The **causes of death** in chronic CHF vary but are most often related to one of the following:

- Sudden electrical event (such as asystole or ventricular fibrillation)
- Hypoxemia (pulmonary edema, pleural effusion)
- Pulmonary embolism leading to fatal hypotension
- Multi-systemic organ failure
- Client desire for euthanasia. This is a particularly common ending and pertains to many factors that include effectiveness of therapy, severity of signs, client (and veterinarian) perceptions about quality of life, and issues of care (medication frequency, visits to the veterinary hospital, costs) among other factors.

Chapter

148 Syncope

John D. Bonagura / Shianne L. Koplitz

OVERVIEW

Syncope, or fainting, is a sudden and unexplained *loss of consciousness and postural tone* usually related to inadequate delivery of oxygen to the brain. This chapter outlines a general approach to the diagnosis of the syncopal patient. Effective therapy of syncope is predicated on identifying and managing the underlying disorder.

Characteristics of Syncope

- The event is often precipitated by exercise, sudden activity, or excitement (sympathetic stimulation). However, syncope can occur during rest or even sleep, especially in cats.
- Along with a loss of consciousness, there is a failure to maintain postural tone, causing falling. If the dog or cat is recumbent at the onset of the event, it is common for the patient to fall backwards or to roll to lateral recumbency.
- Brief stiffening is common along with forelimb rigidity and opisthotonus.
- Minor convulsive activity may be observed, such as focal head twitching. This is more common in cats wherein syncope often resembles a true seizure event.
- Urination during the event is a frequent observation. Defecation may occur but is far less common.
- Mucous membrane color is initially pale pink to white when the cause is low blood pressure; subsequently, cyanotic, normal, or flushed membranes may be observed. If hypoxemia from respiratory disease or a right-to-left shunt is the cause of fainting, cyanosis may precede the spell.
- Following recovery of blood pressure and cerebral function, mentation and behavior are typically normal. However, if the syncope is related to a protracted cardiac arrhythmia or ongoing or progressive pathology, as with a stroke, there may be a longer period of listlessness, stupor, or profound weakness.
- Some patients with syncope also demonstrate pre- or near-syncope. This is characterized by a sudden jerk of the head and body. This apparent "lightheadedness" abates just in time to prevent falling.

Differential Diagnosis

- The *differential diagnosis* of syncope includes seizure disorder or epilepsy; sleep disorder, including narcolepsy; stroke or transient ischemic attack of the CNS; metabolic disease affecting the CNS; and drug intoxication.
  - Syncope is readily confused with *seizure disorders or epilepsy* (see Chapter 127). Facial fits, generalized tonic-clonic movements, and postictal behavioral abnormalities are more typical of true seizures. However, clients can readily confuse the two, and even after obtaining a careful history, an experienced clinician may remain uncertain about the nature of the event.
  - *Sleep disorders* such as narcolepsy are rare (see Chapter 127) but may be precipitated in dogs by eating. The event appears similar to actual sleep, and in some cases, dogs may chew their food and literally fall asleep on the food bowl. Cataplexy, a loss of postural tone with maintenance of consciousness, is rare in dogs and cats.
  - *Strokes or transient ischemic attacks* can cause true syncope or, more commonly, lead to progressive or episodic neurological dysfunction (see Chapter 126).
  - *Central nervous system disorders,* such as primary brain lesions, may lead to altered consciousness and episodic falling, which might be misinterpreted as a syncopal attack (see Chapter 126). Acute vestibular syndromes may lead to falling, but mentation is normal, and the signs are generally obvious during neurological examination (see Chapters 61 and 126).
  - Metabolic diseases may alter cerebral function and be associated with staggering or falling; these include hypoglycemia, hepatic encephalopathy, and hypoadrenocorticism when it causes profound hypotension.
  - Overdose of prescribed drugs or ingestion of human drugs or toxins in the household can at times lead to altered cerebral function as well as hypotension, ataxia, or weakness. The resulting fall may be interpreted as syncope. In some cases, drugs cause profound hypotension leading to true fainting.

ETIOLOGY

General Mechanisms

- Syncope is generally caused by *insufficient oxygen delivery* to the brain.
  - The arterial oxygen content of the blood depends on pulmonary function (arterial pO_2) and the hemoglobin concentration (PCV, hematocrit).
  - Delivery of oxygen-containing blood is achieved by cerebral blood flow, which depends on arterial blood pressure (ABP) and the integrity of the vascular supply to the brain.
- From a pathophysiologic perspective, general causes of impaired cerebral oxygen delivery include:
  - Low arterial pO_2
  - Anemia
  - Cerebrovascular disease
  - Hypotension (low ABP)
- The most common cause of syncope is a sudden fall in ABP. This is typically caused by a cardiac arrhythmia, impairment of cardiac filling, or malfunction of the baroreceptor reflex arc.
- Blood pressure depends on ca*rdiac output* and *systemic vascular resistance.*
  - Cardiac output is the product of heart rate and stroke volume.
  - Stroke volume is modified by ventricular preload (venous return), myocardial contractility (inotropic state), valvular function, and ventricular afterload (impedance to ejection).
  - Stroke volume also is influenced by heart rhythm. Arrhythmias can alter ventricular filling or reduce the effectiveness of ventricular contraction.
  - Systemic vascular resistance depends on autonomic tone to arterioles, local (metabolic) factors that dilate or constrict the vessels, and the baroreceptor reflex systems.
  - Vasoactive drugs also can affect vascular tone.

Non-Cardiovascular Causes of Syncope

Syncope may be caused by disorders other than heart disease. Non-cardiovascular etiologies include:

Cerebral Hypoxia

- Anemia—in particular, moderate to severe or acute anemia.
- Respiratory disease—such patients are usually cyanotic from airway obstruction, pulmonary disease, or pleural effusion.

Cerebrovascular Disease

- This is relatively uncommon in dogs but can occur with severe hypothyroidism and accompanying atherosclerosis of the cerebral vessels in dogs (see Chapter 31); transient ischemic attacks also have been reported in cats.

Stroke

- This is a disruption in cerebral function related to sudden loss of blood supply.
- Hemorrhagic stroke—this is most commonly related to systemic hypertension in dogs and cats.
- Ischemic (thrombotic) stroke—a rare cause of syncope, but it has been observed in cats with feline cardiomyopathy and with bacterial endocarditis in dogs.

Metabolic Disorders

- Hypoglycemia is a relatively uncommon cause of syncope and is more likely to cause weakness, seizures, or coma. However, hypoglycemia can also affect autonomic function, blood vessel tone, and vascular response to changes in posture, predisposing to true syncopal attacks.
- Addison's disease may lead to syncope, likely related to volume depletion (see Chapter 33).
- Plasma volume depletion from any cause, including vomiting and diarrhea, can reduce cardiac output and ABP.

Drugs

- Drugs that affect heart rate, rhythm, plasma volume, or vascular tone may lead to hypotension and syncope. Examples include inadvertent ingestion of a beta-blockers or illicit drugs (cocaine); over-zealous treatment with diuretics; and administration of vasodilator drugs.

Cardiac and Vascular Causes of Syncope

Among the many cardiovascular causes of syncope are the following disorders:

Right-to-Left Shunting

- This can occur with congenital heart malformations including tetralogy of Fallot (see Chapter 154).

Bradyarrhythmias

- Sinus arrest; persistent atrial standstill; high-grade, second-degree, or complete AV block; ventricular asystole (see Chapter 145).

Tachyarrhythmias

- Ventricular tachycardias (often >300 bpm); less often supraventricular tachycardias or atrial fibrillation.

Reduced Cardiac Preload

- This can be due to structural heart disease or reduced venous return.
- Pericardial disease—cardiac tamponade.
- Intracardiac tumor with obstruction to cardiac filling.

- Caudal vena cava obstruction.
- Severe plasma volume depletion.

Valvular Heart Disease

- If sufficiently severe, outflow tract stenosis, atrioventricular valvular stenosis, or mitral or tricuspid regurgitation can limit cardiac output sufficiently to cause or contribute to syncope.

Cardiomyopathy

- Syncope is related to limited cardiac output, development of arrhythmias, or obstruction to blood flow (hypertrophic cardiomyopathy) (see Chapter 150).

Pulmonary Hypertension

- Acquired and congenital causes of pulmonary hypertension represent a common cause of syncope, especially in dogs. This may relate to obstruction of blood flow from the right ventricle, arrhythmias, and inappropriate activation of the baroreceptor reflex.

Congestive Heart Failure

- As with pulmonary hypertension, there may be multiple reasons for syncope in dogs and cats with CHF (see Chapter 147).
- Ischemia as a trigger for inappropriate activation of the baroreceptor reflex is a potential cause of syncope.

Hemorrhage

- Sudden hemorrhage is more likely to lead to hypotension and collapse but can also lead to syncope, as with rupture of a splenic tumor or traumatic injury with blood loss.

Thromboembolism

- A cerebral embolus may lead to a stroke that may include loss of consciousness and falling. The likely cardiac causes would be bacterial endocarditis or, in cats, a form of feline cardiomyopathy.

Loss of Vascular Tone

- Inappropriate vasodilation may follow administration of drugs, hypoglycemia, or activation of the cardiac baroreceptors (see below).

Reflex-Mediated Syncope

Syncope can be caused by inappropriate and prolonged activation of the baroreceptor reflex; this is termed reflex-mediated syncope. A variety of other names for reflex-mediated syncope are encountered including: "vasovagal," "neurocardiogenic," "neural-mediated," "vasodepressor," "cardioinhibitory," and "situational" syncope. While seemingly common, this form of syncope is poorly described in veterinary medicine.

- Autonomic control mechanisms are central to blood pressure control:
  - The baroreceptor reflex controls heart rate, ventricular contractility, and systemic vascular resistance via the autonomic nervous system.
  - Baroreceptors located in the systemic arteries (aortic and carotid sinuses) are well appreciated, but pressure receptors are also present within the ventricular myocardium (unmyelinated C-fibers). The sudden stimulation of these myocardial receptors is capable of triggering a baroreceptor reflex. One of the main reasons for activation of these cardiac receptors is sudden vigorous contraction of the myocardium as might occur with surges of sympathetic tone, excitement, or exercise.
  - Activation of the baroreceptor reflex slows the heart rate and causes vasodilation (reduced vascular resistance) through increased vagal and reduced sympathetic tone. Inappropriate activation of this reflex can lead to excessive vasodilatation and bradycardia, reducing ABP markedly.
  - Syncope can occur when a baroreceptor reflex is triggered inappropriately by sudden sympathetic stimulation of the heart, especially with excitement, or by situations such as coughing, urinating, or vomiting. The reflex can be predominately that of sinus arrest/bradycardia ("cardioinhibitory syncope"), vasodilation ("vasodepressor syncope"), or a mixed response ("vasovagal syncope").
  - In people, this inappropriate reflex activation is most often related to sudden sympathetic surges (as with pain or fright) or from postural (orthostatic) changes that develop with sudden or protracted standing. The sympathetic surge stimulates the heart to maintain ABP and perfuse the elevated head. However, postural activation for this reflex in quadrupeds seems less important than other triggers.
  - Common disease associations for reflex-mediated syncope in dogs include aortic and pulmonic stenosis, pulmonary hypertension, acquired valvular heart disease, and congestive heart failure. The reflex is often triggered by excitement, activity, or coughing (a type of situational syncope).
  - There can be a "disconnect" between the recovery of the sinus node function and the return to normal systemic vascular resistance (which can be delayed). This point is pivotal because on first examination the owner or veterinarian may identify a heart rate that is more than sufficient to maintain ABP (generally >40 beats per minute). However, the arterioles may be persistently dilated, producing an unconscious or very weak animal, with pale or cyanotic mucous membranes.
- Multiple reasons for syncope may be operative in a patient. For example, in a dog with tight congenital subaortic stenosis, possible mechanisms for excitement- or exercise-induced syncope might include: (1) reflex-mediated from stimulation of ventricular

baroreceptors; (2) myocardial ischemia leading to ventricular tachycardia; (3) outflow tract stenosis limiting stroke volume and cardiac output; and (4) effects of a cardiovascular drug, such as high-dose enalapril, that leads to peripheral vasodilation and reduced vascular resistance.

DIAGNOSIS

A number of diagnostic studies are needed to establish a diagnosis of syncope and identify the underlying cause for fainting.

History and Physical Examination

The history should include a medication history and full description of the event(s) as discussed in the Overview.

- Perform a complete physical, ophthalmic, neurological, and cardiovascular examination.
- Measure resting ABP to identify pre-existent hypotension or hypertension. If the patient is taking cardiovascular drugs, measure the ABP a number of times during the day.
- If the patient is currently affected by CHF and receiving potentially hypotensive drugs (diuretics, ACE-inhibitors, vasodilators, beta-blockers), it may be helpful to hospitalize the patient, administer medications, and record the ABP throughout the day. Systolic pressures <60 mm Hg often lead to weakness and syncope.
- If possible, have the client videotape an event. This can be especially helpful if you are uncertain about the nature of the event. Also ask the owner to observe mucous membrane color and to palpate the apex beat during the spell to count a heart rate. Remember that vasodilation can persist beyond bradycardia and an arrhythmia that leads to syncope may be gone by the time the patient is actually touched by the client or veterinarian.

Laboratory Tests

- Routine laboratory tests—Obtain a CBC, full serum biochemistry panel, and urinalysis to screen for anemia and metabolic diseases.
- Perform a heartworm test in endemic areas.
- Endocrine studies (especially for Addison's disease or hypothyroidism) should be considered in dogs (see Chapters 31 and 33).

Diagnostic Imaging

- Obtain thoracic radiographs to evaluate the heart, lungs, and thoracic cavity.
- Obtain a 2D echocardiogram to exclude structural heart diseases, pericardial disease, and mass lesions.
- In some situations, a Doppler echocardiogram may be indicated to screen for evidence of pulmonary hypertension.

Electrocardiography

▼ ***Key Point*** It is pivotal that the clinician understands the cardiac rhythm occurring during a syncopal episode.

There are a number of ways to determine the rhythm.

- *Resting (baseline) ECG*—this is rarely diagnostic. If auscultation is normal, this examination will be positive for the cause of fainting <3% of the time.
- *Holter (ambulatory) ECG*—this 24 to 48 hour examination is better but is a suboptimal study unless the patient is fainting regularly or you strongly suspect a ventricular arrhythmia, sinus arrest, or transient heart block as the cause of the event. The diagnostic yield is between 20% and 40%, depending on the patient and frequency of the spells.
- *Event recorder ECG*—this is the optimal electrocardiographic examination for the syncopal patient.
  - This monitor is different than a Holter 24h ECG. The monitor is small enough for toy breeds and cats and can be worn for one to four weeks. There are two electrodes secured to the chest and hidden under a chest wrap.
  - A constant single lead ECG is recorded on a digital memory chip that is continually updated (erasing "old data").
  - When a "spell" is witnessed, the client promptly presses the large button on the monitor recorder. This stores the ECG for subsequent playback. The time stored is programmable, but is usually set to record 30 to 60 seconds before and 30 to 60 seconds after the button push.
  - Once the patient is stable, the owner calls a toll-free number. After speaking to the recording technician, the owner places the telephone mouthpiece (not the earpiece) over the circle on the recording box, presses another button, and transmits the stored ECG to the service.
  - This ECG is then printed and faxed to the veterinarian's office by the monitor service.
  - Once the ECG is obtained, the cardiac rhythm that occurred during the observed collapse or syncopal attack is known and can be interpreted in light of the clinical findings.
  - Rapid or polymorphic ventricular tachycardia (Fig. 148-1) suggests the likely cause of syncope is ventricular ectopy and unstable rhythm. Periods of protracted sinus bradycardia with sinus arrest are suggestive of sick sinus syndrome. In general, sick sinus syndrome affects typical breeds (miniature schnauzers, West Highland white terriers, cocker spaniels, dachshunds) and the periods of sinus arrest will exceed 7 to 8 seconds before signs are observed.
  - When sinus rhythm or sinus tachycardia is abruptly followed by vagal-mediated arrhythmias such as sinus pause, sinus arrest, AV block, or asystole, the

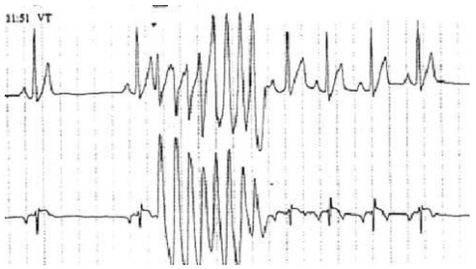

Figure 148-1. Ambulatory (Holter) ECG from a dog (two simultaneous chest leads) showing a period of polymorphic ventricular tachycardia.

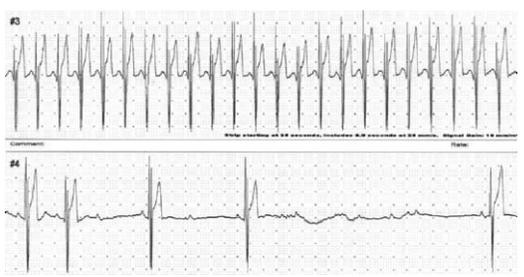

Figure 148-2. Single lead event monitor recording from a dog with fainting believed to be caused by reflex-mediated syncope. The heart rate is initially fast (sympathetic stimulation; strip #3 on top). Suddenly, the heart rate slows (lower strip, #4) leading to sinus bradycardia, some blocked P-waves, and a brief period of sinus arrest. The rhythm is typical of a vagal surge post-sympathetic stimulation. Presumably, the arterioles are also dilating at this time—this is a potent combination for hypotension (paper speed is 25 mm/sec).

diagnosis of reflex-mediated syncope should be considered (Fig. 148-2). This is a more difficult diagnosis because there may be a number of rhythm disturbances as well as artifacts. Typically the heart rate will recover before the dog.
  - Complete AV block with inadequate escape rhythm may be observed as a cause of syncope. In most cases, there will be evidence of conduction disturbance on the routine ECG as well. Transient complete or high-grade, second-degree AV block with ventricular asystole is more common in cats than in dogs but may occur in either species.
- A surgically implantable *loop recorder* is available for patients with very infrequent syncope, but these devices have been used rarely in veterinary practice.
- See Chapter 145 for more information on disorders of cardiac rhythm.

Tests of Baroreceptor Reflexes

- Baroreceptor testing (tilt table) is a common procedure in people with suspected reflex-mediated syncope; this study is not yet developed for routine clinical use in dogs or cats.
- Carotid sinus massage can be attempted in dogs in an attempt to induce sudden sinus node depression, but hypersensitive carotid sinus syndrome is not believed to be important in animals.

TREATMENT

Therapy of the syncopal patient depends entirely on the underlying cause.

- Dogs in CHF should be treated medically with systolic ABP maintained between 90 to 120 mm Hg (see Chapter 147).
- Pacemakers are used for bradyarrhythmias that are severe and persistent (as in sick sinus syndrome or with complete or high-grade, second-degree AV block) (see Chapter 145).
- Anti-arrhythmic drugs are used for tachyarrhythmias (for example, sotalol or mexiletine and atenolol for dogs with malignant ventricular tachycardia) (see Chapter 145).
- For reflex-mediated syncope in dogs, therapy is less certain.
  - In human patients, beta-blockers are used (to prevent sympathetic-induced hypercontractility of the myocardium and stimulation of the C-fibers); however, we have not had particularly good results with beta-blockers in dogs. Paradoxically, drugs that increase SNS tone (theophylline or terbutaline) or reduce vagal efferent effect (hyoscyamine, disopyramide) have worked better and can be tested for clinical benefit.
  - For patients not in CHF, consider supplementation of the diet with table salt to encourage drinking.
  - A pacemaker can be helpful if the major component of syncope is cardioinhibitory, but these devices will be of little value if vasodilation is a prominent component of the events.
- Syncope related to severe pulmonary hypertension is very difficult to manage; consult a cardiologist. Potential treatments include sildenafil (Viagra) to reduce pulmonary vascular resistance (see Chapter 146).

Chapter

149 Valvular Heart Disease

John E. Rush / John D. Bonagura

VALVE FUNCTION AND DYSFUNCTION

Cardiac Valve Structure

The aortic and pulmonic valves separate the left and right ventricles from their respective great vessels. The semilunar valves consist of three individual leaflets that are closed during ventricular diastole and open during ventricular systole. Atrioventricular (AV) valves positioned between the atria and ventricles of the left and right heart are respectively called mitral and tricuspid valves. The left and right AV valves consist of two major leaflets ("tricuspid" is a misnomer in dogs and cats). The AV leaflets are attached via the chordae tendineae to the papillary muscles, which attach to the ventricular wall. The base of each AV valve is supported by a valve annulus. The AV valves open during ventricular diastole and close during ventricular systole.

Normal Function

The heart valves serve as one-way passages for blood and prevent retrograde (regurgitant) blood flow. The cardiac valves open and close in a cyclical pattern, and valve motion is dictated by changes in pressure within the cardiac chambers and great vessels. Competent AV valves permit the development of high ventricular pressures during systole. In a similar fashion, normally functioning semilunar valves prevent retrograde diastolic flow into the ventricles allowing for low ventricular diastolic pressures. Vibration of the heart, blood, and major vascular structures attending closure of the AV valves results in the first heart sound (S1) at the beginning of systole, and oscillation of these structures at the time of closure of the semilunar valves results in the second heart sound (S2) at the onset of ventricular diastole.

Valve Dysfunction

Cardiac valves may be dysfunctional as a consequence of congenital or acquired heart disease. General patterns of disease include:

- Obstruction to flow, termed valvular stenosis.
- Incompetent closure allowing valvular regurgitation (also called valvular insufficiency).

Valvular stenosis is almost always a congenital abnormality in animals. Valvular regurgitation may develop from congenital malformation or acquired diseases. Common anatomic and functional causes of AV valvular regurgitation are listed in Table 149-1.

▼ ***Key Point*** Because the AV valve consists of multiple anatomic components, disease of any portion of the apparatus or geometric changes in the ventricle can lead to AV valvular regurgitation.

Cardiac Murmurs

A hallmark clinical finding in valvular heart disease is a cardiac murmur. Murmurs are produced by high velocity and turbulent blood flow across the valve as the blood moves from a higher to a lower pressure chamber or vessel. With few exceptions, the absence of a cardiac murmur usually excludes the presence of clinically significant valvular disease (see Chapter 142).

- Semilunar valve stenosis or AV valve insufficiency leads to systolic murmurs.
- Semilunar valve insufficiency and AV valve stenosis leads to diastolic murmurs. In general, diastolic murmurs are softer than systolic murmurs of similar hemodynamic consequence.
- Cardiac murmurs may *not* be evident in the following situations:
  - Trivial valve regurgitation or stenosis. (Note: trivial stenosis or insufficiency may be relevant in breeding soundness examinations.)
  - Dynamic ventricular outflow tract obstruction in cats with hypertrophic cardiomyopathy or in dogs with subtle mitral valve malformation. Murmurs are often labile in these situations.
  - Massive, "wide-open" AV valve regurgitation in which the atrium and ventricle act as a common chamber and there is minimal pressure difference across the valve.

Table 149-1. CAUSES OF ATRIOVENTRICULAR VALVULAR REGURGITATION*

Congenital mitral valve dysplasia (MR)
Congenital tricuspid valve dysplasia (TR)
Chronic degenerative (myxomatous) valvular disease (endocardiosis causing MR, TR)
Bacterial endocarditis (MR)
Ruptured chordae tendineae (MR, TR)
Avulsion of the papillary muscle (MR, TR)
Transmural myocardial infarction (MR)
Causes of ventricular or atrial dilation leading to AV valve regurgitation
Patent ductus arteriosus (MR)
Ventricular septal defect/endocardial cushion defect (MR, TR)†
Atrial septal defect (TR)
Aortic regurgitation (MR)
Pulmonary regurgitation (must be severe to cause TR)
Myocarditis—for example, parvovirus, Chagas' disease (MR, TR)
Dilated cardiomyopathy (MR, TR)
Intermediate/restrictive cardiomyopathy (MR, TR)
Atrial muscular dystrophy—"silent atrium" (MR, TR)
Right ventricular cardiomyopathy—RV dysplasia (TR)
Hyperdynamic circulation—AV fistula, anemia, hyperthyroidism (MR, TR)
Chronic bradyarrhythmia—for example, complete AV block (MR, TR)
Pulmonary hypertension, including heartworm disease and chronic left-sided congestive heart failure (TR)
Causes of left ventricular hypertrophy (causing MR)
Subaortic stenosis
Hypertrophic cardiomyopathy
Systemic hypertension—for example, chronic renal disease
Hyperthyroidism
Acromegaly
Causes of right ventricular hypertrophy (causing TR)
Pulmonic stenosis
Pulmonary hypertension
Arrhythmic causes (MR and TR)
Cardiac arrhythmias preventing synchronous closure of AV valves—for example, ventricular premature beats

MR, mitral regurgitation; TR, tricuspid regurgitation.
*While this list is extensive, note that the most common causes of atrioventricular (AV) regurgitation are AV dysplasia, myxomatous degeneration, cardiomyopathy (any form), endocarditis, and hyperthyroidism (cats).
†May include mitral cleft or other AV valve malformation.

- Animals with very low cardiac outputs.
- Heart sounds muffled by lung sounds, pleural or pericardial fluid, or pneumothorax.

VALVULAR DISEASES OF CLINICAL IMPORTANCE

Chronic Valvular Disease

Chronic valvular disease occurs primarily in dogs. This progressive, degenerative disease is also referred to as endocardiosis, chronic degenerative valvular heart disease, chronic "myxomatous" valvular heart disease, or chronic mitral and tricuspid valvular fibrosis.

▼ ***Key Point*** Chronic valvular disease, or endocardiosis, a degenerative disorder of the cardiac valves, is the most important cause of heart disease in dogs.

Congenital Aortic Stenosis

This lesion usually is a *subvalvular* fibrous obstruction, although the lesion may extend to the valve proper (see Chapter 154 for a discussion of congenital valvular disorders).

Congenital Pulmonic Stenosis

A variety of anatomic lesions may contribute to narrowing of the right ventricular outflow tract, pulmonic valve, or pulmonary artery (see Chapter 154).

Congenital Mitral and Tricuspid Valve Dysplasia

Anomalies of the chordae tendineae, papillary muscles, valve cusps, or valve annulus can lead to incompetency or, less commonly, to stenosis of the valves (see Chapter 154).

Infective (Bacterial) Endocarditis

This condition almost always involves the left-sided heart valves in dogs and cats. Destruction of valve tissue commonly results in valvular insufficiency, although large vegetation(s) or valvular fusion may obstruct blood flow and create stenosis.

AV Valvular Regurgitation Due to Cardiomegaly or Cardiomyopathy

Valvular regurgitation may develop secondary to *ventricular or atrial dilation* or *ventricular hypertrophy* related to a variety of causes (see Table 149-1). For example, acquired mitral regurgitation in cats is typically caused by a form of cardiomyopathy.

CHRONIC VALVULAR DISEASE (ENDOCARDIOSIS) IN DOGS

Chronic valvular heart disease is a degenerative disorder of unknown cause affecting the endocardial and subendocardial portions of the valve leaflets, primarily in middle-aged and older dogs. It is not a consequence of endocarditis, although there is good evidence for a genetic predisposition to develop the disease in a number of canine breeds. The AV valves are principally involved, with the mitral valve affected in nearly 100% of cases, the tricuspid in 34%, and the aortic valve in a smaller proportion of cases based on pathology studies.

Pathology

- The valve leaflets in advanced disease are thickened and distorted by nodular changes in the free edge

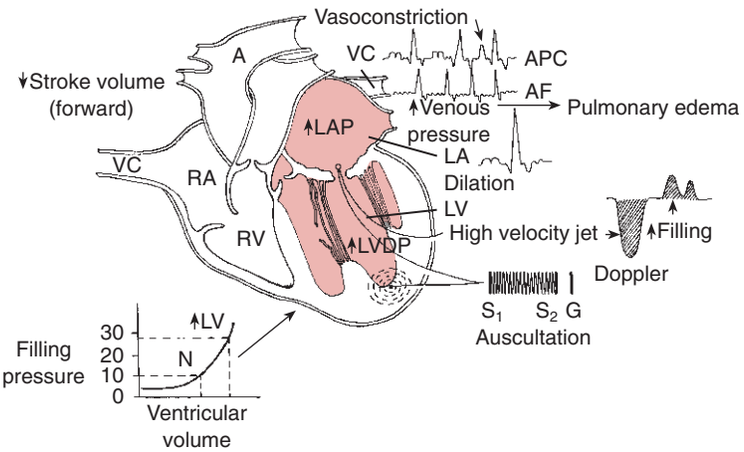

Figure 149-1. Diagrammatic representation of mitral regurgitation. Consult the text for an explanation of abbreviations and symbols.

and base of the valve. The valve surface glistens and the endocardium is grossly intact, distinguishing this degenerative change from endocarditis. In some dogs the valve surface may be increased with redundant connective tissue and billowing of a portion of the leaflets towards the atrium. Histological lesions are myxomatous in nature, characterized by deposition of acid-staining glucosaminoglycans within the valve leaflet and cusp. Collectively these lesions predispose to valvular regurgitation, which is typically slowly progressive in nature.

- The chordae tendineae are thickened near the valve attachment, and *chordal stretch* or *rupture* may be observed. Stretch predisposes to valve prolapse. Sudden rupture of a chord may lead to a flail leaflet and peracute congestive heart failure.
- Secondary *dilation of the left atrium and ventricle* develops in dogs with mitral valvular endocardiosis. Ventricular hypertrophy is of the eccentric type (with dilation of the ventricle) in isolated chronic valvular disease. The mitral valve annulus dilates as the ventricular dimensions increase, leading to further regurgitation and left atrial enlargement. In cases complicated by intercurrent systemic hypertension, there may be inappropriate thickening of the left ventricular wall.
- Focal subendocardial *myocardial fibrosis* may be evident, especially involving the papillary muscles. These fibrotic lesions may be related to narrowing of small, intramural coronary arteries.
- Endocardial sclerosis develops in the left atrium secondary to mechanical irritation from high velocity, regurgitant streams of blood. These "jet lesions" consist mainly of fibrous tissue. Fresh or healed linear left atrial tears commonly are found at necropsy, but rupture of the left atrium with pericardial tamponade rarely is encountered.
- The right ventricle and right atrium can become dilated because of concomitant tricuspid regurgitation, often complicated by pulmonary hypertension from left ventricular failure or intercurrent lung disease.

Pathophysiology

Endocardiosis represents a progressive process and does not cause detectable signs during the earliest period of structural changes. Progressive valvular distortion leads to detectable valvular insufficiency with accompanying cardiac enlargement. Mitral regurgitation (MR) causes left ventricular volume overload, left heart failure, pulmonary hypertension, and predisposes to cardiac arrhythmias (Fig. 149-1). However, heart failure does not develop in all dogs. The entire process usually requires many years, although some breeds (e.g., Cavalier King Charles spaniel) are affected relatively early in life and may have a rapid progression to heart failure.

▼ ***Key Point*** Mitral valve disease is the most important cause of heart murmurs and left-sided congestive heart failure (CHF) in mature dogs.

Mitral Regurgitant Volume

Total left ventricular (LV) stroke volume often is greatly increased, but a large proportion of LV output can be regurgitated into the left atrium. Forward stroke volume, the blood pumped into the aorta, is often maintained at near normal levels until CHF is present or advanced.

Left-Sided Cardiomegaly

Chronic mitral insufficiency increases LV and left atrial (LA) volume. Increases in LA pressure and volume cause progressive LA dilatation. Eccentric hypertrophy with dilatation of the left ventricular chamber results from the volume overload.

Increased Pulmonary Venous Pressure

LA and pulmonary venous (PV) pressures increase for a number of reasons:

- Progressive MR increases LA pressure, initially during systole. If the regurgitant volume increases gradually, LA compliance increases, and the condition is well tolerated. This explains why many dogs have severe cardiomegaly but minimal clinical signs. If the regurgitant volume is very large, or if regurgitation develops suddenly (e.g., chordal rupture), the limits of atrial distensibility are exceeded and mean LA and PV pressures increase, leading to pulmonary edema.
- The left ventricle may develop fibrosis or with progressive myocardial failure demonstrate reduced diastolic compliance and increased resistance to filling. The resulting higher LV diastolic pressure is transmitted to the left atrium and pulmonary veins.

Pulmonary Edema

Elevation of PV pressures increases pulmonary capillary pressure and may lead to pulmonary edema. Reduced forward output may promote retention of sodium and water by the kidneys and contribute to fluid overload. Clinical consequences include tachypnea, hypoxemia, coughing, and exercise intolerance.

Bronchial Compression

The left main-stem bronchus can become trapped between the pulsating aorta and the enlarging atrium. During systole, the bronchus is compressed by combined expansion of the aorta and the left atrium, triggering pressure receptors in the bronchus. As a result, exertional coughing and wheezing may occur even in the absence of lung edema.

Pulmonary Dysfunction

Chronic passive congestion of the lung causes ventilation perfusion inequalities (leading to hypoxemia) and, with chronicity, also might induce pulmonary fibrosis, which increases lung stiffness and the work of breathing.

Myocardial Failure

Chronic volume work by the left ventricle, combined with recurrent neurohormonal activation (renin-angiotensin-aldosterone; sympathetic nervous system; pro-inflammatory cytokines) can cause structural remodeling of the myocardium. Eventually reduced LV contractility and cardiac muscle failure occur ("cardiomyopathy of overload"). LV dysfunction is especially likely in larger dogs with primary mitral valve disease. However, in most cases, CHF often is manifest before substantial myocardial failure can be appreciated by clinical testing.

Low Cardiac Output

If forward stroke volume is inadequate, signs of low output (weakness, exertional or cough-related syncope, and prerenal azotemia) may develop. Low output signs are often associated with the development of pulmonary hypertension and right-sided CHF, although syncope can be the result of arrhythmias or of altered baroreceptor function leading to vasodilation and bradycardia.

Right Ventricular (RV) Failure

Left heart failure with secondary pulmonary hypertension, often combined with tricuspid regurgitation due to endocardiosis, causes progressive RV dilation. RV failure may ensue, as evidenced by hepatomegaly and ascites.

Cardiac Arrhythmias

Arrhythmias are common and can further decrease cardiac output (see Chapter 145).

- Atrial arrhythmias are triggered by dilation of the atria. Atrial premature complexes (APCs) frequently are recorded on the electrocardiogram (ECG). Atrial tachycardia and atrial fibrillation are evident in some cases.
- Ventricular premature complexes (VPCs) develop in some dogs, especially those with myocardial failure, but sustained ventricular tachycardia appears to be less common than in dogs with dilated cardiomyopathy.
- Iatrogenic arrhythmias (e.g., sinus bradycardia, AV block, APCs, and VPCs) may be precipitated by digitalis intoxication or diuretic-induced hypokalemia.

Ruptured Chordae Tendineae

This condition commonly is observed during echocardiographic examination of dogs with advanced MR. Catastrophic CHF may develop acutely; however, depending on the location of the chordal rupture, the added hemodynamic burden may be reasonably well tolerated.

Left Atrial Rupture

Rupture of the left atrium, although uncommon, can cause acute cardiac tamponade, cardiogenic shock, and sudden death. Rarely, splitting of the atrial septum produces an acquired left-to-right shunting atrial septal defect.

▼ ***Key Point*** Rupture of the mitral valve chordae tendineae, the development of sustained atrial tachyarrhythmias, and LA rupture are important diagnostic considerations when rapid hemodynamic deterioration occurs in dogs with chronic MR. Appropriate therapeutic intervention can

stabilize many of these patients, allowing sufficient time for further compensation.

Clinical Signs and Diagnosis

Signalment

Chronic valvular disease is most common in toy and small breeds of dogs (e.g., poodle, Yorkshire terrier, Cavalier King Charles spaniel, schnauzer, cocker spaniel, and dachshund). Some breeds, particularly the spaniels, German shepherds, and Afghan hounds, are prone to both valvular degeneration and dilated cardiomyopathy. Endocardiosis is an incidental finding in many aged dogs. Male dogs are predisposed to the development of CHF with chronic valvular disease.

▼ ***Key Point*** Occasionally, CHF from primary mitral valve disease develops in large-breed dogs, but dilated cardiomyopathy is a more important cause of CHF in these larger dogs.

History

The presenting complaints typically are those attributable to bronchial compression, pulmonary congestion, or low cardiac output and include cough, tachypnea, tiring on exercise, and syncope. Weight loss is a frequent but subtle finding until biventricular or right-sided heart failure develops. Unless there are other metabolic problems, such as hyperadrenocorticism, few dogs with overt CHF are obese. The opposite is often true in dogs with chronic respiratory disease. In general, the clinical signs gradually become more severe, reflecting the progressive nature of the disease. Syncope may be related to one or more of the following problems:

- Cough-syncope—fainting after vigorous coughing caused by decreased venous return, transient bradyarrhythmias, or inappropriate baroreceptor reflex-mediated activation.
- Paroxysmal atrial or ventricular tachyarrhythmias.
- Orthostatic hypotension—sudden weakness after rising may be related to abnormal baroreceptor activity, particularly in volume-depleted dogs.
- Insufficient forward flow from severe MR or from pulmonary hypertension, typically observed at the onset of exercise or with excitement.
- Reflex-mediated (neurocardiogenic) syncope. This may be the most common cause of excitement-induced syncope.
- Iatrogenic issues—hypotension secondary to diuretics, vasodilators, or angiotensin-converting enzyme inhibitors (ACEIs).

Physical Examination

Auscultation

As the disease progresses, the left apical systolic murmur of mitral insufficiency generally increases in intensity, and the duration increases from early systole to midsystole until it extends throughout systole (holosystolic). The murmur of MR radiates in the direction of the regurgitant jet, typically dorsal to the mitral valve on the left hemithorax, but very often to the right hemithorax as well.

▼ ***Key Point*** A systolic murmur heard best over the (palpable) left apex almost always is caused by MR. The murmur may radiate widely.

- A systolic click or short systolic murmur usually indicates early disease. The murmur of MR usually evolves from a soft decrescendo to a loud holosystolic murmur over a period of months to years. In some dogs with peracute CHF or in dogs with systemic hypotension from drug therapy or due to ruptured left atrium, the murmur can become softer and shorter.
- Left apical midsystolic clicks often are detected in asymptomatic dogs and may be confused with a ventricular gallop. These clicks probably indicate chordal laxity and valve prolapse.
- A ventricular gallop (third heart sound) may be heard at the left apex in some dogs with CHF. This sound often resolves after successful therapy.
- Cardiac arrhythmias and pulse deficits may be detected in patients with rhythm disturbances.

Precordial Palpation

The point of the left apical impulse shifts caudoventrally as the left ventricle enlarges. A precordial thrill develops in many dogs with advanced valvular incompetency and is palpable over the left apex or tricuspid valve area. A right-sided thrill is most often identified in dogs with the combination of TR and pulmonary hypertension.

Arterial Pulse

The arterial pulse is variable and depends on forward stroke volume, cardiac rhythm, and current therapy. A good arterial pulse is usually present in dogs with compensated disease. Heart rate typically is increased when CHF is evident.

▼ ***Key Point*** Pronounced sinus arrhythmia is atypical in dogs with untreated CHF caused by mitral valve disease but is common in patients with primary respiratory disease.

Pulmonary Auscultation

As lung congestion develops, ventilatory effort and lung sounds become abnormal. Inspiratory crackles and cyanosis may be detectable. Wheezes, representing "cardiac asthma" from peribronchial edema (cuffing) or left main-stem bronchial compression, may be noted. Pleural effusion may cause muffling of lung or heart sounds on the ventral thorax.

Right-Sided CHF

If the right heart fails, jugular venous pressure and liver size increase. Ascites is typical of advanced right-sided CHF, often with pulmonary hypertension. Pleural effusion usually indicates biventricular CHF, and is particularly common in dogs with atrial fibrillation. Occasionally, a dog is presented with predominant signs of RV failure due to pulmonary hypertension and severe tricuspid regurgitation (TR). Heartworm disease, pericardial effusion, dilated cardiomyopathy, tricuspid valve malformation, and atrial muscular dystrophy/myocarditis should be differential diagnoses in dogs with right-sided CHF.

▼ ***Key Point*** When there is pleural effusion and no jugular venous distention, ascites, or atrial fibrillation, strongly consider non-cardiac causes for the effusion.

Imaging—Radiography and Echocardiography

Cardiac imaging is discussed in Chapter 143.

- Progressive cardiomegaly is detected with left-sided heart enlargement predominating. Cardiac widening and LA enlargement typically are the first abnormalities detected. A vertebral heart score (comparison of length and width of cardiac silhouette to vertebral length caudal from the fourth thoracic vertebra) greater than 10.8 is good evidence of volume overload in dogs with chronic valvular disease. As the disease progresses, LV elongation, left main-stem bronchial compression, and pulmonary venous distention are observed.
- Left-sided CHF causes radiographic abnormalities that include increased lung density (interstitial and alveolar infiltrates) in the perihilar lung zones. These infiltrates characteristically are dorsal and bilaterally symmetric. However, owing to differences in pulmonary lymphatic drainage, edema may be worse in the right caudal lobe, a finding best appreciated in the ventrodorsal or dorsoventral view. Pleural effusion and ascites are present with right-sided or biventricular failure.
- Echocardiographic findings include cardiomegaly, thickened AV valves, and variable changes in LV shortening fraction. Valvular thickening may not be symmetric and often appears to preferentially affect the anterior (septal) mitral leaflet. Valve prolapse of the mitral or the tricuspid valve may be observed. In many cases, ventricular contractility appears normal to increased because the LV ejects a large portion of the total stroke volume backward into the low-resistance left atrium. The shortening fraction is rarely below the lower limits of normal reference values, helping to distinguish this condition from dilated cardiomyopathy. Stretched or ruptured chordae tendineae can result in focal leaflet prolapse or complete loss of valvular support (flail). Doppler studies can demonstrate mitral and tricuspid regurgitant flow and Doppler studies can be used to document the presence of pulmonary hypertension. Often, mild aortic regurgitation (that is silent to auscultation) is evident as well.

Electrocardiography

- The ECG can be normal, and heart rate and rhythm usually are normal until significant cardiomegaly or CHF develops.
- Arrhythmias become common as the disease progresses. Sinus tachycardia, supraventricular premature beats, paroxysmal or sustained atrial or supraventricular tachycardia, atrial fibrillation, and VPCs may be recorded (see Chapter 145).
- Atrial enlargement often causes widening of the P wave (P mitrale) as well as increased P wave amplitude. LV enlargement is suggested by increased voltages in leads II, III, and aV_F, widening of the QRS complex, and slurring or coving of the ST segment (see Chapter 144). Left axis deviation is uncommon.
- A 24-hour ambulatory ECG (Holter) recording or an event monitor ECG is helpful for evaluating dogs with syncope and for determining the need for and response to anti-arrhythmic therapy (see Chapter 148).

Laboratory Tests

Laboratory changes that accompany advancing endocardiosis typically reflect the hemodynamic changes and renal responses that develop in dogs with CHF. Laboratory studies help to identify complications caused by extracardiac diseases (e.g., Cushing's disease, renal failure) and drug therapy (e.g., diuretics).

- Significant pulmonary edema or tissue hypoperfusion causes arterial hypoxemia (decreased PaO_2), and the associated increase in ventilatory effort can cause respiratory alkalosis.
- Mild to moderate increases in blood urea nitrogen (BUN), serum creatinine, and phosphorus are detected in many dogs with endocardiosis as a result of chronic renal disease, decreased cardiac output, or hypotensive drug therapy. Azotemia may improve or resolve following a reduction in diuretic or ACEI dosages, if these can be tolerated without worsening of clinical signs of CHF. Diuretic therapy prevents use of urine specific gravity as a measure of renal interstitial-tubular function.
- Poor hepatic perfusion and hepatic congestion may cause mild to moderate elevations of serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Persistently elevated liver enzymes usually indicate a non-cardiac disorder of the liver, particularly when such changes are marked.
- Serum electrolyte abnormalities are uncommon. Hyponatremia sometimes is detected in dogs with

severe biventricular heart failure, especially in those with marked ascites and polydipsia, and is a poor prognostic sign. Hypochloremia and hypokalemia are usually iatrogenic as a result of diuretic therapy and anorexia. Co-therapy with furosemide and thiazide diuretics is most likely to cause most serious reductions in sodium, potassium, and chloride.

- Assays for plasma brain natriuretic peptide and/or atrial natriuretic peptide may prove useful for establishing a diagnosis of CHF or to provide prognostic information. At present, these tests are only available as research tools however clinically useful tests may be available soon.

Differential Diagnosis

The differential diagnosis of valvular heart disease includes any cardiac disease that leads to a heart murmur (see Table 149-1). The leading differential diagnoses are usually dilated cardiomyopathy, congenital AV valve malformation, and bacterial endocarditis. In dogs with cough or respiratory distress, CHF due to chronic valvular disease must be distinguished from tracheal or bronchial collapse, chronic bronchitis, pulmonary fibrosis, and other primary pulmonary diseases (e.g., pneumonia, thoracic neoplasia, allergic pneumonitis, and non-cardiac cause of pleural effusion).

- The typical age, breed, and clinical presentation make the diagnosis of chronic valvular disease straightforward in most cases.
- The echocardiogram is useful for distinguishing endocardiosis from congenital valve malformation or dilated cardiomyopathy.
- Bacterial endocarditis is associated with clinical findings of a multisystemic disorder. Physical, radiographic, and echocardiographic features of healed mitral endocarditis may be difficult to distinguish from myxomatous changes.
- CHF is commonly misdiagnosed in patients with chronic respiratory disease because these dogs often have cough, shortness of breath, and pulmonary crackles (which can be misinterpreted as "wet lungs," as opposed to small airway dysfunction). Concurrent compensated chronic valvular disease, when present, creates a cardiac murmur and complicates clinical decision making.
  - Determine whether radiographic cardiac enlargement is more consistent with cor pulmonale (right heart enlargement secondary to chronic lung disease) or left heart enlargement with left atrial and ventricular enlargement on both radiographic views.
  - Seek to identify positive findings of heart disease, such as murmur, arrhythmias, abnormal ECG, cardiomegaly (vertebral heart score >10.8) with left atrial enlargement, and pulmonary venous distention. With the possible exception of catastrophic CHF, the diagnosis of endocardiosis should not be considered unless the definitive murmur of MR is evident.
  - If mild CHF is the likely cause of respiratory signs, consider a trial course of furosemide (2 mg/kg, q12h) for 5 to 7 days. Anticipate a good response in cases of left-sided CHF, with concurrent radiographic improvement. Some patients with chronic lung disease also respond partially to diuretics (mechanism uncertain).
  - Pulmonary crackles or a cough without a murmur, a history of untreated, chronic (>6 months) cough, a "honking" cough, right heart enlargement, and marked sinus arrhythmia or slow sinus rhythm are more typical of chronic respiratory disease than of chronic CHF. Dogs with respiratory disease are more likely to be somewhat overweight and have a bronchial pattern on thoracic radiographs. Thoracic radiography, airway cytology and culture, and bronchoscopy can usually establish the cause as respiratory. If required, refer the client to a cardiac specialist for a second opinion.

Treatment

Therapy of chronic valvular disease depends on the stage of disease and severity of clinical signs. Combination drug therapy and dietary management is indicated once CHF has developed. Surgical repair or replacement of a cardiac valve is rare in veterinary practice. The aims of medical therapy are to control clinical signs of CHF, mitigate neurohormonal activation, reduce mitral regurgitant fraction, and prolong life. Diuretics, ACEIs, direct vasodilators, digoxin, pimobendan, pulmonary medications, and dietary measures may be prescribed at various times during the course of the disease. Anti-arrhythmic drugs are required in selected dogs, especially those with atrial fibrillation and serious ventricular arrhythmias. Atrial fibrillation is usually managed with digoxin combined with either a beta-blocker or calcium channel blocker (see Chapter 145). The clinical pharmacology of these cardiac medications is reviewed in Chapter 146. Specific management strategies for the hospital and home treatment of heart failure are discussed in Chapter 147 and summarized in this section. The following is a summary of general therapeutic approaches.

