Anisocoria in Optic Nerve Dysfunction

- A complete unilateral prechiasmal lesion, which involves the retina or prechiasmal optic nerve, creates anisocoria with the smaller pupil contralateral to the side of the lesion (see "Anisocoria in Darkness" and Table 141-3).
- Lesions of the chiasm lead to anisocoria when the fiber destruction is asymmetrical. The PLR may be paradoxical (i.e., the pupil of the eye opposite to that which is directly stimulated will constrict to a greater extent than the eye under stimulation). The reaction may still be paradoxical when the other eye is stimulated. The pupils are generally larger than normal in ambient light (see "Anisocoria in Darkness" and Table 141-3).
- A unilateral lesion of the optic (post-chiasmal) tract always appears with a subtle anisocoria with the smaller pupil ipsilateral to the side with the lesion (see "Anisocoria in Darkness" above and Table 141-3).

Anisocoria in Oculomotor Dysfunction

Injury to the oculomotor nerve's (CN3) preganglionic or postganglionic parasympathetic fibers (GVEs) that constitute the efferent arm of the PLR leads to anisocoria without any visual loss. The pupil on the affected side is widely dilated and fixed (will not move) to direct and indirect light (see "Anisocoria in Darkness" and Table 141-3).

Anisocoria in Oculosympathetic Dysfunction

Lesions in the efferent sympathetic pathway lead to the signs of Horner's syndrome, with anisocoria (miosis on the affected side) as its most diagnostic feature (see Table 141-3). Any or all of the other signs of Horner's syndrome, including the narrowed palpebral fissures from oculosympathetic ptosis (and reverse ptosis), third eyelid protrusion, and enophthalmos, may be present.

Abnormalities of Lacrimation

Loss of reflex tearing, which results in decreased Schirmer 1 tear test values in the unanesthetized eye, occurs with disorders (e.g., inflammation, infection, and neoplasia) of the trigeminal nerve (afferent arm of the trigeminolacrimal reflex) or of the preganglionic or postganglionic parasympathetic neurons of the facial nerve (efferent arm of the trigeminolacrimal reflex) (see Chapter 139).

Topical Diagnosis of Lacrimation Disorders

- *Central facial nerve paralysis:* Paralysis of the proximal portion of the facial nerve containing the preganglionic parasympathetic fibers to the lacrimal gland may lead to a reduction of reflex tearing. The cerebellopontine angle and the petrous temporal bone are likely locations for nerve injury.
- *Otitis media:* Chronic middle ear disease can injure the major petrosal nerve containing the preganglionic parasympathetic fibers (GVEs) of the facial nerve, which innervate the lacrimal gland. This is a leading cause of KCS.
- *Pterygopalatine ganglion injury:* The cell bodies of the postganglionic parasympathetic fibers of the facial nerve are vulnerable to injury from penetrating foreign bodies to the floor of the orbit and from suppurative and non-suppurative extraperiorbital sheath myositis (temporalis and pterygoideus muscles).
- *Lateral orbit injury:* Head trauma can injure the zygomaticotemporal nerve, an eyelid sensory nerve (a branch of the maxillary division of the trigeminal nerve) containing the postganglionic parasympathetic (GVEs of the facial nerve) innervation to the lacrimal gland.
- *Ophthalmic nerve:* Injury to this division of the trigeminal nerve results in corneal anesthesia, loss of the trigeminolacrimal reflex, and diminished Schirmer 1 tear test findings.
- *Xeromycteria:* A dry nasal mucosa occurs in some cases of KCS, leading to an accumulation of dried mucus at the nares on the affected side. This mucus accu-

mulation is often erroneously thought to result from the exit of mucus from an eye with KCS via the nasolacrimal duct. In fact, it is the result of damage to the postganglionic parasympathetic fibers from the pterygopalatine ganglion that course with the caudal nasal nerve (maxillary branch of CN5) to innervate the lateral nasal gland. The lateral nasal gland located near the maxillary sinus functions as a thermoregulatory gland by keeping the nasal cavity moist. Denervation of the lateral nasal gland leads to compensatory hyperplasia and production of the mucus-producing glands within the nasal mucosa, just as the conjunctival goblet cells hypersecrete mucus with KCS. Only a small percentage of KCS cases have mucus collection about the nares as a result of xeromycteria.

- *Paradoxical gustolacrimal reflex:* Crocodile tears are unilateral, profuse tearing in response to stimulation of the taste receptors.

Abnormalities of Salivation

The gustosalivary reflex is demonstrated by patients that have had a successful parotid duct transposition each time they eat. The profuse "tearing-salivation" is mediated afferently by taste receptors on the tongue and efferently by the parasympathetic nervous innervation of the parotid and zygomatic salivary glands. Medical treatment failure for KCS or for circumstances preventing its adequate medical therapy results in the need for parotid duct transposition to sustain a healthy cornea. The same conditions that cause a dysfunctional lacrimal gland may also affect the salivary glands, thereby rendering the parotid gland unsuitable for parotid duct transposition. Determine the health of the parotid gland by assessing parotid secretion prior to duct transposition. The bitter taste of atropine sulfate ophthalmic solution applied directly to the buccal mucosa immediately stimulates the gustosalivary reflex to elicit parotid gland secretion. A pulse-like squirting of parotid secretion from the parotid duct papilla is indicative of adequate secretion. If the parotid secretion slowly flows from the duct orifice without the pulse-like squirting, successful transposition is more problematic.

- *Otitis media:* Disease of the middle ear can injure the preganglionic parasympathetic fibers of the minor petrosal nerve and the otic ganglion and its postganglionic parasympathetic fibers located in the dorsolateral aspect of the auditory tube. These fibers lead to the parotid gland.
- *Otitis externa:* Diseases of the external ear, especially those that ossify the external auditory canal and lead to periauricular tissue damage, can injure the auriculotemporal nerve, a branch of the mandibular division of the trigeminal nerve. This sensory nerve conducts the glossopharyngeal postganglionic parasympathetic fibers arising from the otic ganglion to the parotid gland that is situated between the ear and the angle of the mandible.

▼ ***Key Point*** The otic ganglion and minor petrosal nerves lie close to the major petrosal nerve and may be injured in lesions that injure the major petrosal nerve. Lesions of the dorsorostral middle ear (e.g., from eustachian or auditory tube disease) will lead to KCS, xeromycteria, and xerostomia.

Abnormalities of the Ocular Motor System (Eyelid, Third Eyelid, and Eyeball)

Eyelid Position and Movement Abnormalities

Eyelid Closure Abnormalities

The eyelids will reflexively close to protect vision when the eyes are confronted with bright illumination (dazzle reflex), with a threatening image (menace response), and with noxious tactile stimulation (corneal blink reflex). The muscle responsible for all three closures is the orbicularis oculi innervated by the facial nerve. Observing voluntary eyelid closure prior to testing indicates that the facial nerve and the orbicularis oculi are intact. Failure of one of the eyelid closure responses may result from a disrupting lesion of the afferent arms (optic nerve or trigeminal nerve) of these reactions. Denervation of the orbicularis oculi results in the absence of all three eyelid closure responses. Determine the cause for failure of reflex eyelid closure by separate testing of the various nerve components of the reflex to isolate each nerve.

- *Absent corneal blink reflex:* Test this reflex as described above for eyelid position and movement. Presenting the stimulus (noxious) outside the visual fields avoids stimulating the optic nerve (visual image) and therefore isolates the trigeminal nerve. If the corneal blink reflex is absent but a voluntary blink is present, the trigeminal nerve is dysfunctional (see Table 141-2). Absence of voluntary blink suggests facial nerve dysfunction. When the corneal blink reflex is absent as a result of facial nerve paralysis, there frequently are associated deficits in some or all of the functions served by this nerve.
- *Topical diagnosis of facial nerve disease:* Topical diagnosis along the facial nerve is beyond the scope of this chapter. Schirmer tear testing, facial nerve conduction studies, acoustic reflex testing (to evaluate the facial nerve at the level of the stapedius muscle in the middle ear), brain stem auditory evoked responses (BAER), and magnetic resonance imaging (MRI) can be used to localize the lesion. The BAER is used because CN8 is close to CN7 within the petrous temporal bone, and a lesion at CN7 may therefore be demonstrated by a BAER deficiency in CN8.
- *Eyelid signs with facial nerve paralysis:* Denervation of eyelid closure leads to a widened palpebral fissure, an

increased amount of visible sclera (i.e., scleral showing), and the illusion of proptosis.

- *Absent dazzle reflex:* The dazzle reflex is a subcortical reflex mediated afferently by the optic nerve and efferently by the facial nerve. It produces a bilateral partial eyelid closure (blink or squint) in response to a bright light shined in one eye at a time. To isolate the dazzle reflex (CN2 to CN7) from the corneal blink reflex (CN5 to CN7), avoid touching the cornea or eyelid hair when shining the stimulating light in each eye. The loss of the dazzle reflex when a voluntary blink or the corneal blink reflex is present indicates that the facial nerve is intact and that there is unilateral retinal disease or unilateral optic nerve disease along the afferent pathway to the midbrain (see Table 141-2).
- *Absent menace response:* The menace response is not a reflex but rather a cortically mediated rapid eyelid closure response, with or without head withdrawal, in response to a threatening or unexpected image suddenly appearing within the near visual field. This response requires intact peripheral and central visual pathways, including the cerebellum and the facial nerves.
- In general, the menace response is abolished in the visual fields contralateral to unilateral lesions in specific areas of the cerebral cortex.
- Unilateral lesions in the caudal striate cortex, eyelid region of the motor cortex, and parietal lobe situated between the striate cortex and the motor cortex will cause unilateral disappearance of the contralateral menace response (see Table 141-2).

▼ ***Key Point*** While all three cerebral cortex lesions cause loss of the menace response, only striate cortex lesions cause the ensuing hemianopia.

- Absence of the menace response resulting from destruction of the eyelid region of the motor cortex is due to a partial supranuclear facial palsy and loss of menace response. Parietal lobe lesions entail no visual disturbances or partial facial palsy (voluntary blink remains).
- In dogs, the ipsilateral menace response can be lost and vision can be retained with large unilateral cerebellar lesions. Diffuse cerebellar cortical degenerative lesions cause a failure of the menace response bilaterally, without any visual deficit (see Table 141-2).

▼ ***Key Point*** The menace response (cortical) may be lost when the corneal blink and dazzle reflexes (subcortical) persist.

Eyelid Opening Abnormalities

Neuroanatomic diagnosis of ptosis is dependent upon clinical signs and evidence of neuropathic, neuromuscular, or myopathic disease. Consider the following types:

- *Oculomotor ptosis:* This ptosis results from injury to the oculomotor nerve at any level from the cerebral cortex to the levator palpebrae superioris muscle. Oculomotor ptosis is exaggerated in the lateral two-thirds of the eyelid during eyebrow elevation in the dog if the facial nerve, which innervates the levator anguli oculi medialis muscle, remains intact. This latter muscle assists in lifting the nasal portion of the eyelid and erects the long tactile hairs (pili supraorbitales) of the eyebrow. This muscle action is readily assessed by leading the eyeball into a dorsal and medial position (intorsion) within the orbit, which requires elevation of the eyebrow. Topical diagnosis of oculomotor lesions is enhanced when other functions (e.g., GVEs for PLR and motor fibers for ocular motility) of the oculomotor nerve are disturbed.
- *Oculosympathetic ptosis:* This is a component of Horner's syndrome and results from nerve damage along the efferent sympathetic pathway that innervates the smooth muscles of the eyelid. The lower lid often has an "upside-down ptosis," which creates a narrowed palpebral fissure. Differentiate from oculomotor ptosis. It helps when all or some of the other signs of Horner's syndrome (ipsilateral miosis, enophthalmos, protrusion of the third eyelid) are present.
- *Myopathic ptosis:* This is usually an acquired condition caused by damage to the levator muscle by inflammation, infiltration, or orbital trauma.

Third Eyelid Position and Movement Abnormalities

- *Hyperactive trigeminoabducent reflex:* Painful stimulation of the eyeball and/or adnexal surface (e.g., ectopic cilia) or a trigeminal neuritis will lead to the eyeball retraction response and third eyelid protrusion sign, both mediated by the trigeminoabducent reflex. Third eyelid protrusion leading to third eyelid protrusion sign is strictly active protrusion. Third eyelid protrusion may be assisted by active retraction of the eyeball(s) by the retractor bulbi muscle action, causing an enophthalmos. The enophthalmos leads to passive protrusion of the third eyelid. Although the final common pathway for each reflex (i.e., third eyelid protrusion and eyeball retraction) is mediated by the CN6, each acts independently of the other.
- *Denervation of third eyelid sympathetics (Horner's syndrome):* Denervation of sympathetic neurons to the third eyelid leads to passive protrusion of the third eyelid. This, like the complete Horner's syndrome, is usually unilateral.
- *Third eyelid dysautonomia (so-called Haw):* Any imbalance in the sympathetic-parasympathetic system that innervates the muscles of the third eyelid may lead to protrusion of the third eyelids. This condition is usually bilateral and the protrusion is usually partial, but it may be extensive enough to impair vision. It is more frequently seen in cats but can be seen in dogs,

especially golden retrievers. The cause is unknown. Gastrointestinal dysfunction may antedate the protrusion of the third eyelids or be concomitant.

- *Third eyelid protrusion of tetanus:* Tetanus infections lead to contraction of the skeletal muscles, which is caused by the potent neurotoxin liberated by *Clostridium tetani*. The third eyelids protrude in tetanus as a result of contraction of the lateral rectus muscles, which *actively* protrude the third eyelids. Tetanus also causes contraction of the retractor bulbi muscles, along with all the other extraocular muscles, which leads to enophthalmos and a *passive* protrusion of the third eyelids. The antagonistic contraction of the facial muscles, including the opposing muscles of the eyelid, the orbicularis oculi muscle, and the levator palpebrae superioris muscle, creates a sardonic smile with almond-shaped eyelids.

Eyeball Position and Movement Abnormalities

Ocular Position and Alignment

Strabismus (abnormal eye position) may be congenital or acquired. It is the result of CNS dysfunction, as is commonly observed in Siamese cats, or from peripheral abnormalities to the motor nerves of the eye (CN3, CN4, and CN6). Disorders of the neuromuscular junction and extraocular muscle myopathy may also result in strabismus.

- *Comitant strabismus:* This is an ocular deviation that does not vary with different positions of gaze or with either eye fixating.
- *Incomitant strabismus:* This ocular deviation varies when the direction of gaze changes and/or when either eye fixates.

Ocular Movement

- *Range of movement:* When the range of movement is restricted during version and/or duction movements, *restriction caused by muscle paresis must be distinguished from mechanical restriction*. Such differentiation is accomplished by performing passive and active forced duction tests (see "Forced Duction Tests" under "Eyeball Position and Movement").
- *Oculomotor nerve (CN3) dysfunction:* Damage to the oculomotor (CN3) motor neurons (somatic efferents) leads to ptosis and an inability to rotate the eye upward, downward, or inward. When the unaffected eye is fixating straight ahead (primary position of gaze), the eye is held in a position of divergent (outward and downward) strabismus. The eye can be returned to midline by having the gaze directed to the side opposite the paralysis. The strabismus therefore is incomitant.
- *Trochlear nerve (CN4) dysfunction:* Trochlear nuclear lesions produce effects in the contralateral dorsal oblique muscle. Paralysis of the trochlear nerve results in extorsion (outward rotation) of the eye. This palsy can be readily seen in the cat because the dorsal apex of its elliptical pupil is tilted toward the lateral canthus (12 o'clock position of the eyeball is rotated temporally), whereas in species with round pupils like the dog, the dorsal retinal vessels can be used as one of the indicators of dorsal oblique dysfunction. Since the dorsal oblique muscle normally acts as a depressor on inward and downward gaze, in trochlear nerve dysfunction, leading the eye into this tertiary position of gaze reveals an inability to lower the eyeball in this direction of gaze. During normal outward movement the dorsal oblique muscle acts as an intorter (tilts the 12 o'clock eyeball position nasally). During outward gaze with trochlear palsy, the unopposed ventral oblique muscle exaggerates the extorsion of the eyeball.
- *Abducent nucleus and nerve (CN6) dysfunction:* Abducent nerve (CN6) lesions cause denervation of the lateral rectus muscle and ipsilateral palsy of horizontal gaze. This results in a convergent (incomitant type) strabismus when the normal eye is fixating in the primary position of gaze.
  - In abducent *nucleus* lesions, there is ipsilateral palsy of horizontal gaze during version movements toward the affected side. Neither eye crosses the midline during such version movements.
  - Lesions of the abducent *nerve* usually cause paralysis of both the lateral rectus and the retractor oculi muscles. When the abducent nerve is damaged, the contralateral eye crosses the midline during version movements toward the affected side.
  - The *trigeminoabducent reflex* can be lost if the motor neurons to the retractor bulbi muscles are disturbed.
  - The *vestibulo-ocular reflex* (see Chapter 125) is abnormal with a paralysis of any extraocular muscle.

Nystagmus

Nystagmus is a to-and-fro movement of the eyes and is a normal response to vestibular and optokinetic stimuli. Pathologic nystagmus occurs in disorders of the systems that stabilize images of objects on the retina during head rotations (vestibular system and optokinetic system) or stabilize images of moving objects on the retina (pursuit system).

Congenital Nystagmus

This type is caused by metabolic dysfunction or structural abnormalities of the brain or eye.

- *Sensory congenital nystagmus* is of either the jerk or the pendular type and is associated with disease in the visual sensory system (cataracts, persistent hyperplastic primary vitreous, retinal detachment, aberrant sensory visual pathways). The nystagmus of some Siamese cats serves as an example of congenital sensory nystagmus.

- *Motor congenital nystagmus* is of either the jerk or the pendular type and lacks any primary disease of the visual sensory system. Any decrease in vision is secondary to the nystagmus.

Acquired Nystagmus

This type of nystagmus is often associated with other neurologic signs. *Vestibular nystagmus* is an acquired jerk nystagmus caused by imbalance within the vestibular apparatus, with the corrective quick phases directed away from the side of the lesion.

- In *peripheral vestibular disease,* the nystagmus is mixed because the axis around which the eye rotates relates to the geometric relationships of the semicircular canals. *Vertical-torsional nystagmus* indicates posterior or anterior semicircular canal irritation depending upon the direction of the corrective quick phase's vertical movement. *Horizontal-torsional nystagmus* occurs from complete unilateral labyrinthitis. Positional nystagmus can also be seen in peripheral vestibular disease.
- In central *vestibular disease,* the nystagmus is more purely torsional, horizontal, or vertical. Positional nystagmus can be present.

Abnormalities of the Trigeminal Somatic Sensory System of the Eye and Orbit

If the corneal blink reflex is absent but a voluntary blink is present, the trigeminal nerve is dysfunctional. Evaluate corneal sensitivity with a Cochet-Bonnet aesthesiometer to quantify the extent of sensory loss. Corneal denervation as a result of injury to the trigeminal nerve causes *neuroparalytic (neurotrophic) keratitis,* which results in ulcerative keratitis, corneal degenerative changes, and loss of corneal sensation. Head withdrawal during noxious stimulation of the cornea is also lost because the relay of ocular pain information to the cortex via the thalamus for conscious perception of pain is interrupted. The eyelid position in neuroparalytic keratitis is symmetrical with that of the other eye. Absence of voluntary blink and the dazzle reflex, along with the loss of the corneal blink reflex, supports the diagnosis of facial paralysis.

TREATMENT

Treatment depends upon the type of pathology and the location, the extent, and the duration of the condition. Treatment often involves a combination of modalities, including both surgical and medical. Refer to other chapters in this text for specific treatment for the various afflictions of the eye and nervous system.

PROGNOSIS

In general, patients with diseases manifesting neuro-ophthalmic signs have a better prognosis if the pathology is only inflammatory. The prognosis in infectious diseases and cerebral vascular accidents is more guarded. Neoplastic conditions, although sometimes successfully treated, in general have a poor prognosis.

Section

11 Cardiopulmonary System

John D. Bonagura

Chapter

142 Auscultation and Physical Diagnosis

Robert L. Hamlin

Physical examination follows the obtaining of a complete history and the consideration of the species, age, breed, and sex (see Chapter 1). Diagnosis, or at the very least a number of plausible diagnoses, may be made in many instances by history and signalment; however, following a thorough physical examination, a single, "most likely" diagnosis can be made with reasonable assurance in most patients with cardiac problems.

Physical examination is best performed in a systematic manner, initially conducting those portions that are least likely to aggravate or to cause discomfort to the patient. Physical examination of the cardiovascular system can be separated into four steps: *inspection, palpation, percussion,* and *auscultation*. What separates the physical examination from the remainder of the cardiac examination is the close relationship between the veterinarian and the patient, and, with the exception of the stethoscope, the absence of elaborate instrumentation such as radiography, electrocardiography, or echocardiography.

INSPECTION

Inspect the patient while obtaining the history. Perform the inspection while the animal enters the room; while the pet stands, sits, or walks; while the owner supports the pet; and while the pet stands alone.

Condition, Attitude, and Posture

- *Body condition* of the patient is classified according to the degree of fat.
  - Normal overweight animals usually are not ill from heart failure but may manifest signs caused by pulmonary disease (e.g., chronic obstructive lung disease, pulmonary fibrosis).
  - Animals with moderate to long-standing heart failure are often thin to cachectic.
- *Attitude* of an animal with heart failure is usually depressed.
- *Posture* of animals with heart failure is often:
  - Standing—reluctant to lay down—with thoracic limbs abducted and neck extended to ease ventilation.
  - Swayback with the tail between the legs because of muscular weakness or occasionally caused by digitalis toxicity (from overdosage or impaired renal excretion related to dehydration or primary renal disease). Swayback can also result from electrolyte imbalance—in particularhypokalemia—caused by prolonged or excessive use of diuretics without consumption of sufficient electrolytes.
- Dogs with cardiomyopathy often have weakness of skeletal muscles and dogs with heart failure are often exhausted owing to the work of breathing.

Mucous Membrane Color

- Mucous membranes may be *pink*, *pale*, or *cyanotic*.
- Normal mucous membranes have a deeply saturated pink color. Gentle pressure on the gums will lead to blanching (whiteness) of the membranes. The *capillary refill time* needed to regain normal coloration is about 2 seconds or less.
- Delayed refill time generally indicates peripheral vasoconstriction, often as a compensatory response to reduced arterial blood pressure.
- Bright red membranes associated with a very short refill time may indicate peripheral vasodilation, as might occur with septic shock or during treatment with potent arterial vasodilator drugs.
- Mucous membranes are pale in some patients. *Pallor* indicates anemia or low cardiac output with reflex vasoconstriction (e.g., low output heart failure, severe aortic stenosis, cardiac tamponade), but without pulmonary congestion that often causes cyanosis.

Cyanosis

Cyanosis indicates the finding of dark-blue to purple colored mucous membranes caused by poorly oxygenated (desaturated) hemoglobin. The main reasons for cyanosis are respiratory disease and right-to-left shunting due to congenital heart disease.

- *Methemoglobinemia* (congenital or acquired from drug toxicity) may also alter the color of the mucous membranes.
- Cyanosis to the mucous membranes may be observed in late stages of congestive heart failure or in puppies or young dogs with tetralogy of Fallot or other congenital heart defects with right-to-left shunts. (see Chapter 154)
- Cyanosis occurs much more commonly in all types of pulmonary disease.
- Mucous membranes may be dark red in stages just prior to frank cyanosis.
- Long-standing cyanosis most commonly indicates pulmonary disease, since an animal cyanotic from heart disease usually either dies from the severity of the disease or the cyanosis is relieved with therapy.

Abdominal Distention and Edema

- Abdominal distention may be a result of gas in the gastrointestinal (GI) tract from aerophagia associated with chronic pulmonary disease, respiratory failure, primary GI disease, obesity, abdominal wall weakness (e.g., Cushing's disease) or fluid accumulation.
- Ascites and enlargement of abdominal organs (especially the liver) may indicate systemic venous hypertension or passive congestion due to right-sided heart failure or pericardial disease.
- Primary disease of abdominal organs (e.g., neoplasia) also can cause abdominal distention.
- Pitting edema of the limbs, brisket, and prepuce can be caused by severe right-sided heart failure.

▼ ***Key Point*** Subcutaneous edema in the absence of ascites or jugular distention *argues* against a diagnosis of congestive heart failure

Pattern of Ventilation

Observing the pattern of ventilation is extremely important. Characterize the rate and depth of breathing, and identify dyspnea.

- *Rate of breaths per minute* should be between 12 and 20 for dogs and only slightly higher for cats, but may increase from excitement, fever, anxiety, warm environment, chronic respiratory disease, respiratory failure, left-sided heart failure, or pulmonary injury.
- *Depth of ventilation* is difficult to quantify, but hyperpnea (increased depth) is often a sign of blood gas derangement (e.g., response to metabolic acidosis). It is not often observed in heart disease except with severe pulmonary edema. In upper airway obstruction both the inspiratory and expiratory phases of ventilation may become slower and exaggerated. In pleural diseases, the depth is generally shallow and the rate rapid. An exaggerated expiratory phase is typical of bronchial obstruction.
- *Dyspnea* (labored ventilation or respiratory distress) may occur as increased rate and/or depth of ventilation or merely as increased effort. With dyspnea one observes:
  - Bulging eyes.
  - Flaring nares.
  - Outward motion of thoracic limbs.
  - Reluctance to lay down.
  - Abdominal "pumping."
  - Extension of neck and open mouth breathing
  - A sucking in of the copula (the indentations at the thoracic inlet) during inspiration
- *Pulmonary retraction* is an indention of the thoracic wall caused by fatigue of muscles of ventilation. Regions of the thoracic wall affected must generate greatest tension during ventilation and do not have assistance from thoracic limbs. Pulmonary retraction produces an "hourglass" configuration to the thorax (most evident when viewing the dorsoventral radiograph).

Cough

Cough is a sign of both heart and lung disease. It may be characterized as follows:

- A hacking, honking, brassy cough indicates disease of the large airways, such as tracheobronchial collapse, compression of the left mainstem bronchus due to mitral regurgitation or generalized cardiomegaly, tracheobronchitis, or bronchopulmonary parasitism. This type of cough is seldom due to injury of the parenchyma of the lung and therefore is uncommon in pulmonary edema or pneumonia.

- Subtle or "half-hearted" coughing may be caused by pulmonary edema, pneumonia, or diaphragmatic hernia.
- So-called moist or truly productive coughs usually indicate an exudative process; however, in *late stages of left-sided congestive heart failure* it is common to have serosanguineous pulmonary edema fluid expectorated to gush from the nares and/or mouth.

Jugular Vein Evaluation

Analysis of the *jugular* vein (Fig. 142-1) is simpler if the hair is clipped from around the jugular furrow or if it is moistened with 70% alcohol. Look for pulsations in the vein and estimate the pressure distending it.

- The jugular vein normally collapses totally when the long axis of the head is tilted up at an angle of 45 degrees with the horizontal.
- The jugular vein also normally collapses during inspiration and immediately after the second heart sound.
- If the jugular vein does not collapse, the venous pressure may be elevated owing to heart failure, chronic obstructive pulmonary failure (COPD)/pulmonary fibrosis (PF), or ventricular filling restriction due to pericardial disease.
- A firm, distended jugular vein that collapses briefly immediately after the second heart sound is consistent with cardiac tamponade from pericardial disease. (see Chapter 151) Causes in dogs include hemorrhage into the pericardial sac due to a bleeding neoplasm or rupture of the left atrium with severe mitral regurgitation. Constrictive pericarditis and chronic respiratory disease also can cause similar jugular venous changes.

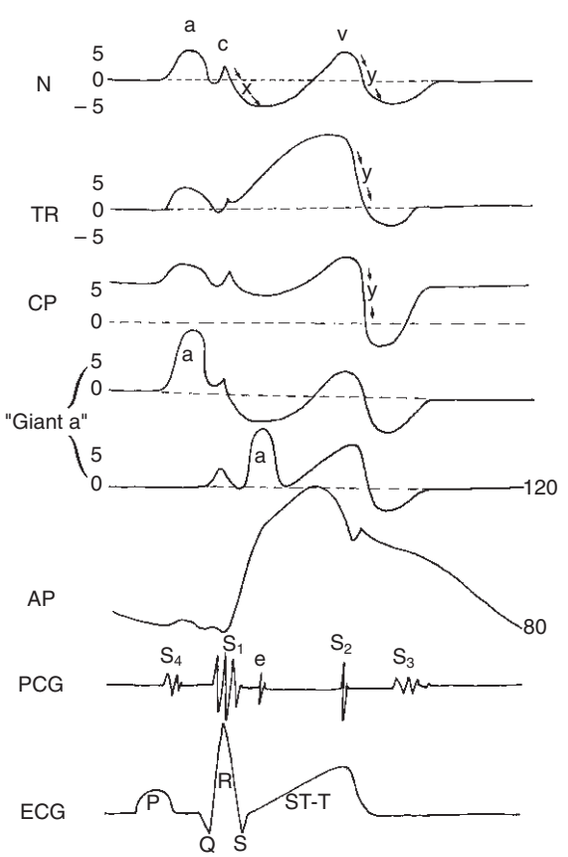

Figure 142-1. Analysis of venous pulses. A normal pulse is shown for reference (N), as are systemic arterial pressure (AP), phonocardiogram (PCG), and electrocardiogram (ECG). Abnormal pulses shown are those produced by tricuspid regurgitation (TR) and constrictive pericarditis (CP); also shown are two types of cannon, or giant, *a* waves.

Vigorous Pulsation of the Jugular Vein

- Jugular venous pulses ("cannon *a* waves") occurring at rates exceeding 120/min with a very slow ventricular rate slow (usually below 60/min) indicates third-degree (complete) or high-grade second-degree atrioventricular block.
- If *cannon a-waves* occur just before the first heart sound it may rarely indicate tricuspid stenosis or possibly stiffness of the ventricles (e.g., pulmonic stenosis).
- Cannon waves (*giant c-v waves*) observed between the first and second heart sounds indicate tricuspid regurgitation.

Hepatojugular Reflux

- Pushing on the abdomen of a standing dog displaces the liver dorsad and "milks" blood from the liver to the right side of the heart, increasing systemic venous return.
- If the right ventricle cannot pump the extra blood through the lungs, or if right ventricular filling is restricted owing to pericardial tamponade or constriction, the extra venous return "wells up" in the atrium and systemic veins. This situation produces added jugular venous distention or a positive hepatojugular reflex.

Miscellaneous

- Inspect the pharynx and mouth to identify: tonsillitis, pharyngitis, salivary mucocele (rannula), elongated soft palate, neoplasia, or periodontal disease.
- Watch the animal walk to identify and to quantify:
  - Exercise intolerance related to heart failure or chronic respiratory disease.
  - Weakness due to heart failure or conditions such as severe aortic stenosis.
  - Neuromuscular or skeletal disease.

PALPATION

Technique

Perform palpation with the animal standing and being held by an assistant with the assistant's hands cupped gently around the patient's neck.

- The examiner stands at the side or back of the animal.
- The examiner places his or her hands in the axilla and slides them caudad stopping at:

1. The second to third intercostal space.
2. The fourth to sixth intercostal spaces.
3. Just caudad to the rib cage.
4. All points on the abdomen.
5. The femoral arteries.

Thorax

- Determine where the heart "thumps" most vigorously against the thoracic wall. The point of maximal impulse is normally at the fifth intercostal space 2–3 fingerbreadths from the left sternal border *and* at the right third intercostal space near the right sternal border.
- The apical impulse starts at the first heart sound and peaks at the time of aortic opening. This impulse can be counted to obtain a heart rate, identify arrhythmias, and compare the frequency to the pulse rate (to detect pulse deficits).
- Cardiomegaly or space-occupying intrathoracic masses may displace the cardiac impulse.
- Ventricular hypertrophy may create a more prominent cardiac impulse.
- Precordial thrills (vibrations from murmurs) indicate the presence of a loud murmur and generally correlate to the point of maximal murmur intensity during auscultation.
- Gently palpate the trachea and then the thorax while observing the pattern and effort of ventilation.

Abdomen

- Gently palpate under caudal ribs to identify hepatomegaly.
- Palpate the abdomen for ascites, organomegaly, or neoplasia.

Femoral Pulses

- *Rate*—Palpate the femoral arteries for pulse rate, which in dogs and in cats is relatively independent of body size.

Heart Rates	Dog	Cat
Quiet (asleep)	50–90	90–120
During examination	80–160	140–220
Exercise	230	230

- *Rhythm*—Evaluate the cardiac rhythm by careful palpation of the pulse rate and regularity.
- *Respiratory sinus arrhythmia*—The average rate is usually as described previously for sleep. The rate speeds up during inspiration but seldom more than three or, at most, four heartbeats during an inspiration. More than four beats during inspiration may indicate abnormal ventilation caused by chronic pulmonary disease. Pulse rate slows during exhalation, occasionally to as low as 30 beats/min but only very briefly.

Pulse Rate and Rhythm

- *Atrial fibrillation* or frequent short bursts of supraventricular or ventricular tachycardia are characterized by rapid pulse rate; irregularly irregular rhythm (i.e., *not* in sync with ventilation); variable intensity; and *pulse deficits* (fewer femoral pulses than heartbeats).
- Rapid and irregularly irregular pulses are found with atrial fibrillation or with supraventricular or ventricular tachycardias in brief bursts.
- However, pulse rate in atrial fibrillation may not be rapid in large-breed dogs with concurrent hypothyroidism; when there is preserved myocardial function; in dogs with relatively slow-conducting atrioventricular nodes approaching complete heart block; or in dogs taking drugs that block atrioventricular nodal conduction (digoxin, beta-blockers, diltiazem).
- Occasionally supraventricular or ventricular *premature beats* occur singly and are characterized by apparent single skipped pulses followed by a pulse stronger than usual.
- Regularly irregular pulses in sync with respirations are found with *sinus arrhythmia.*
- "*Skipped" beats* (when combined with cardiac auscultation) are found with single premature depolarizations.

Pulse Character

- *Force*—Assess the force of the arterial pulse as normal, bounding (hyperkinetic), weak (hypokinetic), or sharp and brief (see Table 142-1 and Fig. 142-1).
- Weak pulses are found in:
  - Heart failure.
  - Aortic stenosis.
  - Dilated cardiomyopathy.
- Extremely bounding (water-hammer) pulses are found in:
  - Patent ductus arteriosus.
  - Aortic regurgitation.
  - Complete heart block with very slow ventricular rate.
- Sharp, "tapping" pulses are often found when the arteries are relatively stiff due to contraction of vascular smooth muscle in response to neuroendocrine activation in heart failure.
- *Absent pulses*—Loss of palpable femoral pulses are found in cats or cats with aortic embolism. In most cats the underlying cause is cardiomyopathy or endocarditis.
- Measurement of *arterial blood pressure* is a logical extension of the physical examination. This procedure is described in Chapter 153.

Table 142-1. TYPICAL SYSTEMIC ARTERIAL* PULSES FOR ANIMALS WITH VARYING PHYSIOLOGIC AND/OR PATHOLOGIC STATES

	Character	Pressure Systolic/ Diastolic	Pressure Differential	Rate	Pulse Character
Normal animal	Normal	120/80	40	Normal	
Patent ductus arteriosus (PDA) or aortic regurgitation (AR)	Bounding	160/40	120	Increased	Aortic stenosis (AS) or early heart failure (HF)	Weak	90/60	30	Increased	
Mitral regurgitation (MR), ventricular septal defect (VSD), late heart failure (HF), or hyperkinetic ventricle (HK)	Sharp, brief	120/80	40	Rapid	

*For example, femoral artery.

PERCUSSION

This is the technique (Fig. 142-2) of thumping on the thorax and/or abdomen to determine the relative density of structures underneath the points of percussion (see also Chapter 166).

Thoracic Percussion

- The normal notes of percussion may be learned by percussing thoraces from many normal male and female animals of varying ages and body conformations. Regions of cardiac dullness are less obvious in quadrupeds than in primates, but large pulmonary lesions or pleural effusion may be detected effectively by percussion.
- Hyper-resonant notes sound like a tympany drum and indicate air-trapping in the lung (as with COPD) or a gas-filled structure (e.g., pneumothorax, gas-filled stomach) underneath. (Hyper-resonant sounds may be illustrated by drinking a can of carbonated beverage, jumping up and down for 15 seconds, and then thumping on the left side of your abdomen just over your stomach.)
- Dull notes sound "dead," like thumping one's skull, and indicate a dense, usually water-filled structure (e.g., pneumonia, pleural effusion, pulmonary edema, consolidation) underneath.
- See Figure 142-2, which integrates the findings of percussion and auscultation for the differential diagnoses of edema/pneumonia; pneumothorax;

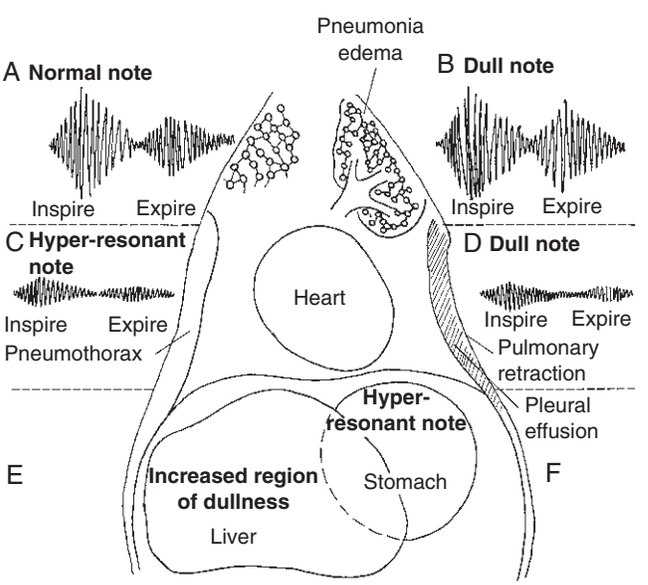

Figure 142-2. Schematic diagram of thorax and cranial portion of the abdomen viewed from the ventral aspect. *A* indicates the normal breath sounds and percussion. *B* shows a dull percussion note and louder than expected inspiratory and expiratory sounds due to pneumonia or edema. *C* represents the hyper-resonant percussion note and diminished breath sounds caused by pneumothorax, as illustrated by air between the thoracic wall and collapsed lung. *D* demonstrates a dull percussion note and diminished breath sounds due to pleural effusion, shown as density between thoracic wall and lungs. *E* indicates dull percussion notes because of an enlarged, dense liver. *F* is a hyper-resonant percussion note caused by gas in the stomach.

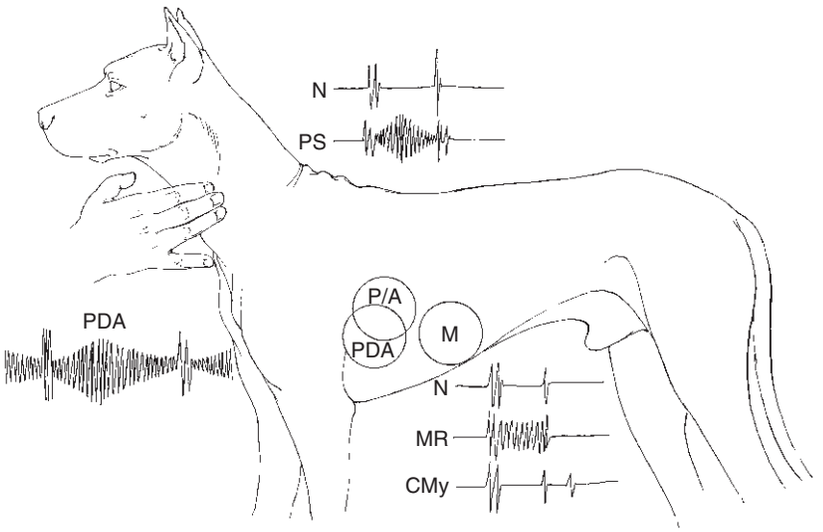

Figure 142-3. Regions where murmurs are heard best on the left hemithorax. Diagrams of murmurs typical of specific defects are shown. Normal (N) heart sounds are indicated above the murmurs of pulmonic stenosis (PS) and mitral regurgitation (MR). The diastolic gallop heard with dilated cardiomyopathy (CMy) is shown below the murmur for mitral regurgitation. PDA is the continuous murmur of patent ductus arteriosus. P/A is the ejection murmur of pulmonic stenosis or aortic stenosis. (Note: Loud murmurs of aortic stenosis may be heard equally on the right base as well.) M demonstrates systolic regurgitant murmur of mitral regurgitation.

pleural effusion; lung consolidation/neoplasia; and COPD/PF.

Abdominal Percussion

- *Hepatic enlargement* generates a dull note over a larger area than expected because the liver is an exceptionally dense structure.
- *Bloated (air-filled) stomach* is distended and generates a hyper-resonant percussion note because skin serves as the head of the drum and the gas in the stomach serves as the air-filled kettle of the drum. The abdomen bloated with gas produces an hourglass configuration with pulmonary retractions. It can be differentiated from organomegaly and/or ascites by the following:
  - It is tympanic (hyper-resonant).
  - It comes and goes quickly.
  - Air is often noted in the esophagus on thoracic radiography.

AUSCULTATION – OVERVIEW

- Auscultation is defined as listening to heart and breath sounds, usually with the aid of a stethoscope.

Methods of Auscultation

Optimal examinations are fostered by:

- A quiet environment, a quiet patient, and a tranquil examiner.
- An animal that is standing and restrained by an assistant standing to the front of the patient and, in dogs, holding the mouth closed to discourage panting.
- Positioning of the auscultator to the back or side of the patient while keeping a hand or arm between the pet's mouth and his or her face.
- A systematic approach to examination of the chest (Figs. 142-3 and 142-4).
- Appropriate use of the stethoscope.
- Understanding of normal heart and breath sounds.
- Integration with other findings—observation, palpation, and percussion.

Stethoscope

- Preferably use a stethoscope with ear pieces large enough to occlude most of the external acoustic meatus but not so large as to be airtight. The internal canal of the ear piece must be clean, and the outside should be sanitized if used by more than one person.
- Two tubes of commercial stethoscope tubing extend from ear pieces to chest piece (these may be wrapped within a single tube).
- There are a wide variety of stethoscope chest pieces used in modern instruments, but they represent variations of the traditional diaphragm and the bell.
- In traditional stethoscopes there is a single hard rubber or plastic diaphragm for characterizing high-pitched sounds and a bell—preferably a deep trumpet bell—for relatively low-pitched sounds.
- The diaphragm does not amplify high-pitched sounds but simply attenuates low-pitched sounds; whereas the bell—particularly the deep trumpet bell—does not preferentially attenuate sound of either frequency.
- Some newer models employ "tunable" diaphragms wherein varying pressure on the chest piece deter-

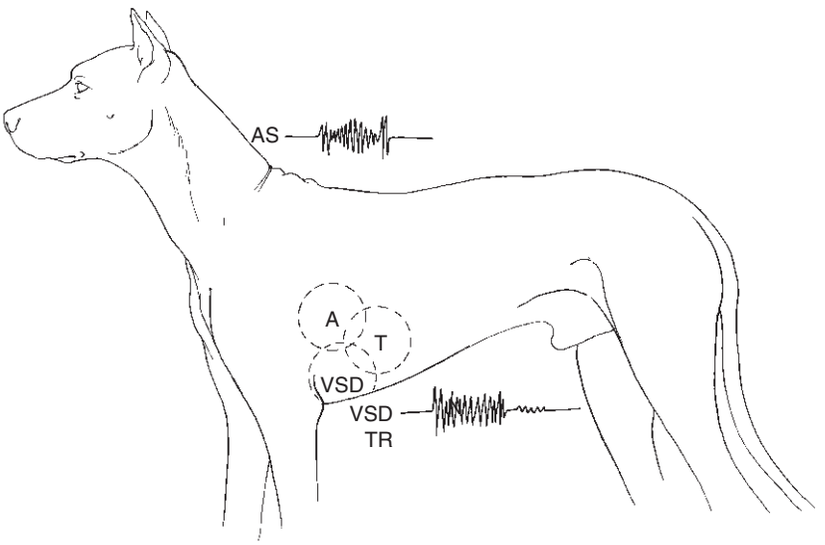

Figure 142-4. Left lateral view demonstrating where murmurs are heard best on the right hemithorax. A is the systolic ejection murmur of aortic stenosis (AS) and may be equally loud at left and right hemithorax. Systolic regurgitant murmur of ventricular septal defect (VSD) is heard best at the right sternal border. A soft diastolic murmur may also be heard from concurrent aortic regurgitation or increased flow across the mitral valve. T indicates where the systolic murmur of tricuspid regurgitation (TR) is heard best.

mines the frequency response characteristics of the system.

Auscultation of the Lungs

Examine the lungs to detect normal breath sounds and abnormal pulmonary sounds. Auscultate over the larynx, trachea, thoracic inlet, and along a number of ventral and dorsal, cranial and caudal locations on each side of the thorax. When possible, keep the patient's mouth closed to prevent panting. Gentle pressure over a nostril may encourage a deeper breath. See Fig. 142-2 for normal and abnormal breath sounds and percussion.)

- Normal *vesicular breath sounds* (sounds made by air tumbling through airways) are heard with sounds of inspiration being louder than sounds of expiration. They are transmitted best in the direction that the air flows, thus inspiratory vesicular breath sounds are heard over the basilar lobes whereas expiratory sounds are either absent or very soft.
- The percussion note of normal resonance is not too dull and not too resonant.

▼ ***Key Point*** In order to know what is "normal," you must auscultate and percuss hundreds of normal animals of various ages, breeds, and conformations.

Auscultation of the Heart

Examine the heart to detect the heart sounds, cardiac rhythm, sound intensity, murmurs, and other abnormalities. Begin by listening over the left apex and the move the stethoscope craniodorsally to the aortic valve area. Identify the first and second heart sounds and make note of any additional sounds such as a midsystolic click or a diastolic gallop sound. Systematically listen across the various areas of auscultation (shown in Figures 142-3 and 142-4). Once identified, classify heart sounds according to:

- *Frequency*—to assess autonomic tone and heart rhythm.
- *Regularity*—to detect arrhythmias.

▼ ***Key Point*** An animal ill from heart disease usually manifests low vagal tone and a reduced—or absent—sinus arrhythmia. Conversely, patients ill from lung disease often manifest an exaggeration of the sinus arrhythmia.

- Intensity
  - The normal first sound (S_1) is longer and duller and most prominent over the left apex. The normal second heart sound (S_2)is higher pitched and louder over the aortic and pulmonary valve areas. Occasionally in dogs, a subtle splitting of the normal second sound may be detected during inspiration.
  - A "booming" S_1 heart sound indicates forceful contraction, rapid atrioventricular conduction (short PQ interval in the ECG), or skinny thorax. A loud first sound also may be detected in dogs with advanced mitral regurgitation with preserved left ventricular function.
  - A "soft" S_1 heart sound indicates weak ventricle, long atrioventricular conduction (PQ interval), obesity, hyperinflation of lungs, pleural effusion, or pneumothorax.
  - A loud S_2 may indicate systemic or pulmonary hypertension.
- Presence of murmurs or a corresponding precordial thrill—a murmur is a prolonged audible vibration during a usually silent period of the cardiac cycle; a thrill is a palpable manifestation of a murmur. A

precordial thrill indicates a murmur of at least grade IV (out of VI).

CLINICAL ABNORMALITIES OF AUSCULTATION, PERCUSSION, AND PALPATION

Findings in Respiratory Disease

Bronchial Disease (see Chapter 162)

- Expiratory wheezes are considered relatively specific for narrowing of intrathoracic airways, particularly in the bronchial tree. Potential causes include:
  - Narrowing of multiple bronchi, as with bronchitis and bronchial asthma
  - Cuffing of bronchi or reactive bronchoconstriction from pulmonary edema or left-sided heart failure
  - Obstruction or collapse of a principal bronchus at the level of the carina. This may indicate heart enlargement (left atrial), compression from hilar lymph nodes, or primary bronchial wall disease/collapse
- Sonorous rhonchi (rattling sounds), localized to the chest, may be indicative of fluid in larger airways as with bronchitis or bronchopneumonia.

Abnormal breath sounds may be evident even before use of the stethoscope. In general, major airway obstruction leads to loud, audible ventilation; whereas, detection of pleural space or lung parenchymal disease often requires intense concentration and good technique.

Upper Airway Obstruction (see Chapter 161)

- Stertor or loud, inspiratory snoring sounds often indicate upper airway obstruction (redundant soft palate; soft tissue mass; nasopharyngeal obstruction). The origin of these sounds must be localized with the stethoscope to the laryngeal and pharyngeal area, as they are likely to be referred to the chest and be confused with pulmonary rhonchi.
- High pitched, inspiratory stridor localized to the larynx usually indicates glottic obstruction or laryngeal paralysis.
- Reversed sneezing is typically due to nasopharyngeal disease or fluid accumulation caudal to the nasal cavity.
- Auscultation or palpation of "honks" related to tracheal wall vibrations may be identified in dogs with tracheal collapse.

Pulmonary Edema, Pneumonia, and Fibrosis

- Breath sounds are termed bronchial or bronchovesicular (i.e., sounds are louder in both inspiration and expiration but are much louder and higher pitched during expiration). The increased intensity arises from these sounds being "made" normally at larger airways but being transmitted better than usual via fluid-logged parenchyma.
- Crackles or rales are also considered signs of parenchymal or very small airway disease.
- Crackles may be audible without the stethoscope, especially in cases of severe pulmonary fibrosis.
- In most instances, detection of crackles requires careful auscultation during inspiration.
- Crackles are indicative of pulmonary parenchymal diseases including edema, pneumonia, hemorrhage, and fibrosis.
- Percussion note is dull when the lung density is increased owing to fluid-filled parenchyma.

Pneumothorax (see Chapter 166)

- All breath sounds are softer than normal because the free air space between the stethoscope chest piece and the lung insulates against the transmission of sound.
- Percussion note is hyper-resonant (i.e., sounds like thumping on a tympany drum) because the thoracic wall acts like a drumhead stretched over an air-filled chamber underneath.

Pleural Effusion (see Chapter 164)

- All breath sounds are softer than normal because free liquid between pulmonary parenchyma and chest wall reflects sound away from its pathway to the stethoscope chest piece.
- Percussion note is dull because the water-filled cavity vibrates at high frequency and low amplitude and is dampened rapidly.

Findings in Heart Disease

The approach to auscultation is somewhat personal and may include examination of specific "valve areas" or more general regions over the heart. Auscultation in the cat differs somewhat from that of the dog because the feline heart is relatively small, more horizontal in axis, and discrete valve areas are more difficult to identify. Some of the key points of cardiac auscultation are indicated below. Other details can be found in chapters throughout this section.

Mitral Valve Region (see Fig. 142-3)

- This region is also known as the left apical region and is at the left fifth intercostal space approximately 2 to 3 fingers' breadth from the left sternal border. In the cat it is close to the sternum at the level of the palpable apical impulse.
- Here S_1 is louder, longer in duration, and lower pitched than S_2. S_1 is mimicked as a "lub;" S_2 is mimicked as a "dup."
- Sounds of mitral valve disease are usually most evident here, but do tend to radiate to the right directly across from the left apex.

- Mid-systolic clicks are often detected in dogs with early mitral valve degeneration and prolapse of the mitral valve.
- The murmur of mitral regurgitation extends from S_1 to, and often through, S_2, and is louder during expiration.

▼ ***Key Point*** The intensity of the murmurs of mitral and tricuspid regurgitation does *not* consistently correlate with the severity of the regurgitation and is influenced profoundly by the force of contraction of the ventricle.

- In dogs and cats with dilated cardiomyopathy, there is often an S_3 gallop producing a set of sounds like lub-dup-uh, especially when heart failure has developed.
- In case of left ventricular hypertrophy with preserved atrial function there may be a prominent S_4 gallop, evident at the apex and often at the base as well.

Craniodorsal Cardiac Base (Pulmonary Artery Region)

- Sounds in this area tend to originate in the aortic valve area caudally, the pulmonic valve area cranioventrally, the ascending aorta, or the main pulmonary artery. This is normally where S_2 is heard best. In cats, the "base" extends more ventrally than in dogs and many feline ejection murmurs are evident close to the sternum but cranial to the apex beat.
- There may be splitting of S_2 caused by the pulmonic valve closing later than the aortic valve—this is particularly pronounced during inspiration during relatively slow heart rates. Wide splitting may be detected with an atrial septal defect or severe pulmonary hypertension, especially when there is also a right bundle branch block.
- Functional ejection murmurs from sympathetic drive, anemia, fever, bradycardia, and the athletic heart are loudest here. Innocent puppy and kitten murmurs are also most likely to be detected in this region.
- The murmur of pulmonic stenosis (see Chapter 154) is heard loudest in this region. It is usually very loud and radiates dorsad, it is shorter in duration than mitral regurgitation, often very rough, and accentuated during inspiration.
- The murmur of aortic stenosis (see Chapter 154) is heard equally loudly here and at the same position on the right hemithorax, but it is usually louder during expiration. Very soft aortic flow murmurs tend to be louder at the left cardiac base.

▼ ***Key Point*** The intensity and duration of the murmur of pulmonic or aortic stenosis generally correlates well with the severity of the stenosis.

Patent Ductus Arteriosus Region

- The continuous murmur of the patent ductus arteriosus (PDA) is heard the loudest at the left third intercostal space over the base of the heart. With this murmur, S2 may not be heard because the murmur of blood rushing through the PDA is loudest during late systole. See Chapters 154 and 155 for more on PDA.

Right Hemithorax

- At the region of the right fourth intercostal space at the sternal border, S_1 is louder than S_2. The systolic murmur of typical perimembranous ventricular septal defect is heard best here, and is louder during exhalation.
- At the region of the right fifth intercostal space above the costochondral junction the systolic murmur of tricuspid regurgitation is heard best and is louder during inspiration. This murmur may be particularly intense with a palpable thrill in the setting of pulmonary hypertension.
- At the region of the right base the systolic murmur of aortic stenosis is almost as loud as at the left base and is louder during exhalation than during inhalation. In cases of severe aortic stenosis, the murmur is frequently louder on the right side.

Chapter

143 Cardiovascular Radiography

John D. Bonagura / Valerie F. Samii

Thoracic radiography and echocardiography are useful in the recognition and assessment of cardiovascular diseases. Other imaging modalities, such as cardiac magnetic resonance imaging, gated computerized tomography, and radionuclide studies, are uncommonly used in routine cardiology practice and have limited indications at this time. This chapter emphasizes the use of radiography in cardiac diagnosis.*

When combined with the results of the clinical examination, thoracic radiographs may contribute to the specific cardiac diagnosis, verify the presence of congestive heart failure (CHF), and assist in the differential diagnosis of respiratory signs such as coughing and dyspnea. Analysis of thoracic radiographs in the diagnosis of respiratory diseases is discussed in more detail in Chapter 159. Essential principles in the application of echocardiography are considered at the end of this chapter. More specific applications of radiography and echocardiography are discussed in other chapters throughout this section.

GENERAL PRINCIPLES OF CARDIAC RADIOGRAPHY

▼ ***Key Point*** The importance of the technical quality of thoracic radiographs is often underestimated. A radiograph with inadequate penetration, exposure during expiration, or poor patient positioning can be very misleading.

Technical errors can be avoided by addressing the following technical points prior to radiographic evaluation for cardiac disease.

Technical Considerations

- The practice should develop routine protocols for thoracic radiography of the cardiac patient.
  - At a minimum, two views, a right or left lateral projection and either a dorsoventral (DV) or a ventrodorsal (VD) projection, are needed for thoracic evaluation.
  - In general, a DV and right lateral projection are usually recommended for cardiac evaluation.
  - In some situations, both right and left lateral projections and VD and DV views are obtained.
- Radiographic technique (see Chapter 4):
  - Expose films at the peak of inspiration.
  - Remember that expiratory films are ineffective for evaluating the lung parenchyma for interstitial pulmonary edema.
  - A long gray-scale (high kilovolt peak, low milliampere-second) technique is most helpful for assessing thoracic disease. Underexposure mimics pulmonary disease by increasing apparent lung density, whereas overexposure leads to an underestimation of the severity of pulmonary changes.
  - Rotation often accentuates normal structures such as the main pulmonary artery on the VD projection or the left atrium or right ventricle on the lateral projection.
  - False apex shifting due to patient rotation on the VD projection may cause overestimation of ventricular size.
  - Consistent positioning and exposure techniques should be used when obtaining follow-up radiographs. This is particularly important when following patients with CHF.

Normal Lateral Radiograph (Fig. 143-1)

Dogs

The following are guidelines for understanding the normal canine lateral thoracic radiograph:

- The cardiac outline is roughly tear-shaped with a narrowed, ventral apex.
- *Orientation*—The long axis creates approximately a 45-degree angle with the sternum (varies with breed).
- *Location*—The cardiac silhouette extends from the third to sixth ribs, and the heart and diaphragm usually touch or overlap.
- *Size*—Ventricles occupy approximately three intercostal spaces. Using the vertebral score method (discussed below) the vertebral heart score (VHS) ranges from 8.5 to 10.6 (mean, 9.7), although studies in specific breeds have demonstrated breed-specific variation.
- The cardiac borders on the lateral projection represent the following:

*The contribution to this chapter made by Dr. C. Wendy Myer, Diplomate ACVR, is gratefully acknowledged.

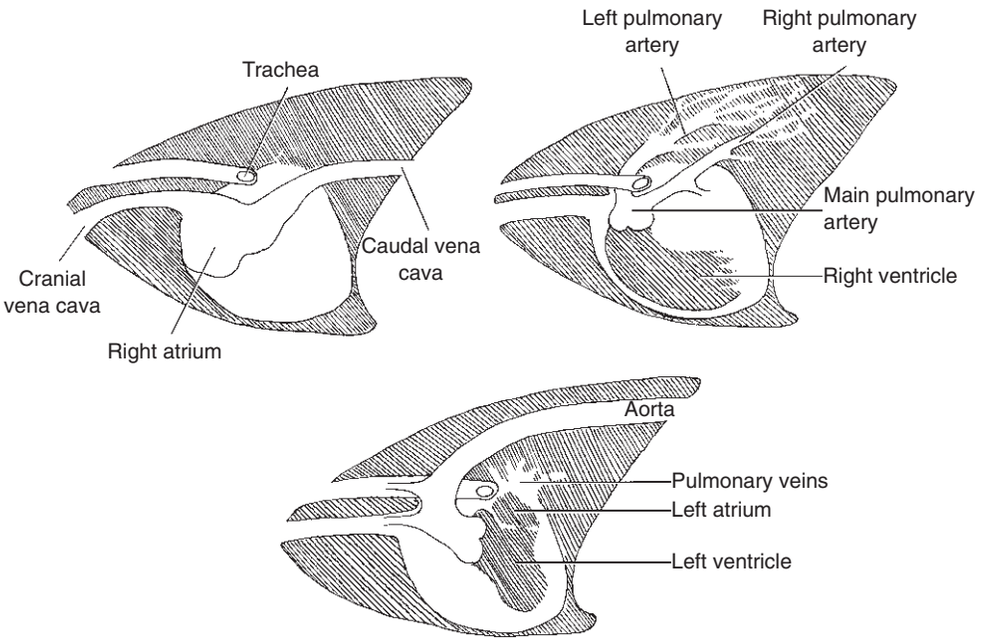

Figure 143-1. Three lateral views of the normal heart showing chamber location.

- Cranial—Rounded border, right ventricle and auricle
- Caudal—Straight border, left ventricle and atrium
- Dorsal—Both atria, pulmonary arteries, cranial and caudal vena cava, and aorta

- *Quadrants*—The cardiac silhouette can be divided into sections on the lateral radiograph by drawing a line from the tracheal bifurcation to the apex parallel to the cardiac axis and a second horizontal line at the level of the vena cava.
  - Atria are dorsal to the horizontal line.
  - Ventricles are ventral to the horizontal line.
  - Right-sided heart structures make up the cranial three-fifths of the heart shadow (remember that the two ventricles overlap owing to the curved ventricular septum).
  - Left-sided heart structures make up the caudal two-fifths of the heart shadow.
- There are some differences between right and left lateral films. Importantly, the left atrial border is more prominent and the cardiac apex appears slightly more elevated on left lateral films.

Cats

The following are guidelines for understanding the normal feline lateral thoracic radiograph:

- The cardiac outline is more elongated and elliptical than that in the dog.
- Cardiac borders are similar to those in the dog.
- *Orientation* is more variable than that in the dog, with a more horizontal major cardiac axis.
- *Location*—The heart and diaphragm are separated by one to two intercostal spaces.
- *Size*—The ventricles occupy approximately 2 to 2.5 intercostal spaces and the heart extends about two-thirds of the VD height of the thorax. The VHS is typically 8.5 to 9.0 in cats.

Normal Ventrodorsal or Dorsoventral Radiograph (Fig. 143-2)

Dogs

The following are guidelines for understanding the normal canine VD or DV thoracic radiograph:

- The cardiac outline has a curved (convex) right border and a relatively straight left border.
- *Orientation*—The apex is slightly to the left of midline, approximately at a 30-degree angle with the spine. The cardiac apex appears slightly closer to the midline on the DV as opposed to the VD projection.
- *Location*—The cardiac silhouette extends from the third to the eighth vertebrae, often overlapping the diaphragm.
- *Size*—The cardiac-thoracic index is about 60% to 65% of the thorax as measured from right to left.
- Cardiac borders (using the clock face analogy):
  - 11 to 1 o'clock—Aortic arch (seen better on the DV projection)
  - 1 to 2 o'clock—Main pulmonary artery
  - 2 to 3 o'clock—Left auricular appendage
  - 3 to 6 o'clock—Left ventricle (includes the apex)
  - 6 to 9 o'clock—Right ventricle
  - 9 to 11 o'clock—Right atrium

Cats

The following are guidelines for understanding the normal feline VD or DV thoracic radiograph:

- The cardiac outline is slightly more elongated than that in the dog.

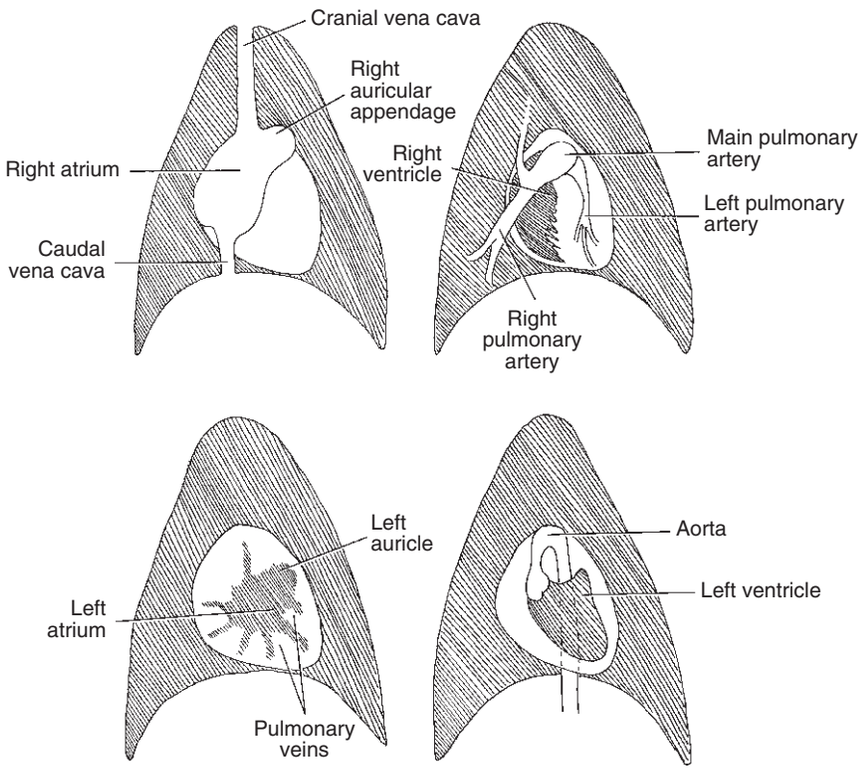

Figure 143-2. Four ventrodorsal views of the normal heart showing chamber location.

- *Orientation*—The apex is at or slightly to the left of midline.
- *Location*—The heart and diaphragm are separated by one to two intercostal spaces.
- Cardiac borders are similar to those in the dog, except that the main pulmonary artery does not contribute to the 1- to 2-o'clock border.

Normal Pulmonary Arteries and Veins

Location and Size

- The cranial lobe artery is dorsal to the bronchus which is dorsal to the vein on the lateral view.
- Arteries are lateral to the bronchus and vein, and originate cranial to the carina on the VD or DV view.
- Veins terminate in the left atrium caudal to the carina (veins are ventral and central).
- Vascular markings are often very prominent in healthy, deep-chested dogs, as well as in cats with hyperinflated lungs.
- Arteries and veins are approximately equal in size.
- Overlapping or superimposition of vessels from both cranial lung lobes can create a misleading appearance regarding vessel size on the lateral view.
- Normal, average vessel-to-rib ratio on the lateral projection is about 0.75 when comparing the artery with the proximal one-third of the fourth rib. However, the range of normal values is quite expansive (0.5–1.25).
- Pulmonary vessels on the VD or DV view should not exceed the width of the ninth rib at the point of intersection. Generally, this intersection creates a "square" as opposed to a rectangle.
- The caudal lobe arteries and veins appear larger on DV views because of distance from the cassette and subsequent magnification. In obese cats, magnification can be substantial and lead to overinterpretation of true vascular size.

Appearance

- Vessels are best seen on the lateral view as they extend into the cranial lobes.
- Vessels in the lung farthest from the cassette are magnified.
- Arteries are denser than veins, are slightly curved, and have dichotomous branching (branches of equal size).
- Veins are less visible, are straighter and blunter than arteries, and have branches of unequal size.

INTERPRETING THORACIC RADIOGRAPHS IN CARDIAC DISEASE

Once an adequately positioned and exposed radiograph has been obtained, the radiographs must be interpreted in a systematic manner. Optimally, the films would be assessed without knowledge of the patient and then reassessed after reading the signalment, clinical history, and examination findings. In most instances this is impractical, but it is clear that including the clinical findings will both assist the evaluation (by provid-

ing a clinical perspective) and hinder an objective assessment (by prejudicing the reader with the clinical diagnosis).

Initial Approach to Interpretation

The following general questions should be addressed during the radiographic assessment of cardiac disease:

- *Are the radiographs of sufficient technical quality?* Is the positioning straight, is the exposure appropriate, and was the film exposed during inspiration?
- *Is cardiomegaly present or absent?* If present, is this cardiac enlargement mild, moderate, or severe?
  - Species and conformational variations are important in this assessment (e.g., barrel-chested dogs normally have wider and more rounded hearts, and the cardiac size appears large relative to the thoracic volume, whereas deep-chested dogs have a narrower, more vertically oriented heart shadow).
  - Owing to marked breed variation, the subjective appearance of heart size may differ between projections. For example, cardiomegaly may be suspected on one view but may not be confirmed on the complementary projection.
  - Concentric ventricular hypertrophy may be underestimated by cardiac size as viewed by radiography.
  - It may be useful to calculate a VHS in dogs, particularly in cases of equivocal cardiomegaly. This score is especially helpful in toy-breed dogs, which often appear to have cardiomegaly by subjective evaluation. The technique is described more fully below.
- *Which specific cardiac chambers are abnormal?* Is more than one cardiac chamber affected? Is the abnormality restricted to one side of the heart, or is it generalized? (See below and Figs. 143-3–143-6.)
- *Is the cardiac apex in its normal position?* If not, is this shift due to poor patient positioning or true cardiomegaly?
  - Left heart enlargement may shift the apex to the right (typical of cats) or to the left. Typically, the heart will also be elongated in the left heart enlargement.
  - Right-sided enlargement may shift the apex to the left but in general does not elongate the heart.
  - Rotation of the heart and shifting of the apex often leads to overestimation of the size of other cardiac chambers. Evaluating the heart on both views may prevent erroneous conclusions in the case of apex shifting.
- *Are the great vessels (aorta and main pulmonary artery) normal or abnormal in appearance?*
- *Are the pulmonary vessels normal, small, or enlarged?* (Also see Chapter 159.) If enlarged, are changes restricted to the arteries (e.g., heartworm disease) or veins (e.g., left heart failure), or are both altered in size (e.g., pulmonary undercirculation or overcirculation)?
- *Is the radiographic opacity of the lung normal, decreased, or increased?* Are areas of increased opacity generalized or focal? If diffuse, what is the distribution of the pulmonary infiltrates (generalized, dorsal-caudal, or cranial-ventral)? What is the radiographic pattern of abnormal density? (See Chapter 159.)
- *Is there pleural effusion?*
  - Pleural effusion can stem from CHF or a noncardiogenic origin.
  - Thoracocentesis is necessary to determine the type of fluid present (see Chapters 3 and 164).
  - The cardiac silhouette is more obscured on a DV projection than on a VD projection in the presence of a mild to moderate amount of pleural fluid due to the effect of gravity on fluid distribution.
  - Patient stress may preclude a complete radiographic examination initially, but further films may be possible following thoracocentesis. If possible, both DV and VD projections should be obtained, as the latter will better delineate the cardiac silhouette.
- *Are the diaphragm and extrathoracic structures normal?* If not, are the changes most likely congenital (e.g., peritoneopericardial hernia) or acquired (e.g., acquired diaphragmatic hernia with related rib fractures)?

Enlargement Patterns for Specific Cardiac Chambers

Signs of Right Atrial Enlargement (Fig. 143-3)

Lateral View

- Right atrial enlargement usually is not seen on this view.
- Loss or filling in of the normal concave angle between the ventral edge of the craniodorsal mediastinum and the cardiac silhouette (the cranial "waist") may be seen due to bulging of the right atrial appendage (right auricle).
- In some cases the cranial waist may become accentuated due to discrete auricular enlargement.

Dorsoventral or Ventrodorsal View

- Bulging of the cranial right heart border (9–11 o'clock) is typical of right atrial dilation.
- Right atrial dilation is often masked by concurrent right ventricular enlargement.
- In cases of severe right atrial dilation, as with tricuspid valve malformation or primary atrial muscle disease (silent atrium), the apex may shift to the left and the craniodorsal mediastinum may bulge on the VD view because of cranial vena caval dilation.

Signs of Right Ventricular Enlargement (Fig. 143-4)

Lateral View

- Increased overall width of the heart
- Rounding of the cranial heart border
- Elevation of the cardiac apex and caudal vena cava
- In severe right ventricular enlargement, elevation of the trachea cranial to the carina and some degree of cardiac elongation

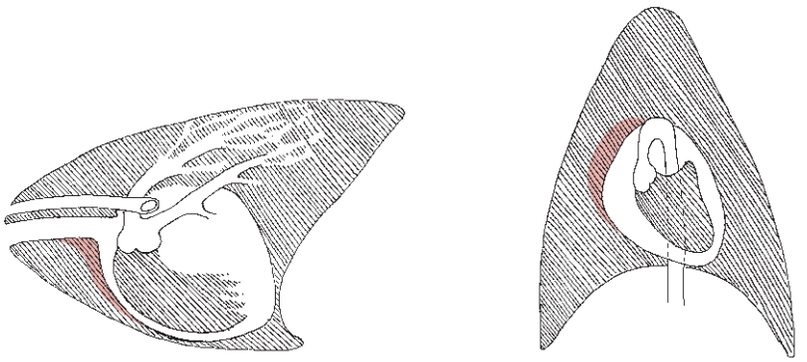

Figure 143-3. Radiographic appearance of right atrial enlargement. The red areas denote the abnormal region.

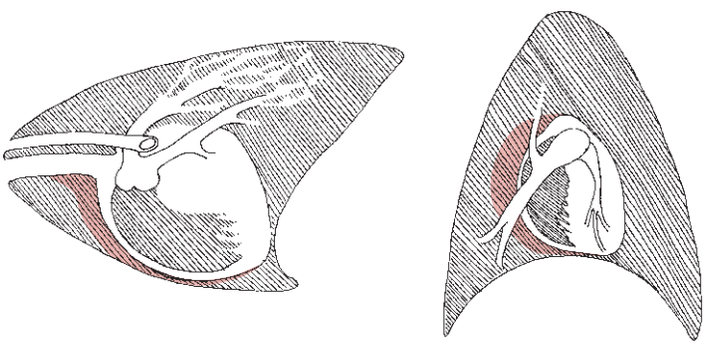

Figure 143-4. Radiographic appearance of right atrial and ventricular enlargement. The red region denotes the abnormality.

Dorsoventral or Ventrodorsal View

- Rounding of the right heart border (6–11 o'clock)
- "Reversed D" appearance if the main pulmonary artery is also dilated
- Increased overall width of the heart
- Decreased distance between the right side of the heart and the thoracic wall or shifting of the apex to the left side

Causes of Right-Sided Enlargement

- Right atrial enlargement (usually normal right ventricle):
  - Right atrial tumor
  - Tricuspid stenosis
  - Cor triatriatum dexter (caudal atrial dilation extending to caudal vena cava)
- Right atrial and right ventricular enlargement:
  - Atrial septal defect (ASD)
  - Atrial myocardial disease
  - Tricuspid regurgitation from any cause
  - Right ventricular cardiomyopathy
  - Chagas myocarditis
  - Pulmonic stenosis
  - Heartworm disease
  - Pulmonary hypertension (some cases)
  - Arrhythmias—Chronic bradycardia, relentless tachycardia, and atrial fibrillation
  - Plasma volume expansion—CHF, circulatory overload, and high output heart disease as with anemia, hyperthyroidism, or systemic arteriovenous fistula
- Right ventricular enlargement (usually normal right atrium):
  - Tetralogy of Fallot
  - Pulmonary hypertension (some cases)

Signs of Left Atrial Enlargement (Fig. 143-5)

Lateral View

- Elevation of the distal end of the trachea with dorsal displacement and compression of the left main stem bronchus between the left atrium and the descending aorta
- Bulging of the caudal-dorsal heart border (dorsal to the caudal vena cava)
- Filling in and loss of the normal caudal indentation of the cardiac border (the caudal waist), or, with marked dilation, accentuation of the caudal waist as the atrium projects caudodorsally

Dorsoventral or Ventrodorsal View

- The left atrium proper is a midline structure and does not normally contribute to the heart border on this view.
- There is displacement and separation of the main stem bronchi as they approach the cranial border of the left atrium and bifurcate around this chamber (producing a "bow-legged cowboy" appearance to the bronchial tree).
- On a well-exposed DV view, the enlarged atrium may be seen as a round, soft tissue mass summated on the caudal heart border.

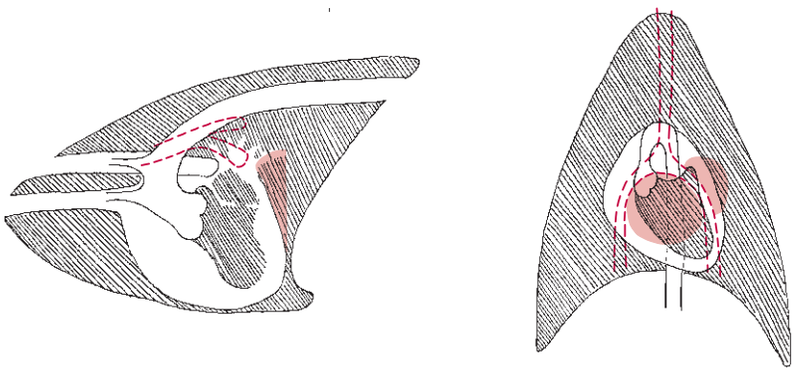

Figure 143-5. Radiographic appearance of left atrial enlargement. The red region denotes the abnormality. (Dotted red lines outline the trachea and main stem bronchi.)

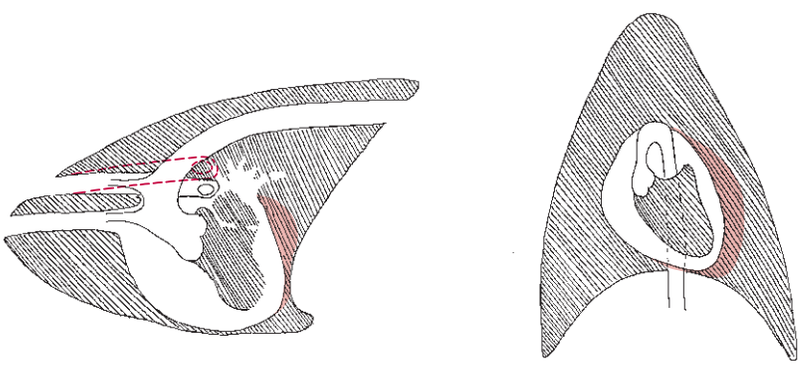

Figure 143-6. Radiographic appearance of left ventricular (with or without atrial) enlargement. The red region denotes the abnormality. (Dotted red lines outline the trachea.)

- Left auricular dilation is seen in dogs as bulging of the left heart border from 2 to 3 o'clock and in cats as a bulge from 1 to 3 o'clock.

Signs of Left Ventricular Enlargement (Fig. 143-6)

Lateral View

- Elongation of the cardiac silhouette and possibly widening of the silhouette
- Rounding of the caudal heart border
- Elevation of the carina and distal end of the trachea (causing the trachea to more closely parallel the spine than the sternum; this finding depends on chest conformation and breed)

Dorsoventral or Ventrodorsal View

- Elongation, rounding, and expansion of the left heart border
- Rounding of the cardiac apex
- Decreased distance between the left heart border and the thoracic wall or shifting of the cardiac apex to the right (especially common in cats)

Causes of Left-Sided Enlargement

- Left atrial enlargement (usually normal left ventricle):
  - Cor triatriatum (sinister)
  - Mitral stenosis
  - Supravalvular mitral ring (supravalvular mitral stenosis)
- Left atrial and left ventricular enlargement:
  - Mitral valve disease—Mitral regurgitation from any cause (endocardiosis, endocarditis, malformation, cardiomyopathy)
  - Left to right shunts—Patent ductus arteriosus (PDA), ventricular septal defect (VSD), and some ASDs, particularly when there is AV valve malformation (endocardial cushion defects)
  - Multiple systemic to pulmonary shunts (bronchial artery to pulmonary vascular tree)
  - Cardiomyopathy (all forms)—Dilated, hypertrophic, restrictive, and unclassified
  - Myocarditis
  - Chronic hyperthyroidism
  - Chronic systemic hypertension
  - Aortic stenosis (left atrial enlargement develops with impending CHF)
  - Aortic regurgitation (left atrial enlargement develops with CHF)
  - Arrhythmias—Chronic bradycardia and relentless tachycardia
  - Plasma volume expansion—CHF, circulatory overload, and high output heart disease as with anemia or hyperthyroidism

Signs of Biventricular Cardiac Enlargement

- This is a relatively common feature of many cardiac disorders.
- It usually is difficult to determine which ventricle is most enlarged on survey films alone; echocardiogra-

phy is very helpful in assessing chamber size and ventricular function.
- The heart appears generally rounded, and usually there is increased sternal contact on the lateral view.

Causes of Biventricular Cardiac Enlargement

Common causes include the following:

- Chronic degenerative valvular heart disease (mitral and tricuspid regurgitation)
- Left-sided heart failure (any cause) with secondary pulmonary hypertension
- Large VSD
- Dilated cardiomyopathy
- Mild to moderate pericardial effusion (mimics cardiomegaly)
- High-output heart failure (moderate to severe anemia, arteriovenous fistula, hyperthyroidism)
- Overinfusion of intravenous fluids

Signs of Microcardia

- A generalized decrease in cardiac size is most often associated with plasma volume contraction, shock, or trauma.
- Decreased cardiac size allows the heart to shift off the midline when the patient is in lateral recumbency, making the heart appear elevated from the sternum similar to the radiographic appearance of pneumothorax.
- Pulmonary circulation often appears diminished.

Causes of Microcardia

- Hypovolemic shock
- Addison's disease
- Hemorrhage
- Protracted vomiting or diarrhea
- Obstructive hepatic circulation (cirrhosis, caudal vena cava obstruction)

Enlargement of the Great Vessels

Aortic Enlargement (Fig. 143-7)

The direction of aortic bulging depends on the underlying etiology, as in the examples that follow.

Causes

- *PDA:* Some cranial bulging of the aortic arch is seen, but the most pronounced bulging is toward the left side at the site of the patent ductus ("ductus bump") (best seen on the DV view). In deep-chested dogs the aortic dilation may be observed just caudal to the aortic arch on the lateral projection.
- *Aortic stenosis:* There is dilation of the ascending aorta (cranioventrally), and often the brachiocephalic artery and aortic arch (in the cranial mediastinum) are dilated secondary to poststenotic turbulence.
- *Tetralogy of Fallot and pulmonary atresia:* Dilation of the ascending aorta due to aortic malalignment and dextropositioned aorta.
- *Persistent right fourth aortic arch:* On the VD or DV view, the aorta may be observed to arch to the right side (mirror-image arch) before connecting to the descending aorta.
- *Age:* Dilation and tortuosity of the ascending aorta, the aortic arch, and the arch extending into the descending aorta may be observed in older cats. Many of these cats also have hyperthyroidism or systemic hypertension, but cause and effect have not been established. Idiopathic dilatation of the ascending aorta and aortic arch also has been observed in many dogs. The appearance can resemble that of a mediastinal mass.

Pulmonary Artery Enlargement

Enlargement of the main pulmonary artery leads to bulging of the left cranial cardiac border at 1 o'clock (DV or VD view) in the dog. Only extreme main PA dilation will be evident in cats.

Causes

- Increased blood flow into the main pulmonary artery (PDA, VSD, ASD): Pulmonary vascular markings are usually increased as well.
- Post-stenotic dilation (pulmonic stenosis): Pulmonary circulation is normal to reduced.
- Pulmonary hypertension (heartworm disease, severe pulmonary thromboembolism, or related to congenital pulmonary vascular disease): Also dilation of lobar pulmonary arteries.

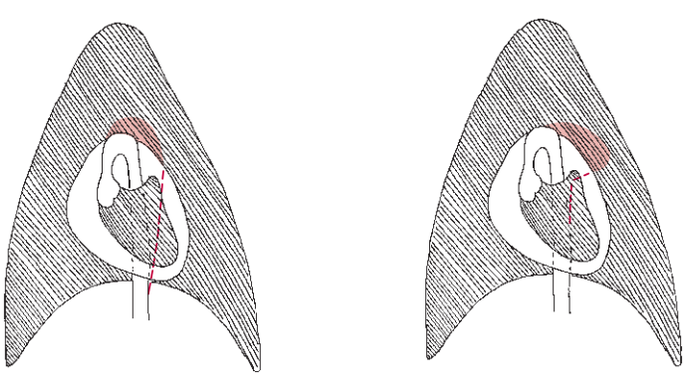

Figure 143-7. Radiographic appearance of aortic enlargement. *Left,* Aortic stenosis. *Right,* Patent ductus arteriosus.

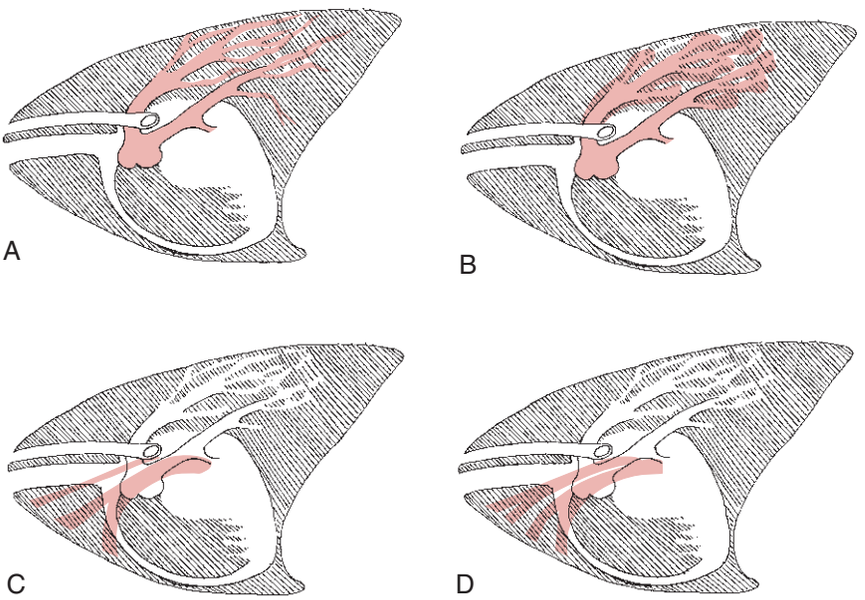

Figure 143-8. Radiographic appearance of pulmonic circulatory disorders. *A,* Normal pulmonary circulation. *B,* Pulmonary arterial hypertension caused by heartworm disease. *C,* Effects of venous congestion due to mitral insufficiency. *D,* Signs of pulmonary overcirculation caused by left-to-right shunt or pulmonary hypertension due to left-sided congestive heart failure.

Pulmonary Vascular Patterns (Fig. 143-8)

- Assessment of pulmonary vascularity requires judgment and evaluation of other cardiac structures.
  - On the lateral view: Evaluate vessels as they extend into the cranial lobes.
  - On the DV or VD view: Evaluate vessels as they extend beyond the heart border. The lobar artery is lateral to the bronchus and vein.
- As indicated above, the lobar artery and vein should be of the same diameter at adjacent levels. On the lateral view, the *average* vessel diameter at the fourth rib is 75% of the width of the proximal one-third of that rib. On the VD projection, the vessels should create a "square" summation density over the ninth rib.
- *Decreased pulmonary vascular markings* (small arteries and veins) are typical of decreased perfusion due to the following:
  - Right-to-left cardiac shunts (e.g., tetralogy of Fallot and Eisenmenger's physiology)
  - Severe pulmonic stenosis
  - Low cardiac output from volume contraction (e.g., shock and Addison's disease)
  - Cardiac tamponade
  - Pulmonary thromboembolism (regional, reduced blood flow to affected areas)
- *Increased pulmonary vascular markings* (large arteries and veins) is often caused by the following:
  - Pulmonary overcirculation (left-to-right shunts such as PDA, VSD, ASD, aorticopulmonary window, and bronchial artery to pulmonary shunts)
  - High output states (thyrotoxicosis)
  - Volume overload (excessive fluid therapy)
  - Possibly enhanced vascularity in the peripheral lung fields
- *Prominence of lobar pulmonary arteries* (arteries > veins) is usually related to pulmonary hypertension caused by the following:
  - Heartworm disease
  - Pulmonary thromboembolism
  - Pulmonary hypertension from parenchymal lung disease (cats > dogs)
  - Eisenmenger's reaction in congenital heart disease
  - Left-sided CHF with pulmonary hypertension (pulmonary veins and venous distention also are prominent)
- *Prominence of lobar pulmonary veins* (veins > arteries) is usually related to venous congestion:
  - Left-sided CHF
  - Compression of pulmonary venous return (regional, from a mass lesion)
  - Cor triatriatum (sinister)
  - PDA (arteries also are enlarged, but lobar veins are often more enlarged than lobar arteries)

Congestive Heart Failure

The clinical diagnosis of left-sided CHF is substantiated by thoracic radiography. Radiographic diagnosis of right-sided CHF is more difficult and must be interpreted with physical examination findings of right heart failure. In advanced disease there may be biventricular CHF with generalized cardiomegaly (Fig. 143-9).

- Left-sided CHF is characterized by left-sided cardiomegaly, pulmonary venous distension, and increased pulmonary density.
- Initially, perivascular interstitial densities that blur vascular margins are observed. These progress to a diffuse interstitial density with airway cuffing prior to alveolar flooding.

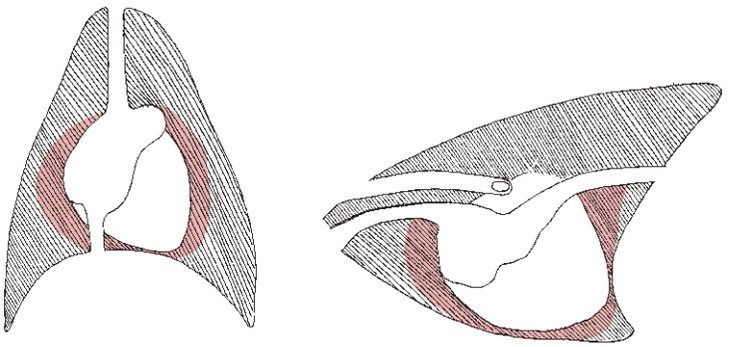

Figure 143-9. Radiographic appearance of generalized cardiomegaly. The red regions denote the abnormalities.

- Alveolar patterns are recognized as fluffy, coalescing densities with increased air-filled bronchi contrasted with the fluid-filled lung (air bronchogram sign). Fluid density structures such as the heart and diaphragm may be obscured (border effacement or silhouetting).
- Distribution of cardiac edema is usually perihilar, dorsal, and bilateral; however, right-sided prominence is common in severe edema due to different lymphatic drainage between the right and the left lungs. Diffuse or dependent infiltrates may be observed in fulminant cardiogenic edema.
- In cats, pulmonary edema is more likely to be localized to the dependent portions of the perihilar caudal lung lobes.
- Expect mobilization of alveolar edema within 48 to 72 hours following aggressive therapy for CHF (see Chapter 147). Radiographic changes often lag behind clinical improvement or deterioration by 12 to 18 hours. Failure to resolve increased pulmonary densities following appropriate treatment should prompt a reconsideration of the diagnosis of cardiogenic lung edema.
- Development of pleural fissure lines and pleural effusion is usually a sign of biventricular CHF and a fluid retentive state. Severe pleural effusion may indicate right ventricular decompensation associated with congenital right heart disease or atrial fibrillation. Cardiac tamponade is another cause of pleural effusion.

Interpretation Pointers

The radiographic features of many cardiac disorders are described in detail in other chapters within this section. Table 143-1 summarizes typical features of common conditions. There are always exceptions. The following statements are designed to assist the clinician in interpreting thoracic radiographs from dogs and cats with cardiac disease.

Verifying Cardiomegaly with the Vertebral Heart Score

As described above, detection of cardiomegaly would seem straightforward; however, in many instances there is uncertainty about heart size. It is critical to obtain an overall opinion based on study of both DV and lateral views. Cardiac elongation usually indicates left ventricular enlargement. Cardiac widening can occur with either left or right ventricular enlargement. When there is doubt, the VHS is invaluable. This can be calculated in about 3 minutes (Fig. 143-10) by following these steps:

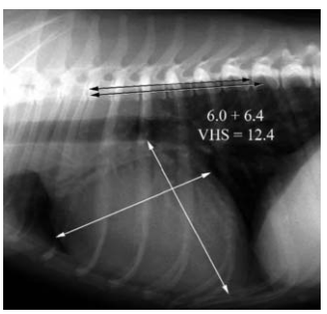

Figure 143-10. Lateral radiograph from a dog with cardiomegaly demonstrating the vertebral heart score.

- Measure the apical-basilar length from the ventral border of right bronchus at level of circular carina to the apex of the heart. This is the major axis measurement.
- Then draw a line perpendicular to your first measurement, extending from the cranial to the caudal heart border. This is the minor cardiac axis. Select the greatest length, but do not extend the measurement into the caudal vena cava or dorsal left atrium.
- Identify the fourth thoracic vertebral body; inspect the dorsal spinous processes to assist localization.
- Measure the VHS from the cranial edge of T4 caudally.
- Count the number of vertebral bodies encompassed in the major + minor axis lengths. Extrapolate to the nearest decimal point.
- A VHS that exceeds 8.0 in a cat is suspicious for cardiomegaly (average value is 7.5 vertebral bodies).
- A VHS that exceeds 10.7 in a dog is likely to indicate cardiomegaly (the normal average is about 9.7 vertebral bodies).

Table 143-1. TYPICAL RADIOGRAPHIC FEATURES OF HEART DISEASE

Disorder	LV	LA	Ao	RV	RA	MPA	Pulmonary Circulation	Additional Findings
Patent ductus arteriosus	+	+	+ Desc Ao	0*	0		+ Artery + Vein	Left-sided CHF
Ventricular septal defect	+	+	0	+†	0†	+	+ Artery + Vein	Left-sided CHF

Mitral regurgitation	+	+	0	+†	0	0	+ Vein 0/+ Artery†	Left-sided CHF
Tricuspid regurgitation	0	0	0	+	+	0	0	Dilated vena cava Right-sided CHF
Aortic stenosis	+	0/+	+ Asc Ao	0	0	0	0/+ Vein 0/+ Artery†	Left-sided CHF
Pulmonic stenosis	0	0	0	+	+	+	0/− Artery 0/− Vein	Right-sided CHF
Tetralogy of Fallot	0	0	+§	+	+	‖	− Artery − Vein	
Dilated cardiomyopathy	+	+	0	+	+	0	+ Vein 0/+ Artery	Biventricular CHF
Hypertrophic cardiomyopathy	+	+	0	0/+†	0/+†	0	+ Vein 0/+ Artery†	Left-sided or biventricular CHF
Restrictive cardiomyopathy	+	+	0	+	+	−	+ Vein 0/− Artery†	Variable findings
Pericardial effusion	+	+	0	+	+	0	0/− Artery 0/− Vein	Possible mass lesion
Hyperthyroidism	+	+	+	+	+	0	0/+ Artery 0/+ Vein	Dilated or tortuous aorta
Pulmonary hypertension	0/+¶	0/+¶	0	+	+	+	−/0/+ Artery −/0/+ Vein¶,#	Lungs may be abnormal or undercirculated
Heartworm disease	0	0	0	+	+	+	+ Artery 0 Vein	Pulmonary infiltrate

*Although the RV may appear enlarged, the echocardiograph demonstrates that LV dilatation accounts for ventricular enlargement; in the rare case of reversed patent ductus arteriosus, the radiograph resembles that of pulmonary hypertension.
†Right-sided cardiomegaly develops if there is pulmonary hypertension due to increased pulmonary flow, increased pulmonary vascular resistance, or both. Otherwise, right-sided cardiomegaly is variable.
‡In the typical ostium secundum (high) atrial septal defect (ASD), blood flows immediately into the RA and the LA doesn't enlarge substantially. In cases of primum ASD with concurrent ventricular septal defect, or mitral dysplasia (endocardial cushion defect), LA dilation also develops.
§The aorta is dextropositioned and receives the most blood flow; this causes widening of the ventrocranial mediastinum on the lateral projection.
‖The pulmonary artery is not dilated because blood preferentially shunts across the ventricular septal defect into the aorta.
¶In cases of pulmonary hypertension secondary to left-sided CHF, left-sided heart structures are enlarged.
#In cases of pulmonary hypertension secondary to left-sided CHF, pulmonary venous distention is also present; in pulmonary hypertension caused by pulmonary vascular disease (e.g., reversed patent ductus arteriosus, primary pulmonary hypertension), peripheral pulmonary vascularity is decreased, whereas central lobar vessels are dilated from pressure.
Ao, aorta; CHF, congestive heart failure; LA, left atrium; LV, left ventricle; MPA, main pulmonary artery; RA, right atrium; RV, right ventricle; 0, no change; +, enlarged or increased; −, decreased; desc, descending; asc, ascending.