The Asymptomatic Dog

- The ideal approach to the management of the asymptomatic dog has not been determined. While ACEI use is still a subject of some debate, the two published clinical trials examining their use in asymptomatic dogs have failed to demonstrate appreciable clinical benefit.
- Some clinicians withhold all therapy until there are objective signs of CHF. Others prefer to prescribe an ACEI, empirically, if there is concurrent systemic

hypertension or evidence of marked cardiomegaly or clearly progressive disease on radiographs or echocardiography.
- There is no evidence that early enforcement of a very low sodium-restricted diet is of benefit. Early diuretic use and/or severe salt restriction activate the renin-angiotensin-aldosterone system and may be counterproductive. Moderation of sodium intake is often recommended at this stage, especially limitation of high sodium treats.

Coughing in the Dog with Mitral Regurgitation

- A harsh cough is often the initial clinical sign of advanced MR. Coughing is a frequent complication of left bronchial compression, a condition that often precedes the onset of overt pulmonary edema. The lack of clear-cut clinical or radiographic evidence of pulmonary edema in the dog with a mitral murmur and cough complicates determination of the cause of cough. Many dogs exercise well (except for an exertional cough) and sleep comfortably without tachypnea. It is unlikely that these dogs have overt CHF unless transient bouts of pulmonary edema develop with exertion.
- The best therapeutic approach to bronchial compression is unresolved.
  - One approach is prescription of an ACEI, possibly combined with a once daily diuretic. Such therapy can decrease cardiac size and blood pressure, which in turn may decrease regurgitant fraction. This therapy also is likely to mitigate transient, exercise-induced pulmonary edema and to delay the onset of more overt signs of CHF.
  - If the cough continues, medications effective for primary airway disease may be helpful. This can include a cough suppressant (butorphanol 0.55 mg/kg, PO, q8–12h or hydrocodone 0.22 mg/kg, PO, q8–12h). An empiric course of a theophylline salt can be tried (10–20 mg/kg of a sustained release preparation, PO, q12h; beware of excitement as a side effect). This should be discontinued if a clear response is not evident within 2 weeks. In dogs with suspected concurrent respiratory disease, consider a brief course of prednisolone (0.5 mg/kg daily for 5–7 days) to reduce inflammation and break the coughing cycle.

Hospital Treatment of Left-Sided CHF

- Once CHF has developed, the initial course of management is based on the severity of clinical signs of pulmonary edema. Initial therapy generally includes cage rest, oxygen if required, and furosemide (2–4 mg/kg, q6–q12h, IV or IM). Some clinicians also add nitroglycerin paste ($\frac{1}{2}$ to 1-$\frac{1}{2}$ inches cutaneously q8–12h) as a venodilator. Others administer aminophylline (10 mg/kg, q8h) if there is a concern about bronchospasm. The efficacy of bronchodilators has not been established, and they may induce tachycardia, arrhythmia, or anxiety in some dogs.
- Moderate to large volume pleural effusion should be removed by thoracentesis. Dogs with concurrent respiratory distress and large volume ascites may benefit from abdominocentesis.
- Life-threatening pulmonary edema requires more aggressive treatment beyond oxygen and high-dose furosemide (also see Chapter 147). Consider a constant rate IV infusion of furosemide. Drugs that reduce left ventricular afterload should be administered unless the patient is hypotensive. The direct arterial vasodilator, hydralazine (1–2 mg/kg, PO), or IV administration of sodium nitroprusside (1–5 µg/kg/min) will promptly lower blood pressure and LV load. Administration of an ACEI such as enalapril (0.5 mg/kg, PO) also reduces load, but the onset of action is slower.
  - The dose of these vasodilators should be titrated to a systolic arterial blood pressure of 85–95 mmHg. Aggressive afterload reduction significantly decreases the mitral regurgitant fraction. Such therapy is especially important in cases of peracute regurgitation caused by ruptured mitral valve chordae tendineae.
- Some patients in severe CHF exhibit marked anxiety and air hunger. Treatment with morphine may be useful if it does not induce vomiting (0.1 mg/kg, administer 25% IM; administer the balance SC 15 minutes later). Alternatively, consider subcutaneous administration of acepromazine (0.025 mg/kg) mixed with buprenorphine (0.005 mg/kg). Some clinicians find that butorphanol (0.25 mg/kg, IM) is an effective sedative with the advantage of not inducing vomiting.

Home Therapy of Left-Sided CHF

- Chronic therapy of heart failure caused by mitral valvular disease includes a maintenance dose of furosemide (2–5 mg/kg, q8–24h), an ACEI such as enalapril or benazepril (0.5 mg/kg, PO, q12–24h), and dietary sodium restriction. Titrate the daily doses of furosemide and the ACEI to clinical signs, objective measures of fluid accumulation, arterial blood pressure (to maintain a systolic pressure of 90–120 mm Hg), and renal function. Reduce dosages if hypotension or progressive azotemia develops. Pimobendan, a potent inotropic drug with vasodilating properties (see Chapter 146), has not been approved in the United States at the time of writing; however, it is available in many countries and represents a valuable drug for management of dogs with CHF due to MR.
- Digoxin also is prescribed by many cardiologists. Use an initial conservative dose (0.005 mg/kg, q12h), and adjust based on serum digoxin concentrations (target is 0.8–1.2 ng/ml at a 10–12 hour trough).

- Atrial fibrillation or frequent atrial ectopic beats represent clear indications for digitalization. Once CHF is controlled and digoxin has been initiated, co-therapy with a beta-blocker or diltiazem may be required to attain better ventricular rate control.
- Digoxin also may be useful to reduce syncopal episodes in dogs where no clear clinical cause for syncope can be established. Digoxin is contraindicated in the setting of complicated ventricular rhythm disturbances or ventricular tachycardia.

▼ ***Key Point*** Combination therapy is preferred in the management of CHF. Monotherapy with a diuretic or a diuretic and sodium-restricted diet is no longer considered appropriate treatment for most dogs because volume depletion activates the renin-angiotensin-aldosterone system.

- Treat progressive or refractory pulmonary edema first by optimizing current therapy. Should q12h ACEI therapy, q8h doses of furosemide, and pimobendan (where available) fail to control this problem, consider adding another vasodilator, digoxin, or a second diuretic.
  - Combination therapy with an ACEI and hydralazine (0.5–1 mg/kg, PO, q12h) or amlodipine (0.05–0.2 mg/kg, PO, q24h daily) can more effectively reduce the mitral regurgitant fraction. Such treatments are best initiated in the hospital, where arterial blood pressure can be monitored frequently. Many dogs can tolerate a systolic blood pressure as low as 80–85 mm Hg initially without overt clinical signs of hypotension, allowing time for further adaptive responses. Blood pressure in this 80–85 mmHg range during chronic management of CHF is sometimes associated with lethargy or weakness. A second vasodilator is also critical in dogs with MR and concurrent systemic hypertension despite full ACEI and diuretic therapy. Amlodipine, hydralazine, carvedilol, or compounded prazosin may be effective for individual patients (Chapter 153).
  - An alternative approach to progressive CHF is the addition of another diuretic, which is described in a following section.

Treatment of Right-Sided Congestive Heart Failure

- Right-sided CHF with ascites or biventricular CHF with pleural effusion is more likely to occur in dogs in which pulmonary hypertension, tricuspid regurgitation, or atrial fibrillation. Pulmonary hypertension usually is a consequence to chronic elevation in left atrial pressure or pulmonary vascular narrowing secondary to chronic CHF or primary lung disease.
- When right-sided CHF dominates the clinical picture, it is not uncommon to notice a reduction of dyspnea and an increase in exercise intolerance. Radiography often demonstrates minimal pulmonary edema, whereas Doppler echocardiography may show signs of pulmonary hypertension, such as high-velocity tricuspid regurgitation.
- Management of dogs with a prominent component of right-sided CHF includes treatment with an ACEI (q12h), furosemide (q8h), pimobendan (if available), and a restricted sodium diet. Digoxin is also useful to control fluid accumulation in many dogs. Should these methods fail then a variety of other strategies can be attempted. Initially, the dog may be hospitalized, treated with subcutaneous furosemide (or other loop diuretic), and receive judicious paracentesis for tense ascites (removing between $\frac{1}{4}$ to $\frac{1}{2}$ of the fluid accumulation). Treat atrial fibrillation if present. Two or 3 days of enforced cage rest and parenteral diuretic therapy may alleviate most of the retained fluid. At that point, treatment strategies can include any (or all) or the following:
  - Markedly increasing the oral dose of furosemide to effect (because poor absorption of the medication may be partially responsible for the refractory ascites).
  - Using flexible subcutaneous diuretic dosing (having the client substitute a subcutaneous dose of furosemide for the usual oral dose).
  - Adding spironolactone (2 mg/kg, PO, q12 to 24h) or another potassium-sparing diuretic to the regimen.
  - Adding hydrochlorothiazide and spironolactone (2–4 mg/kg, PO, q12–24h of the combined product) to the regimen. This approach is especially aggressive because electrolyte reabsorption is blocked at sequential points along the nephron. Accordingly, the potential for volume depletion and electrolyte disturbances is very high and must be monitored carefully (reevaluate the patient, blood pressure, and serum biochemistries at 3 days, 7 days, and 14 days after starting this treatment).
- Pleural effusion in valvular heart disease is often a poor prognostic sign. A neoplastic cause for the effusion should be excluded, and treatment of pleural effusion due to CHF is as discussed previously for right-sided heart failure. Periodic thoracocentesis may be required.

Other Respiratory Complications in Advanced MR

- A persistent, nonresponsive cough in animals with otherwise well-controlled CHF can be a vexing problem. Bronchial compression or intercurrent airway disease may be the culprit in many of these cases. Provided there is no radiographic evidence of pulmonary edema, it is reasonable to continue the current cardiac medications and to add a cough suppressant, such as hydrocodone or butorphanol, or even a brief course of prednisolone, to control the cough.

- In other dogs, signs develop that suggest accelerated pulmonary fibrosis. These dogs have exercise intolerance, some may faint, and some are persistently tachypneic but generally sleep well without any resting dyspnea. Auscultation reveals diffuse inspiratory crackles that might be easily confused with those caused by pulmonary edema. Hypoxemia and pulmonary hypertension may be present, however radiography indicates "clear" lung fields or minimal interstitial density despite marked cardiomegaly. Escalation of diuretic or vasodilator therapy often does not improve the respiratory signs and may predispose the animal to syncope by reducing blood pressure.
- Other reasons for persistent respiratory signs in dogs with MR include tracheal collapse, chronic bronchitis, pulmonary neoplasia, pneumonia, and recurrent pulmonary thromboembolism.

Patient Follow-Up

Follow-up examinations and complications are described in Chapter 147. In general, a repeat examination should be performed 5 to 10 days after initiation of CHF therapy. Testing at the recheck should include historical and physical examination, blood pressure, evaluation of serum BUN, creatinine and electrolytes, and possibly thoracic radiographs. In dogs with stable CHF, follow-up examinations every 2 to 4 months are recommended to titrate therapy and insure owner compliance.

Prognosis

The prognosis for longevity is highly variable. Dogs with heart murmurs but without clinical signs of heart disease may survive for many years and often succumb from a non-cardiac disorder. Clinical signs associated with bronchial compression indicate that sufficient volume overload has developed to compress the airways, but this alone is not an indication of CHF. Once *overt* pulmonary edema or ascites develops, the prognosis for life becomes guarded. Assuming initial stabilization is successful, a survival range of between 3 months and 2 years should be discussed with the client. With good veterinary and home care and a dedicated client, many dogs live for 9 to 12 months or longer before spontaneous death or euthanasia.

BACTERIAL (INFECTIVE) ENDOCARDITIS

Bacterial endocarditis (BE) is a bacterial infection of the valvular or mural endocardium. The mitral and aortic valves are the most common sites of cardiac bacterial infection in dogs and cats. Establishment of a cardiac infection requires a portal of bacterial entry into the circulation, subsequent bacteremia, and colonization of the endocardium. In most cases, bacterial endocarditis is manifested as a multisystemic disorder, and cardiac disease might not be the leading differential diagnosis. In order to diagnose this disease the clinician must maintain a high index of suspicion in animals with multisystemic clinical signs, especially when the differential diagnoses include serious infection or immune mediated disease.

Etiology

- Pathogenic bacteria identified in dogs and cats with bacterial endocarditis include streptococci, staphylococci, corynebacteria, *Escherichia coli, Enterobacter aerogenes,* and *Pseudomonas, Pasteurella, Erysipelothrix,* and *Bartonella* spp. Many of these bacteria are normal inhabitants of the skin, oral cavity, and respiratory and intestinal tracts. Bartonellosis is discussed in Chapter 19.
- Bacteria can gain access to the circulation via external wounds, established infections, and a variety of surgical procedures and invasive medical interventions; however, in many cases, there is no evidence of these sources. Endocarditis may be a sequela to septic arthritis, osteomyelitis, prostatitis, infected catheters, and other infections.
- Immunosuppressive drugs (e.g., corticosteroids, anticancer chemotherapy) also predispose to infection.
- Injudicious use of antibiotics may predispose to infection by resistant or virulent organisms.

Pathogenesis

- The pathogenesis of infective endocarditis involves entry of bacteria into the circulation and invasion of the valve endocardium by direct extension from the bloodstream.
  - Virulent bacteria may attach themselves to the valve surface, ulcerate the endocardium, and invade the valve stroma.
  - Previously diseased valves are believed to be more susceptible, particularly when the endocardium is disrupted. Dogs with subaortic stenosis are at increased risk for endocarditis, presumably because of jet lesions on the aortic valve. Conversely, for uncertain reasons, dogs with endocardiosis are rarely affected with BE.
  - High titers of agglutinating antibodies that cause clumping of bacteria, thereby increasing the size of the infectious inoculum, are thought to play a role in some cases.
- Collagen is exposed once micro-organisms colonize and ulcerate the endocardium, causing platelet aggregation and the local accumulation of fibrin.
  - Vegetations resembling thrombi form on the valve surface. These vary in color from yellowish red to gray and are covered by a thin layer of clotted blood.
  - Lesions usually are localized to the valve but can extend to the mural endocardium, chordae tendineae (causing rupture), or sinuses of Valsalva

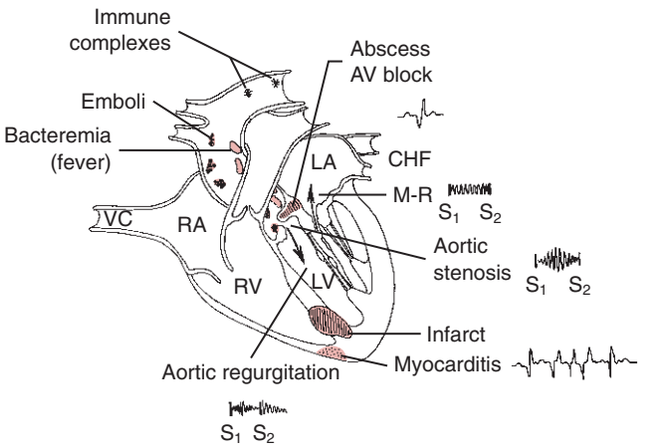

Figure 149-2. Diagrammatic representation of endocarditis. Consult the text for an explanation of abbreviations and symbols.

(this may hasten the spread of septic foci via the coronary arteries to the myocardium).

- Chronic valvular infections are established when layers of fibrin are deposited repeatedly at the site of infection, "protecting" the bacterial colonies from host responses and from many antibacterial agents.
- Deformation of the valve usually results in *valvular insufficiency*. Exuberant vegetation or fibrotic healing may form in such a way as to produce valve stenosis, but this is less common.
- Parts of the vegetation may break off, seeding the various tributaries of the systemic circulation, including the coronary arteries.
  - Intermittent bacteremia causes persistent or recurrent fever.
  - Thromboemboli, which can be septic or "bland" (aseptic), can also be shed from the infected valve.
- Formation of immune complexes is an important host response; these may be filtered into the joints, kidneys, or other tissues; attract complement and leukocytes; and cause inflammation in these tissues.

Pathophysiology

The clinical signs of infective endocarditis result from cardiac injury, bacteremia and sepsis, thromboembolic complications, and immune-mediated processes (Fig. 149-2).

Cardiac Injury

A variety of cardiac manifestations are possible, including

- Mitral and aortic valvular regurgitation.
- Valvular stenosis (less common).
- Coronary occlusion with myocardial infarction.
- Secondary myocardial invasion, causing myocarditis or myocardial abscessation.
- Pericarditis.
- Left-sided CHF (from advanced valvular injury).
- Arrhythmia.
  - Ventricular and supraventricular arrhythmias may be related to endomyocarditis, myocardial infarction from bland thrombi, cardiac dilation, or "toxemia." Extension of aortic root abscesses into the conduction system can cause AV block.

Bacteremia and Metastatic Infection

- Bacteremia causes fever, shivering, malaise, and anorexia.
- Other tissues may be seeded, resulting in brain abscesses, splenitis, osteomyelitis, septic arthritis, pyelonephritis, myositis, or other remote infections.
- In advanced cases, it is difficult to distinguish a primary infection (portal of entry) from a metastatic infection.
- Bacteremia and sepsis may be associated with disseminated intravascular coagulopathy (DIC) and lead to death from septic shock or organ failure.

Immune-Mediated Disease

Immune complexes may form and be trapped in many organs or tissues, with the following effects:

- The kidneys, leading to glomerulonephritis
- The brain and meninges, causing meningoencephalitis
- The joints, causing polyarthritis
- The skeletal muscles, causing myositis and myalgia
- The small blood vessels, leading to vasculitis, thrombosis, or hemorrhage
- The eye, leading to chorioretinitis

▼ ***Key Point*** Do not confuse the clinical findings seen in endocarditis of recurrent fever, multisystemic involvement, polyarthritis, and DIC with those of primary immunologic or neoplastic diseases; such an assumption may prompt inappropriate therapy with corticosteroids.

Thromboembolic Complications

Septic or bland (sterile) thrombi derived from the vegetation may be carried to distant tissues. Consequences include

- Myocardial infarction and myocarditis.
- Renal infarcts, abscess, pyelonephritis, and glomerulonephritis.
- Stroke, meningitis, and encephalitis.
- Bone infarcts and osteomyelitis.
- Vascular obstruction including aortic-iliac occlusion.
- Splenic infarcts.
- Intestinal ischemia.

Because of the low incidence of right-sided endocarditis in small animals, pulmonary embolism and pneumonia are rare. The notable exceptions are BE secondary to infection from patent ductus arteriosus

surgery and infection of a central venous catheter, dialysis catheter, or transvenous pacing lead.

Clinical Signs and Diagnosis

Signalment

Endocarditis is more common in certain large-breed male dogs (e.g., German shepherds) and in dogs with congenital subaortic stenosis.

History

- The history may suggest previous or concurrent infection (especially of the skin, oral cavity, gut, bone, or urogenital tract).
- Certain diagnostic and therapeutic procedures predispose to BE by causing bacteremia (e.g., surgical implants, endoscopy, and dental extractions).
- Persistent use of corticosteroids or antineoplastic drugs or improper use of antibiotics may predispose to BE.

Physical Examination

Physical examination findings may include

- Fever which may or may not be antibiotic-responsive, depression, anorexia, and shaking "chills."
- Polyarthritis (shifting lameness) with or without joint effusion and myalgia.
- Signs of vasculitis with hemorrhages (skin, eye, mucous membranes).
- Multifocal neurological deficits from meningitis or encephalitis.
- Signs of cardiac injury:
  - A cardiac murmur, particularly a "new" or changing murmur.
  - BE destroys portions of the valve; therefore, regurgitant murmurs (MR, aortic regurgitation) usually are present in dogs and cats with BE. A systolic ejection murmur often accompanies the diastolic murmur of aortic insufficiency due to increased LV stroke volume. Large vegetation(s) on the valves also may contribute to valve stenosis murmurs.
  - The pulse pressure increases with aortic insufficiency, which causes hyperkinetic femoral pulses with rapid run-off of diastolic pressure. Always consider BE when aortic regurgitation, which is uncommon in dogs and cats, is present.
  - Signs of overt left-sided CHF or arrhythmias (especially ventricular premature complexes) may develop from cardiac injury.

Laboratory Tests

Complete Blood Count (CBC)

Mild anemia and leukocytosis with neutrophilia and monocytosis may be present. Thrombocytopenia is often present, and red blood cell (RBC) fragments may suggest vasculitis (see Chapter 153) or DIC.

Serum Biochemistries

Biochemical alterations may reflect organ injury from infection, thrombosis, infarction, or poor perfusion from heart failure. Azotemia or liver enzyme elevations are often present, and elevation of serum alkaline phosphatase is common in dogs with gram negative infections. Hyperglycemia or hypoglycemia, hypoalbuminemia, and elevated bilirubin can also be noted.

Tests for Autoimmune Disease

Rheumatoid factor test, Coombs' test, or antinuclear antibody (ANA) assays can be positive in patients with BE.

Blood Cultures

Two or more positive blood cultures, obtained from a patient with compatible clinical signs, strongly suggest BE.

- Cultures are most rewarding if taken near febrile bouts when the animal is not receiving antibiotics. Cultures may be positive before, during, or after bouts of fever.
- Serial positive blood samples, taken 1 to 2 hours apart from different sites, help to rule out the possibility of skin contamination. (Aseptically prepare the skin before obtaining the sample.)
- Transfer sufficient blood (5–10 ml) into special broth media tubes (usual blood:medium ratio of 1:10). Aerobic and anaerobic culture and sensitivity are indicated. Special antibiotic adsorbing media are available for patients who have received antibiotic therapy.
- Some microorganisms are difficult to culture (e.g., *Bartonella* spp.), leading to so-called "culture-negative" endocarditis. Serologic testing and/or PCR testing can help establish a diagnosis of *Bartonella* in these cases. Dogs with culture negative endocarditis, especially those with aortic valve disease, should be suspected of having *Bartonella* (see Chapter 19).
- If a primary source of infection is suspected then cultures should be obtained from this location (i.e., urine culture, bone culture in suspected osteomyelitis, etc.).

Urinalysis

Hematuria, proteinuria, pyuria, or casts may be shown if pyelonephritis or glomerulitis is present. Culture the urine if there are any abnormalities, but do not automatically assume that organisms cultured from urine are responsible for the cardiac infection.

Cardiac Studies

Cardiac studies may substantiate the diagnosis and indicate the degree of cardiac injury. Serial studies after successful antimicrobial therapy are useful,

although complete resolution of valvular pathology is uncommon.

- Radiographs may indicate cardiomegaly, valve calcification (from chronic BE), CHF, or (rarely) embolic pneumonia.
- Electrocardiograms can be normal, but they may indicate chamber enlargement or arrhythmias (most often ventricular premature contractions).
  - ST-T changes, indicating ischemia or infarction, may be present (check precordial leads for these).
  - AV block in endocarditis likely indicates aortic valve involvement with a perivalvular inflammation affecting the bundle of His.
- Echocardiography is useful, especially for diagnosis and prognosis.
  - Routine 2-D or M-mode echocardiography may demonstrate a recent vegetation (oscillating thrombus) or more chronic lesion (thick, hyperechoic valve). Echocardiography is also helpful for identifying hemodynamic overload (cardiomegaly). A negative examination of the valves does not rule out BE.
  - Echocardiography alone may not be sufficient to distinguish mitral BE from advanced mitral endocardiosis.
  - Doppler studies can document both abnormal valvular regurgitation and stenosis. Hemodynamically significant aortic regurgitation is associated with an adverse outcome.
- Progressive cardiomegaly demonstrated by echocardiography or radiography indicates clinically significant valvular injury and is a poor prognostic finding.

Other Studies

Other studies may be abnormal depending on the organ involved. *Cerebrospinal fluid (CSF)* and *joint fluid* cytology and culture may show evidence of septic or aseptic (immune complex) suppurative inflammation.

Treatment

Consider the following principles:

- Use bactericidal antibiotics. Because the bacteria are sequestered within the vegetation, normal defense and healing processes (e.g., granulation) are impeded.
- Because the drug must penetrate fibrin, do not use most sulfa drugs.
- Long-term (1–3 months) therapy is needed to ensure sterilization of the vegetation.
- Ideally, use IV therapy to obtain the highest possible plasma concentrations for the first 5 to 7 days. (This is sometimes impractical.)
- Guide antibiotic therapy by blood cultures. It is appropriate to delay antibiotic therapy for 2 to 4 hours while blood cultures are being obtained, unless the patient is demonstrating signs of septic shock.
- Empirical therapy for BE often includes the following drugs:
  - Penicillins (high doses) are safe and useful for streptococcal infections but have limited efficacy against many staph and other microorganisms.
  - Aminoglycosides, combined with a synthetic penicillin or cephalosporin, provide wider antimicrobial coverage. Use of these drugs requires good patient hydration and careful monitoring for nephrotoxicity. Aminoglycosides should be withheld from animals with concurrent CHF that require furosemide administration.
  - A patient with renal failure may be treated with a newer-generation cephalosporin in lieu of an aminoglycoside.
  - In cases of suspected *Bartonella*, a combination of gentamicin (for 15 days) and doxycycline is recommended, with careful monitoring for nephrotoxicity. Azithromycin, 5 to 10 mg/kg q24h for the first 7 days, then every other day for 6 to 12 weeks, represents another approach to treating patients with confirmed *Bartonella* infection.
- Treat for at least 4 weeks (at least 10–14 days when using an aminoglycoside, with continuation of the penicillin or cephalosporin for the full 4 weeks). Some cardiologists recommend treatment for 6 to 8 weeks. Repeat blood cultures following discontinuation of therapy or if fever should recur.
- If left-sided CHF develops, treat according to guidelines described above for valvular endocardiosis. Remember that vasodilator therapy is contraindicated for dogs with septic shock.
- Use prophylactic antibiotics if the patient undergoes any procedure that may cause bacteremia. (The general subject of prophylactic therapy of BE is unresolved, and no firm recommendations can be made.)

Prognosis

The prognosis for BE is guarded. Negative prognostic predictors include large vegetations with accompanying marked cardiomegaly, CHF, marked aortic regurgitation, gram-negative infections, elevation of serum alkaline phosphatase or hypoalbuminemia, treatment with corticosteroids, delayed diagnosis or treatment with bacteriostatic antibiotics, and premature termination of antibiotics.

- Acute, ulcerative BE may cause dramatic clinical signs but, if promptly treated, may leave only mild cardiac dysfunction.
- Chronic BE with severe valvular destruction is more difficult to treat because severe CHF may develop.
- Echocardiographic evidence of diffuse, large vegetative lesions and documentation of volume overload imply a poor prognosis. The likelihood of CHF is high in these instances.

Chapter

150 Cardiomyopathy

John D. Bonagura / Linda B. Lehmkuhl

OVERVIEW

The left and right ventricles are capable of undergoing significant morphologic change in response to stresses and stimuli. Reaction to increased volume or pressure work frequently leads to chamber dilatation and hypertrophy, along with alterations in the cytoskeletal matrix of the ventricle. Myocardial and chamber responses develop with chronic valvular heart disease, cardiac shunts, systemic and pulmonary hypertension, thyrotoxicosis, and chronic anemia. These responses to stress are directed by various neural, hormonal, and genetic messages acting on the myocardium. These signals influence genetic expression in the cardiomyocyte and interstitial cells, and remodel the ventricle.

"Cardiomyopathy" refers to disease of the myocardium and, by extension, the cardiomyocyte and the supporting collagen and interstitial matrix. Idiopathic or primary cardiomyopathies are those that cannot be explained by a malformation, acquired cardiac lesion, dysrhythmia, or coronary artery disease. Many idiopathic cardiomyopathies are genetic diseases. A more expansive definition of cardiomyopathy accepts that some myocardial diseases can be explained by other disorders, and in such cases, the term *secondary cardiomyopathy* can be used. When myocardial failure develops from chronic volume or pressure overload of the ventricle, the term *cardiomyopathy of overload* has been proposed to explain the remodeling associated with increased ventricular work.

Although there are many known causes of cardiomyopathy, most cases in cats and dogs are idiopathic and thought to represent a genetic disorder. This is particularly true of dilated cardiomyopathy in dogs and hypertrophic cardiomyopathy in cats. What stimulates these genetic factors to cause heart muscle disease is poorly understood, and most cases of cardiomyopathy are irreversible and progressive. But there are special examples that demonstrate that some cardiomyopathic states can be postponed, arrested, or even reversed. For example:

- Chronic tachyarrhythmias cause a cardiomyopathy with loss of myocardial contractility that is reversible if the arrhythmia is resolved.
- Taurine deficiency in cats is a classic example of a reversible dilated cardiomyopathy.
- Regression of left ventricular hypertrophy may occur after successful treatment of systemic hypertension or hyperthyroidism.

Cardiomyopathies often are classified by the postmortem anatomic appearance of the left (or right) ventricle and by the correlative echocardiographic features of ventricular anatomy and function. The most important forms of cardiomyopathy can be classified as follows (see Table 150-1):

- ***Myocarditis*—**An inflammation of the heart muscle observed most often in cats. It may be responsible for premature ventricular complexes, sudden death, or progressive heart failure.
- ***Dilated cardiomyopathy (DCM)*—**A dilated, poorly contracting left ventricle (LV) usually associated with development of congestive heart failure (CHF), cardiac arrhythmias, and sudden death. DCM is a common disease of dogs but is very uncommon in cats.
- ***Hypertrophic cardiomyopathy (HCM)*—**A thickening of the LV walls of unknown or genetic cause and displaying considerable phenotypic heterogeneity. HCM is mainly a disorder of cats and often leads to cardiac murmurs, CHF, or thromboembolic disease.
- ***Restrictive cardiomyopathy (RCM)*—**A heterogeneous and poorly characterized disorder defined by extensive fibrosis in the LV. It is encountered mainly in mature or older cats and is a recognized cause of arrhythmias, CHF, and arterial thromboembolism.
- ***Right ventricular cardiomyopathy*—**A disorder that affects mainly (or initially) the right ventricle resulting in either CHF or ventricular arrhythmias.
- ***Unclassified cardiomyopathy*—**Primary LV diseases that are not easily classified as HCM, DCM, or RCM. Some cases are probably related to myocardial infarction.
- ***Cardiotoxicity*—**The heart also can be damaged by a number of cardiotoxins, some of which are listed in Table 150-1. The outcome of cardiotoxicity is often an arrhythmia, conduction disturbance, sudden death, or development of a secondary dilated cardiomyopathy.

Table 150-1. CAUSES OF CARDIOMYOPATHY (CM)

Disorder*	Feline	Canine
Myocarditis		
Noninfective	Idiopathic	Idiopathic
	Thymoma (immune-mediated)	Trauma
Infective	Toxoplasmosis	Bacterial
	Feline infectious peritonitis?	Parvovirus
		Distemper virus
		Systemic mycoses
		Lyme carditis (*Borrelia*)
		Chagas disease (*Trypanosoma cruzi*)
Dilated CM (DCM)‡	Taurine deficiency	Idiopathic†
	Idiopathic	Carnitine or Taurine deficiency
	Potassium iodide toxicity	Breed-"specific" DCM†
	Hyperthyroidism	Doberman pinscher
	Sustained ventricular or supraventricular tachycardia	Boxer dog
		Cocker spaniel
	Chronic hypokalemia (causes taurine deficiency?)	"Giant" purebred dogs
		Springer spaniel muscular dystrophy
		Sustained ventricular or supraventricular tachycardia
Hypertrophic CM	Idiopathic† (familial?)	Idiopathic
Left ventricular concentric hypertrophy	Acromegaly (rare)	Hypertension
	Hypertension†	Hyperthyroidism (iatrogenic)
	Hyperthyroidism†	
Restrictive-intermediate CM	Idiopathic*	
Arrhythmogenic right ventricular cardiomyopathy	Idiopathic	Boxer dog (genetic)†
		English bulldog (genetic?)†
Cardiotoxicity	Sodium iodide	Catecholamines including brain-heart syndrome and pheochromocytoma
		Doxorubicin
		Digitalis purpurea (foxglove) and *Strophanthus* spp.
		Toad (*Bufo*) toxicity
		Chocolate toxicity

*Both primary (idiopathic) and secondary causes of cardiomyopathy are considered here.
†Most important types.
‡Also see infective and noninfective myocarditis because DCM can develop secondary to severe inflammatory disease.

This chapter will next describe the clinical features of feline cardiomyopathies and the therapy of related complications. Following this is a consideration of canine DCM and arrhythmogenic cardiomyopathy.

FELINE HYPERTROPHIC CARDIOMYOPATHY

Overview and Pathophysiology of Feline HCM

- Feline idiopathic HCM is characterized by hypertrophy and thickening of the left ventricle unexplained by congenital heart disease, systemic hypertension, or an endocrinopathy.
- The condition is genetic in a number of feline breeds, including the Maine coon cat, Persian cat, and the Ragdoll. Thus far, one sarcomeric mutation has been identified.
- The pattern of ventricular hypertrophy in this disease is variable as demonstrated at necropsy or by 2D echocardiography.
  - Symmetrical concentric hypertrophy of the LV walls and papillary muscles is considered typical of feline HCM, but there is substantial variation in the location and severity of hypertrophy in this disease.
  - The main histologic finding is of myocardial cell hypertrophy with fiber disarray. Small, intramural coronary arteries are often narrowed. Microscopically, there is fibrosis between myocytes. Focal areas of infarction or inflammation may be observed.
  - The left atrium (LA) is usually dilated and the wall may be hypertrophied from increased pressures needed to fill the LV. Atrial or auricular clots are found attached to the chamber wall in some cases.
- The natural history of untreated feline HCM is quite variable following a benign or lethal course; a brief or protracted clinical disease; and sometimes remarkable recovery from life-threatening complications. Some cats remain asymptomatic for many years before succumbing (if ever) to the disease.
- Clinical signs in HCM are explained by left-sided CHF, complications of arterial thromboembolism (ATE), LV outflow tract obstruction, or arrhythmias capable of causing syncope or sudden cardiac death.
- The differential diagnosis for the clinical signs of HCM in cats is extensive (Tables 150-2 and 150-3),

Table 150-2. DIFFERENTIAL DIAGNOSIS OF FELINE CARDIOMYOPATHY AND HEART FAILURE*

Other Causes of Dyspnea/Tachypnea
Airway obstruction
Nasopharyngeal polyp
Laryngeal paresis
Tracheal or esophageal foreign body, neoplasm, granuloma, abscess
Mediastinal masses
Lymphoma or thymoma
Primary bronchopulmonary disease
Bronchial asthma/bronchitis
Lungworms and lung flukes
Pneumonia (viral, bacterial, fungal, toxoplasmic)
Neoplasia
Aspiration
Pulmonary vascular disease/embolism
Heartworms/spontaneous worm death
Noncardiogenic pulmonary edema
Electrocution
Trauma (shock lung)
Anaphylaxis
Trauma
Diaphragmatic hernia
Pulmonary hemorrhage/edema
Pneumothorax
Hemothorax
Pleural effusion
Pyothorax
Hemothorax
Feline infectious peritonitis (FIP)
Lymphoma-associated effusion
Chylothorax
Hyperthermia/fever
Anemia
Methemoglobinemia
Acetaminophen toxicity
Cetacaine
Abnormal ventilatory pattern
Metabolic acidosis
Central nervous system disease
Other Causes of Acute Lameness/Paresis/Gait Abnormality
Musculoskeletal pain or injury
Bite wounds
Hypokalemia (weakness)
Peripheral neuropathy
Related to diabetes mellitus
Spinal cord disease
Injury
Neoplasia
FIP infection
Extradural mass/granuloma
Urinary obstruction
Causing abdominal pain and reluctance to move
Other Causes of Cardiac Murmurs/Gallops/Arrhythmias/ Cardiomegaly
Congenital heart disease
Especially spetal defects and mitral valve dysplasia
Congenital peritoneopericardial-diaphragmatic hernia
Bacterial endocarditis
Pericarditis
FIP infection
Idiopathic
Bacterial
Neoplastic
Lymphoma
Mesothelioma
Cardiac neoplasia
Lymphoma
Cor pulmonale
Heartworms
Severe chronic respiratory disease
Chronic degenerative valvular disease (mitral, aortic)
Dilation of the aortic root with aortic regurgitation
Cardiac arrhythmias (primary electrical disturbances)
Chronic bradyarrhythmias
Atrioventricular block in aged cats
Tachyarrhythmias and premature complexes
Sedatives, tranquilizers, anesthetic drugs
Chronic or severe anemia
Hyperthyroidism
Acromegaly
Systemic hypertension
Chronic renal disease
Hyperthyroidism
Idiopathic
Electrolyte abnormalities
Hyperkalemia
Urinary obstruction
Hypokalemia
Renal disease

*The most common clinical presentations of feline cardiomyopathy are dyspnea from congestive heart failure, rear-limb paresis from aortic thromboembolism and inactivity. The veterinarian often detects a murmur, gallop rhythm, arrhythmia, or cardiomegaly during examination.

and includes congenital heart disease, myocarditis, and other forms of primary cardiomyopathy (RCM, DCM). When an echocardiogram demonstrates thickening of the LV, specific disorders causing LV hypertrophy must be excluded including

- Mitral valve malformation causing dynamic obstruction of the LV outflow tract with secondary hypertrophy.
- Congenital aortic or subaortic stenosis.
- Hyperthyroid heart disease (thyrotoxicosis).
- Hypertensive heart disease.
- Focal basilar septal hypertrophy associated with aortic dilatation (aortoannular ectasia).
- Acromegaly (growth hormone excess).

- The *pathophysiology* of feline HCM (Figure 150-1) is relevant to the diagnosis and drug therapy of this disease. The presumptive cause of CHF is ventricular diastolic dysfunction, because most cats with HCM have a normal to hyperdynamic LV ejection fraction.
  - Diastolic dysfunction is the inability to fill the left ventricle with normal LA pressures.
  - Early diastolic dysfunction is characterized by abnormal myocardial relaxation with a vigorous LA contraction to support late diastolic filling. This situation is associated with the atrial (S4) gallop so often detected in these cats.
  - Progressive ventricular disease is associated with reduced chamber compliance with loss of passive

Table 150-3. COMMON FELINE CARDIAC DISEASES

Disorder	Necropsy and Echo (Anatomic Diagnosis)	Typical Clinical Problems	Etiologic diagnosis
Pericardial effusion and pericardial disease	• Peritoneopericardial diaphragmatic hernia (PPDH) • Secondary to CHF • Infection (including FIP) secondary to infection • Neoplastic related (LSA) • Echo: echo-free space around heart; +/− mass lesions; often observe *left*-sided cardiomyopathy; Liver and fat in PPDH	• Unexplained cardiomegaly (PPDH) • CHF as a cause of PE • CHF as consequence of PE and cardiac tamponade • Systemic illness (infection, neoplasia)	• Congenital (?genetic)—PPDH • Infectious (coronavirus) • Lymphosarcoma • Immunosuppression (?)
Septal defects—VSD, ASD, ECD	• Ventricular or atrial septal defect • AV valve malformation (ECD) • Echo: above lesions with volume overload of affected chambers	• Systolic heart murmur • Cardiomegaly • CHF • Cyanosis (reversed shunt)	• Congenital • Genetic?
Dilated cardiomyopathy (DCM) *phenotype*	• Cardiac chamber dilatation (typically left sided chambers +/− right sided) • Echo: cardiac dilatation & loss of myocardial contractility	• CHF—left-sided; biventricular • Arterial thromboembolism • Arrhythmias • Sinus bradycardia • Hypotension • Soft heart sounds • Secondary AV valvular regurgitation	• Idiopathic DCM • Taurine deficiency DCM • Moderate to severe anemia • Fulminant myocarditis
Hypertrophic cardiomyopathy (HCM) *phenotype*	• Left ventricular hypertrophy that is concentric or regional • Focal septal LVH (aged cats; dilated aortic root) • Echo: LV hypertrophy; variable; possible LA dilation	• Abnormal auscultation: heart murmur, gallop, arrhythmia • Thyroid adenoma in cases of hyperthyroidism • Target organ injury: brain, eyes, kidneys, and heart in systemic hypertension	• *Primary* HCM: genetic or idiopathic cardiomyopathy
Restrictive cardiomyopathy *phenotype*	• Left ventricular endomyocardial fibrosis or myocardial fibrosis (multifocal or generalized) • LV wall infarction • Echo: Marked bi-atrial dilatation; variable LV anatomy, wall motion, and systolic function	• Abnormal auscultation: gallop, arrhythmia, heart murmur • CHF—biventricular • Chylothorax (from CHF) • Arterial thromboembolism • Arrhythmias • Sudden cardiac death	• Idiopathic RCM • Antecedent myocarditis • Chronic HCM with myocardial injury from coronary thromboembolism, coronary vascular disease, or neurohormonal injury
Unclassified or "Intergrade" cardiomyopathy	• Left ventricular myocardial disease with variable morphologic characteristics with Echo showing systolic and diastolic LV function	• CHF—left sided or biventricular • Arterial thromboembolism • Arrhythmias • Sudden cardiac death	• Prior HCM with progressive myocardial failure or infarction (?) • Myocarditis (?)
Congenital mitral valvular disease	• Mitral valve dysplasia (MV malformation; generally causes MR; rarely MS) • Echo: Mitral valve malformation; LA and LV dilatation	• Systolic heart murmur • Development of CHF	• Congenital • Genetic?
Heartworm disease	• Pulmonary vascular disease • Pulmonary thromboembolism, pneumonitis, and fibrosis • Aberrant infection • Echo: parasites in the PA	• Signs related to pulmonary disease (cough), vomiting • Dyspnea and lung infiltrates due to thromboembolism or spontaneous worm death • CHF—chylothorax (uncommon)	• Dirofilaria immitis—adult parasites found in the pulmonary arteries and heart
Arrhythmias: PACs, PVCs; AV block	Necropsy or Echo may demonstrate cardiac lesions but often there is no overt structural lesion	• Syncope • Sudden cardiac death • CHF	• Cardiomyopathy • Degeneration of conduction system • Metabolic disorders • Hypoxia

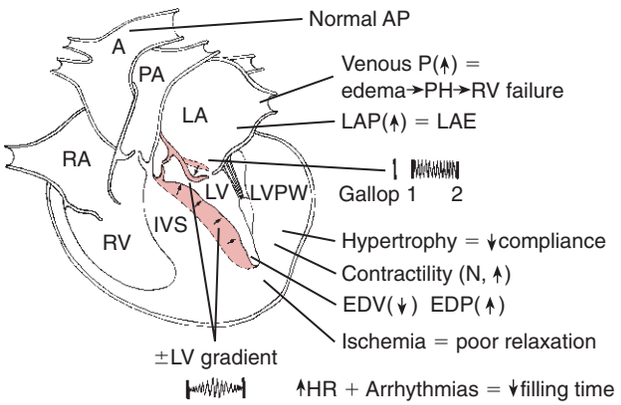

Figure 150-1. Diagrammatic representation of hypertrophic cardiomyopathy. Explanation of abbreviations can be found in text.

LV ventricular distensibility. Tissue injury and fibrosis increase myocardial and chamber stiffness, requiring elevated LA filling pressures. This creates a situation of rapid early diastolic filling that becomes restricted as the stiff ventricle is distended. This correlates to a ventricular (S3) or summation (S3+4) gallop.

- As the left atrium distends, a loss of atrial contractility may develop. This reduces filling effectiveness and also predisposes to stagnant flow, formation of atrial thrombi, and atrial fibrillation.
- The roles of myocardial ischemia, infarction, and neurohormonal activation in the pathogenesis of progressive tissue injury and cardiac dysfunction are possible therapeutic targets because β-blockers and angiotensin system inhibitors blunt these detrimental responses.
- Demand ischemia—the sudden increase in myocardial oxygen demand that outstrips coronary blood supply—may contribute to the sudden development of left-sided CHF (flash pulmonary edema) so often observed in stressed cats with HCM. Ischemia impairs myocardial filling and contraction. For this reason, drugs with anti-ischemic effects (atenolol, diltiazem) are often prescribed in this disease.
- Systolic abnormalities are identified in some cats with HCM. These include subtle abnormalities detected only by tissue Doppler echocardiography; identification of apical or free wall-infarcts; regional wall motion abnormalities; or rarely, a global loss of LV systolic function.
- Dynamic and labile pressure gradients between the LV and aorta are often identified during ejection across the LV outflow tract. In most cases, systolic gradients stem from either septal and papillary muscle hypertrophy (midventricular obstruction) or systolic anterior motion (SAM) of the mitral valve causing mitral septal contact. These abnormalities can be documented on high-quality echocardiographic studies. The presence of significant SAM is invariably associated with an eccentric jet of mitral regurgitation (MR), readily seen by color Doppler examination.
- Some chronic cases of HCM appear to evolve into a restrictive form of cardiomyopathy with either regional wall dysfunction (suggestive of myocardial infarction) or globally reduced LV systolic function (suggesting fibrosis or ischemia). Rarely, a cat will progress to a grossly dilated form of disease.

Clinical Findings in Feline HCM

The clinical presentation and examination findings in feline HCM are variable.

- Male cats are predisposed in some reports, and cats of any age, including young cats, may be affected. As previously noted, certain breeds are at genetic risk for this disease, and it is not uncommon to examine affected cats that are related.
- Most often, the idea of HCM is prompted by auscultation of a murmur or gallop sound in a cat that has no other signs of heart disease. Nonspecific signs such as lethargy or anorexia may be reported.

▼ ***Key Point*** Most cats with HCM are healthy and asymptomatic for the disease.

- When symptomatic for left-sided CHF, a cat will demonstrate tachypnea and dyspnea, signs attributable to pulmonary edema or pleural effusion. Cough can occur but is an inconsistent sign.
  - Stress, fever, moderate-to-severe anemia, thyrotoxicosis, anesthesia, surgical procedures, trauma, or fluid therapy may precipitate CHF in a previously stable cat.
  - Prior therapy with corticosteroids may be another risk factor, though cause and effect are not firmly established.
- Urgent presentation may follow ATE to the terminal aorta, a forelimb, or cerebrum.
- Syncope or sudden cardiac death can occur but are less common than in the human disease. Sudden death may be explained by a coronary embolus, a ventricular arrhythmia, or if signs of CHF are unrecognized and the cat succumbs to hypoxia.
- Typical physical examination features of HCM include various combinations of the following:
  - Gallop rhythm—This is related to ventricular diastolic dysfunction or heart failure.
  - Systolic murmur—Murmurs are commonly due to MR or dynamic LV outflow obstruction. These murmurs can vary, often increasing in intensity with higher heart rates (and higher sympathetic tone). This finding is not specific because functional ejection murmurs also become more intense with increasing sympathetic drive, and functional

murmurs are extremely common in cats of all ages.
  - Clinical signs of ATE—These are discussed below.
  - Auscultatory evidence of pulmonary edema or pleural effusion include increased bronchovesicular sounds, crackles or a fluid line, indicating CHF.
  - Prominent left apical impulse is a sign of possible LV hypertrophy.
  - Arrhythmias may be detected in some cats with HCM.
- ABP is usually normal in cats with HCM; however, some cats demonstrate profound hypotension associated with cardiogenic shock (along with hypothermia and bradycardia).
  - Low ABP also may be detected in the cat receiving diuretic and ACEI therapy for CHF.
  - Systemic hypertension may cause secondary LV hypertrophy; but HCM does not cause systemic hypertension.