- As with any diagnostic test, there will be some false-negative and false-positive results.

Atrial Dilatation in Chronic Mitral Regurgitation

The degree of left atrial dilation seen radiographically usually corresponds to the severity of chronic valvular regurgitation; however, in acute heart failure or with a ruptured chorda tendinea, left atrial enlargement may be underwhelming in the face of life-threatening alveolar infiltrates. Compression of the left main stem bronchus by the enlarged left atrium may cause coughing and persist following resolution of lung edema. This finding is often associated with recurrent coughing.

Canine Dilated Cardiomyopathy

Dilated cardiomyopathy is the second most important cause of CHF in dogs. There is no specific radiographic finding for this disease, and features are similar to those of chronic valvular endocardiosis. Generalized cardiomegaly is typical. Echocardiography is needed for definitive diagnosis.

Valentine-Shaped Hearts in Cats

This finding on the VD/DV radiograph is not specific for any one condition and can be observed with a variety of congenital and acquired diseases. It typically indi-

cates left ventricular enlargement and left auricular dilation, along with an apex shift to the right.

Rupture of the Left Atrium

Acute pericardial effusion in dogs with chronic mitral valve disease may indicate left atrial rupture. Typically, the pulmonary vascularity is reduced and the caudodorsal border of the left atrium becomes rounded.

Peritoneopericardial Hernia

This is a relatively common malformation in cats and can be readily confused with cardiomegaly from cardiomyopathy (see Chapter 150). A persistent mesothelial remnant is often evident ventral to and parallel to the caudal vena cava (which is displaced dorsally).

Pericardial Effusion from Congestive Heart Failure

Cats with CHF often develop pericardial effusion that clears with effective medical therapy. This can lead to relatively dramatic differences in cardiac size in "before and after" films.

Diuretic Therapy and Heart Size

Effective diuretic therapy of severe CHF is usually associated with reductions in both heart and lung volumes.

GENERAL PRINCIPLES OF ECHOCARDIOGRAPHY

Echocardiography is an advanced imaging modality that has become the gold standard for noninvasive cardiac diagnosis. A number of different echocardiographic formats are used in clinical practice, including the two-dimensional, M-mode, and Doppler examinations (color Doppler, pulsed wave, tissue Doppler, and continuous wave). Echocardiography has become increasingly sophisticated, and the combined modalities have largely replaced cardiac catheterization and angiocardiography for diagnosis and assessment of cardiac lesions. Appropriate use of the technology requires understanding of heart diseases, along with advanced training in diagnostic imaging. Specific echocardiographic findings in cardiac disease are discussed in a number of chapters within this section.

A detailed discussion of echocardiography and the various imaging planes and modalities used in diagnosis is beyond the scope of this book. However, the following comments are offered to place this imaging technique into an appropriate context.

- Veterinarians often find referral for echocardiography helpful or even essential for establishing a cardiac diagnosis. Examples include the following:
  - Definitive diagnosis of congenital heart disease
  - Assessment of cats with signs of heart disease (murmurs, gallops, cardiomegaly)
  - Recognition of dilated cardiomyopathy in dogs
  - Diagnosis and evaluation of pericardial disease
  - Diagnosis of pulmonary hypertension
  - Evaluation of dogs with chronic valvular heart disease
  - Assessment of dogs and cats with persistent arrhythmias
- Echocardiography should be performed and echocardiograms should be interpreted by individuals that appreciate pertinent issues and questions regarding specific cardiovascular diseases.
- The echocardiographic examination is not a substitute for a careful clinical examination or assessment. A veterinarian capable of integrating information from all sources, including the history and physical examination, radiography, and laboratory tests, should direct the treatment plan. These decisions should not be abdicated to any sonographer unless that individual has a full understanding of the entire clinical situation and has physically examined the patient.
- While limited echocardiographic examinations have their place, a referring veterinarian should expect an echocardiographic (with Doppler) examination to generate the following information:
  - Pertinent congenital or acquired anatomic lesions (morphologic diagnosis)
  - Estimates of cardiac great vessel and chamber size (dilatation and hypertrophy)
  - Quantitation of ventricular systolic function
  - Estimates of ventricular diastolic function
  - Evaluation of blood flow and valvular function
  - Estimates of hemodynamics (pressure/flow)
  - Overall significance of a lesion

Chapter

144 Electrocardiography

Francis W. K. Smith, Jr. / Larry Patrick Tilley / Michael S. Miller

Electrocardiography is the graphic representation of the electrical activity of the heart with time displayed on the x-axis and voltage displayed on the y-axis. Electrocardiograms (ECGs) are easy to perform and readily available to practicing veterinarians. There are numerous indications for performing ECGs, and the examination provides information that is useful and often pivotal to the diagnosis and management of cardiac and systemic disturbances. Veterinarians or their technicians can perform and interpret their own ECGs or utilize readily available fax, transtelephonic, or computer consultation services.

GENERAL PRINCIPLES OF ELECTROCARDIOGRAPHY

Indications for Performing Electrocardiography

Electrocardiography is the examination of choice for diagnosis of a normal cardiac rhythm and arrhythmias and for monitoring the effect of antiarrhythmic therapy. There are a number of clinical indications for recording and interpreting an ECG:

- To diagnose an arrhythmia detected on physical examination (auscultation, arterial pulse deficits, palpable precordial heart beat irregularities, or abnormal jugular venous pulsations).

▼ ***Key Point*** Perform an ECG on all animals with tachycardia or bradycardia and on all cats with any irregularity in rhythm. Perform an ECG on any dog with an irregularity in rhythm that is related to a pulse deficit or is not related to phases of respiration.

- To identify arrhythmias or conduction disturbances in patients with a history of syncope, seizures, or exercise intolerance.
- To monitor the effectiveness of antiarrhythmic therapy. In this regard, the ambulatory (Holter) ECG is the best approach for monitoring effectiveness of antiarrhythmic therapy for ventricular arrhythmias.
- To assess cardiac size in patients with known or suspected cardiac disease. While the ECG is not a very sensitive indicator of heart size, a cardiac enlargement pattern usually correlates with cardiac chamber enlargement or hypertrophy. The more criteria for heart enlargement present in a patient, the more likely the heart is enlarged. Most dogs with normal hearts will not exhibit heart enlargement patterns on ECGs.

▼ ***Key Point*** A normal ECG does not rule out a diagnosis of heart enlargement. Thoracic radiographs and echocardiography are more sensitive tests for evaluating heart size.

- To help individualize and monitor therapy in patients with heart failure by accurately assessing cardiac rhythm. It is important to understand that a diagnosis of congestive heart failure (CHF) cannot be made based on an ECG alone.

▼ ***Key Point*** An arrhythmia or a heart enlargement pattern supports the diagnosis of heart disease but does not confirm CHF. Obtain thoracic radiographs, along with an ECG, in a patient suspected of having CHF. The ECG is useful in patients with heart failure for the diagnosis and treatment of associated arrhythmias.

- To evaluate patients with suspected digoxin or other cardiac drug toxicity.
- To screen for electrolyte disturbances, especially hyperkalemia, hypercalcemia, and hypocalcemia.
- To look for evidence that may support the diagnosis of pericardial effusion, hypothyroidism, hyperthyroidism, or hypoadrenocorticism (Addison's disease).

Technique for Recording an Electrocardiogram

- For accurate measurements, place the patient in right lateral recumbency.

▼ ***Key Point*** If the animal is dyspneic or if restraint would be dangerous to the patient, obtain a rhythm strip with the animal supported in any comfortable position.

Table 144-1. ELECTRODE PLACEMENT

Chest Lead	Placement of the V Lead
CV_5RL (rV_2)	Fifth intercostal space on the right side near the sternum
CV_6LL (V_2)	Sixth intercostal space on the left side near the sternum
CV_6LU (V_4)	Sixth intercostal space on the left side at the costochondral junction
V_{10}	Over the dorsal spine of the seventh thoracic vertebra

- Wet the skin with alcohol or ECG electrode gel and attach the electrodes just above the elbows and stifles.
- Hold the upper limbs perpendicular to the long axis of the patient and parallel to the floor. If the thoracic limbs are not parallel and perpendicular to the long axis of the animal, the mean electrical axis will be altered.
- Record approximately three to four complexes in each of the six limb leads, and then record a long lead II strip for rhythm evaluation. Push the standard calibration button at the beginning and end of each recording.
- Chest leads can be obtained using the lead V electrode while keeping the limb leads attached. See Table 144-1 for electrode placement.
  - Chest leads are not necessary for all patients. However, they may be quite useful when the ECG complexes in the limb leads are small and difficult to evaluate. Often, P waves that cannot be seen in the limb leads become apparent on a chest lead.
  - Evaluation of chest leads may also be helpful in evaluating heart enlargement patterns.
  - The chest leads most commonly used in veterinary patients are CV_5RL (rV_2), CV_6LL (V_2), CV_6LU (V_4), and V_{10}.

Normal Cardiac Conduction

The ECG records the electrical activity of the heart. Electrical impulses originate in specialized pacemaker tissue in the sinus node of the right atrium. The impulse rapidly traverses the atrium, causing atrial contraction, and then slows as it passes through the atrioventricular (AV) node located at the proximal portion of the interventricular septum. Electrical activity then rapidly passes through the bundle of His, the anterior and posterior branches of the left bundle branch, the right bundle branch, and the terminal Purkinje fibers. This causes activation of the interventricular septum and the left and right ventricular myocardium (Fig. 144-1).

Components of the Electrocardiographic Tracing (Fig. 144-2)

- P wave indicates atrial depolarization.
- P-R interval indicates time for conduction of the impulse from the sinoatrial (SA) node to the AV node and delay of the impulse in the AV node, His bundle, bundle branches, and Purkinje system.
- QRS complex indicates ventricular myocardium depolarization.
- Q wave (lead II) is associated with depolarization of the interventricular septum.
- R wave (lead II) is associated with depolarization of the left ventricle.

Figure 144-1. Normal conduction pathway in the heart. (From De Sanctis RW: Disturbances in cardiac rhythm and conduction. In Rubenstein R [ed]: Scientific American Medicine, section 1, subsection VI. © 1991 Scientific American, Inc. All rights reserved.)

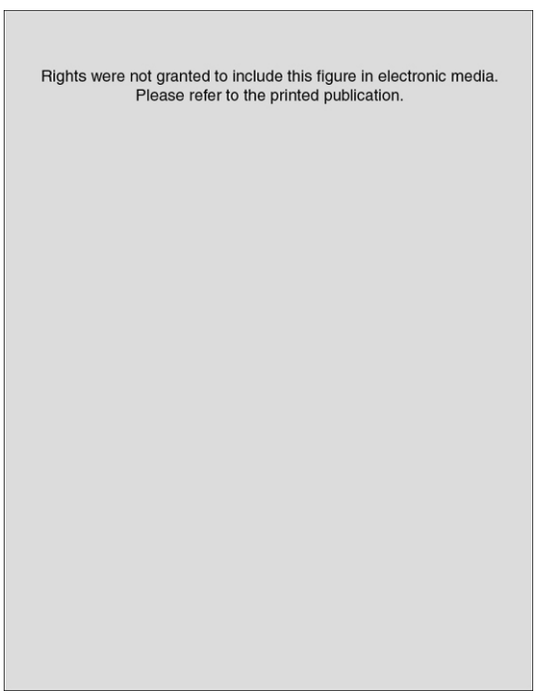

Figure 144-2. Normal electrocardiogram with components labeled. (From Tilley LP: Essentials of Canine and Feline Electrocardiography, 3rd ed. Philadelphia: Lea & Febiger, 1992.)

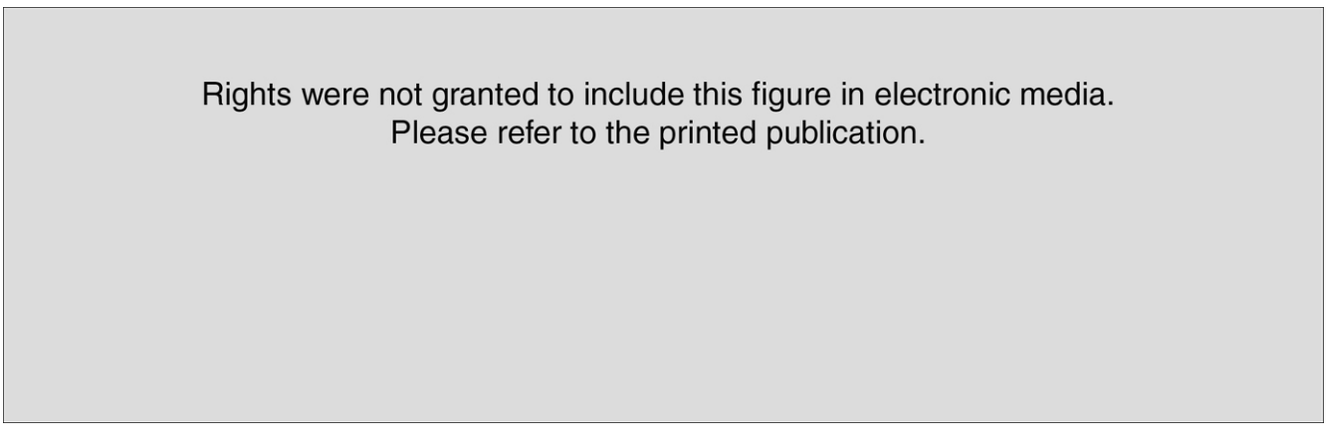

Figure 144-3. Electrocardiogram from a cat. Lead aVR is isoelectric. Lead III is perpendicular to aVR. The QRS deflection in lead III is positive, making the axis +120 degrees. If lead III had been negative, the axis would have been −60 degrees. (From Tilley LP: Essentials of Canine and Feline Electrocardiography, 3rd ed. Philadelphia: Lea & Febiger, 1992.)

- S wave (lead II), when present, is associated with depolarization of the right ventricle.
- T wave indicates ventricular repolarization.
- Q-T interval indicates an approximate interval of ventricular systole.

How to Evaluate the Electrocardiogram

- Always evaluate the ECG from left to right.
- Identify and label the ECG waveforms (P-QRS-T).
- Calculate the approximate heart rate (HR) by counting the number of R-R intervals in 3 seconds (two sets of time markers at 50 mm/second) and multiplying by 20.
- Determine the mean electrical axis.
  - One of the easiest ways to approximate the axis is to identify the isoelectric lead (sum of the positive and negative deflections of the QRS complex closest to zero).
  - Determine the perpendicular lead, and evaluate that lead to see if the complexes are positive or negative.
  - The axis is in the direction of the main deflection of the perpendicular lead (see Fig. 144-3 for an example).
  - If all leads are isoelectric, an axis cannot be determined in the frontal plane.
  - An alternative approach is to identify the frontal plane lead with the largest net positive QRS complex. In dogs, the frontal axis is normal if lead II or aVF is largest, the axis is deviated to the left if lead I or lead aVL is most positive, and the axis is deviated to the right if lead III or lead aVR is most positive.
  - A normal axis does not exclude the possibility of a cardiomegaly pattern or conduction disturbance.
- Determine the rhythm.
  - A sinus rhythm has nearly constant P-R and R-R intervals (usually varying by <10%).
  - A sinus arrhythmia has a nearly constant P-R interval, but the R-R interval varies, usually with the phase of respiration.
- Measure the height and width of the complexes.
- Determine the P-R and Q-T intervals and evaluate the S-T segment.
- Compare the heart rate, rhythm, and sizes of the complexes with the normal values (Table 144-2).

ELECTROCARDIOGRAPHIC ABNORMALITIES

Electrocardiographic abnormalities can be divided into those involving heart rate and rhythm and those involving the configuration of the complexes. This chapter discusses abnormalities involving the ECG complexes. Arrhythmias are discussed in more detail in Chapter 145.

Intraventricular Conduction Disturbances

- The right bundle branch is thinner and therefore more susceptible to injury than the left bundle branch.
- Injury to more than one bundle branch may result in first-, second-, or third-degree AV block.
- A bundle branch block does not cause significant hemodynamic changes and therefore does not warrant therapy.
- Rate-related bundle branch blocks can occur intermittently in association with either bradycardia or tachycardia. The right bundle branch cells have a longer refractory period than the left bundle branch cells. This makes the right bundle more sensitive to abrupt changes in the heart rate.

Table 144-2. NORMAL CANINE AND FELINE ELECTROCARDIOGRAM VALUES*

	Canine	Feline
Heart rate (HR)	Puppy: up to 220 bpm Toy breeds: up to 180 bpm Standard: 70–160 bpm Giant breeds: 60–140 bpm	120–240 bpm
Rhythm	Sinus rhythm Sinus arrhythmia Wandering pacemaker	Sinus rhythm
P wave		
Height	Maximum: 0.4 mV	Maximum: 0.2 mV
Width	Maximum: 0.04 sec (giant breeds 0.05 sec)	Maximum: 0.04 seconds
P-R interval	0.06–0.13 sec (>0.13 sec in giant breeds)	0.05–0.09 sec
QRS		
Height	Small breeds: 2.5 mV maximum Large breeds: 3.0 mV maximum†	Maximum: 0.9 mV
Width	Small breeds: 0.05 sec maximum Large breeds: 0.06 sec maximum	Maximum: 0.04 sec
S-T segment		
Depression	No more than 0.2 mV	None
Elevation	No more than 0.15 mV	None
Q-T interval	0.15–0.25 sec at normal HR	0.12–0.18 sec at normal HR
T waves	May be positive, negative, or biphasic Amplitude range ± 0.05–1.0 mV in any lead	Usually positive and <0.3 mV
Electrical axis	+40° to +100°	0° to ±160°
Chest leads		
CV_5RL (rV_2)	T positive; R < 3.0 mV	
CV_6LL (V_2)	S < 0.8 mV; R < 3.0 mV	R < 1.0 mV
CV_6LU (V_4)	S < 0.7 mV; R < 3.0 mV	R < 1.0 mV
V_{10}	QRS negative; T negative except in Chihuahua	T negative; R wave/Q wave <1

*Measurements are made in lead II unless otherwise stated.
†Not valid for thin, deep-chested dogs <2 years of age.
bpm, beats per minute; HR, heart rate; mV, millivolts; sec, seconds.

Right Bundle Branch Block (Fig. 144-4)

- ECG characteristics of right bundle branch block (RBBB) include the following:
  - QRS width greater than 0.07 second (dog) or 0.06 second (cat)
  - Right axis deviation
  - Wide S waves in leads I, II, III, and aVF and lower left precordial leads, such as CV_6LL and CV_6LU
  - W-shaped pattern in V_{10}
  - Terminal QRS complex positive in aVR and aVL and M-shaped in CV_5RL
- Incomplete RBBB may be present if the aforementioned criteria are present but complexes are of normal width. Incomplete RBBB can be a normal variant in beagles. The pattern may be confused with a left posterior fascicular block (for which criteria are not firmly established).
- Differentiate RBBB from right ventricular enlargement by radiographs or echocardiography. Right ventricular enlargement and RBBB can occur together.
- RBBB has been associated with the following conditions: congenital malformations such as pulmonic stenosis, cardiac surgery, cardiac needle puncture or cardiac arrest, cardiac neoplasia, trauma, *Trypanosoma cruzi* infection (dog), cardiomyopathy, hyperkalemia (cat), acute ventricular dilation, balloon valvuloplasty, and doxorubicin cardiotoxicity. RBBB may be an incidental finding in patients without apparent cardiac disease.

Left Bundle Branch Block (Fig. 144-5)

- ECG characteristics of left bundle branch block (LBBB) include the following:
  - QRS width greater than 0.07 second (dog) or 0.06 second (cat)
  - QRS positive in leads I, II, III, aVF, CV_6LL, and CV_6LU
  - QRS negative in leads aVR, aVL, and CV_5RL
  - Absent or small Q wave in leads I, CV_6LL, and CV_6LU (dog)
  - Q wave absent in leads I and CV_6LU (cat)
- LBBB indicates greater cardiac damage than RBBB—often cardiomyopathy.
- Differentiate LBBB from left ventricular enlargement by radiographs or echocardiography. Left ventricular enlargement and LBBB also can occur together.

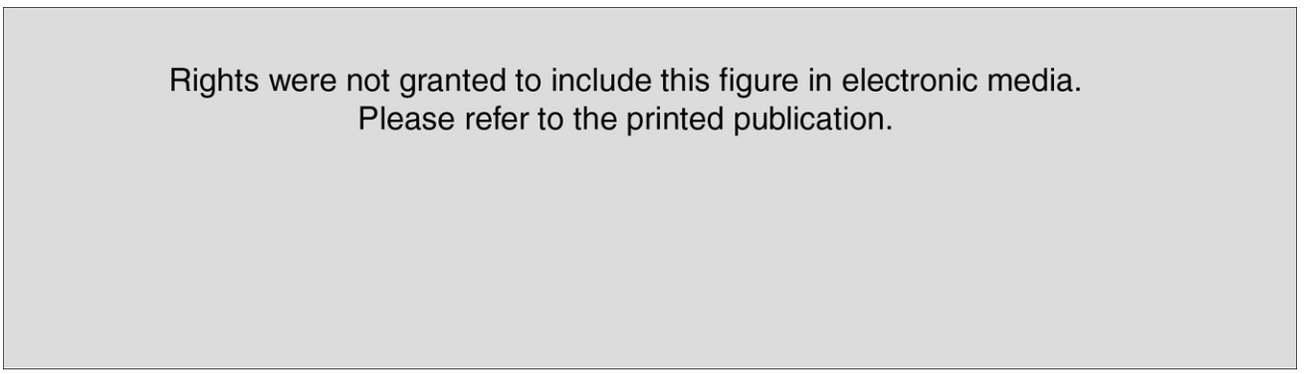

Figure 144-4. Example of right bundle branch block in the dog. Note the right axis (−110); the wide S wave in leads I, II, III, and aVF; and the M-shaped CV_5RL and W-shaped V_{10}. (From Tilley LP: Essentials of Canine and Feline Electrocardiography, 3rd ed. Philadelphia: Lea & Febiger, 1992.)

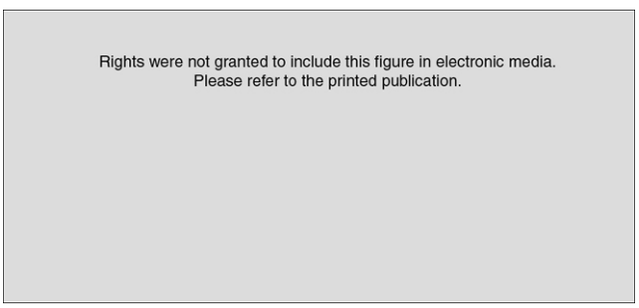

Figure 144-5. Left bundle branch block in a dog. Note the wide QRS complexes (0.08 sec). This electrocardiogram could also be consistent with left ventricular enlargement. (From Tilley LP: Essentials of Canine and Feline Electrocardiography, 3rd ed. Philadelphia: Lea & Febiger, 1992.)

- LBBB is most often associated with the following conditions:
  - In dogs—Cardiomyopathy, cardiac needle puncture, subaortic stenosis, and doxorubicin cardiotoxicity
  - In cats—Uncommon but associated with hypertrophic cardiomyopathy

Left Anterior Fascicular Block (Fig. 144-6)

- ECG characteristics of left anterior fascicular block include the following:
  - QRS width normal
  - Left axis deviation (dog < +40 degrees, cat < 0 degrees)
  - Small Q and tall R in leads I and aVL (small Q not essential)
  - Deep S wave in leads II, III, and aVF (exceeding the R wave)
- Associated conditions include hypertrophic cardiomyopathy, causes of left ventricular hypertrophy, hyperkalemia, ischemic cardiomyopathy, and cardiac surgery.
- Differentiate from left ventricular enlargement, altered position of the heart within the thorax, hyperkalemia, and ventricular preexcitation.

Left Anterior Fascicular Block and Right Bundle Branch Block (Fig. 144-7)

- ECG characteristics include the following:
  - QRS width greater than 0.07 second (dog) or 0.06 second (cat)
  - Left axis deviation
  - S waves deep and wide in leads I, II, III, aVF, and CV_6LU
  - Small Q and tall R in leads I and aVL
  - M-shaped QRS in lead CV_5RL
- Associated conditions are the same as for left anterior fascicular block.

Aberrant Conduction

- A sinus or premature atrial complex that is conducted through a bundle branch or myocardium during the absolute or relative refractory periods may result in an abnormal QRS-T complex. The resultant condition is called (phasic) aberrant ventricular conduction. The abnormal complex may assume the appearance of an RBBB or LBBB pattern or a more subtle widening or altered morphology of the normal QRS complex.
- Aberrancy is more common at slower heart rates or during sudden changes in R-R intervals, as might occur with atrial fibrillation or premature atrial complexes. Aberrant complexes usually have an RBBB pattern because of the longer refractory period of the right bundle branch cells.
- Aberrant beats are frequently confused with ventricular premature complexes (VPCs).
  - Look for P waves to differentiate the two.
  - An aberrantly conducted beat will have an associated P wave with a normal or slightly prolonged P-R interval.

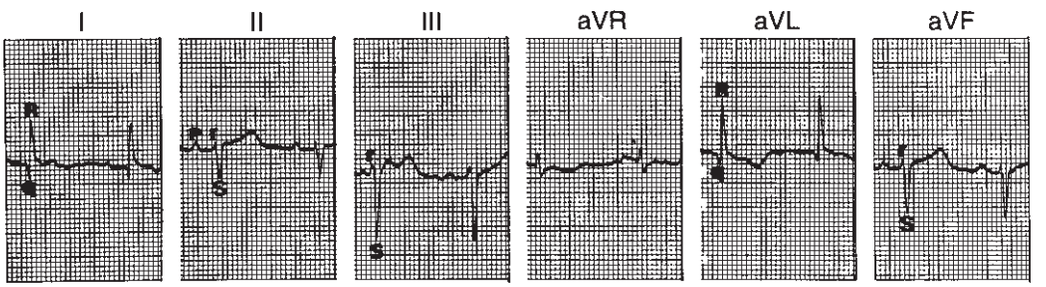

Figure 144-6. Left anterior fascicular block in a cat with hypertrophic cardiomyopathy. (From Tilley LP: Feline electrocardiography. Vet Clin North Am 7:257, 1977.)

Figure 144-7. Left anterior fascicular block and right bundle branch block in a cat with hypertrophic cardiomyopathy. (From Tilley LP: Essentials of Canine and Feline Electrocardiography, 3rd ed. Philadelphia: Lea & Febiger, 1992.)

- VPCs do not have associated P waves with consistent P-R intervals. Refer to Chapter 145 for further discussion.

Preexcitation

Anatomy

In some patients, additional electrical pathways are present that allow electrical impulses to bypass the AV node and go directly to the bundle of His or ventricular myocardium. Electrical impulses in these patients simultaneously go through the AV node. Traditionally these accessory pathways have been called by their eponyms, particularly the bundles of Kent (that allow direct AV conduction) and the James fibers (that bypass the AV node and connect to the bundle of His) (Fig. 144-8). Today these eponyms have been largely replaced by the more encompassing term *accessory pathway.*

Rights were not granted to include this figure in electronic media.
Please refer to the printed publication.

Figure 144-8. Anatomy of accessory pathways. (From Tilley LP: Essentials of Canine and Feline Electrocardiography, 3rd ed. Philadelphia: Lea & Febiger, 1992.)

Electrocardiogram Characteristics

Electrical conduction through these accessory pathways is faster than through the AV node, resulting in a shortened P-R interval. If impulses are conducted over the bundles of Kent, the QRS complexes will be of longer duration and preexcitation of the ventricle will be manifested as a delta wave at the beginning of the complex (Fig. 144-9). The *delta wave* indicates the direct depolarization of the ventricular myocardium via the bypass tract. If the preexcitation impulse is conducted by the James fibers, the P-R interval will be of short duration but the QRS complexes will be of normal duration with no delta waves. This finding is due to the impulses bypassing the AV node but still activating the ventricles through the bundle of His, the bundle branches, and the Purkinje system. P waves are normal, and a 1:1 relationship exists between P waves and QRS complexes. In most patients, no clinical signs are seen with this conduction disturbance. However, reentrant supraventricular tachycardia can develop in association with

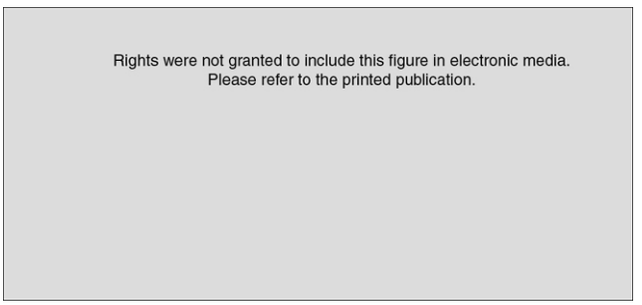

Figure 144-9. A dog with ventricular preexcitation and a history of syncope. The arrow points out the delta wave. (From Tilley LP: Essentials of Canine and Feline Electrocardiography, 3rd ed. Philadelphia: Lea & Febiger, 1992.)

preexcitation, and when associated with a "Kent" bundle is often termed the Wolff-Parkinson-White syndrome. These rhythms are discussed in Chapter 145.

Associated Conditions

Preexcitation is often noted as a congenital finding without other evidence of organic heart disease. Preexcitation may be seen in conjunction with other congenital cardiac diseases, such as atrial septal defect. In cats, preexcitation has been associated with hypertrophic cardiomyopathy.

Abnormalities of the QRS Complexes

Electrical Alternans (Fig. 143-10)

- Electrical alternans is a pattern of alternating configurations of the ECG complexes. The most common pattern is a variation in the height (taller to shorter) of the QRS complexes.
- Electrical alternans is classically associated with a large pericardial effusion that allows pendulous swinging of the heart. Electrical alternans is not present in all cases of pericardial effusion and is not considered a sensitive finding.
- An often-overlooked reason for electrical alternans is supraventricular tachycardias, often propagated through an accessory pathway. Atrial tachycardia or atrial flutter with a high rate of AV nodal conduction may also cause electrical alternans.
- Other reasons for this ECG finding are alternating bundle branch block and myocardial disease.
- Tachypnea (e.g., pleural effusion) can cause "pseudoalternans" when cardiac and respiratory rates are synchronized.

Small Complexes

Low-amplitude QRS complexes (R wave < 0.5 mV in lead II in dogs) may be a normal variant and may be associated with pericardial effusion, pleural effusion, pulmonary edema, hypothyroidism, obesity, pneumothorax, and hypoalbuminemia and with any cause of severe myocardial damage and loss of cardiac muscle mass. Axis deviation will also reduce the R wave amplitude in dogs, although larger voltages should be observed in the lead parallel to the axis shift. Some dogs with cardiomyopathy (e.g., boxers) demonstrate relatively low QRS voltages.

Increased Amplitude Complexes

High-amplitude complexes are generally defined in dogs as a Q wave > 0.5 mV or an R wave > 2.5 to 3.0 mV (using lead II). This finding may be a normal variant, especially in young, deep-chested dogs. Some breeds, such as the Doberman pinscher, may normally have deep Q waves. In most cases, high amplitude suggests cardiomegaly as described below.

Splintered, Notched, or Slurred QRS Complexes

Splintered or notched QRS complexes may be observed in conduction disorders and are best seen in leads I, II, and aVF. In some cases notching or splintering represents a nonspecific conduction disturbance related to old age or myocardial disease. There are some recognized associations. Tricuspid valve malformation may lead to splintered R waves, and some dogs with ventricular septal defects have wide, notched Q waves. When the R wave of a QRS complex ascends rapidly but the

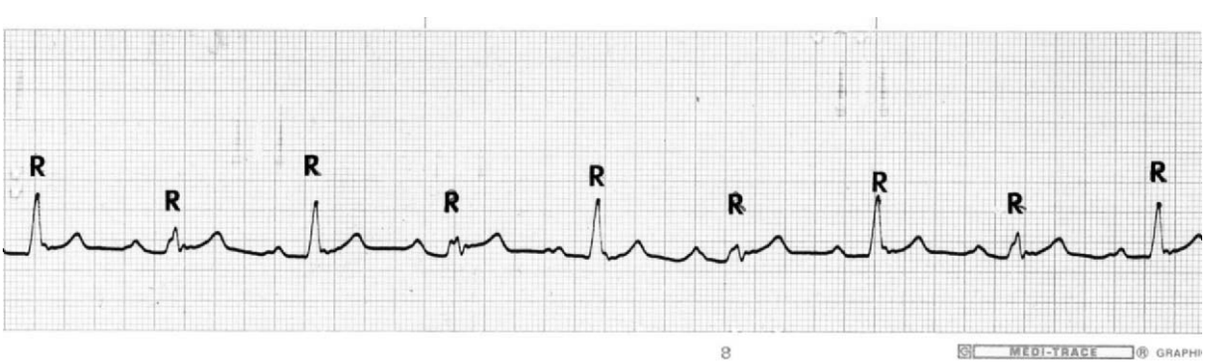

Figure 144-10. Electrical alternans in a dog with pericardial effusion.

descent is slower and slurred, the possibility of myocardial disease or conduction delay should be considered, particularly when the S-T segment is also abnormal (see below).

Abnormalities of the S-T Segment

The S-T segment and T waves represent periods of repolarization of the ventricles. In general, abnormalities can be primary disorders of repolarization (as with ischemia) or secondary changes caused by an abnormality of the QRS complex. The normal S-T segment should be approximately the same horizontal level as the baseline, considered the segment immediately in front of the P wave.

S-T Elevation

- S-T elevation (dog > 0.15 mV in lead II, III, or aVF or those leads with dominant R waves) is seen with myocardial hypoxia, pericarditis, some cases of pericardial effusion, and digitalis toxicity.
- Transmural myocardial ischemia causes S-T segment elevation in leads overlying the injured myocardium.

S-T Depression

- S-T depression (dog > 0.2 mV in lead II, III, or aVF or those leads with dominant R waves) is seen with myocardial hypoxia, hyperkalemia or hypokalemia, and digitalis toxicity.
- Subendocardial myocardial ischemia causes S-T segment depression in leads overlying the ischemic and infarcted myocardium.
- Pseudodepression of the S-T segment is common and is due to prominent T_a waves (atrial repolarization waves). Atrial enlargement, atrial disease, or sinus or atrial tachycardias can lead to prominent atrial repolarization waves, depressing the segment between the P wave and the QRS complex below the baseline and leading to S-T segment depression.

Other S-T Changes

- S-T segment changes can occur secondary to bundle branch blocks, myocardial hypertrophy, and VPCs. The changes in the S-T segment are in the opposite direction from the main QRS deflection. The S-T segment change in these conditions is often one of slurring or coving of the S wave into the T wave.
- Artifact related to baseline motion.
- Normal variant.

Abnormalities of the Q-T Interval

- Q-T interval changes are relatively nonspecific. The Q-T interval is inversely related to the heart rate, being shorter with more rapid heart rates. As a general rule, the Q-T interval should be less than half the preceding R-R interval.
- Q-T prolongation is associated with hypokalemia, hypocalcemia, hypothermia, quinidine administration, intraventricular conduction disturbance (associated with prolongation of the QRS complex), bradycardia, ethylene glycol toxicity, strenuous exercise, and central nervous system disturbance.
- Q-T interval narrowing is associated with hypercalcemia, hyperkalemia, and digitalis administration.

Abnormalities Involving the T Waves

- T wave changes are relatively nonspecific and often the consequence of an abnormal QRS complex. In general, the T wave in dogs should not be more than one-fourth the height of the associated R wave (Q or S wave, if either is larger than R) or more than 1.0 mV in any lead.
- In most leads, normal T waves may be positive, negative, or biphasic.
- Polarity is usually consistent on serial ECGs if heart rate is constant. T waves should be positive in CV_5RL in dogs older than 2 months of age and negative in V_{10}, except in the Chihuahua.
- *Large T waves* can be seen with myocardial hypoxia, intraventricular conduction disturbance, ventricular enlargement, and hypothermia and in animals with heart disease and bradycardia.
- *Large and sharply pointed (positive or negative) T waves* are associated with hyperkalemia.
- *Small biphasic T waves* can be seen with hypokalemia.
- *Nonspecific T wave changes* can be seen secondary to metabolic disturbances (hypoglycemia, anemia, shock, fever), drug toxicities (digitalis, quinidine, procainamide), and neurologic disease.
- *T wave alternans* (alternating positive and negative T waves) has been reported secondary to hypocalcemia, high levels of circulating catecholamines, and sudden increases in sympathetic tone and may be a risk factor for ventricular arrhythmias.

Electrolyte Disturbances

Electrocardiography is not very sensitive or specific in diagnosing systemic disturbances. However, it can be useful as a rapid screening test for certain electrolyte disturbances (particularly moderate to severe hyperkalemia).

Hyperkalemia

ECG changes vary with the degree of hyperkalemia.

- The earliest change is the development of sharply pointed (spiked) T waves (Fig. 144-11), followed by a reduction in the height of the P waves and a prolongation of the P-R interval.
- The QRS complexes then start to widen, and the P waves disappear (atrial standstill).

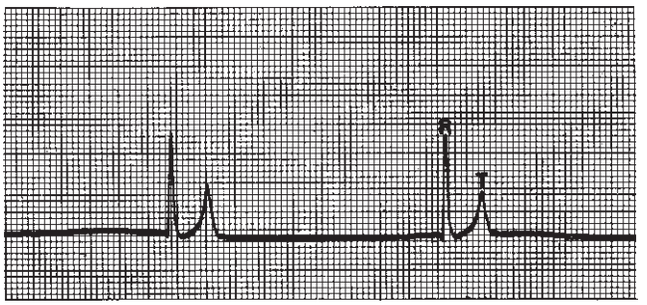

Figure 144-11. Atrial standstill and tall spiked T waves in a dog with severe hyperkalemia associated with Addison's disease.

- The QRS complexes become progressively wider and more bizarre in shape, and cardiac arrest or ventricular fibrillation follows.
- AV block and escape beats may also be seen with hyperkalemia.

Hypokalemia

- Q-T prolongation may develop, along with prominent U waves. A U wave is a repolarization deflection of the Purkinje fibers that occurs after the T wave; however, U waves are uncommon in dogs and cats.
- T waves may be small and notched.
- The S-T segment becomes progressively depressed.
- P-R prolongation and an increase in the height and width of the P and QRS complexes may be seen.

Hypercalcemia

- Q-T interval may be shortened.
- S-T segment shortening and depression have been reported.

Hypocalcemia

- Q-T prolongation develops.
- Duration of S-T segment correlates with the severity of hypocalcemia.
- T wave alternans has been reported.

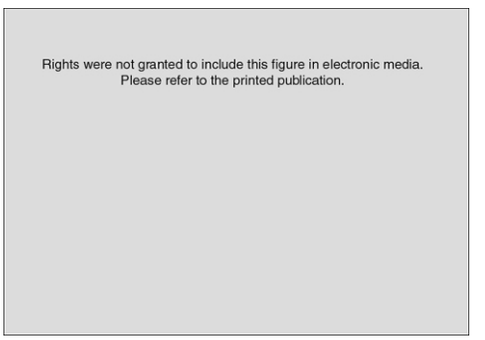

Figure 144-12. Wide and notched P waves in a dog with left atrial enlargement secondary to degenerative mitral valve disease. (From Tilley LP: Essentials of Canine and Feline Electrocardiography, 3rd ed. Philadelphia: Lea & Febiger, 1992.)

- Deep wide T waves, tachycardia, and tall R waves may be present.

Heart Enlargement Patterns

Left Atrial Enlargement

Left atrial enlargement is characterized by wider-than-normal P waves in lead II (Fig. 144-12).

- Dog and cat P waves are greater than 0.04 second (>0.05 second in giant-breed dogs).

Left Ventricular Enlargement

Left ventricular enlargement is characterized by one or more of the following (Fig. 144-13):

- Left axis orientation (dog < +40 degrees, cat < 0 degrees)
- S-T slurring or coving
- QRS duration > 0.06 second (dog) or 0.04 second (cat)
- Tall R waves
  - *Dog:* R greater than 3.0 mV in leads II, aVF, V_6LU (V_4), CV_6LL (V_2), and CV_5RL (rV_2). R greater than 1.5 mV in lead I. Sum of R wave amplitude in leads I and aVF greater than 4.0 mV.

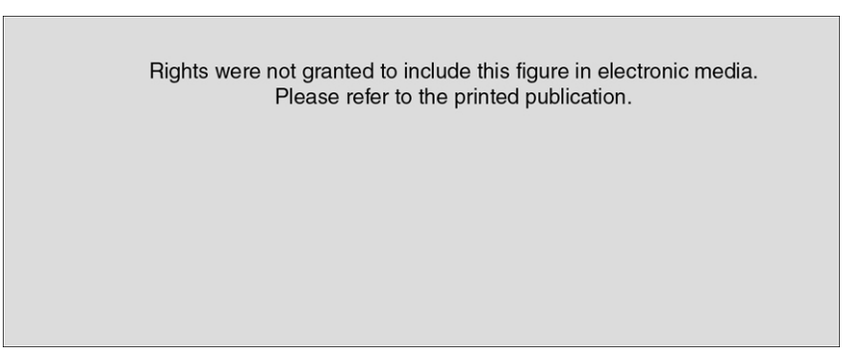

Figure 144-13. Tall and wide QRS complexes and S-T slurring *(arrow)* indicate left ventricular enlargement in this cat with hypertrophic cardiomyopathy. (From Tilley LP: Essentials of Canine and Feline Electrocardiography, 3rd ed. Philadelphia: Lea & Febiger, 1992.)

- *Cat:* R > 1.0 mV in CV_6LU (V_4). R > 0.9 mV in lead II or aVF. R wave or Q wave > 1.0 in V_{10}.

Right Atrial Enlargement

Right atrial enlargement is characterized by taller-than-normal P waves in lead II (Fig. 144-14).

- *Dog:* P > 0.4 mV (or prolonged P wave in some dogs).
- *Cat:* P > 0.2 mV (tall P waves may also indicate left atrial enlargement in cats).

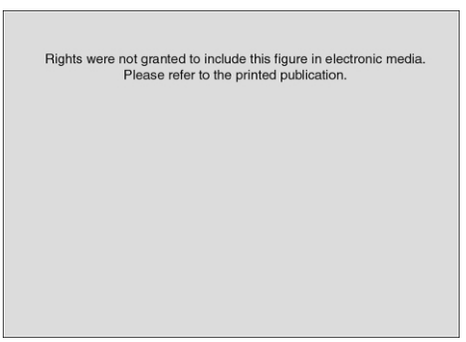

Figure 144-14. Tall P waves suggestive of right atrial enlargement. (From Tilley LP: Essentials of Canine and Feline Electrocardiography, 3rd ed. Philadelphia: Lea & Febiger, 1992.)

Right Ventricular Enlargement

Right ventricular enlargement is characterized by one or more of the following (Fig. 144-15):

- Right axis orientation (dog > +100 degrees; cat > +160 degrees)
- S wave in leads I, II, III, and aVF
- S wave in lead I greater than 0.05 mV (dog)
- Chest leads
  - *Dog:* S greater than 0.8 mV in CV_6LL (V_2). S greater than 0.7 mV in CV_6LU (V_4). R/S ratio less than 0.87. T positive (except for the Chihuahua) and W-shaped QRS complex in V_{10}.
  - *Cat:* Prominent S waves in CV_6LL (V_2) and CV_6LU (V_4); T positive in V_{10}.

SPECIAL DIAGNOSTIC PROCEDURES

Postexercise Electrocardiography

Patients with suspected cardiac disease or arrhythmia, based on auscultation or history of syncope or exercise intolerance, may have normal resting ECGs. Sometimes, an arrhythmia can be documented by repeating an ECG after vigorous exercise. T wave changes or S-T segment abnormalities may become apparent following exercise, suggesting underlying myocardial disease.

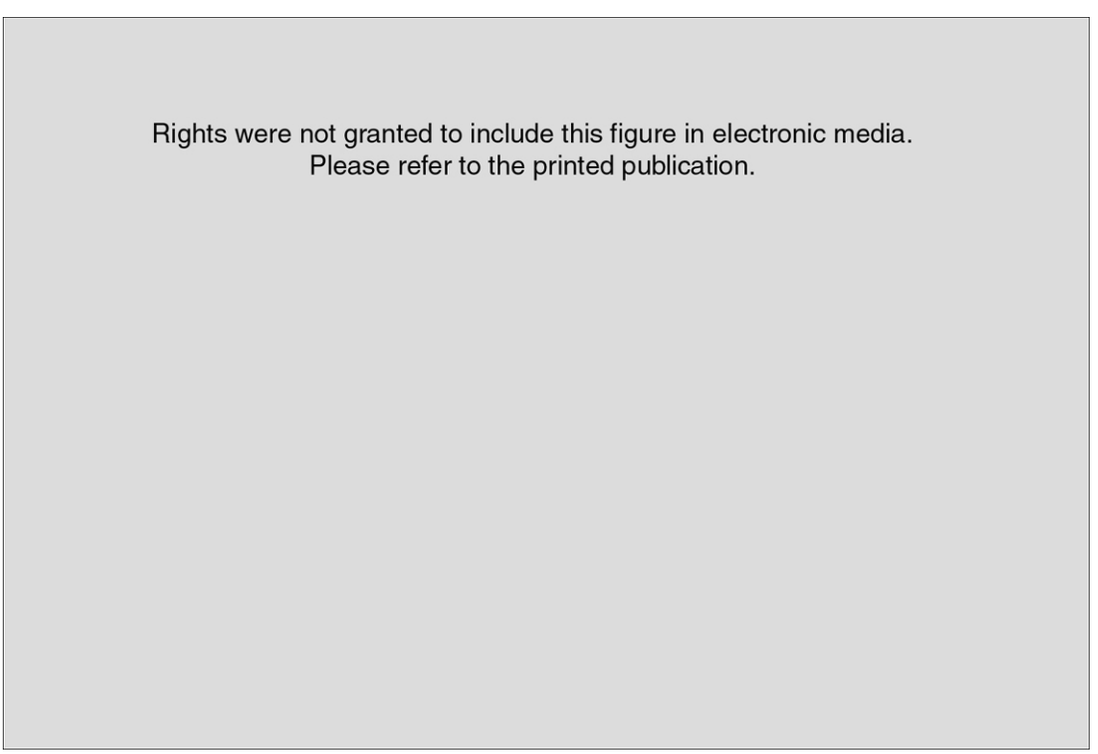

Figure 144-15. Marked right axis deviation in a dog with advanced heartworm disease and evidence of right-sided heart failure. (From Tilley LP: Essentials of Canine and Feline Electrocardiography, 3rd ed. Philadelphia: Lea & Febiger, 1992.)

Vagal Maneuvers

Indications

- Vagal maneuvers are sometimes useful in evaluating supraventricular tachycardias. A sudden surge of vagal tone may slow or block conduction down the AV node. This effect may terminate reentrant supraventricular tachycardia or "uncover" atrial flutter or tachycardia when there is regular AV conduction and atrial activity is buried within the ST-T.
- Vagal maneuvers may also help evaluate baroreceptor and sinus node functions.

Technique

- While running a lead II rhythm strip, vigorously massage the carotid sinuses that are located under the mandible in the jugular furrow.
- If this maneuver does not break the tachycardia, apply gentle, progressive ocular pressure.
- If still unsuccessful, apply ocular pressure and carotid sinus massage.

Interpretation

- If a supraventricular tachycardia breaks abruptly and the rhythm remains normal for at least a short time after stopping the vagal maneuver, the arrhythmia was probably reentrant atrial (supraventricular) tachycardia.
- If the rate gradually slows during the vagal maneuver and then speeds up again after the vagal maneuver, the rhythm is probably sinus tachycardia.
- If multiple P waves (>300/min) are observed, related to vagal-induced AV block, either atrial tachycardia or flutter is likely.
- If there is no change during the vagal maneuver, no conclusion can be made regarding the nature of the supraventricular tachycardia.
- Another area in which a vagal maneuver may be helpful is in trying to rule out bradyarrhythmia as a cause of syncope. If the vagal maneuver results in prolonged periods of sinus arrest or produces AV block, this supports sinus or AV nodal disease as a cause of syncope.

Holter Monitoring

Holter monitors provide a 24-hour ECG recording (Fig. 144-16). These recordings are ideal for identifying intermittent arrhythmias, determining the frequency and severity of arrhythmias, and monitoring the efficacy of antiarrhythmic drug therapy.

- Holter monitoring may be helpful in patients with syncope in which routine ECGs and laboratory evaluation do not confirm a diagnosis. If arrhythmias are identified on Holter monitoring of a patient with a history of syncope, the cause of the collapsing episodes may be discovered, although an event monitor is more specific in this situation (see below).

▼ ***Key Point*** The veterinarian cannot be certain that an arrhythmia identified on a Holter recording of an animal with syncope is the cause of the animal's problem, unless the animal has a syncopal episode or related clinical signs at the same time the arrhythmia is recorded.

- Holter monitoring is also used as a screening tool for the diagnosis of arrhythmogenic right ventricular cardiomyopathy (boxer cardiomyopathy) in boxers and occult cardiomyopathy in Doberman pinschers.
  - While in most breeds normal animals will have fewer than 25 VPCs in 24 hours, the threshold for normal may be higher in boxers The presence of greater than 100 VPCs, couplets, or runs is highly suggestive of arrhythmogenic right ventricular cardiomyopathy in boxers.
  - In Doberman pinchers, the presence of VPCs is a risk factor for development of dilated cardiomyopathy. In one study of Doberman pinschers with normal echocardiograms, all animals with greater than 50 VPCs per 24 hours, 94% with greater than 10 VPCs per 24 hours, and 94% with couplets or triplets of VPCs developed echocardiographic evidence of dilated cardiomyopathy within 1 year. However, not all Dobermans pinschers with VPCs develop cardiomyopathy and the absence of VPCs on a 24-hour Holter study does not rule out the subsequent development of dilated cardiomyopathy.
- When using Holter monitoring of antiarrhythmic therapy, a greater than 85% reduction in the frequency of VPCs in an indication of effective arrhythmia suppression.
- Holter monitoring is offered by some veterinary cardiologists and transtelephonic ECG services, and it sometimes can be arranged through a local medical cardiologist. Holter recordings should be reviewed by a veterinary cardiologist, as technicians trained to read human Holter studies often overinterpret atrial premature complexes on canine ECGs.

Event Recorders

Event or loop recorders are the best diagnostic tool for identifying arrhythmias as the cause of syncope. These are small digital ECG recorders that can easily be worn by even small dogs and cats.

- These units record a continuous 5-minute loop of an ECG. After the veterinarian attaches the system, the animal is sent home. When the animal has an event (e.g., syncope, collapse, or seizure) the owner pushes a button to activate the memory feature, which preserves the ECG in memory for a preprogrammed

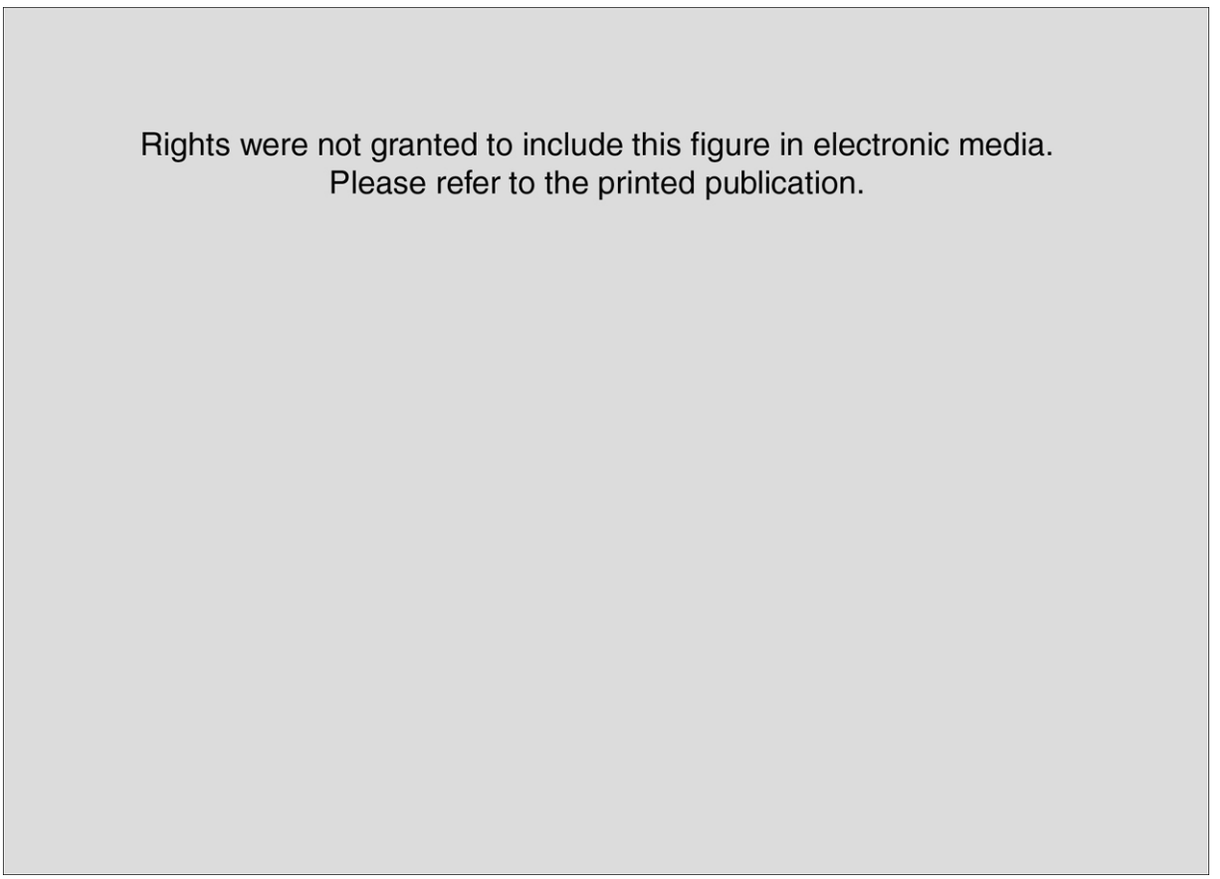

Figure 144-16. Printouts of three displayed time segments from a 24-hour electrocardiographic recording (Holter monitoring). The period of ventricular tachycardia can be easily recognized and correlated with the times of occurrence by referring to the digital time entries displayed adjacent to the electrocardiographic data. Detected ventricular ectopic activity can be efficiently enlarged, especially on the 15-second time segment (bottom frame) for more complete analysis and documentation. (From Tilley LP: Essentials of Canine and Feline Electrocardiography, 3rd ed. Philadelphia: Lea & Febiger, 1992.)

time before, during, and following the event. After the recording is made, it can be transmitted transtelephonically for printing and interpretation of the ECG.

- In animals with frequent syncopal episodes, an event monitor is preferable to a Holter monitor for making a diagnosis because the event recording is timed with the clinical signs. In a study of 60 collapsing animals, 51 tracings (85%) were diagnostic, ruling out arrhythmias in 65% and confirming arrhythmias in 35%.

Lidocaine Response Test

Patients with sustained, wide, complex tachycardia (ventricular tachycardia or atrial tachycardia with a bundle branch block) may be administered lidocaine (2–4 mg/kg IV) to help establish a diagnosis. Termination of the arrhythmia suggests the disturbance is a lidocaine-responsive, ventricular tachycardia. Occasionally, an atrial tachycardia will break following the administration of lidocaine.

Atropine Response Test

Patients with symptomatic bradyarrhythmia may be administered a test dose of atropine (0.05 mg/kg IM or SC) and undergo an ECG 30 minutes later. This test is helpful in determining the role of vagal tone in the bradyarrhythmia and whether or not oral anticholinergic drugs (e.g., hyoscyamine) might alleviate some symptoms associated with the bradycardia, particularly when pacing is not an option.

Chapter

145 Disorders of Cardiac Rhythm

Michael S. Miller / Larry Patrick Tilley / Francis W.K. Smith, Jr.

Cardiac arrhythmias include disorders of cardiac impulse formation, conduction, rate, and regularity. Terms such as dysrhythmia, ectopia, and ectopy also are used to identify arrhythmias. Cardiac arrhythmias can be benign and clinically insignificant, or they can cause clinical signs. They can even progress to malignant arrhythmias that lead to heart failure, syncope, or sudden death.

Causes of cardiac arrhythmias include heart disease and disorders involving the autonomic nervous system, endocrine system, electrolytes, and other body systems. Anesthetic agents and other drugs can precipitate rhythm disturbances. Cardiac arrhythmias are diagnosed and classified electrocardiographically; see Chapter 144 for additional pertinent information regarding electrocardiography. A summary of the clinical pharmacology of drugs used in the treatment of congestive heart failure (CHF) is found in Chapter 146.

ETIOLOGY

- Cardiac arrhythmias are classified in Table 145-1. They occur with congenital or acquired cardiac disease or systemic disorders (Table 145-2).
- Cardiac pathology does not necessarily correlate with the type and severity of arrhythmias.
- Arrhythmia variation in animals with cardiac or systemic disorders may be explained by the complex interactions among cardiac cell transmembrane potentials, the autonomic nervous system, and body fluids.

MECHANISMS

- The normal cardiac impulse is generated automatically in the sinus node and is spread through the atria rapidly and sequentially via the His bundle, the bundle branches, and the intraventricular conduction system to the ventricular myocardium.
- The normal atrioventricular (AV) node serves as a bridge between the atria and the ventricles and slows the cardiac impulse prior to rapid impulse conduction through the ventricles.
- Cardiac rhythm disturbances develop from diverse electrophysiologic mechanisms.
- Enhanced automaticity in sinus node or subsidiary pacemaker cells can generate tachycardias or ectopic rhythms. Such activity may be influenced by sympathetic activity.
- Triggered activities are common causes of ectopic rhythms and tachycardias. Early or late afterdepolarizations follow a previously driven (sinus) depolarization. The premature impulses occur when the cell spontaneously depolarizes during or just after repolarization.
- Reentry, a common arrhythmia mechanism, typically is caused by functional dissociation of cardiac tissue, a unidirectional block in one pathway, and slowed conduction in the other pathway. The impulse then returns to the origination point by retrograde conduction through the unidirectionally blocked pathway.
- Electrophysiologic mechanisms, arrhythmia manifestations and accompanying clinical signs and symptoms may vary widely among dogs with specific inherited cardiac diseases. Arrhythmogenic mechanisms can be modified (for better or for worse) by autonomic activity, heart rate, and many cardiac and non-cardiac drugs.

DIAGNOSTIC APPROACH

Systematic Evaluation of the Electrocardiographic Strip

See also Chapter 144.

- Is sinus rhythm or an arrhythmia present?
- Is the heart rate rapid, slow, or normal?
- Are P waves present?
  - *Yes.* Do the P (atria) waves occur at regular or irregular intervals? What are the height, width, and direction?
  - *No.* What reason or abnormality explains the absence of the P wave? Is the P wave superimposed

Table 145-1. CLASSIFICATION OF CARDIAC ARRHYTHMIAS

Supraventricular Rhythms
Sinus rhythm
Sinus arrhythmia
Sinus bradycardia
Sinus tachycardia
Atrial premature complexes
Sinus block and/or arrest
Atrial tachycardia
Atrial/supraventricular tachycardia (reentrant)
Atrial flutter
Atrial fibrillation
Atrioventricular junctional rhythm

Ventricular Rhythms
Ventricular escape (rhythm)
Ventricular premature complexes
Idioventricular tachycardia
Ventricular tachycardia
Ventricular asystole
Ventricular fibrillation

Conduction Disorders
Atrial standstill
First-degree AV block
Second-degree AV block
Complete (third-degree) AV block

Arrhythmias and Conduction Disturbances
Sick sinus syndrome
Ventricular preexcitation and the Wolff-Parkinson-White syndrome

on a portion of the QRS complex, S-T segment, or T wave? Is the arrhythmia atrial standstill, atrial fibrillation, atrial flutter, AV junctional escape rhythm, or atrial tachycardia?
- Do the QRS (ventricular) complexes occur with regularity and uniformity? What is their morphology? If wide and bizarre, is this due to a ventricular arrhythmia or caused by a premature atrial impulse that is aberrantly conducted, or is bundle branch block evident?
- What is the relationship between the P waves and the QRS complexes? Is the relationship consistent?
- If AV dissociation is present, from where does the QRS complex evolve? Are AV junctional and/or Purkinje or idioventricular foci involved?

Questions To Be Answered in the Interpretation of Cardiac Arrhythmia

- What is the possible mechanism for the arrhythmia?
- Is it sinus, atrial, AV junctional, or ventricular in origin?
- Is there a conduction abnormality?
- What is the severity and frequency of the arrhythmia?

SUPRAVENTRICULAR RHYTHMS

Sinus Rhythm

Definition

- Impulses originate in the sinus node.
- The rhythm is regular with less than a 10% variation in the R-R interval.
- There is a normal P wave for each QRS complex, with a constant P-R interval.
- The heart rate is between 60 and 180 beats per minute (bpm) in dogs and between 120 and 240 bpm in cats.

Etiology and Clinical Significance

- Sinus rhythm is a normal resting rhythm in dogs and cats and requires no therapy.
- Animals with symptomatic cardiac disease or noncardiac disease may show a sinus rhythm.

Sinus Arrhythmia

Definition

- Impulses originate in the sinus node.
- The rhythm is irregular with more than a 10% variation in the R-R interval.
- There is a normal P wave for each QRS complex, with a constant P-R interval.
- A wandering pacemaker (a change in the morphology of the P wave due to a change in pacemaker location or conduction) is often present.
- Heart rates are similar to those for sinus rhythm.

Etiology and Clinical Significance

- Sinus arrhythmia is a normal rhythm variation in the resting dog, often correlated with varying levels of sinus node vagal tone, which changes with respiration (decreased vagal tone and increased heart rate during inspiration).
- Sinus arrhythmia is unusual in cats.
- Pronounced sinus arrhythmia occurs in the normal resting dog and in dogs and cats with respiratory disease.

Treatment

- No treatment is required unless there is symptomatic bradycardia, in which case anticholinergics or sympathomimetics may be helpful.

Sinus Bradycardia

Definition

- Impulses originate in the sinus node but at a slower-than-normal frequency.

Table 145-2. CAUSES OF CARDIAC ARRHYTHMIAS

Cardiac Causes in Dogs

- Heredity (genetics not documented in all cases)
  - Doberman (His bundle degeneration)
  - English springer spaniel (persistent atrial standstill)
  - Miniature schnauzer, dachshund, cocker spaniel, West Highland white terrier (sick sinus syndrome)
  - Pug, Dalmatian (sinus node disease)
  - Pug (stenosis and degeneration of the His bundle)
  - Wolff-Parkinson-White syndrome
  - Golden retriever (Duchenne muscular dystrophy)
  - German shepherd (ventricular tachyarrhythmia)
- Atrial and/or ventricular arrhythmias
  - Atrial enlargement, secondary to congenital defects or acquired disease
  - Cardiomyopathy
  - Congenital heart disease
  - Congestive heart failure
  - Mitral valve disease (congenital and acquired)
  - Myocarditis, endocarditis
  - Myocardial ischemia
  - Trauma
  - Drugs
- Conduction system disease
  - Acquired sinus and AV node disease (sick sinus syndrome)
  - Cardiomyopathy
  - Neoplasia
  - Surgical damage to conduction tissue
  - Trauma
  - Vascular (e.g., microscopic intramural myocardial infarction)
  - Ventricular septal defect and other congenital defects
  - Infection (Lyme disease)
  - Drugs
  - Degeneration

Cardiac Causes in Cats

- Heredity (rare)
  - Wolff-Parkinson-White syndrome
- Atrial and ventricular arrhythmias
  - Cardiac enlargement secondary to congenital heart defects
  - Cardiomyopathy
  - Neoplasia
  - Trauma
  - Systemic diseases
- Conduction system disease
  - Cardiomyopathy
  - Neoplasia
  - Idiopathic fibrosis in older cats

Noncardiac Causes in Dogs and Cats

Dogs and Cats

- Acidosis or alkalosis
- Autonomic nervous system imbalance (parasympathetic or sympathetic); central nervous system (pain, excitement, fear); respiratory, gastrointestinal, organic brain disease
- Drug toxicity (e.g., digitalis, preoperative sedatives, anesthetic agents, catecholamines, antiarrhythmic agents, bronchodilators)
- Electrolyte disorders (hyperkalemia, hypercalcemia, hypokalemia, hypocalcemia, hypomagnesemia)
- Endocrinopathies (hypothyroidism, hyperthyroidism, Addison's disease, pheochromocytoma)
- Hypothermia
- Hypovolemia
- Hypoxia, anemia
- Mechanical stimulation (cardiac catheterization, intravenous catheter)
- Neoplasia
- Shock
- Toxemia, sepsis
- Trauma

Adapted from Miller MS, Tilley LP: Treatment of arrhythmias and conduction disturbances. *In* Miller MS, Tilley LP, eds.: Manual of Canine and Feline Cardiology. Philadelphia: WB Saunders, 1995, with permission.

- The rhythm is regular.
- There is a normal P wave for each QRS complex, with a constant P-R interval.
- The heart rate is <70 bpm in dogs (<60 bpm in giant breeds) and <120 bpm in cats.

Etiology and Clinical Significance

- Sinus bradycardia may be a normal physiologic rhythm variation resulting from high levels of resting vagal tone.
- Hypothyroidism, sinus node disease (sick sinus syndrome), elevated cerebrospinal fluid pressure, and hypothermia are among the pathologic causes of sinus bradycardia.
- Drugs that can cause a sinus bradycardia include acepromazine, xylazine, other alpha$_2$-agonists (e.g., medetomidine), narcotics, digoxin, beta-blockers, diltiazem, pilocarpine, and general anesthetics.
- Animals with sinus bradycardia are often asymptomatic.
- Clinical signs of weakness, lethargy, and syncope may accompany sinus bradycardia.

Treatment

- Asymptomatic dogs or cats require no specific therapy.
- When correlated with signs of weakness or syncope, an atropine response test should be performed (0.04 mg/kg IM) followed by an electrocardiogram (ECG) in 15 to 30 minutes.
- If there is an increase in the cardiac rate following atropine administration, the animal may benefit from oral anticholinergic agents (Table 145-3).
- A poor clinical response to atropine suggests the need for a temporary or permanent cardiac pacemaker in symptomatic animals.

Figure 145-1. Sinus block and/or arrest with a ventricular escape beat in a dog. (Lead II rhythm strip, paper speed 50 mm/sec; 1 cm = 1 mV.)

- CHF may also develop, in which case consider diuretics and vasodilators as adjunctive treatment. Digitalis may exacerbate the sinus bradycardia in these cases. Hypotension may develop from vasodilator therapy.

Sinus Block and/or Sinus Arrest (Fig. 145-1)

Definition

- A primary disorder of the sinus node resulting in lack of generation of the cardiac impulse or its poor propagation across surrounding tissue.
- It is not possible to distinguish between sinus block and sinus arrest in dogs because of the normal variation in the R-R interval (sinus arrhythmia).
- The heart rate is variable and is often correlated with a bradycardia or slow sinus arrhythmia.
- The rhythm is regularly irregular or irregular with pauses.
- There is a normal P wave for each QRS complex with a pause equal to or greater than 2 times the normal R-R interval.
- The P wave may vary in shape if a concurrent wandering pacemaker is present.

Etiology and Clinical Significance

- Sinus arrest may be consistent with an increase in vagal tone (e.g., ocular pressure, irritation of the vagus nerve, brachycephalic breeds, or respiratory disease).
- Diseases of the atria (including fibrosis, cardiomyopathy, and neoplasia) and drug toxicity (e.g., digitalis, propranolol, quinidine, xylazine, and acepromazine) may result in sinus arrest.
- Sinus arrest is one of the arrhythmias of the sick sinus syndrome.

Electrocardiographic Differentials

- Sinus block and/or sinus arrest can be confused with marked sinus arrhythmia or with sinus bradycardia and non-conducted atrial premature complexes (APCs).

Treatment

- Treat the same as sinus bradycardia.

Sinus Tachycardia

Definition

- Impulses originate in the sinus node but at a faster-than-normal frequency.
- The rhythm is regular.
- There are normal P waves for each QRS complex.
- The heart rate is >140 bpm in the giant breeds, >180 bpm in toy-breed dogs, and >240 bpm in cats.

Etiology and Clinical Significance

- Sinus tachycardia may be a normal physiologic rhythm resulting from high sympathetic tone occurring with exercise or excitement.
- Sinus tachycardia may also occur with conditions such as stress, anxiety, pain, shock, fever, anemia, CHF, hyperthyroidism, and pheochromocytoma.
- Drugs (e.g., atropine, sympathomimetic agents, theophylline, ketamine, and light anesthesia) and intoxicants (caffeine, chocolate, cocaine) also can cause sinus tachycardia.

Electrocardiographic Differentials

- Other supraventricular tachyarrhythmias confused with sinus tachycardia include paroxysmal (atrial or AV junctional) tachycardia, atrial flutter with 2:1 AV block, and ventricular tachycardia when sinus tachycardia is associated with wide QRS complexes.
- A vagal maneuver (e.g., carotid sinus or ocular stimulation for 5 to 10 seconds) may result in a transient, gradual slowing of the sinus tachycardia.

Treatment

- Identify and treat the underlying cause of the sinus tachycardia.

Table 145-3. COMMON ANTIARRHYTHMIC DRUGS: FORMULATIONS, INDICATIONS, AND DOSAGES

Drug Trade Name	Formulation	Indications	Dosages	Comments
Amiodarone (Cordarone)	Tab: 200 mg	Class III antiarrhythmic agent; indicated for severe refractory atrial and ventricular arrhythmias	Dog: 10–20 mg/kg PO q12h Cat: None	Use as last resort for recurrent hemodynamically unstable ventricular tachycardia Takes weeks to achieve therapeutic levels
Atenolol (Tenormin)	Tab: 25, 50, 100 mg OS: 25 mg/ml Inj: 0.5 mg/ml	Atrial and ventricular arrhythmias, hypertrophic cardiomyopathy, hypertension, aortic stenosis	Dog: 0.25–1.0 mg/kg PO sid–bid Cat: 6.25–12.5 mg total dose PO sid–bid	Less bronchoconstriction, vasoconstriction, interference with insulin therapy than with non-selective beta-blockers Taper dose when discontinuing therapy Decrease dose with renal disease
Atropine sulfate*	Inj: 0.05, 0.1, 0.3, 0.4, 0.5, 0.8, 1.0 mg/ml	Sinus bradycardia, AV block, sick sinus syndrome, cardiac arrest	Dog: 0.01–0.04 mg/kg IV, IM, IO 0.02–0.04 mg/kg SC tid–qid (IT: double dose) Cat: Same	May transiently worsen bradyarrhythmia More potent chronotropic effects than glycopyrrolate
Digoxin* (Lanoxin)	Tab: 0.125, 0.25, 0.5 mg Inj: 0.25 mg/ml Elixir: 0.05 mg/ml Cap: 0.05, 0.1, 0.2 mg	Supraventricular arrhythmias, myocardial failure	Dog: *Maintenance dose*—0.22 mg/m^2 PO bid, 0.0055–0.01 mg/kg PO bid *IV loading dose*—0.0025 mg/kg IV bolus repeated hourly 3–4 times (total up to 0.01 mg/kg). Begin oral therapy 12 hours later *Oral loading dose*—Twice maintenance dose for first 24–48 hours Cat: 0.01 mg/kg PO qod (Tab preferred) 0.007 mg/kg PO qod (with furosemide and aspirin)	Toxicity potentiated by hypokalemia, hyponatremia, hypercalcemia, thyroid disorders, hypoxia Dose on lean body weight; reduce dose 10%–15% with elixirs Therapeutic range 1–2 ng/ml 8 hours after a dose Rapid digitalization not recommended except in emergency Reduce dose 50% with quinidine
Diltiazem (Cardizem, Dilacor)	Tab: 30, 60, 90, 120 mg Inj: 5 mg/ml Cardizem: 120, 180, 300 mg Dilacor: 120, 180, 240 mg	Supraventricular arrhythmias, hypertrophic cardiomyopathy, hypertension	Dog: 0.5–2.0 mg/kg PO tid (consider higher dose of 5 mg/kg based on recent studies) 0.1–0.2 mg/kg IV bolus, then 2–6 µg/kg/min IV CRI *Dilacor*—1.5–6 mg/kg PO sid Cat: 1.0–2.5 mg/kg PO tid 0.1–0.2 mg/kg IV bolus, then 2–6 µg/kg/min IV CRI *Dilacor*—30–60 mg PO sid	Less myocardial depression than verapamil Dilacor capsules contain 60-mg tablets used for dosing cats
Epinephrine* (Adrenalin)	Inj: 1:1000 conc (1 mg/ml) 1:10000 conc (0.1 mg/ml)	Cardiac arrest	Dog: 0.2 mg/kg IV, IO q3–5min Double dose for IT administration Cat: Same	Monitor with ECG Previously recommended dose of 0.02 mg/kg may be safer starting dose if defibrillator is not available
Esmolol (Brevibloc)	Inj: 10, 250 mg/ml	Supraventricular tachyarrhythmias, ventricular tachycardia, dynamic outflow tract obstruction	Dog: 50–500 (usually 50–100) µg/kg IV bolus every 5 minutes (up to 500 µg/kg) 50–200 µg/kg/min CRI Cat: Same	Ultra–short-acting beta$_1$-selective beta-adrenergic blocker
Glycopyrrolate* (Robinul)	Inj: 0.2 mg/ml	Sinus bradycardia, AV block, sick sinus syndrome	Dog: 0.005–0.01 mg/kg IV, IM 0.01–0.02 mg/kg SC Cat: Same	Longer duration of action with less of a chronotropic effect than atropine
Isoproterenol (Isuprel)	Inj: 1:5000 (0.2 mg/ml)	Short-term management of sinus bradycardia, AV block, sick sinus syndrome	Dog: 0.04–0.09 µg/kg/min IV (titrate up to effect) 10 µg/kg/min IM, SC qid Cat: Same	
Lidocaine* (Xylocaine)	Inj: 5, 10, 15, 20 mg/ml (without epinephrine)	Ventricular arrhythmias	Dog: 2–8 mg/kg slowly IV or IO (double the dose IT) in 2-mg/kg boluses followed by IV drip at a dosage of 25–75 (occasionally up to 100) µg/kg/min CRI Cat: 0.25–0.75 mg/kg IV over 5 min	Use with caution in cats Drug of choice for initial control of ventricular tachycardia Effects increased by high potassium and decreased by low potassium Seizures controlled with diazepam

Metoprolol (Lopressor)	Tab: 50, 100 mg/kg Inj: 1 mg/ml	Atrial and ventricular arrhythmias cardiomyopathy	Dog: 0.25–1.0 mg/kg PO tid Cat: Same	Less bronchoconstriction, vasoconstriction, interference with insulin therapy than with non-selective beta-blockers Taper dose when discontinuing therapy
Mexiletine (Mexitil)	Cap: 150, 200, 250 mg	Ventricular arrhythmias	Dog: 5–8 mg/kg PO bid–tid Cat: None	Reduce dose with liver disease Take with food to reduce GI side effects Synergistic effect when combined with beta-blockers
Procainamide* (Procan SR, Pronestyl SR, Procainamide CR)	Cap: 250, 375, 500 mg Tab: 250, 375, 500 mg Tab Procan, Pronestyl SR; 250, 500, 750, 1000 mg Inj: 100, 500 mg/ml	Ventricular and supraventricular arrhythmias, WPW syndrome	Dog: 10–30 mg/kg IM PO qid (Procan SR, Pronestyl SR, Procainamide CR; tid) 2 mg/kg IV over 3–5 min up to total dose of 20 mg/kg 20–50 µg/kg/min CRI Cat: 3–8 mg/kg PO, IM tid–qid	Beware of hypotension with IV administration Effects increased by high potassium and decreased by low potassium Monitor ECG: 25% prolongation of QRS is sign of toxicity Fewer GI and CV side effects than quinidine Use with caution in cats Reduce dose with severe renal and liver disease
Propranolol* (Inderal)	Tab: 10, 20, 40, 60, 80, 90 mg Inj: 1 mg/ml OS: 4, 8, 80 mg/ml	Atrial and ventricular arrhythmias, hypertrophic cardiomyopathy, hypertension, thyrotoxicosis	Dog: 0.2–1.0 mg/kg PO tid 0.02–0.06 mg/kg IV over 5–10 minutes C < 4.5 kg: 2.5–5 mg PO bid–tid C > 4.5 kg: 5 mg PO tid–tid 0.02–0.06 mg/kg IV over 5–10 minutes	Non-selective beta-blocker Start with low dose and titrate to effect Taper dose when discontinuing therapy Reduce dose with liver disease
Quinidine gluconate* (Quinaglute Dura-Tabs)	Tab: 324 mg Inj: 80 mg/ml	Ventricular and supraventricular arrhythmias, WPW syndrome, conversion of atrial fibrillation	D:† 6–20 mg/kg PO, IM qid 6–20 mg/kg PO tid with sustained release products 5–10 mg/kg IV (very slowly) Cat: None	Decrease digoxin dose 50% when using quinidine Effects increased by high potassium and decreased by low potassium Monitor ECG: 25% prolongation of QRS is sign of toxicity Has vagolytic, negative inotropic, vasodilating properties Reduce dose in CHF, hepatic disease, hypoalbuminemia Quinidine base (%) in each quinidine salt Quinidine gluconate (62%): 324-mg Tab = 200 mg of quinidine
Quinidine polygalacturonate (Cardioquin)	Tab: 275 mg			
Quinidine sulfate* (Quinidex)	Tab: 200, 300 mg Tab SR: 300 mg Inj: 200 mg/ml			
Sotalol (Betapace)*	Tab: 80, 120, 160, 240 mg	Ventricular arrhythmias	Dog: 1–3.5 mg/kg PO bid Cat: 1/8 of 80-mg Tab PO bid	Antiarrhythmic agent with class II (beta-blocking) and class III effects May be proarrhythmic when administered as sole agent in young German shepherds with inherited ventricular arrhythmias
Tocainide (Tonocard)	Tab: 400, 600 mg	Ventricular arrhythmias	Dog: 10–20 mg/kg PO bid–tid Cat: None	Oral analogue of lidocaine Giving with food may decrease GI upset
Verapamil* (Calan, Isoptin)	Tab: 40, 80, 120 mg Inj: 2.5 mg/ml	Supraventricular arrhythmias, hypertrophic cardiomyopathy	Dog: 0.05–0.20 mg/kg slow IV (1–2 minutes) in boluses of 0.05 mg/kg given at 10- to 30-minute intervals (to effect) Cat: None	Diltiazem is safer alternative in heart failure Potent vasodilator and negative inotrope

*Available in a generic preparation.

†Note: Dosage calculated for quinidine base equivalent, which varies with each quinidine salt. See Comment column.

AV, atrioventricular; Cap, capsules; CHF, congestive heart failure; conc, concentration; CRI, constant rate infusion; ECG, electrocardiogram; GI, gastrointestinal; Inj, injectable; IT, intratracheal; OS, oral solution; Tab, tablets; WPW, Wolff-Parkinson-White.

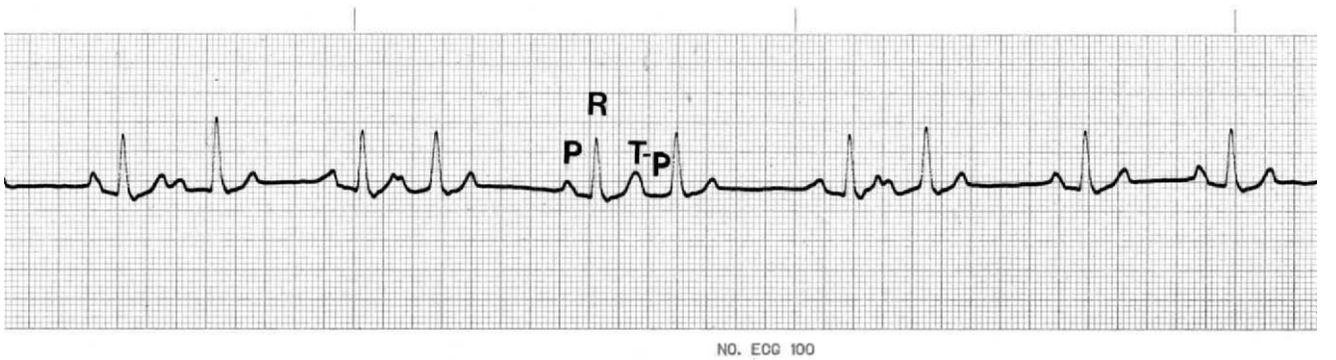

Figure 145-2. Atrial premature complexes in a dog. (Lead II rhythm strip, paper speed 50 mm/sec; 1 cm = 1 mV.)

- Antiarrhythmic drugs are seldom required.
- Administer atenolol (6.25 mg total dose q12–24h PO) or propranolol (2.5 mg total dose q8–12h PO) to hyperthyroid cats with intractable tachycardia (i.e., unresponsive to antithyroid medication).
- Administer digitalis for sinus tachycardia in CHF. Digoxin will reestablish normal baroreceptor function and lessen sympathetic tone.

Atrial Premature Complexes (Fig. 145-2)

Definition

- Impulses originate from an atrial focus, often other than the sinus node.
- The rhythm is irregular and the heart rate varies with the sinus node rate.
- There is usually an abnormal P' wave (premature P wave) followed by a normal QRS complex. The P'-R interval of the APC may vary from the sinus rhythm P-R interval. The P' wave may have various morphologies and may be fused with the T wave of the preceding beat.
- The P′ wave may occur so early in the cardiac cycle that the AV conduction system will be refractory and the impulse will not be conducted to the ventricles (e.g., APC with physiologic AV block).
- The pause following the APC is often less than fully compensatory because of premature depolarization and resetting of the sinus node. Full compensatory pause occurs when the R wave-to-R wave interval surrounding the APC is equal to two normal R-R intervals.
- The QRS complex is usually normal, but the intraventricular conduction system may be, in a relative or absolute refractory period, causing a bizarre (abnormal shape or direction) QRS complex. This abnormality is termed an APC with aberrant ventricular conduction.

Etiology and Clinical Significance

- APCs often indicate underlying cardiac disease (e.g., chronic valvular fibrosis, cardiomyopathy, congenital defect, or cor pulmonale) resulting in atrial enlargement.
- Other causes include electrolyte disturbances, thyrotoxicosis, hypoxia, anemia, drug toxicity (e.g., digitalis, dobutamine, or dopamine), toxemia, and increased sympathetic tone.

Electrocardiographic Differentials

- Sinus rhythm with APCs may be confused with marked sinus arrhythmia and ventricular premature complexes during auscultation, and with ventricular premature complexes on the ECG, when APCs are conducted with aberrant ventricular conduction.
- A P′ wave preceding the abnormal QRS complex and a similarity of the initial deflection of the QRS complex compared with a preceding normal beat supports the diagnosis of aberrant conduction.

Treatment

- Infrequent APCs may be a normal variation and do not require treatment.
- If this arrhythmia is associated with CHF, treat the arrhythmia with digoxin.
- If the APCs are associated with poor hemodynamic status without myocardial failure, prescribe digoxin, diltiazem, or a beta-blocker (e.g., propranolol or atenolol) (see Table 145-3).

Atrial Tachycardia (Figs. 145-3 and 145-4)

Definition

- Atrial tachycardia indicates rapid, abnormal impulses originating from an atrial site other than the sinus node.
- The atrium and/or AV junctional areas may be involved in a reentrant circuit that allows the impulse to restimulate the atrium, as well as to pass to the ventricles. (A vagal maneuver may abolish this arrhythmia.)
- An abnormal automatic focus in the atrium may also be responsible for this arrhythmia. (A vagal maneu-

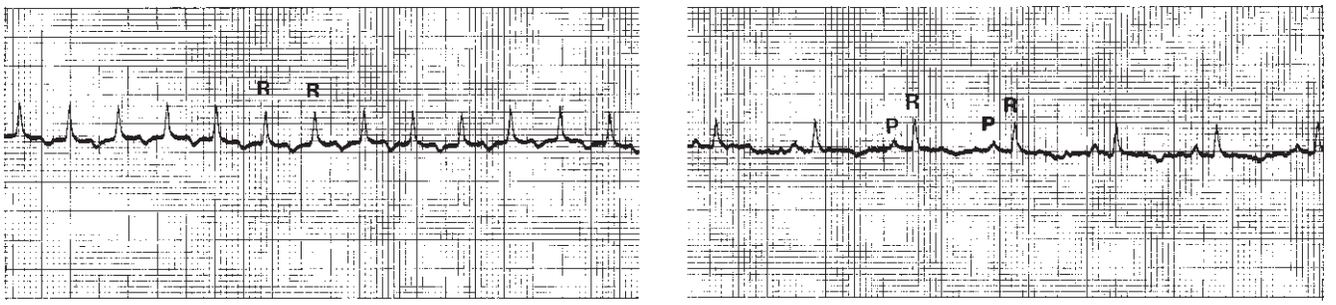

Figure 145-3. Paroxysmal atrial tachycardia *(left)* and after termination by a vagal maneuver *(right)* in a cat. (Lead II rhythm strip, paper speed 50 mm/sec; 1 cm = 1 mV.)

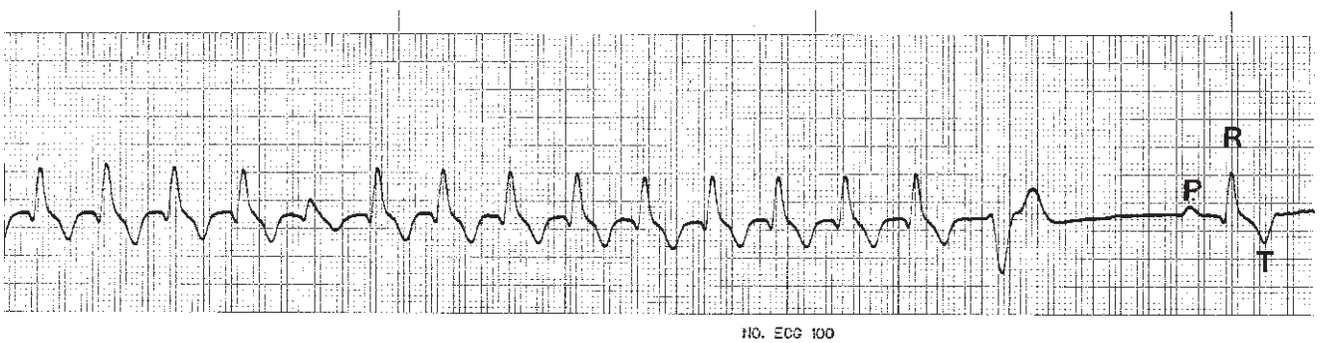

Figure 145-4. Paroxysmal atrial tachycardia terminated after a ventricular premature complex in a dog. (Lead II rhythm strip, paper speed 50 mm/sec; 1 cm = 1 mV.)

ver will cause AV block but not abolish the atrial tachycardia.)
- The heart rate is >140 to 180 bpm in dogs and >240 bpm in cats, in which it often approaches 300 bpm.
- The rhythm is usually regular but may be slightly irregular.
- There is a P′ wave for each QRS complex, although the P′ wave is usually of different morphology than the sinus P wave. The P-R interval is constant.
- The P′ wave may not be evident because it may be fused with the preceding T wave or occur simultaneously with the preceding QRS complex.
- The QRS complex may also be of different morphology because of aberrant ventricular conduction.
- An irregular R-R interval may be caused by concurrent AV block or by multifocal atrial tachycardia (P' waves varying in shape, the firing of two or more ectopic atrial foci).

Etiology and Clinical Significance

- Atrial tachycardia suggests severe myocardial or conduction system disease.
- This arrhythmia also may be secondary to digitalis toxicity or may occur under general anesthesia.
- Systemic disease that results in autonomic nervous systemic abnormalities also may be a cause.
- In cats, this arrhythmia is correlated with cardiomyopathy and hyperthyroidism.

Differential Diagnosis

- Atrial tachycardia can be confused with sinus tachycardia, AV junctional tachycardia, and atrial flutter.
- A vagal maneuver may be helpful diagnostically. Abrupt termination suggests AV nodal reentry, whereas transient AV block may develop with atrial tachycardia or atrial flutter, allowing abnormal P′ waves or atrial flutter waves to be identified at the baseline.

Treatment

- Sustained (non-paroxysmal) atrial tachycardia often is associated with weakness, hypotension, CHF, and syncope and requires immediate therapy.
- A vagal maneuver (ocular pressure or carotid sinus pressure) (see Chapter 144) may terminate an atrial tachycardia but generally only causes transient block of ectopic P' waves.
- If CHF is present, administer digitalis for the arrhythmia. IV digoxin, given cautiously, may slow the ventricular response and improve the clinical status (see Table 145-3).
- If digoxin is ineffective, IV diltiazem, verapamil, esmolol, or propranolol may convert supraventricular tachycardia (or atrial tachycardia) to sinus rhythm or slow the ventricular response rate. Use propranolol and verapamil with great caution because they

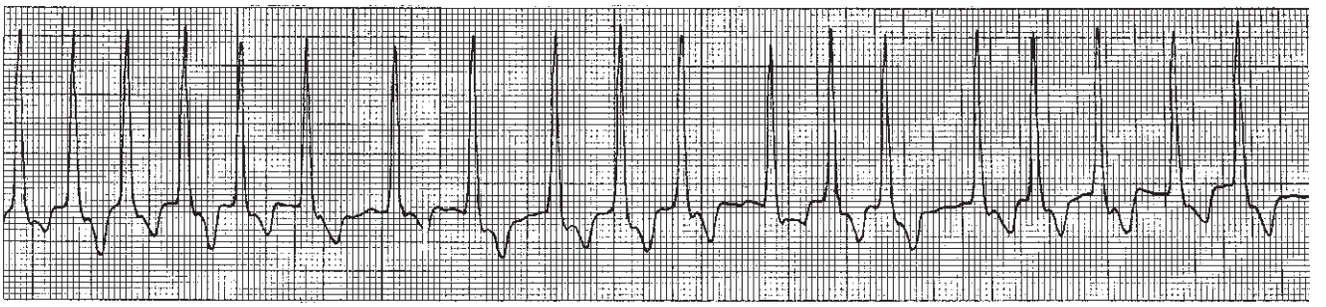

Figure 145-5. Atrial fibrillation in a dog. (Lead II rhythm strip, paper speed 50 mm/sec; 1 cm = 1 mV.)

may depress cardiac contractility and exacerbate CHF.

- For atrial tachycardia without CHF, initiate therapy with diltiazem, verapamil, or a beta-blocker (e.g., esmolol, atenolol, propranolol, or sotalol).
- Intramuscular procainamide or quinidine gluconate also have been used to convert atrial tachycardia to normal sinus rhythm in dogs with refractory atrial tachycardia.
- Atrial (supraventricular) tachycardia associated with accessory pathways (most commonly reported in Labrador retrievers) may respond acutely to IV therapy with diltiazem, verapamil, or procainamide. For long-term management, oral procainamide with or without a beta blocker is recommended. Digoxin is generally not recommended as it may preferentially direct current to the accessory pathway, which can be dangerous should atrial fibrillation develop. A class III antiarrhythmic such as sotalol or amiodarone can be tried in refractory cases.
- Radiofrequency catheter ablation following electrophysiologic mapping of reentrant or accessory pathway circuits is available at select referral centers for refractory symptomatic atrial tachyarrhythmias as a potential arrhythmia cure without permanent implantation devices.
- Reserve electrical cardioversion for refractory cases, to be administered only by an experienced veterinary cardiologist possessing the proper equipment.

Atrial Fibrillation (Fig. 145-5)

Definition

- A high number of disorganized atrial impulses, caused by a disorder of reentry within the atria, bombard the AV node, leading to an irregular rhythm.
- Many of these impulses approach the AV node in a refractory period and are not conducted to the ventricles, or they affect the conduction of subsequent impulses (concealed conduction).
- The heart rate is usually rapid (often >180 bpm in dogs and >240 bpm in cats), and the rhythm is irregular.

▼ ***Key Point*** The lack of P waves, an irregularly irregular rhythm on all ECGs leads, and an arterial pulse deficit are the hallmarks of atrial fibrillation.

- No P waves are seen, but there are normally shaped QRS complexes. Instead of P waves, small or large oscillations (f waves) are present.
- There may be some variation and widening of the QRS complexes due to aberrant ventricular conduction or bundle branch block. Subtle beat-to-beat variation may be observed in cats with atrial fibrillation.

Etiology and Clinical Significance

- Atrial fibrillation commonly occurs in patients with cardiomyopathy, advanced chronic valvular heart disease, pericarditis, and progressive congenital heart disease.
- Other rare etiologies include severe ischemia or shock (gastric dilatation-volvulus after cardiac arrest), atrial tumor (hemangiosarcoma), and electrolyte disturbances (hyperkalemia).
- Loss of atrial contraction decreases the stroke volume and cardiac output. The rapid ventricular rate also results in poor cardiac output.
- "Slow" atrial fibrillation (ventricular response rate <100 bpm) may signify drug toxicity (e.g., digitalis or a beta blocker), concurrent AV block, or very low sympathetic tone.
- Atrial fibrillation without echocardiographic evidence of structural heart disease is often termed lone atrial fibrillation. The ventricular response rate is relatively slow, typically in the 70- to 120-bpm range during a routine examination. Auscultation is more suggestive of sinus arrhythmia than atrial fibrillation. This condition develops most commonly in giant-breed dogs such as Irish wolfhounds.

Differential Diagnosis

- Atrial fibrillation can be confused with frequent APCs, AV junctional tachycardia with AV block, atrial tachycardia with AV block, and atrial flutter with AV block.

- Atrial flutter usually shows a regular R-R interval, and the atrial oscillations (F waves) are larger than f waves.

Treatment

- Since most dogs and virtually all cats with this arrhythmia have heart failure, digoxin is the initial treatment of choice to slow the ventricular response (see Table 145-3). Rarely, a sinus rhythm will return.
- After approximately 3 to 7 days, if the ventricular rate is not controlled, add a calcium channel antagonist such as diltiazem (begin with 0.5 mg/kg q8h) and increase the dose slowly until the resting ventricular rate is adequately controlled. The optimal ventricular response rate for dogs or cats with CHF and atrial fibrillation has not been determined, but most clinicians aim for rates of <140 to 160 bpm. Once CHF has been controlled, beta-blockers can cautiously be added to slow the rate further. Beta-blockers have greater negative inotropic effects than diltiazem and therefore are more likely to induce signs of CHF in marginally compensated patients with myocardial failure. However, studies in humans indicate that, when tolerated, long-term use of beta-blockers such as carvedilol and metoprolol actually improves myocardial function (see "Beta-blockers" in Chapter 146 for details).
- Although it is unusual to convert atrial fibrillation to normal sinus rhythm in dogs, the antiarrhythmic drugs (procainamide, quinidine) or calcium channel blockers (verapamil, diltiazem) may be useful for this purpose provided the dog is not in heart failure. In perioperative patients without CHF, IV or oral diltiazem is a good choice as it quickly controls the ventricular rate and may be associated with conversion to normal sinus rhythm. A normal-sized heart, recent onset of atrial fibrillation, and lack of CHF favor the use of these drugs (or electrical cardioversion). Quinidine use requires real caution as it may increase the ventricular response rate.
- Direct current, electrical cardioversion is another option for conversion of atrial fibrillation to normal sinus rhythm. Recent reports indicate a high rate of cardioversion with the newer biphasic cardioversion devices. General anesthesia is required. Maintenance of sinus rhythm requires chronic administration of amiodarone; otherwise, atrial fibrillation is likely to recur very soon in many dogs. The indications, risk-benefits, and selection of patients for this procedure should be discussed with a cardiac specialist.