Diagnostic Tests in HCM

A number of routine diagnostic tests are helpful in recognizing and staging HCM.

- The *electrocardiogram* may be abnormal, but results are very inconsistent. Increased amplitude R-waves in lead II (exceeding 0.7–1.0 mV.) or a left axis deviation compatible with concentric hypertrophy or left anterior fascicular block may be observed.

▼ ***Key Point*** A normal ECG does not exclude a diagnosis of cardiomyopathy.

- *Thoracic radiographs* can be normal, but in moderate to severe disease will demonstrate abnormalities.
  - Cardiomegaly (elongation), apex shifting (to the right or left), and LA enlargement (most evident as an auricular bulge on the DV view) are common findings.
  - In cats with CHF, the cardiac silhouette may be further enlarged by a small to moderate pericardial effusion caused by CHF. Cardiac silhouette size may be reduced considerably after diuretic therapy.
  - Prominent pulmonary vascular patterns may indicate pulmonary hypertension secondary to elevated LV diastolic pressure or fluid retention.
  - Increased lung densities are compatible with pulmonary edema and may be focal, patchy, diffuse, and often in more dependent areas than is typical for dogs with CHF.
  - Pleural effusion is common in acute CHF and in chronic, longstanding cases of heart failure. Evaluation of the effusion typically reveals a modified transudate and sometimes chylothorax.
- Routine *CBC and clinical chemistries* are unremarkable in most cases unless there is thromboembolism or intercurrent disease. The creatine kinase (CK), AST, and ALT all derived from skeletal muscle origin are markedly elevated in thromboembolism to the limb(s).
  - *Renal function* may become impaired in cats with concurrent renal disease or in those treated for heart failure with diuretics and ACEIs. In many cases of advanced, treated CHF there will be mild to moderate azotemia.
  - Serum *thyroxine* is normal in cats with idiopathic HCM (unless they are manifesting two diseases).
  - A number of recent reports indicate the potential value of measuring serum or plasma cardiac *troponin-I* (cTN-I) since this protein increases in cats with HCM. This may become a useful screening test for identifying cats with HCM.

▼ ***Key Point*** In a large percentage of cats with systolic murmurs, echocardiography demonstrates a normal heart or trivial cardiac pathology. Heart murmurs in these cases are considered functional, likely related to sympathetic stimulation of the heart.

- *Echocardiography*—Definitive diagnosis and staging of HCM relies on echocardiography and Doppler studies interpreted in light of clinical findings.
  - Typical HCM is characterized echocardiographically by papillary muscle thickening, generalized thickening of the LV walls (generally to 6 mm or more in diastole), normal to decreased intraluminal size, and normal or increased systolic shortening fraction.
  - There is a marked heterogeneity to the pattern of hypertrophy, and not all wall segments may be involved.
    There may be generalized involvement with greater involvement of the septal or free wall segments.
    Some cats demonstrate markedly asymmetric hypertrophy mainly affecting the LV free wall. This finding usually portends development of CHF.
    Conversely, focal midventricular hypertrophy, even with midventricular obstruction, is usually benign. In older cats, isolated, focal, dorsal septal hypertrophy is a common finding. Whether this represents true HCM, or a growth response to aortic dilation and altered subaortic blood flow, is uncertain, but the condition is generally benign.
  - Increased left atrial size is a strong indicator of risk for ATE or CHF.
  - Doppler studies may demonstrate MR, dynamic obstruction, or abnormal LV filling patterns. Early diastolic dysfunction is characterized by abnormal myocardial relaxation, shown on Doppler studies as delayed LV relaxation in early diastole with a vigorous LA contraction to support late diastolic filling.
  - Progressive ventricular disease is associated with reduced chamber compliance. Doppler studies

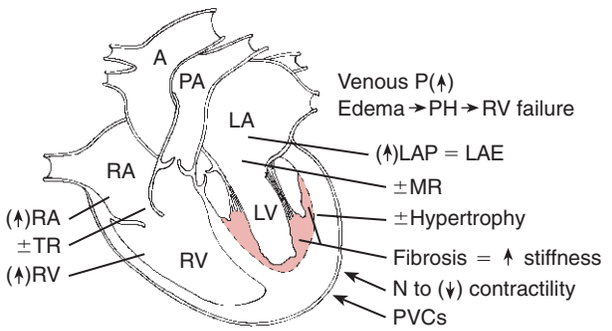

Figure 150-2. Diagrammatic representation of restrictive cardiomyopathy. Explanation of the abbreviations can be found in the text.

often show a prominent early filling (E-) wave with trivial atrial contraction (A-) wave. These findings generally precede development of CHF.

- The differential diagnosis of feline cardiomyopathy is extensive (Table 150-2), including other cardiovascular and noncardiac disorders.

FELINE RESTRICTIVE CARDIOMYOPATHY (RCM)

Feline RCM represents a heterogeneous disorder, and some latitude is used in placing cats within this category. The disorder described below might be interpreted by others as "intermediate cardiomyopathy" or as "unclassified cardiomyopathy."

Overview and Pathophysiology of Feline RCM

- The key pathologic feature is diffuse or multifocal endomyocardial or myocardial fibrosis.
- The pathogenesis of these lesions is undetermined. Antecedent myocarditis seems a likely, though unproven, initiating cause. In other cats, RCM clearly represents a late stage of HCM complicated by myocardial fibrosis or myocardial infarction.
- A variety of necropsy lesions have been observed in cats demonstrating clinical features of RCM.
  - LV endomyocardial fibrosis may be patchy, multifocal, or diffuse in distribution.
  - The left ventricle can exhibit regional hypertrophy, but overall the walls are not thickened. Often there is regional thinning or infarction of the LV free wall or apex interspersed with focal hypertrophy. Prominent papillary muscle hypertrophy or fibrosis is evident in some cats.
  - The LV cavity may be dilated but is usually normal to reduced in size.
  - Extreme endocardial fibrotic scarring can involve the mitral valve apparatus, lead to mid-ventricular stenosis, or obliterate the LV apex.
  - A common feature of RCM is striking biatrial dilation.
  - Systemic thromboemboli are common and LA and ventricular mural thrombi may be observed.
  - Histologic lesions include endocardial thickening, endomyocardial fibrosis, myocardial interstitial fibrosis, myocyte hypertrophy, and focal myocytolysis and necrosis. Arteriosclerosis of intramural coronary arteries may be recognized.
- The *pathophysiology* of RCM in the cat is unresolved but in many ways fits the "intermediate" label initially suggested by Harpster (Figure 150-2).
  - Echocardiography generally demonstrates mild systolic dysfunction, regional LV wall dysfunction, mild mitral or tricuspid valvular regurgitation, elevated LA pressures, and impaired LV distensibility with a "restrictive" filling pattern (tall but abbreviated E-wave; small A-wave).
  - Myocardial or endomyocardial fibrosis is the most likely explanation for these abnormalities.
  - Progressive increases of LA pressure develop, and the combination of ventricular dysfunction, atrial stiffness, and renal retention of sodium elevate pulmonary venous pressures and predispose to CHF and to pulmonary hypertension.
  - Pulmonary edema, pleural effusion, jugular venous distention, and hepatic congestion are typical manifestations of CHF in this disease. Clinically a diagnosis of "biventricular" CHF is often made.
  - Stasis of blood and the stretched LA places affected cats at risk for atrial thrombi and systemic thromboembolism.

Clinical Findings in Feline RCM

- The clinical findings and diagnostic studies of RCM are in many ways similar to those of HCM with a few notable differences.
  - Most cats with RCM are middle aged or older and present with signs of CHF or ATE.
  - Some have previously been diagnosed with HCM.
  - The most consistent physical auscultatory finding is a loud gallop sound; murmurs are variable and less common than in HCM.
  - Premature ventricular or atrial beats are common, leading to an irregular rhythm and arterial pulse.
  - Signs of elevated systemic venous pressure, including hepatomegaly, pleural effusion, and elevated jugular venous pressure, are common. This may indicate RV dysfunction from RV involvement, pulmonary hypertension, or simply the generalized response of fluid retention in compensation for chronic left heart failure.
- The *electrocardiogram* is frequently abnormal showing cardiomegaly patterns, axis deviations, or conduction disturbances along with atrial or ventricular ectopy.
- Thoracic *radiography* is often impressive and characterized by LA dilation and cardiac elongation that is typical of LV enlargement.

- The cardiac apex can be pointed or rounded.
- Some cats manifest astounding biatrial enlargement. Pericardial effusion may further enhance cardiac silhouette size.
- Pleural effusion is typical.

- *Echocardiography* demonstrates a number of possible abnormalities. The most characteristic feature of RCM viewed by echocardiography is marked LA or biatrial dilation, mildly reduced shortening fraction, and irregular or hyperechoic ventricular walls, +/− bands spanning the LV. Often there is marked wall thinning typical of myocardial infarction. Infarction or severe myocardial fibrosis often creates a segmental, hypocontractile wall.
- *Clinical laboratory tests* of cats with RCM are not specific and most abnormalities are attributable to CHF, diuretic therapy, or thromboembolism as described above for HCM. A plasma or whole blood taurine should be measured in cats with decreased LV ejection fraction. Analysis of pleural effusates indicates a transudate, modified transudate, or chyle. The predominant cells present are macrophages, mesothelial cells, and small lymphocytes unless there is chylothorax, in which case, well-preserved neutrophils may be more numerous in response to the irritation.

DILATED CARDIOMYOPATHY IN CATS

As shown by Pion and colleagues, dietary deficiency of taurine accounted for the vast majority of feline cases of dilated cardiomyopathy. Today DCM in cats is a relatively rare occurrence requiring echocardiographic evaluation for diagnosis. Taurine deficiency may still be observed in cats eating mostly "custom" diets or dog food, but most cases of DCM are idiopathic or a consequence of myocarditis.

- The primary post-mortem lesions of primary DCM are left-sided or four-chamber dilatation, accompanied by necropsy findings of CHF. There is no demonstrable congenital, coronary, or valvular heart disease. Histological findings include myocyte loss with prominent interstitial fibrosis and variable degrees of hypertrophy, myocytolysis, and inflammation (which is typically minimal).
- Left-sided or biventricular CHF, often complicated by systemic thromboembolism, are the typical consequences of this disorder. These conditions are readily identified by careful clinical examination and results of thoracic radiography.
- Certain breeds are historically at risk for DCM, notably the Burmese cat.
- Classic physical examination features of DCM include soft heart sounds (from reduced contractility or pleural effusion); gallop rhythm with or without a systolic murmur; hypokinetic arterial pulses; dull left apical impulse; and clinical signs of profound CHF. Exceptional cases are seen prior to onset of CHF.
- Cats with DCM are very likely to present in "cardiogenic shock" with sinus or junctional bradycardia, marked hypothermia, and severe hypotension (systolic ABP <70).
- Ophthalmic examination may indicate hyperreflective lesions of retinal degeneration adjacent to the optic disk (if the cause is taurine deficiency).
- The principle functional disturbance of DCM as shown by *echocardiography* is marked reduction of myocardial contractility as measured by shortening or ejection fractions. Morphologically, a dilated, thin-walled, hypokinetic left ventricle is observed often with dilatation of the other cardiac chambers. Ventricular filling also is impaired related to abnormal relaxation of the muscle and pronounced cardiac dilatation, which reduces diastolic compliance. There is often MR and TR by Doppler studies.

OTHER FELINE MYOCARDIAL DISEASES

A number of other diseases that affect the myocardium of the cat are briefly considered below.

- Myocarditis—Nonsuppurative myocarditis occurs sporadically in cats. The cause is unknown and definitive diagnosis requires microscopic examination of myocardium. Since myocardial biopsy is difficult in cats, and enzyme or plasma troponin-I elevations are nonspecific for inflammation, the diagnosis is usually tentative or reserved for the necropsy table. Some cats with myocarditis are presented for ventricular arrhythmias, while others develop fulminant heart failure, RCM (chronic myocarditis, healing phase), or thromboembolism.
- Right Ventricular Cardiomyopathy—A cardiomyopathy involving the RV has been reported in cats. The clinical findings can be explained by right-sided myocardial failure and severe right ventricular cardiac dilatation. There may be atrial standstill or apparent atrial fibrillation. A murmur of tricuspid regurgitation may be evident. Ventricular ectopic rhythms are common. Pleural effusion and ascites can develop from CHF and sudden death may occur. Diagnosis depends on echocardiography and exclusion of other predominately right-sided diseases such as atrial septal defect, tricuspid valve malformation, and pulmonary hypertension.
- Hyperthyroidism—Clinical findings of hyperthyroid heart disease are common in older cats with functional thyroid tumors. Thyrotoxicosis causes cardiac hypertrophy related to a hypermetabolic state, peripheral vasodilation, and increased demands for cardiac output. In addition, increased sympathetic activity and elevated thyroid hormone concentrations may stimulate myocardial hypertrophy.

- In chronic cases of hyperthyroidism, the left ventricle becomes hypertrophied. Concurrent systemic hypertension may contribute to this hypertrophy.
- Constitutional signs such as weight loss and abnormal behavior are typical. A thyroid "slip" is generally identified during physical examination.
- Cardiovascular findings can include sinus tachycardia (that can approach 300 per minute); premature atrial or ventricular complexes; hyperkinetic (bounding) arterial pulses; gallop sounds; and systolic murmurs (either functional ejection murmurs or murmurs stemming from mitral or tricuspid regurgitation).
- Isolated systolic hypertension or combined systolic/diastolic hypertension may be evident.
- In most situations, it is practical to obtain thoracic radiographs to evaluate cardiopulmonary status. Most examinations show only mild cardiomegaly characterized by cardiac elongation and mild LA prominence. In this group of cats, echocardiography is unlikely to contribute materially to the management of the patient.
  When done, typical echocardiographic findings include LV wall hypertrophy, mild LV dilation, normal to mildly increased left and right atrial dimensions, and hyperdynamic LV.
- ECG recordings often demonstrate sinus tachycardia (>240/min); cardiomegaly (increased QRS voltages); axis deviation (to the left or right); and premature atrial or ventricular complexes.
- In most cases, the cardiovascular complications of hyperthyroidism regress following successful treatment of the underlying condition.
  LV hypertrophy usually decreases *except* in the cat with concurrent diseases of uncontrolled hypertension or with primary (idiopathic) HCM.
  Hypertension may improve or resolve as cardiac output decreases with reduction of thyroid concentration; however, *other* causes of hypertension may endure (especially primary renal disease), requiring medical management with amlodipine.
  Sinus tachycardia and premature beats usually resolve with initiation of anti-thyroid medication (methimazole, Tapazole). Persistent tachycardia may indicate concurrent CHF or a need for low-doses of a beta-blocker (atenolol, $\frac{1}{4}$ of a 25-mg tablet PO, once or twice daily).
- In a small percentage of cats, the cardiac effects of hyperthyroidism are manifested in a more clinically significant manner. Thoracic radiographs will demonstrate that the heart is moderately to severely enlarged, and careful scrutiny may indicate a small (or even a large) pleural effusion. In these patients, a full cardiac workup is indicated.
  Re-examination of the patient may indicate prominent jugular pulses or overt jugular venous distension, compatible with plasma volume expansion and heart disease.
  In advanced hyperthyroidism, there can be sufficient cardiac dysfunction and volume expansion to cause more generalized cardiomegaly. Echocardiography often shows biatrial dilatation with normal or even reduced LV shortening fraction despite thickened LV wall measures.
  Affected cats should be evaluated for concurrent hypertension, anemia, or renal failure.
  Great care must be taken when administering fluid therapy as large pleural effusions may occur. Thoracocentesis may be needed.
  In cats with advanced cardiac disease, anti-thyroid medication should be initiated without delay; beta-blockers avoided to prevent cardiac depression; and an ACEI prescribed for cardiac protection, control of incipient (or overt) CHF, and for antihypertensive effects.
- Therapy of hyperthyroid heart disease is predicated on controlling the underlying disorder and is discussed in Chapter 31. Treatment of CHF as a complication of hyperthyroidism is discussed below.

- Systemic hypertension—Cats with systemic hypertension may develop progressive LV disease with concentric ventricular hypertrophy. The left ventricle and small coronary arteries represent one of the "target organs" of high blood pressure.
  - Most healthy cats have systolic ABP measurements of <150 to 160 mm Hg in the hospital setting. Persistent elevation of ABP, particularly values exceeding 160 to 170 mm Hg in the presence of target organ injury, is highly suggestive of hypertensive disease.
  - While systemic hypertension does increase the LV workload and stimulates myocardial hypertrophy, heart failure is not a common complication of this disease unless hypertension progresses unchecked or is superimposed on another form of heart disease.
  - Initial clinical signs more often are referable to the other target organs, namely the eyes (retinal hemorrhages, detachments), brain (depression, abnormal behavior, stroke), and kidneys (progressive azotemia).
  - Dissection of the aorta is a rare vascular complication of hypertension.
  - The cardiac changes of hypertension most often resemble mild HCM. Often there is a gallop sound or murmur (of uncertain origin), along with mild cardiac enlargement, evident by radiography or echocardiography. As many of these cats are older, there may be degenerative changes of the aorta observed such as aortoannular ectasia (dilatation) or aortic redundancy.
  - The diagnosis of hypertension is usually straightforward and is discussed in detail in the Chapter 153 in this section.

- Assessment of hypertension can be more complicated. For example, hypertension in a hyperthyroid cat may be related to
  High cardiac output from LV hypertrophy and a sympathetically-driven heart.
  Increased aortic impedance or stiffness, related to concurrent aortoannular ectasia.
  Abnormalities of plasma volume or renin-angiotensin regulation from concurrent (often masked) renal disease.
- Causes of systemic hypertension, including intrinsic renal disease, hyperthyroidism, and Conn's syndrome should be sought.
- LV hypertrophy may regress following successful control of blood pressure.
- The treatment of systemic hypertension in cats is discussed fully in Chapter 153.

SYSTEMIC ARTERIAL THROMBOEMBOLISM IN CATS

Acute arterial thromboembolism is most commonly associated with cardiomyopathy, though it may be encountered in multisystemic disorders including hematologic disease, endocarditis, and cancer.

- Thrombi generally arise in the LA/auricle. Many are large and traverse the aortic arch to lodge in the terminal aorta. This creates the classic "saddle thrombus" at the origin of the external and iliac arteries. The saddle thrombus also obstructs the internal iliac branches (serving the tail) and obstructs flow in the femoral arteries (as these extend directly from the external iliac system).
- Smaller clots may be diverted to other vascular beds, causing myocardial infarction (with arrhythmias, sudden death, or acute CHF); thrombotic stroke; forelimb monoparesis; renal infarcts; or rarely, mesenteric ischemia with severe colic.
- The pathogenesis of atrial thrombus formation is likely related to atrial dilation, stagnant blood flow, reduced atrial contractility, exposure of platelets to subendocardial collagen, and other ill-defined hemostatic factors particular to the cat. Impaired collateral blood flow is believed to be pivotal in the genesis of clinical signs of ATE, since simple ligation of the femoral arteries does not reproduce the syndrome in cats.
- Historical signs of ATE typically include the sudden inability to walk (or use a forelimb), severe pain with vocalization and obvious distress, and rapid or deep breathing patterns.
- Physical examination usually reveals a distressed, non-ambulatory patient, often assuming a sitting position with extended, firm, and painful rear limbs.
  - Respiratory rate is increased either from pain or concurrent CHF. Radiography is often needed to delineate the basis for dyspnea. Management of CHF is needed in some cats (see above).
  - Results of cardiac auscultation depend in part on the experience of the examiner, but often a murmur or gallop sound will be detected. In some cats, heart sounds are remarkably normal.
  - Shock-like signs are evident in some cats, probably related to systemic reaction and release of mediators from the thrombus. ABP must be measured in a forelimb.
  - Bradycardia is likely to be associated with hypotension and require additional treatments such as dobutamine.
  - Laboratory tests are variable and probably relate in part to any underlying disease. Stress-related hyperglycemia is typical, and a variety of electrolyte abnormalities may be seen.
- Diagnosis of aortoiliac ATE is straightforward and based on the usual history and results of physical examination demonstrating the triad of peripheral vascular disease, muscle injury, and peripheral neuropathy.
  - Loss of regional *vascular supply* leads to cold, pulseless, pale limbs. Doppler flow signals within the proximal femoral arterial system are absent indicating no flow. With reduced collateral blood flow, the superficial rectal temperature is often reduced, and the thermometer should be lubricated and very carefully advanced to obtain a more representative body temperature.
  - Severe *skeletal muscle injury* with extensive rhabdomyolysis occurs.
    This leads to ischemic contracture with severe muscle pain, as well as release of high levels of CK, AST, and ALT from damaged muscles into the blood.
    The limbs are typically very firm to palpation (especially the semitendinosus and gastrocnemius muscles).
    Since muscle contains very high concentrations of potassium that also leak out from the cell, there may be profound hyperkalemia following reperfusion of the damaged tissues.
    Some cats develop antibiotic-responsive fever within 2 to 7 days of the thrombotic event; we treat affected cats empirically with amoxicillin trihydrate + potassium clavulanate (Clavamox) for 10 days.
    Development of limb edema indicates severe tissue injury and portends a very poor prognosis for limb recovery. In some cases, tissue necrosis and limb contracture may require wound management or even limb amputation.
  - Peripheral (ischemic) *neuropathy* is identified.
    Motor function is absent in the rear limbs (or forelimb in the case of a brachial thrombus). Tail movement is lost in the typical saddle thrombus.

Neurological signs are usually bilateral, but there may be some asymmetry noted between the limbs; this often correlates with presence or return of pulse on the least-affected side.
After 24 to 48 hours, a relatively clear superficial sensory level can be detected in the proximal limb; with time, this descends toward the toes.
With revascularization, tail function returns first, and motor function is restored from proximal to distal.
Residual, distal proprioceptive deficits are common but do not prevent functional limb use.

- Recovery from the thrombus is *common,* and after 72 hours many cats have already begun to revascularize the limbs spontaneously. Mortality in the first 72 hours is generally due to one of three factors: (1) euthanasia; (2) reperfusion hyperkalemia; or (3) uncontrolled CHF, usually present at the time of admission.
  - Most studies report a worst-case scenario of about 35% recovery (release) rate because cats that are euthanatized without treatment or given sufficient time for recovery are included. Obviously, the client's and the veterinarian's perceptions and expectations weigh heavily into these figures. When euthanatized cats are not considered, at least 50% of cats are reported to be released from the hospital in most retrospective studies. More recent surveys, including the largest Minnesota study, demonstrate up to a 75% release rate for cats supported and managed aggressively for their disease.
  - Concurrent CHF worsens the prognosis. In the retrospective study of Smith and colleagues the difference in median survival for cats released from the hospital was 77 days for CHF cats compared to 223 days for those without CHF.
  - Despite the potential for short-term success, the complication of ATE creates difficult decisions for clients. The risk for future ATE is very high (probably exceeding 50% within 6 months); however, subsequent embolic events are often better tolerated, presumably related to development of collateral circulation. Clients also must be advised regarding the severity of the underlying heart disease (which should be evaluated by radiography, echocardiography, and an ECG).
- Management of ATE is discussed below.

THERAPY OF FELINE CARDIOMYOPATHY

A number of CV drugs are used in the management of myocardial and other feline CV disorders. While there some well-conducted studies of antihypertensive therapy in cats, there is little in the way of controlled and sufficiently powered clinical studies that address the treatment of asymptomatic HCM, therapy of heart failure, or management of ATE in cats with primary cardiomyopathies. Accordingly, treatment approaches to myocardial diseases remain largely empiric and are certainly guided by experience and clinical prejudice.

Major therapeutic end-points deal with survival, client observed symptoms, and the need for hospitalization related to clinical signs of disease. More theoretically based treatments (and the rationale for many current recommendations for therapy) consider drug effects on: (1) left ventricular function (diastolic filling; dynamic obstruction during systole); (2) protection of the myocardium from stress, catecholamines, or neurohormones; (3) prevention or control of CHF; (4) prevention or treatment of ATE; and (5) prevention of arrhythmias and sudden cardiac death.

The clinical pharmacology of specific drugs used in treatment of CHF in cats is detailed in "Cardiovascular Drugs" elsewhere in this section. The management of systemic hypertension in cats is discussed in detail in Chapter 153.

Management of the Asymptomatic Cat with HCM

In most practices, asymptomatic HCM is the most common form of idiopathic cardiomyopathy identified in cats. The main benefits of any therapy in this group would relate to: (1) improved ventricular diastolic function; (2) reduction of dynamic outflow tract gradients with decrease in MR; (3) reduced chance of sudden cardiac death; (4) prevention of ATE; or (5) regression of LVH. Currently, no data indicate a substantial benefit of therapy in asymptomatic cats with HCM, and it is well known that many cats live for years without apparent problems.

- Increasingly, cats with asymptomatic or mild HCM and normal LA size are left untreated. Many cats show little progression of disease at follow up. Thus, in the asymptomatic cat, the veterinarian could reasonably consider prescribing no therapy or, empirically, a β-adrenergic blocker or diltiazem. Some clients will indicate that their cat is more active when receiving treatment, but this may simply represent a placebo effect.
- Initially, cats with asymptomatic disease are examined by repeated echocardiography within 1 to 3 months of initiation of any stable therapy regimen and again 6 to 12 months later, depending on the level of concern for impending CHF or ATE. Echocardiography has the advantage of providing objective measures of wall thickness and LA size, and a Doppler study can be used to document a reduction in the dynamic obstruction and associated MR when these flow disturbances are identified at initial examination.
- The stable cat is seen every 6 to 12 months, with the intervals extending if follow up examinations show no disease progression. In many cases, the disease is unchanging, but in others, there is clear progression

and eventually signs of CHF or ATE occur, even years after initial diagnosis.

- Therapy with Atenolol–β-blockers are recommended in the management of HCM with moderate to severe LV outflow tract obstruction. Atenolol is most often prescribed for this purpose as it is a twice daily drug (compared to tid propranolol). The usual starting dose of atenolol is ¼ of a 25-mg tablet PO for 3 days and thereafter ¼ tablet PO q12h. Dosage is adjusted to achieve an examination heart rate of 120 to 160/min. Typically cats receive ½ tablet in the AM and either ¼ or ½ tablet in the PM.
  - Atenolol effectively reduces LVOT gradients and consistently slows the heart during times of stress (for example, a veterinary examination).
  - Cardiac benefits of beta–blockers in cats with HCM include preventing sinus tachycardia, reducing dynamic outflow obstruction, decreasing SAM and attendant mitral regurgitation, and prolonging diastole. Myocardial oxygen demand is reduced through decreases in heart rate, contractility, and blood pressure.
  - Unfortunately, the net effect of beta–blockade on diastolic function in cats with HCM is unknown (see "Cardiovascular Drugs" for a discussion).
  - Beta–blockade is especially helpful for reducing pressure gradients caused by dynamic LV outflow obstruction in cats with HCM. The murmur of mitral regurgitation generally becomes softer following beta-blockade, and the peak outflow tract velocity is substantially reduced in the majority of cats given an adequate dose of atenolol. In a small European study, another beta-blocker (propranolol), was associated with regression of LV hypertrophy, but this finding is inconsistent, and should not be expected.
  - Beta-blockers are contraindicated in cats with overt hypotension, bradycardia, uncontrolled pulmonary edema, AV block, or recent arterial thromboembolism (until collateral circulation has been restored); furthermore, their value in cats with recent-onset CHF appears to be unfavorable, based on a recent multicenter study, and should not be routinely prescribed for short-term management of the CHF patient.
  - Therapy with Diltiazem—When HCM is characterized by moderate to severe LV hypertrophy without obstruction, and especially when there is concurrent LA dilatation, diltiazem may be a therapeutic consideration. Dosing typically involves a long-acting preparation as standard diltiazem dosed at ¼ of a 30-mg tablet PO q8h is simply impractical for most cat owners. Dilacor XR (brand of diltiazem) can be administered at a dosage of 30 mg once or twice daily (open the 240 mg capsule and cut the four 60-mg pills in half). Others have used long-acting diltiazem capsules (Cardizem CD) compounded in a palatable syrup, starting at 30 mg of diltiazem once daily. The bioavailability and dosing regimens of these preparations have been issues. Diltiazem is thought to improve LV relaxation, but the precise mechanism for this benefit has not been elucidated (See "Cardiovascular Drugs" for a discussion).
  - Overall, diltiazem should reduce myocardial oxygen demand by decreasing contractility, blood pressure, and heart rate (though less effectively than atenolol).
  - While diltiazem is a negative inotrope, effects on reducing dynamic outflow tract gradients have been somewhat disappointing at the doses commonly used.
  - While the chronic administration of diltiazem has been reported to decrease LV hypertrophy in cats with very severe HCM, it is very uncommon to observe regression, even with prolonged therapy.
  - Thus, the main reason to choose diltiazem therapy in cats with HCM is for potential improvement of diastolic function and for prevention or treatment of CHF in HCM.
  - Contraindications to administration of diltiazem in cats are uncontrolled CHF, sinus bradycardia, hypotension, and AV block.
  - Bradycardia, hypotension, depression, and skin reactions (erythema/edema) have been observed in some cats receiving this drug. Anorexia is a relatively common client complaint. Adverse effects were reported in just over 20% of cats in one clinical report.
  - As with atenolol, diltiazem does not appear to have a role in the short-term management of CHF in cats.
  - ACEI Therapy—The potential of an angiotensin converting enzyme inhibitor (ACEI) to benefit HCM has not been demonstrated thus far, except in cats with overt CHF. Theoretically ACEI, especially with more 'tissue-sensitive' ACEI (such as ramipril) could prevent progressive myocardial injury or fibrosis in asymptomatic HCM. However, with no firm evidence of benefit, the authors' recommendations are to reserve an ACEI for cases of documented CHF or when moderate to severe LA dilatation is documented by echocardiography (especially in the setting of Doppler evidence of elevated LA pressure).

Hospital Management of the Cat with Acute CHF

Treatment of acute heart failure in cats is a challenge and may require aggressive initial treatment.

- Efforts are directed at improving tissue hypoxia, relieving stress, and reducing the venous and pulmonary capillary pressures.
- Many cats can be managed medically using the F–O–N–S approach (furosemide–oxygen–nitroglycerine–sedation). Thoracocentesis is performed if

there is a moderate or large pleural effusion. Intubation for 2 to 6 hours of artificial ventilation may be needed to manage impending respiratory arrest in cats expectorating edema fluid.

- Initial dosages of furosemide are typically 2 to 4 mg/kg IV/IM, followed by 1 to 2 mg/kg boluses IV or IM every 6 to 8 hours until the cat is stable.
- The cat should be placed at rest, administered oxygen (40–50%) by cage oxygenator, and sedated in most cases to relieve anxiety (butorphanol, 0.25 mg/kg, mixed with acepromazine, 0.05–0.1 mg/kg, with the cocktail administered subcutaneously. If rectal temperature is <99°F, or in the setting of bradycardia, avoid the acepromazine).
- Nitroglycerin (2%) ointment is also administered at a dose of ¼ inch, q12h for moderate to severe pulmonary edema.
- If an IV can be established without stress, a constant rate infusion of furosemide can be substituted for repeated boluses (calculate the daily dose and infuse continually for 24 hours). This treatment is continued for 24 to 48 hours. The CRI of lasix can be supplemented with additional IV boluses as needed.
- The cat with cardiogenic shock (hypothermia, bradycardia, systolic ABP <70 mm Hg) is treated with IV dobutamine infusion (2.5–10 mcg/kg/min titrated to an ABP of 90–100 mm Hg) for 24 to 48 hours. This is an effective therapy for cardiogenic shock regardless of the underlying form of cardiomyopathy.
- Once the cat has been diuresed and ventilation is stable, oxygen is withdrawn, nitrate ointment discontinued, and the dosage of furosemide reduced. The ultimate dose of furosemide should be titrated to the severity of pulmonary edema or pleural effusion.
- Many cats develop hypokalemia and pre-renal azotemia during intensive diuretic therapy. Fresh water and palatable food should be available shortly after diuresis has been initiated.
- Mild cases of renal failure need not be treated, but if the cat refuses to eat and drink after 24 to 36 hours of therapy, judicious fluid therapy of a balanced solution (e.g., 20–30 ml/kg/day) combined with potassium supplementation (IV or oral) will be needed.
- Liquid nutritional support given by an indwelling nasogastric tube may be considered if anorexia persists for more than 60 hours; however, most cats begin to eat following effective resolution of CHF.

Home Management of the Cat with Chronic CHF

- Therapy of chronic CHF in the cat with cardiomyopathy is based on two drugs: furosemide (1–2 mg/kg, PO, once or twice daily) and an ACEI, such as enalapril or benazepril (0.25–0.5 mg/kg, PO, once or twice daily, up-titrating the dose over a number of weeks). Spironolactone (6.25 mg, or ¼ of the 25-mg tablet, once daily) can be given for empiric cardioprotection and potassium-sparing effects.
- Since these cats also have LA dilation, a treatment to prevent thromboembolism is usually considered (see below). However, aspirin therapy when combined with an ACEI and diuretic may predispose to renal failure. When aspirin is prescribed for this purpose, ultra-low doses (5 mg per cat, q24–72h) may be a safer alternative.
- In general, neither atenolol nor diltiazem should be administered to cats with overt CHF, as such therapy has been shown to be either detrimental or not beneficial to short-term outcome.
- After at least 1 month of stable CHF control, atenolol can be considered for the cat with severe LVOT obstruction. Begin at ¼ of a 25-mg tablet once daily and cautiously up-titrate the dosage over several weeks to relieve obstruction. Excessive doses may worsen CHF, leading to pleural effusion or recurrent pulmonary edema.
- The benefits of diltiazem in cats with CHF from HCM have not been proven but might be considered once a cat is very stable on furosemide + ACEI +/− spironolactone.
- Cats with dilated cardiomyopathy are evaluated for taurine deficiency (particularly at-risk breeds including the Burmese, Abyssinian, and Siamese) and treated with taurine (250–500 mg twice daily for 12 weeks) pending results of a whole-blood taurine analysis.
- The bioflavonoid, Rutin (250 mg q12h), is prescribed when there is evidence of recurrent pleural effusion with chylothorax. Rutin improves macrophage function and may reduce reactive pleuritis by decreasing the accumulation of chylomicrons within the pleural space.
- Clinical trials with the inodilator pimobendan are underway in cats and may provide an additional treatment for cats with chronic CHF.
- The overall efficacy of heart failure therapy can be gauged by monitoring respiratory rate and depth at home and by regular re-examinations. Consideration of the affected cat's activity level, appetite, and interaction with family members offers a reasonable gauge of quality of life. Objective measures of CHF control can be obtained by a careful physical and cardiovascular examination and from inspection of serial thoracic radiographs. Morphologic or functional progression of heart disease can be assessed by echocardiography if desired.
- Clinical reevaluation should include a client interview; physical examination; ABP measurement; serum biochemical profile; thoracic radiographs (even one lateral view can provide objective evidence regarding fluid retention); and a focused, recheck echocardiogram.
- The timing of specific examinations depends on clinical circumstances and economic considerations but initially should occur within the first 7 to 10 days from initial diagnosis of CHF and continue every one to two weeks until the CHF is controlled and renal func-

tion stable. Thereafter, the interval may be extended to every one to three months, depending on the patient's progress.

- In general, progressive azotemia indicates the effects of diuretics plus an ACEI. If possible, the doses should be reduced.
- In some cats the heart may stabilize and allow drug diuretic therapy to cease.
- In other cases, there is a clear need to simply tolerate azotemia to prevent pleural effusion or pulmonary edema.
- Treatment of ventricular tachycardia (VT) in cats with CHF is very problematic. Propranolol (2.5–5 mg, PO, q8h), atenolol (6.25 mg, PO, once or twice daily), and procainamide ($^1/_4$ of a 250-mg capsule compounded or mixed in the food q8h) have been used. Sotalol has been used in cats, but it is hard to dose, and in research studies was effective mainly at the beta-blocking dosage. Negative inotropic effects of each of the mentioned drugs; poor client and patient compliance; and lack of efficacy studies limit the application of each of these treatments. In general, therapy of VT is reserved for symptomatic (i.e., syncopal) patients or those with dangerous ventricular arrhythmias documented by ECG.
- Diltiazem is a very effective blocker of AV nodal conduction and represents an excellent choice for heart rate control in cats with atrial fibrillation.
- The long-term prognosis of CHF in cats is guarded and quite variable.
- Although some reports indicate a survival time of six months or less, a 1-year survival is not uncommon following onset of heart failure, provided the client can medicate the cat at home and is willing to obtain consistent veterinary care. Some cats have been successfully managed for CHF for over 2 years.
- Remarkably, some cats with CHF can be weaned from medications (the reason is unknown); whereas, others have a relentless downhill course requiring higher and higher doses of diuretics or regular thoracocentesis.
- Progressive CHF, refractory pleural effusion, or ATE each present formidable obstacles to long-term survival in some cats.

Treatment and Prevention of Systemic Arterial Thromboembolism (ATE)

Management of thromboembolic complications in feline cardiomyopathies remains a serious challenge. Beyond the anticipated spontaneous revascularization of the limbs (once sufficient time elapses), there is no established medical, surgical, or interventional catheter treatment available for resolving acute ATE in cats. Unfortunately, there are no prospective studies demonstrating efficacy of any preventative treatment.

- Acute thromboembolic event—Treatment requires high-quality critical care, good nursing, and "tincture of time." There remains a propensity to euthanize cats with ATE within the veterinary community though published data suggest at least a >50% chance for good functional recovery and a median survival time of over 7 months for cats without CHF. Prognosis has been discussed previously in this chapter.
- For clients requesting care, sufficient time (at least 7 days) should be allowed for improvement. In most cases, a 2 to 3 day hospital stay is needed. Most cats show improvement within 48 to 72 hours with conservative therapy, and pain is markedly diminished within 36 hours of the event.

▼ ***Key Point*** Management of pain is the main therapeutic concern during the first 24 hours of treatment of cats with arterial thromboembolism.

- The initial treatment of cats with ATE involves analgesia with opioids. If the ABP is normal, acepromazine (0.05–0.1 mg/kg) is added to sedate the patient. Opioids for use in cats include:
  - Butorphanol—This drug is both an agonist and antagonist of the mu receptor, and can be dosed at 0.2–0.4 mg/kg IM/SQ q6–8h. While this drug is readily available in veterinary practices, it is a relatively weak analgesic for this magnitude of pain. Butorphanol should be considered only in the "step-down" of analgesic therapy (with potential to reverse some effects of other mu agonists).
  - Buprenorphine (Buprenix)—Dosed at 0.005 to 0.01 mg/kg, IM or SQ, q6h buprenorphine is a longer acting (partial) mu agonist and a better alternative to butorphanol.
  - Hydromorphone or Morphine—These opiates are full mu agonists and can be used in cats at 0.1 mg/kg IM q6–8h. Beware of respiratory depression, CNS excitation, or hyperthermia. If possible, combine with acepromazine.
  - Fentanyl—Fentanyl is a potent mu agonist and can be infused at 2 mcg/kg as an initial slow IV bolus and then maintained at 1 to 5 mcg/kg/hour. It also can be combined with acepromazine.
  - The opiate + acepromazine combination provides effective analgesia/sedation for many cats in moderate distress.
  - Epidural anesthesia is very effective in controlling rear limb pain in cats with ATE, but the injections require expertise in local analgesia and may increase the risk for epidural hemorrhage in cats receiving anticoagulation therapy.
  - Sodium bicarbonate (1 mEq/kg, IV, over 10–20 minutes) is sometimes administered to cats in shock with documented evidence of metabolic acidosis and/or hyperkalemia from muscle necrosis and reperfusion.
- Control of body temperature—Many cats with ATE are hypothermic, especially those with concurrent CHF. While a warm and preferably oxygen enriched

environment should be supplied, it is important to avoid over-heating cats with ATE.
  - Damaged limbs cannot dissipate heat normally and may burn.
  - Opiates used for analgesia may impact the thermoregulatory center. Sometimes cats on opiates will pant and this will abate once the external environmental temperature is lowered, a heating blanket removed, or a dose of acepromazine administered.
  - If elevated temperatures persist, true fever may be evident. Alternative causes of ATE should be considered, including bacterial endocarditis or disseminated neoplasia. However, in most cases the fever is related to the ATE and usually responds to IV cefazolin or oral Clavamox.
- Heparin is administered in ATE to prevent further thrombosis (initial dose is 200–300 U/kg intravenously, then subcutaneously at 100–200 U/kg every 8 hours for 48–72 hours).
- Some clinicians also administer one baby aspirin (81 mg) to cats that present within 2 to 3 hours of an ATE event.
- Beta-blockers, especially propranolol, should be avoided until the cat is walking without difficulty.
- If CHF is not an issue, an IV catheter is placed in a forelimb and *maintenance fluid therapy* is administered to maintain urinary output and reduce hyperkalemia following reperfusion.
- Excitement has waned for IV streptokinase (90,000 IU IV over 30 min followed by 45,000 I.U./hour for 3–6 hours) Streptokinase is no longer available. Excitement has waned for IV tissue plasminogen activator (0.25–1 mg/kg/hour to a total dose of 1–10 mg/kg). This expensive treatment is difficult to control and carries a very high mortality rate probably related to reperfusion hyperkalemia. The clinician must appreciate that limb reperfusion—whether spontaneous or induced by a thrombolytic drug—can lead to fatal hyperkalemia from rapid reperfusion of necrotic muscles.
  - Most cats are released from the hospital in about 3 days, provided there is evidence of revascularization (femoral pulses, improved motor function to the tail and proximal limbs). Clients should be counseled regarding home care, which includes
    Protecting the limbs from trauma or burning; daily inspection for edema.
    Maintaining a written log of progress relative to limb function and ambulation.
    Providing a low stress environment, comfortable bed, and an area for the cat to convalesce. It is likely that the bed will be soiled with urine or stool, so it may be helpful to use easily washable fabrics or apply appropriate protection to the bedding.
    Offering highly palatable food and fresh water that is readily available near the bed and supplemented with hand-feedings to encourage eating and drinking.
    Placing a litter pan relatively near the bed and assisting the cat in using the litter pan if necessary. If constipation becomes a problem, a small amount of soluble fiber ($^1/_4$ teaspoon of guar gum or Benefiber) or canned pumpkin mixed in the food may soften the stool.
    Administering any prescribed medications for CHF.
    Administering a drug to prevent further thrombotic episodes (see the following).
- Prevention of ATE—Drug prevention against thromboemboli is recommended when there is atrial enlargement (>17 mm on 2D echo) or a prior history of ATE. The aggressiveness of treatment is usually proportional to the risk. High risk cats include those with any of the following findings: prior documented thromboembolism; established thrombus in the LA or appendage; evidence of spontaneous LA echocardiographic contrast; a LA dimension exceeding 20 mm, especially with loss of an active auricular contraction (measured by PW Doppler echocardiography); or atrial fibrillation.

Three empirical approaches for prevention have developed:

- Aspirin to interfere with platelet function (81 mg coated, buffered aspirin given every third day or ultra-low dose aspirin given at 5 mg per cat, every 24–72 hours). This is the easiest to administer preventative but has the disadvantage of relatively poor efficacy.
- Daily warfarin to inhibit vitamin-K dependent clotting factors (starting at $^1/_2$ of a 1-mg tablet daily). This approach creates practical problems in terms of dosing and monitoring and creates some risk for iatrogenic hemorrhage.
- Low molecular weight heparin, subcutaneously injected, once or twice daily to inhibit thrombogenesis. Dalteparin or enoxaparin, each dosed at 100 U/kg SQ q12h, have been used (though once-daily dosing with dalteparin also might be successful). There has been empirical success with these drugs, but expense and the requirement for injection have limited widespread use.

These specific approaches, as well as additional details about preventing thromboembolism, are discussed more fully in Chapter 153, along with newer treatment approaches such as clopidogrel bisulfate (Plavix $^1/_2$ of a 75-mg tablet daily).

CANINE CARDIOMYOPATHY

Myocardial diseases are a common cause of heart failure, arrhythmia, and cardiovascular mortality in the dog, following chronic valvular heart disease in preva-

lence and clinical importance. Recognized forms of cardiomyopathy in dogs include the following conditions.

- *Dilated Cardiomyopathy* (DCM)—The most common canine myocardial disease is idiopathic (genetic) dilated cardiomyopathy. DCM is characterized by decreased left ventricular ejection fraction, cardiac remodeling with LV dilatation, and congestive heart failure. Arrhythmias—both atrial and ventricular—are common during all phases of the disease. Sudden cardiac death is relatively common in affected breeds.
- *Arrhythmogenic Right Ventricular Cardiomyopathy* (ARVC)—Aside from DCM, the most often recognized form of cardiomyopathy is arrhythmogenic right ventricular cardiomyopathy (ARVC), best characterized in the boxer dog, and associated with ventricular ectopy, syncope, heart failure, and sudden cardiac death. A less common variant of this disease is right ventricular dysplasia, characterized by severe replacement of myocardium with connective tissue and progressive right-sided CHF.
- *Persistent Atrial Standstill*—This disorder is caused by replacement of atrial myocardium with fibrous connective tissue. Consequences are chronic bradycardia and right-sided CHF, mainly affecting Springer spaniels.
- *Idiopathic Hypertrophic Cardiomyopathy* (HCM)—The condition of true HCM is rare in dogs but included in the differential diagnosis of left-sided CHF and sudden death. Hypertrophic cardiomyopathy must be distinguished from congenital subaortic stenosis, mitral malformation causing dynamic subvalvular aortic stenosis, hypertensive heart disease with secondary hypertrophy, and disease caused by iatrogenic thyrotoxicosis.
- *Secondary Cardiomyopathies*—Causes of canine myocardial disease include profound hypothyroidism, iatrogenic hyperthyroidism, doxorubicin (Adriamycin) administration, catecholamine injury (including pheochromocytoma), head trauma (brain-heart syndrome), systemic carnitine deficiency, severe taurine deficiency, protracted myocardial ischemia, and Duchenne's myopathy.
- *Cardiomyopathy of Overload*—Chronic volume or pressure overload (caused by congenital shunts, valvular diseases, and hypertension) can progress to the "cardiomyopathy of overload," wherein the ventricle is hypertrophied and systolic myocardial function impaired.
- *Tachycardia-induced Cardiomyopathy*—Relentless supraventricular or ventricular tachycardias are causes of reversible myocardial failure.
- *Inherited Arrhythmogenic Cardiomyopathy in German Shepherds*—This is a malignant ventricular tachycardia of young German shepherds that has been described in detail by Moise and colleagues.
- *Myocarditis*—Cardiac inflammation in dogs can be due to Chagas' disease (in endemic areas), septicemia, Lyme disease, and in newborn puppies by parvovirus.