Atrioventricular Junctional Rhythm

Definition

- Impulses are generated in the AV junctional tissue and spread backward (retrograde) through the atrium and forward (antegrade) to the ventricles.
- The heart rate varies with the mechanism—that is, a passive escape rhythm (60 bpm) versus an enhanced AV junctional rhythm (>60 bpm but <100 bpm) versus a junctional tachycardia (>100 bpm in the dog).
- The rhythm usually is regular.
- The negative P′ wave may occur before, during, or after the normal QRS complex. The P′-R or R-P′ interval is constant.
- The P′ wave location depends on the area of impulse generation and the relative speed of retrograde conduction through the atrium compared with antegrade conduction through the AV node, His bundle, and ventricular conduction system.

Etiology and Clinical Significance

- Digitalis toxicity may cause an AV junctional rhythm. When abnormally rapid, this arrhythmia is difficult to distinguish from atrial tachycardia.
- An AV junctional escape rhythm may occur in patients with depressed sinus node function, as in the sick sinus syndrome.
- Myocarditis may be associated with an enhanced AV junctional rhythm or AV junctional tachycardia. The rhythm has been observed in dogs with advanced heartworm disease.

Differential Diagnosis

- AV junctional rhythm can be confused with atrial standstill and slow atrial fibrillation.

Treatment

- Usually no treatment is needed and the rhythm reverts spontaneously, especially with correction of the underlying disorder.
- If weakness or syncope is associated with a slow AV junctional rhythm, atropine, dobutamine, or isoproterenol may be used in an attempt to accelerate the sinus node to help regain function as the primary pacemaker.
- Oral anticholinergic agents also may be useful for chronic therapy of junctional escape rhythm.
- If CHF is present with an enhanced AV junctional rhythm, administer digitalis.

VENTRICULAR RHYTHMS

Ventricular Premature Complexes

(Figs. 145-6–145-8)

Definition

Impulses arising from a focus below the AV node and AV junction create ventricular ectopic complexes. In some situations, these ectopic QRS complexes are normal mechanisms (escapes) that rescue the heart during sinus arrest or AV block. However, when ven-

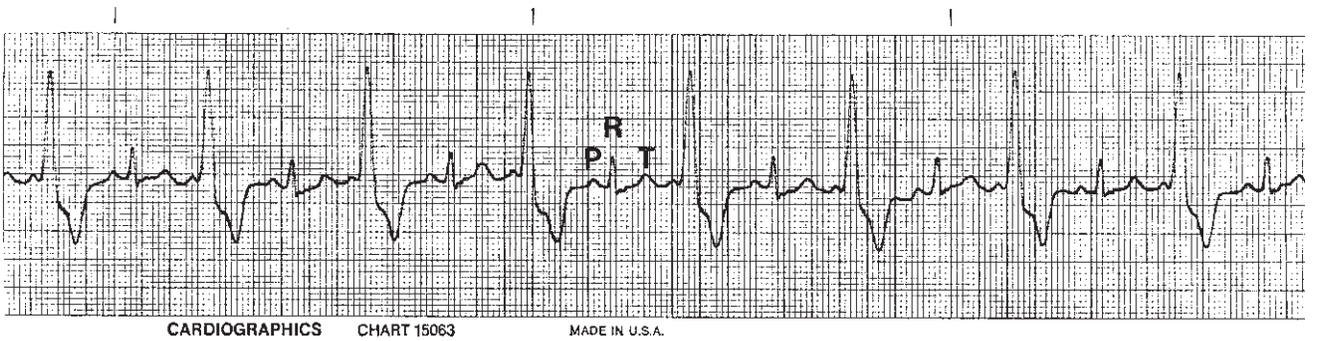

Figure 145-6. Ventricular premature complexes in a cat. (Lead II rhythm strip, paper speed 50 mm/sec; 1 cm = 1 mV.)

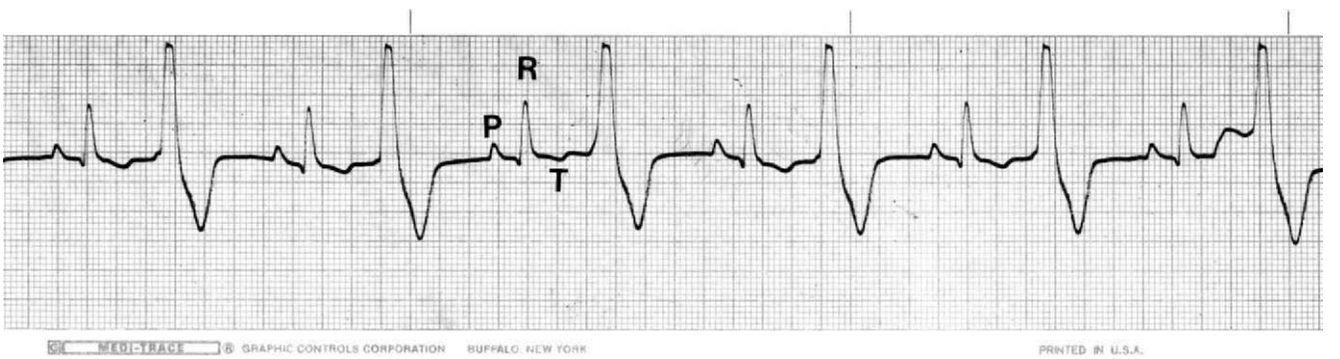

Figure 145-7. Ventricular premature complexes in a dog. (Lead II rhythm strip, paper speed 50 mm/sec; 1 cm = 1 mV.)

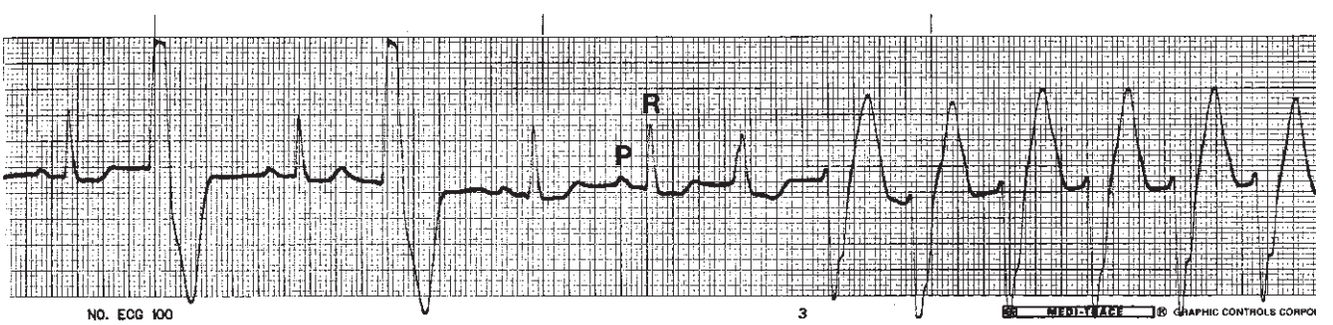

Figure 145-8. Sinus rhythm with ventricular premature complexes (right ventricular foci) and paroxysmal ventricular tachycardia (left ventricular foci) in a dog. (Lead II rhythm strip, paper speed 50 mm/sec; 1 cm = 1 mV.)

tricular ectopics are premature relative to the dominant cardiac rhythm, the ectopic impulses are called ventricular premature complexes (VPCs), also known as premature ventricular complexes or ventricular extrasystoles. The following are characteristics of VPCs.

- The heart rate is variable, depending on the frequency of VPCs; the rhythm is irregular.
- VPCs are usually related (coupled) to normal beats. If a VPC is not coupled to a normal beat, the origination site is referred to as a parasystolic focus.
- Usually there is a full compensatory pause following a VPC (i.e., the R-R interval of the two sinus complexes bounding the VPC is equal to two normal R-R intervals).
- Interpolated VPCs occur between normal beats and are not followed by a compensatory pause. The P-R interval of the next conducted sinus beat is slightly prolonged.
- P waves that are seen are normal in shape but are not associated with the QRS complex of the VPCs. The QRS complex often is wide and bizarre.

- The P-R interval of the sinus beat following a VPC may be prolonged due to retrograde conduction of the VPC into the AV node, resulting in conduction delay of the subsequent sinus beat. This is characteristic of an interpolated VPC.
- If the major deflection of the QRS complex is negative in lead II, the ectopic focus likely is in the left ventricle; if the major deflection is positive in lead II, the ectopic focus probably is in the right ventricle. Boxers with arrhythmogenic right ventricular cardiomyopathy typically have VPCs with predominantly positive deflections in lead II.

Etiology and Clinical Significance

- The ventricular arrhythmia may be due to cardiac disease (e.g., cardiomyopathy, CHF, myocarditis, or endocarditis; see Table 145-2).
- VPCs are often identified in the clinical settings of trauma, electrolyte disturbances, gastric dilatation and volvulus, pancreatitis, splenic disease, autonomic changes, hypoxia, systemic infections, ischemia, and drug toxicosis.
- Frequent VPCs or VPCs occurring during the preceding Q-T interval may be electrically unstable (depending on underlying heart disease) and may progress to ventricular tachycardia and/or fibrillation and sudden death.
- A 24-hour tape-recorded (Holter) ECG may be necessary to assess the severity of a ventricular arrhythmia (see Chapter 144, Fig. 144-16).

Differential Diagnosis

- VPCs can be confused with APCs with aberrant ventricular conduction and right or left bundle branch block.

Treatment

- VPCs do not generally require antiarrhythmic therapy.
- Consider antiarrhythmic therapy for:
  - Frequent *symptomatic* VPCs (>20–30 bpm)
  - Repetitive complexes or runs of VPCs at very rapid rates (e.g., >180 bpm), especially if causing signs or hypotension
  - Multifocal QRS configurations (not a definite indication)
  - R on T phenomena (vulnerable period for development of ventricular fibrillation), in which the VPC occurs during the Q-T interval of the previous complex
  - Associated clinical signs of poor cardiac output (e.g., weakness, dyspnea, and syncope) are probably the clearest indication for therapy.
- Do not treat ventricular escape complexes (while the QRS complex is similar to a VPC in configuration, these are not premature but occur at the end of pauses). Escapes represent a safety mechanism for maintaining cardiac output.
- Antiarrhythmic drugs commonly used to control VPCs in the hospital setting include IV lidocaine and parenteral procainamide (rarely quinidine) (see Table 145-3). Electrolyte imbalances and pain should be managed as these issues may contribute to VPCs in hospitalized patients.
- For chronic therapy of VPCs, the choice depends a great deal on the concern about repetitive rhythms and risk, as well as the appreciation of drug cost and toxicity. Beta-blockers such as atenolol, sotalol, and propranolol are often chosen for isolated VPCs, and in cats are the beta-blockers are the principle drugs used. Mexiletine, procainamide, and (rarely) tocainide are other options, but they have more side effects and are probably better reserved for more malignant arrhythmias (see Table 145-3 for dosages and Chapter 146 for a discussion of the clinical pharmacology of these drugs).

Ventricular Tachycardia (Figs. 145-8–145-10)

Definition

- Repetitive ventricular impulses (more than three VPCs in a row) are discharged from one or more ventricular foci and capture the ventricles.
- This arrhythmia may be paroxysmal (non-sustained) or sustained.
- The rate usually is >100 bpm in dogs and >150 bpm in cats.
- Once established, the rhythm tends to be regular unless the arrhythmia is intermittent or variable exit block develops (between Purkinje cells and ventricular myocardium).
- The P waves that are seen are normal in shape but have no fixed relationship to wide and bizarre QRS complexes. This independence is described as *AV dissociation*. Rarely, retrograde P waves are observed in the S-T segment because of ventricular to atrial conduction.
- A sustained ventricular rhythm faster than an escape (idioventricular) rhythm but slower than the above mentioned rates is termed an idioventricular tachycardia.

Etiology and Clinical Significance

▼ ***Key Point*** Ventricular tachycardia can be well-tolerated or represent a life-threatening arrhythmia that, if sustained, may lead to hypotension, myocardial ischemia, syncope or seizures, shock, and sudden death. Each case must be individually evaluated.

- Some patients with ventricular tachycardia show no clinical signs, especially if there is no underlying

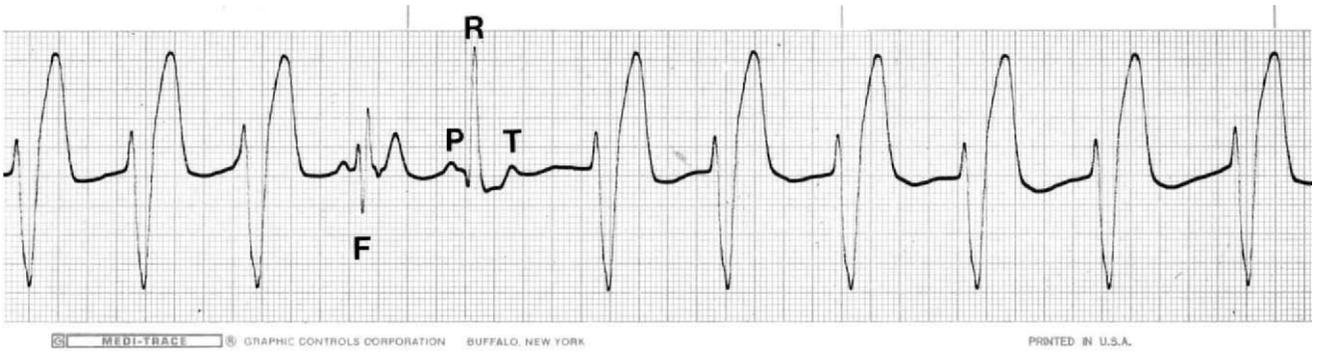

Figure 145-9. Paroxysmal ventricular tachycardia showing fusion beat (F) in a dog. (Lead II rhythm strip, paper speed 50 mm/sec; 1 cm = 1 mV.)

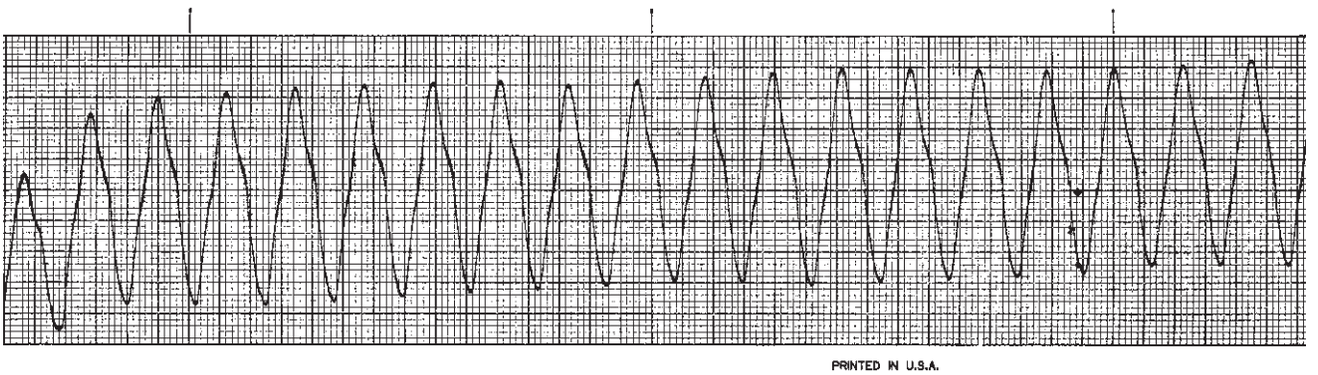

Figure 145-10. Ventricular tachycardia-flutter in a dog. (Lead II rhythm strip, paper speed 50 mm/sec; 1 cm = 1 mV.)

primary cardiac disease and the rate is not too rapid.
- All etiologies of VPCs (e.g., primary and secondary cardiac disease; see Table 145-2) may lead to a ventricular tachycardia; however, not all are dangerous to the patient.

Differential Diagnosis

- Ventricular tachycardia can be confused with supraventricular rhythms—sinus tachycardia, atrial tachycardia, or atrial fibrillation—when ventricular conduction is abnormal (as with left or right bundle branch block).

Treatment

- Antiarrhythmic therapy is required for some patients with sustained ventricular rhythms. Exceptions include patients with the following:
  - Complete heart block in which the ventricular rhythm may be an escape mechanism
  - "Slow" ventricular rhythms (also called idioventricular tachycardias) in which the ectopic rate is <180 bpm, the rate does not cause hypotension, and the rhythm alternates with the sinus rhythm
  - Acid-base or electrolyte disturbances, such as hypomagnesemia, hypokalemia, or hyperkalemia, that may respond to specific electrolyte or fluid therapy.
  - Hypomagnesemia can cause or potentiate ventricular tachycardia. Magnesium chloride (1–2 mg/kg/min for 20–30 minutes) can also exert a primary antiarrhythmic effect.

▼ ***Key Point*** Cats with ventricular tachycardia associated with hypokalemia may respond to simple KCl therapy (IV in fluids, oral) (see Chapter 5).

- Lidocaine hydrochloride without epinephrine (2–3 mg/kg) via slow IV administration is the initial treatment of choice in the dog.
  - If necessary, repeat the lidocaine bolus several times at 5- to 10-minute intervals. Higher dosages will increase the likelihood of toxicity.
  - Lidocaine also may be used in the cat (initial bolus of 0.25 mg/kg, slowly IV); beware of seizures.
  - The maximum total dosage for dogs is 8 mg/kg over 10 to 15 minutes. Seizures and vomiting may occur in dogs with toxic doses.
  - Administer diazepam IV for seizures.

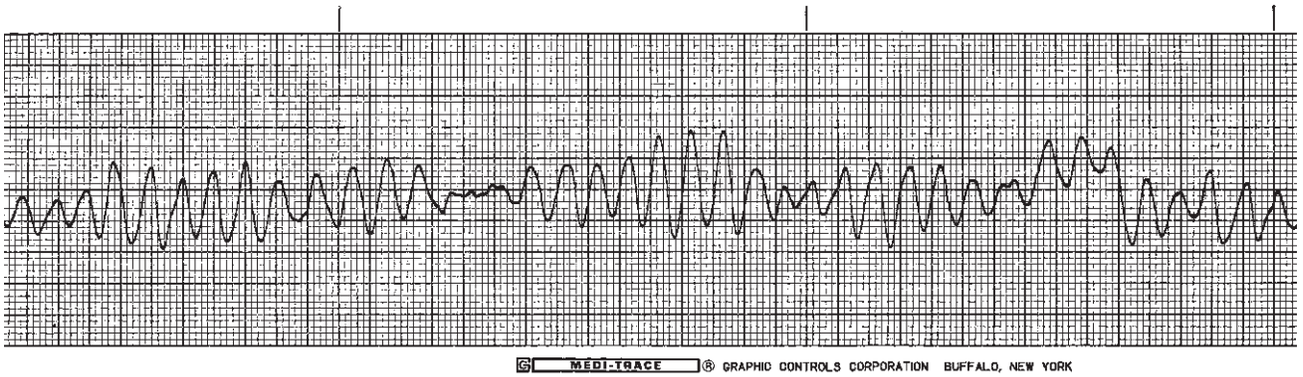

Figure 145-11. Ventricular fibrillation in a dog. (Lead II rhythm strip, paper speed 50 mm/sec; 1 cm = 1 mV.)

- Hypotension or sinus arrest also may occur if the bolus is administered too rapidly (especially in cats).
- The therapeutic effect of lidocaine is short lived, and repeated boluses or constant rate infusion may be required for a sustained antiarrhythmic effect. To calculate the amount of lidocaine to be added to IV fluids over 6 hours, use the following equation for any given infusion rate of 30 to 80 µg/kg/min:

$$\text{Body weight (kg)} \times 30 \text{ to } 80\,\mu\text{g/kg/min} \times 0.36 = \text{Lidocaine (mg)}$$

- Once the arrhythmia is controlled with lidocaine, initiate intramuscular or oral therapy with procainamide, or begin oral therapy with mexiletine or sotalol (see Table 145-3), and slowly reduce the lidocaine infusion over a 24- to 48-hour period. Alternative but less frequently used drugs include tocainide, quinidine, and amiodarone. Also manage hypokalemia, hypomagnesemia, and acidosis because they may cause therapeutic failure.
- When lidocaine therapy is contraindicated or impractical, either procainamide or quinidine, administered intramuscularly, may provide initial control of ventricular tachycardia.
- Prolonged oral therapy may be necessary in dogs with structural or primary heart disease. Most cardiologists prescribe sotalol or mexiletine plus a beta blocker such as atenolol for long-term control. For example, sotalol or a combination of mexiletine and atenolol are often effective for treatment of ventricular tachycardia associated with boxer arrhythmogenic right ventricular cardiomyopathy. Effective arrhythmia suppression is supported by a greater than 85% reduction in the number of VPCs on a Holter monitor following initiation of therapy.
  - Other antiarrhythmic drugs that may be useful include propranolol, quinidine, procainamide, tocainide and rarely amiodarone. See Chapter 146 for information about the various adverse effects of these drugs.
- Reserve electrical cardioversion for refractory or life-threatening ventricular tachycardia that will not respond to medicine.
- If a ventricular arrhythmia worsens with therapy, consider that antiarrhythmic drug toxicity (proarrhythmia) may be the cause, rather than worsening disease. For example, German shepherds may be prone to a proarrhythmic effect when sotalol is used as a single agent therapy. Sotalol combined with mexiletine reduces the frequency of VPCs in young German shepherds with inherited ventricular arrhythmias.
- Multiform ventricular tachycardia (torsades de pointes) due to procainamide or quinidine toxicity may be a life-threatening complication of antiarrhythmic medication.
- If the arrhythmia is well controlled, consider discontinuing the antiarrhythmic agent after a 2- to 3-week period. This may avoid complications of long-term therapy and the expense of antiarrhythmic drugs. Evaluate the ECG before each decrease in dosage, or within 1 week after stopping the medication. A Holter monitor (long-term ambulatory ECG) is the best way to determine antiarrhythmic drug efficacy and to guide withdrawal of therapy.
- In cases of refractory or recurrent ventricular tachycardia, consult a cardiologist.
- Radiofrequency catheter ablation following electrophysiologic mapping of ventricular tachyarrhythmic circuits is available at select referral centers for refractory symptomatic ventricular tachyarrhythmias as a potential arrhythmia cure without permanent implantation devices.

Ventricular Fibrillation (Fig. 145-11)

Definition

- Cardiac impulses are generated and propagated in the ventricles in a chaotic, asynchronous manner.
- The heart rate is rapid and disorganized.
- The rhythm is irregular.

- There are no P waves present, and there are no recognizable QRS complexes. There are continuous positive and negative oscillations that are chaotic and bizarre. The oscillations may be large (coarse) or small (fine).

Etiology and Clinical Significance

▼ ***Key Point*** The most common arrhythmia associated with cardiac arrest is ventricular fibrillation.

- There is no effective cardiac output.
- Conditions such as myocardial ischemia, electrolyte imbalance, autonomic nervous system imbalance, hypoxia, hypothermia, slow conduction, increased automaticity, drug toxicity, and unstable ventricular arrhythmias cause electrical instability and trigger ventricular fibrillation.
- Ventricular fibrillation is associated with a very grave prognosis.

Differential Diagnosis

- Differentiate ECG artifacts (e.g., 60-cycle electrical interference, respiratory movement, or use of electrocautery during surgery) from the ventricular fibrillation. A palpable arterial pulse and rhythmic precordial heartbeat rule out ventricular fibrillation.

Treatment

- Perform cardiopulmonary resuscitation (CPR) immediately (see Chapter 157).
- Electrical defibrillation is mandatory.
- Intracardiac lidocaine or other drugs are rarely successful in converting ventricular fibrillation to normal sinus rhythm.
- Open-chest cardiac massage may be effective in converting ventricular fibrillation to normal sinus rhythm if no defibrillation equipment is available (particularly in the cat). External blows to the chest (thumpversion) are far less effective.

Ventricular Asystole

Definition

- No impulses are generated from atrial, junctional, or ventricular pacemakers.
- There is no cardiac rate or ventricular rhythm.
- No QRS complexes are seen.

Etiology and Clinical Significance

- Ventricular asystole is associated with cardiac arrest and if left untreated is a lethal arrhythmia.

Differential Diagnosis

- Differentiate ECG artifacts (e.g., electrocardiograph is not on a proper lead or is connected improperly) from ventricular asystole.

Treatment

- Perform CPR immediately (see Chapter 157).
- Epinephrine, along with CPR, may be lifesaving.

CONDUCTION DISORDERS

Atrial Standstill

Definition

- Impulses are not generated in the sinus node and any native atrial activity is poorly conducted or non-conducted through the atrial tissues.
- The heart rate is <60 bpm in dogs and <160 bpm in cats.
- No P waves are seen, and the QRS complexes are normal or bizarre depending on the intraventricular conduction. The S-T segment may be elevated or depressed. The T wave may be tall due to shortened repolarization (see Chapter 144, Fig. 144-11).
- The rhythm may be regular or irregular.

Etiology and Clinical Significance

▼ ***Key Point*** Atrial standstill is a life-threatening abnormality when associated with hyperkalemia (hypoadrenocorticism, acute renal failure, urinary obstruction, and diabetic ketoacidosis).

- Persistent atrial standstill occurs in English springer spaniels (it may be correlated with a muscular dystrophy), as well as other breeds; it develops occasionally in cats with dilated cardiomyopathy in which there is degeneration and fibrosis of the atrial myocardial cells.
- There is cardiac enlargement, but electrolytes are normal with persistent atrial standstill.

Differential Diagnosis

- Differentiate atrial standstill on multiple lead ECGs from AV junctional rhythm, idioventricular rhythm, and atrial fibrillation with complete heart block.

Treatment

- If hyperkalemia is present, deliver emergency therapy to dilute and transfer extracellular potassium into the cells, thereby restoring normokalemia.
- Administer 0.9% saline, 40 to 90 ml/kg/hour, until hyperkalemia and hypovolemia are corrected.
- In addition, administer 2 mEq/kg of sodium bicarbonate very slowly IV. This may restore more narrow QRS complexes and increase myocardial contractility; repeat the dose if needed within 15 to 30 minutes. Beware of paradoxical cerebral acidosis.
- As an alternative therapy to sodium bicarbonate, administer 0.5 U of regular insulin per kilogram of

body weight coupled with 2 g of dextrose (in a 5–10% dextrose drip) per unit of insulin, slowly IV.
- For life-threatening conditions, give calcium gluconate (1 ml of 10% solution per 10 kg of body weight, slowly IV) to counteract the cardiotoxic effects of hyperkalemia. Administer with ECG monitoring.
- If hypoadrenocorticism is the cause of hyperkalemia, mineralocorticoid and glucocorticoid replacement is necessary (see Chapter 33).
- In the English springer spaniel with symptomatic atrial standstill, a permanent cardiac pacemaker is required. Consult a cardiologist.

Incomplete (First- and Second-Degree) Atrioventricular Block

Definition

- The cardiac impulse is delayed or intermittently blocked in the region of the AV node or AV junction.
- The heart rate is variable, depending on the rate of the sinus node pacemaker and the AV conduction sequence.
- The rhythm usually is regular in first-degree AV block (unless other arrhythmias are present) and irregular in second-degree AV block.
- *First-degree AV block* shows a prolonged but constant P-R interval (AV conduction) with normal P wave and QRS complexes at a 1:1 ratio.
- *Second-degree AV block* has normal P wave and QRS complexes with a constant P-R interval and with intermittent P waves not followed by QRS complexes.
  - In *Mobitz type I (Wenckebach) AV block,* the P-R interval is gradually prolonged before a dropped ventricular beat occurs. The rhythm is regularly irregular.
  - In *Mobitz type II AV block,* a consistent P-R interval occurs prior to a dropped ventricular beat. The rhythm often is irregular.

Etiology and Clinical Significance

- First-degree and Mobitz type I second-degree AV blocks often are caused by an increase in vagal tone (e.g., in brachycephalic breeds and in patients with respiratory, gastrointestinal, or neurologic disease), digitalis, and sedatives (e.g., xylazine and acepromazine).
- Antiarrhythmic drugs (beta-blockers, quinidine, procainamide, diltiazem, digoxin, and verapamil) and AV nodal disease are associated with these types of AV block.
- Physiologic AV block may occur following ectopic beats or atrial tachyarrhythmias that occur during the AV node's absolute or relative refractory periods (will slow or block the impulse).
- Mobitz type II AV block is a more advanced degree of block occurring in the AV junction, His bundle, or below. It may progress to a complete heart block. Causes include the following:
  - Idiopathic fibrosis (older dogs and cats), hereditary stenosis of the His bundle in the pug and Doberman pinscher, and hypertrophic cardiomyopathy in dogs and cats
  - Neoplastic infiltration secondary to metastatic neoplasia
  - Profound electrolyte disorders
  - Infection (e.g., Lyme disease or aortic valve endocarditis)
- The development of clinical signs (e.g., weakness, syncope, and CHF) depends on the degree of AV block, ventricular rate, and ventricular function.
- In cats there may be abrupt fluctuation among sinus rhythm, incomplete, and complete AV block. Older cats (>12 years) may tolerate second- and third-degree AV block very well, and these bradyarrhythmias may be incidental findings.

Differential Diagnosis

- Differentiate complete AV block from advanced second-degree AV block on the ECG.

Treatment

- Treatment usually is not required for Mobitz type I AV block. If the block is related to drug toxicity, stop the drug or lower the dosage.
- Therapy for Mobitz type II AV block depends on the clinical signs. If the cardiac rate is slow and weakness or syncope is evident, begin therapy with atropine, dobutamine, isoproterenol, or a temporary or permanent cardiac pacemaker. Oral therapy with hyoscyamine or theophylline may be helpful for long-term therapy if pacemaker implantation is not possible.

Complete (Third-Degree) AV Block (Fig. 145-12)

Definition

- The cardiac impulse is completely blocked in the region of the AV junction and/or the His bundle.
- The atrial rate (P-P interval) is within normal limits, and there is a slow idioventricular escape rhythm. The rhythm is usually regular. In dogs, an idioventricular escape rhythm has a rate of 40 to 60 bpm.
- An enhanced AV junctional or idioventricular rhythm (AV dissociation) has a more rapid rate, with the ventricular rate approaching the atrial rate.
- In cats, the escape rhythm is often quite a bit faster, between 80 and 120 bpm.
- The P wave is completely dissociated from the QRS complex.
- The P-R interval is variable, and usually there are many P waves with few QRS complexes.
- The morphology of the QRS complexes varies depending on the origin of the ventricular escape rhythm.

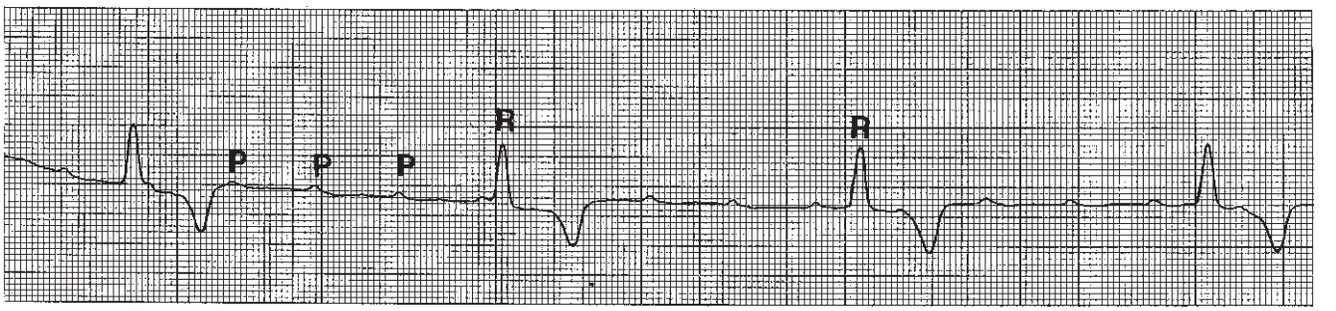

Figure 145-12. Complete (third-degree) atrioventricular block in a cat. (Lead II rhythm strip, paper speed 50 mm/sec; 1 cm = 1 mV.)

Etiology and Clinical Significance

- Complete AV block often is associated with the clinical signs of weakness, syncope, and CHF in dogs. This rhythm is often well tolerated in cats and often is detected as an incidental finding during routine exams of geriatric cats.

Differential Diagnosis

- Differentiate complete AV block on the ECG from advanced second-degree AV block, atrial standstill, and ventricular tachycardia (idioventricular rhythm).

Treatment

- A permanent cardiac pacemaker is the only consistently effective long-term treatment in symptomatic animals. A temporary transvenous pacemaker is indicated for life-threatening AV block. This condition can arise in the setting of a complete block with concurrent runs of ventricular tachycardia that is then followed by periods of ventricular asystole.
- Drugs that may be tried for short-term stabilization and treatment include atropine, isoproterenol, dobutamine, and corticosteroids (anti-inflammatory). It is rare to achieve conduction from drug therapy. An IV dobutamine or isoproterenol infusion may be useful for increasing the rate of the ventricular escape rhythm during required surgical procedures.
- In situations in which pacemaker implantation is not an option, oral therapy with methylxanthines (e.g., theophylline or aminophylline) or sympathomimetics (e.g., albuterol or terbutaline) may accelerate the ventricular escape rhythm.

Intraventricular Conduction Disturbances

Right bundle branch block, left bundle branch block, left anterior fascicular block, and combined right bundle branch–left anterior fascicular blocks are described and illustrated electrocardiographically in Chapter 144.

OTHER ARRHYTHMIAS AND CONDUCTION DISTURBANCES

Sick Sinus Syndrome

Definition

- In sick sinus syndrome (SSS), cardiac impulses are generated in the sinus node at a slower-than-normal rate or are blocked from exiting the sinus node.
- The atria and AV node may also be involved, resulting in an atrial tachyarrhythmia (e.g., atrial tachycardia, flutter, or fibrillation).
- A bradycardia-tachycardia syndrome may occur, with alternating periods of slow and rapid heart rates caused by sinus or ectopic atrial tachycardia.
- There is a normal P wave for each QRS complex. The P-R interval is constant unless the bradyarrhythmia-tachyarrhythmia syndrome is present.

Etiology and Clinical Significance

- SSS occurs predominantly in geriatric, small-breed females. Miniature schnauzers, cocker spaniels, West Highland white terriers, and dachshunds are overrepresented.
- Clinical signs of SSS are variable but often include weakness and syncope.

Differential Diagnosis

- Differentiate the multiple ECG abnormalities included in SSS from isolated sinus bradycardia, sinus block and/or arrest, and atrial tachycardia due to other causes. A poor (blunted) response to atropine (<50% increase in heart rate) supports the diagnosis of SSS.

Treatment

- If the animal is asymptomatic, no therapy is required.
- Anticholinergic drugs are rarely successful in symptomatic dogs.
- In animals with bradycardia-tachycardia syndrome, an artificial ventricular-demand pacemaker may be

required for long-term control of bradyarrhythmias and digoxin, propranolol, or diltiazem may control the tachyarrhythmia; however, do not use these drugs unless a pacemaker is implanted.

Ventricular Preexcitation and Wolff-Parkinson-White Syndrome

Definition

- In ventricular preexcitation the cardiac impulses are generated in the sinus node but spread to the ventricle simultaneously across an anomalous conduction pathway (accessory pathway or bundle of Kent), as well as the AV node. The QRS complex is essentially a fusion beat from two sources. (See Chapter 144 for additional information.)
- In Wolff-Parkinson-White (WPW) syndrome, a premature impulse finds the bypass pathway or AV node during its refractory period but traverses the other pathway, allowing the development of a macroreentry circuit that contributes to a tachycardia. The current moves in a circle: from atrium, to AV node, to ventricle, to accessory pathway, back to the atrium (or it travels in the opposite direction).
- During ventricular preexcitation, the cardiac rate and rhythm are normal. During the tachycardia of the WPW syndrome, the rate may be very rapid (e.g., 300 to 400 bpm).
- The P waves are normal in ventricular preexcitation and are retrograde and often unrecognizable in WPW syndrome (they are usually buried in the S-T segment).
- Depending on the type of accessory pathway present, the QRS complex may be widened with notching of the R wave (delta wave) or with a discrete wave just in front of the QRS (see Chapter 144 and Fig. 144-9). During the tachycardia of WPW syndrome, the QRS complex may be normal (typical), wide, or bizarre, depending on the direction and location of the circuit of the reentrant tachycardia.
- The P-R interval is short during sinus rhythm with ventricular preexcitation. During the WPW tachycardia, there is one retrograde P wave that follows each QRS complex (1:1 AV conduction).
- A short P-R interval may be correlated with a normal QRS complex if the anomalous pathway bypasses the AV node to the area of the His bundle (Lown-Ganong-Levine syndrome in humans).

Etiology and Clinical Significance

- Ventricular preexcitation and WPW syndrome may be congenital problems in the dog or cat that occur with or without other congenital heart defects (e.g., atrial septal defect, valvular dysplasia, or hypertrophic cardiomyopathy). Labrador retrievers are predisposed.

Differential Diagnosis

- Differentiate the tachycardia of WPW syndrome from AV junctional tachycardia, atrial tachycardia, and ventricular tachycardia.

Treatment

- Ventricular preexcitation without tachycardia requires no therapy.
- In animals with WPW syndrome, control and conversion of the sustained tachycardia can be attempted with a vagal maneuver (e.g., ocular or carotid sinus pressure); with drugs that block the AV node, such as diltiazem, verapamil, or adenosine; with drugs that effect the accessory pathway (procainamide or sotalol); or with direct current shock that depolarizes the entire circuit.
- Long-term control is best obtained by referral for radiofrequency catheter ablation of the accessory pathway.

THERAPEUTIC PRINCIPLES

- Determine a precise diagnosis for the arrhythmia. In most cases, the precise mechanism of the arrhythmia will not be known.
- Eliminate non-cardiac causes (e.g., acid-base and electrolyte abnormalities, hypothermia, hypovolemia, hypoxemia, anemia, infections, and other systemic problems) before using an antiarrhythmic drug.
- Stop other drug therapy if it may be the cause of the arrhythmia (e.g., digitalis, xylazine, or acepromazine).
- Treat heart failure if present.
- Drug therapy for cardiac arrhythmias is intended to prevent clinical signs such as weakness, syncope, seizures, personality changes, and CHF. Also, drug therapy may decrease electrical instability and the likelihood of progression to a lethal arrhythmia (e.g., ventricular fibrillation).
- Select the antiarrhythmic drug best suited to the underlying cause of the arrhythmia. See Chapter 146 for descriptions of the various antiarrhythmic cardiac drugs and refer to Table 145-3 for dosages.
- The benefit or complications of similar antiarrhythmic therapy may vary widely among breeds, such as ventricular tachyarrhythmias in German shepherd puppies (may be ineffective), boxers (variably effective), and Doberman pinschers (variably effective).
- Although arrhythmia frequency and complexity may be reduced, and clinical signs lessened, no antiarrhythmic studies to date have shown sudden death prevention in any canine or feline breed.
- An abolition or reduction in clinical signs or symptoms remains the key reason for the administration and expense of antiarrhythmic drugs.

- Be aware of synergistic effects of antiarrhythmic drugs (e.g., digoxin and propranolol may additively delay AV conduction) and of antagonistic effects (e.g., quinidine may cause serum digoxin levels to rise, increasing the possibility of digoxin toxicity).
- Refractory arrhythmias may require a combination of antiarrhythmic agents, although these may increase the possibility of drug-related toxicity (e.g., digoxin and diltiazem or atenolol for atrial fibrillation and mexiletine and atenolol or sotalol and mexiletine for ventricular tachycardia).
- Be aware that some arrhythmias may require antiarrhythmic drugs in addition to other therapeutic modalities (e.g., for SSS with bradyarrhythmia-tachyarrhythmias, a pacemaker for the bradyarrhythmia and an antiarrhythmic drug for the tachyarrhythmia).
- Be aware of the proarrhythmic potential of antiarrhythmic drugs.
- Digoxin can cause any arrhythmia and conduction disturbance. Monitor ECGs frequently.

Chapter

146 Cardiovascular Drugs

John D. Bonagura / Karsten E. Schober

Pharmacologic interventions allow the veterinarian to impact pathophysiologic processes in animals with cardiovascular (CV) diseases. To effectively use drugs affecting the heart and circulation, the clinician must understand the pathophysiology of the disease and appreciate the relevant pharmacology of the drugs prescribed. This chapter reviews aspects of cardiovascular pharmacology that are particularly applicable to clinical small animal veterinary practice. Most drugs used to treat CV diseases in dogs and in cats prescribed in an extra-label manner and dosages are at best approximate for many of these agents. Specific drugs and commonly recommended dosages are listed in Table 146-1. Drugs used in management of cardiopulmonary-cerebral resuscitation are discussed in Chapter 157. Management of shock is discussed in Chapter 156.

DIURETICS

Diuretics are a standard of chronic congestive heart failure (CHF) therapy and are administered for two main purposes: (1) diuresis of the patient with pulmonary edema or body cavity effusions and (2) prevention of the chronic sodium and water retention that characterizes chronic CHF. Diuretics are also antihypertensive agents but do not represent an important treatment approach for high arterial blood pressure (ABP) in dogs and cats. Diuretics should be administered with a sodium-restricted diet that is proportional to the severity of CHF.

Furosemide

Furosemide is the most often used diuretic. It acts by inhibiting the co-transporter of chloride in Henle's loop with resultant losses of chloride, sodium, water, calcium, magnesium, potassium, and water-soluble vitamins in the urine. Bumetanide and torsemide are related human drugs infrequently used in veterinary practice.

- Parenteral administration of furosemide is associated with a rapid onset of diuresis, usually within 30 minutes of injection. IV administration also may be associated with release of beneficial venodilating prostaglandins. However, fast intravenous administration may also acutely stimulate the sympathetic nervous system and the rennin-angiotensin-aldosterone system, leading to an initial increase in systemic vascular resistance, blood pressure, heart rate, and left ventricular filling pressure; therefore, IV use should be reserved for severe CHF.
- Furosemide is a "high-ceiling" diuretic, demonstrating a graded dose-response effect. The drug must be delivered by renal blood flow to be effective. Reduced renal blood flow from CHF or volume depletion; renal failure; an NSAID such as aspirin; or hypoproteinemia can negatively impact delivery of furosemide to the proximal tubule. Malabsorption or decreased delivery of furosemide may be relevant in explaining refractory ascites in cases of severe right-sided CHF.
- Furosemide preparations include proprietary veterinary and generic veterinary formulations of 12.5 and 50 mg tablets; 20, 40, and 80 mg tablets (for human patients); injectable 1% and 5% solutions (10 mg/ml and 50 mg/ml); and 1% syrup (10 mg/ml).
- The usual parenteral dosage range for hospital therapy is 1 to 4 mg/kg; IV, IM, SC two to four times daily as needed. Cats tolerate lower dosages of diuretics when compared to dogs and are more likely to develop hypokalemia and azotemia.
- In life-threatening CHF, furosemide should be given by slow IV bolus. An alternative method of administration that may be more effective is constant rate IV infusion of furosemide. Following an initial bolus of 0.5 to 1 mg/kg, the dose earmarked for the next 24 hours can be constantly infused with a small volume pump.
- Oral furosemide is used for long-term treatment of CHF. Dosages are typically 2 to 6 mg/kg one to three times daily, titrated to the magnitude of fluid retention. Oral furosemide seems less potent (presumably from poorer absorption or renal delivery) when compared to parenteral furosemide at equal doses. One strategy for treating refractory ascites or pulmonary edema in the chronic CHF patient involves intermittent subcutaneous administration of furosemide at home. Injections are given in place of the regularly

Table 146-1. CARDIOVASCULAR DRUG DOSING—CANINE AND FELINE PATIENTS

Drug	Preparation(s)	Usual Dosage*
Amlodipine	Norvasc, 2.5-mg tablet size	DOG: 0.05–0.2 mg/kg q12h–24h CAT: $^1/_4$–$^1/_2$ tablet dose, once or twice daily
Amiodarone	Cordarone injection, 50 mg/ml Cordarone and USP scored tablets, 200 mg	DOG: Loading dose of 10 mg/kg PO q12h for 1 week; thereafter 5 mg/kg PO q12–24h For IV use: 3–5 mg/kg over 60 min, followed by 5–10 mcg/kg/min CRI
Amrinone	Inocor, 5 mg/ml (20-ml vials)	DOG: 1–3 mg/kg IV followed by 30–100 mcg/kg/min constant rate infusion
Atenolol	Tenormin and USP tablets, 25 and 50 mg	DOG: 0.25–1.5 mg/kg PO q12h CAT: 6.25–12.5 mg dosage, once or twice daily (up-titrate dosages for both species)
Atropine	USP: 0.4 and 0.5 mg/ml for injection	0.01–0.04 mg/kg, IV, IM, SQ
Benazepril hcl	Lotensin tablets, 5, 10, 20, 40 mg	DOG: 0.25–0.5 mg/kg PO q12–24h (initial daily dose typically 0.5 mg/kg daily) CAT: 0.25–0.5 mg/kg PO q12–24h (as per dog)
Butorphanol	Torbutrol 0.5 mg/ml for injection Torbutrol tablets, 1, 5, 10 mg	DOG: 0.25–0.5 mg/kg, SQ, IM for sedation DOG: 0.5 mg/kg PO q6–12h as an antitussive CAT: 0.2–0.3 mg/kg in a cocktail with acepromazine (0.05–0.1 mg/kg), SQ, IM
Carvedilol	Coreg tablets, 3.125, 6.25, 12.5 mg	DOG: initiate dosage in canine DCM at 0.05–0.1mg/kg PO q12h for 2 weeks; up-titrate the dose every 2–4 weeks provided marked lethargy, progressive CHF, or relative bradycardia develop (HR < 100/minute during examination) do not develop. Typical dose target is 0.2–0.4 mg/kg PO q12h for canine DCM.
Digoxin	Lanoxin, Cardoxin, USP tablets, 0.125, 0.25 mg Elixirs of 0.05 mg/ml and 0.15 mg/ml Lanoxin for injection, 0.25 mg/ml	DOG: 0.0055–0.0075 mg/kg q12h, PO CAT: $^1/_4$ of a 0.125 mg Lanoxin tablet q48 to 72 hours
Dihydrocodone	Hycodan, 5-mg tablets	DOG: 1.25–5.0 mg, PO q8–24h for cough
Diltiazem	Cardizem and USP tablets, 30, 60, 90, 120 mg Dilacor XR capsules 120, 180, 240 mg Cardizem CD capsules 120, 180, 240 mg Diltiazem for injection 50 mg/ml	DOG: 0.5–2.0 mg/kg PO q8h (up-titrate dose) DOG/CAT: 0.1 mg/kg IV (can repeat every 15 minutes to 0.5 mg/kg while monitoring arterial blood pressure). CAT: 0.5–2.0 mg/kg PO q8–12h for standard diltiazem; $^1/_2$ of a 60 mg Dilacor pellet (taken from the capsule) q12–24h PO; or compounded Cardizem CD starting at 30 mg PO q12h
Dobutamine	Dobutrex for injection, 250 mg (20 ml vial)	DOG: 2.5–20 mcg/kg/min, constant rate IV infusion. CAT: 2.5–10 mcg/kg/min CRI
Dopamine	Intropin, USP for injection, 200 mg, 400 mg vials	2–10 mcg/kg/min, constant rate IV infusion
Enalapril	Enacard, USP tablets: 1.25, 2.5, 5, 10, 20 mg	DOG: 0.25–0.5 mg/kg PO q12–24h (initial daily dose typically 0.5 mg/kg daily) CAT: 0.25–0.5 mg/kg PO q12–24h (as per dog)
Epinephrine	Adrenaline, USP 1:1,000 (1 mg/ml), 1:10,000	DOG, CAT: 0.05–0.2 mg/kg, IV or intratracheal (only for status asthmaticus or cardiopulmonary-cerebral resuscitation)
Esmolol	Brevibloc for injection, 100 mg/ml (10-ml vial)	DOG, CAT: Initial IV loading dose of 100 to 500 mcg/kg administered over one minute, followed by a 25–150 mcg/kg/min constant rate infusion.
Furosemide	Furosemide for injection, 10 mg/ml and 50 mg/ml Veterinary Lasix tablets, 12.5, 50 mg Furosemide USP tablets, 20, 40, 50, 80 mg Furosemide 1% oral syrup (10 mg/ml)	DOG: 2–6 mg/kg q8–12h as needed, IV, IM, SQ, PO CAT: 1–4 mg/kg q12h as needed, IV, IM, SQ, PO Following initial bolus, CRI can be used to deliver 24h dose
Heparin USP	Heparin USP for injection	CAT: 150–250 units/kg initial dose, SQ, IV 50–200 units/kg q8h, SQ
Hydralazine	Apresoline, USP tablets, 10, 25, 50 mg	DOG: 1–3 mg/kg PO, q12h (up-titrate dose to ABP effect)
Hydrochlorthiazide	Hydrodiuril, USP tablets, 25, 50 mg	DOG, CAT: 1–4 mg/kg q24–48h, PO
Isosorbide dinitrate	Sorbitrate, Isordil, USP tablets, 5, 10 mg	DOG: 2.5–5 mg orally bid
Lidocaine	Xylocaine, USP for injection, 2% (20 mg/ml, without epinephrine)	DOG: 2 mg/kg IV bolus, can repeat up to 8 mg/kg over a 10-minute period; 25–75 mcg/kg/minute constant rate IV infusion (check blood potassium concentration if no effect); CAT: 0.25–1.0 mg/kg, slow IV injection over a 3–5-minute period

Table 146-1. CARDIOVASCULAR DRUG DOSING—CANINE AND FELINE PATIENTS—cont'd

Drug	Preparation(s)	Usual Dosage*
Lisinopril	Prinivil unscored tablets, 2.5, 5, 10, 20, 40 mg	DOG: 0.25–0.5 mg/kg q12–24h, PO
Magnesium	20% $MgCl_2$ solution for injection (contains 1.97 mEq of Mg++ per mL)	DOG: 0.75–1 mEq/kg/24h IV infusion (50% of total dose can be given in 2–4 hours if necessary) For ventricular fibrillation: 0.15–0.30 mEq/kg IV over 5–10 min
Metoprolol tartrate	Toprol-XL scored tablets, 25 mg	DOG: Start at $^1/_4$ of a 25 mg tablet once daily; up-titrate every 2 weeks to 12.5 mg q12h, PO (for a 20–30 kg dog)
Mexiletine	Mexitil, USP capsules, 150, 200, 250 mg Mexitil, 250 mg for injection	DOG: 5–8 mg/kg q8h, PO DOG: 2.5 mg/kg bolus IV given over 10 min, followed by 30 mcg/kg/min for 3 hours CRI, followed by 5–8 mcg/kg/min CRI for 24–48 hours IV (currently available in Europe)
Nitroprusside sodium	Nitropress, Nipride 50 mg/vial	Usual dosage range is 2–10 mcg/kg/min CRI Begin at 0.5–1 mcg/kg/minute and uptitrated If possible limit infusion to 24 hours
Nitroglycerine ointment (2%)	Nitrol, Nitro-bid, Nitrostat, USP 15 mg per inch Minitran transderm patches 2.5, 5, 10, 15 mg/24 hr	DOG: $^1/_4$–1 inch topically q12h; Patch: 2.5–10 mg (small–giant dog) CAT: $^1/_4$ inch topically q12h
Pimobendan	Vetmedin capsules, 1.25, 2.5, 5 mg	DOG: 0.3–0.6 mg/kg/day, divided; usual dose is 0.25 mg/kg q12h PO (give 1 hour before feeding)
Prazosin	Minipress, 1-, 2-, 5-mg capsules	1 mg/15 kg q8–12h PO
Procainamide	Pronestyl, USP for injection, 100 mg/ml; 500 mg/ml Procainamide SR, USP capsules and tablets, 250, 375, 500 mg	DOG: 2 mg/kg (IV) to a maximum total dose of 20 mg/kg over a 30-minute period; 25–40 mcg/kg/min IV infusion; 8–20 mg/kg, IM or SQ q4–6h; 10–20 mg/kg q8h PO (sustained release preparation) CAT: 3–8 mg/kg q6–8 h IM or PO
Propranolol	Inderal, USP for injection, 1-mg ampoule Tablets, 10, 20, 40, 60, 80 mg Inderal LA capsules, 60, 80, 120, 160 mg	DOG, CAT: 20–60 mcg/kg over 5–10 min, IV DOG: 0.5–1.0 mg/kg q8h, PO (use with caution in CHF) Can up-titrate dose from 0.1 mg/kg q8h, PO CAT: 2.5–5.0 mg dose q8h, PO (use with caution in CHF)
Spironolactone	Aldactone, USP tablets, 25 mg	DOG: 0.5 mg/kg–1.0 mg/kg q12–24h, PO
Sotalol	Betapace, USP scored tablets, 80, 160, 240 mg	DOG: 1–2 mg/kg q12h, PO
Tocainide	Tonocard, USP tablets, 400, 600 mg	DOG: 10–20 mg/kg q8h (rarely prescribed today; available in Europe)
Verapamil	Isoptin, 5-, 10-mg ampoules for injection; Isoptin, Calan, 40-, 80-, 120-mg tablets	DOG: 0.05 mg/kg, IV every 10–30 minutes to a maximum cumulative dose of 0.2 mg/kg
Warfarin	Coumadin 1-, 2-mg scored tablets	CAT: 0.5 mg PO, initial daily dose; compounding may be needed

Check dosing information and standard textbooks for specific dosing recommendations.
Prescription of many of these drugs in small animal patients constitutes an *extra-label* use and vary across different countries; Clients should be so advised.
Recommendations are based on current standards of veterinary practice.
Many drugs must be titrated to effect, especially in dogs and cats with congestive heart failure.
Consider drug interactions when prescribing multiple drugs.

scheduled oral treatment. This can be initiated three times weekly and increased or decreased as necessary. Chronic subcutaneous administration may lead to granuloma like swellings in some dogs.

▼ ***Key Point*** Chronic monotherapy with furosemide leads to sodium and volume depletion and activates homeostatic vasoconstricting (renin-angiotensin) and sodium retaining responses. These effects are deleterious in the heart failure and are countered by co-administration of an angiotensin converting enzyme inhibitor (ACEI) and control of dietary sodium intake.

Adverse Effects

Adverse effects of furosemide and other diuretics relate mainly to volume depletion and electrolyte loss.

- Consequences in the patient may include azotemia, hypochloremia, metabolic alkalosis, and potentially hypokalemia (though this effect is usually blunted by adequate food intake and by an ACEI).
- Magnesium depletion also may develop.
- Hypokalemia and hypomagnesemia predispose to premature complexes, digitalis intoxication, loss of efficacy of class I anti-arrhythmic drugs, and increased likelihood of drug-induced ventricular arrhythmias in animals treated with class III anti-arrhythmics.
- Excessive diuretic doses can be detected by regular measurement of blood pressure and the serum BUN, creatinine, and electrolytes.
- Azotemia is very common in dogs and especially in cats requiring daily furosemide treatment. Mild to moderate azotemia is acceptable in a patient with persistent fluid accumulation because the edema or effusion is likely to worsen if furosemide dosage is

decreased. In contrast, the dose of furosemide should be reduced in a patient with azotemia and no evidence of edema.

Spironolactone

Spironolactone is a potassium- (and magnesium) sparing diuretic that antagonizes the effects of aldosterone by binding to mineralocorticoid receptors in the distal collecting duct. Though a weak diuretic, it is often added to a comprehensive CHF therapy regimen that includes furosemide, an ACEI, and a positive inotrope. Eplerenone is a related drug that is not widely used in veterinary practice.

- Spironolactone prevents sodium reabsorption, spares potassium and magnesium, and most importantly, it antagonizes the cardiotoxic effects of aldosterone on the myocardium. Early use of this drug should be considered in CHF owing to potentially favorable effects on preventing myocardial fibrosis.
- Spironolactone, like digoxin, also improves baroreceptor function in dogs with CHF.
- Spironolactone is available in 25- and 50-mg tablets. Typical dosages for cardioprotection range from 6.25 to 25 mg once or twice daily and generally fall within a dosage range of 0.5 to 2 mg/kg daily. Dosages are somewhat empiric and related to severity of CHF and patient size; in human patients, even low dosages are cardioprotective.
- Hyperkalemia occasionally occurs from the combined effects of the spironolactone added to an ACEI. For this reason, potassium supplements should not be administered concurrently with spironolactone.
- Use of spironolactone in occult dilated cardiomyopathy without overt CHF is not of proven value and there is no substantive diuretic effect in dogs without CHF.

Hydrochlorothiazide

Hydrochlorothiazide (HCT) is occasionally used in combination with furosemide and spironolactone for management of refractory fluid retention. HCT primarily blocks the sodium transporter in the distal convoluted tubule and the connecting segment but also has action across the proximal tubule. This effect inhibits sodium, chloride, and water reabsorption. HCT is a moderately potent diuretic, but when used in combination with furosemide, the diuretic impact is greatly magnified as HCT prevents distal sodium reabsorption that escapes the effects of the loop diuretic.

- HCT is a "low ceiling diuretic" because the maximal response is reached at relatively low dosage.
- HCT is available in a variety of tablet sizes, some of which represent combination products. HCT is often formulated with spironolactone (25 mg of each in the 50-mg tablet) or triamterene (to spare potassium) as these combinations increase the diuretic effect while sparing potassium.
- The usual dose of HCT is 1 to 2 mg/kg daily provided the drug can be tolerated. Unfortunately, the "sequential nephron blockade" of fluid and electrolyte reabsorption during combination diuretic therapy is frequently too potent: the result is rapid volume and electrolyte depletion.
- To minimize the risk of acute renal failure and electrolyte disturbances, HCT is administered every other day for the first week of therapy, and serum chemistries and blood pressure are then reevaluated.
- If renal function and electrolytes remain stable, the frequency of dosing can be increased to once daily administration, added to the previously established furosemide-spironolactone regimen.

Adverse Effects

Profound hyponatremia, hypokalemia, and hypochloremia may develop with HCT, regardless of treatment with spironolactone or an ACE inhibitor. These consequences often promote withdrawal of HCT therapy.

Nesiritide

Nesiritide, or synthetic human brain natriuretic factor (h-BNP), has been developed as a "smart diuretic" and this drug may be applicable to veterinary practice. Naturally occurring BNP is released from the heart during volume expansion and leads to natriuresis and vasodilation.

- Nesiritide (labeled for human use) appears to be effective in dogs. It enhances urinary output and reduces aldosterone effects in furosemide-treated dogs; increases urine volume in normal dogs and those with experimental CHF; and demonstrates minimal electrophysiologic effects on the canine heart.
- There is potential for volume depletion and azotemia, so renal function should be followed.
- Currently the drug is too expensive for routine use, but it may be considered in stabilization of life-threatening pulmonary edema.

Monitoring of Diuretic Therapy

Diuretics contract plasma volume and dosing must be adjusted to control fluid accumulation while preventing hypotension, weakness, dehydration, electrolyte disturbances, and azotemia. In most cases, simple monitoring of ABP along with serum creatinine and BUN are sufficient to ensure the dose is not excessive.

Most adverse effects develop within the first two to three weeks unless other medications change or complications develop (e.g., digoxin toxicity with vomiting).

Monitor diuretic therapy as follows:

- Examine the jugular veins. If prominent or distended, volume depletion is not likely an issue and higher diuretic doses are likely to be tolerated.

- Measure the total protein, PCV, BUN/creatinine, and ABP to assess the plasma volume status.
- Measure the serum electrolytes to screen for hyponatremia, hypochloremia (disregard if mild), hypokalemia (never disregard). Hypomagnesemia often tracks hypokalemia.
- Metabolic alkalosis may be evident by increased or normal bicarbonate concentration in the face of a low serum chloride. As with hypochloremia, this abnormality is typically ignored unless moderate or severe.
- Diuretic complications are treated by reducing the diuretic dosage and, if necessary, infusing crystalloids (5% dextrose in water or 0.45 NaCl/2.5% dextrose; either fluid should be supplemented with potassium chloride at 10–20 mEq KCl per 500 ml fluid).
- Patients with primary renal disease and CHF pose a treatment challenge, as volume depletion reduces renal blood flow. It is difficult to support renal function and still control edema or effusions in patients with advanced CHF.
- Provided the patient is drinking, chronic administration of subcutaneous fluids is illogical, as the same effect can be obtained by simply lowering the diuretic dosage (which generally worsens the CHF).
- Mild to moderate azotemia often must be accepted if CHF therapy is to be successful. Hemodialysis would be optimal for controlling uremia and volume status but is not widely available or accessible.
- Progressive azotemia and accompanying signs of uremia (anorexia, vomiting, and depression) frequently prompt the euthanasia of affected patients.

POSITIVE INOTROPIC DRUGS (CARDIOTONICS)

Positive inotropic drugs increase the availability of calcium to cardiomyocytes, thereby enhancing the strength of heart contraction. This class of drugs includes the digitalis glycosides (digoxin, digitoxin), catecholamines (dobutamine, dopamine), phosphodiesterase inhibitors (milrinone), and calcium sensitizers (pimobendan).

Digoxin

Digoxin is the oldest inotropic drug in common use. (Digitoxin is used rarely and will not be discussed.) Digoxin is indicated in therapy of moderate to severe CHF caused by dilated cardiomyopathy, chronic valvular heart disease, or untreated congenital heart disease in dogs. It is rarely prescribed to cats. Digoxin is especially useful when CHF is complicated by atrial fibrillation or frequent premature atrial complexes. The cardiac glycosides have *not* been shown to prolong survival in CHF.

- Following oral or IV administration, digoxin inhibits the sodium–potassium ATPase that activates a sodium calcium exchanger, which increases calcium influx. The inotropic effect is mild when compared to potent drugs such as dobutamine or pimobendan.
- Digoxin also sensitizes arterial baroreceptors, leading to a withdrawal of sympathetic activity and increased vagal efferent tone to the heart. This effect slows the sinus node rate at rest and decreases the ventricular rate response to atrial fibrillation (by impairing AV nodal conduction).
- Canine data suggest that digoxin may inhibit the renin–angiotensin system and decrease sympathetic nerve discharge.
- Digoxin administered orally decreases systemic vascular resistance, venous tone, and central venous pressure and induces diuresis in patients with CHF.
- Digoxin given IV may cause systemic and coronary vasoconstriction and can produce transient myocardial ischemia. Therefore, IV administration is not recommended.
- Digoxin is mainly a drug for management of advanced CHF caused by predominately systolic dysfunction. The drug is particularly indicated in the setting of atrial fibrillation and CHF.

▼ ***Key Point*** Digoxin is unlikely to provide satisfactory control of ventricular response rate to atrial fibrillation unless used in combination with diltiazem or a beta-blocker. However, as a positive inotrope, digoxin is the first drug used in treatment of atrial fibrillation in the setting of CHF.

While some veterinarians use the examination heart rate to decide if they will prescribe digoxin, there is no established basis for this approach or for predicting the potential benefit of the drug. Digoxin does little to mitigate heart rate due to high sympathetic tone, stress, or exercise; heart rate benefits of increased vagal tone are most evident in the resting state.

- Digoxin should not be used in some clinical settings and is contraindicated in others.
- Digoxin plays no role in the acute hospital therapy of CHF unless it is complicated by atrial fibrillation.
- Digitalis is not prescribed for isolated diastolic problems such as pericardial disease or HCM.
- We do not prescribe digoxin for occult (asymptomatic) heart disease as other drugs (ACEI and beta-blockers) are more likely to be cardioprotective and digoxin may aggravate ventricular ectopy.
- Overt contraindications to digitalization include frequent or complex ventricular ectopy; moderate to severe renal failure (reduced elimination); myocarditis, sinus node disease, or heart block (vagal effects can depress nodal functions); hypokalemia (increases potential for arrhythmias); ventricular pre-excitation (AV block may lead to preferential conduction

down the accessory pathway); and known individual hypersensitivity (typically anorexia) to the drug.
- Drug interactions may occur with quinidine, verapamil, and amiodarone resulting in increased serum digoxin concentration.
- Digoxin is administered typically by the oral route. Intravenous use is uncommon today in small animals. Available digoxin preparations include tablets (0.125, 0.25, 0.5 mg) and elixirs (0.05 and 0.15 mg per ml). The usual daily dose for the dog is 0.0055 to 0.0075 mg/kg, PO, twice daily.
- Monitoring of therapy can be accomplished by client interview for adverse signs; auscultation for arrhythmias; an ECG when heart rhythm disturbances are detected; and most importantly, a serum digoxin level. Following a week of consistent treatment, a blood sample is obtained 8 to 12 hours post dosing; the therapeutic goal for a trough level is 0.8 to 1.2 ng/ml.

Adverse Effects

Common adverse effects of digoxin include anorexia, depression, vomiting, diarrhea, and cardiac arrhythmias. Arrhythmias are explained by either increased vagal tone (causing sinus node depression or AV block) or enhanced calcium entry into cells, leading to membrane oscillations, increased automaticity (particularly in the His-Purkinje fibers), and subsequently premature complexes. Ventricular bigeminy and ectopic junctional rhythms also have been observed in dogs with digitalis toxicity.

Catecholamines

The catecholamines used most often in emergent management of CHF are dobutamine and dopamine. These drugs stimulate cardiac beta- and alpha–receptors to increase contractility in a dose-dependent manner via the second messenger effect (increased generation of cyclic AMP or IP_3 for beta- and alpha–receptor stimulation, respectively). In patients with CHF, the heart rate generally increases slightly during infusion of catecholamines. The effects of catecholamines on systemic arterioles are dose dependent but include vasodilation at lower doses ($beta_2$ effect) and vasoconstriction (alpha effects) at higher infusion rates.

- Dobutamine HCl is an injectable catecholamine (synthetic analogue of dopamine) with dose-dependent positive inotropic effects that are far greater than digitalis glycosides. Effects on blood vessels are dose-dependent and depend on the predominant drug effect and availability of sympathetic receptors.
- Both beta and alpha effects are inotropic, but myocardial beta-receptor density is far greater in dogs and cats.
- Myocardial receptor density is altered in chronic canine CHF, and the beta-receptor density (especially $beta_1$) is reduced. Accordingly, the dose of dobutamine required for cardiac stimulation may be higher than that used for healthy dogs in other settings (as with anesthesia). Constant rate infusion can lead to further down regulation of beta-receptors occurring within several hours (tachyphylaxis), requiring higher doses to maintain the same inotropic effects.
- In resistance arterioles, the $beta_2$ effect of catecholamines causes vasodilation, while alpha-receptor stimulation constricts the vessels.
- Dopamine, the precursor to nor-epinephrine, has similar effects but causes more tachycardia and pulmonary and systemic vasoconstriction than dobutamine for equivalent inotropic doses. For these reasons, dopamine is used less often in CHF but is preferred if bradycardia or severe hypotension is present.
- *Indications for catecholamines*—The principal use of dobutamine or dopamine in CHF is therapy of cardiogenic shock, which can be defined clinically as severe CHF accompanied by hypotension (systolic ABP <80 mm Hg and a mean ABP <50 mm Hg) with evidence of poor perfusion (pale mucous membranes and elevated blood lactate). This situation is often accompanied by hypothermia and in cats is also associated with sinus bradycardia (HR <160/min). Dobutamine also can be used to support the dog with chronic refractory CHF that is retaining fluid and is unresponsive to high dose diuretic therapy.
- The immediate goal of catecholamine therapy in CHF is the short-term (24–48 hours) support of myocardial contractility to achieve a higher stroke volume and cardiac output. Such therapy, when administered with other drugs for heart failure such as diuretics and nitrates, frequently stabilizes the patient. Ideally this benefit will occur mainly through an increase in stroke volume, without excessive increases in heart rate or vascular resistance.
- Clinical measures of improvement during catecholamine infusion include increases in ABP and urinary output; enhanced tissue perfusion, as judged by heightened level of consciousness, normal rectal temperature, pink mucous membrane color, and shortened refill time; and improved muscle strength.
- Clinical use of dobutamine in dogs with CHF involves a constant rate intravenous infusion with initial suggested rate of 2.5 mcg/kg/min. Dobutamine is added to 5% dextrose solution and infusion controlled by an automated dose syringe or infusion pump.
  - The initial dose can be increased in 30 to 60 minutes to 3.75 or 5 mcg/kg/min and then uptitrated as needed to clinical effect.
  - Objective markers of drug effect are increases in rectal temperature and ABP. A target ABP of 90 to 100 mm Hg systolic is a reasonable goal, and the infusion should be maintained at a level to prevent higher ABP or tachycardia.
  - Rarely are infusions of >10 mcg/kg/min needed.

  - After 24 to 48 hours of dobutamine, the infusion can be reduced by 50% every 2 to 4 hours with monitoring of ABP. If blood pressure is maintained at >85 mm Hg systolic, the drip can be discontinued.
  - If ABP fails to increase in dogs with cardiogenic shock, consideration should be given to adding or substituting dopamine for more potent vasoconstriction. Dose rates are indicated in Table 146-1.
  - Atrial fibrillation is not a contraindication for use of dobutamine. In most cases, ventricular rate response is unchanged or actually slows during dobutamine infusion, presumably from improved ABP and withdrawal of endogenous sympathetic tone. Digoxin can be used in combination with dobutamine to help control ventricular response rate.
- Cats with CHF, hypotension, and bradycardia can benefit from infusions of dobutamine. This includes feline patients that have suffered a myocardial infarction superimposed on pre-existent cardiomyopathy.
  - Typically an infusion of 2.5 mcg/kg/min is initiated. Infusion rates exceeding >7.5 mcg/kg/min are uncommonly needed.
  - The infusion rate can be increased every 30 to 60 minutes to achieve an ABP of 90 to 120 mm Hg systolic. In most cases, heart rate also will increase to more appropriate levels for a cat with CHF.
  - Clinical assessment of benefit is similar to that for dogs. Most cats receive dobutamine for 24 to 36 hours.
- Contraindications for catecholamines are mostly relative. Ventricular ectopy may worsen and should be carefully monitored by ECG monitor. Hypokalemia may worsen with catecholamine infusion, so electrolyte imbalances should be corrected.

Adverse Effects

Adverse effects of catecholamines are predictable extensions of sympathomimetic stimulation and include sinus tachycardia; premature supraventricular and ventricular complexes; ventricular tachycardia that can progress to ventricular fibrillation; anxiety; tremors; elevated ABP; and seizures (mainly in cats). Simply stopping or lowering the infusion rate controls most adverse effects as the drug is rapidly hydrolyzed within minutes of administration. Life-threatening side effects can be treated with the ultrashort-acting beta-blocker esmolol (100–500 mcg/kg dose infused over 5–10 minutes with HR and ABP monitoring).

Inodilators

The word "inodilator" pertains to positive inotropic drugs that also demonstrate significant vasodilator effects. The combination of increased myocardial contractility and left ventricular afterload reduction result in a potent increase in ventricular stroke volume.

Milrinone and Amrinone

Milrinone and amrinone are PDE-III inhibitors that prevent the degradation of cyclic AMP, the second messenger of the beta-adrenoceptor. This leads to accumulation of the cyclic nucleotide and a potent positive inotropic effect. Cyclic AMP also functions as a peripheral vasodilator, especially in dogs, so that reduced left ventricular afterload further improves cardiac performance.

These drugs are administered by IV infusion, are relatively expensive, and are used infrequently in veterinary practice, though canine studies with oral and IV milrinone showed both acute and chronic benefit of this drug.

Clinical indications for IV milrinone would be the combination of severe systolic dysfunction and tachycardia (as PDE-III inhibitors have relatively little effect on heart rate, even at higher doses) or the patient with acute-on-chronic heart failure, already receiving beta blockade and in need of acute inotropic support that bypasses the beta-receptor.

Pimobendan

Pimobendan (Vetmedin) is classified as a calcium sensitizer, as well as a phosphodiesterase inhibitor with vasodilator properties. It is approved for veterinary use in many countries and completing clinical trials in other countries (including the USA). Pimobendan is an inodilator with a novel mode of action on contractility. Whereas digitalis and catecholamines increase the transport of calcium into the cardiomyocyte, pimobendan increases the *sensitivity* of the actin-myosin contractile apparatus to available calcium.

Compared to other inotropic drugs, pimobendan offers a number of advantages.

- It is far more potent than digoxin and does not cause anorexia. Furthermore, pimobendan is not reported to impact off-loading of calcium from the contractile apparatus, which suggests it will not impair diastolic function (a potential problem with digitalis).
- Pimobendan is superior to pure phosphodiesterase inhibitors in canine models of CHF, emphasizing the benefit of the calcium sensitization.
- Pimobendan is administered by the oral route yet still carries a potent inotropic effect. For this reason, it serves as a second choice to dobutamine (or dopamine) infusion for hospital treatment of low cardiac output. ABP must be followed to insure that excessive vasodilation does not develop secondary to PDE inhibition. Thus, while dobutamine is the drug of choice for cardiogenic shock, pimobendan may be more practical in many practice situations.
- Unlike digoxin, catecholamines, and pure PDE-III inhibitors, pimobendan is noteworthy for an apparent lack of sensitization to ventricular arrhythmias.
- One disadvantage of pimobendan is a relative lack of effect on heart rate in atrial fibrillation.

- Pimobendan is indicated in the therapy of heart failure in dogs caused by dilated cardiomyopathy and is also beneficial in treatment of CHF due to chronic valvular heart disease or untreated congenital heart diseases in dogs. It has also been used for "prevention" of CHF in breeds with advanced occult DCM such as that encountered in the Doberman pinscher. Where available, pimobendan has often replaced digoxin for treatment of canine CHF.
- There is no logical reason for prescribing pimobendan to the exclusion of "standard CHF therapy" of furosemide and an ACE-inhibitor, along with dietary sodium restriction. This trio provides an excellent pharmacologic profile for treatment of advanced CHF in dogs.
- It is likely that pimobendan will be useful in cats with CHF, though extra-label feline use requires far more study.
- Digoxin, diltiazem, or a beta-blocker (carvedilol) can be added for heart rate control in cases of atrial fibrillation.
- Pimobendan capsules (1.25, 2.5 and 5 mg) are available for veterinary use in many countries. The usual canine dose is 0.25 mg/kg PO q12h. In clinical trials doses ranging from 0.3 to 0.6 mg/kg daily (once or divided bid) have been effective. Pimobendan should be given at least 1 hour before feeding for maximal effect. The drug has demonstrated an anti-thrombotic effect in some *in vitro* studies, and this may prove useful in animals as well. Drug expense may limit its use.

Adverse Effects

Adverse effects of pimobendan appear to be minimal. Unlike other inotropic drugs, ventricular ectopy is not believed to worsen under pimobendan. The heart may literally "pound" under the influence of this inodilator, and impact on degree of mitral regurgitation is a theoretical concern that has not been established in studies of CHF in dogs.

VASODILATORS AND ANGIOTENSIN CONVERTING ENZYME INHIBITORS

The vasodilator drugs are a heterogeneous group of agents that dilate arteries or veins. Vasodilators act by varying cellular mechanisms, often with predominant effects on arteries or veins. The class of drugs includes the nitrates (nitroglycerin, sodium nitroprusside), hydralazine, calcium channel blockers (amlodipine, diltiazem), phosphodiesterase inhibitors (milrinone, pimobendan, sildenafil), and the numerous drugs that act as an angiotensin converting enzyme inhibitor (ACEI).

Overview

Vasodilators are used in both hospital therapy and chronic management of CHF.

- These drugs have hemodynamic effects that pertain mainly to reduction in preload or afterload. In addition, the clinician must consider the effects of any given vasodilator on neurohormonal activation.
- Venodilator drugs reduce *preload* (filling pressures) through venous pooling. Decreased filling pressures counteract edema formation and decrease ventricular wall tension by reducing preload.
- Arteriolar dilators are thought to decrease *afterload* of the left ventricle by lowering ABP and reducing vascular resistance (though afterload is not simply blood pressure). Because the failing left ventricle is very sensitive to afterload, the higher the load, the greater the wall tension and myocardial oxygen consumption and the lower the ventricular stroke volume. Reducing afterload with a vasodilator also decreases mitral regurgitant volume and increases cardiac output.
- As a consequence of sudden drops in ABP, the direct vasodilators often create an undesirable activation of the sympathetic and renin-angiotensin-aldosterone systems. In contrast, the ACEI exert favorable hemodynamic and neurohormonal effects by inhibiting these systems. Accordingly, direct vasodilators are usually administered with an ACEI.
- "Direct" vasodilators such as nitroglycerin and sodium nitroprusside are often used in hospital therapy of left-sided CHF (see below).
- While the calcium-channel blocker/vasodilator amlodipine occasionally is used in chronic CHF, an ACEI is the vasodilator of choice in chronic management of CHF due to valvular disease, cardiomyopathy, and congenital heart disease. ACEIs are considered "balanced" arterial and venous vasodilators; they also decrease the neurohormonal activity that has been associated with morbidity and mortality in CHF.
- Phosphodiesterase inhibitors are also vasodilators. This effect may explain part of the benefit of pimobendan in management of chronic canine CHF or sildenafil (Viagra) in treatment of pulmonary hypertension.
- The third-generation beta-blocker carvedilol (Coreg) is used increasingly in treatment of dilated cardiomyopathy and exhibits alpha-adrenergic blocking activities; this action confers vasodilator properties to carvedilol.

Nitroglycerine

Nitroglycerine (NTG) induces nitric oxide–mediated vasodilatation in the vascular endothelium. When applied topically (2% ointment) NTG acts mostly as a systemic venodilator. The potency of the drug administered IV in dogs is unchallenged, but the overall benefit

of topical administration on filling pressures requires further study.

- Systemic venodilation may reduce pulmonary venous pressure by translocating pulmonary venous blood to dilated splanchnic veins. However, there may be great individual variability in NTG effects with respect to redistribution of fluid.
- Nitrate tolerance develops if NTG is administered too frequently; therefore, the drug is usually given once or twice daily allowing a nitrate-free interval.
- *Indications* for NTG therapy include hospital therapy of pulmonary edema. Home use of NTG may be considered in dogs with nocturnal dyspnea (apply at bedtime) or in difficult to medicate dogs that will tolerate topical therapy.
- NTG comes as a 2% ointment with applicator dose sheets. There is approximately 15 mg NTG per inch of ointment, but the dose depends also on the surface area covered.
- The approximate canine dose (from toy breed to giant breed) $^1/_2$ to 2 inches, cutaneously, q12–24h.
- Alternative approaches include the use of nitrate patches (5, 10 mg) that are removed after 12 hours to provide a nitrate-free interval.

Adverse Effects

Adverse effects of NTG are apparently few, though potentially a reduced preload could lead to a lower cardiac output.

Sodium Nitroprusside

Sodium nitroprusside (Nipride) is a potent dilator of both systemic arterial and venous smooth muscle (generating NO in vascular smooth muscle). Benefits of therapy are rapid reduction in ABP and venous pressures (from venous pooling) with reduced mitral regurgitation fraction, decreased LV afterload (increasing forward flow), and less pulmonary edema.

- *Indications* for nitroprusside are hospital treatment of life-threatening pulmonary edema and severely reduced cardiac output when caused by cardiomyopathy or mitral valvular disease, as well as in the emergent treatment of systemic hypertension. In addition, controlled hypotension during surgery of patent ductus arteriosus or certain brain lesions may be accomplished by nitroprusside infusion.
- Therapy with sodium nitroprusside is usually prompted when initial doses of furosemide and nitroglycerin fail to provide relief from pulmonary edema, or when pulmonary edema is so fulminant that the patient is expectorating bloody froth or the chest x-ray demonstrates a "white lung" or "white-out."
- When used in the setting of pre-existing systemic hypotension, dobutamine (or dopamine) should be infused simultaneously to increase cardiac output and prevent further lowering of blood pressure.
- Nitroprusside may increase intracranial pressure. Therefore, it should not be used for the management of hypertensive encephalopathy.
- Nitroprusside must be given IV, and it is important to follow instructions regarding drug preparation and delivery (read the insert).
- For CHF, initial nitroprusside doses of 0.5 to 2.5 mcg/kg/min are generally well tolerated and the infusion rate can be increased to 5 mcg/kg/min (or higher) if necessary. However, doses > 5 mcg/kg/min are uncommonly required for dogs with only CHF. Titrate the dosage to a systolic ABP of 85 to 100 mm Hg, and avoid use for more than 48 hours.
- Wean the patient from the drug over a 4 to 6 hour period.
- Owing to the risk of hypotension, frequent monitoring of ABP is important when using this drug. An automated, ABP monitor can track the trends.

Adverse Effects

The most common *adverse effects* are related to hypotension, which is readily controlled by stopping or reducing the drip. After 24 to 48 hours of therapy, additional adverse effects including cyanide accumulation and toxicosis become a concern.

Sildenafil

Sildenafil (Viagra) is an inhibitor of phosphodiesterase-5 and demonstrates pulmonary arterial, as well as selective systemic arterial vasodilation. The mechanism of action is reduced degradation of cyclic GMP, the intracellular mediator of nitric oxide.

- The drug has been used effectively in some in human patients with pulmonary hypertension, and empiric use of the drug in canine pulmonary hypertension has been communicated using typical starting doses of 0.5 to 1 mg/kg, PO two to three times daily. Higher doses (2–3 mg/kg PO q8h) may be tolerated and are often required to reduce pulmonary vascular resistance.
- The drug is expensive and clinical trial data in animals are lacking.
- *Indications* for sildenafil are evolving but include the treatment of dogs with right-sided CHF and documented pulmonary hypertension (based on Doppler echocardiography or cardiac catheterization). Heartworm infected dogs with right-sided CHF or profound pulmonary hypertensive disease also might benefit, particularly during the adulticide treatment interval. Another indication for sildenafil may be management of pulmonary hypertension associated with congenital heart disease.

Adverse Effects

Adverse effects include systemic hypotension, so ABP should be monitored carefully.

Hydralazine

Hydralazine induces vasodilation in systemic arterioles, possibly by altering potassium channels in vascular smooth muscle.

- Hydralazine causes significant vasodilation within 2 hours of oral administration to dogs, usually reaching a near peak effect within 3 to 5 hours post administration.
- *Indications* for hydralazine are severe left-sided CHF in the setting of mitral regurgitation in dogs, particularly following rupture of a chorda tendineae, and in the therapy of refractory systemic hypertension in dogs or cats.
- Hydralazine is a potent arteriolar vasodilator and by decreasing systolic and diastolic ABP, left ventricular afterload decreases, mitral regurgitation decreases, and antegrade stroke volume increases. While not as potent or as rapid acting as nitroprusside, the combination of hydralazine plus nitroglycerin offers a combined vasodilator approach that is easier to deliver in the private practice setting.
- Hydralazine (Apresoline 10 and 25 mg tablets) is typically dosed at 0.5 to 2 mg/kg orally q12h. Higher doses may be tolerated. In acute CHF, the dose should be titrated to achieve a systolic ABP of 90 to 100 mm Hg.

Adverse Effects

Adverse effects of hydralazine include hypotension with reflex sinus tachycardia; anorexia; and activation of neurohormonal reflexes. The latter problem makes hydralazine a poor choice for chronic CHF therapy.

Angiotensin Converting Enzyme Inhibitors (ACEI)

The renin-angiotensin-aldosterone system (RAAS) is triggered by inadequate blood pressure, reduced renal blood flow, and sympathetic stimulation of the kidneys. RAAS activation is increased chronically in CHF and contributes to the morbidity and mortality of chronic CHF. An ACEI blocks the conversion of AT–I to AT–II by inhibiting the converting enzyme of angiotensin (a kininase). ACEIs also decrease aldosterone formation and may reduce sympathetic nervous system activity.

- The onset of vasodilation with an ACEI is not as abrupt or as marked as with IV nitroprusside or oral hydralazine; however, the ACEIs are arterial vasodilators (via inhibition of AT-II release) and also venodilators (by preventing degradation of kinins).
- Commonly used ACEIs are enalapril (veterinary products Enacard and Cardiovet), benazepril (veterinary product Fortecor; human product Lotensin), ramipril (veterinary product Vasotop, human product Altace), quinapril (Accupril), and lisinopril (Prinivil), with others available in various countries.
- Comparative ACEI trials with proven major end points (need for hospitalization, objective symptom scores, survival) are lacking in dogs and cats, making the choice of one specific ACEI over another relatively empiric and one of personal choice.
- Some ACEIs are pro-drugs and must be converted to active forms by transformation in the liver (e.g., enalapril to enalaprilat).
- Most ACEIs are eliminated by the kidney. Hepatic elimination of benazepril is a potential benefit for dogs and cats with renal failure.
- Some ACEIs may demonstrate greater cardiac tissue selectivity; however, major end-point benefits of one ACEI versus another (in terms of survival or CHF signs) have not been shown for dogs or cats.
- Principle *indications* for an ACEI include empiric cardioprotection in occult dilated cardiomyopathy (early heart failure); management of CHF; and treatment of systemic hypertension.
- Additional indications for an ACEI are treatment of renal disease with proteinuria and cardioprotection following the rare documented myocardial infarction.
- Because ACEIs may control or prevent secondary hypertrophy in models of pressure overload, there is some interest in treatment of asymptomatic ventricular hypertrophy with ACEIs; examples include subaortic stenosis, pulmonic stenosis, and hypertrophic cardiomyopathy. However, these uses currently are speculative, and ACEI treatment is generally limited to management of incipient or established CHF in these conditions.
- The use of ACEIs in dogs and in cats with CHF is discussed below.
- Management of *systemic hypertension* using ACEIs is well established in both dogs and in cats.
- ACEIs lower ABP and partially mitigate neurohormonal activation caused by high-renin hypertension or following direct vasodilator therapy with amlodipine.
- For dogs with hypertension, an ACEI is often the first drug chosen, particularly in cases where elevated pressure is associated with glomerular disease.
- In cats, amlodipine is a more effective antihypertensive for moderate to severe hypertension, but the combination of benazepril (or another ACEI) along with amlodipine makes good sense in the cat with hypertension and renal disease.
- It should be emphasized, however, that some cats do not respond effectively to monotherapy with an ACEI and require either amlodipine or a beta-blocker to achieve effective blood pressure control (for details, see Chapter 153).

ACE-Inhibitors for Heart Failure in Dogs

As a group, the ACEIs are helpful for long-term management of canine heart failure, increasing survival, and reducing clinical signs of CHF.

- In dogs with acute CHF, therapy with an ACEI is generally initiated following initial diuresis or at the time of release from the hospital.
- The combination of an ACEI, furosemide, spironolactone, and a positive inotropic drug (digoxin or pimobendan) represents the main treatment approach for chronic CHF in dogs.
- The use of an ACEI in dogs with asymptomatic heart disease is less defined.
- Current data (from three studies) indicate no clear benefit in the early use of ACEI in asymptomatic canine mitral valve disease in small-breed dogs. However, many cardiologists empirically initiate ACEI therapy once interval changes demonstrating progressive cardiomegaly are demonstrated by radiography or echocardiography.
- In contrast to degenerative mitral valve disease in small-breed dogs, most cardiologists do start empiric ACEI treatment (often with a beta-blocker) in dogs with proven occult dilated cardiomyopathy, which represents an early form of heart failure. A similar approach is taken in larger sized dogs with chronic mitral regurgitation and echocardiographic evidence of LV systolic dysfunction.
- Dosing for enalapril (Enacard), benazepril (Fortecor), and lisinopril is initially 0.5 mg/kg PO once daily and for ramipril (Vasotop), 0.125 mg/kg per day.
- In moderate to severe CHF, increasing the dosage of enalapril or benazepril to twice daily is recommended after one or two weeks of therapy.
- Under-dosing may reduce overall benefit of ACEI, as the effect is probably dose-related.

ACE-Inhibitors for Heart Failure in Cats

While there are no published, placebo-controlled trials of ACEIs in cats, both benazepril and enalapril appear useful clinically in management of feline CHF.

- Regardless of cause, the combination of furosemide and an ACEI is the current mainstay of therapy for CHF in cats as supported by a recent controlled clinical trial.
- Whether or not the angiotensin inhibitors can reduce myocardial hypertrophy in cats with primary cardiomyopathies is unknown, but there is no hard evidence for this. Therefore, empiric therapy with an ACEI in cats with cardiomyopathy is not recommended by us until there is LA dilation or convincing Doppler evidence of elevated LA pressure (both of which suggest impeding CHF).
- Reducing ABP in cats with asymptomatic HOCM is a potential concern, but treatment with an ACEI does not appear to worsen dynamic LVOT obstruction.
- The usual dosage of enalapril or benazepril in cats is 0.25 to 0.5 mg/kg q24h, but in advanced disease, it can be given bid.

Monitoring ACEI Therapy

ACEI therapy is monitored by measuring ABP and with periodic monitoring of renal function, serum sodium, and potassium.

- Consider published dosing guidelines when prescribing.
- Measure ABP at each visit (target range is a systolic pressure of 90–120 mm Hg).
- Follow renal function (BUN/creatinine), serum sodium, and potassium; measure these within 7 to 14 days of initiating therapy or after changing the dosage.
- Mild hyperkalemia is not an indication to discontinue therapy.

Adverse Effects

- Adverse effects of an ACEI are generally related to effects on blood pressure, intra-renal hemodynamics, and serum electrolytes. Combination of an ACEI with aspirin or a diuretic increases the likelihood of renal failure.
- Volume depletion superimposed on dilatation of the efferent arteriole in the glomerulus can lead to reversible renal failure, which can be acute in the occasional case. In most cases, mild to moderate azotemia develops.
- Therapy of ACEI-induced renal failure includes reducing the doses of diuretic and ACEI and administering fluid therapy judiciously. If systolic blood pressure is < 85 mm Hg, or if BUN/creatinine increase by 2 to 3 times over pretreatment levels, the dose of the ACEI, furosemide, or both, should be reduced by 33% to 50%.
- Some patients are seemingly dependent on angiotensin-II effects for maintaining glomerular filtration pressure, and these patients may not tolerate any dose of an ACEI. Such cases are unusual in dogs.
- Mild hyperkalemia is more likely in patients receiving spironolactone concurrently. Provided the potassium is < 6 mmol/L, the situation is not of great concern. Clients should be instructed to avoid potassium supplements.

BETA-ADRENERGIC BLOCKERS

Overview

The heart contains a rich supply of $beta_1$ receptors and a smaller number of $beta_2$ receptors. Stimulation of cardiac beta-receptors increases heart rate (chronotropy), contractility (inotropy), relaxation (lusitropy), conduction velocity (dromotropy), and subsidiary pacemaker excitability (bathmotropy). Blood vessels contain a

number of extrasynaptic beta$_2$ receptors; when stimulated the vessel undergoes vasodilation.

Beta-adrenergic blockers (beta-blockers) diminish each of the above effects of sympathetic stimulation on target organs. Beneficial and adverse effects of beta-blockade are readily understood by simply "reversing" the physiologic effects of beta-receptor stimulation.

When beta-receptors are chronically blocked the number of beta-receptors increases. This change explains some of the benefits of long-term beta-blockade in heart failure. Conversely, sudden withdrawal of beta-blocker therapy may expose the heart to excessive stimulation from catecholamines.

Treatment with a beta-blocker prolongs diastole as a function of a slower heart rate. This allows more time for ventricular and coronary arterial filling.

Beta blockers initially decrease resting cardiac output by about 10% to 20%, causing a compensatory reflex rise in the peripheral vascular resistance so that ABP is largely unchanged. Vascular resistance and ABP begin to fall 1 to 2 days after initiation of therapy. The overall effects of beta-blockers on blood pressure are complex, but in general ABP decreases.

There is a *reduction of myocardial oxygen demand* following beta-blockade, reducing so-called "demand ischemia." Beta-blockers reduce the myocardial oxygen imbalance (relative to the delivery of oxygen) that develops in hypertrophied hearts with sympathetically mediated tachycardia, hyper-contractility, or elevated blood pressure.

The net effect of beta-blockers on *diastolic function* of the heart, especially in cats with HCM or dogs with subaortic stenosis, is unknown. Beta stimulation improves relaxation (lusitropy) in healthy cardiac muscle and also in some canine models of cardiac disease; accordingly beta-blockers should not directly improve myocardial relaxation. However, indirect effects of beta-blockers, especially slowing of heart rate and reduction of myocardial oxygen demand, may be beneficial to diastolic function. Furthermore, in some studies beta-blockade has been shown to reduce diastolic calcium leakage from the sarcoplasmatic reticulum in cardiomyopathic hearts, reduce diastolic calcium overload, and improve ventricular relaxation.

The beta-blockers used in veterinary practice can be classified as first generation (non-selective beta-blockers such as propranolol); second generation (selective beta$_1$-blockers such as metoprolol and atenolol); and third generation blockers such as carvedilol (with alpha-adrenergic blocking effects and anti-oxidant properties).

Most beta-blockers are lipophilic, cross the blood-brain barrier, and are eliminated by the liver. Those beta-blockers that cross the blood-brain barrier may be more beneficial in prevention of sudden cardiac death. Compared to other beta-blockers, atenolol, sotalol, and nadolol are different, with hydrophilic nature and renal elimination.

Indications and Clinical Uses of Beta-Blocker Therapy

There are a number of indications and uses for beta-blockers in small animal practice. While most of the drugs in this class may be substituted for each other on a pharmacologic basis, clinical experience and limited research studies offer guidelines for the use of specific beta-blockers in certain situations. Some of the most common disorders treated with beta-blockers are indicated below.

Cardioprotection in cardiomyopathies, chronic heart failure, and with congenital heart defects

- Long term use of beta-blockers in *heart failure* can retard the progress of myocardial failure; support ventricular ejection fraction; reverse cardiac remodeling; and prevent sudden cardiac death in experimental canine models similar to spontaneous DCM. A variety of mechanisms have been proposed for this benefit, but the major effect is believed to be reduction in catecholamine injury to the heart and prevention of sympathetic-induced ventricular arrhythmias.
- While the precise value of beta-blockade in chronic canine cardiomyopathy or chronic valvular heart disease is under study, increasingly, cardiologists prescribe beta-blockers as "cardioprotection" against the injurious effects of the sympathetic nervous system on heart muscle.
- A beta-blocker is indicated in the dog with discovered, well-documented, "occult" dilated cardiomyopathy; such patients generally tolerate beta-blockers well.
- It is more difficult to initiate beta-blocker therapy in the dog with established CHF, largely because of the advanced state of heart failure observed in most canine patients. In addition, the available dosing forms of human drugs pose a limiting factor, since very small dosages must first be given.