Overview and Pathophysiology of Canine DCM

- Dilated cardiomyopathy is an idiopathic, genetic, or familial myocardial disease characterized by left ventricular or biventricular dilation, reduced myocardial contractility, and histologic abnormalities within the ventricle.
  - Necropsy studies and 2D echocardiography often demonstrate four-chamber dilatation with profound enlargement of the left ventricle and left atrium.
  - CHF is often identified in canine patients and at post-mortem examination.
  - Microscopic lesions include absence of inflammation, attenuated wavy fibers, or fibro-fatty replacement of myocytes; interstitial fibrosis; and other alterations in the cytoskeletal matrix.
  - Extramural coronary arteries are normal and the valves unremarkable, except in older dogs with concurrent mitral or tricuspid valve endocardiosis.
- The disease in most dogs is believed to be familial, and in Doberman pinschers is probably a dominant trait. The time-course of progression of DCM is reportedly great; however, some patients clearly develop LV dysfunction within a very short time interval.
- A deficiency of a myocardial metabolic substrate (such as L-carnitine or taurine) is identified in a very small percentage of affected dogs, often related to familial disease or gross dietary deficiencies. While supplementation with these micronutrients or other nutriceuticals (such as coenzyme Q_{10}) may be beneficial to the energetics of a failing cardiac muscle, such treatment does not reverse canine DCM except in rare cases of systemic substrate depletion.
- As systolic dysfunction progresses, there is a limited cardiac output which is compensated for by activation of neurohormones and cytokines released to support arterial blood pressure.
  - Neurohormonal assault causes further myocardial damage.
  - As the left ventricular ejection fraction continues to decrease, the heart dilates, and ventricular diastolic dysfunction can be recognized by detailed echocardiographic studies.
  - Secondary atrioventricular valvular regurgitation often develops leading to murmurs of mitral or tricuspid regurgitation.
  - Exercise capacity is reduced as an early sign of heart failure.
  - Arterial under-filling promotes renal sodium retention, which expands the plasma volume. Combined

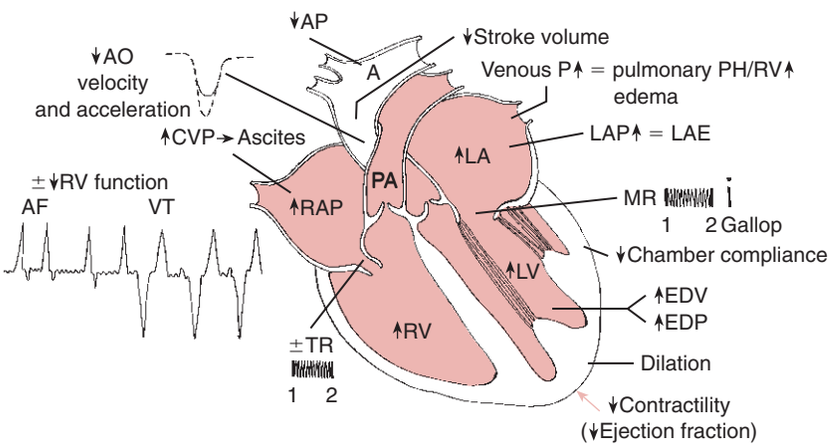

Figure 150-3. Diagrammatic representation of dilated cardiomyopathy. Explanation of the abbreviations can be found in the text.

with reduced left ventricular performance, venous pressures increase and CHF ensues.

- Arrhythmias can occur at any time during the course of DCM. Syncope, sudden cardiac death, or the onset of CHF are potential consequences of rhythm disturbances. Sudden death is especially common in Doberman pinschers with DCM. Frequently, biventricular CHF is precipitated by development of AF in a dog with previously "compensated" DCM (See Figure 150-3).
- Dilated cardiomyopathy occurs most often in middle-aged and older large and giant breed dogs, such as the Doberman pinscher, Great Dane, Irish wolfhound, Newfoundland, and boxer, but DCM can affect dogs of any age and many other breeds.
  - Often male dogs are predisposed or more likely to be affected at a young age. In breeds at risk, older dogs often tend to be females.
  - In addition to a high prevalence in the larger breeds, DCM is recognized regularly in a variety of spaniel and retriever breeds, in Dalmatians, and Portuguese water dogs. DCM occurs sporadically in small canine breeds.
  - The genetic and familial basis for DCM is obvious in many breeds, but the specific mutations or alleles responsible have not yet been demonstrated.
- The four most common clinical presentations of DCM are: (1) occult DCM; (2) CHF; (3) cardiac arrhythmia; and (4) sudden cardiac death. The first three of these conditions will be reviewed. The reader is also directed to the Chapter "Heart Failure in the Dog" for detailed descriptions of treatment plans for canine heart failure; "Cardiovascular Drugs" for discussions of the clinical pharmacology and use of drugs for heart failure and arrhythmias; and "Cardiac Rhythm Disturbances" for a review of electrocardiographic features of arrhythmias.

Occult Dilated Cardiomyopathy

- Occult DCM refers to the overtly *healthy* dog with evidence of *systolic dysfunction* by echocardiography. Some also consider the diagnosis of occult DCM viable when a breed-at-risk for DCM, such as a Doberman pinscher or Irish wolfhound, develops persistent or recurrent atrial or ventricular *arrhythmias* that can not be attributed to another recognized cause.
  - In this regard, there is some cross-over and reasonable debate between the designation of occult DCM with arrhythmia and a normal echocardiogram and that of *arrhythmogenic cardiomyopathy*, in which the principle disturbance is electrical and the echocardiogram is normal (see below). Myocardial dysfunction certainly develops in many, but not all dogs with persistent cardiac arrhythmias. But there is little doubt that many dogs with DCM spend time as "arrhythmogenic cardiomyopathy" before progressing to a more typical dilated form.
  - For the purpose of this discussion, we classify dogs with persistent arrhythmias and a normal echocardiogram as "arrhythmogenic cardiomyopathy" and those with LV dysfunction—with or without arrhythmias—as "occult DCM". While this distinction may seem academic, there is a clear trend to use cardioprotective drugs such as beta-blockers and ACEIs in dogs with occult DCM. Thus, one's perspective on the requirement to demonstrate systolic dysfunction before labeling a patient "occult" DCM may influence whether or not early intervention is prescribed.
  - Most diagnoses of occult DCM are made after a breeder requests that a cardiologist screen an important dog or following a veterinary examination that uncovers a murmur or arrhythmia.
- *Echocardiography*—The *diagnosis* of occult DCM is traditionally based on echocardiographic examina-

tion, with the minor axis estimate of LV systolic function (the shortening fraction) as the diagnostic criterion.
- LV shortening fraction = LV diastolic dimension minus the LV systolic dimension, divided by the LV diastolic dimension).
- Values below 25% are considered suspicious for occult DCM, but there is no unanimity about one specific figure that indicates myocardial failure. Some healthy dogs live for many years with shortening fractions <20%. A single linear approach to diagnosis also can be questioned because larger dogs shorten relatively more in the apical to basilar direction, and this motion is not assessed by shortening fraction.
- However, some data in Doberman pinschers indicate that specific ventricular measurements, such as an end-diastolic dimensions of >49 mm or end-systolic dimensions >42 mm, are highly predictive of DCM.
- Before accepting a diagnosis of occult DCM, the clinician should request more detailed echocardiographic measures of systolic function including LV short-axis shortening area (normally >48%), apical-to-basilar mitral annular motion, and volumetric estimates of LV ejection fraction (normally >45–50% in single plane models). Advanced Doppler methods of assessment are also available but require further definition.
- Serial echocardiographic examinations are very helpful in establishing a downward trend in LV function. One should accept however that a 5% to 8% day-to-day variation is not uncommon in measured or calculated echocardiographic variables, so that large differences and trends are more meaningful than tiny up or down movements.

- *Holter ECG*—The 24-hour ambulatory ECG is a useful adjunct in the diagnosis of occult DCM or arrhythmogenic cardiomyopathy. The Holter recording may help establish the diagnosis in breeds highly prone to DCM with cardiac arrhythmias, such as Doberman pinschers. Most cardiologists consider >50 VPCs per day clearly abnormal. Some consider even lower numbers of VPCs abnormal. In dogs in which ventricular ectopy is evident from auscultation and routine ECG, a Holter recording provides more objective information about the severity of the rhythm disturbance.
- *Other diagnostics*—Future directions are likely to lead to more dependence on *biomarkers* (troponins, natriuretic peptides) for identification of myocardial disease in breeds at risk or when screening echocardiograms return ambiguous results.
  - Breeders are always hoping for tests that will provide the earliest recognition of disease, but it is unrealistic to expect phenotype testing, no matter how sophisticated, to identify all genetically affected animals within a breeding line.
  - Many dogs that develop DCM do not demonstrate any signs until their later years, long after breeding has ceased.
  - In this regard, genetic testing will be a better answer for this particular group of clients and dogs.
- *Management* of occult DCM involves protection of the myocardium and management of serious arrhythmias.
  - An ACEI is prescribed for dogs with documented occult DCM based on echocardiography. Enalapril or benazepril at 0.5 mg/kg PO once or twice daily is appropriate. If LV function is very poor, b.i.d. dosing should be attained over a 2-week time. In the report of O'Grady and colleagues, in Doberman pinschers, treatment with enalapril roughly doubled the time duration between diagnosis of occult DCM and onset of overt signs of heart failure.
  - Beta-blockade with carvedilol or metoprolol also is cardioprotective and should be considered in dogs with occult DCM.
    In large breed dogs, long-acting metoprolol is usually well tolerated ($^1/_2$ of a 25-mg tablet, q12h).
    Carvedilol (Coreg) is relatively expensive, but dogs with occult DCM are more likely to tolerate it than dogs with overt CHF. Optimal target dosages are unknown, but initial dosing of 0.1 mg/kg PO q12h can be increased every 2 to 4 weeks to a target of 0.4 to 0.5 mg/kg q12h. If lethargy or exercise intolerance develops, insure that CHF has not been precipitated.
  - Blood pressure and renal function tests should be followed with these medications.
  - If cardiac arrhythmias are also present, a 24-hour Holter ECG should be done to assess arrhythmia severity (unless a routine ECG already shows that it is severe) and antiarrhythmic therapy considered. This is discussed more fully below under arrhythmogenic cardiomyopathy.
- *Prognosis*—Prediction of survival in occult DCM is difficult
  - One of the problems relates to that of precisely establishing a diagnosis of occult DCM.
  - Once unambiguous evidence of LV systolic dysfunction is identified (LVSF typically 15% or less in a dog with sinus rhythm and normal ventricular conduction), the development of CHF is likely within 6 to 12 months, even in the setting of cardioprotective drugs.
  - When less stringent criteria are set for diagnosis of occult DCM, many dogs will still be alive 2 to 4 years later.

DCM with Congestive Heart Failure

Advanced cases of DCM usually present with a history of exercise intolerance and clinical signs of CHF.

- Syncope related to ventricular arrhythmia or neural mediated syncope (inappropriate bradycardia and vasodilation) may be reported by the owner.
- Physical examination reveals signs typical of CHF:
  - There can be marked weight loss and cachexia.
  - The arterial blood pressure usually is normal owing to vasoconstriction and neurohormonal activation, but it will be decreased in profound DCM with cardiogenic shock.
  - Auscultation may reveal atrial and ventricular gallops, systolic murmurs, or arrhythmias.
  - The intensity of the first heart sound and strength of the arterial pulse is often diminished, indicating reduced LV contractility and stroke volume.
  - Crackles of pulmonary edema or a pleural fluid line may be evident.
  - Clinical signs of left-sided CHF include tachypnea, respiratory distress, abnormal breath sounds, and coughing related to pulmonary edema.
  - Right-sided CHF is characterized by jugular pulses and jugular venous distension, hepatomegaly, and ascites.
  - Pleural effusion is common in biventricular failure.
- Diagnostic studies in advanced cases of DCM.
  - The standard 6-lead ECG may demonstrate a number of abnormalities:
    Cardiomegaly (wide or tall P-waves; wide or increased amplitude QRS complexes).
    Myocardial disease (wide QRS, slurred R-wave descent with ST-segment coving, small complexes in boxers and English bulldogs; left bundle branch block).
    Atrial or ventricular premature complexes; atrial fibrillation; or ventricular tachycardia.
  - The signal averaged ECG may demonstrate late potentials indicating increased risk for ventricular fibrillation.
  - Thoracic radiography reveals cardiomegaly and typical vascular and pulmonary parenchymal features of heart failure. Pleural effusion is common.
  - The echocardiogram shows left ventricular dilation with reduced LV shortening fraction. Other common findings include:
    Increased mitral E-point to septal separation.
    Decreased LV or septal wall excursions.
    LA dilation.
    Variable right-sided cardiomegaly.
    Doppler evidence of mitral regurgitation and tricuspid regurgitation.
    Possible evidence for pulmonary hypertension.
    Diastolic ventricular dysfunction with a restrictive filling pattern.
- Routine chemistry laboratory tests are usually normal or reflect intercurrent disease, consequences of CHF, or complications of CHF therapy.
  - Specialized blood tests for taurine may be performed in selected cases (mainly in American cocker spaniels, golden retrievers, Newfoundlands, breeds atypical for DCM, and in dogs receiving all lamb and rice diets).
  - Cardiac troponin-I is usually elevated along with increased plasma ANP and BNP.
- Therapy of CHF associated with DCM is discussed in detail in Chapter 147.
- *Principles of Hospital Management of CHF include*
  - Administer *furosemide* (2–5 mg/kg IV); follow this with repeated IV or IM injections. Alternatively begin a constant rate infusion of furosemide.
  - Provide supplemental *oxygen* by nasal prongs or other method appropriate for the size of the dog. If oxygen is unavailable, direct a fan to the facial region to minimize dyspnea.
  - Administer *nitroglycerin* ointment topically (1–1.5 inches for a large breed dog q12h).
  - Treat life-threatening pulmonary edema with afterload reduction using an infusion of sodium *nitroprusside* (0.5–2.5 mcg/kg/min is the typical dosage range) with careful attention paid to arterial blood pressure. Titrate the infusion to a systolic value of 90 to 100 mm Hg. A less effective alternative for load reduction is enalapril at 0.25 to 0.5 mg/kg PO q12h.
  - Perform *thoracocentesis* if there is a moderate to large pleural effusion.
  - For CHF with systemic hypotension begin an infusion of *dobutamine* (2.5–10 mcg/kg/min) for 24 to 48 hours. Dobutamine can have benefits beyond the period of infusion.
- In the setting of hypotension, arterial vasodilators such as nitroprusside or an ACEI should be avoided until the pressure is stabilized by dobutamine.
- In dogs with AF, digoxin (0.01mg/kg PO q12h for the first two doses; 0.005 mg/kg PO q12h thereafter) is prescribed to control the ventricular rate response.
- Principles of long-term home management of CHF include
  - Furosemide (2–4 mg/kg PO q8-12h)
  - Spironolactone (1–2 mg/kg PO once or twice daily)
  - Enalapril or benazepril (0.25 mg/kg PO q12h; increase to 0.5 mg/kg PO q12h after the first reevaluation)
  - Digoxin (0.003–0.005 mg/kg PO q12h) unless there are contraindications for therapy such as ventricular ectopy or renal failure.
  - Pimobendan (Vetmedin, 0.2–0.3 mg/kg PO q12h) if available, generally supplants digoxin except in AF when both drugs are administered.
  - A sodium-restricted diet.
  - A β-blocker may be considered to blunt the cardiotoxic effects of the sympathetic nervous system; however, heart failure must be well controlled first. Consider carvedilol (Coreg), starting at 0.05 to 0.1 mg/kg PO q12h; up-titrate the dose every 2 to 4 weeks to a target of 0.2 to 0.4 mg/kg PO q12h.

Having pimobendan on-board facilitates up-titration of the beta-blocker.
Unfortunately, the prescription drug (Coreg) is expensive.
Dosing can be difficult in that dogs may not tolerate the negative inotropy of any β–blocker.

- When AF complicates CHF, diltiazem (up-titrate from 0.5–2.0 mg/kg PO q8h) is prescribed to control ventricular rate (see details in next section). Once heart rate is controlled, a long-acting form of diltiazem can be substituted (using the same total daily dose, but administered once or twice daily).
- Fish oil supplements containing omega-3 fatty acids may improve appetite and reduce cardiac cachexia (EPA—30–40 mg/kg PO daily; DHA—20–25 mg/kg PO daily).
- In dogs with a diagnosis of hypothyroidism, ensure that the plasma level is checked to prevent iatrogenic hyperthyroidism, a condition that increases the demand for cardiac output and is arrhythmogenic. In general, even a giant breed dog with hypothyroidism should not receive more than 0.6 to 0.8 mg of L-thyroxin daily.
- For serious ventricular arrhythmias in the setting of CHF: mexiletine (5–8 mg/kg tid) plus a low dose beta-blocker. Amiodarone or procainamide are alternatives, but results have not always been favorable. Optimally, a Holter ECG should be used to assess therapy.

Arrhythmogenic Cardiomyopathy

The term "arrhythmogenic cardiomyopathy" is a useful expression that refers to recurrent or persistent ventricular or atrial arrhythmias in the setting of a normal echocardiogram. The most commonly observed rhythm disturbances are PVCs and ventricular tachycardia (VT). However, atrial rhythm disturbances may be recognized including atrial fibrillation, paroxysmal or sustained atrial tachycardia, and atrial flutter.

- As discussed above, some dogs affected with arrhythmogenic cardiomyopathy clearly progress to classic DCM; however, many others do not. Thus, in some dogs, the key to clinical management of cardiomyopathy is control of the cardiac arrhythmia.
- ARVC—Arrhythmogenic cardiomyopathy with ventricular arrhythmias is particularly common in the boxer dog (and also in English bulldogs), where the term *arrhythmogenic right ventricular cardiomyopathy* (ARVC) is used to indicate the putative origin of arrhythmia. This term has largely replaced the "boxer cardiomyopathy" designation, but Harpster's original classification is still useful.
  - Many boxers demonstrate only isolated PVCs (upright or with a left bundle branch block morphology in leads I and II). Many boxers carry this Type I designation for years without incident.
  - Boxers often collapse or faint due to sustained VT; these were classified as Type II.
  - Some boxers will progress to develop more "classic" DCM as well, often with marked biventricular CHF. Ventricular and atrial arrhythmias are common in these Type III dogs.
- *Doberman Pinschers*—The Doberman pinscher is another breed that often manifests ventricular ectopics prior to the development of overt myocardial failure (DCM). Many of these dogs die suddenly, without premonitory bouts of syncope and before the onset of heart failure. Others progress to classic DCM with left-sided or biventricular CHF.
- *Lone AF*—The Irish wolfhound, Great Dane, and Newfoundland are giant breeds prone to AF without obvious impairment of LV contractility. Frequently, onset of AF is preceded by atrial premature complexes or paroxysmal atrial tachycardia or flutter.
  - This can be considered another form of arrhythmogenic cardiomyopathy, though it is more often designated as lone AF or occult DCM.
  - In one report, the average time interval between recognition of AF and CHF in Irish wolfhounds was about 2 years, but progressive DCM was a common feature of many dogs.
  - The results of other reports indicate that a relationship between AF and DCM is less clear.
- *Clinical Assessment*—A data base should be obtained from dogs with suspected arrhythmogenic cardiomyopathy, including
  - Careful review of clinical signs relevant to the arrhythmia.
  - Medication history.
  - Complete physical examination.
  - CBC and serum biochemical profile (including electrolytes).
  - Serum troponin-I (cTn-I).
  - Routine ECG with a long rhythm strip.
  - Ambulatory (Holter) ECG, especially when the rhythm is characterized by only isolated atrial or ventricular premature complexes and there are no related clinical signs. The Holter ECG is particularly important in the asymptomatic patient with a rhythm strip that does not indicate a clear need for therapy.
  - Echocardiogram.
  - Thoracic radiograph (optional).

From this information, the clinician should determine the most likely *etiology* of the rhythm disturbance and also attempt to judge the *overall clinical significance* of the arrhythmia. This assessment is pivotal to any therapeutic decisions.

- *Differential Diagnosis*—Arrhythmogenic cardiomyopathy must be distinguished from other causes of cardiac arrhythmias with normal left ventricular function.

- Other recognized disorders associated with cardiac arrhythmias should be excluded, for example:
  Cardiac tumors (hemangiosarcoma)
  Electrolyte imbalance (hypokalemia, calcium disturbances)
  Systemic hypertension
  Splenic tumor
  Postoperative or traumatic ventricular arrhythmia (caused by ischemia and reperfusion injury).
- A drug history should be obtained to ensure the arrhythmia is not caused by drugs or hormones that increase sympathetic tone (including excessive supplementation of L-thyroxin).
- In those cases where LV systolic function is reduced, a revised diagnosis of DCM with arrhythmia is appropriate, so long as a tachycardia-induced cardiomyopathy is eliminated.
  Sustained tachyarrhythmias can cause a reversible tachycardia-induced dilated cardiomyopathy; this is most likely when the tachycardia is relentless, with few intervals of sinus rhythm.
  In such cases, it is valuable to assess LV function before and 3 to 4 weeks after control of the tachyarrhythmia. Once the rhythm or heart rate response has been controlled, a more objective assessment of ventricular function can be obtained.

- *Management Approach*—Successful management of isolated arrhythmias in dogs is similar to that associated with treatment of arrhythmias in CHF, but with the advantage that normal ventricular function allows a wider selection and higher dosages of anti-arrhythmic drugs to be used. Most of the drugs used to control heart rhythm also depress cardiac function. This effect limits anti-arrhythmic drug use in heart failure. In this regard, the clinician should be vigilant, since an arrhythmia may be the first sign of progressive myocardial disease, and DCM and CHF may develop in the future.
  - The first question to address is whether the arrhythmias should even be treated. For example, isolated PVCs or atrial premature complexes probably should not be treated with potent anti-arrhythmic drugs unless there have been signs related to collapse or syncope.
  - The goals of therapy are three: prevent sudden death; prevent or reduce clinical signs; and protect the ventricle from tachycardia-induced cardiomyopathy.
  - When anti-arrhythmic therapy is prescribed, discuss the adverse drug effects with the owner, the importance of follow up ECGs (including Holter recordings), and discuss the potential for pro-arrhythmia (worsening of the rhythm).
  - Remember that the duration of therapy depends on the likely etiology of disease. In many cases of arrhythmogenic cardiomyopathy, treatment will be lifelong.
  - Have the client record any symptoms that might be related to the arrhythmias or possible adverse effects of the drugs.
  - Follow up with the patient at regular intervals. Begin with a client interview and routine auscultation. Follow with a standard ECG (if an arrhythmia is detected). Consider the use of a Holter ECG.
  - When a patient is stable on routine ECGs and is receiving a consistent dose of medication, perform another Holter ECG.

▼ ***Key Point*** Evaluate the response to therapy with both a routine ECG and a Holter ECG.

- *Lone Atrial Fibrillation*—In dogs with lone AF, Holter data provide insight about the daily heart rate and the exercise heart rate. Average daily heart rates that exceed 90 to 95/min or moderate-level exercise heart rates that exceed 200/min are reasonable grounds for slowing the heart rate response to AF or referring for cardioversion.
  - *Beta-blocker therapy* for heart rate control—Control of the ventricular rate response can be achieved with atenolol (0.5–1 mg/kg PO q12h) or metoprolol (12.5 mg PO twice daily in giant breeds). These drugs are also potentially cardioprotective if the AF is a premonitory sign of future DCM.
    For the first three days, the initial dose of the beta-blocker should be 50% of the prescribed dose, to prevent undue lethargy.
    Thereafter, the drug dose can be titrated up over 2 to 4 weeks to achieve an appropriate average daily heart rate (generally in the range of 70–80/min).
  - *Diltiazem therapy* for heart rate control—The use of this calcium channel blocker (dosed at 1–2.0 mg/kg PO q8h) is effective in controlling heart rate but does not confer the "cardioprotection" of beta-blockers should the arrhythmia represent early DCM. An initial dose of 0.6 mg/kg PO q8h for the first day is recommended before increasing the dose. Diltiazem can be used in combination with a beta-blocker. A long-acting preparation of diltiazem can also be used if q8h dosing is difficult (using the same total daily dosage, divided q12h).
  - *Digoxin therapy*—While digoxin can be prescribed for lone AF, cardiac glycosides are less effective for controlling excessive exercise-related rates and are not recommended by us when there is no evidence of heart failure.
  - *Cardioversion*—The conversion of AF back to sinus rhythm is definitely possible in dogs with lone AF. The use of procainamide, sotalol, or amiodarone for this purpose has met with mixed, and generally unfavorable, results. However, electrical DC biphasic cardioversion is highly successful in the setting of lone AF, especially in giant breeds, provided low-dose amiodarone is administered following the

procedure to maintain normal rhythm. This procedure requires referral to a cardiologist.

- *Ventricular arrhythmias and ventricular tachycardia*—Grading the severity of ventricular arrhythmias in terms of relative risk for sudden death is difficult but highly pertinent to management of these dogs. Once this had been done, and if a decision is made to treat the arrhythmia, a long-term plan for management should be established.
  - Relative Risk—Clearly the presence of clinical signs (collapse, syncope) is an indication to control ventricular tachycardia if the clinician is certain that a tachyarrhythmia is the basis for the episodes. In most cases, the situation is less clear cut, and the clinician must "grade" the arrhythmia in terms of severity.

    Isolated PVCs or runs of monomorphic, "slow" VT (usually <160/min) frequently are not treated. Couplets are not necessarily more dangerous than single PVCs, but closely timed couplets may indicate a higher "grade" of arrhythmia.

    Polymorphic VT (including torsade de pointe); non-sustained but flutter-like runs of VT; long runs of monomorphic, fast VT (exceeding 200/min); frequent multiform PVCs; and PVCs falling on the prior T-waves (R on T) suggest a higher grade or complexity of the arrhythmia. Anti-arrhythmic therapy is usually recommended.

    When serious arrhythmias are evident on a routine ECG, there is probably no need to perform a Holter ECG until after therapy has begun, especially in the dog with clinical signs. When a routine ECG shows "low-grade" arrhythmias such as isolated PVCs or runs of "slow" VT, it is reassuring to know if the results of a 24-hour Holter ECG support a low grade of complexity before deciding not to treat.

    When doubt remains, obtain consultation if possible.

▼ ***Key Point*** Decisions about initiating anti-arrhythmic therapy are imperfect, and dogs with recurrent PVCs or VT—whether on or off therapy—always carry a risk for sudden cardiac death. No anti-arrhythmic drug has been proven to prevent sudden death in dogs.

  - *Isolated PVCs*—Generally, it is better not to treat isolated PVCs. However, when they are frequent (such as >10,000 per day or about 7 PVCs per minute) they may be difficult to ignore. One well tolerated approach is to prescribe a beta-blocker such as atenolol (0.5–1 mg/kg PO q12h), which will likely reduce the total number of ectopics but not create a pro-arrhythmic situation.
  - *Ventricular Tachycardia*—When treatment is elected, the choice of drug depends largely on personal preference, but some recommendations can be advanced. The Chapter "Cardiovascular Drugs" describes the clinical pharmacology, use, and adverse effects of these drugs.

    Sotalol (1–2 mg/kg PO q12h) is generally well tolerated in dogs and clearly improves Holter ECG recordings in some breeds (such as boxers). This drug should not be used in German shepherds with inherited ventricular ectopy.

    Mexiletine—An oral drug related to lidocaine, mexiletine (Mexitil) is an effective ventricular anti-arrhythmic in many dogs (5–8 mg/kg PO q8h). We combine it with a β-blocker such as propranolol (0.5–1 mg/kg PO q8h) or atenolol (0.5–1 mg/kg PO q12h). Anorexia, tremors, and vomiting are adverse effects. For unresponsive patients, sotalol (1 mg/kg PO q12h) can be substituted for the other beta-blocker.

    Amiodarone (Cordarone) is an effective drug for VT, but may be more pro-arrhythmic and carries a higher incidence of adverse effects than sotalol. With a long elimination half-life, a loading dose is used initially (5–10 mg/kg PO q12h) followed by a lower maintenance dose (4–6 mg/kg PO once daily).

    Procainamide—The use of a long-acting procainamide preparation (15–20 mg/kg PO q8h) is recommended as procainamide HCl has a very short elimination half-life in dogs. As with mexiletine, it may be more effective when combined with a beta-blocker.

Chapter

151 Pericardial Diseases

John D. Bonagura

The pericardium consists of two mesothelial-lined membranes: the visceral layer (epicardium) that is tightly adhered to the myocardium and the reflection of this membrane that forms the parietal pericardium. Between these is a space that contains the heart, origins of the major arteries, and terminations of the vena cava and pulmonary veins. The normal pericardial space also contains a very small amount of serous, lubricating pericardial fluid. The normal pericardium limits acute cardiac dilatation, maintains cardiac geometry, contributes to ventricular compliance and interdependence, reduces friction, and provides a barrier from inflammation. The pericardium is not essential to survival and can be removed surgically.

- The most important congenital forms of pericardial disease are congenital *peritoneopericardial diaphragmatic hernia* (PPDH) and the relatively rare congenital *pericardial cysts* (which will not be discussed in this chapter).
- The main acquired pericardial diseases in dogs and cats are pericardial effusion (PE), constrictive pericarditis, and constrictive-effusive pericardial disease. In many cases, PE is related to the presence of a cardiac or heart-base neoplasm.
- *PE* is the accumulation of excessive or abnormal fluid within the pericardial space.
- *Cardiac tamponade* refers to a state of cardiac compression and impaired filling from increased intrapericardial pressure. While mass lesions and cysts can compress the heart, the majority of cases are caused by a PE.
- The total volume within the pericardial space is finite. Pericardial fluid accumulation can occur only if the parietal pericardium stretches (increasing the volume of the pericardial space) or the volume within the cardiac chamber shrinks.
- Since the parietal pericardium contains few elastic fibers, it is not easily distended in the setting of acute fluid accumulation. For this reason, even small volumes of acute intra-pericardial hemorrhage can produce cardiac tamponade.
- When parietal effusion develops more gradually, the parietal pericardium and pericardial space expand substantially. Progressive pericardial stretching, combined with increases in venous pressure, permit a situation in which large volumes of PE may develop. Effusions exceeding one liter may accumulate in larger dogs.
- *Pericardial constriction* occurs secondary to pericardial inflammation or scarring. The normally strong pericardium becomes thicker and fluid within the space is reabsorbed. Eventually the pericardial membranes act as a "shrink wrap" about the heart.
- *Constrictive-effusive pericardial disease* is a condition that includes both pericardial restriction and a small volume of pericardial fluid.
- Pericardial diseases can eventually cause congestive heart failure (CHF).

▼ ***Key Point*** Pericardial disease is one of the most common causes of right-sided heart failure in the dog. In older dogs, cardiac or heart-base neoplasia is a common etiology.

PERITONEOPERICARDIAL DIAPHRAGMATIC HERNIA

PPDH is a defect in the embryologic septum transversum that separates the peritoneal from the pericardial space. Defects permit direct communication of abdominal organs or tissue with the heart. PPDH is relatively common in cats and also can develop in dogs. (Weimaraner dogs and schnauzers are predisposed.) Males may be predisposed. Himalayan and domesticated long-haired cats were more likely to be affected by PPDH in one study.

In cats, it is typical for the hernia to contain mainly fat with one or more lobes of liver. In the dog the hernia may be subtle, containing only falciform fat, or there may be liver or loops of intestine contained.

Clinical Signs

Many affected dogs and cats are without overt clinical signs, unless the hernia is large and there is a large volume of herniated abdominal content within the thorax. Infrequently, liver strangulation may lead to signs of discomfort.

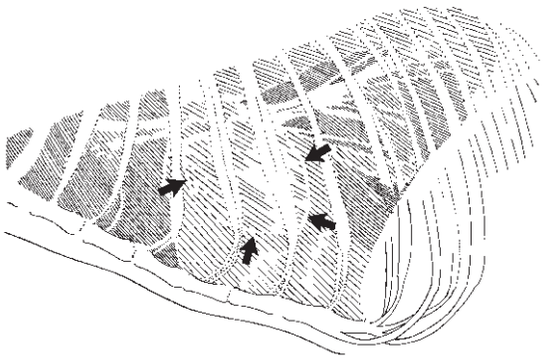

Figure 151-1. Representation of the enlarged cardiac silhouette and double-density cardiac shadow caused by omental fat in a patient with peritoneopericardial diaphragmatic hernia. Arrows indicate the edge of the heart.

Diagnosis

Physical Examination

- The diagnosis may first be suspected during routine examination as heart sounds may be muffled or displaced.
- Often there is a systolic murmur, which may be functional or represent a concurrent cardiac defect.
- Abdominal palpation may reveal a concurrent umbilical hernia.
- In a small percentage of patients, there are clear anomalies of the sternum; these may be palpable or evident by radiography.

Diagnostic Imaging

- Careful radiographic examination leads one to suspect the diagnosis (Fig. 151-1).
- One typically observes altered radiographic density in the caudoventral portion of the pericardial space. The heart and carina are usually displaced craniodorsally, as are pulmonary venous entries to the left atrium.
- Ventral to the caudal vena cava there may be a soft tissue shadow, the persistent mesothelial remnant that delineates the dorsal border of the hernia.
- Intestinal loops may create an unusual gas pattern within the mediastinum (pericardial space).
- Ultrasonography of the thorax, or a barium swallow (if intestinal loops are present) will be diagnostic.

Treatment

Treatment of PPDH is surgical and optimally accomplished at the time of spay/neuter. Surgical results have indicated a very favorable outcome. However, a PPDH often is an incidental finding in mature animals, and in these cases, surgical intervention may not be warranted unless intestines are contained within the thorax or the risk of herniation is deemed high. Consultation with an experienced surgeon can be helpful in these patients.

Cardiac tamponade is a rare complication of PPDH. Entrapment of a loop of bowel or strangulation of the liver requires prompt recognition and surgical management.

PERICARDIAL EFFUSION

Etiology

- Acquired PE is very common in dogs and is observed sporadically in cats.
- *Transudation* into the pericardial space occurs secondary to PPDH, right-sided CHF, cysts, hypoalbuminemia, infections/toxemia, and causes of increased vascular permeability. These fluid accumulations tend to be relatively small and are often incidental necropsy or ultrasound findings. Small effusions do not to impair heart function. There are two noteworthy clinical situations that do merit comment.
  - Mass lesions at the heart base, including chemodectomas, can obstruct lymphatic drainage leading to a large and compressive transudative PE.
  - In cats with severe CHF, a very large PE may develop which may resolve with successful medical therapy of heart failure.
- *Exudation* into the pericardial space is usually caused by infective or non-infective pericarditis; these conditions are relatively uncommon in small animals.
  - Nocardia infection and perforating foreign bodies are potential causes of septic pericarditis in dogs and cats.
  - Fungal involvement of the pericardium is recognized with coccidiomyocosis in the dog or with opportunistic fungi in immunosuppressed dogs (e.g., aspergillosis).
  - Idiopathic, sterile (inflammatory) pericarditis can develop occasionally in the dog and also may be a consequence of recurrent, idiopathic intrapericardial hemorrhage.
  - Pericarditis in cats has been associated infrequently with feline cardiomyopathy but does occur in the polyserositis form of infection with feline infectious peritonitis virus.
- *Idiopathic intrapericardial hemorrhage* (with or without secondary pericardial reaction) is relatively common in dogs. This is a disorder of dogs typically less than 7 or 8 years of age, though it can occur in older dogs. As the name suggests, the etiology is unknown. Recurrent bleeding evokes an inflammatory reaction with pericardial thickening that can be difficult to distinguish from mesothelioma. Constrictive or constrictive-effusive pericardial disease can develop.
- *Neoplasia* of the heart, heart base, or pericardium frequently leads to a hemorrhagic effusion in dogs.
  - *Hemangiosarcoma* of the right atrium is especially common in dogs >7 years of age. Tumors can be isolated to the heart or multicentric with splenic

involvement and pulmonary or distant metastasis. Metastatic disease is very common.
  - *Aortic body tumor* (or *chemodectoma*) originates from the base of the aorta and grows along the heart base, often along the path of least resistance. Metastatic disease is very unusual.
  - Ectopic (heart-base) *thyroid carcinoma* can cause a large heart base mass that is more likely to invade the myocardium.
  - *Mesothelioma* of the pericardium also occurs frequently, but the diagnosis is often difficult as discussed below. Progressive growth is typical and the pericardium may scar or constrict.
  - *Lymphosarcoma* of the right atrium and ventricles is an important cardiac neoplasm in the cat but is considered a rare cause of PE in dogs. It is frequently multicentric.
  - *Metastatic carcinoma* to the heart or pericardium is rare in dogs or cats.
  - Other cardiac tumor types (e.g., fibrosarcoma) have been reported but are rare.
- *Left atrial rupture* can occur in dogs with mitral regurgitation from chronic valvular endocardiosis. Linear tears develop within the stretched left atrial wall and occasionally transmural separation occurs leading to sudden cardiac tamponade.
- *Uncommon causes* of pericardial hemorrhage include blunt chest trauma; puncture of the heart (knife, bullet, and missile); coagulopathy, and as a complication of thoracocentesis.
- *Chyle* is a very rare fluid type in the pericardial space.

Pathophysiology

- The cause and underlying pathophysiology of a pericardial disorder influences the clinical presentation. An understanding of these processes (Fig. 151-2) is instructive relative to diagnostic studies and therapy.

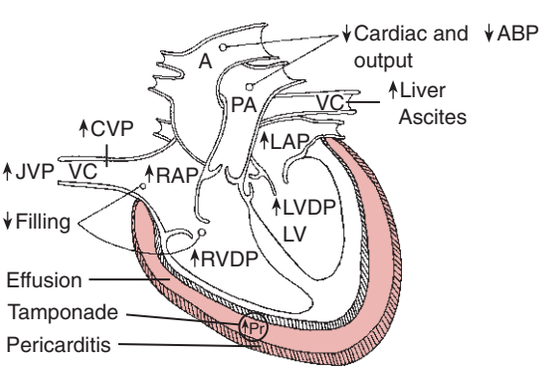

Figure 151-2. Diagrammatic representation of pericardial effusion. See text for explanation. A, aorta; ABP, arterial blood pressure; CVP, central venous pressure; JVP, jugular venous pressure; LAP, left atrial pressure; LV, left ventricle; LVDP, left ventricular diastolic pressure; PA, pulmonary artery; Pr, pressure; RAP, right atrial pressure; RVDP, right ventricular diastolic pressure; VC, vena cava.

- Inflammatory disease within the pericardial space may create clinical signs related to localized chest discomfort or constitutional signs of systemic inflammation. This is especially true in cases of septic pericarditis.
- *Cardiac tamponade* is the major pathophysiologic event in PE and represents the state of cardiac compression caused by increased intrapericardial fluid pressure. The normally negative inspiratory pericardial pressure becomes positive. This can be documented in clinical cases by a simple fluid manometer attached to a drainage catheter that has entered the pericardial space.
  - Tamponade is the mechanism by which low cardiac output and congestive heart failure (CHF) develop with PE.
  - Intrapericardial pressures can rise rapidly as the elastic limits of the membrane are exceeded (a steep pressure to volume relationship).
  - Increased (positive) intrapericardial pressure develops leading to diastolic collapse of the right atrium and the right ventricle along with compression of the vena cava.
  - Reduced right ventricular filling decreases preload and cardiac output; systemic hypotension occurs if sympathetic and fluid-retaining compensatory mechanisms are insufficient.
  - Syncope, collapse, or sudden death may occur if systemic hypotension is severe.
  - However, given sufficient time ABP is reestablished by combinations of heightened sympathetic discharge, systemic vasoconstriction, renal retention of sodium and water, and elevated venous pressures.
  - Extremely high venous pressures are characteristic of chronic pericardial diseases. Congestive heart failure, with a predominately right-sided component (ascites, pleural effusion, subcutaneous edema) is the consequence of *chronic* cardiac tamponade or constriction.
  - Additional hemodynamic features include equilibration of diastolic pressures in the ventricles, atria and great veins, and accentuated respiratory variation in ABP (pulsus paradoxicus).
- Diastolic equilibration of pressures requires cardiac catheterization for documentation.
- Pulsus paradoxicus is readily identified by palpation or ABP measurement with a Doppler flow system and is defined as an exaggerated fall in the ABP and pulse pressure during inspiration (see "Physical Examination").
- Pulsus paradoxicus is explained by exaggeration of the normal respiratory-induced variation in right and left-sided cardiac filling. Left ventricular filling and systemic arterial pressure fall as right ventricular filling is augmented by negative inspiratory pleural pressures. Since the total volume with the pericardial space is finite, the increased venous return shifts the ventricular septum into the left

ventricle during inspiration, reducing LV preload and stroke volume. As a result, palpable pulse pressure and measured systolic ABP decline during inspiration and increase with expiration as the process is reversed.

Diagnosis

The clinical diagnosis of PE follows a logical course from history and physical examination to selection of diagnostic tests. These studies should establish the diagnosis, etiology, and clinical significance of a PE. The electrocardiogram, thoracic radiography, fluoroscopy, abdominal ultrasonography, and echocardiography offer complementary information.

▼ ***Key Point*** Echocardiography is the clinical gold standard for diagnosis of PE.

Pericardiocentesis can be both diagnostic and therapeutic in this disorder. Diagnosis in some patients requires surgical exploration with biopsy of the pericardium or surrounding tissues.

Signalment

PPDH is more common in young dogs and cats but may be an incidental finding in older animals. Dogs >7 years of age are more likely to develop cardiac or heart base neoplasia. Golden retrievers and St. Bernard dogs are predisposed to idiopathic pericardial hemorrhage; brachycephalic breeds to chemodectoma; golden retrievers, Labrador retrievers, German shepherds, and many other breeds to hemangiosarcoma; golden retrievers to mesothelioma.

History

Collapse or syncope are particularly common signs with acute cardiac tamponade (e.g., sudden hemorrhage). Dogs with a history of sudden collapse are more likely to have an underlying neoplastic cause. Syncope also can occur after diuretic therapy of right-sided congestive heart failure (because elevated venous pressures are needed to maintain cardiac filling and cardiac output and this compensation is lost with volume depletion).

- Clients may note abdominal distension from CHF.
- Signs of illness may be present when there is underlying multicentric or metastatic neoplasia, septic pericarditis, or abdominal disease.

Physical Examination

- Patients with acute cardiac tamponade may be hypotensive with palpable distention of the jugular vein. A systolic ABP <90 mm Hg should be treated as an emergency with consideration for prompt pericardiocentesis.
- Elevated jugular venous pressure, distant heart sounds, and respiratory variation in blood pressure (pulsus paradoxicus) constitute the classic "triad" of physical findings in cardiac tamponade.
- The central venous pressure is generally quite high in PE, often exceeding 12 cm H_2O [normal <5 cm H_2O].
- The recognition of pulsus paradoxicus is not difficult and, in some cases, is obvious from simple palpation of the femoral arteries.
- When using a Doppler flow method for diagnosis, the pressure cuff should be slowly deflated to identify a consistent inspiratory fall and expiratory rise in systolic blood pressure. The intensity of the Doppler flow sound also changes, becoming fainter during inspiration (indicated reduced stroke volume).
- Pulsus paradoxicus is highly suggestive, though not specific for cardiac tamponade. Respiratory distress with marked variation in intrathoracic pressure can also lead to respiratory variation in the pulse. Panting can make it difficult to recognize pulsus paradoxicus.

▼ ***Key Point*** Pulsus paradoxicus is an often-overlooked physical examination finding of cardiac tamponade.

- Right-sided CHF is more typical of PE and is associated with elevated jugular venous pressure, hepatomegaly, ascites, and possibly pleural effusion. In one study, CHF was more commonly associated with idiopathic pericardial hemorrhage. Experimental PE in dogs leads to interstitial lung edema, but in clinical cases, it is rare to diagnosis overt left-sided CHF.
- Fever or thoracic pain may indicate infection or inflammation within the pericardial space.
- Cardiac auscultation of PE is characterized by muffled heart sounds. A pericardial friction rub may indicate pericarditis, but this is atypical of dogs and cats with PE.
- Breath sounds are muffled and there will be tachypnea or respiratory distress when pleural effusion complicates pericardial disease.
- Evidence of systemic disease, such as lymphosarcoma or hemangiosarcoma of the spleen might be noted during a complete physical examination.

Laboratory Tests

- Routine blood tests in pericardial disease may simply reflect the consequences of heart failure or prior diuretic therapy.
- The CBC may indicate inflammation, infection, or hemorrhage. Increased numbers of circulating nucleated RBCs are suggestive of hemangiosarcoma of the spleen (and heart). In cases of severe hemopericardium, the patients may be anemic due to blood loss or exhibit the nonregenerative anemia of chronic illness. Evidence of disseminated intravascular coagulopathy is evident with disseminated hemangiosarcoma.

- Serum troponins (cTnI) may increase with PE and are higher in the setting of cardiac neoplasia, especially in cases of hemangiosarcoma.
- Analysis of pleural or peritoneal effusions generally indicates fluid of an obstructive origin (transudate, modified transudate, or infrequently chyle). Bacterial cultures of the effusate, serum fungal titer (coccidiomycosis), or ELISA tests for FeLV or FIP (cats) may be positive when pericarditis is related to these infections.

Electrocardiogram

An **electrocardiogram** may show any of the following:

- Decreased amplitude QRS complexes (<1mV in all frontal plane leads in dogs). This finding is common but inconsistent.
- Electrical alternans (with large effusates and swinging of the heart). This is a relatively specific but insensitive finding in PE.
- ST segment elevation indicating a current of epicardial injury. This abnormality should be evident in >1 frontal plane lead and is observed most often with pericarditis.
- ST segment depression is more typical of subendocardial ischemia, which may indicate reduced blood pressure or coronary perfusion.
- Cardiac rhythms are variable.
- Sinus tachycardia is typical of cardiac tamponade, and the heart rate generally declines following pericardiocentesis.
- Vagal mediated reflexes can be invoked from stimulation of receptors within the pericardium, promoting a sinus arrhythmia with wandering pacemaker or even a "relative" bradycardia (in terms of blood pressure).
- In PE without tamponade, normal sinus rhythm or sinus arrhythmia may be observed.
- Atrial and ventricular arrhythmias are not uncommon and may develop secondary to myocardial cardiac tumors, ischemia, or concurrent primary heart disease.

Diagnostic Imaging

Radiographic techniques are valuable for identifying cardiomegaly, vascular abnormalities, pulmonary lesions, and pleural effusion.

- With moderate to severe PE, the cardiac silhouette enlarges, loses its angles and waists, and eventually becomes globular in shape ("basketball or soccer ball heart").
- The contour of the heart may become particularly sharp, related to diminished motion of the distended membrane.
- The region over the left atrium often appears more rounded as opposed to the more square appearance of true cardiomegaly.
- Should a metallic foreign body be observed over the heart on two views, constrictive or constrictive-effusive disease is likely.
- Pulmonary vascularity is often reduced from low cardiac output. This finding is in contrast to CHF from cardiomyopathy or valvular disease, wherein vascular prominence is more common.
- If CHF has developed, there may be increased pulmonary interstitial densities, distension of the caudal vena cava, hepatomegaly, or pleural effusion.
- Heart base tumors may deviate the trachea (generally to the right and dorsally), producing a mass effect. Occasionally, it may be difficult to distinguish another mediastinal tumor or a large lung tumor from a heart base tumor.
- In cases of isolated intracardiac tumor without pericardial effusion, there may be a distinct, rounded bulge in the region of the right atrium (DV projection) or right auricle (lateral projection).
- Fluoroscopy, if available, may demonstrate increased heart size with reduced cardiac motion.
- Pneumopericardiography can identify intrapericardial mass lesions, but this examination is rarely done today as echocardiography is safer and more accurate.
- Advanced imaging examinations such as computerized tomography and MRI angiography are referral examinations that require rapid acquisition systems and gating of the cardiac cycle. These methods may be useful in evaluation of mass lesions.
- Radiopharmaceutical studies may be helpful to identifying tumors of neural crest origin (chemodectoma).

Abdominal Ultrasonography

- Examination of the spleen, liver, and peritoneal space is indicated in older dogs or cats with PE.
- Hepatic venous distention and enlargement of the caudal vena cava are suggestive of right-sided CHF.
- The presence of free abdominal fluid may indicate CHF or hemorrhage of an abdominal tumor.
- The spleen and liver may demonstrate mass lesions suggesting hemangiosarcoma or metastatic disease.