▼ ***Key Point*** Since beta-blockers are *potent* negative inotropic drugs, never begin therapy until CHF is well controlled with diuretics and ACEI.

- In dogs that have received long-term beta-blockade, the eventual development of CHF should prompt a reduction, but not discontinuation, of the dose. Typically a 25% to 50% dose reduction is undertaken, and CHF is controlled with diuretics, ACEI, and inotropic drugs.
- Dogs with CHF caused by aortic or pulmonic stenosis may become dependent on heart rate to maintain cardiac output in the setting of a fixed obstruction. In these patients, the beta-blocker dose should be reduced to permit an examination heart rate of at least 100 to 120/min.
- While any beta-blockers could theoretically benefit the failing heart, *carvedilol and long-acting metoprolol*

are the beta-blockers most often used for cardioprotection in cases of dilated cardiomyopathy or chronic valvular disease in dogs (see below).

- Beta-Blockers also may confer cardioprotection in hypertrophic hearts *prior* to the onset of ventricular failure. One possible mechanism is *reduction of myocardial oxygen demand*, especially in times of exercise or stress. *Atenolol and propranolol* are most commonly used for cardioprotection in HCM and in concentrically hypertrophied hearts related to congenital heart disease.
  - Reduction of myocardial oxygen demand may be especially beneficial in diseases where "demand ischemia" develops during tachycardia; for example, with HCM and congenital heart diseases characterized by concentric ventricular hypertrophy.
  - The benefit of beta-blockers in long-term management of feline HCM has not been confirmed; nevertheless, atenolol is often used for cardioprotection and to reduce dynamic outflow obstruction.
- In *congenital subaortic stenosis* beta-blockers are cardioprotective and recent reports suggest that survival is prolonged in cases of severe SAS compared to untreated dogs. Presumably a similar benefit would be observed in severe pulmonic stenosis, but this has not been verified.
- In *congenital pulmonic stenosis* and in *tetralogy of Fallot*, beta-blockers decrease dynamic right ventricular outflow obstruction caused by hypercontractility of thickened myocardium.
  - Benefit also may be observed following balloon valvuloplasty wherein RV shortening might increase due to the sudden drop in afterload.
  - *Propranolol and atenolol* are the beta-blockers most commonly used for reducing RV dynamic outflow obstruction.
- Beta-Blockers *reduce dynamic left ventricular outflow obstruction*, including that associated with mitral-septal contact in cats and dogs with hypertrophic obstructive cardiomyopathy, with reduced LV cavity size, and associated with mitral valve malformation.
  - This benefit is attained by reducing the rate of myocardial contraction, especially under circumstances of heightened sympathetic tone, and delaying the onset of systolic anterior motion of the mitral valve.
  - *Atenolol* is most commonly used for reducing LV dynamic outflow obstruction.
- The beta-blockers are considered "broad-spectrum" *anti-arrhythmic drugs*.
  - Atrial and ventricular ectopic beats may be suppressed by effects on automaticity of fibers and reduction of sympathetically mediated calcium influx. Beta-Blockers are used often as co-therapy with another anti-arrhythmic drug such as mexiletine or digoxin.
  - In atrial tachyarrhythmias, such as atrial fibrillation, beta-blockers reduce ventricular response rate, especially when combined with digoxin or diltiazem. This effect is achieved by reducing conduction velocity across the AV node.
- Sinus tachycardia is blunted by beta-blockade, an effect that may be beneficial in feline HCM; congenital mitral stenosis; in thyrotoxicosis; pheochromocytoma; and in certain toxicities (cocaine, caffeine, chocolate).

The choice of beta-blocker varies:

- *Esmolol*, *propranolol*, and (in some countries) *sotalol* are available for IV use when needed.
- *Sotalol* is the most potent beta-blocker used for arrhythmia control.
- *Atenolol* is used more often as co-therapy with other anti-arrhythmic drugs, or as monotherapy when supression of frequent single premature complexes is a goal.
- *Atenolol and carvedilol* are most often used in control of heat rate in patients with atrial fibrillation.
- In *hyperthyroidism*, elevated sympathetic tone is a factor in the systemic clinical signs and in the cardiotoxicity of the condition; beta-blockers attenuate this effect. *Atenolol* is most commonly used for this purpose.
- Beta-Blockers are effective drugs for co-therapy of *systemic hypertension* and can be used with calcium channel blockers or ACEI. Blood pressure is reduced by effects on lowering heart rate and stroke volume, decreasing cardiac output, and possibly by central effects and reduction of beta-receptor mediated renin release. *Atenolol and carvedilol* are especially appropriate for this use.
- In *pheochromocytoma*, control of hypertension should begin with an alpha-blocker (phenoxybenzamine or prazosin); subsequently, as blood pressure falls, a beta-blocker can be added for heart rate and rhythm control. *Propranolol* is most often used for this purpose.
- In reflex mediated (vasovagal, neurocardiogenic) syncope, beta-blockers reduce the stimulation of ventricular mechanoreceptors, an effect that may blunt the resultant reflex bradycardia and vasodilation.

Contraindications for Beta-Blocker Therapy

- *Untreated CHF*, as inotropy and heart rate initially are depressed (don't give beta-blockers to "wet" patients).
- *Systemic hypotension*, as reduction of heart rate and contractility will worsen the situation.
- *Bradyarrhythmias* including sinus bradycardia, sinus node disease (sick sinus syndrome), and atrioventricular block, as beta-blockade suppresses nodal function.
- When long-cardiac cycles or slowing of the heart rate triggers ventricular ectopy (e.g., in the inherited ventricular tachycardia of German shepherd dogs).

- *Peripheral vascular disease* and *arterial thromboembolism*, especially the non-selective beta-blockers, because $beta_2$ blockade may lead to vasoconstriction.
- *Bronchial disease* and particularly reactive airway disease (*asthma*), as $beta_2$-blockade may promote bronchoconstriction.
- *Insulin-dependent diabetes mellitus*, because the sympathomimetic signs of hypoglycemia may be masked and therefore ignored.
- *Relative drug contraindications* are many, but include:
  - When a beta-blocker is combined with digoxin or diltiazem, as all three drugs suppress SA and AV nodal function.
  - When a beta-blocker is combined with diltiazem or class IA or class III anti-arrhythmics, as these drugs are all negative inotropic drugs.
  - When a beta-blocker is on board or administered during general anesthesia owing to depression of heart rate and myocardial function (in cases of long-standing beta-blocker therapy, the perioperative dose is reduced, but the drug is not stopped).
  - Use of a water-soluble beta-blocker, such as atenolol or sotalol, in patients with renal failure.

Clinical Pharmacology of Specific Beta-Blockers

There are a large number of beta-blockers available for hospital use or extra-label prescription. The drugs most often used in small animal practice are briefly described below, along with guidelines for choosing effective doses.

Propranolol

- *Propranolol* is a first generation, lipophilic, non-selective beta-blocker that is convenient to use in terms of dosing size (10-mg tablets that can be quartered) but not in terms of dosing frequency (tid is needed).
- Propranolol has more "inverse agonism" than other beta-blockers and this leads to greater depression of myocardial contractility. Therefore, it is not an optimal drug for use in patients with CHF.
- This non-selective, marked negative inotropic effect is useful in treatment of tetralogy of Fallot or in pulmonic stenosis wherein hyperdynamic RV contraction may contribute to outflow tract obstruction and to exercise-induced cyanotic spells. In addition, propranolol may help to control right-to-left shunting by blunting $beta_2$-dependent vasodilation that occurs with exercise.
- Usual dosing in non-CHF patients is approximately 0.5 to 1 mg/kg PO q8h.
- Propranolol can be used to up-titrate other beta-blockers as the propranolol tablet size permits conservative dosing while allowing the patient to acclimate to beta-blockade. For example, very small doses of 0.05 to 0.1 mg/kg, PO, q8h can be started; this is about $^1/_4$ of a 10-mg tablet in a large breed dog.

Atenolol

- *Atenolol* is a hydrophilic $beta_1$-receptor blocker, with renal elimination. It is one of the most commonly used beta-blockers in veterinary practice with numerous clinical indications for dogs and cats (discussed above).
- Atenolol (Tenormin and generic 25-mg tablets) is readily divided into quarters of 6.25 mg.
- The tolerated dose of atenolol depends greatly on ventricular function. In the setting of myocardial dysfunction, lower doses should be used. It should be used very cautiously, if at all, in the setting of CHF.
- The value of adding atenolol in cats with CHF due to HCM appears to be unfavorable, especially in the setting of recent-onset failure.
- In cats with well-controlled CHF (receiving furosemide and an ACEI) and with moderate to severe residual outflow tract obstruction, atenolol may be added cautiously if the cat is free of pulmonary edema.
- If CHF occurs in a cat that has received long-term beta-blockade, the dose should be reduced by 25% to 50%, but atenolol should not be stopped.
- To maintain a 24-hour effect, atenolol should be given on a bid. basis.
- In cats, atenolol is dosed initially at $^1/_4$ of a 25-mg tablet PO once daily for three days, then $^1/_4$ tablet q12h. The usual dosage range in cats is $^1/_2$ tablet in the AM and $^1/_4$ to $^1/_2$ tablet in the PM. Small cats may be well maintained on $^1/_4$ tablet q12h.
- Effective dosing in cats can be estimated by the examination heart rate. After 1 to 2 weeks of regular dosing, the examination heart rate should fall between 120 and 160/min, despite the stress of the veterinary environment. Lower rates prompt dose reduction; higher rates a dosage increase.
- Additionally, in cats with HCM with dynamic LV outflow obstruction and mitral regurgitation, the intensity of the heart murmur(s) and the outflow tract velocity as measured by Doppler echocardiography should be diminished.
- In dogs, the usual dose of atenolol is 0.5 to 1 mg/kg PO once daily for 3 days and then 0.5 to 1 mg/kg PO q12h. Dogs with normal LV function may tolerate higher dosages, in the range of 1.5 mg/kg PO q12h. Examination heart rates of <80/minute may indicate excessive dosing, and the heart rate should be reassessed following mild to moderate exercise.

Metoprolol Tartrate

- *Metoprolol tartrate* is a selective ($beta_1$), lipophilic, beta-blocker that has been best studied in experimental canine studies of cardioprotection. Sold only as a human drug (Lopressor, Toprol-XL, among others),

the sustained release preparation is especially cardioprotective.
- Despite these benefits, the smallest available long-acting tablet is the scored 25-mg Toprol-XL. This makes the initial dosing and up-titration difficult in CHF.
- In asymptomatic DCM or for cardioprotection, a dose of $^1/_2$ tablet PO q12h is a reasonable initial target for a large-breed dog.

Carvedilol

- *Carvedilol* (Coreg) is a nonspecific, lipophilic beta-blocker with mild alpha-adrenergic blocking properties. Carvedilol is also a highly potent anti-oxidant. Despite the cost, Coreg is used increasingly in veterinary practice for treatment of myocardial dysfunction in dogs.
- Carvedilol is used mainly for cardioprotection in heart failure. This drug may be better tolerated than other beta-blockers because alpha-blockade causes peripheral vasodilation and reduces left ventricular afterload.
- The anti-oxidant effects of carvedilol are believed to be highly beneficial in reducing myocardial injury caused by pro-inflammatory cytokines.
- The dose of carvedilol must be up-titrated over a number of weeks to months in dogs with CHF. Initially, the patient should be under heart failure therapy and free of edema.
- The suggested starting dose of carvedilol for a large breed dog with DCM is 0.05 to 0.1 mg/kg PO q24h (about $^1/_2$ to one 3.125 mg tablet q12h). The aim is to increase the dosage every 2 to 4 weeks provided the drug is tolerated (no worsening of CHF, not too lethargic, examination HR is >90/min and systolic ABP is >90 mmHg).
- As the dosage is increased larger tablets (6.25 mg, 12.5 mg) can be used.
- Heart rate may be a reasonable guide to an upper dosage with an arbitrary examination HR target of between 90 and 120/min for dogs in sinus rhythm.
- Should fluid retention worsen, the daily dosage must be lowered. Unfortunately, some dogs have difficulty tolerating even the lowest dosages of carvedilol and the drug must be discontinued.

Esmolol

- *Esmolol* (Brevibloc) is an ultrashort-acting, nonspecific beta-blocker available for IV use. The main value of esmolol relates to its short duration of action, as the drug is rapidly hydrolyzed by plasma esterases.
- Esmolol may be useful for patients requiring rapid intravenous control of arrhythmias; a brief infusion allows one to judge the efficacy and tolerability of the drug in that patient.
- Duration of action is typically less than 10 minutes after dosing.
- Dosing depends in part on ventricular function. If systolic function is normal, an initial 500 mcg (0.5 mg) per kg loading dose that can be administered over 1 to 5 min (use the longer interval in anesthetized animals). This is followed by a 50 to 150 mcg/kg/min constant rate infusion. ABP should be monitored during treatment.

Sotalol

- *Sotalol* is a beta-blocker with prominent Class III anti-arrhythmic effects. This drug is discussed under "Anti-arrhythmic Drugs."

Adverse Effects of Beta-Blockers

Toxicity of beta-blocker therapy is associated with the listed relatively predictable, anti-sympathetic effects. Treatment involves lowering the dose in most cases. Sudden withdrawal in cases of long-term therapy can be dangerous because beta-blockade allows up-regulation of beta-receptors. Bradycardia and cardiac depression can generally be overcome by administration of atropine or infusion of dopamine. If this fails, an alpha-adrenergic agonist (phenylephrine) can be used to raise ABP. Reversal of refractory cardiac depression also can be achieved with drugs that bypass the beta-receptor. Although glucagon has been suggested, the use of a PDE inhibitor like milrinone or a calcium sensitizer such as pimobendan (beware of vasodilator effects) may be better.

- Symptomatic hypotension with lethargy and depression
- Sinus bradycardia (examination HR < 120/min in cats; < 60/min in dogs)
- Reduced myocardial contractility
- Progressive cardiac chamber dilatation (including left atrial enlargement)
- Prolongation of the P-R interval on the ECG and AV blocks
- Precipitation of CHF
- Cough from bronchoconstriction following block of $beta_2$-receptors (mainly in cats)

CALCIUM-CHANNEL BLOCKERS

Overview

Calcium channels are critical to function of cardiac and vascular smooth muscle. Sinus and AV nodal cells are dependent on calcium-mediated depolarization. Calcium ions cross the cell membrane across calcium channels in the form of "slow current." Thus, pacemaker function and atrioventricular conduction are tied to calcium entry into these specialized cells. Calcium entry into cardiac and vascular myocytes triggers the intracellular release of stored calcium from the

sarcoplasmic reticulum. This event leads to muscle contraction or vasoconstriction.

The calcium channels are modulated by a number of receptors including the beta- and alpha-receptors in heart muscle and the alpha-receptor and angiotensin II receptor in vascular smooth muscle. Each of these receptors increases current flow across the calcium channel.

A calcium channel blocker (CCB) binds to L-type, voltage-dependent calcium channels and inhibits the entry and physiologic effects of calcium in cardiac and vascular cells.

The effects of CCB are predictable based on the mechanism of action:

- In general, the CCBs exert negative inotropic, chronotropic, and dromotropic (conductive) effects.
- Vascular smooth muscle is relaxed by CCBs, leading to peripheral vasodilation and coronary vasodilation.
- In some cases, peripheral effects will activate a baroreceptor reflex in response to lowered blood pressure. This may increase sympathetic tone to the heart, leading to indirect cardiac effects (that may in part be blunted by *direct* effects of the CCB on rate, contractility, and conduction).
- Therapy with CCBs often results in cardiac effects that are similar to those of beta-blockers; however, the CCBs are not considered cardioprotective in the same manner as beta-blockers.
- Different CCBs have varying degrees of vascular selectivity. Of the two most commonly used CCBs in veterinary medicine, the dihydropyridine CCB amlodipine has high vascular selectivity and is used mainly as a vasodilator drug. In contrast, diltiazem affects the heart and cardiac nodal tissues as well as effecting vasodilation. Diltiazem is used mainly for its effects on the heart.

Indications for Calcium Channel Blockers

Amlodipine

- *Amlodipine* is used exclusively as a vasodilator drug in veterinary small animal practice.
- As a potent, dose-dependent arterial vasodilator, amlodipine is useful in treating both cats and dogs with *systemic hypertension.*
- Amlodipine is also beneficial in advanced management of CHF due to mitral regurgitation, particularly when further ABP and afterload reduction are needed beyond that offered by an ACEI and diuretic. This situation may be encountered in end-stage CHF or when heart disease is complicated by systemic hypertension.

Diltiazem

- *Diltiazem* is used for two main purposes in small animal patients.
- Diltiazem is an effective *anti-arrhythmic drug* in the management of supraventricular arrhythmias. In particular, diltiazem is useful in treatment of *supraventricular* tachycardias.
- Diltiazem blocks AV nodal conduction and helps to control the ventricular response rate in *ectopic atrial tachycardia*, *atrial flutter,* and *atrial fibrillation* (usually as co-therapy with digoxin and possibly a beta-blocker). Compared to beta-blockers, diltiazem often provides better heart rate control and is less likely to exacerbate CHF but does not confer the same degree of cardioprotection against progressive myocardial disease.
- In atrial fibrillation/flutter of recent onset, IV administration of diltiazem controls ventricular response rate acutely and may also convert some patients back to normal sinus rhythm.
- When used to treat regular *supraventricular tachycardias*, diltiazem may break an orthodromic, re-entrant tachycardia that is AV nodal dependent. This situation develops when there is a functional accessory AV pathway (as in Wolff-Parkinson-White type syndrome).

▼ ***Key Point*** Diltiazem is a drug of choice for management of supraventricular tachycardias in dogs and in cats.

- Diltiazem may improve *ventricular filling* in cats with HCM.
- Diltiazem slows heart rate increasing filling time.
- Relaxation may improve (a positive lusitropic effect). Possible mechanisms for this benefit might include reflex activation of the sympathetic nervous system (in response to CCB induced vasodilation); improved coronary circulation; or other direct effects on calcium uptake into the sarcoplasmic reticulum.
- Although the chronic administration of diltiazem has been reported to decrease LV hypertrophy in cats with *very severe* HCM, initial enthusiasm for obtaining regression has been lost, and it is rare to observe regression of hypertrophy even with prolonged therapy.
- Diltiazem may exert an anti-platelet effect in cats; the clinical relevance of this is undetermined.

Contraindications for Calcium Channel Blockers

- Uncontrolled CHF, especially with diltiazem, owing to the negative inotropic and chronotropic effects.
- Systemic hypotension, with any CCB, as additional vasodilation will further lower ABP.
- Bradycardias, sinus node disease, and atrioventricular blocks, as CCB, especially diltiazem, will suppress nodal function.
- For amlodipine, the presence of tachyarrhythmias, as vasodilation may trigger a baroreceptor reflex with increased sympathetic traffic to the heart.

- Digitalis intoxication, as further block of the AV node may develop.

Clinical Use of Calcium Channel Blockers

Amlodipine

- Amlodipine (Norvasc) is a human drug commonly prescribed in extra-label treatment of hypertension in cats and dogs. Amlodipine is also used in advanced canine CHF as an afterload reducer. As the elimination half-life of this drug is long (about 24 hours in dogs), it may take a week to identify maximal benefit or side effects of therapy.
- The *anti-hypertensive effect* of amlodipine (Norvasc) is well established, and at usual feline dosages of $^1/_4$ to $^1/_2$ of a 2.5-mg tablet per cat, one to two times daily, ABP is often well controlled. In practice the combination of amlodipine (AM) with an ACE inhibitor (PM) is often chosen for cats with hypertension associated with renal disease.
- In dogs with hypertension, the initial starting dose is 0.05 to 0.2 mg/kg PO q12h. In dogs with refractory hypertension, the dosage may need to be much higher, up to 0.5 mg/kg PO q12h. Often amlodipine is used as co-therapy with an ACEI. This approach has merit for dogs with glomerular disease and also helps to control the high cost of Norvasc.
- In dogs with refractory CHF, amlodipine has been added to standard CHF therapy to further reduce afterload. Some dogs are better controlled when systolic ABP is maintained at approximately 90–100 mm Hg, and this level may not be achieved by ACEI alone. The doses required for this purpose are usually lower than for dogs with hypertension, and doses as low as 0.05 to 0.1 mg/kg PO once daily may improve pressure control and reduce load. The dose can be up-titrated to twice daily after a few days with strict attention to ABP.

Diltiazem

- Diltiazem (Cardizem) is the most commonly used CCB for treatment of arrhythmias and is effective for treatment of supraventricular tachycardias, including atrial fibrillation. This CCB is also used by some clinicians in the empirical management of feline HCM.
- Diltiazem is supplied as a solution for injection (5 mg/ml) and for oral use as 30- and 60-mg tablets. Sustained release diltiazem includes Dilacor, Cardizem-CD, generic diltiazem-CD, and diltiazem HCl extended release capsules.
- One also must be mindful that diltiazem is a negative inotropic drug, so the initial dose should be low and the drug dose up-titrated with attention to ABP and cardiac rhythm.
- For intravenous use, an initial bolus of 0.05 to 0.1 mg/kg, given IV over 5 to 10 minutes is appropriate for dogs and cats. Doses can be repeated every 15 to 30 minutes to a *cumulative dose* of 0.3 to 0.5 mg/kg, provided systolic ABP is >90 mm Hg.
- In *atrial fibrillation*, heart rate control can be gained by up-titration of the oral dosage.
- For initial oral therapy, 0.5 mg/kg q8h is appropriate. Provided CHF is under control, the dose of diltiazem can be rapidly increased (increasing each successive dose by about 0.25 mg/kg) to a target of about 1.5 mg/kg PO, q8h.
- Some patients require even higher doses (up to 2 mg/kg q8h, or greater), but care must be taken to prevent hypotension or excessive myocardial depression, particularly in the setting of CHF.
- The optimal target examination heart rate response in atrial fibrillation is between 100 and 150/min during clinical examination (or ECG).
- An alternative to three times daily dosing with standard diltiazem is twice daily treatment with a long-acting diltiazem preparation such as Cardizem-CD or Dilacor. These sustained release drugs may be compounded. Dilacor comes in tablet form (within a capsule that is readily opened), and can be cut in half. The same total daily dose of diltiazem should be given but now in two divided doses. The effects of breaking tablets on long-acting drug effects is uncertain.
- In cats under therapy for HCM, the usual dose of standard diltiazem is 7.5 mg ($^1/_4$ of a 30-mg tablet), PO q8h. This dosing interval is generally impractical for cat owners, and an alternative approach is to administer Dilacor, $^1/_2$ of a 60-mg tablet, once daily. Some clinicians use this drug on a bid. basis in cats, but there is a higher incidence of adverse effects. Cardizem-CD can be compounded into a palatable syrup, starting at 30-mg per cat once daily. However, preliminary pharmacokinetic studies reported a lower bioavailability and suggest the tolerated dosage might be as high as 10 mg/kg once daily. Unfortunately, detailed clinical studies with sustained release preparations are unavailable.
- Overall, diltiazem should reduce myocardial oxygen demand in HCM by decreasing contractility, blood pressure, and heart rate. (Though heart rate is less effectively controlled when compared to atenolol.)
- Effects on reducing dynamic outflow tract gradients have been disappointing at the doses commonly used. (Atenolol appears better for this purpose in HCM with obstruction.)
- Thus, the main reason to choose diltiazem therapy in cats with HCM is for potential improvement of diastolic function and for prevention or treatment of CHF in HCM.
- In a recent multicenter study of cats with recent onset CHF, the addition of diltiazem to background furosemide therapy did not provide any clear short-term benefits; however, some clinicians will establish diltiazem therapy at the time of follow-up, after initial stabilization of CHF with furosemide and an ACEI.

- As for beta-blockers, the long-term benefit of diltiazem in feline HCM has not been demonstrated.

Combined therapy of Calcium-Channel Blockers and Beta-Blockers

On occasion, the combination of a beta-blocker and a CCB will be considered. Since many of the pharmacologic effects on the heart are similar, the clinician must be mindful of adverse effects (see below).

- Diltiazem and carvedilol may be used in combination in dogs with CHF and atrial fibrillation. Initially digoxin and diltiazem are used to control heart rate; subsequently, carvedilol is up-titrated as described above. This may permit a dose reduction in diltiazem.
- Diltiazem and atenolol is sometimes considered for cats with HCM and severe dynamic LV outflow tract obstruction. This combination of drugs must be used with great care because of additive depressive effects on heart rate, AV conduction, contractility, and blood pressure.
- In patients with unresponsive hypertension, the addition of a beta-blocker (atenolol, carvedilol) to amlodipine or ACEI-amlodipine is generally well tolerated.

Adverse Effects of Calcium Channel Blockers

The adverse effects of CCB are extensions of their pharmacologic activities. Treatment involves withdrawing the drug or lowering the dose. Bradycardia and cardiac depression can generally be overcome by administration of atropine or infusion of dopamine. Hypotension from excessive vasodilation responds to infusion of an alpha-adrenergic or mixed alpha/beta agonist (phenylephrine, ephedrine, adrenaline). Calcium infusions may be beneficial but are proarrhythmic. Common adverse effects of CCB include

- Depression and weakness, usually from hypotension
- Hypotension from vasodilation or depression of cardiac output
- Worsening or precipitation of CHF from cardiac depression (reduced contractility and heart rate)
- Bradycardia from sinus or AV nodal depression (sinus bradycardia; AV block)
- Anorexia, salivation, and weight loss (cats)
- Skin reactions, including erythema and localized edema
- Constipation is often reported in human patients and may occur in some animals

ANTI-ARRHYTHMIC DRUGS

Overview

The anti-arrhythmic drugs are used to treat disorders of heart rhythm. These drugs can be classified based on their electrophysiologic characteristics (the Vaughan–Williams classification); however, this ordering is not ideal, and other schemes have been proposed.

The Vaughan-Williams classification places anti-arrhythmic drugs in one of four classes (or subclasses). As with any classification, it is limited and does not consider other potentially useful drugs with anti-arrhythmic effects. For example, the anti-cholinergic effects of atropine; the parasympathetic effects of digoxin; the delayed AV nodal conduction caused by (potassium-channel opening with) adenosine; and the membrane stabilizing effects of the magnesium salts are not included.

- *Class I* anti-arrhythmic drugs reduce the rate of Na+ influx by blocking the rapid sodium channel. These drugs generally decrease the rate of depolarization, slow conduction, and increase overall refractory period of cells; these are subdivided as follows:
  - IA (e.g., quinidine, procainamide, disopyramide) lengthen the action potential duration and the refractory period.
  - IB (e.g., lidocaine and mexiletine) shorten the action potential duration but increase the refractory period;.
  - IC (e.g., flecainide, propafenone) produces little effect on action potential duration but slows conduction.
- The *Class II* anti-arrhythmic drugs block beta adrenoceptors and decrease sinus node rate, slow AV nodal conduction, and reduce arrhythmias related to high sympathetic tone. Central effects may also be evident with some lipophilic drugs.
- The *Class III* anti-arrhythmic drugs prolong action potential duration by blocking potassium channels and also increase cell refractoriness. These include the drugs amiodarone and sotalol. These drugs generally do not change automaticity or conduction velocity.
- The *Class IV* drugs block the movement of calcium ions across the slow calcium dependent channel and include verapamil and diltiazem. Effects are a decreased heart rate, slowing of AV nodal conduction, and other less well-defined anti-arrhythmic effects.
- Effective use of any anti-arrhythmic drug depends on clinical response and experience. There is very little published information regarding anti-arrhythmic therapy of cats.

▼ ***Key Point*** Every drug used to treat arrhythmias is considered an extra-label drug use in veterinary practice, and treatment recommendations are based mainly on clinical experience with various arrhythmias.

Hypokalemia and hypomagnesemia decrease or nullify the beneficial effects of many anti-arrhythmic

drugs, especially class I agents. Electrolyte disorders can also predispose to pro-arrhythmic effects with Class IC and III agents.

The indications and drugs of choice for various arrhythmias are quite varied and are summarized in Chapter 145. Lidocaine, mexiletine, procainamide, sotalol, amiodarone, diltiazem, and the beta-blockers have been used most often in clinical practice with varying degrees of effectiveness and toxicity. Typical dosages of these drugs are summarized in Table 146-1 and "essential use" is summarized below.

Anti-arrhythmic drugs not only affect electrical activity of cardiac tissues but can also negatively reduce myocardial contractility. Additional effects may develop indirectly related to activation of the autonomic nervous system.

Aside from the beta-blockers, most anti-arrhythmic drugs demonstrate a pro-arrhythmic effect in a small percentage of patients. This and other potential adverse effects make the use of anti-arrhythmic therapy a true risk-benefit proposition.

▼ ***Key Point*** Anti-arrhythmic drugs must be used cautiously in the setting of CHF. Most anti-arrhythmic drugs are negative inotropes and are likely to worsen CHF.

Common Indications for Anti-arrhythmic Drugs

As discussed under the individual anti-arrhythmic drugs, more than one agent may be indicated for the treatment of a specific arrhythmia. Selection of one drug over another often is based on clinical experience, published trial, or simply personal preference. Some drugs are more likely to depress heart function and ABP, while others have a better adverse-risk profile. These various effects are often considerations in anti-arrhythmic drug choice. Some guidelines are indicated below:

Sinus bradycardia

- Atropine, glycopyrrolate, or catecholamines in the hospital; oral anti-cholinergic or sympathomimetic drugs can be tried for chronic oral management (cardiac pacing is better)

Supraventricular tachycardias

- Commonly used: digoxin (with CHF), diltiazem, beta-blockers
- Less often used: sotalol, amiodarone, procainamide

AV block

- Atropine or catecholamines can be tried for hospital management (cardiac pacing is preferred)

Ventricular arrhythmias

- Commonly used: lidocaine, procainamide, esmolol, magnesium salts for hospital therapy
- Commonly used: sotalol, mexiletine, beta-blockers for chronic therapy in dogs
- Less often used: procainamide, amiodarone, propafenone in dogs
- Commonly used: beta-blockers for chronic therapy in cats
- Less often used: sotalol or procainamide in cats

Arrhythmias in setting of CHF

- For atrial fibrillation, begin with digoxin and then add diltiazem; with control of CHF, a beta-blocker can be considered.
- Boxers, Doberman pinschers, and other breeds often develop CHF complicated by complex ventricular ectopy. Mexiletine or procainamide (+/– beta-blocker such as carvedilol) is most often used to control ventricular tachycardia in the CHF patient.
- Sotalol is an effective anti-arrhythmic, but demonstrates prominent beta-blocking properties, and should not be prescribed in the setting of uncontrolled CHF.
- Amiodarone is also a negative inotropic drug, but is probably preferable to sotalol in the setting of CHF and also may be better tolerated than mexiletine in some dogs.
- Mexiletine often leads to GI or neurological side effects in dogs with CHF.

The clinical pharmacology and clinical use of specific anti-arrhythmic drugs, based on the Vaughan Williams Classification (I–IV), are summarized below.

Procainamide

- Procainamide (Class IA) is a "broad–spectrum" anti-arrhythmic agent with potential value for the treatment of acute atrial fibrillation; suppression of atrial, junctional, and ventricular premature complexes; control of atrial and ventricular tachycardias; and potential suppression of AV nodal bypass tracts.
- The drug is available for injection, oral administration (capsules), and sustained release products. The short elimination half-life of 2 to 4 hours in the dog necessitates frequent administration. Limited sustained-release oral preparations of these drugs are available, allowing q6–8h oral dosing. Dosing guidelines are indicated in Table 146-1.
- Procainamide is sometimes administered to control PVC's and to maintain sinus rhythm following conversion of sustained or paroxysmal ventricular tachycardia in the dog and infrequently in the cats.
- Procainamide can be given to dogs already receiving or unresponsive to a lidocaine infusion. The drug is particularly versatile as it can be given IV, IM, or SQ, and then orally to maintain sinus rhythm.
- The long-term use of procainamide is considered in some dogs needing chronic treatment for ventricular tachycardia, though less often than for sotalol or

mexiletine. A sustained release preparation must be prescribed to maintain blood levels, and it is suggested that the drug be co-administered with a beta-adrenergic blocker unless there is CHF.

Adverse effects

- Procainamide is hypotensive when given too rapidly by intravenous bolus. This is explained by depressive effects on myocardial contractility and by peripheral vasodilation.
- As with other class IA drugs (and class III drugs), the prolongation of the action potential can serve as a proarrhythmic stimulus, worsening the ventricular rhythm.
- Atrioventricular block can occur (from the direct depressive effect on the infranodal bundle of His and bundle branches). Do not use procainamide in the setting or pre-existent AV block.
- Prolongation of the QRS and QT intervals can occur with eventual development of a polymorphic ventricular tachycardia or ventricular fibrillation (pro-arrhythmia). If the QRS complex prolongs to >25% of baseline, stop the drug and reduce the dosage.
- Procainamide can lead to lupus erythematosus in dogs and has been associated with immune mediated reactions and changes in hair color.

Lidocaine and Mexiletine

Lidocaine, mexiletine, and the rarely used tocainide (Class IB) have similar electrophysiologic properties. (Chronic tocainide use causes numerous side effects in dogs including renal failure and ocular injury; this drug should not be prescribed). Lidocaine (IV) and mexiletine (oral) are the drugs in Class IB most often administered for control of ventricular tachycardia in dogs. These drugs decrease automaticity of cardiac tissues by a class I effect (see above). Refractoriness is minimally prolonged. Lidocaine also reduces disparities in action potential duration preferentially in ischemic tissue, making it suitable for preventing re-entrant ventricular arrhythmias in the setting of myocardial ischemia. Lidocaine may also be used for acute cardioversion of atrial fibrillation into normal sinus rhythm in vagally induced atrial fibrillation.

- *Lidocaine* has a very rapid onset of action after IV administration and a terminal halflife in dogs of 0.9 hours. It is then quickly metabolized by the liver (1–3 hours). Intravenous boluses must be repeated (every 10–20 minutes) or supplemented with a constant rate IV infusion (see Table 146-1). Dosing guidelines are indicated in Table146-1.
- Effectiveness of therapy depends on the extracellular K+, which must be maintained in the normal range.
- Initial administration of lidocaine as a bolus (or loading infusion) followed by simultaneous use of smaller boluses with constant intravenous infusion is the usual method for controlling acute ventricular tachycardia in the dog. Lidocaine is relatively easy to control, and compared to other anti-arrhythmics, has minimal adverse hemodynamic effects, making it the drug of choice for hospital management of ventricular tachycardia.
- The cat is quite sensitive to the *neuroexcitatory* side effects of lidocaine, which must be given to this species slowly and at lower dosages.
- It is common for arrhythmias to become less responsive to lidocaine. This is particularly true when there is inattention to potassium (and magnesium) supplementation in hospitalized patients. When lidocaine does fail, it can be combined with procainamide if another injectable medication is required and may still provide anti-fibrillatory and analgesic effects to the patient.
- When long-term therapy is needed, lidocaine may be followed by treatment with sotalol or mexiletine and a beta-blocker.
- *Mexiletine* is used to suppress ventricular arrhythmias; unlike lidocaine, it can be given orally. The drug is often combined with a beta-blocker for chronic management of severe ventricular arrhythmias in the dog. Mexiletine can be effective but carries a higher side-effect profile than sotalol, an alternative treatment for chronic ventricular tachycardia.

Adverse effects

- CNS excitation including anxiety and twitching, often followed by depression
- Focal or generalized convulsions (control with diazepam)
- Depression of sinus or AV nodal function, particularly in the cat
- Hypotension is uncommon but can occur with too-rapid injection.
- Drug interactions
- Both propranolol and cimetidine reduce liver blood flow and delay excretion of lidocaine and mexiletine.
- CHF, hypotension, and halothane anesthesia may reduce lidocaine clearance and require lower dosages to prevent toxicity.

Beta-Adrenergic Blockers

Indications, contraindications, and clinical pharmacology of the beta-blockers (Class II) have been described previously. Sotalol is a beta-blocker with powerful Class III effects and is described below. The beta-blockers are "broad spectrum" anti-arrhythmic drugs, and key points regarding arrhythmia control of these drugs are summarized below:

- Treatment of severe sinus tachycardia in drug toxicities or hyperthyroidism.
- Suppression of atrial premature complexes and some atrial tachycardias.

- Depression of AV nodal conduction, decreasing the ventricular rate response to atrial flutter/fibrillation.
- Used as monotherapy to control isolated ventricular PVCs or combination with a Class I anti-arrhythmic drug for management of ventricular tachycardia or complex ventricular rhythms.
- Ultra-short acting IV beta blockade (esmolol) or graded IV doses (propranolol) can be used to control ventricular arrhythmias in the critical care setting (following trials of lidocaine and procainamide).
- Oral administration of a beta-blocker (atenolol, metoprolol, or propranolol) may be useful for long-term therapy of PVCs.
- Adverse effects have been discussed previously. Of highest importance is the negative inotropic effect of beta-blockers in the setting of uncontrolled CHF or hypotension.

Sotalol and Amiodarone

Sotalol and amiodarone (Class III) prolong the action potential duration by blocking potassium channels and also exert beta-blockers effects (sotalol > amiodarone).

- The principal indications for these agents are life-threatening or refractory ventricular arrhythmias.
- Class III drugs, particularly amiodarone, also have been used to prevent recurrence of atrial fibrillation in dogs following successful electrical cardioversion. Conversion of atrial fibrillation to sinus rhythm is possible, but relatively uncommon with either drug.
- *Sotalol* is the drug of choice for many clinicians for the long-term treatment of malignant ventricular arrhythmias. It is eliminated by the kidneys. In dogs peak plasma concentrations are attained within 2 hours. Oral dosages of 1 to 2 mg/kg q12h are well tolerated in dogs with normal ventricular function. Sotalol has been used occasionally in cats. Malignant ventricular arrhythmias can be exacerbated by hypokalemia in sotalol-treated patients.
- *Amiodarone* is a complicated drug (exhibiting varying degrees of class I, II, III, and IV activities) and considered an effective anti-arrhythmic drug with a prolonged duration of action (days) and an extremely long elimination half-life and hepatic metabolism.
- Bretylium and ibutilide are other drugs with class III properties. Bretylium tosylate is used in humans for prevention of ventricular fibrillation. Ibutilide has been used in people to rapidly convert atrial fibrillation to normal sinus rhythm; use in animals has been limited mainly to experimental models.

Adverse effects

- Amiodarone has an arm's length of side effects associated with chronic use, including impaired thyroid dysfunction, hepatotoxicity, neutropenia, corneal microdeposits, and potentially fibrosis of the lung. Lower dosages may be safer.
- Both sotalol and amiodarone depress myocardial contractility so use these drugs in CHF with caution. Sotalol in particular should be avoided in the setting of CHF or pronounced myocardial dysfunction. Amiodarone appears better tolerated in dogs with CHF.
- Lengthening of the QT interval from prolongation of the action potential duration offers both anti-arrhythmic benefit and proarrhythmic risk with all Class III drugs. A highly malignant form of polymorphic ventricular tachycardia (of the torsade de pointes variety) may develop.

Calcium Channel Blockers (Diltiazem)

The calcium channel blockers (Class IV) have been discussed previously. Diltiazem and the prototype drug verapamil block the L-type calcium channel and alter membrane responsiveness of SA and AV nodal cells, as these are highly dependent on slow (calcium) current for depolarization. The following comments pertain mainly to anti-arrhythmic effects of these drugs.

- Diltiazem is the CCB most often used in dogs and in cats with supraventricular tachyarrhythmias. Diltiazem has profoundly depressant effects on AV nodal conduction and therefore slows the ventricular response rate to ectopic atrial tachycardia, atrial flutter, and atrial fibrillation. This effect is typically greater than for beta-blockers at equivalent negative inotropic doses. Infrequently CCB therapy leads to conversion to sinus rhythm.
- Calcium channel blockers are also useful for supraventricular tachycardias that use the AV node as part of the re-entrant tachycardia circuit. By blocking the orthodromic (downward) path of current, the electrical circuit is abolished and sinus rhythm may resume.

Adverse Effects

Adverse effects have been described previously.

- Reflex sinus tachycardia, secondary to vasodilation may develop; however, diltiazem directly depresses sinoatrial nodal function so the effect may be blunted. Accordingly, a CCB should be used cautiously in sick sinus syndrome or in dogs with sinus node dysfunction.
- In the setting of pre-existent AV block, diltiazem (or verapamil) is contraindicated.

Chapter

147 Heart Failure in Dogs

John D. Bonagura / Bruce Keene

Heart failure (HF) is a state wherein the cardiac output is inadequate to meet the perfusion needs of the metabolizing tissues and exercise capacity is limited. The causes of HF in dogs are diverse, but there are stereotypical cardiovascular and systemic responses to impaired cardiac function, regardless of cause. This chapter provides a brief overview of HF; considers the causes and diagnoses of HF in dogs; and reviews treatment plans for management of the cardiac failure patient. The clinical pharmacology and pathophysiologic rationale for drugs used in treatment of HF are detailed in Chapter 146. Management of HF in cats is discussed in the chapter "Cardiomyopathy" (Chapter 150).

OVERVIEW

Heart failure is a not a specific disease but a pathophysiologic disorder. Some of the key abnormalities of this condition are summarized below, and the pathophysiologic rationale for using particular cardiovascular drugs is summarized in Chapter 146. The reader is directed to other textbooks for a detailed review of pathophysiology of HF.

- HF is triggered by a cardiac lesion (or injury) that leads to *systolic* or *diastolic dysfunction* of the heart. Decreased cardiac output and blood pressure (often called "arterial underfilling") are pivotal events that initiate the syndrome of HF.
- The decrease in blood pressure is countered by adaptations of the neuroendocrine system, kidney, heart muscle, and blood vessels.
- There is increased activity of vasoconstrictor and sodium-retaining control systems; attenuation of vasodilator and natriuretic systems; activation of fetal-gene programs within the heart; and increased activity of tissue mediators that lead to myocardial and vascular hypertrophy, fibrosis, and inflammation.
- The well-compensated cardiac patient often maintains basal (resting) cardiac output and blood pressure within the normal range. This is achieved through vasoconstriction, mild volume expansion, and redistribution of blood flow.
- Vasoconstriction is a prominent feature of HF and is mediated by sympathetic nervous system activation, the renin-angiotensin system, release of arginine vasopressin, and local endothelial mediators such as endothelin. These systems represent therapeutic targets for both current and for future drug developments.
- The excess sodium and water retention characteristic of the syndrome of congestive heart failure (CHF) is mediated by sympathetic stimulation that alters renal blood flow, the release of aldosterone and vasopressin, and inhibition of natriuretic hormones that are released from the stretched heart. The need for diuretics and dietary sodium restriction in CHF stems from activation of these compensatory responses.
- The heart itself changes in structure and function in a process called cardiac remodeling. As heart disease progresses there is increasing dependence on myocardial hypertrophy, cardiac dilatation, and heart rate to maintain cardiac output. At the same time, structural alterations in the intercellular matrix of collagen and connective tissue impair the filling and pumping functions of the myocardium. Key mediators of cardiac injury include norepinephrine, angiotensin II, aldosterone, and pro-inflammatory cytokines. The increased use of "cardioprotective" drugs in HF are aimed at blunting these mediators and the tissue damage caused by them.
- Despite the effectiveness of these combined compensations for maintaining arterial blood pressure, these systems become increasingly *maladaptive*. This concept is central to the progression and the treatment of HF.
- Compensatory mechanisms activated in advanced heart disease are so effective that clinical signs of cardiac failure may be evident only with *exercise* when pulmonary venous pressure increases and perfusion of skeletal muscles becomes limited.
- With worsening cardiac function *hemodynamic* abnormalities become prominent.
- Decreases in cardiac output, systemic arterial blood pressure (ABP), and tissue perfusion develop, accompanied by increases in systemic and pulmonary vascular resistances.

Table 147-1. OVERVIEW OF MORPHOLOGIC/ANATOMIC DIAGNOSES

Developmental disorder or malformation
Vascular change: congestion, edema, hemorrhage, thrombosis, infarction
Inflammation
Degeneration
Necrosis
Apoptosis (programmed cell death)
Hypertrophy
Neoplasia
Disruptive defects such as trauma
These lesions may be encountered in the pericardium, myocardium, endocardium-valves, conduction system, or blood vessels of the heart or circulation.

Table 147-2. OVERVIEW OF ETIOLOGIC DIAGNOSES

D = developmental disorders; degenerative lesions
A = anomalies, autonomic dysfunction, anemia
M = metabolic diseases (endocrine diseases, electrolyte disturbances, renal failure), mechanical problems (such as a foreign body)
N = neoplasia or nutritional disorder
I = infectious, inflammatory, ischemic, immune, iatrogenic and idiopathic diseases
T = tumor, trauma or toxin

- Inadequate tissue perfusion contributes to exercise intolerance, azotemia, and metabolic disturbances such metabolic acidosis.
- Elevations in pulmonary arterial, venous, and capillary hydrostatic pressures lead to clinical signs of CHF.
- While hemodynamics may explain many clinical signs, morbidity and mortality of HF are related strongly to the tissue effects of accentuated neurohormonal and cytokine activities that develop in response to the failing heart.
- Chronic therapy of CHF is aimed at modulating and countering these responses to minimize clinical signs of CHF, protect tissues, and prolong life.

ETIOLOGY

Next in this chapter we will consider the key causes of heart disease in dogs, as well as an overview of cardiac disease classification and applicable diagnostic studies. The following are salient points regarding cardiac diagnosis and the clinical workup.

Classification

Identifying the predominant form and cause of heart disease and classifying the pathophysiologic mechanism of cardiac failure allows the clinician to direct appropriate therapy and render a more accurate prognosis. Cardiac diagnoses can be classified in a number of ways.

- The *morphologic* or *anatomic* diagnosis refers to the *lesions* one might observe during gross or microscopic examination of the heart or blood vessels (Table 147-1). It is also helpful to classify CV diseases relative to the *anatomic components* of the system affected; this is often included into the anatomic diagnosis as follows: pericardial diseases; myocardial diseases; valvular and endocardial diseases; disorders of the impulse forming and conduction system (arrhythmias); and vascular diseases.
- The *etiologic* diagnosis indicates the putative *cause* of cardiovascular disease and includes genetic disorders and errors of metabolism (Table 147-2). A sub-classification of the etiologic diagnosis includes general designations of "*congenital*" heart disease and "*acquired*" heart disease.
- The *physiologic* diagnosis represents the *disruption in cardiovascular function* that results from cardiovascular disease, including the clinical signs observed in the patient. This diagnosis can be general or relatively specific. For example, contractility failure, hemodynamic overloads, diastolic failure, and arrhythmia are considered general pathophysiologic mechanisms for reduced cardiac output and heart failure. Examples of more specific cardiovascular diagnoses include syncope, valvular regurgitation, left to right shunt, and cardiac murmur (Table 147-3).