Echocardiography and Doppler Studies

The echocardiogram is a highly sensitive test for detecting PE and cardiac tamponade and, in some cases, may demonstrate the etiology of disease. The distinction between idiopathic, hemorrhagic PE, and bleeding from a tumor may not be possible unless a high resolution, technically proficient echocardiogram is recorded from each side of the thorax and using multiple angled views. If the patient is stable (with ABP >90 mm Hg), and echocardiography is readily available, a brief delay is acceptable to obtain detailed imaging prior to pericardiocentesis. Cardiac and heart base tumors are more readily seen when surrounded by fluid.

- Bilateral pleural effusion is a common finding in pericardial diseases complicated by CHF. Fibrin stands and pulmonary atelectesis may be observed in some cases.
- Accumulation of fluid is evident as a sonolucent (generally black) space between the epicardium and normally hyperechoic pericardial/mediastinal interface. The fluid space typically extends from apex to base. In the most subtle effusions, the space is evident only during systole.
- Fluid with a mixed intrapericardial echogenic pattern is suggestive of an exudate or recent hemorrhage into the pericardial space.
- Acute hemorrhage may lead to a minimal effusion; for example, rupture of the left atrium may be associated with a small (<25 cc) effusion but with severe hemodynamic consequences. Conversely, in chronic cases, the PE can be great (exceeding one liter in larger breed dogs).
- Recognition of prolonged diastolic collapse (inversion) of the right atrial wall or early diastolic collapse of the right ventricular wall is supportive of increased intrapericardial pressure and is usually diagnostic of cardiac tamponade. Ventricular collapse may vary during the respiratory cycle. There can be false positives (large pleural effusion alone can cause this in dogs) and false negatives (as elevated CVP can distend the right heart chambers opposing obvious diastolic collapse).
- Cardiac mass lesions are often found in mature dogs with PE. These may be observed by transthoracic or transesophageal echocardiographic techniques. The chemodectoma (aortic body tumor) originates from the aortic root and surrounds the base of the heart; these tumors can become very large. The major differential diagnosis is the normal hyperechoic fat pad between the aorta and pulmonary artery.
- Hemangiosarcoma is usually identified within the right auricle or the right atrium (where it may resemble a smooth thrombus with focal attachment). The tumor may also invade and grow along the right atrioventricular groove.
- Mesothelioma is difficult to diagnose. The pericardium may appear thicker and one may identify roughly circular or oral tumors attached on the inner surface of the pericardium (blood clots may appear similar).
- Lymphoma in cats usually infiltrates the right atrium and the cardiac septa and is typically multifocal.
- Doppler studies can be useful in diagnosing the elusive constrictive pericardial disease. One characteristic feature is *marked* variation in cardiac filling profiles with ventilation.
- Extremely large mass lesions will impair right atrial filling, tricuspid inflow, or right ventricular outflow. These obstructions are usually accompanied by abnormal Doppler filling or ejection velocities.

Pericardiocentesis

- Fluid samples can be collected for analysis in cases of PE by the technique of pericardiocentesis. Drainage of the pericardium is also therapeutic (see "Therapy" for more details).
- Measurement of "static" intrapericardial fluid pressure prior to removing any PE can be accomplished by attaching one end of a saline-filled extension tube to the intrapericardial catheter and the other end to a central venous pressure manometer (prior to any drainage). While somewhat crude, the results can be instructive. Cases of tamponade demonstrate a high (positive) pressure, usually >12 cm to 15 H_2O above the midsternal line, with the patient resting in lateral recumbency. The pressure becomes subatmospheric following pericardiocentesis and rises and falls with ventilation. With constrictive-effusive pericardial disease, PE without tamponade, or isolated pleural effusion, the intrapericardial pressure may be near normal (i.e., near zero cm H_2O).

Fluid Analysis

- A sample of fluid can be collected anaerobically for measurement of pH. However, the pH of pericardial fluid is usually not diagnostic, unless it is very low (<7.0), a finding suggestive of pericardial inflammation. Values of 7.3 to 7.4 or greater are more typical of neoplasia or recent hemorrhage.
- Collected fluid eventually should be evaluated by a clinical pathologist. A Diff-quick stain can be used to screen a slide for obvious septic pericarditis while awaiting results from the laboratory.
- Fluid can be classified simply as a transudate, exudate, hemorrhage, or chyle.
- Except in cases of lymphosarcoma or septic inflammation, cytologic examination may not be especially helpful.
- It can be difficult to conclusively identify neoplastic cells within pericardial effusates. The problems include poor exfoliation of hemangiosarcoma and chemodectoma and the tendency to over-interpret reactive mesothelial cells as diagnostic of mesothelioma.

Confirming the Etiology and Establishing Prognosis in Pericardial Effusion

Knowledge of the underlying cause of pericardial disease has a great impact on disease management, prognosis, and client decisions. The prognosis of pericardial disease depends on the cause. Unfortunately, even with a high quality transthoracic echocardiographic examination and expert interpretation of pericardial fluid cytology, the underlying etiology for PE may be inconclusive.

▼ ***Key Point*** Establishing an etiology of pericardial effusion is pivotal as survival time in idiopathic pericardial effusion is very long when compared to neoplastic causes.

Idiopathic Pericardial Hemorrhage

In young dogs with PE, the diagnosis of *idiopathic pericardial hemorrhage* is one of exclusion. Such a diagnosis is tenable in the absence of a cardiac mass and with cytological findings of intrapericardial hemorrhage and mesothelial reaction without signs of infection or inflammation. Many dogs with idiopathic hemorrhagic PE recover completely following repeated pericardiocentesis or subtotal pericardiectomy. In one study, dogs undergoing pericardiectomy for idiopathic PE had a median survival of 1,218 days compared with 532 days for those not undergoing surgery.

Pericarditis

If cytology demonstrates an *infective* or *inflammatory pericarditis* in a dog or a cat, consider the condition a surgical disease. The prognosis with infective or inflammatory pericarditis is always guarded, but with prompt recognition a good outcome may be realized. The best long-term results will be obtained with subtotal pericardiectomy prior to the onset of constrictive pericarditis.

Neoplasia

Once dogs have achieved the age of 6 to 8 years, idiopathic hemorrhagic effusion or pericarditis remain viable diagnoses; however, *cardiac* or *related neoplasia* is the main etiologic consideration for PE. This conclusion impacts the prognosis considerably, and clients should be so advised. The clinician's and the client's expectations, resources, and perspective will influence management options in this group of canine patients. Nearly all published studies detailing prognosis with pericardial disease are retrospective, making it impossible to compare different treatment approaches or determine true prognosis.

Chemodectoma

Chemodectomas (aortic body tumors) often grow slowly, and in many cases, the PE can be palliated for more than one year with a pericardial window or subtotal pericardiectomy (with or without surgical removal or reduction of the primary tumor). In one small study of dogs with PE due to chemodectoma, median survival was 730 days with surgery. The prognosis is grave when the tumor is very large and the mass compresses vital structures or pulmonary venous drainage.

Right Atrial Hemangiosarcoma

The prognosis for *right atrial hemangiosarcoma* based on my experience and published information is very poor overall (although there are always exceptional cases). Some studies suggest benefit of partial pericardiectomy and others report no benefit. Even with chemotherapy (with or without surgical resection and pericardiectomy), most dogs do not survive for six months. Many dogs have multicentric disease or metastasis by the time of diagnosis (also see Chapter 28).

Ectopic Thyroid Carcinoma

Ectopic thyroid carcinomas can be particularly invasive and have a grave prognosis unless the tumor responds dramatically to chemotherapy.

Mesothelioma

Mesothelioma is a very difficult cancer to manage and chronic disease can be associated with pericardial constriction. The long-term survival reported for mesothelioma in the literature has been totally incongruous (ranging from weeks to years), and this confusion simply verifies the difficulty of establishing the diagnosis with certainty in many dogs. Clients should be given a poor prognosis but hope that the biopsy may not predict the actual biological behavior of the disease. Most dogs that are treated undergo a pericardiectomy during the collection of biopsy samples. Chemotherapy (see below) has not been very beneficial.

Idiopathic Pericardial Effusion

PE without an obvious cause is a common clinical dilemma is the older dog with PE but without a clearly delineated cardiac or heart base tumor. Following pericardiocentesis, one of two general courses can be followed to establish the etiology, prognosis, and treatment options: 1) regular surveillance with follow-up imaging; or 2) surgical exploration of the thorax and pericardium, especially with recurrent effusion.

Monitoring and Reevaluation

When the risk of neoplastic-associated PE is high, recommend repeated echocardiographic and ultrasound examinations of the heart and spleen (for example, at 2 weeks, 3 months, and 6 months after initial presentation), along with routine chest radiographs (for metastatic disease). Not only does this allow detection and management of recurring PE, but negative findings help to exclude neoplasia as a cause of disease.

- Hemangiosarcoma sufficient to cause PE should be relatively aggressive in behavior and demonstrable on repeated evaluation.

- While chemodectomas are slow growing tumors, regular reevaluation with echocardiography at the intervals noted above should reveal in time a heart base mass.
- Where available, referral for transesophageal echocardiography should be considered for identification of occult cardiac mass lesions. This technique has a higher sensitivity than for transthoracic examination. However, anesthesia is needed and the patient first must be stabilized.
- Referral for advanced imaging (high speed, gated, CT or MRI) may be useful for identifying a cardiac mass lesion, a predisposing abdominal tumor (usually hemangiosarcoma), or pulmonary metastasis.

Diagnostic Surgical Exploration

- Exploration of the thorax is a viable option for the older dog with PE of unknown etiology. Mesothelioma creates the greatest diagnostic problems, as even follow-up imaging studies may not be conclusive with this cancer.
- There are some who believe that time will separate cases of idiopathic hemorrhage with mesothelial reaction from true cases of mesothelioma. The latter is likely to have a progressive and more malignant course of unresponsive effusion. However, other reports indicate a potentially long survival time with this tumor.
- When definitive diagnosis is deemed important, consideration should be given to surgical examination of the thorax and pericardial space. Pericardiectomy should be done at the same time.
- Surgical exploration or a thoracoscopy procedure may be helpful in this type of patient. Exploratoration offers the chance to identify a cardiac or heart base mass, obtain a pericardial biopsy sample, and create a large pericardial window that may prevent recurrent cardiac tamponade. The last point is important because even with surgical examination and biopsy of the pericardium, an etiology may not be certain.
- Advise clients that even with a surgical approach to diagnosis, a definitive prognosis may not be possible, and consultation with the pathologist and an oncologist may be needed.
- Pericardial tissues can respond to hemorrhage or other insults with the formation of reactive tissue growth, including reactive pericardial fronds. Benign mesothelial cells have been reported to embolize to regional lymphatics (generally a sign of malignancy).
- Examination of these tissues and the cells that exfoliate from them can prompt an erroneous diagnosis of neoplastic disease. To complicate issues further, there are reported cases of long-term idiopathic hemorrhage transforming to mesothelioma.

Treatment

The treatment of PE involves consideration of the underlying etiology and initial stabilization with pericardiocentesis. Following this procedure, the potential for repeated pericardial taps or for various surgical and catheter-based methods must be considered on a case-by-case basis. Consultation with a cardiologist, oncologist, or surgical specialist may be helpful.

Pericardiocentesis

- Aspiration of PE is the treatment of choice for initial stabilization of the patient. Because of the steep pressure volume relationship of pericardial disease, removing even a modest amount of PE (25–50% of the total) is likely to relieve tamponade, improve ventricular filling, and increase cardiac output.
- The procedure can be performed using a long needle; a through-the-needle catheter; an over-the-needle intravascular catheter; a commercial thoracocentesis or pericardiocentesis drainage system; or a cardiac catheter inserted by a percutaneous, transthoracic approach. A long needle becomes relatively dangerous as the PE volume is reduced; a through-the-needle catheter tends to kink; and percutaneous catheterization of the pericardial space is only recommended if there is an intent to place a balloon dilation catheter (for balloon pericardiotomy).
- While commercial pericardiocentesis catheter drainage systems work well, for dogs >6 kg, I prefer a 14- to 16-gauge Angiocath or similar over-the-needle catheter.
- I use a 23- or 21-gauge butterfly infusion needle for cats or very small dogs.
- Place an intravenous catheter for administration of emergency drugs. ECG leads should be attached for rhythm monitoring. An ABP cuff is secured to monitor blood pressure.
- If ABP is stable, mild sedation is often tolerated and improves the procedure for all.
- In dogs, butorphanol at 0.2 to 0.4 mg/kg IM is generally safe.
- In cats butorphanol 0.25 mg/kg IM followed by 2 to 5 mg of ketamine, IV will provide about 5 minutes of restraint.
- Should symptomatic hypotension develop after sedation, infuse saline solution intravenously or administer dopamine (2–5 mcg/kg/min). Administer atropine (0.02–0.04 mg/kg, IV or IM) if symptomatic bradycardia occurs.

Technique

1. The tap can proceed from the right side (cardiac notch) or left hemithorax, depending on operator preference, the situation, and echocardiographic

findings. The author prefers the right-sided intercostal approach to avoid the larger left coronary vessels.

2. Place the patient in (left) lateral recumbency and the spine elevated slightly with a radiographic foam wedge. Starting in this oblique position and later rotating the animal as needed facilitates fluid withdrawal and patient restraint during the procedure. Others prefer to perform the procedure in dogs while the patient is standing.
3. The needed depth of penetration and the ideal puncture site can be guided by echocardiography. Alternatively, one can simply note the strongest palpable cardiac impulse as this is the location where the pericardium has been expanded closest to the chest wall.
4. An initial surgical preparation of the skin is made and a local skin circular infiltration of 2% lidocaine (about 1 ml) is made into the skin and subcutaneous tissues using a 25- or 23-gauge needle. Subsequently, inject another 1 to 1.5 ml of lidocaine within the intercostal space to infiltrate the intercostal muscles and pleura through which the needle will penetrate. Perform a second surgical preparation of the skin.
5. After gloving for the procedure, create a sterile working area using the opened glove envelope or a sterile towel placed on a Mayo stand or table. The over-the-needle catheter is dissembled and one or two small side holes are cut in the distal $^1/_3$ of the catheter using a sterile #11 scalpel blade (fold the catheter gently and shave a corner at the bend). Reinsert the puncture needle carefully into the catheter. Sterile tubing is connected at one end to a three-way stopcock and at the other to a drainage syringe (35 or 60 ml) and placed on the sterile tray. Prepare sterile vacuum tubes (one with EDTA) for sample submission. Use a bowl or large graduated cylinder to collect the bulk of drained fluid.
6. Next, advance the catheter through the skin. While some operators prefer to make a small stab incision with the #11 blade, this is not necessary for an Angiocath type catheter. The skin should be penetrated completely by pulling it outward with one hand while directing the catheter tip into the subcutaneous tissues.
7. Holding the catheter firmly with two hands, redirect the needle, and then advanced deliberately in a smooth motion through the subcutaneous tissue, intercostal muscles, pleura, pleural space, and finally into the pericardial space. Generally, there is no need to attach a syringe for aspiration. There is usually some drag as the catheter crosses the pericardium; in the case of thick pericardium it may be a substantial resistance.
8. Once fluid enters the catheter tip, advance the system 2 to 3 mm more and then the needle is held securely with one hand while advancing the outer catheter into the pericardial space.
9. Monitor the ECG for extrasystoles in case the heart is pricked with the needle or catheter. (Note: dorsal approaches may cause the catheter to perforate the atrium and this will not be associated with premature ventricular complexes.)
10. Once the pericardial space is entered, fluid (usually bloody) flows across the needle without the need for aspiration. Failure of fluid to well into the needle suggests an intrapleural location or pericardial effusion without tamponade.
11. Hold the catheter in place and withdraw the inner needle. Attach the male-end of the 3-way stopcock to the catheter.
12. If intrapericardial pressure will be measured, do it *immediately* with the CVP-manometer column attached to the 3-way stopcock. Intrapericardial pressure rapidly declines with evacuation of the fluid.
13. After measuring intrapericardial pressure, collect fluid samples for cytology (EDTA and plain tubes) and culture (with samples submitted pending results of cytology).
14. Observe the tube without anticoagulant for clotting. If immediate clotting develops, the sample is likely from the heart and the catheter should be withdrawn.
15. The position of the catheter tip can be determined by echocardiography during injection of saline (or some of the effusion) back into the catheter. The sudden appearance of microbubbles within the cardiac chambers indicates a perforation. In most cases of perforation, there will be PVCs evident on the ECG.
16. Drain the effusion with the syringe attached to the tubing. The sac should be emptied as completely as possible. Slight manipulation of the patient (gentle rolling, elevating the hindquarters) may help in fluid retrieval.
17. If negative pressure is obtained, inject $^1/_2$ cc of fluid back into the line to clear it; if negative pressure is again detected, it is likely the pericardial space has been emptied or the catheter tip has migrated into the pleural space (if there is pleural fluid, a different color fluid may be obtained, usually serosanguinous).
18. Owing to the relatively inelastic properties of the pericardium, the initial volume of fluid removed will often show immediate benefit with improvement in attitude, color, peripheral pulse pressure, and ABP.
19. Once completed, quantify the aspirated fluid volume. Repeated echocardiography can be used to verify the benefit of the procedure.
20. Evaluate a sample of the effusate by microscopy for cellular abnormalities and bacteria and is then cul-

tured (aerobic, anaerobic) if appropriate based on cytology.

21. If pH is to be measured, save a sample anaerobically.

Medical Therapy

- Intravenous saline, at shock doses, may be needed in cases of hypotension due to severe or sudden cardiac tamponade; however, in experimental tamponade volume infusion is not always beneficial.
- Thoracocentesis is a helpful adjunct in large pleural effusions.
- Ascitic effusions need not be tapped if pericardiocentesis is performed. The ascitic fluid usually resolves within 2 to 5 days.
- In patients with culture-negative, idiopathic, pericardial hemorrhage, conservative treatment with catheter drainage may be "curative," though diligent follow-up (for at least one year) is needed to assure that re-effusion or constrictive pericardial disease does not develop.

▼ ***Key Point*** While furosemide can decrease elevated venous pressures and reduce fluid retention, diuretic therapy is not a substitute for pericardiocentesis in the symptomatic patient. Furthermore, these drugs may reduce ventricular filling predisposing to hypotension, syncope, and renal failure.

- In general, diuretics are contraindicated except in recurrent, neoplastic-related right-sided CHF in which venous pressures can become exceptionally high and there is no other available treatment.
- Following successful pericardiocentesis, it is appropriate to administer one 1-mg/kg dose of furosemide SQ to enhance renal excretion of sodium (and overcome the sodium-retaining consequences of cardiac tamponade that may persist for a period following pericardiocentesis or pericardiectomy).
- Empirical use of antibiotics or of corticosteroids has offered no certain benefit and is not recommended. Drugs that prevent fibrosis might be considered, but these have not been suitably investigated in dogs and cats.
- When PE is due to coccidiomycosis, specific antifungal treatment should be administered.
- Aside from exceptional individual response, most cardiac and heart base tumors are either unresponsive to chemotherapy or develop drug resistance after periods of initial success.
- PE associated with hemangiosarcoma is best managed by pericardiocentesis and then by an established chemotherapy protocol for this neoplasm (see Chapter 28). Otherwise, the prognosis is dismal. Median survival was prolonged by chemotherapy to about 6 months, but as indicated above, a one year survival is very uncommon and other studies report median survivals of shorter duration.
- PE due to chemodectoma is poorly responsive to drug therapy. In cases of very large mass lesions, an oncologist should be consulted if clients wish to explore additional options.
- Mesothelioma is highly resistant to most chemotherapy protocols. Cisplatin and triethylenethiophosphoramide (thiotepa) have been used. An oncologist should be consulted.
- Balloon catheter dilation of the pericardium can be performed using percutaneous, transthoracic techniques to rip the pericardium and create a palliative window for cases of PE due to cardiac neoplasia. This approach requires special equipment and training.

Surgical Therapy

- Surgery (see Chapter 167 for principles of thoracic surgery) may be necessary for successful management of pericardial diseases, including recurrent idiopathic pericardial hemorrhage, septic pericarditis, chronic inflammatory pericarditis, and in treatment or palliation of PE related to tumors.
- Subtotal pericardiectomy (ventral to the phrenic nerves) may be needed in recurrent idiopathic hemorrhagic effusion, especially in younger dogs. Failure to perform surgical resection when there is recrudescence of PE predisposes the dog to development of constrictive pericarditis. In one small study, median survival in dogs treated by pericardiectomy was significantly longer. After two pericardiocentesis procedures, recommend surgery at the next recurrence of PE.
- The treatment for infective pericarditis includes broad spectrum antibiotics, followed by specific antibiotic therapy (based on aerobic and bacterial anaerobic culture), catheter drainage of the PE, and subsequent surgical removal of as much of the pericardium as possible. A pericardial window is inappropriate for these patients. A foreign body should be sought during exploration. Place chest drains and the postoperative management should follow that appropriate for pyothorax (see Chapter 164).
- As discussed in detail above, surgery is also indicated if there is a need to explore and biopsy the pericardium to rule out a tumor. The surgical approach depends on the case and the management goals.
- Palliative, subtotal pericardiectomy to create a pericardial "window" can be performed by thoracoscopy or mini-thoracotomy (with long instruments).
  - This approach provides reasonable access for direct examination and pericardial tissue biopsy in neoplasia-associated or suspected PE.
  - Morbidity is low and recovery fast with this approach.
  - Surgical access is more limited than with a standard thoracotomy.
  - Thoracoscopy requires special instruments and training.

Table 151-1. SURGICAL PROCEDURES FOR MANAGEMENT OF PERICARDIAL DISEASE

Subtotal Pericardiectomy

1. Perform either a right-sided or left-sided thoracotomy or a sternotomy (see Chapter 167).
2. Perform a subtotal pericardiectomy ventral to the phrenic nerve.
3. Identify the phrenic nerves on the dorsal right and left sides of the pericardial sac.
4. After placing pericardial stay sutures make a stab incision 1 cm ventral to the nerve.
5. Remove pericardial fluid via suction.
6. Incise the pericardium circumferentially using scissors. Avoid trauma to the myocardium and to the phrenic nerves.
7. Control hemorrhage via electrocautery (avoid touching the heart).
8. Place a thoracic drain tube.
9. Close the thoracotomy or sternotomy routinely.
10. Always perform histopathologic evaluation of the pericardium to rule out neoplasia (e.g., mesothelioma).

Excision of Heart Base Tumors

When heart base tumors have been determined by echocardiography or by MRI to be small and not invading major vessels, the tumor may be surgically removed. These tumors are slow-growing and rarely metastasize.

1. For better access to the tumor, perform a sternotomy.
2. Several hours of very delicate and intense surgery are necessary to remove these tumors.
3. Also perform a pericardiectomy.

In the rare situation in which the tumor is completely resectable, a good prognosis is warranted.
When heart base tumors are inoperable, continued pericardiocentesis or pericardiectomy is necessary.

Excision of Right Atrial Hemangiosarcoma

1. A small suspected hemangiosarcoma requires prompt attention. Perform a right-sided thoracotomy (see Chapter 167).
2. Examine the lungs for possible metastasis.
3. Remove the right atrial lesion if it is both small and easily isolated. Submit the tissue for histopathologic evaluation.
4. An alternative to open thoracotomy for pericardiectomy is thoracoscopy. However, specialized equipment and expertise are needed for this technique.
5. To remove atrial appendage tumors:
6. Double-clamp the atrial appendage with Satinsky clamps proximal to the tumor.
7. Incise the tissue between the clamps, and remove the tumor.
8. Oversew the appendage over the clamp using 4-0 polypropylene (Prolene, Ethicon; Summervilles, NJ) with simple continuous sutures.
9. Carefully remove the clamps, and place a second simple continuous suture layer.
10. Place additional sutures at areas of bleeding.
11. Alternatively, use surgical staples (TA, US Surgical; Norwalk, CT) to close the atrial tissue prior to tumor removal.
12. Place an indwelling chest tube, and close the incision routinely.

Once healing has occurred, initiate chemotherapy (see Chapter 26). In the majority of cases, by the time a suspected hemangiosarcoma lesion is evident, it has already metastasized.

- A full thoracotomy or a sternotomy is needed when the plan calls for a full exploration of the pericardial space and heart base, resection of a well-circumscribed neoplasm, or creation of a standard subtotal pericardiectomy (see Table 151-1). Surgical resection of some tumors is feasible, but it may be difficult to completely remove all neoplastic tissue.

CONSTRICTIVE PERICARDIAL DISEASE

Etiology

Pericardial constriction is relatively uncommon in dogs and cats and most often develops from chronic pericarditis, recurrent hemorrhage, intrapericardial foreign body, or as a consequence of diffuse mesothelioma. Most cases begin as an inflammatory PE. As the pericardium scars and contracts, fluid is reabsorbed. Eventually the heart is encased in a rigid, possibly calcified, compartment.

The fundamental pathophysiology of constrictive disease is restriction of ventricular filling. Cardiac filling is confined to early diastole, at which point further ventricular expansion is "checked" by the constrictive pericardium. Cardiac output becomes limited, and elevated venous pressures are required to compensate for the diastolic dysfunction. This leads to right-sided (or biventricular) CHF.

The term "constrictive-effusive" pericarditis refers to a state of constrictive physiology with concurrent PE (but without tamponade). It probably represents a transition from pericarditis with effusion to constrictive disease.

Diagnosis

- In most cases there are typical clinical findings of *advanced right-sided CHF*, often with remarkable jugular venous distension. Pulsus paradoxicus may be present.
- *Heart sounds* are normal to soft, but there may be a prominent diastolic sound (pericardial knock) associated with abrupt termination of ventricular filling. Some dogs have prominent tricuspid regurgitation.

Diagnostic Imaging

- *Radiography* often demonstrates a relatively normal heart size. There may be pleural effusion. The vena cava may be dilated from elevated venous pressures. A metallic foreign object in the pericardial space is of clinical significance and is probably tied to the disorder.
- *Electrocardiography* may show a normal ECG; atrial fibrillation; reduced voltage QRS complexes, or ST-segment elevation. If the rhythm is sinus, P-waves may be wide or enlarged.
- *Echocardiography*
  - 2D imaging—biatrial dilatation is typical, with more right atrial dilatation. The pericardium may appear thickened. In pure constrictive disease there is no PE, but a small to moderate PE is evident in constrictive-effusive disease. Systolic function is normal or mildly depressed.
  - Doppler echocardiographic recordings of the mitral and tricuspid inflow reveal marked early filling (E waves) with attenuated mid- to late diastolic filling. The early annular motion (Ea) of the mitral annulus is preserved or exaggerated. There may be prominent tricuspid regurgitation.
  - Disparate rates of ventricular filling are reflected by prominent and multiple diastolic movements of the ventricular septum on 2D and M-mode echocardiography; this is supported by marked variation in transvalvular inflow velocity signals related to the phase of ventilation.

Cardiac Catheterization

- *Right heart catheterization* may be needed to secure the diagnosis. The patient should be euvolemic prior to the intervention (or receive an IV fluid challenge during the catheterization).
- A prominent "y" descent occurs in the venous pressure tracing. This initial decline in ventricular diastolic pressure is quickly followed by a marked pressure increase and plateau, as the balance of ventricular filling requires very high venous/atrial/ventricular diastolic pressures.
- The right ventricular pressure curve typically shows an initial diastolic "dip" which is quickly followed by a "plateau" in the pressure tracing (square-root sign).

Treatment

- The treatment of choice for constriction is surgical removal of the parietal pericardium and decortication of the epicardium if that layer is involved. The surgery is difficult and carries a significant risk and is best done by an experienced thoracic surgeon.
- The operation is facilitated by residual fluid in the pericardial space (constrictive-effusive disease).
- Fibrosis of the epicardium prevents a definitive cure, and the long-term success of the procedure will require a "wait-and-see" attitude.
- Postoperative management includes pain management, monitoring for arrhythmias, treatments to prevent pulmonary thromboembolism (low dose heparin), and low dose furosemide for one or two days to facilitate diuresis in cases of right-sided CHF.

Chapter

152 Heartworm Disease

Clay A. Calvert / Laura G. Ridge

Heartworm disease is a common problem in many areas of the world, particularly in tropical and subtropical regions. The disease has been endemic along the southeastern Atlantic and Gulf coasts of the United States as far west as Texas for more than 50 years. Heartworm infection has spread north and west to most areas of the United States, but the prevalence is still low at high elevations and in most northern states. Endemic foci frequently occur in regions with otherwise low prevalence. It is difficult to eliminate heartworms from a region once they have been established; therefore, all dogs should be tested regularly, and veterinarians should be alert for dogs that emigrate from endemic regions.

Wild animal reservoirs include wolves, coyotes, foxes, California gray seals, sea lions, and raccoons. Ferrets are also susceptible.

ETIOLOGY AND PATHOGENESIS

Heartworm infection is produced by the parasite *Dirofilaria immitis* and is transmitted to dogs mostly by 10 to 15 important species of mosquitoes, usually *Culex, Aedes,* and *Anopheles* spp. Mosquitoes can transmit infective larvae (L_3) 2 to 3 weeks after ingesting a blood meal. Infection rates vary among cats in endemic regions but are usually 10% to 20% of that of dogs within the same enzootic region. Being male, large, and outdoors increases the risk of canine infection, but hair coat length does not affect the risk.

Life Cycle in Dogs

- Female mosquitoes are the intermediate hosts and acquire the first-stage larvae (microfilaria) during feeding on infected dogs. Two molts then occur to produce the infective L_3 stage.
- Larvae development within the mosquito to the third stage usually requires 1 to 2.5 weeks, depending on the ambient temperatures.
- Mosquitoes can survive the development of only low numbers (<10) of larvae.
- Larvae development within the mosquito requires an average daily temperature of at least 57°F.
- The cooler the temperature, the longer the time required for L_3 to develop. The warmer the temperature, the shorter the time required for L_3 development.
- Mosquitoes have a maximum life span of about 30 days.
- Transmission is unlikely to occur during the dry, cold months of the year, even in most warmer climates within the United States. This is because when the temperatures are only modestly low, the time required for development for L_1 to L_3 may exceed the lifespan of the mosquito.
- Third-stage larvae (L_3) infect the dog via the bite wound created during the feeding of the mosquito. The next molt to the (L_4) stage occurs within 2 weeks.
- Larvae migrate through the subcutaneous tissues and vascular adventitial tissues for approximately 100 days. During this time, two molts occur.
- Young adults (fifth-stage, or L_5, larvae) enter the vascular system at 3 to 3.5 months post-infection.
- Young adult *Dirofilaria immitis* worms are in the small pulmonary arteries at 5 to 6 months post-infection.
- Adult worms are thought to have a natural lifespan of 3 to 5 years in the dog.
- Microfilaria are thought to have a natural lifespan of 1 to 2 years in the dog.

▼ ***Key Point*** Patent infection in dogs, as evidenced by microfilaremia, occurs approximately 6 months after transmission from the mosquito.

- Microfilaria, when present, increase in concentration for the next 6 months, plateau for several months, and then decrease if further infection does not occur.
- Microfilaremia does not occur in 10% to 67% of all heartworm infections and many of these are the result of an immune-mediated host reaction. Microfilaria-specific antibody-mediated, occult infections occur in the presence of persistent host antibody excess. Antibody-dependent leukocyte adhesion entraps microfilaria in the pulmonary microcirculation.
- In most endemic regions, the incidence of occult infections, other than drug induced, is approximately 20% to 25% of all heartworm infections.

- Microfilaria-leukocyte (neutrophils and eosinophils) complexes are engulfed by phagocyte cells of the mononuclear phagocyte system, resulting in granulomatous inflammation.
  - Predominately eosinophilic inflammation, with minimal granulomatous inflammation, produces allergic pneumonitis.
  - Progressive granulomatous inflammation occasionally leads to pulmonary eosinophilic granulomatosis.
- Other causes of occult mature infections include single sex infections and one high-dose (>200 mcg/kg) ivermectin administration.
- Dogs administered macrolide prophylaxis that are or become infected will not have microfilaremia.
- Serodiagnostic tests are negative in male-only infections and with infections less than 7 months post-L_3 inoculation.

Life Cycle in Cats

- The cat is relatively resistant to infection, requiring a greater L_3 inoculum. Some cats appear to be immune. Consequently, the infection rate in unprotected cats is likely to range from one-fifth to one-tenth that of unprotected dogs in an endemic area. Some mosquito species, as intermediate hosts, do not like to feed on cats. The numbers of infective larvae that mature are less than in dogs, and the pre-patent period is usually one to two months longer.
- The natural survival time of adult worms in the cat is thought to be no more than 2 years.

Epizootiology

Prevalence

- Heartworm infection is most common in tropical and subtropical climates.
- Infection rates in unprotected dogs approach 50% along the Atlantic and Gulf coasts as far inland as 150 miles.
- Most unprotected dogs in highly endemic regions eventually become infected.
- The prevalence in cats varies by geographic region:
  - Much lower than dogs in some areas.
  - Similar to dogs in some areas.
  - The incidence is probably higher than suspected.

Signalment

- Male dogs are infected more often probably because of increased outdoor exposure.

▼ ***Key Point*** Dogs housed outdoors have a four- to five-fold increased risk of heartworm infection when compared to indoor dogs.

- Infection is diagnosed most often in dogs 4 to 7 years of age. In highly endemic regions, infection is common in younger dogs.

Pathogenesis

Disease onset and severity largely reflect the number of adult heartworms, which can vary from 1 to more than 250 in a single dog. In infected cats, the average number of adult worms is 3 to 6, depending on the concentration of infected mosquitoes and the ambient temperature in any given region. Acute dyspnea and sudden death are more common in cats despite the low worm burden.

Worm Location

- Until the adult worm burden exceeds 50 in a 25-kg dog, nearly all worms are located in the pulmonary arteries.
- Worm burdens of approximately 75 are associated with worms located in the right atrium.
- The vena cava syndrome typically is associated with worm burdens of 100 or more.

Response to Live Worms in Dogs

- Pulmonary pathology is produced beginning with the young adults (L_5).
- Even if infection is identified 7 months post-infection with L_3, the L_5 have already been in the pulmonary arteries for a few months and some pathology has occurred.
- Pulmonary arterial endothelial damage and subsequent myointimal proliferation most often affects the caudal and intermediate lung lobes, that is, those receiving the highest blood flow.
- Pulmonary lobar arterial enlargement, tortuosity, and obstruction of smaller branches begin within a few weeks of worm arrival.
- Intrapulmonary blood flow is obstructed as the disease progresses, and blood is diverted to less severely affected lobes.
- Small downstream arterioles become damaged and leak plasma and inflammatory cells into the surrounding lung parenchyma. This causes interstitial and alveolar lung infiltrates and granulomatous inflammation.
- Pulmonary arterial obstruction and lung inflammation cause fever, coughing, dyspnea, hemoptysis, leukocytosis, and thrombocytopenia.
- Pathology is more severe and accelerated in active dogs, relative to inactive dogs, for any given worm burden.
- Small dogs do not tolerate heartworm infection as well as large dogs, presumably because of the small size of their pulmonary arteries.

Response to Live Worms in Cats

The response of cats and ferrets is similar to that of dogs. However, there is more arterial muscular hypertrophy. In cats, parenchymal pathology differs from that of dogs in that there is more alveolar Type II hyperpla-

sia. This creates a barrier to oxygen diffusion that is more severe than in the dog. Mortality in cats and ferrets is higher than in dogs.

Response to Dead Worms

- The most severe disease is seen in response to dead worm fragments that are swept into small arterioles.
- Worm death may be spontaneous or from melarsamine dihydrochloride (Immiticide, Merial) administration.
- Pulmonary vascular compliance and blood flow become impaired to varying degrees and severe arterial disease results in pulmonary hypertension, increased right ventricular afterload, and eventually right-sided CHF.
- Parenchymal lung disease (infarction and consolidation) occurs secondary to pulmonary arterial thromboembolism and increased vascular permeability.

CLINICAL SIGNS

The clinical signs associated with heartworm infection reflect the adult worm burden, duration of infection, and host-parasite interaction. Respiratory signs are most prominent.

Clinical Signs in Dogs

- Exercise intolerance, coughing, dyspnea, and respiratory crackles occur in dogs with moderate and advanced heartworm disease.
- Hemoptysis occurs in severe disease and is caused by pulmonary thromboembolism. It can be seen before, but occurs more often after adulticide treatment.
- Acute dyspnea and increased pulmonary alveolar densities may develop secondary to spontaneous worm death.

Syncope

Syncope is associated with severe pulmonary arterial disease and pulmonary hypertension.

Elevated Central Venous Pressure

Signs of elevated central venous pressure indicate severe pulmonary hypertension with incipient or overt right-sided CHF. Clinical signs include prominent jugular pulse, distended jugular veins, hepatomegaly, and ascites.

Hemoglobinuria

Hemoglobinuria commonly occurs in association with the vena cava syndrome (i.e., acute hemolytic crisis caused by obstruction of the vena cava with adult worms) and occasionally when severe pulmonary arterial disease results in fragmentation hemolysis due to fibrin-thrombus formation. Thrombocytopenia is usually a consequence of these complications.

Nephrotic Syndrome

This syndrome occasionally occurs as the result of severe glomerular disease manifested as amyloidosis or immune complex glomerulonephritis (see Chapter 77). Manifestations can include proteinuria, hypoalbuminemia, hypercholesterolemia, azotemia, ascites and occasionally peripheral edema.

Clinical Signs in Cats

Clinical signs of heartworm infection in cats are somewhat different than in dogs. The most common signs are vomiting, collapse or syncope, asthma-like syndrome, coughing, sudden death, and occasionally central nervous system signs. Signs occur most often several months after infection and again when young adult worms arrive in the pulmonary arteries. Severe pulmonary complications and death are most likely to occur whenever one or more adult worms dies, either spontaneously or as a result of Immiticide administration.

- Respiratory signs
  - Coughing in cats usually is associated with allergic or parasitic lung diseases; heartworm disease represents one cause.
  - Coughing is not a prominent feature of cardiomyopathies in cats.
  - Asthmatic signs are a common manifestation and often occur about 3 to 4 months post-infection. A strong antibody response at this time may destroy the developing larvae. If not, then a period of quiescence occurs only to have asthma-like signs reoccur in some cats 7 to 8 months post-infection.
  - Dyspnea.
- Vomiting (intermittent) is a common sign (approximately 20%) and occurs sporadically. It often is not associated with eating, but vomitus may include food. Mucus and bile are often the major components of the vomitus. Vomiting and coughing in the same cat should increase the index of suspicion.
- Sudden death related to spontaneous worm death and thromboembolism is more common in cats than in dogs.
- Neurologic signs, usually seizures, occur occasionally when aberrant worm migration to the brain occurs.

DIAGNOSIS

The diagnosis of heartworm infection is usually based on a positive immunodiagnostic test result. Microfilaria in the peripheral blood can be detected in some dogs by a direct smear or a concentration test (modified Knott test or milipore filter [Difil, Evsco]) in dogs with

or without clinical or radiographic findings consistent with the disease. Testing puppies younger than 6 months of age is not indicated.

Affected cats are usually negative for microfilaria but may have characteristic radiographic abnormalities. A positive enzyme-linked immunosorbent assay (ELISA) test for heartworm antigen, antibody, or both, may be present by 7 months following infection.

History in Dogs

- The history in dogs with heartworm infection varies considerably. Many infections are discovered in asymptomatic dogs by immunodiagnostic screening.
- Most heartworm-infected dogs have not received prophylactic therapy.
- Some dogs are totally without signs; others have unexplained tachypnea, exercise intolerance, or cough.
- Signs consistent with pulmonary hypertension with or without overt right-sided CHF are associated with severe heartworm disease.

History in Cats

- The history in cats varies considerably. Most infected cats have not been receiving prophylaxis. Lethargy and decreased appetite may be reported by the owners.
- Coughing, emesis, and sudden or episodic dyspnea are typical signs in cats.
- Sudden death may be the first sign of infection.
- Congestive heart failure is uncommon.

Physical Examination

- Findings vary from clinically normal to signs of right-sided CHF (see Chapter 147).
- Pulmonary crackles and loud bronchial sounds may be auscultated.
- Signs consistent with pulmonary hypertension, such as exercise intolerance, dyspnea, tachypnea, syncope, and splitting of the second heart sound, may be present.

Laboratory Studies

- Standard laboratory studies vary, depending on the patient's age, clinical signs, and preference of individual clinicians.
- The minimum pretreatment database for all dogs suspected of having heartworm infection includes packed cell volume (PCV), blood urea nitrogen (BUN), urine specific gravity, urine protein determination, and heartworm antigen test.
- We recommend thoracic radiographs because they reveal more about disease severity than any other single test.
- The minimum data base for cats should include thoracic radiographs.
- Cardiac ultrasound and fecal studies for lungworms are useful for the differential diagnosis of heartworm infection, feline asthma, cardiomyopathy, bronchitis, pulmonary fibrosis, and lung parasites.
- A tracheal or bronchial wash may be useful for detecting lung parasitic lesions such as those produced by *Filaroides* spp.
- Cardiac ultrasound is a sensitive test in experienced hands.

Screening in Dogs

Screening for heartworm infection usually is done in the late spring in cooler climates to maximize the likelihood of detecting infections acquired in the previous year. In hotter climates, where the transmission season is longer than 6 months, infections may be acquired as late as November and early December, and these infections are not detectable until May or June. Antigen testing is the preferred method. Test 7 months after the end of the transmission season in a given locale.

Screening in Cats

Combined antibody and antigen testing is recommended for cats. Although a positive antigen test confirms infection in cats, many infected cats are antigen-test negative. Most symptomatic infections in cats can be identified by cardiac ultrasound. A negative antibody test weighs heavily against the diagnosis.

Immunodiagnostic Tests

- These tests must be performed in strict compliance with the manufacturer's instructions. False-positive test results are usually the result of poor technique.
- Immunodiagnostic testing currently is the recommended screening procedure.
- The absence of circulating microfilaria in infected dogs is common (10–50%), and microfilaremia is rarely detected in infected cats.
- In some highly endemic regions, such as Hawaii, as many as 50% of infected dogs lack circulating microfilaria.

Heartworm Antigen Tests

Serodiagnosis of adult heartworm antigens in dogs is accomplished readily by membrane and microwell ELISA tests and membrane immunochromatographic tests. A number of very specific and sensitive tests are available. Test time duration is less than 30 minutes and for some tests is approximately 10 minutes. All of these tests can be performed with plasma or serum samples, and the majority can be run with whole blood.

- Positive antigen test results are the result of the presence of adult female worms. The antigen is associated with the worms' reproductive tracts.
- The particular test employed is influenced by the number of tests performed daily, the amount of

whole blood or serum required, and the speed of results.
- Some tests, such as Dirochek (Synbiotics), are very efficient for testing multiple samples simultaneously. Either serum or plasma is required.
- Weakly positive test results should be verified by repeat testing using a different antigen test.
- Most immunodiagnostic tests (ELISA based) are semiquantitative because rapid and strong positive test results are thought to be related to higher antigen concentrations.
  - Low antigenemia indicates a low adult heartworm burden and reduced risk of post-adulticide thromboembolic complications.
  - High antigenemia may be the result of a heavy worm burden and increased risk of thromboembolism.
  - Large quantities of antigen released from dead worms results in a quick, strong test reaction but does not necessarily mean that the worm burden is high.
  - Alternative adulticide treatment protocols for heavy worm burdens are recommended.
- Immunodiagnostic tests are the tests of choice in dogs receiving monthly macrolide prophylaxis.
- In cats, antigen tests are specific but are less sensitive, and false-negative results are common. False-negative test results are explained by low worm burden, male-only infections, and infection with young (<7 month old) female worms that have immature reproductive tracts. When adult worm infection is present in cats, the antigen test is usually positive if there are 3 or more mature female worms.

Heartworm Antibody Tests

Heartworm-associated antibody tests are useful to rule out infections in cats. Antibodies may appear by 2 to 3 months post-infection and are usually present by 5 months. A positive antibody test indicates exposure but not necessarily active infection; thus, use antibody tests in conjunction with antigen testing and other clinical information.

- Asthma-like signs due to developing larvae often occur months before the antigen test can become positive.
- Larvae-induced antibodies can persist after the larvae have been killed by a macrolide drug.
- A negative test result weighs heavily against the diagnosis.
- A strongly positive test result indicates preadult infection, live adult infection, or persistent (at least 6 months) antibodies after adult heartworm death. An antigen test and perhaps cardiac ultrasound are needed to confirm the diagnosis.
- Intermediate titers should be repeated in 1 month, if necessary. Also, other tests that may support a diagnosis should be evaluated—thoracic radiographs, echocardiography, serum globulins (hyperglobulinemia), CBC (eosinophilia, basophilia).

Microfilaria Detection

- In dogs, the incidence of occult (amicrofilaremic) infections is greater than the incidence of false-negative antigen test results.
- Annual microfilarial detection tests are required for dogs receiving diethylcarbamazine prophylaxis.
- Microfilarial detection tests are indicated for heartworm antigen-positive dogs if the intent is to kill the microfilaria rapidly using milbemycin oxime (Interceptor, Novartis).
- Evaluate a direct blood smear immediately after procurement of a blood sample. If the direct smear is negative, a concentration test is indicated.
- The Knott test (a centrifugal concentration test) or a filter test is at least 25% more sensitive for the detection of microfilaria. Each concentration test methodology has advantages and disadvantages, but efficacy is similar.
- Microfilarial testing is only performed if there is intent to rapidly kill microfilaria, when present.

Radiography

Pulmonary Arterial Disease

- A common finding in heartworm infected dogs is dilation of the main pulmonary artery segment at the one o'clock position on the ventrodorsal or dorsoventral projection. The main pulmonary artery segment is not visible in the cat because of its midline position.
- Tortuosity and abrupt pruning of the arteries (the latter due to thromboembolism) are best seen on the dorsoventral projection; the caudal lobar vessels are the most severely affected.
- The caudal lobar arteries, especially the right, are the first to enlarge and typically are the most severely diseased. The diameters of the caudal lobar arteries should not exceed that of the ninth rib at the point of their superimposition. If the lobar arteries are at least 1.5 times the diameter of the ninth ribs, then severe (Class 3) arterial pathology has occurred.
- The cranial lobar arteries are best evaluated on the lateral projection; their diameters should not exceed that of the proximal portions of the third or fourth ribs.

▼ ***Key Point*** Thoracic radiography is the most important diagnostic test for determining the severity of heartworm disease.

Parenchymal Lung Disease

- Parenchymal lung disease (patchy, ill-defined infiltrates) results from the pulmonary arteriolar thromboembolism with leakage of plasma and inflammatory cells into the adjacent tissues.

- Severity varies; disease is most prevalent in the caudal and intermediate lung lobes and is most concentrated surrounding the lobar arteries.

Allergic Pneumonitis

- It is associated with occult infections, eosinophilia, coughing, and dyspnea.
- This incidence is 10% to 20% of occult infections.
- This mixed diffuse interstitial-alveolar lung disease is best visualized in the caudal lobes.
- It often occurs with minimal pulmonary arterial enlargement.
- It may be mistaken, on radiographs, for left-sided CHF (pulmonary edema) or blastomycosis.
- It responds rapidly to anti-inflammatory dosages of corticosteroids continued for 3 to 7 days.
- Begin adulticide treatment soon after clinical and radiographic signs subside.

Feline Asthma-Like Syndrome

- Coughing, wheezing, and dyspnea are consistent with feline heartworm infection.
- Radiographic picture resembles feline asthma.
- It first occurs around 4 months post-inoculation of L_3.
- Can be episodic with mature infections.
- May be associated with eosinophilia or basophilia.

Clinical Pathology

No abnormal test results are pathognomonic for heartworm infection.

Complete Blood Count

- *Eosinophilia and basophilia* are the most common abnormalities in dogs.
  - Eosinophilia is more common; the highest eosinophil and basophil counts tend to occur in occult infections.
  - *Dipetalonema reconditum* infections produce eosinophilia equal to or greater than that associated with heartworm disease.
- *Neutrophilic leukocytosis,* often with a left shift, occurs with pulmonary thromboembolism.
- *Thrombocytopenia* commonly is associated with severe pulmonary arterial and parenchymal lung disease.
  - Activated clotting time is increased marginally to moderately in many cases.
  - DIC develops in some animals with severe thromboembolic disease.
- *Hemoglobinuria,* usually accompanied by thrombocytopenia, is seen with the vena cava syndrome and with severe pulmonary thromboembolic disease. Heparin, 75 to 200 U/kg q8hr SC, usually reduces hemoglobinuria and improves thrombocytopenia caused by severe lung disease.

Serum Biochemistries and Urinalysis

- *Azotemia* may occur in dogs with complicated infections.
  - Prerenal azotemia can be caused by dehydration or right-sided CHF.
  - Primary azotemia can result from glomerulopathies, including immune complex disease and amyloidosis.
- *Increased serum hepatic enzyme levels* may occur; however, increases up to 10-fold do not affect treatment, complications, or survival.
- *Hepatic insufficiency,* evidenced by increased serum bile acid levels, can occur, but mild to moderate increases do not alter the treatment protocol.
- *Proteinuria* is common and is most pronounced in patients with severe infections or renal amyloidosis. Proteinuria, when severe, produces hypoalbuminemia.
  - Nephrotic syndrome is a contraindication to treatment.
  - In the absence of hypoalbuminemia, proteinuria usually resolves after effective heartworm treatment.
- *Hypoalbuminemia* occurs in some dogs with severe infections; hyperglobulinemia is common in dogs and cats with chronic heartworm disease.
- Loss of albumin into the third space occurs with right-sided CHF and is complicated by hepatic insufficiency, intestinal congestion, and free-water retention.

Electrocardiography

Electrocardiography (ECG) is sometimes helpful for evaluation of arrhythmias in animals with severe heartworm disease. The ECG is not a component of the minimum data base. The ECG is not a sensitive test for identification of mild-to-moderate right ventricular hypertrophy. Even though the ECG will reflect severe hypertrophy, clinical signs and thoracic radiograph analysis provide much more clinical information.

- A right ventricular hypertrophy pattern is common in dogs with severe pulmonary hypertension and is found in 90% of dogs with overt right-sided CHF (ascites). However, significant pulmonary hypertension may exist in the absence of ECG abnormalities.
- Occasionally, cardiac rhythm disturbances occur in dogs with severe infections. Atrial fibrillation is the most common arrhythmia, especially in larger breeds.

Ultrasonography

- Evidence of right ventricular and pulmonary artery enlargement can be detected by two-dimensional (2-D) echocardiography in patients with moderate to severe pulmonary hypertension.

- Occasionally, worms may be detected in the right ventricle, main pulmonary artery segment, and main lobar arteries.
- Ultrasonography is particularly useful in antigen-negative cats.
- Echocardiography is the test of choice for diagnosis of caval syndrome (mass of worms is found in the tricuspid valve orifice).
- The echocardiographic features of severe heartworm disease include right ventricular eccentric hypertrophy, septal flattening, underfilling of the left ventricle and left atrium, dilation of the main pulmonary artery segment and main arteries, and high velocity tricuspid and pulmonic regurgitation, the latter two being indicative of pulmonary hypertension.

CLASSIFICATION OF HEARTWORM DISEASE SEVERITY

Severity of heartworm disease is determined by worm burden, duration of infection, and host responses to the worms. Most severe pulmonary complications are associated with occult infections. Three classes are defined that correlate to clinical signs and pulmonary arterial and lung parenchymal disease, though the classification does not clearly separate clinical signs related to lung parenchymal injury from that due to pulmonary vascular disease and pulmonary hypertension. Class assignment may assist in customizing Immiticide treatment.

- Class 1: Asymptomatic or mild clinical signs.
- Class 2: Moderate clinical and radiographic abnormalities.
- Class 3: Severe clinical and radiographic abnormalities, including right-sided CHF.
- Caval syndrome: This syndrome is sometimes referred to as Class 4. However, caval syndrome is not an indication that the severity of lung disease is worse than that of Class 3. Rather, it is a syndrome caused by obstruction of blood flow into and through the right heart. It is complicated by mechanically induced hemolysis and hepatic failure due to acute passive congestion.
- The outcome in Class 1 and 2 patients is excellent when proper treatment and restriction of activity are accomplished.
- The outcome for Class 3 patients is far less encouraging and treatment is labor intensive and expensive.

TREATMENT

The goal of treatment is to kill all adult heartworms and to accomplish this with minimal drug toxicity and a tolerable degree of pulmonary thromboembolism caused by the dying worms. Microfilaria should be eliminated, but rapid kill is not required. Gradual elimination of microfilaria over a period of 6 to 8 months with monthly macrolide administration is acceptable.

Patient Selection

Although most heartworm-infected dogs can be treated successfully, there are exceptions. Immiticide should not be administered to cats because a safe and effective treatment regimen has not been developed.

Contraindications to Adulticide Treatment

- In cats adulticide is not recommended.
- Hepatic failure
- Overt nephrotic syndrome
- Advanced renal failure
- Combination of right-sided CHF and severe renal azotemia
- Concomitant life-threatening disorders

Treatment of Old Dogs

- Experience is limited in the treatment of very old dogs. Heartworm disease pathology may be nonprogressive in old dogs that have chronic infections with low worm burdens.
- Low antigen level is seen.
- Class 1 patients do not require treatment.
- Monthly administration of ivermectin (Heartgard, Merial) at the standard prophylactic dosage (see "Prevention" section) will gradually kill adult worms over a period of 16 to 30 months.

Treatment of Cats

- Treat asthma-like signs with prednisolone (1.0–2.0 mg/kg, daily for 10 days; then taper the dose to 1.0 mg/kg every other morning.
- Do not use aspirin in cats.
- Immiticide should not be used until a safe and effective dosage and treatment schedule for cats has been determined, which is unlikely. Each worm will cause pulmonary thromboembolism when it dies. If multiple worms die over a short time period, lethal pulmonary thromboembolism is likely.
- It is generally believed that 30% to 50% of cats survive their infections.

Adulticide Therapy in Dogs

- The approved available adulticidal agent is Immiticide. The following regimens have proved effective in dogs (see "Aspirin," this chapter).
- Highly efficacious
- Reasonably good therapeutic index
- Easy to administer

Standard Immiticide Protocol

- The manufacturer recommends that Class 1 and Class 2 heartworm infections be treated by the standard Immiticide protocol.

- 2.5 mg/kg Immiticide injected IM twice, 24 hours apart.
- The two doses contain 0.75 mg/kg of total arsenic.
- Two injections (separated by approximately 24 hours) are given into the epaxial musculature at the level of the third to fifth lumbar vertebrae. One injection is given on each side of the dorsal midline.
- The appropriate volume of the reconstituted drug is aspirated into a syringe, and then a new needle is placed on the syringe.
- For dogs weighing more than 10 kg, use a $1^1/_2$-inch 22-gauge needle, and for smaller dogs, use a 1-inch 23-gauge needle.
- The injection should be completed before the needle is withdrawn, and finger pressure should be applied over the needle tract during and for a short time after withdrawal.

Alternate Immiticide Protocol

- Class 3 infections, pound dogs, and dogs with high antigen concentrations should be treated by the alternate Immiticide protocol. Many clinicians prefer to treat all infections, including Class 1 and Class 2, using the alternate protocol.
- There is concern that the high kill rate associated with the standard Immiticide protocol may provoke more frequent or more severe post-treatment pulmonary thromboembolism.
- A single, initial injection (2.5 mg/kg) is used. Approximately 50% (most males and some of the females) of adult worms are killed; therefore, post-adulticide thromboembolic complications are reduced.
- Two follow-up injections, each at the same dosage as the previously administered injection, at a 24-hour interval, are administered after 1 to 3 months. Post-treatment thromboembolism reoccurs, but the severity is reduced because fewer worms are present.
  - The extra 1 to 3 months required for maximum worm kill is seldom detrimental to the outcome.
  - Current data indicate that 100% of male and 98% of female worms are killed.

▼ ***Key Point*** Use the alternate Immiticide protocol to treat dogs with Class 3 infections, pound dogs, and those with high antigen concentrations.

Treatment of Class 3 Heartworm Disease

- Severe pulmonary arterial disease occurs in 10% of infected dogs in highly endemic regions. Infections are often occult. There are at least four treatment options.
- Option 1 is recommended for dogs that do not require continuous supplemental oxygen therapy, are eating, and have normal or pale pink mucosal color.
- Option 2, 3, or 4 is recommended for hemodynamically unstable dogs that require oxygen support; are anorectic; and have very pale, grey, or cyanotic mucosal color.

Option 1

Use the alternate Immiticide protocol (see the preceding section). Supportive therapy, such as judicious fluid administration, low-salt diet, and diuretics or short-term corticosteroids may be indicated.

Option 2

- Extraction of adult worms from the pulmonary arteries.
- Use only for patients with many worms in the right heart and pulmonary arteries.
  - High antigen concentration suggesting a high worm burden.
  - Ultrasound confirmation of high worm burden.
- Requires fluoroscopy and long, flexible, alligator forceps or a horsehair brush that is introduced into the right jugular vein via a surgical approach and manipulated through the heart into the pulmonary arteries. Numerous passages to grasp and remove worms are required and is accomplished with the aid of fluoroscopy.
- This procedure is highly effective in experienced hands.
- After the patient has been stabilized, treat with Immiticide to kill any remaining worms.
- Usually assume that some worms are not removed based on:
  - Persistent ultrasound detection of worms.
  - Positive antigen test result after 4 to 6 months.

Option 3 for Extremely Severe Class 3 Infections

- Cage confinement and aspirin in conjunction with the alternate Immiticide protocol (see the preceding section).
- Place patient in cage confinement for 1 week before, during, and for 3 weeks after adulticide therapy. Strict cage confinement may be the most important component of treatment.
- Begin Immiticide therapy after 1 week of cage confinement.
- Give aspirin (5 mg/kg daily) throughout the treatment period, beginning 1 week before adulticide therapy and continuing for 3 weeks after the second course of treatment.
  - Gastrointestinal (GI) bleeding is possible.
  - Monitor the hematocrit.

- Although efficacy is not proven and incomplete at best, consider GI protection with an H_2 blocker and/or sucralfate.
- Prescribe a diuretic and low-salt diet for patients with concomitant overt right-sided CHF.
- Low-dose (0.25 mg/kg once daily) enalapril (Enacard, Merial) is initiated after 48 hours of furosemide administration. Gradually increase the dosage to 0.25mg/kg q12h after one week, and then cautiously to 0.5 mg/kg q12h after one or two additional weeks. Hypotension is the primary adverse action of this treatment.
- If the patient lives long enough to complete the treatment, the survival rate can be 70% to 80%.
- This option is time consuming, labor intensive, and expensive.

Option 4 for Extremely Severe Class 3 Infections

- Cage confinement and heparin in conjunction with the alternate Immiticide protocol (see "Adulticide Therapy" section).
- Place patient in cage confinement for 1 week before, during, and for 3 weeks after the second adulticide treatment.
- Give heparin (50–100 units/kg, SC, q8hr) for 1 week before, during, and for 3 weeks after the second course of Immiticide treatment.
- Prescribe supportive therapy as above for overt right-sided CHF.
- Survival rate can be greater than 70% to 80% if the patient lives long enough to complete the treatment.
- This option is time consuming, labor intensive, and expensive.
- Prolonged hospitalization is usually required because of the SC injection of heparin.

Side Effects and Efficacy

- Mild myositis of 1 to 3 days duration often is observed after Immiticide injections. Approximately one-third of treated dogs experiences some swelling, and a sterile seroma occurs uncommonly.
- If an injection of Immiticide causes a local reaction, then consider administration of an antihistamine and rapid acting corticosteroid before subsequent injections.
- Hepatic and renal toxicity associated with Immiticide is uncommon; toxic doses produce non-cardiogenic pulmonary edema.
- Immiticide (2 doses) kills at least 90% of the adult worms.
- Confirmation of efficacy can be established at 4 months after Immiticide injection by antigen testing.
  - At least 80% seroconversion occurs.
  - Mean antigen concentration is reduced to 1% of pretreatment levels, indicating nearly complete elimination of worms.
  - Repeat the antigen test 4 months after the two injections of the standard protocol. If it is positive, wait 2 months and then retest.

Drug Storage

- Immiticide is purchased as a lyophilized powder that does not require refrigeration and has a shelf life of at least 2 years.
- Reconstituted drug must be kept refrigerated.

Post-Adulticide Complications

- Strict patient confinement is essential for 4 to 6 weeks post-treatment. Reduced blood flow demand through the pulmonary arteries is beneficial to diminish endothelial damage and to promote vascular repair.
- Thromboembolic complications may occur from several days to 4 or even 6 weeks post-adulticide.
- Most complications occur between 1 to 3 weeks post-adulticide.
- Most severe reactions occur in dogs with Class 3 infections and those associated with high antigen concentrations.
  - Coughing, gagging, lethargy, anorexia, tachypnea, dyspnea, syncope, hemoptysis, and fever are common.
  - Thrombocytopenia, inflammatory leukogram, and prolonged activated clotting time often are observed.
  - Radiographic evidence of parenchymal lung disease is usual.

Treatment of Vena Cava Syndrome

- Vena cava syndrome (Class 4) is uncommon except in highly endemic regions. It is associated with large numbers of worms in the right heart and vena cava. It is seen most often in the late spring and early summer in young dogs that have received a heavy L_3 inoculation over a short time period the previous year.
- Acute cardiovascular collapse and shock occur.
  - It is rapidly lethal unless surgical treatment is provided quickly.
  - Clinical signs variably include a systolic heart murmur, gallop heart rhythm, and hemoglobinuria.
  - Echocardiography is diagnostic.
- Surgical retrieval of the worms is the only recommended acute treatment.
  - Use minimal sedation.
  - Administer local anesthesia and perform surgical cutdown on the right jugular vein.
  - Introduce and advance long, flexible alligator forceps or a horsehair brush to the heart base and retrieve as many worms as possible from the vena cavae and right atrium during multiple passages. The procedure is finished when several passages fail to retrieve additional worms.

  - This is highly effective but experience is required for optimal results.
- Provide supportive care for 1 to 3 weeks.
- Immiticide treatment then is administered to eliminate remaining worms.

When to Initiate Macrolide Prophylaxis in Infected Dogs

- Macrolide prophylaxis can be initiated prior to, at the same time as, or within one month after Immiticide treatment.
- In microfilaremic infections, if acute microfilaricide treatment is not intended, Heartgard or Revolution can be initiated for prophylaxis. The sooner prophylaxis is begun, the sooner the microfilaria will disappear, and the shorter the reservoir time.

Rapid Microfilaricide Therapy

- Always complete adulticide treatment before initiating acute microfilaricide treatment. Attempts to eliminate microfilaria before completion of adulticide treatment are only partially effective.
- Adverse reactions to microfilaricide treatment can occur and are related to high microfilarial concentrations.
- Rapid death of high numbers (>40,000/ml) of microfilaria may produce adverse effects. Most dogs have much lower concentrations.
- Adverse reactions are more likely in small dogs.
  - Less than 10% incidence overall.
  - Usually mild and include mostly transient defecation and salivation.
  - Cardiovascular shock is uncommon and responds to fluids and corticosteroids, if detected early in its course.
  - Decreased appetite and lethargy may be observed for 1–2 days even when no acute reaction occurs.
  - Prediction of reactions is possible if microfilarial concentrations are determined, but this is not routinely performed.

▼ ***Key Point*** Interceptor is the most practical, effective microfilaricide. We recommend against the use of other drugs, such as ivermectin, for rapid microfilaricide action. Treatment recommendations are based on published research because Interceptor is not FDA-approved for use as a microfilaricide.

Milbemycin Oxime (Interceptor)

- Administer at 0.5 mg/kg.
- Administer the drug in the morning, and observe the patient throughout the day for signs of toxicity, such as vomiting, depression, diarrhea, and shock. If cardiovascular instability is suspected, give IV lactated Ringer's solution (20 ml/kg) with a soluble corticosteroid (dexamethasone SP, 2 mg/kg, IV).
- Further testing for microfilaria is not required. Persisting microfilaria levels will be low, the patient will not serve as a reservoir, and Heartgard, Interceptor, or Revolution monthly prophylaxis will eliminate any remaining microfilaria.

Therapy Variations

Occult Infections

Microfilaricide therapy is not indicated in the absence of microfilaremia.

Microfilaria: To Treat or Not to Treat

- Some veterinarians do not administer a microfilaricide with acute-kill capability. It is important to eliminate the reservoir, but slow kill with monthly prophylaxis is acceptable.
- There is an absence of proven pathologic changes associated with microfilaria.
- With the advent of highly sensitive antigen tests, it is no longer necessary to document the persistent elimination of microfilaria to confirm the elimination of adult worms.
- Macrolide prophylaxis eliminates microfilaria in 6 to 8 months.
- There is fear of adverse reaction in collies.
- There is no FDA-approved microfilaricidal drug.

When to Start Prophylaxis

- Prophylaxis usually is initiated within 4 weeks of the first Immiticide.
- Immiticide is larvacidal, which closes the window to re-infection.
- The "reach-back" effect of all macrolides also closes the window of re-infection.
- Prophylaxis can be initiated prior to adulticide therapy.

Confirmation of Adulticide Efficacy

- Four months after adulticide treatment, an antigen test should be performed.
  - After the first 2 doses of the standard protocol or after the third dose of the alternate protocol.
- A strongly positive test result indicates that live heartworms remain.
  - Uncommon.
  - Re-treatment is recommended.
- A weakly positive test result may be the result of a few persisting live worms.
  - Wait two additional months and retest.
  - Whether to retreat is controversial. Very few worms are likely to have survived. Retreatment may not be necessary.
- Retreatment is recommended for Class 3 infections, if clinical signs persist, and for performance dogs.

Adjunct to Adulticide Therapy

Aspirin

- Reduces pulmonary arterial lesions and improves intrapulmonary blood flow.
- For only the most severe cases of Class 3 disease, we recommend prescribing 5 mg/kg, q24h, PO, beginning 7 days before, during, and continuing for 21 days after the first part of the standard or alternate Immiticide protocols.
- Combine with strict cage confinement.
- Avoid the combination of aspirin and glucocorticoids (increased risk of serious gastrointestinal ulceration).

Heparin

- Can be used for the most severe cases of Class 3 infections instead of aspirin.
- Use approximately 75 units/kg, SC q8h, for 1 week before, during, and for 21 days after adulticide treatment.
- Combine with strict cage confinement.
- May be more effective than aspirin.
- Requires extended hospitalization unless the client can administer heparin at home.

Corticosteroids

- Reduces parenchymal disease in the lungs but promotes thrombosis and reduces pulmonary arterial blood flow if used for longer than 10 to 14 consecutive days.
- Do not use routinely but only as needed to control sequellae (see the following discussion).

Oxygen

- The only effective means of dilating the pulmonary arteries.
- For Class 3 infections associated with dyspnea, orthopnea, or congestive heart failure.
- Administer intranasally or by oxygen cage.

TREATMENT OF SEQUELLAE

Occult Heartworm Allergic Pneumonitis

- This complication occurs in 10% to 20% of patients with occult infections.
- Clinical signs include dyspnea, coughing, respiratory crackles, and exercise intolerance.
- Thoracic radiographs reveal diffuse interstitial-alveolar infiltrates.
- Eosinophilia is common, and in tracheal lavage cytology, eosinophils usually predominate.
- The syndrome responds well to oral prednisone (1–2 mg/kg, q24h for several days). Stop prednisone therapy after 3 to 7 days and begin Immiticide therapy.

Pulmonary Eosinophilic Granulomatosis

- This uncommon complication of occult heartworm disease probably results from the granulomatous inflammation known to be associated with occult infections. The reaction in many cases is progressive and assumes a neoplastic-like behavior.
- Clinical signs are coughing and dyspnea.
- Eosinophilia and basophilia are common findings, and hyperglobulinemia may occur.
- Pleural effusion (eosinophilic) occurs occasionally.
- Intrathoracic lymphadenopathy is always present.
- Peripheral lymphadenopathy is occasional.
- Multiple pulmonary nodules develop simultaneously and sequentially, grow at variable rates, and are 1–10 cm in diameter or larger.
- The trachea, liver, spleen, kidneys, abdominal lymph nodes, and intestines sometimes are infiltrated with eosinophils and eosinophilic granulomas.
- Combination chemotherapy is recommended:
  - Prednisone (50 mg/m^2 q24h) plus azathioprine (Imuran) (50 mg/m^2, q24h PO for 7–10 days; then alternate days).
  - Therapy usually results initially in partial or complete remission, but relapse is common even with continued aggressive therapy or when drug dosages are reduced.
  - The duration of therapy is indefinite, and the prognosis is poor.
- Consider lung lobectomy for focal lesions. However, small lesions in multiple lobes may not be detected.

Thromboembolic Lung Disease

This common sequellae of moderate to severe pulmonary arterial disease can occur before adulticide therapy but is most common 7 to 21 days after adulticide therapy. In dogs:

- Clinical signs include coughing, dyspnea, fever, and occasionally hemoptysis.
- A regenerative leukocytosis with thrombocytopenia usually is present.
- Thoracic radiographs reveal severe pulmonary arterial disease with periarterial parenchymal disease of variable severity.
- The following therapy usually is successful:
  - Initiate cage confinement for 5 to 10 days.
  - Administer prednisone (1.0 mg/kg, q24h for 3–10 days).
  - Use intranasal or cage-administered oxygen for dyspneic patients.

PREVENTION

- A microfilarial examination always is indicated before initiation of drugs that can be associated with an

acute adverse reaction. These drugs are Interceptor and diethylcarbamazine.

- Prevention should be in place whenever the average daily temperature exceeds approximately 57°F. Year-round prevention usually is practiced in hotter climates, even though transmission is less likely in December and January in the continental United States. With the advent of macrolide prophylaxis, a microfilarial examination prior to prophylaxis is necessary only if Interceptor is used.
  - Start as early as 6 to 8 weeks of age.
  - In cooler climates, start puppies on prophylaxis as soon after 6 to 8 weeks of age as dictated by seasonal risk.
  - Monthly prophylaxis should be started within 1 month of the transmission season. The monthly administered macrolide drugs kill migrating larvae during the first 6 to 8 weeks after L_3 inoculation.
- Interceptor is a potent microfilaricide at the preventative dosage.
  - Test for microfilaria before prescribing.
  - Adverse reactions can occur if the microfilarial count is high.
- Successful prophylaxis is confirmed by a negative antigen test result 1 year after initiation.
- Macrolides are safe for collies when prescribed according to the label.
- In infected dogs, prophylaxis with Heartgard or Revolution can be initiated prior to or within one month of the initiation of Immiticide. The only advantage of initiation of prophylaxis prior to or less than one month of initiating Immiticide is that microfilaria, if present, will be eliminated sooner, assuming that acute microfilaricide treatment with Interceptor is not planned.
- Macrolide prophylaxis interferes with larval embryogenesis, which reduces the circulating levels of microfilaria. Furthermore, these drugs gradually kill existing microfilaria over a period of 6 to 8 months.

▼ ***Key Point*** In all studies to date, owner administration compliance has been poor.

Ivermectin

- Heartgard (MSD-AgVet) at a dosage of 6 to 12 mcg/kg given monthly, is an effective preventive drug. A chewable formulation of ivermectin plus pyrantel pamoate is an effective heartworm preventive that also controls ascarid and hookworm infections.
- Drug reactions are rare at the recommended dosage.
- Chronic administration of ivermectin suppresses microfilaria in heartworm-positive dogs.
- The reach-back larvacidal action is 100% at one month and nearly 100% at two months.
- If initiated 4 months following L_3 inoculation and continued for at least 1 year, the likelihood of developing infection is reduced by at least 98%.
- When administration is begun 5.5 months post-L_3 inoculation, the subsequent adult worm burden is reduced by about 50%.
- When administration is begun 6.5 months post-L_3, the subsequent adult worm burden is reduced by about one third.
- Heartgard Plus kills adult heartworms slowly over a 16- to 30-month period.
- A dose of 24 µg/kg administered monthly is an effective heartworm prophylaxis in cats, and it removes and controls hookworms in this host.

Milbemycin Oxime

- Interceptor at a dosage of 0.5 to 0.99 mg/kg is an effective once-a-month preventive agent for heartworm disease in dogs and cats.
- It is not as effective as ivermectin at preventing the maturation of larvae when monthly administration is started 4 months post-L_3 inoculation.
- It also controls hookworm, roundworm, and whipworm infestations.
- One dose of Interceptor at the prophylactic dosage will kill most microfilariae within 24 hours. If the microfilaria concentration is high, an adverse reaction is likely.

Selamectin

- Selamectin (Revolution, Pfizer Animal Health) is a topical parasiticide and heartworm preventative drug. The recommended minimum monthly dosage is 6 mg/kg. It is recommended for use in dogs more than 6 weeks of age and is available in 6 separate dose strengths.

Moxidectin

- Moxidectin (ProHeart, Fort Dodge/American Cyanamid), 1 to 3 mcg/kg, is an effective once-a-month heartworm preventive. This drug has been carefully scrutinized because of reports of adverse effects. The incidence of adverse effects is low.

▼ ***Key Point*** All macrolide preventive drugs eliminate microfilaria, either quickly or slowly. For this reason, chronic dosing with Heartgard, Revolution, ProHeart, or Interceptor leads to "occult" status in infected dogs.

- In cats, all monthly prophylactic drugs can be administered without prior testing and without fear of adverse reactions.

Diethylcarbamazine

- Diethylcarbamazine (2.5–3.0 mg/kg, PO) given daily is an effective prophylactic drug. If the owner skips more than 2 days of treatment, do not reinstitute pre-

ventive treatment before performing a microfilarial concentration test. Diethylcarbamazine has been largely supplanted by the macrolide drugs.

▼ ***Key Point*** Never initiate diethylcarbamazine treatment in microfilaremic dogs because a severe reaction may develop.

- Duration of efficacy is short because the drug appears to affect the L_3 to L_4 (larval) molt 9 to 12 days postinfection.
- Begin therapy before the mosquito season and continue for 2 months after the first frost (or year-round in regions that have mosquitoes all year).
- All diethylcarbamazine products are equally effective.
- Combination diethylcarbamazine and oxibendazole (Filaribits Plus; Pfizer) controls intestinal helminths. An occasional side effect of oxibendazole is increased liver enzyme activity, icterus, and hepatic insufficiency, which are usually reversible after drug discontinuation.

Missed Doses of Macrolide Prophylactic Drugs

- One dose of any macrolide will kill all larvae that have infected a dog in the previous month.
- One dose of Heartgard, Interceptor, or Revolution will kill virtually all larvae that have infected a dog during the prior two months.
- Heartgard, Interceptor, and Revolution will prevent almost all infections from maturing after three consecutive doses are missed, providing that at least 12 consecutive monthly doses are subsequently administered.
- Heartgard will prevent over 95% of infections from reaching maturity after four consecutive doses are missed, providing that at least 12 consecutive subsequent doses are administered.
- Interceptor will prevent approximately 40% of infections from maturing if four consecutive doses are missed, providing that at least 12 consecutive subsequent doses are administered.

Macrolide Efficacy Against Adult Heartworms

- Heartgard will kill almost all adult heartworms if administered every month for 30 months.
- We rarely recommend Heartgard for adulticide treatment.
- Progressive pulmonary pathology will occur during at least the first 15 months.
- We recommend Immiticide for almost all infections.

Retesting Dogs Receiving Macrolide Prophylaxis

- Macrolide prophylactic drugs are highly efficacious, and therefore annual retesting often is not performed; however, we recommend annual retesting.
- Owner compliance has been proven to be poor in all regions examined.
- Inadequate dosing is likely in growing puppies.

Chapter

153 Vascular Diseases

John D. Bonagura / Rebecca L. Stepien

Diseases of blood vessels are quite common in small animal patients. Hypertension represents a fundamental disorder of the vascular system with wide-ranging impact. The vascular endothelium or vessel wall can become a target tissue for a multisystemic disease. Vascular obstruction or disease also impairs organ function by limiting tissue perfusion or obstructing venous return.

This chapter considers some of the important disorders of the vascular system in small animals. Systemic hypertension is an emerging disorder of clinical importance to dogs and cats. Systemic arterial and systemic venous thrombosis can lead to sudden and devastating clinical deterioration of organ or tissue function. Systemic and pulmonary embolisms are recognized as complications of a number of diseases. Additional vascular disorders of clinical importance include vasculitis, arteriosclerosis, atherosclerosis, vascular neoplasia, and arteriovenous fistula.

SYSTEMIC HYPERTENSION

Overview of Blood Pressure

The blood pressure profile consists of a systolic (peak) pressure, a diastolic (minimal) pressure, and a mean pressure. The pulse pressure is the difference between systolic and diastolic pressures. The mean pressure represents the best estimate of tissue perfusion and is approximated as the diastolic pressure plus $^1/_3$ of the pulse pressure.

Blood pressure can be normal, low, or high. The precise limits of normal arterial blood pressure (ABP) in dogs and cats is still a subject of investigation and some debate. Low blood pressure or hypotension is discussed elsewhere, in the Chapters on Shock (Chapter 156) and Heart Failure (Chapter 147). Systemic arterial hypertension is an increase in systolic or diastolic ABP and is considered in this chapter.

Hypertension is identified by measurement of the ABP. Instantaneous blood pressure is usually measured noninvasively, using either a Doppler flow technique or an oscillometric method. The mechanisms and causes of hypertension vary and require some understanding of normal blood pressure and factors that influence these measures.

Systolic Blood Pressure

- Peak ABP depends on the prior diastolic pressure, the ventricular stroke volume, and the compliance of the arterial system (especially the aorta). Systolic pressure is most often used for the diagnosis of systemic hypertension because systolic blood pressure is easier to measure accurately than diastolic pressure, and because the majority of hypertensive dogs and cats have systolic or combined systolic/diastolic hypertension.
- The upper limit of normal for ABP depends on the species, the method of measurement, and the conditions of examination.
- In dogs, pressures >160 mm Hg (by the Doppler-flow method) are suspicious for hypertension. Values persistently greater than 180 mm Hg are diagnostic of hypertension, provided the dog is quiet, does not have tachycardia, and is not struggling.
- In cats, pressures >150 mm Hg are suspicious for hypertension, and values persistently greater than 160 mm Hg are considered diagnostic for hypertension (although some authors propose 170 mm Hg as the cutoff). Although "white-coat hypertension" related to the stress of examination has been reported in cats more frequently than dogs, both cats and dogs may have stress- or excitement-related elevations of blood pressure.
- In some animals, systolic pressures measured by oscillometric methods are about 10 to 20 mm Hg lower than those measured by Doppler-flow or direct arterial puncture methods. Thus, a systolic pressure of 170 mm Hg by an oscillometric method in a dogs is probably indicative of hypertension.

Diastolic Blood Pressure

- Diastolic ABP depends on systemic vascular resistance, heart rate, and cardiac output.
- Vasodilation associated with systemic diseases (anemia, hyperthyroidism) or arterial vasodilator therapy often lowers diastolic pressure. Conversely, spontaneous or

drug-induced vasoconstriction increases diastolic (as well as systolic) ABP.
- Diastolic pressure is detected with variable accuracy by oscillometric recording devices, but is more difficult to estimate with the Doppler flow method.
- Diastolic pressures exceeding 100 to 110 mm Hg are generally considered to be high, assuming that the animal is not excited during the recording. Values exceeding 120 mm Hg are generally treated for hypertension.

Mean Blood Pressure

- The mean arterial pressure is the geometric mean pressure during the cardiac cycle and is closer to the diastolic than the systolic reading.
- Oscillometric ABP devices measure this variable by detecting maximum oscillations in the blood vessel wall that correspond to the mean ABP. Provided the systolic and diastolic pressures can be recorded, the mean can be estimated as:

$$\text{MAP} = (\text{diastolic pressure}) + (\tfrac{1}{3}\,[\text{systolic pressure} - \text{diastolic pressure}])$$

Arterial Pulse Pressure

- The pulse pressure, or difference between systolic and diastolic ABP, is the basis for the palpable pulse identified during physical examination. The systolic and diastolic pressures are closely related in most circumstances so that each will increase or decrease proportionately. However, as indicated above, there are differences in the determinants of each pressure and situations are encountered where maximal and minimal pressures diverge.
- Aortic input impedance affects systolic ABP. For example, a potential reason for isolated systolic hypertension in older cats is the increase in aortic stiffness associated with idiopathic aortic dilation.
- Stroke volume has a marked effect on systolic ABP. Stroke volume is increased in cases of increased left ventricular filling (Frank-Starling effect) and increased sympathetic activity. Simply increasing stroke volume usually increases both systolic and diastolic pressures. But there are situations in which stroke volume increases but diastolic pressure decreases. This is especially likely in the setting of peripheral vasodilation, abnormal run-off of aortic blood flow, or when the heart rate is especially slow. Examples include:
  - Anemia
  - Thyrotoxicosis
  - Administration of arterial vasodilator drugs
  - Patent ductus arteriosus
  - Moderate to severe aortic regurgitation
  - Large arteriovenous fistula
  - Bradycardia (from drugs or chronic heart block)
- In these situations the arterial pulse is often bounding and measurement of systolic pressure does not provide a comprehensive picture of ABP or perfusion pressure.

Etiology

The precise mechanisms underlying hypertension in animals are not well understood except in experimental cases. Inability to regulate plasma volume (renal disease or hyperadrenocorticism), excessive adrenergic activity (pheochromocytoma), increased cardiac output (hyperthyroidism), and activation of the renin-angiotensin system (glomerular disease) are likely candidates. The clinical associations of systemic hypertension should be appreciated because some disorders are treatable and management may minimize the need for antihypertensive therapy. While systemic hypertension is considered idiopathic or "essential" in some dogs and cats, a number of well defined clinical disorders have been associated with increases in ABP.

- Renal disease (particularly glomerular disease)
- Hyperadrenocorticism—both Cushing's disease in dogs (with glucocorticoid excess) and Conn's disease in cats (associated with mineralocorticoid excess and hypokalemia) can lead to hypertension.
- Pheochromocytoma—a catecholamine-producing tumor of the adrenal medulla.
- Hyperthyroidism—both spontaneous disease in cats and iatrogenic disease in dogs
- Diabetes mellitus—in both dogs and cats
- Drugs—particularly the alpha-adrenergic agonists (such as phenylpropanolamine) that lead to vasoconstriction.
- Central nervous system (CNS) disorders—if associated with excessive sympathetic output.
- Idiopathic or "essential" hypertension—hypertension of undetermined cause.

▼ ***Key Point*** Systemic hypertension should be approached initially as a symptom or complication of another disease condition rather than a disease in itself. Only after underlying diseases have been excluded by appropriate testing can systemic hypertension be deemed "idiopathic."

Clinical Signs

Injury to arterioles or larger arteries or the direct transmission of pressure across the microcirculation is responsible for many of the clinical signs of hypertension. Additionally, the left ventricle must hypertrophy to maintain an increase in pressure work. Other clinical signs may be attributed to the underlying disease responsible for elevated ABP.

▼ ***Key Point*** The eyes, brain, heart, and kidneys are the main target organs of injury in cases of systemic hypertension.

Brain Abnormalities

- *Cerebral or brainstem injury* can result from hypertension owing to brain edema or hemorrhagic stroke. Clinical signs include signs of intracranial abnormalities, including abnormal mentation, neurologic deficits, head tilt, seizures, and coma. Presumably, as with human patients with hypertension, dogs and cats also develop "headaches" and this may account for some of the inactivity observed in affected small animals.

Ocular Abnormalities

- *Ocular abnormalities* include retinal edema, hemorrhage, and detachments. These lesions can progress to blindness. Sudden blindness also may develop due to intraocular hemorrhage and hyphema. Recognition requires careful ophthalmic examination. Acute lesions are often superimposed on chronic retinal changes.

Cardiac Abnormalities

- The *heart* generates the pressure in hypertension and may also be injured by work and the high pressures distributed across the coronary vascular system.
- A systolic cardiac murmur of uncertain cause or an atrial (S_4) gallop sound may indicate hypertensive heart disease. A systolic heart murmur may represent mitral regurgitation, flow into a dilated aorta, or dynamic ventricular outflow tract obstruction related to the hypertrophic disease.
- Concentric left ventricular hypertrophy and resultant cardiomegaly are the markers for chronic hypertension and can be identified by an echocardiogram (most sensitive), electrocardiogram (increased voltages or left-axis deviation), or thoracic radiograph (least sensitive).
- Coronary arteries also are injured from high arterial pressures.
- While congestive heart failure (CHF) stemming from hypertensive heart disease is relatively uncommon in dogs and cats, distinguishing left ventricular hypertrophy due to systemic hypertension from primary hypertrophic cardiomyopathy or hyperthyroid heart disease in cats can be a challenge. In dogs with chronic mitral valve disease, systemic hypertension increases the load on the left ventricle and increases the regurgitant volume. Persistent hypertension may prevent effective drug control of CHF in these dogs.

Kidney Abnormalities

- The *kidneys* are both a source and target of hypertension. Abnormal renal contour or size, proteinuria, and mild-to-moderate azotemia often are found in hypertensive animals. Hypertension injures glomerular vessels and damages renal tissues. In some cases it may be difficult to discern if hypertension is the cause or the consequence of renal disease and hypertension secondary to chronic renal disease promotes further glomerular damage.

Other Manifestations

- Other blood vessels can be injured in patients with hypertension.
- Epistaxis or bleeding from other sites also has been reported with hypertension, especially the labile hypertension of pheochromocytoma.
- Chronic systemic hypertension can lead to aortic dilatation even in relatively young animals. Rarely, the aorta can tear leading to a dissection of blood between layers.

Diagnosis

- When evaluating the hypertensive patient, search for an underlying cause, as treatment may reduce the need for antihypertensive drugs.
- Consider the history, and determine if any medications that might increase ABP have been prescribed (such as thyroid hormone; alpha-adrenergic agonists; antihistamine combinations with vasoconstricting properties).
- At a minimum, perform routine diagnostic studies that include a full serum biochemical profile; complete urinalysis; serum thyroxin; and either abdominal radiographs or optimally an abdominal ultrasound examination with particular attention to the kidneys and adrenal glands.
- Diagnosis of hypertension requires measurement of ABP using either an arterial puncture attached to a pressure transducer or an indirect determination that uses a reliable technology and consistent technique.
- Both oscillometric methods and Doppler flow methods have been used successfully for measuring ABP in dogs. Systolic ABP is slightly underestimated by the oscillometric technique.
- Systolic pressures can be readily determined in cats using Doppler flow meter and occlusion cuff on a fore or hind limb. Oscillometric measurements can be obtained from cats using an appropriately-sized cuff at the tailhead in the sternal animal. Oscillometric measurements using a tail cuff may underestimate Doppler-obtained blood pressure.
- Care must be taken to consider normal variation in excited animals. Slight differences (5–10 mm Hg) between front and back limbs are normal in many animals, and the cuff size (diameter) is critical to prevent overestimation (too small a cuff) or underestimation (too wide a cuff).

▼ ***Key Point*** Since the development of systemic hypertension is usually an indication for life-long therapy, the diagnosis should be as certain as pos-

sible. One or two high pressure readings in the setting of overt target-organ injury are sufficiently conclusive. However, in otherwise healthy animals, repeated measures—preferably over a number of days—should be obtained before establishing a diagnosis.

Technique for Measuring Blood Pressure

Because technical details are very important in establishing a correct diagnosis, consider the following *technical pointers for measuring blood pressure*:

- Understand your recording unit and how it works.
- Practice on numerous animals of different sizes. Practice improves skill and confidence. Train others to measure ABP and compare results. When using Doppler methods, learn to evenly decrease the pressure in the cuff and manometer.
- Measure ABP in calm animals that are comfortably restrained—in many clinical situations, it is advantageous to let the pet rest in its caretaker's arms or lap for the measurements. Avoid measuring ABP in sedated animals.
- Have a supply of different-sized pediatric cuffs (e.g., #1–#6 pediatric cuffs) available. Place nonelastic, self-adhesive tape (such as Vetwrap) around the cuff to prevent slippage.
- Do not allow the cuff tubing leading to the manometer to kink.
- Measure the limb and use an appropriate sized cuff. The cuff must compress the limb evenly and occlude the artery with the approximate pressure recorded by the manometer. Use the smallest cuff appropriate for the limb size. Cuff diameter should be 40% of the limb circumference in dogs and between 30% and 40% of the limb circumference in cats. There is often a 10- to 20-mm Hg difference between next sized cuffs; wider variations suggest a technical error in recording or a cuff problem.
- Place the cuff around the distal radius (antebrachium), metatarsus or tailhead, around a relatively cylindrical portion of the appendage. Secure the cuff with wrap and attach it to the manometer. The inflatable bladder of the cuff should be positioned directly over the underlying artery.
- Place the patient in either lateral or sternal recumbency on a *padded table*, in a *quiet room*, with *calm people*. Gently restrain the patient, and give the pet time to acclimatize to the environment.
- Measure heart rate (HR). If it is high (e.g., >160 in a dog; >240 in a cat), try to help the animal relax before proceeding.
- Consider the site of measurement relative to heart level. The cuff should be at the level of the heart during measurement. ABP should not be measured in a standing animal unless a tail cuff is used.
- Inflate the cuff one or two times, slowly and gently, and allow the animal to experience what will happen during measurement. Then record the pressure.
- With a Doppler method, place the crystal palmar (or plantar) and just distal to the large carpal (metatarsal) pad. Use subtle medial-lateral; anterior-posterior movements to detect the arterial signal. In cats and small dogs, or in patients with low blood pressure, use a light touch and copious ultrasound gel (not rectal jelly) to obtain an optimal acoustic signal. Clipping the hair can be helpful. Once a reading is obtained, repeat the measurement two more times noting the values and the concurrent HR.
- For Doppler flow systems, consider using earphones attached to the available output plug to reduce the loud, popping on/off sound of crystal movement, a noise that may startle the patient. At a minimum, do not place the audio speaker near the patient's head.
- If using an automated oscillometric device, attach the cuff at the tail base, the antebrachium, or the metatarsus. Place the two cuff lines on either side of the artery (which is generally ventral and slightly medial). Measure HR with a stethoscope. It should correspond almost exactly with the automated monitor. If it does not, do not accept the displayed values.
- If the ABP value is "low" (systolic pressure < 90 mm Hg) try the next *smaller* cuff. If it is still low, go to the hind limb to verify the value. If the animal is not symptomatic, interpret the clinical situation and determine the most likely cause (for example, volume depletion, sedatives, or cardiovascular drugs).
- If the ABP is high (systolic pressures of >180 mm Hg in dogs; >160 mm Hg in cats), try the next sized larger cuff, as this will more easily compress the artery. If ABP is still high (or <20 mm Hg lower than the last measurement), the initial measurement is probably accurate, but verify it by placing the cuff at an alternative site (e.g., from forelimb to metatarsus or tail).
- Labile hypertension may indicate a "white-coat" effect from examination stress or, in some patients, a true labile situation (as with pheochromocytoma in dogs).
- With either measurement method, obtain 3 to 5 measurements with approximately 30 seconds between measurements. Discard any obviously spurious readings and use the average of the repeated measurements to obtain a representative reading for that session.
- Interpret the findings of elevated ABP in conjunction with other clinical findings. In animals with ocular, renal, CNS, or cardiac disease, an elevated ABP measurement is more likely to represent a true finding of hypertension. If other clinical findings are negative, measure the pressure at another time or day.
- Be confident of the diagnosis of "hypertension" before initiating drug therapy.

Treatment: General Measures

- Treat the underlying problem (e.g., hyperthyroidism or hyperadrenocorticism) whenever possible; however, remember that in some cases there may be more than one reason for hypertension and that correction of one problem will not insure a normotensive state. For example, many older cats have preexisting renal disease as one risk factor and later develop hyperthyroidism, which can compound the hypertension.
- If pressure is very high (>200 mm Hg) or if target organ injury is evident (especially if there is ocular or cerebral disease), treat the hypertension before addressing the underlying disorder.
- Modest dietary sodium restriction is reasonable in treating hypertension, however, there is little evidence that severe sodium restriction will benefit most dogs and cats with hypertension. Attempting to control significant hypertension by diet alone is ill-advised, and diet should be viewed as simply an adjunct to antihypertensive drug therapy.
- Drug therapy is generally required to treat hypertension. ABP can be lowered pharmacologically by reducing cardiac output or reducing systemic vascular resistance by dilating systemic arterioles.
- Therapy of systemic hypertension usually involves a stepwise approach, starting with a moderate dosage of one drug, increasing the dose to the desired effect as needed, or adding other drugs if required.
- Consider possible drug interactions when prescribing multiple drugs.
- There are also some particular situations wherein a specific regimen of drugs is more desirable, for example, in glomerular disease or in hypertension associated with pheochromocytoma.
- A variety of drugs can be prescribed for treatment of hypertension. These and specific pointers for clinical use, are described below (also see Chapter 146 for more details).

Drug Therapy for Systemic Hypertension

Calcium Channel Blockers

- Most clinicians initiate treatment of systemic hypertension in cats with the calcium-channel antagonist/vasodilator amlodipine besylate (Norvasc). Dihydropyridines such as amlodipine and felodipine are more vascular selective than other calcium channel blockers such as diltiazem. Although diltiazem may slow heart rate, it is not recommended as a primary therapy for systemic hypertension.
- Amlodipine is an effective and well-tolerated therapy for hypertension in cats, based on a number of small, but convincing, clinical studies. Clinical experience indicates amlodipine at higher doses is effective for blood pressure control in dogs.
- The starting dose in cats is $^1/_4$ of a 2.5-mg tablet PO once daily. In some cases, higher doses, up to 1.25 mg PO q12h, may be needed.
- In hypertensive dogs, amlodipine is dosed initially at 0.1 to 0.2 mg/kg PO q12h. Response is variable in dogs, though it tends to be very good at higher dosage ranges of 0.2 to 0.5 mg/kg PO q12h.
- Amlodipine has a relatively slow onset in dogs, and a prolonged duration of action. Unless urgent control of ABP is needed, increase the dose gradually, over several weeks to target ABP levels (usually <140 mm Hg).
- Amlodipine monotherapy works better than an angiotensin-converting enzyme inhibitor (ACEI), beta-blocker, or diuretic in cats, and is the drug of choice for hypertension that is severe (>200 mm Hg systolic ABP) or associated with overt target organ injury (retinal or CNS signs).
- Comparison to ACEI: amlodipine is more effective than benazepril in lowering ABP, but is not considered directly renoprotective (aside from reducing ABP) in patients with significant proteinuria.
- The combination of amlodipine with benazepril or enalapril is reasonable in cats or in dogs with documented renal disease with proteinuria. Optimal ABP control may be facilitated by the amlodipine besylate, whereas benazepril may reduce proteinuria and delay progression of renal disease, especially in cats.
- Amlodipine is relatively expensive, compared to generic or veterinary enalapril or benazepril, and this may be an important issue in large dogs wherein combined therapy may allow for dose reduction of amlodipine.
- One approach to combination therapy is administration of amlodipine once daily in the morning and the ACEI once daily after noon. If higher doses of both drugs are needed, they can be administered together, twice daily. In addition, there is a combination capsule of 10 mg amlodipine/2.5 mg benazepril (Lotrel) that may be useful in some larger patients or might be compounded for individual use.