Causes

The most important causes of *canine* heart disease involve a limited number of acquired disorders and a handful of important congenital heart defects. These conditions, as well as usual diagnostic findings, are summarized in Table 147-4 and in other chapters across this section. The most important acquired cardiac disorders responsible for HF in dogs are:

- *Mitral and tricuspid valvular endocardiosis*, which is characterized by progressive and chronic atrioventricular valve degeneration often with valve prolapse and ruptured mitral valve chordae tendineae. Atrial arrhythmias, left mainstem bronchial compression, CHF, left atrial rupture, and systemic hypertension may complicate the picture.
- *Dilated cardiomyopathy*, which is a primary myocardial disorder of progressive contractility failure leading to heart failure. Often associated with cardiac arrhythmias such as atrial fibrillation and ventricular tachycardia; the condition is "idiopathic" but certainly genetically predisposed in many dogs. Sudden death is common.
- *Pericardial effusion* causing cardiac tamponade (impaired filling of the heart from compression) is under-recognized. The main causes in dogs are idio-

Table 147-3. OVERVIEW AND DEFINITION OF PHYSIOLOGIC CV DIAGNOSES

Arrhythmia (dysrhythmia)—disorder of electrical impulse formation or conduction leading to an abnormal heart rate or rhythm.
Bradyarrhythmia—a cardiac arrhythmia characterized by a slow heart rate as with sinus bradycardia, sinus arrest, atrial standstill, or atrioventricular block.
Cardiac murmur: functional—a prolonged audible vibration associated with blood flow in the heart or great vessels but unrelated to structural heart disease (also termed physiologic or innocent murmur); functional murmurs are often caused by anemia, fever, thyrotoxicosis, elevated sympathetic tone, or protracted bradycardia.
Cardiac murmur: organic—audible vibration associated with abnormal blood flow in the heart or great vessels associated with structure disease; these murmurs typically indicate pathology affecting the heart valves or a congenital shunt.
Congestive heart failure—an advanced pathophysiologic state of heart failure characterized by renal sodium retention, elevated venous pressures, and fluid accumulation in the lung, subcutaneous tissues, or body cavities.
Contractility failure—a general mechanism of ventricular dysfunction; see myocardial failure.
Diastolic heart failure (diastolic dysfunction)—impairment of ventricular diastolic filling or distensibility as with concentric hypertrophy of the ventricle or pericardial disease; the ventricle must be filled by higher than normal filling (venous and atrial) pressures.
Heart failure—a pathophysiologic state caused by systolic or diastolic failure of the heart and characterized by neurohormonal activation and inadequate cardiac output relative to exercise and tissue perfusion demands.
Hemodynamic overload—a condition characterized by increased demand on the ventricle to pump a greater stroke volume or a higher pressure than normal; typically these are subdivided into volume overloads and pressure overloads (see the following).
Hypertension—elevated systemic arterial blood pressure; in dogs systolic values exceeding 160 mm Hg are suspicious and those >180 mm Hg are considered elevated
Hypotension—reduced systemic arterial blood pressure; when systolic ABP is <90 mm Hg, clinically significant hypotension is possible.
Myocardial failure—loss of ventricular myocardial contractility leading to systolic dysfunction as with dilated cardiomyopathy or chronic volume or pressure overload.
Pressure overload—condition wherein the ventricular systolic (pumping) pressure must be higher than normal to eject the stroke volume; usually associated with hypertension or obstruction to ejection as with aortic stenosis.
Pulmonary hypertension—elevated pulmonary arterial blood pressure generally caused by left-sided heart failure, pulmonary vascular or parenchymal disease, or marked increase in pulmonary blood flow (without concomitant decline in pulmonary vascular resistance).
Shock—an acute, life-threatening disorder characterized by diminished tissue perfusion, impaired oxygen delivery, altered metabolism, and tissue injury; various causes of shock include cardiogenic shock (from profound heart failure), hypovolemic shock (from fluid loss or hemorrhage), and distributive shock (excessive vasodilation secondary to sepsis, anaphylaxis, or spinal injury).
Shunting: left-to-right—abnormal flow of blood from the systemic to the pulmonary circulation as with ventricular septal defect or patent ductus arteriosus.
Shunting: right-to-right—abnormal flow of blood from the pulmonary to the systemic circulation as with tetralogy of Fallot or PDA with elevated pulmonary vascular resistance.
Sudden cardiac death—cardiac arrest due to asystole or ventricular fibrillation.
Syncope—sudden loss of consciousness and postural tone caused by reduced cardiac output, excessive vasodilation, or both.
Systolic heart failure (systolic dysfunction)—impairment of ventricular systolic pumping that limits stroke volume and cardiac output; typical of dilated cardiomyopathy, severe valvular heart diseases, and myocardial failure due to chronic volume or pressure overloads.
Tachyarrhythmia—a cardiac arrhythmia generally characterized by a fast heart rate, as with sinus tachycardia, atrial tachycardia/flutter/fibrillation, supraventricular re-entrant tachycardia, and ventricular tachycardia.
Valvular regurgitation—incompetency or insufficiency of the valve permitting backflow of blood during systole (mitral, tricuspid valves) or diastole (aortic, pulmonic valves).
Valvular stenosis—narrowing and obstruction to flow across a valve (or adjacent tissue) during systole (aortic, pulmonic valves) or diastole (mitral, tricuspid valves).
Volume overload—condition wherein the ventricular systolic (pumping) volume is higher than normal; usually associated with a left-to-right shunt, a regurgitant heart valve, or chronic bradycardia.

pathic pericardial hemorrhage in young dogs and cardiac tumors (e.g., hemangiosarcoma, chemodectoma, and mesothelioma) in older dogs.

- *Systemic hypertension* is most often secondary to chronic glomerular or renal tubular disease, Cushing's disease, or uncommon tumors such as pheochromocytoma. Essential or idiopathic disease is also recognized. Target organs in hypertension include the brain, eyes, heart, and kidneys.
- *Pulmonary hypertension* with right-sided heart failure is most often due to the preventable disorder dirofilariasis, but also can be secondary to chronic left heart failure or severe bronchopulmonary disease; some cases are idiopathic.
- *Arrhythmias* can be recognized that are unassociated with overt structural heart disease such as cardiomyopathy. These primary disorders of electrical impulse formation or impulse conduction include sinus node dysfunction (sick sinus syndrome), lone atrial fibrillation, atrioventricular blocks, and arrhythmogenic cardiomyopathy, such as arrhythmogenic right ventricular cardiomyopathy in the Boxer or English bulldog, or sustained reentrant supraventricular tachyarrhythmias in Labrador retrievers.
- *Bacterial endocarditis* (infection of the cardiac valves) is relatively uncommon in dogs but may lead to a variable clinical syndrome that includes bacteremia, systemic inflammation (fever, leukocytosis), constitutional illness (depression, anorexia, shivering), metastatic infection (brain, kidneys, bone), immunologic phenomena (polyarthritis, glomerulonephritis), thromboembolic disease, and cardiac injury (valvular regurgitation, arrhythmias, CHF).

Table 147-4. COMMON CANINE DISEASES

Disorder	Necropsy & Echo (Anatomic Diagnosis)	Typical Clinical Problems	Etiologic diagnoses
Pericardial effusion	• Hemorrhagic effusion (esp. dogs <8 years) • Neoplastic- related effusion (esp. in dogs >8 years of age) • Infective pericarditis • Cysts • **Echo:** echo-free space around heart; +/− mass lesions	• Hypotension and sudden collapse due to cardiac tamponade • Right-sided CHF (chronic pericardial disease)	• Idiopathic bleeding (may be recurrent) • Various cardiac and heart base neoplasms: hemangiosarcoma, chemodectoma (aortic body tumor), mesothelioma, ectopic thyroid carcinoma • Infection from a migrating foreign body or from a fungus (e.g., Coccidioidomycosis)
Dilated cardiomyopathy (DCM) phenotype	• Cardiac chamber dilatation (typically left sided chambers +/− right sided) • Myocardial fibrosis; wavy fibers or fibro-fatty replacement of myocytes • **Echo:** cardiac dilatation and loss of myocardial contractility	• CHF, left sided • CHF, biventricular • Atrial fibrillation • Secondary AV valvular regurgitation • PVCs • Sudden cardiac death • Less commonly: right ventricular cardiomyopathy with right-sided CHF	• Idiopathic dilated cardiomyopathy (genetic; giant breeds and spaniels; unrelated to structural lesions of the valves, congenital malformations, or ischemia) • Cardiomyopathy of chronic volume overload (related to chronic valvular regurgitation or shunt) • Tachycardia-induced DCM • Taurine deficiency DCM (spaniels, other breeds?)
Arrhythmogenic cardiomyopathy	• As per DCM above • Myocarditis is evident histologically in some dogs • Right ventricular fibro-fatty tissue replacement (Boxers) • No lesions (functional cellular defect) in others • **Echo:** no lesions; may progress to DCM	• PVCs • Ventricular tachycardia • PACs, PAT • Atrial fibrillation • Near syncope • Syncope • Sudden cardiac death	• Genetic in a number of breeds: • German shepherd dogs (young) • Boxers (arrhythmogenic RV cardiomyopathy) • Doberman pinschers (often occult DCM) • Irish wolfhounds (often show PACs, AF) • Giant breed dogs (PACs, VPCs, AF precede DCM) • English bulldogs, Mastiffs (similar to boxers?)
Chronic mitral and tricuspid valvular regurgitation	• Valvular endocardiosis (degenerative disease) of the mitral and tricuspid valves • Chordae tendineae stretch (mitral and tricuspid valves) or rupture (mitral valve) • Left atrial tears • **Echo:** thickened valve(s); prolapse; volume overload; LV function often preserved; PH	• Systolic murmur of MR or TR • Mitral systolic click • Left bronchial compression • Left-sided or biventricular CHF • PACs; atrial fibrillation • Pulmonary hypertension • Cardiac tamponade from ruptured LA	• Genetic predisposition; typically affects older, smaller breed dogs with marked predilection for some breeds such as small breed spaniels • Premature disease in cavalier King Charles spaniel
Endocarditis	• Infection (vegetation) of the mitral or aortic valve(s) • **Echo:** valvular thickening; shaggy oscillating mass (acute, subacute BE); hyperechoic thickened valve (chronic BE); variable degrees of left-sided cardiomegaly	• Systemic inflammation: fever, systemic signs of infection, elevated WBC • Metastatic infection • Immune mediated signs such as polyarthritis • Thromboembolism • Cardiac signs: heart murmur (systolic for MV; diastolic for AV), CHF	• Bacterial infection of the heart valve
Congenital valvular diseases	• Subaortic stenosis • Mitral valve dysplasia (MV malformation; generally causes MR; rarely MS) • Pulmonic valve stenosis • Tricuspid valve dysplasia (typically causes TR; rarely tricuspid stenosis) • **Echo:** valvular (or subvalvular or supravalvular) malformation; ventricular hypertrophy (concentric or eccentric); atrial dilatation (MVD, TVD); post-stenotic dilatation (SAS, PS)	• Systolic heart murmur • Cardiac arrhythmias from progressive cardiomegaly or concurrent electrical defects (TV dysplasia) • Development of CHF in severe cases • Syncope • Sudden cardiac death (especially with outflow obstruction) • Endocarditis (SAS) • Right-to-left shunting across PFO (PS, TVD)	• Congenital VHD is presumed to be genetic in origin: • SAS: especially in golden retrievers and Newfoundland dogs with many other breeds also affected • MVD: great Danes, German shepherds, bull terriers, others • PS: Labrador retrievers, terrier breeds, bulldogs, beagles, others • TVD: Labrador retrievers, OES, large breed dogs, others

Table 147-4. COMMON CANINE DISEASES—cont'd

Disorder	Necropsy & Echo (Anatomic Diagnosis)	Typical Clinical Problems	Etiologic diagnoses
Heartworm disease (Dirofilariasis)	• Pulmonary vascular disease • Secondary right-sided cardiomegaly (cor pulmonale) • Pulmonary complications (infarction, pneumonitis, fibrosis) • **Echo:** variable findings related to severity of PH; adult parasites in TV orifice in caval syndrome	• Signs related to pulmonary disease (cough, tiring) • Right-sided cardiac dysfunction (exercise intolerance, right-sided CHF) • Caval syndrome • Glomerular disease	• *Dirofilaria immitis*—adult parasites • Pathology related to microfilaria(?) such as eosinophilic pneumonitis
PDA	• Persistently patent ductus arteriosus • Left-sided cardiomegaly • Dilated aorta and PA • **Echo:** above lesions hypertension—shunt	• Continuous heart murmur • Left-sided CHF • Atrial fibrillation • Pulmonary hypertension and shunt reversal (rare)	• PDA is presumed to be a genetic disorder affecting many canine breeds such as poodles, schnauzers, Irish setters, dachshunds numerous other breeds

Arrhythmias:
• Sinus node disease (sick sinus syndrome)
• Atrial arrhythmias (premature complexes, atrial fibrillation, atrial standstill)
• Atrioventricular (AV) blocks
• Re-entrant SVT from accessory pathway
• Ventricular arrhythmias (premature complexes, ventricular tachycardia)
	PM or Echo may demonstrate cardiac lesions but often there is no overt structural lesion	• Bradycardia
		• Tachycardia
		• Irregular heart rhythm
		• Variable heart sounds
		• Sudden pauses
		• Weakness, syncope, CHF, sudden death
			• Structural heart diseases
			  • Myocardial fibrosis
			  • Myocarditis
			  • Myocardial ischemia or infarction
			  • Degeneration of the conduction system
			• Functional electrical disorders (no obvious anatomic substrate)
			  • Autonomic nervous system imbalance
			  • Metabolic and endocrine diseases
			  • Hypoxia, anemia
			  • Drugs
			  • Extracardiac diseases: splenic, GDV, sepsis

- Malformations or *congenital heart diseases* in dogs represent about 5% to 10% of patients seen in cardiology referral practices. Congenital heart defects are recognized in most cases by detection of a murmur during the puppy vaccination sequence. Malformations are definitively diagnosed by echocardiography with Doppler studies. Optimal management should involve a clinician experienced in congenital heart disease.

The most important of the canine congenital heart defects include the following:

- *Aortic stenosis* (generally subvalvular AS)—A subvalvular narrowing of the left ventricular outflow tract, leading to pressure overload of the left ventricle. Outcomes in severe disease include exercise intolerance, syncope, sudden death, and congestive heart failure. Dogs are at higher risk for bacterial endocarditis.
- *Patent ductus arteriosus*—The persistence of the fetal ductus arteriosus leading to a left-to-right shunt and volume overload of the left ventricle. Untreated cases are likely to die from left-sided CHF.
- *Pulmonic stenosis*—A subvalvular, valvular, or supravalvular narrowing of the right ventricular outflow tract, leading to pressure overload of the right ventricle. Outcomes in severe disease include exercise intolerance, syncope, sudden death, right-to-left shunting across a septal defect or foramen ovale, and right-sided congestive heart failure.
- *Mitral valve malformation*—Dysplasia of the mitral valve that can lead to progressive left-sided volume overload, atrial fibrillation, or CHF. Rarely the lesion causes mitral stenosis.
- *Tricuspid valve malformation*—Dysplasia of the tricuspid valve that can lead to progressive right-sided volume overload, atrial fibrillation, or right-sided CHF. Rarely, the lesion causes tricuspid stenosis.
- *Ventricular septal defect (VSD)*—A persistent opening between the ventricular cavities; clinical significance depends on the size of the defect.
- *Tetralogy of Fallot*—A large VSD, pulmonary stenosis, right ventricular hypertrophy, and dextropositioned aorta. A cause of cyanosis from right-to-left shunting but rarely leads to CHF.

- The *peritoneopericardial diaphragmatic hernia* is an uncommon pericardial defect in puppies.

▼ ***Key Point*** The most important reasons for CHF in dogs are degenerative valvular disease, dilated cardiomyopathy, pericardial diseases, and heartworm heart disease. These conditions can be complicated by systemic hypertension, pulmonary hypertension, and arrhythmias such as atrial fibrillation or ventricular tachycardia.

DIAGNOSIS

History and Clinical Signs

The diagnosis of heart disease involves a systematic examination that begins with consideration of *species, age, breed,* and *sex.*

There are obvious risks for cardiovascular disease relative to these factors. Young animals will be suspected of congenital heart disease; mature animals of acquired, degenerative, and neoplastic diseases. There are dozens of genetic breed predispositions to cardiovascular diseases. These tend to be tabulated in standard reference textbooks and are described in other chapters within this volume.

- The *history of clinical signs* in heart disease is variable. Many patients have no overt clinical signs until CHF develops. No historical sign is specific for HF.
- Signs of *low cardiac output*, such as exercise intolerance or syncope may be observed, but are subtle and may be overlooked by dog owners.
- Syncope—the sudden loss of consciousness and postural tone—is often observed with structural cardiovascular lesions and cardiac rhythm disturbances, from inappropriate reflex activation (neurocardiogenic syncope), in pulmonary hypertension, and following treatment with drugs that lower arterial blood pressure.
- Hypertensive heart disease may be overshadowed by injury to other target organs such as the eyes (blindness), brain (stroke or hypertensive encephalopathy), or kidneys (renal failure).
- Endocarditis results in multisystemic signs that include evidence of inflammation, immune system activation, cardiac injury, thrombosis, and metastatic infection.
- Respiratory signs such as cough and dyspnea are common in heart disease. These may stem from pulmonary edema, pleural effusion, heartworm disease, thromboembolism of the lung, or compression of the left bronchus.
- The most sensitive sign of heart failure is *exercise intolerance.* However, signs of *"congestive" heart failure* are more obvious and indicate problems related to fluid accumulation.
- Pulmonary edema and effusions in body cavities are typical of advanced heart disease with left-sided CHF. Chief clinical signs are tachypnea, dyspnea, and cough.
  - Right-sided CHF in dogs generally causes exercise intolerance and abdominal enlargement from hepatomegaly and ascites.

Physical Examination

The *physical diagnosis* is pivotal in heart disease and involves a systematic examination. Key aspects of the examination include

- Inspection for obvious signs of *right-sided CHF* and for cardiac *cachexia* (loss of lean muscle mass, typically along the spine).
- Examination for *jugular venous* distension or jugular pulse abnormalities. Elevated jugular venous pressure is indicative of right-sided CHF, pericardial disease, large pleural effusion, or cranial mediastinal mass. Jugular venous pulses may indicate a lesion on the right side of the heart (such as pulmonary hypertension or tricuspid regurgitation).
- Examination for *arterial pulse abnormalities*, including hypokinetic (small stroke volume), hyperkinetic (large pulse pressure), or pulse deficits (arrhythmias). Pulsus paradoxicus may be detected in cardiac tamponade.
- Measuring of *arterial blood pressure* by oscillometric methods or Doppler flow methods. Blood pressure should be measured in *every* cardiac patient to identify hypertension and hypotension and to monitor drug effects (diuretics, vasodilators, ACE inhibitors).
- Palpation of the *precordium* for the apical location, strength, and precordial thrills.
- *Auscultation* of the heart and lungs to detect abnormalities that include
  - Heart sounds that are too soft or too loud.
  - Cardiac arrhythmias (bradycardia, tachycardia, irregular rhythm).
  - Gallop sounds (loud atrial or ventricular filling sounds indicating ventricular diastolic dysfunction).
  - Clicks—most often indicative of mitral valve disease.
  - Murmurs (prolonged audible vibrations).
  - Abnormal breath or lung sounds—loud bronchial sounds or fine crackles are typical of pulmonary edema from left-sided CHF.
- Examination of *mucous membranes* and capillary refill time: If the membranes are pale, rule out anemia or systemic vasoconstriction; if cyanotic, evaluate for respiratory dysfunction, cardiogenic shock, or right-to-left shunting
- *Abdominal palpation* for hepatomegaly or ascites, which are typical signs of right-sided CHF.
- Ocular examination to identify *retinal hemorrhage* and *retinal detachment*, which are common consequences of systemic hypertension in dogs.

- It should also be noted that dental disease has *never* been proven as a cause of heart disease in dogs. However, periodontal disease may negatively affect the respiratory system by allowing recurrent aspiration of infected materials or possibly by stimulating the immune system.

Diagnostic Evaluations

A number of routine laboratory studies are useful in the diagnosis of cardiovascular diseases of dogs and these are discussed in more detail within other chapters of this text.

- *Thoracic radiographs* are important for evaluating the heart, lungs, and pleural space (see Chapters 4, 143, and 159).
  - Key points about radiographs include the presence of cardiomegaly, identification of vascular abnormalities, and observing for radiographic changes compatible with CHF.
  - Typical radiographic findings of left-sided CHF are left-sided cardiomegaly, pulmonary vascular (venous) prominence, and parenchymal densities compatible with CHF.
  - Radiographs are essential in the differential diagnosis of respiratory problems in small animals.
- The *electrocardiogram* (ECG, EKG) is especially important for diagnosing arrhythmias and conduction disturbances. The ECG also may demonstrate cardiomegaly patterns or abnormalities in pericardial disease or ischemia, but the true sensitivity and specificity of this examination is unknown (see Chapter 144).
  - Canine ECGs exhibit great differences in terms of normal voltages. Typically, the normal canine QRS complex is <3.0 mV in any limb lead, with 2.5 mV representing a more sensitive but less specific value for cardiomegaly. However, some normal deep chested dogs have very large voltages.
  - Right axis deviation usually indicates RV hypertrophy or conduction delay. Left axis deviation is either normal or indicative of left ventricular disease or partial conduction delay.
- The *echocardiogram* is the noninvasive gold standard for diagnosis of heart disease. Key aspects of the echocardiographic and Doppler studies include identification of cardiac lesions and cardiomegaly; measurement of ventricular systolic and diastolic function; assessment of valvular heart disease, identification of abnormal flow patterns, and quantitation of pressure gradients.
- Other *clinical laboratory tests* may be useful for identifying the causes or consequences of heart disease or heart failure in particular instances. Commonly used tests include heartworm tests, blood cultures, levels of serum troponin (CTnI), thyroid function tests, serum potassium (and electrolytes), renal function tests (BUN, serum creatinine), and striated muscle enzymes (CK, AST). In the future, greater reliance on biomarkers can be expected. For example, ANP and BNP and their pro-hormones are increased in heart failure and may be useful as screening tests for patients with dyspnea.

TREATMENT

A large number of drugs impact the heart and the vascular system. The clinical pharmacology of these drugs is summarized in "Cardiovascular Drugs" (Chapter 146).

- Some treatments for CHF demonstrate rapid *hemodynamic effects*, increasing cardiac output or reducing pulmonary venous pressures or left ventricular afterload. Examples include furosemide, dobutamine, sodium nitroprusside, and pimobendan.
- Others treatments modulate *neurohormonal* or *inflammatory mediators* of CHF. These are often considered "cardioprotective treatments." Examples include angiotensin converting enzyme inhibitors (ACEI), spironolactone, beta-blockers, and omega-3 fatty acids.
- Still other treatments represent mainly *symptomatic therapy*. For instance, sedatives, oxygen, and thoracocentesis all serve a specific therapeutic purpose.
- Understanding the clinical use of these drugs singly and in combination with others is critical. The clinician should be mindful of the indications and contraindications for drug use; drug dosing; findings that indicate drug benefit; and method to identify adverse drug effects.
- The following treatment recommendations are general approaches to management of CHF in dogs. In almost every case, the cause of CHF will be related to chronic mitral/tricuspid valvular disease or dilated cardiomyopathy, but the treatment plans are also applicable to CHF due to congenital heart disease or pulmonary hypertension. Management of cardiac tamponade does not involve drugs and is described in Chapter 151.

Acute Heart Failure: Standard Hospital Treatment Plans

Combining **F**urosemide, **O**xygen, **N**itroglycerine (or **N**itroprusside) and **S**edation represents a treatment plan applicable to most cases of CHF regardless of cause and is especially effective in mild to moderate pulmonary edema. In life-threatening pulmonary edema, additional consideration should be given to afterload reducers. In cardiogenic shock, potent positive inotropic drugs should be administered.

Basic Therapy for CHF

- The F-O-N-S therapy plan delivers the following benefits: diuresis is initiated; pO2 is increased; ventricu-

lar preload is reduced; the tendency towards pulmonary edema is reduced; and anxiety is relieved.
- If necessary, additional treatments can be added to this protocol.
- For life-threatening pulmonary edema, an afterload reducer such sodium nitroprusside, hydralazine, or enalapril can be initiated (see below).
- For cardiogenic shock (CHF with hypotension), a potent positive inotrope such as dobutamine or pimobendan can be administered (see below).
- Loop diuretics such as furosemide are generally effective in acute pulmonary edema. However, these drugs must be carried by renal blood flow to the proximal nephron where furosemide is actively secreted into the filtrate before passing to the loop of Henle. In severe CHF with impaired renal perfusion, furosemide may not be effectively delivered to the proximal nephron.
- For this reason, use a relatively high initial furosemide dose (4–5 mg/kg, IV) in cases of severe CHF. The dog should be checked every 30 minutes for evidence of diuretic effect (observation for urination and palpation of the urinary bladder).
- Once diuresis ensues, the dose is reduced to 2 mg/kg q8–12h, IV or IM.
- Alternatively, a constant rate IV infusion of furosemide can be instituted. Following a bolus injection, the total dosage anticipated for the next 24 hours in calculated and delivered evenly by a syringe or other type of infusion pump.
- Nitroglycerine ointment ($^1/_2$–2 inches, cutaneously, q12h), if effective, works by pooling blood in capacitance veins and away from the pulmonary veins.
- Butorphanol (0.25 mg/kg IM) is the recommended sedative of choice for dogs in CHF.
- Most mild to moderate cases of CHF will respond very well to this treatment plan.

Life-Threatening Pulmonary Edema

A more aggressive approach to afterload reduction should be undertaken in the situation of life-threatening pulmonary edema. In particular, a potent alternative to nitroglycerine is the "balanced" vasodilator *sodium nitroprusside*. The main indication for nitroprusside is life-threatening pulmonary edema from left heart failure. Other afterload reducers available for hospital treatment include hydralazine and ACEI.

- This clinical situation is often related to rupture of a mitral chorda tendinea or development of atrial fibrillation, creating so-called acute on chronic HF.
- Clinically life-threatening pulmonary edema is characterized by severe dyspnea, hemoptysis, expectoration of pink froth, marked alveolar infiltrates on the thoracic radiographs ("white-out"), or failure of furosemide and nitroglycerine to relieve clinical signs of respiratory distress.
- Another indication for afterload reduction in hospital treatment of CHF is the dog with concurrent systemic hypertension. High ABP increases both the load on the LV and the volume of mitral regurgitation.

▼ ***Key Point*** Reducing arterial blood pressure is one of the most effective methods for reducing the severity of mitral regurgitation.

- The main contraindication to afterload reducers such as nitroprusside is pre-existent symptomatic or severe hypotension (<80 mm Hg systolic).
- Nitroprusside sodium is dosed in canine CHF at 0.5 to 5 mcg/kg/min, by IV infusion (carefully follow label directions for formulation). Frequent ABP monitoring should be scheduled. One can titrate the dose of nitroprusside drugs to a systolic ABP of 85 to 100 mm Hg (as well as to clinical signs) and continue treatment for 24 hours or less in most cases.
  There are alternatives to the use of nitroprusside:
  - One approach is the combination of nitroglycerine ointment with oral hydralazine (starting at 1–2 mg/kg PO). Hydralazine is a potent afterload reducer with relatively rapid onset of action.
  - An ACEI (0.5 mg/kg of enalapril or benazepril PO) also can be used in this acute situation; however, the onset of effect is slower and the control of ABP less reliable when compared to nitroprusside or hydralazine. The ACEIs are generally used for transition to home therapy and then for long-term management of CHF.
- The decision to unload the left ventricle with an arterial vasodilator ultimately requires good clinical judgment, and the aggressiveness of afterload reduction should relate to the severity of the pulmonary edema.
- Once the pulmonary situation is stabilized, taper the nitroprusside over about 6 hours (or stop the nitrate/hydralazine). At that time, begin the ACEI that will be continued during the home care process (see below).

Cardiogenic Shock

The finding of cardiogenic pulmonary edema or pleural effusion with severe hypotension (ABP <80 mm Hg) and other indicators of low cardiac output (pallor, hypothermia, depression, elevated blood lactate) is highly suggestive of cardiogenic shock. Volume infusion is inappropriate to raise ABP in this setting, and in most cases there is a need to stimulate myocardial contractility to improve pump function and facilitate diuresis.

- Other potential causes of cardiogenic shock include myocardial infarction (rare) and massive pulmonary embolus, for example, after treatment for adult heartworms.
- Dogs with CHF due to dilated cardiomyopathy (often Doberman pinschers) represent the typical case of cardiogenic shock.
- Initial treatment is the same as discussed above.
- Begin with basic heart failure therapy F-O-N-S therapy, These patients are hypotensive and often

very depressed; sedation is rarely needed. Determine if thoracocentesis is needed, as dogs with cardiogenic shock may have both pulmonary edema and pleural effusion.

- If there is a moderate-to-large pleural effusion, tap the chest.
- The most important therapy to administer in cardiogenic shock is a potent positive inotropic drug. The goal is to increase ABP by augmenting cardiac output. In most cases, the catecholamine *dobutamine* is administered as a constant rate intravenous infusion.
- Dobutamine (or dopamine) can effectively increase ABP in these patients primarily by a positive inotropic effect (at lower doses), by arterial vasoconstriction, or through an increased heart rate (at higher doses, generally >5 mcg/kg/min).
- Neither vasoconstriction (afterload mismatch) nor sinus tachycardia (increased oxygen demand) represent an advantage to a failing left ventricle; thus, the main goal of catecholamine treatment is stimulating myocardial contractility (and filling) while minimizing increases in vascular resistance and HR.
- Following initial F-O-N-S therapy, allow the patient 30 minutes to stabilize while preparing the dobutamine solution. Place an IV catheter in a peripheral vein and attach ECG monitoring leads (if available) and a blood pressure cuff for repeated monitoring of ABP.
- One method for preparing a stock solution of dobutamine for dogs follows:
  - Obtain 5% dextrose in water solution and the needed infusion set(s).
  - Add potassium chloride (8 mEq KCl per 500 ml D5W).
  - Add 250 mg of dobutamine to the 500 ml of 5% dextrose solution, yielding an approximate concentration of 500 mcg dobutamine per ml.
  - Hang the bag of 500 ml D5W with additives, attach the appropriate infusion set for accurate delivery, and flush and prime the line with dobutamine solution.
  - Attach the infusion line to the infusion pump. Begin the dobutamine infusion at a rate of 2.5 mcg/kg/min, and increase the dose after 30 to 60 minutes to 5 mcg/kg/min if tolerated. Doses greater than 10 mcg/kg/min are rarely used in our hospital.
- One can use the following guide for a *5-mcg/kg/min–infusion rate*; adjust as needed:

Weight (kg)	Micrograms per min	Micrograms per hour	Total ml of fluid per hour
10	50	3,000	6
20	100	6,000	12
30	150	9,000	18
40	200	12,000	24
50	250	15,000	30
60	300	18,000	36

- Re-measure the clinical variables often to assess the trend.
- Therapeutic effects of dobutamine include increased cardiac output, elevated ABP, increased tissue perfusion (better color and shorter refill time, stronger pulse), increasing body temperature, and improvement in attitude and strength.
- Adverse effects, necessitating dose reduction, include increasing heart rate, excessive vasoconstriction, and induction of extrasystoles. Seizure activity and vomiting are infrequently observed.
- Once the ABP is stable (systolic pressure in the 90 to 100 mm Hg range), other vasoactive drugs can be added to unload the left ventricle. The approach is similar to that discussed in the previous section.
- As a minimum, an ACEI such as enalapril or benazepril (0.25–0.5 mg/kg, PO once or twice daily, depending on ABP) should be initiated since these drugs benefit neurohormonal status, reduce aldosterone secretion, and reduce afterload. This seems the most practical vasodilator to add in this setting, as it will also constitute part of the home treatment.
- Alternatively, sodium nitroprusside (see the previous section) can be initiated if there is life-threatening pulmonary edema, starting at the conservative dose of 0.5 mcg/kg/min and titrated in concert with the dobutamine to maintain a systolic ABP of 90 to 100 mm Hg.
- After 24 to 48 hours of dobutamine therapy, reduce the dobutamine rate by 50% every 2 to 4 hours until you have reached 1.25 mcg/kg for 4 hours, then stop the infusion. If you cannot wean the patient from dobutamine (i.e., ABP is too low), increase the infusion rate to increase ABP and either increase the enalapril (to 0.5 mg/kg PO q12h) or begin pimobendan (if available).
- Eventually *establish home therapy* with oral furosemide, an ACEI, and digoxin (or pimobendan).

Use of Positive Inotropes in Hospital Therapy of CHF

Positive inotropic drugs are mainly used in treatment of specific situations such as CHF with hypotension or when atrial fibrillation complicates HF.

- The use of *dobutamine* (or dopamine) for cardiogenic shock has been discussed.
- *Milrinone*, an IV inodilator that acts by PDE inhibition, is rarely used in veterinary practice but is both a potent inotrope and afterload reducer.
- Where available, the inodilator drug *pimobendan* should be considered strongly for both hospital and home therapy of CHF. Pimobendan is a calcium sensitizer/vasodilator.
  - The drug is very potent and may be considered in place of dobutamine, when IV therapy is impractical.
  - One risk of pimobendan therapy in the setting of cardiogenic shock is the potential to reduce blood pressure via vasodilation, so ABP should be monitored carefully.

- Alternatively, the patient can be started on dobutamine and then bridged over to pimobendan for potent oral inotropic support and afterload reduction.
- It should be noted that some dogs already receiving pimobendan have improved following dobutamine infusion; the drugs are not interchangeable.
- Generally, digoxin is not administered in the urgent care of CHF patients; however, in the setting of HF with atrial fibrillation *digoxin* should be started (see below).

Management of the Dog with CHF and Atrial Fibrillation

- After confirming the rhythm diagnosis with an ECG, administer digoxin (Lanoxin) using a modified loading dose (0.01 mg/kg PO q12h for two doses), and then begin maintenance treatment (0.005 mg/kg, PO, q12h).
- To gain better control of the heart rate, after 24 to 48 hours of HF stabilization, add the calcium channel antagonist diltiazem to block the AV node (starting at 0.5 mg/kg, PO, q8h). This will better control ventricular rate response.
- Provided ABP is >90 mm Hg, one can up-titrate the dose of diltiazem at each subsequent dosing interval.
- Usual target doses of diltiazem are 1.0 to 1.5 mg/kg, PO, q8h (though higher doses may be needed) in order to obtain a "resting" hospital heart rate of 120 to 160/minute.
- On follow up examination, determine if the dog can tolerate low-to-moderate doses of a beta-blocker such as carvedilol or metoprolol (see above). Beta-blockers are cardioprotective and also slow heart rate in atrial fibrillation.
- The clinician must be aware of the negative inotropic effects of diltiazem and beta-blockers.
- While beta-blockers have more theoretical benefits in terms of "cardioprotection," they depress myocardial function more than diltiazem for equivalent heart rate control.
- The author recommends controlling heart rate with digoxin and diltiazem initially and subsequently adding carvedilol for additional rate control once the patient is "dry."
- Another option for treatment of AF is DC cardioversion. Pros and cons of such therapy should be discussed with a cardiologist.

Management of the Dog with CHF and Ventricular Tachycardia

In settings of CHF with ventricular tachycardia, it may be worthwhile to consult with a cardiologist. Treatment of isolated ventricular premature contractions with anti-arrhythmic drugs is not recommended.

▼ ***Key Point*** Digoxin is contraindicated in the presence of complicated or repetitive ventricular arrhythmias.

- *Lidocaine* (2 mg/kg IV boluses; 40–60 mcg/kg/minute, IV infusion) or *procainamide* (2 mg/kg IV boluses to 10 mg/kg; or 10–20 mg/kg, IM, q6h; or 25–40 mcg/kg/min, IV infusion) are most often used to attain initial rhythm control.
- *Mexiletine* (5–8 mg/kg, PO, q8h) is an oral alternative treatment to lidocaine.
- Anti-arrhythmic drugs, in general, are problematic in the setting of HF. Most drugs (except lidocaine and mexiletine) significantly depress myocardial function.
- While lidocaine and mexiletine are the safest in terms of myocardial contractility, reduced hepatic blood flow could lead to drug accumulation and toxicity (tremors, anorexia, vomiting, seizures).
- Procainamide can be used in dogs that fail to respond to lidocaine, but procainamide exerts a negative inotropic effect and also may cause peripheral vasodilation.
- Since sotalol has significant beta-blocking actions, it should be avoided in this setting.
- Amiodarone is also a beta-blocker but is probably a better choice in this setting provided liver toxicity does not develop.
- Any of the ventricular anti-arrhythmic drugs may also be pro-arrhythmic in dogs (worsening the ventricular tachycardia).

Home Therapy of CHF

The transition from hospital to home therapy of CHF usually begins after 24 to 72 hours of hospital treatment, depending on severity of CHF. During that interval the initial diagnostic workup of thoracic radiographs, serum biochemical profile, ECG, and echocardiogram should have been completed. ABP should have been measured frequently during this time. Often a follow up "renal/electrolyte panel" will be done prior to release, as vigorous diuretic therapy may alter these serum biochemical values. In patients with severe pulmonary edema on admission, repeated thoracic radiographs should be obtained to insure control of the CHF.

Transition to Home Therapy

The following sequence is typical:

- Parenteral furosemide is replaced with oral furosemide.
- Oxygen is discontinued.
- Nitroglycerine is replaced with an ACEI, a balanced vasodilator with cardioprotection properties.
- A decision is made regarding initiation of digoxin or pimobendan.
  - Pimobendan is a very effective drug for therapy of CHF and works very well with the combination of furosemide and an ACEI.
  - Digoxin is a weak inotropic drug but is clearly useful in atrial fibrillation and should be considered where pimobendan is unavailable. Relative

contraindications to digitalis include complex ventricular ectopia, azotemia, sinus node dysfunction, or pre-existent atrioventricular block.
- Spironolactone (a weak, potassium-sparring diuretic) is initiated for cardioprotection against effects of aldosterone.

Initial Home Treatment Plan

For chronic CHF due to valvular heart disease or dilated cardiomyopathy, home therapy consists of the following:

- A maintenance dose of furosemide (typically 2–4 mg/kg, PO, q12h)
- An ACEI, usually enalapril at 0.25 mg/kg, PO, q12h)
- Spironolactone (0.5–2 mg/kg, PO, daily)
- Digoxin (0.005 mg/kg, PO, q12h) is prescribed for dogs with DCM or advanced CHF if not contraindicated.
- Where available, pimobendan (0.2–0.3 mg/kg, PO, q12h) is prescribed instead of digoxin for dogs with dilated cardiomyopathy or advanced valvular heart disease.
- Moderate dietary sodium restriction is discussed with the client; a prescription diet may be dispensed.

Initial Reevaluation

- The typical patient is reevaluated in 7 to 10 days.
- At that time the history is explored regarding appetite, attitude, exercise capacity, ability to sleep comfortably, and presence of "symptoms."
- A physical examination is conducted and ABP measured.
- A serum biochemical profile is performed.
- A serum digoxin concentration is measured (draw blood 8–12 hours post-dose; target concentrations are 0.8–1.2 ng/ml).
- Prior therapeutic results and current clinical signs will determine if another thoracic radiograph or an ECG is needed. Continual respiratory problems or abnormal thoracic auscultation are indications for radiography. An arrhythmia is the main indication for another ECG.
- A repeated echocardiogram is unnecessary and rarely guides adjustments in drug dosages in canine CHF.
- At this visit, dosage adjustments are made to current drugs:
  - Furosemide therapy is individualized to thwart fluid retention (increasing doses for progressive edema) or to mitigate azotemia or hypotension (decreasing doses to improve renal perfusion).
  - Spironolactone is continued.
  - The dosage of enalapril (or benazepril) is increased to the "optimal dosage" of 0.5 mg/kg, PO, q12h if renal function and ABP are satisfactory (i.e., BUN or creatinine have not increased by >1.5 to 2 times baseline and systolic ABP is >90 mm Hg). This upward adjustment is especially important in dogs with DCM or advanced chronic valvular disease.
  - If not prescribed initially, digoxin or pimobendan should be reconsidered for dogs with advanced CHF. Atrial fibrillation is an indication for digoxin.

Other Therapeutic Considerations

- If the patient is stable and CHF well controlled, consideration should be given to additional "cardioprotection" therapy with a beta-blocker such as carvedilol (Coreg) or metoprolol-long acting. Initial doses of carvedilol (also an alpha blocker and potent antioxidant) is about 0.05 to 0.1 mg/kg, PO, q12h.
- The dose can be increased every 2 to 4 weeks with a target of 0.2 to 0.4 mg/kg q12h for dogs with CHF due to dilated cardiomyopathy.
- The benefits of beta-blockade in small-breed dogs with valvular endocardiosis are uncertain and a topic of current study
- See Cardiovascular Drugs (Chapter 146) for a more complete discussion of beta-blockers, as well as side effects of these drugs.
- Weakness, bradycardia (HR <80), or worsening CHF may indicate inability to tolerate the beta-blocker. In these cases, the drug dose should be reduced slightly and other medications (furosemide, pimobendan) increased if possible.
- The dietary supplements with omega-3 fatty acids (EPA, DHA) may be of benefit in cardiac cachexia. The use of other nutriceuticals, such as taurine, L-carnitine, co-enzyme $Q_{10,}$ or L-arginine, should be considered on a case-by-case basis.
  - Currently there is little to no evidence to support widespread use of these supplements in canine CHF, and many are expensive.
  - Some prescription diets are supplemented with a number of these nutrients.
- Cough suppressants, such as hydrocodone or butorphanol, are useful for coughing in small breed dogs with bronchial compression or concurrent tracheal collapse, but first ensure that effective treatment of pulmonary edema has occurred.
- If atrial fibrillation develops, control it as discussed above, by adding diltiazem to digoxin initially and later up-titrating carvedilol or another beta-blocker.
- Treat serious ventricular tachycardia with mexiletine or other anti-arrhythmic drugs such as amiodarone (with care).

Progressive Left-Sided CHF

When left-sided CHF with pulmonary edema advances despite optimized initial therapy, other treatments can be considered.

- In dogs with left-sided CHF, the clinician should ensure that the patient is not hypertensive (as might occur with chronic renal disease or Cushing's disease).

Elevated ABP should be aggressively lowered if hypertension is found.
- First optimize the ACEI dosage to 0.5 mg/kg, PO, q12h.
- If this fails consider adding amlodipine (0.05–0.1 mg/kg daily as an initial dose).
- Alternatively, assess the effect of carvedilol (Coreg) on ABP.
- Even if the ABP is normal, cautiously reducing systolic pressure with the combination therapy of an ACEI and amlodipine can reduce afterload, MR, and left atrial pressure in refractory left-sided CHF due to MR.
- If pimobendan is not licensed, attempt to obtain extra-label permission for its use.
- Alternative approaches include increasing diuretic doses or using subcutaneous furosemide, as discussed below for right-sided CHF.

Progressive Right-Sided CHF

Chronic right-sided CHF with refractory ascites generally stems from one of the following problems: mitral valve regurgitation that is complicated by pulmonary hypertension and tricuspid regurgitation; superimposition of atrial fibrillation on any heart disease; dilated cardiomyopathy; or pulmonary hypertension (including dirofilariasis and idiopathic PH).

- In addition to standard therapy of furosemide, spironolactone, dietary sodium restriction, and digoxin or pimobendan, there should be increased emphasis on dietary sodium restriction. Exercise restriction also may be beneficial (controlled walks only).
- Thoracocentesis should be done for any dog with a large pleural effusion.
- Tense ascites should be partially drained (about $^1/_3$ to $^1/_2$ of the volume) to relieve discomfort, but be careful about distinguishing hepatomegaly from ascites. Recurring body cavity effusions indicate that adjustment in medical therapy will be needed.
- Spironolactone dosage can be increased to 1 to 2 mg/kg, PO, q12h.
- For pulmonary hypertension that has been documented by Doppler echocardiography, a trial course of sildenafil (Viagra) at 1 to 2 mg/kg, PO, q12h may be of some benefit, but clinical trials are lacking and the drug is expensive.
- Pimobendan clearly can benefit some dogs with chronic cardiac ascites and should be obtained whenever possible
- If these measures fail, consider prescribing hydrochlorothiazide, but remember that sequential nephron blockage can induce acute volume depletion and renal failure, so start with low every other day dosing (1–2 mg/kg, PO, daily) and recheck renal function and electrolytes after 3 or 4 doses have been given.
- An alternative (and safer) approach to more advanced diuretic therapy is to administer oral furosemide and spironolactone and enhance the furosemide effect by intermittent dosing of furosemide subcutaneously.
  - While this can be done through repeated hospital visits, in most cases, we preload syringes for clients and instruct them in proper techniques for subcutaneous injection.
  - Initially substitute one of the oral doses of furosemide with the same injectable dosage. Start with an every other day regimen.

PATIENT FOLLOW-UP

When assessing the effectiveness and tolerability of cardiovascular drug therapy, consider the following key points:

- The client **interview**—review the medications; consider the owner's overall assessment of quality of life; discuss the dog's appetite, activity, and ability to sleep comfortably; respiratory symptoms; and exercise capacity.
- Identify any signs of possible drug **intoxication.**
- Concentrate on the **physical examination** signs of CHF: elevated jugular venous pressure, hepatomegaly, ascites, thoracic auscultation, and overall body condition (cachexia).
- Measure the arterial **blood pressure.**
- Test **renal function** and measure **electrolytes** if indicated.
- Assess the **cardiac rhythm** by auscultation; record an ECG if indicated by auscultation.
- Determine if thoracic **radiography** is indicated; review the chest films for control of edema and effusions.
- Determine serum concentrations of drugs if indicated (e.g., **serum digoxin**).

CHF PROGRESSION

Congestive heart failure may become complicated or progressive for a number of reasons related to cardiac or extracardiac issues. Some of the factors to consider include

- Progression of valvular disease or myocardial dysfunction
- Heightened neurohormonal compensation
- In dogs with MR, cardiac complications of ruptured chorda tendinea, left atrial tear, atrial fibrillation
- Medication problems: insufficient or excessive therapy for stage of disease; poor client compliance or inadequate follow up; negative inotropic drugs (beta-blockers, calcium-channel blockers, anti-arrhythmics)
- Excessive exercise
- Poor or unpalatable diet, excessive sodium intake

- Medical conditions that increase cardiac demands and workload: hypertension, hyperthyroidism (iatrogenic in dogs), anemia, infections (especially with fever)
- Other medical conditions: neoplasia, renal failure, chronic respiratory disease
- Environmental stress (heat, high humidity)
- Iatrogenic causes: excessive or inappropriate drug therapy causing hypotension, dehydration, renal failure

PROGNOSIS

The prognosis of canine CHF depends on the cause, severity, and care received.

- Many dogs survive >1 year following the first signs of CHF provided they receive optimal veterinary and home care, including extra-label drugs such as carvedilol and pimobendan combined with "standard" therapy of furosemide-spironolactone, an ACEI, and dietary modifications.
- The prognosis for DCM is always more guarded, especially in Doberman pinschers. Once CHF has progressed to severe ("functional class IV") failure, the outlook is generally guarded-to-poor and a 3- to 9-month prognosis is typical.
- There are no critical studies that *prospectively* examine prognostic criteria across all groups. The multicenter enalapril (North America) and benazepril (European) studies clearly indicate improved survival and reduction of clinical signs in canine CHF caused by DCM or chronic valvular disease when an ACEI is added to background therapy of furosemide +/− digoxin.
- Where pimobendan is available to treat canine DCM or advanced valvular heart disease, the long-term outcome also appears more favorable when compared to "conventional" therapy with furosemide and digoxin or even furosemide and an ACEI. (Though it is illogical not to combine pimobendan with furosemide and an ACEI.)
- Beta-blockers slow the progression of cardiac dilatation and HF in experimental canine myocardial diseases, and a drug like carvedilol should be part of the long-term treatment regimen, especially in DCM, provided it is tolerated.

Causes of Death