▼ ***Key Point*** In most feline patients, amlodipine besylate is the drug of choice for treatment of severe systemic hypertension and is generally effective as a single therapy when dosed appropriately.

Angiotensin-Converting Enzyme Inhibitors

- Hypertension in dogs or cats can be treated with an ACEI, typically *benazepril* (human Lotensin in the United States; veterinary Fortecor in many other countries) or *enalapril* (veterinary Enacard).
- The initial dose of an ACEI for cats is between 0.5 and 1 mg/kg PO once daily.
- Dogs are usually treated at 0.5 mg/kg PO q12h.

- An ACEI is particularly reasonable therapy in dogs and cats with mild hypertension and concurrent glomerular disease (see Chapter 77).
- As indicated above, in patients with moderate to severe hypertension, an ACEI is best added to the calcium channel blocker amlodipine besylate.

Diuretics

- In comparison to human patients, diuretic therapy of hypertension of dogs and cats is inferior and rarely undertaken.
- Diuretics decrease cardiac filling and cardiac output and lower ABP. However, diuretic monotherapy is rarely successful in controlling hypertension in small animals, and the resulting volume contraction can worsen azotemia and activate the renin-angiotensin system.
- Diuretics are more appropriate as adjunctive therapy in urgent hypertensive situations or in patients with where hypertension and congestive heart failure are both evident.
- A loop diuretic such as furosemide (1–2 mg/kg q12–24h) is most often used. This can be combined with spironolactone (0.5–1 mg/kg daily).
- If diuretics are used, they may be combined with an ACEI to limit further activation of the renin-angiotensin-aldosterone system.

Beta-Adrenergic Blockers

- Beta blockers decrease heart rate, cardiac output, and plasma renin activity. These and possibly other (central) effects are antihypertensive.
- Currently, these drugs are used mainly in co-therapy of four conditions:
- As an add-on drug to amlodipine and an ACEI in the rare case of unresponsive hypertension that requires "triple therapy" for control. Atenolol is chosen in cats; atenolol or carvedilol in dogs.
- In cats, as an initial management for mild hypertension associated with protracted sinus tachycardia and high cardiac output due to hyperthyroidism, *atenolol* (1–2 mg/kg PO q12–24h) is typically chosen. The daily dose often requires down-adjustment (or drug discontinuation) to prevent bradycardia once the hyperthyroid state is controlled with methimazole. In hyperthyroid cats with severe hypertension, a combination of amlodipine and atenolol can be used.
- In dogs with degenerative valvular heart disease and systemic hypertension caused by hyperadrenocorticism or chronic renal disease, the use of *carvedilol* (Coreg; dosed at 0.5–1 mg/kg PO q12h) may control hypertension and provide cardioprotection. Carvedilol is also an alpha-adrenergic blocker. The drug is expensive, and cost may limit its use. In dogs with concurrent CHF, first control the condition with diuretics and an ACEI before starting carvedilol.
- In dogs with functional pheochromocytoma to control heart rate, arrhythmias, and blood pressure, a beta blocker (*propranolol* starting at 0.25 mg/kg PO q8h) should be administered only *after* initial therapy with the nonselective alpha-blocker phenoxybenzamine or the alpha$_1$-adrenergic blocker prazosin (see below). If there is concern about beta-blockage, a brief infusion of the ultra–short-acting nonselective blocker esmolol (500 mcg/kg/minute infusion over 10 minutes) can be given as a test. In canine patients with concurrent non-cardiogenic pulmonary edema ("pheo-lung") or a catecholamine-induced dilated cardiomyopathy, beta-blockers must be used with great care if at all to prevent further impairment of pulmonary or cardiac function.

Other Vasodilators

- *Sodium nitroprusside*—an infusion of nitroprusside represents aggressive antihypertensive therapy in the setting of severe target organ injury, hemorrhagic stroke, and uncontrolled CHF.
- This drug is used mainly in dogs.
- Dosing in systemic hypertension is generally higher than that required for treatment of CHF (see Chapter 147).
- Initially begin at 2.5 mcg/kg/min; the infusion rate can be increased every 15 minutes by 1 mcg/kg/min to a maximum of 20 mcg/kg/min. Some dogs are highly resistant to even high-rate infusions.
- *Hydralazine*—The direct-acting arterial vasodilator hydralazine (1–3 mg/kg PO q12h) can be used in unresponsive systemic hypertension. In animals receiving other antihypertensive medications, hydralazine therapy should be initiated at the low end of the dosing range and titrated up slowly as needed to control ABP.
- *Prazosin*—the alpha-adrenergic blocker prazosin is an older medication that is not used very often today. While somewhat inconvenient to dose (coming in only 1-mg, 2-mg, and 5-mg capsules), it can be highly effective in dogs unresponsive to other medications, particularly in the case of pheochromocytoma (when *phenoxybenzamine* or Dibenzyline is unavailable).
- The initial dose of prazosin may result in profound drop in ABP. Blood pressure should be monitored carefully during therapy.
- An initial dose of 0.5 mg (discard $^1/_2$ of the capsule contents) can be given to most dogs. The usual dose in dogs is one 1-mg capsule, q8–12h; if higher doses are needed, the 2-mg capsule can be used.
- In cats, prazosin can be dosed at 0.5 mg PO, twice daily.

Follow-Up of Drug Therapy

- Reevaluate blood pressure regularly to ensure efficacy and prevent further organ injury.

- Be diligent in looking for signs of drug toxicity, including hypotension (weakness, depression, syncope, progressive renal failure).
- Follow serum biochemistries with particular attention to indicators of renal function.
- Continue to manage the underlying condition if known.
- As there are no large, prospective studies to guide therapy, treat each patient individually.

THROMBOSIS AND THROMBOEMBOLISM

General Concepts

- *Thrombosis* refers to the local formation of a blood clot within a blood vessel. Thrombi are potentially dangerous owing to obstruction of blood flow. Thrombi may develop in arteries or veins.
- *Embolism* is the sudden occlusion of an artery that occurs when an organized substance is carried from one point to another by the vascular system.
- A thrombus that is dislodged from the site of formation and is carried by the blood to another location is termed a *thromboembolus*.
- Systemic thromboembolism occurs when a thrombus is carried from a formation site in the left side of the heart to the termination of an artery within the systemic circulation.
- Pulmonary thromboembolism indicates that a thrombus formed within a systemic vein and dislodged, traveling with venous return across the right side of the heart and into the pulmonary arteries.
- Thrombosis may be initiated by different mechanisms (see Chapter 23).
- A systemic arterial thrombus typically starts with activation and aggregation of platelets (white thrombus). Arterial thrombosis frequently is initiated by injury to vascular endothelium or atrial endocardium.
- Stasis of blood and activation of clotting factors is thought to cause systemic venous thrombosis (red thrombus). Deficiencies of plasma antithrombin appear to predispose to venous thrombosis. Frequently venous thrombosis is associated with trauma, systemic inflammation, neoplasia, or other disorders favoring a pro-coagulant environment.
- A thrombus or embolus obstructs blood flow. Consequences of vascular obstruction include *ischemia* (lack of blood flow), *infarction* (*necrosis* of tissues nourished), and associated inflammatory reactions.
- *Systemic arterial thrombi* can be clinically silent or life-threatening, depending on the specific vessels, tissues, or organ injured.
- *Systemic venous thrombi* obstruct systemic venous return, typically leading to local edema from impaired venous drainage.
- *Pulmonary embolism* alters the normal relationship between lung perfusion and ventilation, impairs right ventricular function, and may produce considerable pulmonary parenchymal damage.

Etiology

A number of clinical disorders are associated with the development of thrombi or emboli in systemic arteries or veins (Table 153-1).

Pathophysiology

- The pathogenesis of clinical signs depends on the acuteness of injury, location of vascular obstruction, magnitude of thrombosis, collateral circulation, the tissue affected, and inflammatory mediators.
- The pathological consequences of ischemia or infarction of the *systemic circulation* include:
  Bone—Infarcts and zones of bone necrosis
  Brain—Ischemia-induced neuronal damage, edema, cell necrosis, hemorrhagic necrosis
  Limbs—Muscle ischemia, rhabdomyocytolysis, pain, peripheral neuropathy
  Myocardium—Myocardial ischemia or infarction, arrhythmias, abnormal ventricular wall motion, ventricular dysfunction, heart failure, sudden cardiac death
  Spinal cord—Neuronal degeneration, ischemic or hemorrhagic necrosis
  Kidney, adrenal gland, liver, spleen, or gut—Infarcts, hemorrhages, and parenchymal necrosis may occur with subsequent organ dysfunction
  Skin—Infarcts or cutaneous hemorrhages
- Pathological consequences of ischemia or infarction of the systemic venous or pulmonary arterial circulation include:
  - Lung—Pulmonary embolism and pulmonary parenchymal injury leading to ventilation-perfusion inequality in the lung.
  - A massive pulmonary embolus can obstruct the left or right pulmonary artery, severely limit cardiac output, and lead to hypotension, myocardial ischemia, and cardiac arrest.
  - Embolization of smaller pulmonary vessels can cause pulmonary infarction and also initiate the release of vasoactive chemicals that cause lung edema and inflammation.
  - Recurrent pulmonary thromboembolism reduces vascular cross-sectional area, increases pulmonary vascular resistance, and predisposes patients to chronic pulmonary hypertension. Acute or chronic pulmonary hypertension may result in signs of right-sided congestive heart failure (e.g., ascites, jugular distention).
  - Systemic veins—Obstruction of venous return, elevation of venous and capillary pressures, and edema of dependent tissues.

Table 153-1. CAUSES OF THROMBOSIS AND THROMBOEMBOLISM

Systemic Arterial Thrombosis/Thromboembolism	Systemic Venous or Pulmonary Arterial Thrombosis/Thromboembolism
Cardiac Disease/Origin	***Hypercoagulable states***
Feline cardiomyopathy (from the left atrium)	Deficiency of antithrombin III (protein-losing nephropathies)
Bacterial endocarditis (thrombi shed from the vegetation)	Venous stasis
Penetrating foreign body (needle, porcupine quill)	Systemic inflammatory reaction
Atrial fibrillation (rare, except in cats)	***Specific Disorders (Multiple Mechanisms)***
Missile—gun bullets or pellets that directly penetrate the vascular system	Cushing's disease
Aberrant filarial parasites within systemic arteries *(Dirofilaria immitis)*	Immune-mediated hemolytic anemia
Cartilaginous embolism of the spinal cord vessels	Pheochromocytoma
Inflammation of the blood vessel wall (arteritis or vasculitis)	Verminous pulmonary arteritis (Dirofilariasis; Angiostrongylosis)
Direct trauma or iatrogenic injury to arterial blood vessels	Heartworm embolus from adulticide therapy (dogs) or spontaneous worm death (cats)
Polycythemia	Invasive neoplasm
Disseminated intravascular coagulopathy	Diseases of veins
Torsion of a vascular pedicle (splenic torsion, mesenteric torsion)	Venous inflammation (phlebitis) from catheters, trauma, or drugs
Artificial heart valve	Thrombophlebitis—phlebitis with localized thrombus formation
	Fat emboli (from long bone fractures)
	Air emboli (from catheters or procedures such as cystography or cryosurgery)
	Retrograde venous embolus of the spinal cord
	Cardiac Disease/Origin
	Tricuspid valve thrombus
	Intracardiac tumor
	Intracardiac catheter
	Central line dialysis catheter
	Pacing lead

Diagnosis

- The clinical diagnosis of thrombosis or embolism requires a high level of suspicion. A sudden onset of clinical signs is typical of some conditions; other disorders are chronic in nature.
- The physical examination and laboratory signs of embolism depend on a number of factors, including the:
  - Vascular system involved and the tissues served by affected vessels.
  - Acuteness of the obstruction and magnitude of tissue injury.
  - Degree of collateral circulation available to support the affected region.
- Clinical abnormalities of thrombosis/thromboembolism range from subtle to obvious. Table 153-2 indicates some of the typical clinical and laboratory findings of various thrombotic or embolic diseases.
- Advanced *imaging studies* can be useful in confirming the diagnosis of arterial thrombosis or embolism. (see Chapter 4) The optimal examination varies with the suspected cause and tissues injured. In some cases the thrombus may be imaged directly; in others, perfusion deficits may be identified. Specialists should be consulted regarding specialized radiographic, ultrasonographic, echocardiographic, angiographic, and radionuclide studies.
- Clinical laboratory tests may demonstrate changes attributable to decreased blood flow, organ ischemia, or tissue necrosis.
- The diagnosis of cutaneous and appendicular thrombosis/embolism usually can be made from physical examination.
- Cutaneous vasculitis usually leads to hemorrhages and edema.
- Aortoiliac thrombosis (Chapter 150) causes typical clinical signs (see Table 153-2) along with marked elevations in skeletal muscle enzymes.
- A diagnosis of superficial venous thrombosis or thrombophlebitis is made from inspection and palpation of superficial veins and tissues.
- Duplex Doppler ultrasound can be used to examine the vessel lumen and interrogate blood flow patterns in ambiguous cases.
- Myocardial infarction is diagnosed by characteristic ECG changes, progressive elevations of cardiac troponin-I, and by echocardiographic wall motion studies.
- Diagnosis of abdominal thrombosis or embolism may be difficult and require surgical exploration in the case of an acute abdomen. In many cases, however, abdominal ultrasound with Doppler studies may show the presence of a thrombus and associated obstruction to flow from the aorta.

Table 153-2. CLINICAL FINDINGS IN THROMBOSIS AND THROMBOEMBOLISM

Organ or Tissue	Possible Clinical Findings	Laboratory Examination—Possible Findings
Brain	Ischemic neuropathy or "thrombotic stroke" Fainting, falling, persistent neurologic deficits, coma, or seizures	MRI or contrast CT can demonstrate imaging abnormalities Secondary changes in CSF
Spinal cord	Rapidly progressive segmental spinal cord disease Signs depend on the level and extent of cord injury	MRI or contrast CT can demonstrate imaging abnormalities Secondary changes in CSF Myelogram negative for extradural compression
Limbs	Sudden onset of limb weakness or paresis Affected limb(s) are pale, cold, and pulseless Absence of Doppler flow signals in affected arterial system Signs of ischemic lower motor neuron sensory and motor neuropathy Ischemic myopathy (pain, muscle contracture, possible late-onset edema) Bone infarcts may be associated with diffuse or shifting lameness or pain	Duplex Doppler studies show lack of blood flow in affected system Angiogram positive for obstruction (rarely necessary) Elevated muscle enzymes (CK > > > AST > > ALT) Increased blood lactate Hyperkalemia and hypermagnesemia (with reperfusion)
Myocardium	Discomfort, anxiety, tachypnea Premature ventricular complexes Hypotension Progressive heart failure Sudden cardiac death	ECG abnormalities (acute ST-T segment deviation, infarction patterns, ventricular arrhythmias) Elevated creatine kinase-MB Elevated serum troponin-I (cTn-I) Echocardiographic abnormalities (regional ventricular wall hypokinesis)
Mesenteric and splanchnic vessels*	Possible abdominal pain (colic) Severe abdominal pain if aortic thrombus or mesenteric ischemia Acute onset of hindlimb weakness or paralysis if thrombus is in caudal aorta Acute renal failure if thrombus is cranial to kidneys Shock	Serum biochemical abnormalities may reflect end-organ injury (azotemia or an Addisonian crisis) Abdominal ultrasound can frequently identify the presence and location of the thrombus Duplex Doppler studies of abdominal vessels may be revealing Arteriography positive for obstruction (rarely done) Exploratory surgery may indicate vascular obstruction Ancillary testing in dogs with aortic thrombi often reveals protein losing nephropathy or Cushing's disease
Skin	Cutaneous hemorrhages, petecchiae, or ecchymosis may be evident	Laboratory tests compatible with vasculitis
Pulmonary embolism	Sudden onset of tachypnea or dyspnea Possible mild pyrexia Variable heart rate, but may be increased Acute, severe: hypotension from impaired right-ventricular function sudden death Chronic: clinical signs of pulmonary hypertension; possible right-sided CHF Loud S_2; tricuspid regurgitation murmur in pulmonary hypertension	Thoracic radiographs may show nonspecific parenchymal changes, localized pleural effusion, or redistribution of blood flow (away from affected areas), but may be normal Radiographic signs of heartworm infection when due to dirofilariais Large proximal thrombi and heartworms may be identified by echocardiography with imaging of the pulmonary arteries in some cases Distal thrombi must be diagnosed from radionuclide scans (perfusion defects) or pulmonary arteriography Normal d-dimer test argues against pulmonary thromboembolism Positive heartworm tests when due to dirofilariasis
Systemic venous thrombosis	Cutaneous veins are swollen and may be "knobby" in appearance Superficial veins do not collapse, and may be warm and painful (thrombophlebitis) Subcutaneous edema in the tissues drained by the venous system Deep venous thrombosis involving the external iliac veins may lead to bilateral limb edema Bilateral jugular thrombosis can lead to intermandibular edema Thrombosis of the cranial vena cava causes intermandibular and pectoral edema, pleural effusion, or chylothorax There may be signs of pulmonary thromboembolism with any venous thrombus	Duplex Doppler echocardiography positive for thrombus or altered pattern of blood flow pattern of blood flow

*Thrombosis or volvulus of renal, adrenal gland, splenic, or splanchnic arteries

- Pulmonary thromboembolism is a difficult diagnosis. It may be suspected from the history and medical workup, but there are no readily available tests for definitive diagnosis (see Table 153-2). Radionuclide scans that show perfusion deficits may be highly suggestive in the absence of concurrent lung infiltration or a history of chronic respiratory disease (as parenchymal disease may affect perfusion). Doppler-echocardiographic studies documenting *acute*, high velocity tricuspid and pulmonic insufficiency is suggestive of pulmonary thromboembolism in a patient at risk for this complication.
- D-dimer assay may be positive in patients with pulmonary embolism; however, this result is not specific and may be positive in other disorders. A negative d-dimer test is more likely to be helpful in excluding pulmonary embolism.

Treatment

Principles of Therapy

- Principles of therapy for thrombosis and thromboembolism include prevention of further thrombosis, treatment of the underlying disorder, removal or disintegration of the clot when possible, and supportive care to damaged tissues.
- Thrombolytic therapy with tissue plasminogen activator has not been evaluated adequately in veterinary medicine. Although potentially effective in clot lysis, the high cost of the drug, the high incidence of adverse effects (including severe reperfusion hyperkalemia), the narrow window of time in which the medication must be delivered, and the high mortality associated with therapy of some conditions have limited the use of this medication in veterinary patients. A specialist with experience in thrombolysis should first be consulted.
- See Chapter 150 for details about treating thromboembolism associated with feline cardiomyopathies.

Heparin Therapy

Heparin is a heterogeneous anticoagulant that inhibits coagulation and is used in the prevention and management of systemic venous and arterial thrombosis and thromboembolism. Heparin is administered by injection, either subcutaneously or intravenously (as a bolus or constant rate infusion).

Formulations

- *Unfractionated sodium and calcium heparin* contain higher and lower molecular weight fractions. Unfractionated heparin binds with antithrombin (formerly AT-III) and inactivates a number of coagulation enzymes, most prominently activated thrombin (factor IIa) and activated factor X (Xa). This inactivation and the effects of the chosen doses can be measured using standard prothrombin and activated partial thromboplastin times; both values are prolonged with unfractionated heparins.
- *Low-molecular weight heparin* (LMWH), including *enoxaparin* (Lovenox) and *dalteparin* (Fragmin) preferentially inhibit factor Xa. These anticoagulants do not prolong the standard coagulation tests, and dosing must be assessed by less-available anti-Xa assays.

Indications

- Heparin therapy—either unfractionated or fractionated (LMWH)—is indicated in patients known to be at high risk for development of thrombosis. Heparin does not dissolve clots but reduces the expansion of existing clots and may prevent new thrombus formation.
- Common disorders managed by heparin include arterial thromboembolism in feline cardiomyopathy, pulmonary thromboembolism, catheter thrombosis of central lines, thrombophlebitis, thrombosis of the jugular vein, suspected deep venous thrombosis in the limb or abdomen, protein-losing nephropathy (provided plasma transfusion has been administered to replenish antithrombin), and some cases of acute bacterial endocarditis. In severe heartworm disease, the use of heparin during the post-adulticide period may reduce adverse effects and limit secondary thrombosis around dead worms.
- Heparin is also used for short-term prevention of thrombosis in patients at high risk for delayed thromboembolism after surgery, trauma, or during recovery from systemic inflammatory diseases.
- Low-dose heparin is often used in the management of disseminated intravascular coagulopathy (discussed more fully in Chapter 23)

Contraindications

- Heparin is contraindicated in overt bleeding, particularly in cases of CNS hemorrhage. Effects of heparin on platelets are complex and thrombocytopenia may occur. Heparin is teratogenic and long-term use may lead to other adverse effects such as bone loss. Overdoses can be reversed with protamine sulfate.

Administration

- Recommended doses of unfractionated heparin vary widely, ranging from 10–75 IU/kg SC q8h for "prevention" of thrombosis or treatment of disseminated intravascular coagulation to 200 to 300 IU/kg SC q8h or by constant rate IV infusion for cases of established thrombosis (e.g., aortoiliac thromboembolism in cats).
- In management of acute thromboembolism, an initial IV dose of 250 to 300 IU/kg IV can be administered, followed by 150 to 200 IU/kg SC q8h (do not administer IM).

- Obtain a baseline clotting profile and adjust the dose to maintain the activated partial thromboplastin time (APTT) or prothrombin time at approximately 2 to $2^1/_2$ times baseline; alternatively, the international normalization ratio (INR) prothrombin time can be prolonged to a value of 2.0 to 3.0.
- Doses of LMWH for veterinary medicine require further definition, but for dalteparin and for enoxaparin consider 100 IU/kg SC q12h, though once-daily dosing with dalteparin might be successful in some cases.
- In dogs dosages of 100 IU/kg to 200 IU/kg of enoxaparin have been used clinically.
- While LMWH can be used long term, drug expense and the need for one to two injections daily has limited the use of these drugs for long-term prevention of thromboembolism in dogs and cats.

Aspirin Therapy

- *Aspirin* inhibits cyclooxygenase and blocks the formation of thromboxane A_2 in platelets. Aspirin has been recommended for the prevention of arterial thromboembolism in a number of conditions including feline cardiomyopathy, canine heartworm disease, bacterial endocarditis, and after cardiac valve repair in dogs. However there is little objective published information regarding risk/benefit of therapy.
- Aspirin probably has little, if any, role in the therapy of established thrombotic disease aside from a single dose administered within 2 hours of an acute arterial thromboembolic event.
- Doses of aspirin are empirical, and there are doubts regarding efficacy in preventing clots.
- Commonly used doses in dogs with heartworm disease are 5 mg/kg PO q12–24h.
- In cats with cardiomyopathy, the traditional dose is one coated, adult, low-dose regimen aspirin of 81 mg per cat, PO every three days. However, ultra-low dosages of 5 mg per cat daily may be equally effective.
- Gastric ulceration is a concern with any dose of aspirin. Do not use aspirin with other anticoagulants or with corticosteroids because of the risk of fatal GI bleeding. Concurrent gastric protection with famotidine may be helpful in animals with signs of gastric irritation on aspirin therapy. The use of buffered aspirin is preferred to limit gastrointestinal upset.

Warfarin Therapy

- *Warfarin* (Coumadin) inhibits vitamin K-dependent factors important in coagulation. Extra-label warfarin has been used in home care of dogs and cats to prevent recurrent pulmonary thromboembolism in dogs and to inhibit arterial thromboembolism in cats with cardiomyopathy.
- There is more experience using warfarin in the cardiomyopathic cat that either has survived an embolic episode or is at high risk for future thromboembolism.
- Tablets can be crushed and $^1/_2$ of a 1-mg tablet PO daily is recommended. The second $^1/_2$ of the same tablet should be used on the subsequent day (as the tablet formulation may not be uniform). Ideally, when initiating warfarin therapy the cat should first receive heparin at 100 IU/kg q8h for 24 to 48 hours because warfarin initially creates a hypercoagulable state.
- Dosing is difficult in cats because $^1/_2$ of a tablet is often insufficient and $^3/_4$ of a tablet may be too much! The use of split dosing (alternating $^1/_2$ and $^3/_4$ tablet dosages) may be useful; alternatively, it is reasonable to ask a compounding pharmacy to dissolve a number of tablets into a solution so long as the drug remains stable.
- The initial dosage for dogs is approximately 0.1 to 0.2 mg/kg, PO daily. As in cats, split dosing may be needed to obtain benefit while limiting risk of hemorrhage.
- The optimal dose of warfarin should prolong the prothrombin time; for example, the INR should be prolonged to a value of 2.0 to 3.0 when a standard value is available for cats in the testing laboratory. Otherwise, a 2x to 3x prolongation over the baseline time may be used. The urine and stool should be carefully evaluated for fresh blood, a finding that indicates a need for downward dosage adjustment.
- Because of difficulties in dosing, numerous drug and food interactions, and the need to frequently test the clotting times, the overall use of warfarin in small animals is very low.
- Animals receiving warfarin therapy should not be allowed outside exercise without supervision.

Other Drugs to Prevent Coagulation

- *Clopidogrel bisulfate* (Plavix) has been studied in healthy cats. The drug inhibits ADP receptors on platelets. Based on studies in healthy cats, a possible dose of $^1/_2$ of the human Plavix 75 mg tablet (containing 97.8 mg of clopidogrel bisulfate = 75 mg of clopidogrel base) may be a reasonable daily dose for a cat. There are no published studies of efficacy in cardiomyopathic cats or long-term studies of toxicity. Use is strictly extra-label.
- *Abciximab* is a glycoprotein IIb/IIIa receptor antagonist that inhibits aggregation of platelets. There are limited feline data regarding this drug and no published studies of clinical use.

Surgery or Catheter Intervention

- *Surgical intervention* is recommended infrequently in the management of vascular thrombosis. Some blood vessels are simply inaccessible.
- Surgery in cats with iliac thrombosis due to cardiomyopathy is complicated by the risk of anesthesia,

development of disseminated intravascular coagulation, and the severe reperfusion hyperkalemia that can develop following revascularization.
- When suprarenal aortic thrombosis is suspected, abdominal ultrasound should be performed to evaluate the aorta and renal vessels. A positive study is an indication for surgery. Monitor ECG and serum potassium carefully intra-operatively and postoperatively.
- Other indications for surgery of arterial thrombosis include multiple splenic thromboses, suspected bowel infarction or volvulus, and bleeding/thrombosis with associated mechanical compression (e.g., extradural bleeding).
- *Catheter-based interventions* for the management of systemic or pulmonary arterial thrombosis/thromboembolism have not advanced in veterinary medicine. The use of embolectomy (Fogarty) catheters has not been evaluated satisfactorily in animals, but this technique often is limited by the small size of many veterinary patients. Similarly, the cost and risks of localized thrombolytic therapy delivered via an intracardiac catheter has deterred advancement of this area.

VASCULITIS

Etiology

- There are a number of causes of arteritis (inflammation involving arterioles or arteries) and phlebitis (inflammation of veins).
- *Arteritis* may develop as a component of multisystemic infections, including infectious canine hepatitis, (see Chapter 16), feline infectious peritonitis (see Chapter 10), and Rocky Mountain spotted fever (see Chapter 17). Immune-mediated arteritis is believed to be important in feline infectious peritonitis, systemic lupus erythematosus, idiopathic vasculitis in Akita, spitz, and Doberman pinscher dogs, and following some drug reactions. Cutaneous manifestations of vasculitis are discussed in other chapters in this text.
- *Phlebitis* is generally related to injection of irritating drugs or chemicals or physical trauma caused by indwelling catheters, often with secondary infections. Thrombophlebitis indicates a situation of vein inflammation with accompanying thrombosis.

Clinical Signs

- Clinical signs of vasculitis are related to local and systemic release of inflammatory mediators, increased vascular permeability, and interruption of the vascular endothelial lining; potential signs include:
  - Fever
  - Subcutaneous edema
  - Cutaneous hemorrhages
  - Coagulation disorders including thrombocytopenia and disseminated intravascular coagulopathy
  - Thrombosis and ischemic injury (see previous discussion of thrombosis)
  - Thrombocytopenia
- Vasculitis syndromes—Specific clinical vasculitis syndromes commonly seen in cats and dogs include:
  - Feline infectious peritonitis (see Chapter 10)
  - Verminous arteritis associated with dirofilariasis and *Angiostrongylus vasorum* infection (uncommon in the United States)
  - Rocky Mountain spotted fever, a tick-borne infection caused by *Rickettsia rickettsii* that affects dogs and human beings. Invasion of vascular endothelial cells causes vasculitis with mononuclear inflammation, microscopic thrombosis, and microinfarction. The condition is a multisystemic disorder that can affect the heart (myocarditis and arrhythmias), brain, blood (thrombocytopenia, neutropenia), and skin (edema, rash). Fever is common, and death may occur (see Chapter 17 for details).

Treatment

- Treatment of vasculitis depends on the underlying cause.
- Management of FIP (see Chapter 10), systemic lupus erythematosus (see Chapter 24), immune-mediated vasculitis (see Chapter 24), and Rocky Mountain spotted fever (see Chapter 17) are discussed elsewhere in this text.
- Antimicrobials such as doxycycline are often administered empirically while awaiting results of serologic tests.
- Immunosuppressive doses of glucocorticoids are indicated for the management of some vasculitides.
- Thrombotic complications may require prophylactic heparin to prevent disseminated intravascular coagulation (see under “Heparin Therapy”).
- Treatment of thrombophlebitis of superficial veins is supportive.
  - Remove any catheters from the affected vein or limb.
  - Hot-pack the area and gently wrap the limb to reduce edema and self-trauma.
  - If there is risk of infection, select a broad-spectrum antibiotic.
  - If there is a concern about extension of the thrombus centrally, examine the vessel using duplex Doppler ultrasound.
  - Therapy with unfractionated heparin or LMWH should be instituted, especially if there is a likelihood of pulmonary embolism (see above).
- For home therapy either long-term LMWH or warfarin should be considered until the problem has resolved.

- Chemical phlebitis can be treated with topical dimethyl sulfoxide (DMSO) and a corticosteroid ointment (q8–12h) with concurrent administration of prednisolone (0.5 mg/kg PO q12h).

ARTERIOSCLEROSIS AND ATHEROSCLEROSIS

Etiology

Arteriosclerosis

- *Arteriosclerosis* is a chronic arterial metamorphosis characterized by loss of elasticity, luminal narrowing, and proliferative and degenerative lesions of the intima and media.
- Coronary arteriosclerosis, prominent in older dogs with endocardiosis, has been related to small and microscopic areas of myocardial fibrosis. Presumably this is due to ischemic necrosis and infarction of myocytes secondary to reduced perfusion.
- Similar lesions also have been observed in dogs with congenital subaortic stenosis, in dogs with diabetes mellitus, and in cats with hypertrophic cardiomyopathy.
- Small-vessel (intramural) arteriosclerosis may contribute to the morbidity of other cardiac disorders by causing ischemia-induced arrhythmias (e.g., premature ventricular contractions) or increased myocardial stiffness (e.g., hypertrophic cardiomyopathy, subaortic stenosis).

Atherosclerosis

- *Atherosclerosis* pertains to the arteriosclerotic state that also includes fatty degenerative changes in the arterial wall. This is the typical underlying lesion of coronary artery disease in human patients, but is quite rare in small animals.
- Naturally occurring atherosclerosis occurs in severe canine hypothyroidism (see Chapter 31) when serum cholesterol concentrations are very high (generally >750 mg/dl).

▼ ***Key Point*** In canine and feline patients, clinically important hyaline arteriosclerosis is primarily related to the intramural coronary vasculature. The overall clinical significance of arterial degenerative changes in animals is relatively small compared with that in human beings.

Diagnosis

- The diagnosis of arteriosclerosis and atherosclerosis in clinical patients is difficult. Suspect this condition in patients with severe hypercholesterolemia and in association with the aforementioned cardiac disorders.
- Suspect acute myocardial infarction due to extramural coronary thrombosis with respiratory distress, ventricular arrhythmias, and severe ST-T segment changes on the ECG (particularly ST-T segment elevation). Echocardiography may reveal regional hypokinesis of the left ventricular free wall. Diagnosis is presumptive because coronary angiography is rarely performed in animals, but any of the above findings in conjunction with an elevated cardiac troponin-I (cTnI) concentration is suggestive of acute myocardial infarction. In some animals, acute myocardial infarction, superimposed on other heart disease, may lead to acute congestive heart failure.
- In the differential diagnosis of extramural coronary artery obstruction or thrombosis, rule out embolic complications of bacterial endocarditis.

Treatment

- Treatment of arteriosclerosis includes treatment of the underlying disease and the complications of ischemia. There are no published studies regarding management of acute coronary syndromes in dogs or cats. Drugs used in management of cardiovascular disease are discussed in Chapter 146.
- In cases of presumed myocardial infarction, administer oxygen and nitroglycerin ointment.
- Beta blockers such as carvedilol or atenolol decrease myocardial oxygen consumption and may be cardioprotective in animals with multifocal small vessel coronary arteriosclerosis. Their use in acute myocardial infarction is appropriate provided the patient does not demonstrate bradycardia, hypotension or signs of congestive heart failure.
- Calcium channel blockers (e.g., diltiazem, 0.5–2.0 mg/kg, q8h PO) may act as a coronary vasodilator and prevent coronary vascular spasm.

VASCULAR NEOPLASIA

Etiology

- Vascular tumors can be primary or metastatic. The endocardium and vascular elements of the heart also may become neoplastic. Primary arterial and venous tumors are uncommon:
- Carotid and aortic body tumors (chemodectomas) can act as space-occupying lesions in the neck, cranial thorax, or in the area of the ascending aorta and base of the main pulmonary artery.
- Aortic body tumors are an important cause of pericardial effusion in older dogs. These tumors also may be an incidental finding at necropsy (see Chapter 151).
- Tumors from vascular elements (e.g., hemangiosarcoma) and malignancies metastatic to blood vessels are described in detail in Chapter 28. Hemangiosarcoma is the most common intracardiac tumor. Multicentric involvement (e.g., liver, spleen, heart) is common. Pulmonary metastasis is frequent.

- Tumor-related hemorrhage into the pericardial space can cause cardiac tamponade.
- Intraluminal obstruction to venous return (usually of the caudal vena cava) causes ascites. This is most common with intracardiac hemangiosarcoma; however, other primary intracardiac tumors, such as myxoma and fibrosarcoma, can cause similar problems. When neoplastic lesions impinge on the cranial vena cava, jugular distention and subcutaneous edema of the head and neck may be seen.
- Extravascular neoplasms may invade blood vessels; for example, obstruction of the caudal vena cava can develop secondary to ingrowth of a pheochromocytoma from the adrenal medulla (see Chapter 33).

Clinical Signs

- Clinical signs depend on the type and location of the tumor
- Signs of cardiac or vena caval neoplasia are usually those of right-sided CHF (hepatomegaly, ascites, pleural effusion) or acute cardiac tamponade (hypotension and collapse).
- Compression of the cranial vena cava (e.g., from mediastinal lymphoma) can cause intermandibular and ventrocervical subcutaneous edema.

Diagnosis

- The differential diagnosis of caudal vena cava obstruction includes idiopathic sclerosis, neoplasia, kinking, or trauma of the caudal vena cava.
- Imaging studies are very useful in diagnosis. (see Chapter 4)
- Radiographic studies may demonstrate mass lesions; however, the cardiac silhouette may be radiographically normal when the obstruction is intraluminal.
- Nonselective angiography (peripheral venous injection) or selective angiography may demonstrate vascular obstruction or interruption.
- Ultrasound studies may demonstrate dilated hepatic veins typical of obstructed hepatic venous drainage or solid tissue mass lesions around blood vessels.
- Echocardiography can reveal intracardiac mass lesions.
- Computerized tomography and magnetic resonance imaging angiography are advanced methods to evaluate vascular mass lesions.
- Radiopharmaceutical studies may be helpful to identify tumors of neural crest origin (chemodectoma, pheochromocytoma).
- Although blood tests are not diagnostic for vascular tumors, an elevated cTnI concentration in an animal with pericardial effusion is supportive of the presence of hemangiosarcoma. Patients may be anemic due to blood loss in cases of severe hemopericardium, or exhibit the nonregenerative anemia of chronic illness. Evidence of disseminated intravascular coagulopathy may be noted.

Treatment

- Treatment of vascular neoplasia is complicated and requires surgery, and possibly chemotherapy (see Chapter 26). Most patients should be transferred to a referral hospital for advanced imaging, staging, and management.

ARTERIOVENOUS FISTULA

Etiology

- An arteriovenous (AV) fistula is a congenital or acquired communication between artery and vein.
- Congenital lesions tend to be multiple and involve the limbs or the thorax.
- A post-traumatic fistula is usually a single direct connection associated with abnormal healing of the injured blood vessels; a limb, an ear, or even the tail may be affected.
- Rarely, declawing operations and tumors have been associated with AV fistula formation in the feline paw.
- Thyroid carcinoma may lead to a cervical AV communication in dogs. AV fistulas also have been reported secondary to other tumors.
- An hepatic AV fistula is a special type of congenital vascular malformation. This condition usually is associated with portal hypertension and ascites (see Chapter 71).
- Multiple congenital aortic to pulmonary fistulas may create a pathophysiology similar to patent ductus arteriosus.

Clinical Signs

- Clinical signs of an AV fistula include local vascular changes (due to venous hypertension) and cardiac manifestations (due to increased cardiac output required to perfuse the shunt). Any combination of the following signs may be observed:
- AV fistulas are most common in a limb; associated signs may include: subcutaneous edema, pain, inability to use the limb, a warm or cool extremity, distended and tortuous superficial veins, and abnormal tissue growth.
- A continuous murmur (bruit) may be detected by auscultation over the affected area as blood shunts continuously through the fistula.

▼ ***Key Point*** A positive Branham sign may be present in large AV shunts; slowing of the heart rate follows digital occlusion of the artery as the result of a sudden increase in arterial resistance and pressure.

- Multiple aortic-to-pulmonary AV fistulas usually lead to left heart enlargement from increased venous return. Pulmonary overcirculation may be evident.

However, due to the low resistance of multiple shunts (that eventually enter the pulmonary veins), a heart murmur may be absent making the initial diagnosis very difficult.
- A large AV fistula will increase cardiac output (equal to the shunt flow). Compensation may be manifested by tachycardia, cardiomegaly, and increased pulmonary vascularity
- Increased cardiac work, cardiac dilation, renal retention of sodium and water, elevation of venous filling pressures, and eventually congestive heart failure (in the case of large shunts).

Diagnosis

- Diagnosis of AV fistula is made by clinical signs, ultrasonography (including Doppler studies), and selective angiography if necessary. These studies may generally require transfer of the patient to a referral hospital.

Treatment

- Ligation or removal of the shunt is the treatment of choice.
- The surgical approach usually is guided by imaging and vascular contrast studies.
- Other methods of vessel occlusion (e.g., catheter-delivered "umbrellas" or "coils") have not been used routinely in veterinary practice but can be useful in single fistulas that are clearly demarcated by angiography.
- The prognosis is good for animals with acquired AV fistulas that are not associated with malignancy.
- Congenital AV fistulas may be problematic and involve difficult surgical procedures.
- Limb amputation may be necessary if the exact location of the shunt cannot be isolated and ligated or if the limb becomes devitalized (see Chapter 116).
- Management of hepatic AV fistulas may require partial hepatectomy of the involved lobe.

Chapter

154 Congenital Heart Disease

Henry W. Green / John D. Bonagura

ETIOLOGY

- Congenital heart disease (CHD) is a general term indicating malformation of the heart or great vessels. CHD is present at birth and represents the most common cause of cardiovascular disease in animals younger than 1 year of age.
- Diagnosis, staging, and management of CHD can be complicated, and the purpose of this chapter is to offer a framework for recognition and understanding of common cardiac malformations in dogs and cats.
- Common defects based on prevalence in referral centers include:
  - In dogs: patent ductus arteriosus (PDA), subvalvular aortic stenosis (SAS), pulmonic stenosis (PS), atrial and ventricular septal defects (ASD, VSD), mitral and tricuspid valvular dysplasia (malformation), persistent right aortic arch, tetralogy of Fallot, and cor triatriatum dexter.
  - In cats: atrial and ventricular septal defects, mitral and tricuspid valve dysplasia, patent ductus arteriosus, tetralogy of Fallot, and aortic stenosis.
  - Congenital peritoneopericardial diaphragmatic hernia is a common defect of the diaphragm and pericardium (see Chapter 151).

▼ ***Key Point*** Most congenital heart defects are considered to have a genetic basis, but the mode of inheritance is most often unknown or impacted by multiple genes.

- Even in cases of suspected autosomal dominant inheritance, the penetrance of the lesion may be incomplete, making clinical recognition difficult or impossible. Furthermore, there are no genetic tests available for detection of carriers. This situation makes genetic counseling difficult.
  - Animals with even mild CHD should not be bred.
  - Dogs or bitches with normal cardiac phenotype that produce CHD-affected puppies in more than one litter should be removed from breeding programs.
  - Breeding dogs with equivocal cardiac status based on echocardiography and Doppler studies should be bred only if other important characteristics are considered strong or outstanding.
- Other factors—including environmental, chromosomal, infectious, toxicologic, nutritional, and drug-related—may result in CHD; however, little is known concerning the direct cause and effect relationships in dogs and cats.

CLINICAL APPROACH

The vast majority of CHD cases are recognized initially by cardiac auscultation. A routine 6-lead electrocardiogram (ECG) and thoracic radiographs will also provide diagnostic information in cases of moderate to severe CHD; however, these studies are likely to be negative in mild disease. Definitive diagnosis requires advanced echocardiography with Doppler studies. The general approach to diagnosis based on initial auscultation findings is summarized in Figure 154-1 along with typical ECG and radiographic features. The following are some pointers regarding diagnosis and assessment of CHD in dogs and cats.

- As a general rule, soft ejection type murmurs in otherwise healthy puppies or kittens can be followed through the vaccine sequence. Increasing murmur intensity, other physical abnormalities (stunted growth, cyanosis), or any suggestion of clinical signs (exercise intolerance, dyspnea) should prompt immediate evaluation by a veterinarian with experience in congenital heart disease. A loud systolic murmur, a diastolic murmur, or a continuous murmur is not likely to be innocent and should be evaluated promptly.
- The signalment, physical examination findings, 6- or 9-lead ECG, and thoracic radiographs may provide a provisional diagnosis and help to guide any initial treatment plans.
  - PDA, VSD, SAS, and mitral valve malformation are more likely to lead to left-sided cardiomegaly, a finding that may be evident on ECG or thoracic radiographs. With ASD, PS, and tricuspid valve malformation, right-sided cardiomegaly might be identified.

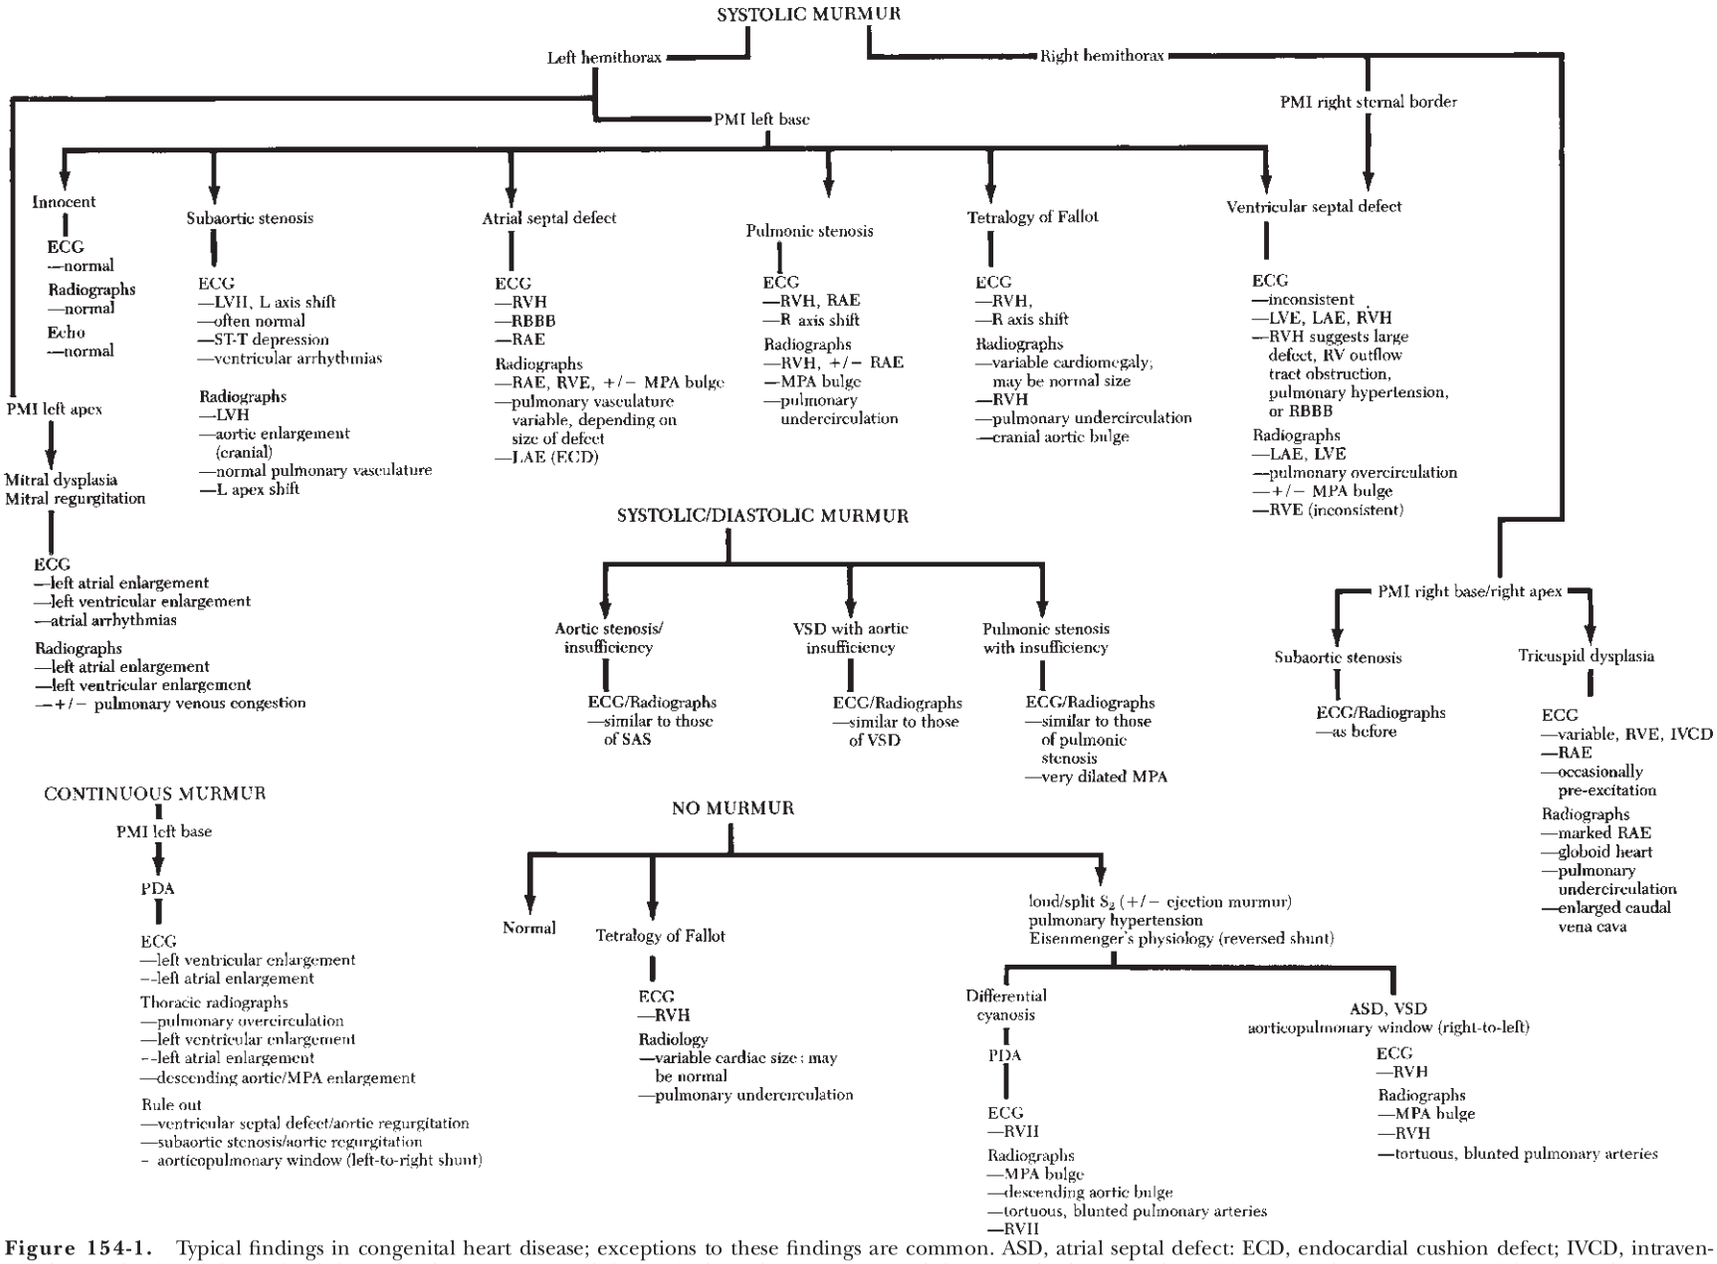

Figure 154-1. Typical findings in congenital heart disease; exceptions to these findings are common. ASD, atrial septal defect: ECD, endocardial cushion defect; IVCD, intraventricular conduction defect; LAE, left atrial enlargement; LVE, left ventricular enlargement; LVH, left ventricular hypertrophy; MPA, main pulmonary artery; PDA, patent ductus arteriosus; PMI point of maximal intensity; RAE, right atrial enlargement; RBBB, right bundle branch block; RV, right ventricle; RVE, right ventricular enlargement; RVH, right ventricular hypertrophy; SAS, subaortic stenosis; VSD, ventricular septal defect.

- Radiographs are particularly helpful for recognizing pulmonary vascular changes and congestive heart failure (CHF). However, such examinations are not definitive in terms of diagnosis, and do not substitute for expert evaluation using echocardiographic techniques.

▼ ***Key Point*** Definitive diagnosis and staging of CHD requires advanced imaging with echocardiography and Doppler studies. In ambiguous cases, cardiac catheterization and angiocardiography are necessary. Advanced cardiac evaluations are best obtained by referral to a cardiologist.

- When a dog or cat is suspected of having CHD consider the following points:
  - Animals presenting with one defect may have concurrent or complicating cardiac issues. For example, combinations of outflow tract obstruction and atrioventricular valvular dysplasia generate a less favorable prognosis. In chronic volume overload, as with uncorrected PDA, progressive myocardial failure or development of atrial fibrillation can impact prognosis negatively.
  - Young animals with relatively severe lesions often appear totally normal to the client and may remain compensated for months to years. The presence of exertional symptoms is generally an indication of serious CHD. Delaying cardiac evaluation until the onset of clinical signs is a serious clinical error, as by that time therapeutic options may be limited or less effective.
  - Early therapeutic intervention may slow or eliminate irreversible myocardial damage and prevent heart failure. For example, after successful closure of a PDA, most dogs will live a normal life without need for cardiac follow-up.
  - CHF or arrhythmic death may occur suddenly and unexpectedly in dogs or cats with CHD.
- Progressive pulmonary vascular disease develops in some patients with left-to-right shunts (PDA, VSD, ASD, aorticopulmonary window) or congenital mitral stenosis. Elevated vascular resistance can cause severe pulmonary hypertension (PH) in these patients.
  - PH due to vascular injury and high resistance increases pulmonary artery, right ventricular (RV), and right atrial pressures; reduces left-to-right shunting; and limits venous return to the left atrium.
  - This development usually improves symptoms (and facilitates growth), but the benefit is temporary. Severe pulmonary vascular disease eventually limits cardiac output, causes progressive exercise intolerance, and often leads to arterial desaturation (a reduced oxygen content due to low partial pressure of oxygen). Desaturation is related to either right-to-left shunting of blood across a defect (Eisenmenger's physiology) or development of bronchoesophageal collateral vessels that mix low-oxygen venous return with pulmonary venous blood.
  - A typical consequence of shunt reversal is progressive secondary polycythemia, a complication that can lead to a markedly elevated hematocrit and hyperviscosity syndrome.
  - Advanced pulmonary vascular disease changes the examination findings to that of marked RV hypertrophy, pulmonary artery dilation, and reduced size of the left heart chambers. In the case of shunt lesions, the right-to-left shunt serves as a needed pressure-relief valve for the right side, but predisposes to arterial desaturation and polycythemia. This situation is generally irreversible and explains why a "reversed" PDA cannot be corrected surgically without fatal consequences.

DIAGNOSIS

The balance of this chapter discusses the general approach to recognition of cardiac malformations from the perspective of the first examiner. Key points about prevalence, physical examination, and interpretation of diagnostic studies is presented along with an overview of management options for common defects. The reader is referred to the supplemental reading for a more complete review of specific defects and various complications of CHD.

Despite the technical advances in cardiology, a thorough history and physical examination is an essential part of the diagnostic process. In the evaluation of CHD, cardiac auscultation is especially important (Fig. 154-1), and experienced examiners can often establish a tentative diagnosis based on auscultation and breed predisposition (Table 154-1).

Signalment and History

Age, breed, and sex should be considered when evaluating animals for suspected CHD. As many specific breed predilections are identified—especially in dogs—a predisposition can be useful in formulating the differential diagnoses. Table 154-1 is a guide to breed for the most commonly recognized disorders, but is not a comprehensive listing.

- CHD is most often an incidental finding, discovered at the time of initial immunization.
- Most animals with CHD are asymptomatic when first examined, often in the face of hemodynamically severe defects. Thus do not conclude that the defect is mild in a patient with an unremarkable history.
- *Stunted growth* often indicates a patient with CHF or a right-to-left shunt (cyanotic heart disease). Signs of CHF may include coughing, exercise intolerance, orthopnea, tachypnea, respiratory distress, or abdominal distension.

Table 154-1. BREED AND SEX PREDILECTIONS FOR CERTAIN CONGENITAL CARDIAC DEFECTS*

Defect	Predilection
Patent ductus arteriosus (PDA)	Poodle, Bichon friese, collie, Pomeranian, German shepherd, Shetland sheepdog, and many other breeds (female : male, 2.2 : 1)
Pulmonic stenosis (PS)	Beagle, bulldog, fox terrier, miniature schnauzer, Chihuahua, Samoyed, Labrador retriever
Subaortic stenosis (SAS)	Newfoundland, boxer, German shepherd, German shorthaired pointer, golden retriever, rottweiler, bull terrier
Ventricular septal defect (VSD)	English bulldog, springer spaniel
Atrial septal defect (ASD)	Samoyed, boxer, Doberman pinscher
Mitral dysplasia	Great Dane, German shepherd, bull terrier (male > female)
Tricuspid dysplasia	Great Dane, German shepherd, Weimaraner, Labrador retriever (male > female)
Tetralogy of Fallot	Keeshond, English bulldog

**Note:* SAS, PDA, and PS are the most common defects in dogs. ASD/VSD and atrioventricular valve dysplasias are the most common defects in cats.

- *Exercise intolerance* is usually a sign of advanced CHD.
- *Syncope and exertional collapse* are usually signs of severe CHD and may be related to:
  - Right-to-left shunts (hypoxemia)
  - Ventricular outflow tract obstruction (e.g. aortic and pulmonic stenosis)
  - Intermittent ventricular arrhythmias
  - Inappropriate activation of cardiac baroreceptors following sympathetic stimulation (reflex-mediated syncope)
  - CHF

Physical Examination

Exam findings of particular importance in CHD include palpation of the precordium, auscultation of the heart, evaluation of the femoral arterial and jugular venous pulses, and inspection of mucous membranes. In addition, perform a careful respiratory and abdominal evaluation for signs of left- or right-sided CHF.

Precordial Palpation

The left and right apical impulses—the points of the strongest cardiac movements on each side of the thorax—identify the relative mitral valve area on the left and the tricuspid valve area on the right. Palpation is useful in localizing normal and abnormal cardiac sounds.

- A precordial heave is an apical impulse that is stronger than normal and often indicates hypertrophy or enlargement of the underlying ventricle. RV hypertrophy is suggested by a right-sided impulse of greater intensity than that on the left. Caudal displacement of the left apical impulse beyond the 6th intercostal space (ICS) may indicate cardiac dilatation.
- A precordial thrill is a palpable vibration, a manifestation of a loud heart murmur that identifies the point of maximum intensity (PMI).

Cardiac Murmurs

- Murmur characteristics may be suggestive of a particular cardiac defect (see Fig. 154-1 and Chapter 142). Most murmurs associated with CHD are systolic. A continuous murmur is due to PDA or, rarely, from an aorticopulmonary window. A diastolic murmur is most likely due to aortic regurgitation, a condition that may coexist with VSD, aortic valvular malformation, or SAS complicated by aortic valvular endocarditis. Atrioventricular valvular stenosis (or supravalvular stenotic ring) is a rare cause of diastolic heart murmurs.
- Distinguishing an innocent (functional) murmur from one caused by CHD, especially in the case of mild aortic stenosis or trivial mitral malformation, may be difficult if not impossible.
  - Murmurs caused by clinically-significant CHD are typically louder and of longer duration than innocent murmurs.
  - Innocent murmurs are often intermittent, may be musical, and usually diminish or resolve by 16 to 24 weeks of age. Murmurs that persist are more likely to suggest cardiac malformation.
  - A particularly difficult issue for breeders is the persistence of a soft ejection murmur in the absence of an echocardiographic imaging lesion. It may be impossible to determine if CHD is present or not.
- With the exception of ventricular outlet obstruction (SAS or PS), murmur intensity or duration does not correlate reliably with the severity of the cardiac lesion. For example, dogs with severe tricuspid valve dysplasia may have soft murmurs, whereas a small and restrictive VSD can create a very loud murmur.
- A murmur may be soft or absent in the following serious situations: right-to-left shunting defects with polycythemia, pulmonary or aortic atresia, large unrestrictive VSD, tricuspid dysplasia, or severe PH.

Pulse Evaluation

Inspect the jugular venous pulse and palpate the femoral arterial pulse. The arterial pulse character depends on the pulse pressure (systolic minus diastolic pressure), the stroke volume of the left ventricle (LV), and the rate of pressure rise during LV ejection.

- *Jugular venous distension* or pulsations suggest right-sided heart disease, for example, PS, tricuspid regurgitation, or right-sided CHF.
- Weak, hypokinetic, or late-rising arterial pulses suggest outflow obstruction as in significant subaortic stenosis, LV dysfunction, volume depletion, or heart failure. Conversely, bounding (hyperkinetic or waterhammer) pulses are most commonly associated with PDA or aortic regurgitation, as these situations create a wide pulse pressure.

Mucous Membranes

- Normal membranes are pink with a capillary refill time of <2 seconds. Membrane pallor suggests poor perfusion or anemia (evaluate for intestinal parasitism, especially hookworm infection). Pallor and prolonged refill time suggest heart failure or reduced blood pressure with reactive vasoconstriction.
- *Cyanosis* (blue-colored mucous membranes) develops from a low arterial oxygen tension with >5g/dl of desaturated hemoglobin. Pulmonary dysfunction due to left-sided CHF or concurrent bronchopneumonia is the most common cause of cyanosis in CHD. Lesions that allow right-to-left shunting, such as tetralogy of Fallot, can lead to persistent or exercise-induced cyanosis in the absence of pulmonary dysfunction.
  - *Right-to-left shunting* requires a source of high right-sided resistance, and a communication or shunt proximal to the obstruction. With this combination, desaturated right-sided blood may enter the left side of the circulation.
  - Reasons for high resistance include PH from high vascular resistance, PS, mid-RV obstruction, and tricuspid valve disease (either stenosis or severe regurgitation that raises right atrial pressure).
  - The lesion allowing shunting can be a patent foramen ovale, ASD, VSD, or PDA. Additionally, in certain complex defects, there may be only a single great vessel exiting the heart; one ventricle that serves each great vessel; or transposition of the great vessels. Each of these situations allows mixing of pulmonary venous and systemic venous blood and may lead to cyanosis.
  - The term "*differential cyanosis*" generally refers to the condition of pink oral membranes and cyanotic caudal membranes (best seen in the vulva or prepuce). This is most typical of reversed PDA caused by a large ductus and severe PH.

Electrocardiography

The ECG is of little value in recognition of mild CHD. Diagnostic yield increases when evaluating rhythm disturbances or identifying cardiac chamber enlargement in the presence of moderate to severe cardiomegaly (see Chapter 144). Common chamber enlargement patterns are summarized below.

- Left-Ventricular Hypertrophy—Tall R waves >2.5 to 3.0 mV in lead II in dogs or >0.9 mV in cats usually indicate eccentric hypertrophy of the LV. A left axis deviation is also compatible with concentric LV hypertrophy, though septal defects may lead to a similar axis shift. Common causes of LV enlargement include PDA, SAS, VSD, and mitral valve dysplasia.
- Right-Ventricular Hypertrophy—Right axis deviation with S waves in leads I, II, III, aVF, and V2 to V6 suggest RV hypertrophy. Common causes include PS, tetralogy of Fallot, ASD, tricuspid dysplasia, and PH. Splintered R-waves also may be observed with tricuspid valve malformation.
- Atrial Enlargement—a P wave duration of >0.04 seconds is suggestive of left or right atrial dilation; a P wave >0.4mV in dogs indicates right atrial dilation.

Thoracic Radiography

Routine thoracic radiography is used for evaluation of cardiac size and chamber enlargement; assessment of the great vessels; and evaluation of pulmonary circulatory dynamics (see Chapter 143).

- Determination of left-sided vs. right-sided cardiomegaly is informative in the differential diagnosis of CHD. While echocardiography is a more accurate method for assessing chamber size and wall thicknesses, the radiograph may be helpful. In particular, marked elongation of the heart is suggestive of LV dilatation, as with PDA. Conversely, concentric hypertrophy of a ventricle secondary to outflow obstruction may be underestimated by radiography.
- Remember that young puppies have a relatively dominant RV shadow until approximately 8 to 12 weeks of age.
- Dilation of the main pulmonary artery is suggestive of PS, a left-to-right shunt, or PH.
- Dilatation of the ascending aorta is typical of subaortic stenosis and pulmonary atresia; dilation in the descending aorta is typical of PDA (ductus bump).
- Radiographs are especially helpful for observing pulmonary vascular changes as with left-to-right shunts (overcirculation) or right-to-left shunts or severe PS (undercirculation).
- Radiographs also provide objective proof for the presence or absence of CHF.
- Radiographic changes associated with common malformations are summarized in Figure 154-1.

Echocardiography

Echocardiography represents a noninvasive method for obtaining detailed images of cardiac anatomy and assessment of cardiac function. Supplemented with Doppler studies of blood flow, the echocardiographic examination has largely replaced invasive cardiac

catheterization and angiocardiography for definitive diagnosis of CHD. Echocardiography provides information that is not only diagnostic but also supportive of surgical and catheter-based therapeutic interventions.

- Two-dimensional (2D) echocardiography allows identification of the anatomical defect(s). Among lesions that can be imaged are patent foramen ovale, ASD, VSD, PS, SAS, mitral valvular malformation, tricuspid valvular malformation, and the internal structure of a PDA. An estimate of the size and severity of a defect can also be obtained with high quality 2D images.

▼ ***Key Point*** Trivial or mild lesions of CHD may not be evident by 2D imaging.

- With 2D and M-mode imaging, the degree of myocardial hypertrophy or chamber dilation can be assessed as well as subsequent functional changes in heart function. This allows evaluation of overall significance of the cardiac lesion. Mild disease usually causes few anatomic or functional changes in the heart.
- Color and spectral Doppler echocardiography are used to detect normal and abnormal blood flow and measure the direction and velocity of blood flow in the heart and great vessels. Doppler studies can be used to provide estimates of intracardiac pressures. Combined with 2D imaging, these modalities provide highly accurate, noninvasive quantitation of the severity of a cardiac lesion. Doppler methods also may allow estimation of pulmonary arterial pressure, shunt ratio, magnitude of stenosis, and regurgitant fraction.
- Contrast echocardiography can be performed by injecting agitated saline or other gas-containing microbubbles into a peripheral vein to improve detection of cardiac shunting defects (particularly right-to-left shunts). These studies can be performed when Doppler technology isn't available or to improve Doppler echocardiographic studies.
- A summary of common echocardiographic findings in CHD is found in Table 154-2.

Cardiac Catheterization

Cardiac catheterization is an invasive procedure useful for diagnosing structural malformation and assessing physiologic abnormalities when echocardiographic Doppler studies are equivocal or when therapeutic, catheter-based intervention is beneficial. Because of its relatively invasive nature and the necessity for general anesthesia, catheterization has limited applications. These include:

Table 154-2. ECHOCARDIOGRAPHIC AND DOPPLER FEATURES OF SELECT CONGENITAL HEART DEFECTS

Defects	Echocardiographic and Doppler Features
Patent ductus arteriosus (PDA)	Dilated left atrium, left ventricle, and pulmonary trunk; possible identification of PDA; turbulent flow in main pulmonary artery, with retrograde diastolic flow and increased transmitral and aortic flow velocities, reduced LV systolic myocardial function
Pulmonic stenosis (PS)	Right ventricular hypertrophy, right atrial and pulmonary artery enlargement, outflow tract obstruction, thickened valve leaflets, septal flattening and/or paradoxical septal motion, high-velocity flow (>1.5 m/sec) across the pulmonic valve
Subaortic stenosis (SAS)	Left ventricular (LV) hypertrophy, dilated aorta, subvalvular narrowing, high-velocity flow (>2.0 m/sec) across the aortic valve
Ventricular septal defect (VSD)	Variable chamber enlargement, most commonly left atrial and ventricular, possible identification of defect, right ventricular hypertrophy if pulmonary hypertension (PH) or very large defect, visualization of flow across defect, may be bidirectional; increased transmitral and PA flow velocity, right-to-left shunt in the case of PH (Doppler or bubble study)
Atrial septal defect (ASD)	Right atrial and ventricular enlargement, possible identification of defect, main pulmonary artery enlargement, flow across defect, increased velocity flow across tricuspid (diastole) and pulmonic (systole) valves
Mitral valve dysplasia	Left atrial and left ventricular enlargement, abnormal mitral valve anatomy, increased transmitral diastolic flow velocity, turbulent retrograde systolic transmitral flow
Tricuspid valve dysplasia	Right atrial and ventricular enlargement, abnormal tricuspid valve anatomy, increased transtricuspid diastolic flow velocity, turbulent retrograde systolic transtricuspid flow
Tetralogy of Fallot	Right ventricular hypertrophy, right ventricular outflow tract obstruction, identification of VSD, overriding aorta, small left heart, contrast study indicating right-to-left shunting, septal flattening and flattening and/or paradoxical septal motion, right-to-left flow across VSD (Doppler or bubble study), decreased diastolic transmitral flow, possibly increased transaortic systolic flow, increased flow velocity across the pulmonic valve
Pulmonary hypertension (PH)	Right ventricular hypertrophy, right atrial enlargement, dilated main pulmonary artery, visualization of associated shunt, right-to-left shunt by Doppler or bubble study, increased flow *acceleration* across pulmonary valve

- Delineating ambiguous anatomic lesions.
- Identifying vascular abnormalities that evade ultrasound studies, such as some systemic to pulmonary shunts or multiple arteriovenous fistulas.
- Facilitating interventions such as balloon valvuloplasty for PS, balloon dilation for severe SAS, or transcatheter occlusion of shunts.

These procedures require referral to a cardiologist or a clinical specialist with advanced training, equipment, and expertise in the diagnosis and management of CHD.

TREATMENT OF COMPLICATIONS OF CONGENITAL HEART DISEASE

Definitive or palliative therapy for CHD often requires surgery or a catheter-based intervention. Prior to such treatments, establish a definitive diagnosis. Symptomatic medical therapy can be directed for complications of severe CHD such as CHF or arrhythmias. PH is a problematic complication to address. Severe polycythemia also requires management.

Congestive Heart Failure

- Most forms of CHD lead to progressive volume or pressure overload of the affected ventricle. With time, diastolic and systolic ventricular function decline and cardiac output becomes limited. This situation is worsened by development of mitral or tricuspid valvular regurgitation or atrial fibrillation. The end-result is development of left- or right-sided CHF.
- An important differential diagnostic consideration for right-sided CHF in a puppy or a young dog is cor triatriatum dexter. This disorder is characterized by the partitioning of the right atrium by an obstructive membrane that impairs venous return from the caudal vena cava.
- When CHD progresses to CHF, the medical therapy is very similar to that used for acquired heart disease (detailed in Chapter 147).
- Initial management of left-sided CHF involves treatment with furosemide (2–4 mg/kg IV, IM, or SC), oxygen, and 2% nitroglycerine ointment. Sedation with butorphanol (0.25 mg/kg IM or SC) may be added if necessary.
  - If this approach fails to control the CHF, and the cause is a left-to-right shunt, sodium nitroprusside (0.5–2.5 mcg/kg/min infusion) can be used to reduce the arterial pressure and magnitude of shunting.
  - Alternatively, enalapril or another angiotensin-converting enzyme inhibitor (ACEI) can be initiated to reduce afterload and reduce left-to-right shunting (see Chapter 147).
  - Maintain systolic blood pressure in the 80 to 120 mm Hg range, particularly in cases of aortic stenosis where hypotension can reduce coronary perfusion.
- Chronic medical therapy of CHF in dogs with CHD is identical to that described in Chapter 147 and includes furosemide, an ACEI, spironolactone, and often digoxin or (where available) pimobendan. In cats, the initial use of furosemide and an ACEI is appropriate.
- The use of beta-blockers in treatment of dogs with CHF is unresolved, and care must be used to avoid bradycardia, especially in dogs with fixed obstructions such as SAS and PS, as cardiac output in these conditions is relatively heart-rate dependent. For dogs already taking beta-blockers as cardioprotection, once CHF develops, the beta-blocker should be continued, the dosage reduced if needed to obtain a target examination heart rate in the 100 to 140/min range.
- In some cases, medical therapy for CHF may be discontinued if definitive repair of the defect can be successfully performed. This is particularly true in young dogs or cats with PDA.

Arrhythmias

- Controlling arrhythmias in the setting of severe CHD may help to maintain a compensated state and to prevent sudden death.
- Atrial fibrillation is particularly destabilizing to dogs with CHF; treat to achieve heart rate control with digoxin, diltiazem, and a beta-blocker. Electrical cardioversion is another option to restore sinus rhythm. Specific therapy of arrhythmias is discussed in Chapter 145.
- Re-entrant supraventricular tachycardia due to an accessory pathway may be encountered in some dogs with tricuspid dysplasia, particularly Labrador retrievers.
- Ventricular arrhythmias have been particularly associated with SAS and PS. Holter ECG monitoring may be indicated to screen for rhythm disturbances, especially in dogs with exertional symptoms. Chronic therapy of clinically significant ventricular tachycardia may include sotalol, mexiletine plus a beta-blocker, amiodarone, or procainamide.

Pulmonary Hypertension

- The presence of PH due to high vascular resistance is difficult to manage, as the vascular changes responsible are typically irreversible. The evaluation of PH usually requires referral to a specialist experienced in CHD.
- PH usually develops rapidly in dogs with large left-to-right shunts. In cats it is more gradual and, if caught, can be arrested by closure of a left-to-right shunt. Drugs that reduce pulmonary vascular resistance such as sildenafil (Viagra) at initial doses of 0.5 to 2 mg/kg q12h PO may be beneficial in cases of

advanced PH. Currently this therapy is very expensive. Arterial blood pressure must be monitored, as reduced systemic resistance will lead to greater right-to-left shunting.
- Controlled exercise is important to prevent exertional collapse or dyspnea. This may be difficult to achieve in puppies or kittens.

Polycythemia

- In cases of right-to-left shunting due to obstructive lesions of the right heart (PS, tricuspid stenosis), balloon valvuloplasty or surgery may decrease right-sided pressures and control the cause of shunting. Care must be exercised with a large ventricular septal defect, since florid left-to-right shunting may develop across the VSD.
- Phlebotomy may be required in patients with right-to-left shunting and secondary polycythemia. A packed cell volume (PCV) of 62% to 65% is often well tolerated, but values exceeding 68% to 70% are likely to cause exercise difficulties or stroke-like signs.
- Usual treatment measures for polycythemia include periodic phlebotomy with replacement by IV or subcutaneous crystalloid fluid (see Chapter 22 for a discussion of management of polycythemia).
- When the need for phlebotomy becomes too frequent, bone marrow suppression can be attempted using hydroxyurea. Treatment may not work, and anorexia, gastrointestinal disturbances, and skin rash may limit tolerability of the drug. A regular complete blood count and platelet count should be performed.

TREATMENT AND PROGNOSIS OF SPECIFIC DEFECTS

In addition to management of complications of CHD discussed above, the potential to more definitely treat the specific malformation is inviting. Unfortunately, many of these conditions require an operation during cardiopulmonary bypass by a highly skilled cardiothoracic surgeon. Even extracardiac procedures such as PDA ligation or catheter-based treatments for PDA or PS can end badly if the clinician is inexperienced.

▼ ***Key Point*** Surgical or interventional management of cardiac defects should be performed only by properly trained and experienced clinicians in a fully equipped and staffed hospital.

Patent Ductus Arteriosus

- Closure is strongly recommended in left-to-right shunting defects as the 1-year mortality for untreated dogs exceeds 60%. In the reversed (right-to-left) shunting PDA, closure of the defect is contraindicated and therapy is focused on reducing complications of PH and polycythemia by periodic phlebotomy (see above).
- Thoracotomy and surgical ligation of the ductus is very successful with perioperative mortality that should be <5% at experienced surgical centers (see Chapter 155). Closure generally results in complete resolution of signs. A postoperative murmur of mitral regurgitation is common, due to LV stretch, but is generally gone by the time of suture removal.
- Less invasive transcatheter techniques for closure of PDA have gained significant popularity and have superseded surgery at some institutions. As with surgery, success is greatest in the hands of experienced operators. Embolization coils are best suited for small to medium diameter defects; the Amplatzer occluding device has been used for larger diameter (>4mm) defects.
- The prognosis following isolated closure of a PDA is excellent. A normal lifespan can be anticipated, and most cases do not require any cardiac follow-up. Exceptions to this rule include dogs with marked LV systolic dysfunction (determined by echocardiography), dogs with prior CHF, or dogs with atrial fibrillation. Refer these patients to a cardiologist for evaluation.
- Reversed PDA has a poor prognosis, though with vigilant therapy some patients live beyond 5 years of age, affected mainly by rear limb weakness during exercise.

Ventricular and Atrial Septal Defects

- Surgical closure of septal defects is the definitive treatment but requires cardiopulmonary bypass and open heart surgery. While this has been successfully performed, it is not commonly practiced in veterinary medicine.
- Palliative pulmonary arterial banding, creating a supravalvular PS, has been used successfully to reduce the left-to-right shunt of a VSD. This procedure is recommended only for those animals with rapidly progressive cardiomegaly and overt or impending CHF. Simple cardiomegaly is not an indication for banding, as very few of these patients ever develop CHF.
- Transcatheter occlusion devices have been developed for closure of septal defects, but are still experimental.
- Right-to-left shunting may develop in dogs or cats with VSD due to PH, valvular or subvalvular PS, or progressive, mid-ventricular fibromuscular obstruction (so-called double-chambered RV). Exercise intolerance and polycythemia may develop. Treatment is as described above for polycythemia.
- The prognosis for septal defects is variable.
  - CHF associated with ASD is rare in dogs, but may develop in cats, especially in those with endocardial cushion defects and large communications.

- A small, restrictive VSD carries an excellent prognosis for longevity. CHF associated with VSD is actually quite rare because most patients are "naturally-selected" for smaller defects and rarely require any intervention. Thus, the prognosis for dogs that attain 16 weeks of age without signs of CHF is good.
- The exception is the dog with a VSD and aortic root prolapse or aortic malalignment defects because severe (audible) aortic regurgitation may occur, and CHF can develop in middle age from LV volume overload.
- Cats with VSD are more likely to develop CHF, especially if the detect is large (50% of aortic diameter).

Tetralogy of Fallot

- Definitive surgical treatment for tetralogy of Fallot includes closure of the VSD and removal or bypass of the stenosis under cardiopulmonary bypass.
- Palliative surgery involves creation of an extra-cardiac shunt between the systemic and pulmonary circulations (e.g., Blalock-Tausig shunt). Such shunts increase pulmonary flow, improve arterial saturation, and may produce significant clinical improvement. The major limitation is the extent to which these shunts will remain patent.
- Animals with a sedentary lifestyle will often tolerate this disease well, especially if the PS is not too severe. Some will live for 5 or more years. Exercise creates vasodilation in skeletal muscle and increases tissue oxygen demands; accordingly, most tetralogy of Fallot patients have signs of tachypnea and exercise intolerance with exertion.
- Sudden death is common consequent to progressive hypoxemia, polycythemia and cardiac arrhythmias.
- Avoid drugs that cause systemic vasodilation in these patients, as right-to-left shunting may be exacerbated.
- Beta-blockage with the nonspecific beta-blocker propranolol (start at 0.25 mg/kg PO q8h and up-titrate over 4 weeks to 1 mg/kg PO q8h) may be beneficial by reducing exercise-induced RV hyper-contractility, an event that can add a dynamic component to RV outflow obstruction. The $beta_2$ blocking effect should theoretically benefit by preventing some exercise-induced peripheral vasodilation.
- Manage polycythemia as described above (see Chapter 22).

Pulmonic Stenosis

- Transcatheter balloon valvuloplasty is the treatment of choice for PS when the lesion is characterized by valvular thickening with commissural fusion. In experienced hands the procedure mortality is <5% and the dilation results in a 50% or greater reduction of RV systolic pressures. If the cases are chosen carefully, almost all treated dogs will benefit. Therapy should not be delayed as gradients and muscular hypertrophy can progress with time and growth.
- When PS is complicated by severe muscular hypertrophy and subvalvular fibromuscular obstruction, balloon valvuloplasty combined with atenolol therapy (1–2 mg/kg PO, q12h) is the initial treatment of choice. In some cases the dynamic muscular obstruction resolves over time; otherwise, atenolol can be continued for life.
- Surgical techniques such as patch grafting, pulmonary valve repair or resection, or surgical dilation have been used and are still indicated in cases with severe (fibro-) muscular RV obstruction, a broad subvalvular fibrous ring, or in dogs where PS is complicated by marked pulmonary valvular hypoplasia.
- In cases that cannot be treated more definitively, atenolol provides cardiac protection and is well tolerated.
- PS with patent foramen ovale, ASD, or VSD may progress to right-to-left shunting with polycythemia, and is treated accordingly.
- Mild to moderate PS (peak pressure gradients measured by Doppler studies of <50 and 100 mm Hg, respectively) generally carry a good prognosis (survival of 8 years or more). Some dogs in the 75 to 100 mm Hg range do benefit from valvuloplasty in terms of exercise capacity and reduction of RV hypertrophy. Comparatively, severe disease (Doppler echocardiographic gradient >100 mmHg) increases the likelihood of sudden death or CHF.

Subaortic stenosis

- Aortic stenosis is rare in cats. In dogs, subvalvular obstructions are common and prognosis and management recommendations depend mainly on the magnitude of the peak pressure gradient as measured by Doppler echocardiography. As a general rule, gradients <50 mm Hg indicate mild SAS; peak Doppler-derived pressure gradients of >80 to 100 mm Hg indicate severe SAS.
- Transcatheter balloon dilation of the stenotic orifice has been performed and successfully reduces LV pressure gradients by approximately 50%. This benefit, however, becomes attenuated over time, and the procedure has largely been abandoned, though it may be a consideration for severe cases of SAS.
- Open surgical resection of the stenotic lesion provides the best long-term success in terms of reduction of gradients, but it requires cardiopulmonary bypass, and long-term survival has been disappointing.
- Beta-blockade with atenolol (1–2 mg/kg PO q12h) improves survival over historical controls and median survival of >4 years has been reported in dogs with even very severe SAS (>120 mm Hg). Atenolol is recommended for all dogs with a gradient >50 mm Hg.

Beta-blockade is particularly helpful in the specific situation of dynamic SAS caused by mitral valve malformation wherein beta-blockade may completely alleviate the obstruction and allow regression of LV hypertrophy.

- Unfortunately, severe SAS carries a discouraging prognosis owing to premature death. Sudden arrhythmic cardiac death and progressive LV dysfunction with development of CHF are typical outcomes. Mature dogs with mild SAS are more likely to live normal lives, though some still experience sudden death.
- Dogs with even mild disease are at higher risk for development of bacterial endocarditis. Therefore, administer prophylactic antibiotics during elective surgical procedures or whenever wound contamination is an issue.

Atrioventricular Valve Dysplasia (Stenosis)

- Balloon valvuloplasty has been performed with variable success in dogs with tricuspid and mitral valvular or supravalvular stenosis.
- Surgical repair of affected valves can be attempted. Replacement of dysplastic valves has been performed successfully with cardiopulmonary bypass.
- Most cases are treated medically when signs of CHF or atrial fibrillation develop. Consideration should be given to ACEI (enalapril) and to beta-blocker (carvedilol or metoprolol) therapy for establishing cardioprotection in dogs with severe mitral regurgitation and associated cardiomegaly.
- Tricuspid malformation, associated with an ASD, may lead to right-to-left shunting; secondary polycythemia should be managed (see under "Polycythemia").
- Mild mitral or tricuspid valvular dysplasia is often well tolerated; however, severe lesions lead to CHF and arrhythmias such as atrial fibrillation. Dogs with severe mitral disease usually develop CHF in early to middle age, particularly when the valve is both stenotic and incompetent. Many dogs with relatively severe tricuspid regurgitation survive for 7 or 8 years before CHF ensues.
- Tricuspid stenosis is typically associated with an ASD or patent foramen ovale, leading to secondary polycythemia.

Chapter

155 Surgical Correction of Patent Ductus Arteriosus

Eric R. Schertel

Ligation of the patent ductus arteriosus (PDA) in dogs and cats is a rewarding surgical procedure. When performed by an experienced surgeon, the combined operative/postoperative mortality rate is relatively low (8–10%) compared with surgery of other forms of congenital heart disease. The long-term prognosis after correction is excellent. However, like any thoracic or cardiovascular procedure, special attention to the details of anesthetic and surgical techniques is necessary for success. An accurate diagnosis is important, as is a thorough knowledge of the anatomy and physiology of the cardiovascular system.

ANATOMY AND PHYSIOLOGY

- The ductus arteriosus is a remnant of the left sixth aortic arch and connects the pulmonary artery and the descending aorta in the fetus and newborn. Its continued patency after birth results in left-to-right shunting of blood causing volume overload of the left atrium and ventricle. In severe cases, left ventricular failure may be present.
- The relationship of the descending aorta, main pulmonary artery, and right and left pulmonary arteries with the PDA must be appreciated (Fig. 155-1).
- The PDA may vary in size and shape but generally is approximately one-fifth to one-fourth the diameter of the aorta, or slightly smaller than the left main pulmonary artery. The PDA is usually short (0.5–1.0 cm), bridging the small distance between the aorta and pulmonary artery.
- The left vagus nerve lies over the ductus and is immediately underneath the visceral pleura. The recurrent laryngeal nerve arises from the vagus and courses caudal and medial to the PDA.
- Rarely, a persistent left cranial vena cava may be found coursing over the pulmonary artery. This does not pose a surgical problem in PDA ligation.

PREOPERATIVE AND PERIOPERATIVE CONSIDERATIONS

- Consult the chapter on congenital heart disease (see Chapter 154) for details of diagnosis and medical management.
- Institute conservative medical management before surgery when there is evidence of heart failure. More aggressive medical management may not benefit the patient as much as surgery.
- Mortality with surgery is higher when congestive heart failure (CHF), atrial fibrillation, or substantial myocardial failure is present. The mortality of nonsurgically managed PDA patients also is high. Thus, if conservative therapy for heart failure is not effective in 24 to 48 hours, surgery combined with intensive medical management is the appropriate course of action in most patients.
- Administer IV fluids judiciously during anesthesia and surgery, especially in animals with heart failure.
- Perioperative mortality is 8% to 10% according to published reports.
- Perioperative complications occur in 10% to 15% of cases.

LIGATION OF THE PATENT DUCTUS ARTERIOSUS

Objectives

- Careful exposure and definition of the ductus arteriosus through a left fourth intercostal space thoracotomy. (The left fifth space may be indicated in cats.)
- Double ligation of the ductus without trauma to the vessels or other surrounding structures.

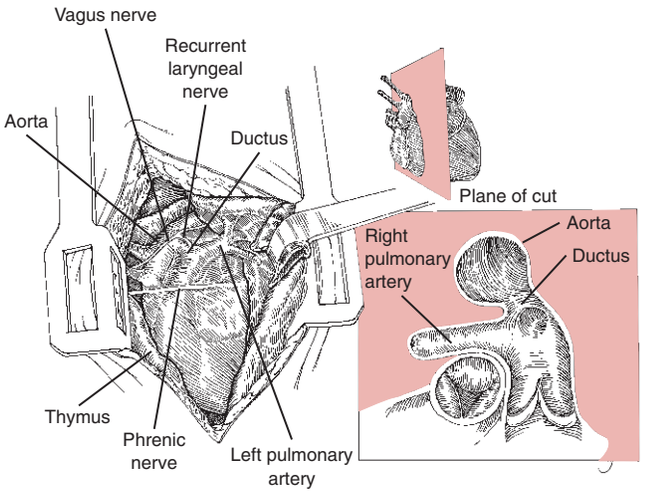

Figure 155-1. Retraction of the left cranial lobe of the lung allows exposure of the region of the ductus.

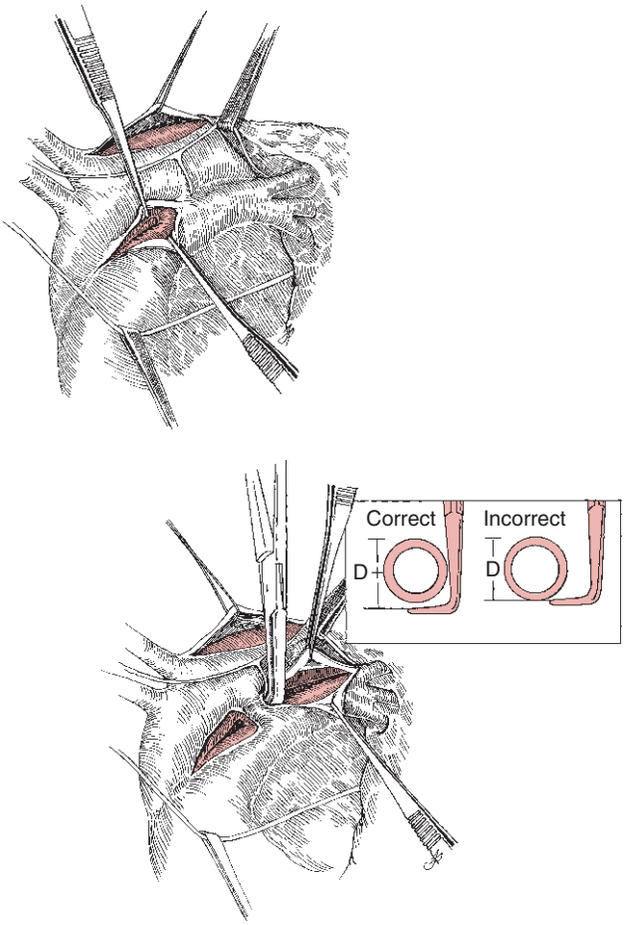

Figure 155-2. Exposure of the ductus. *Top,* Initial area of dissection. *Bottom,* Use of closed right-angle forceps to dissect the region behind the patent ductus arteriosus. See text for further details.

Equipment

- General surgery pack and standard suture, plus instruments required for thoracic surgery (see Chapter 167).
- Assorted sizes of right-angle forceps
- Vascular clamps, preferably pediatric/infant ductus clamps (three pairs)
- Multipurpose peripheral vascular clamps (two pairs)
- Suture; silk, sizes 3-0 up to 1-0, and non-absorbable, 5-0 or 6-0, on a cardiovascular needle

Technique

1. Use an appropriate anesthetic regimen based on the preoperative assessment of cardiac function (see Chapter 2 for discussion of anesthesia techniques). Positive pressure ventilation is required during the majority of the procedure.
2. Place the patient in right lateral recumbency. Clip and aseptically prepare the left thorax from the cranial border of the scapula to rib 13, and from the dorsal to the ventral midline. Include the left shoulder and axilla, and extend past the elbow.
3. Perform a standard left fourth intercostal space thoracotomy (see Chapter 167).
4. Identify the region of the ductus following caudal retraction of the left cranial lung lobe (see Fig. 155-1). Retract the lobe with a moist sponge or laparotomy pad.
5. Elevate the vagus nerve and encircle with silk suture or umbilical tape for retraction to expose the PDA. Identify the location of the recurrent laryngeal nerve as it courses from the vagus to the caudal aspect of the ductus.
6. Palpate the thrill in the main pulmonary artery for reference.
7. Begin blunt and sharp dissection cranial and caudal to the PDA. Extend the dissection caudally between the aorta and left main pulmonary artery for a distance of at least 1.5–2 times the diameter of the ductus (Fig. 155-2, *top*). Extend the dissection cranioventrally between the aorta and main pulmonary artery a similar distance. The depth of the dissection should be at least equal to the width of the ductus (Fig. 155-2, *inset*). Dissect adjacent to the relatively thick-walled aorta.
8. Consider preparing the craniodorsal aspect of the aorta just distal to the left subclavian artery by reflecting the pleura and adjacent mediastinal tissues. This requires a small amount of time and ensures a clear path for clamp placement if hemorrhage control is necessary (see below).
9. The pericardium has a variable insertion at the level of the ductus. It may be inserted on the aortic side or on the main pulmonary artery side of the ductus. Thus, the ductus occasionally is within the pericardium. In these circumstances, incise the pericardium at its insertion on the ductus or aorta.

10. Once the cranial and caudal aspects of the ductus are exposed, initiate blunt dissection behind the PDA using right-angle forceps (Fig. 155-2, *bottom*). Take care to identify the depth of the ductus. Accomplish dissection behind the ductus by inserting closed forceps, spreading gently, and removing the forceps. Carry out dissection *adjacent* and *parallel* to the surface of the aorta.
11. I prefer caudal to cranial dissection to avoid repeated work in the cranial aspect of the ductus. The vascular structures of the cranial region are more readily damaged and are most prone to hemorrhage. However, minor medial dissection in this area often is necessary.
12. When the majority of the medial dissection is complete, gently separate the aorta and main pulmonary artery cranial to the ductus to allow identification of the tips of the right-angle forceps as they are passed from caudal to cranial. When the tips are visible, carefully incise the remaining *fascia* over the tips of the forceps with a #15 blade. This is preferable to repeated efforts at pressing through this fascia.

▼ ***Key Point*** Do not cut any tissue unless you are certain that it is fascia and not vessel wall.

13. Individually pass two strands of 1-0, 2-0, or 3-0 silk or polyester suture, depending on the size of the dog or cat, and the size of the ductus (Fig. 155-3, *top*).
14. Attenuate the ductus prior to ligation to observe the hemodynamic effects. If bradycardia is observed, atropine may be given. Double-ligate the ductus, aortic side first. Palpate the pulmonary artery again for ductal-related thrill or turbulence.
15. If hemorrhage is encountered from perivascular structures, control with pressure, ligation, or cautery. If the ductus ruptures and aggressive hemorrhage is encountered, first use digital pressure to control blood loss. Next, place vascular clamps on the aorta in the previously prepared region just caudal to the left subclavian artery and cranial to the ductus (Fig. 155-3, *bottom*). Also place clamps caudal to the ductus on the aorta and across the base of the ductal origin from the pulmonary artery. Identify the region of hemorrhage and suture with 5-0 or 6-0 nonabsorbable suture on a cardiovascular needle. A recent study evaluated the use of deliberate hypotension for dogs with hemorrhage during PDA dissection. Intravenous nitroprusside was used to lower blood pressure and reduce bleeding, allowing continued dissection and ligation of the ductus. See Supplemental Reading for more information.
16. Subcutaneously tunnel a #5 or 8 Fr. red rubber tube from a small wound made caudal to the skin incision. Place the tube in the thorax through the thoracotomy. Close the thorax in a routine manner, incorporating the temporary thoracic tube (see Chapter 167).
17. After evacuating air and fluid from the thorax, remove the temporary thoracic tube. If hemorrhage or inadvertent lung injury occurs, place a standard indwelling thoracic tube (see Chapter 3).

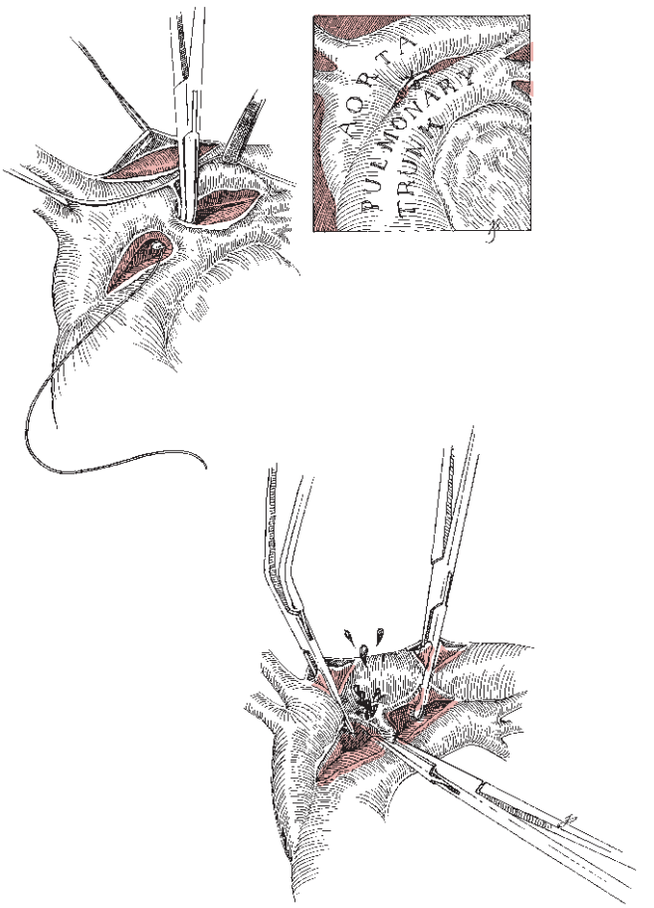

Figure 155-3. *Top,* Suture placement for double ligation of the ductus. *Bottom,* Procedure for controlling hemorrhage after ductus rupture.

POSTOPERATIVE CARE AND COMPLICATIONS

Short Term

▼ ***Key Point*** Close postoperative monitoring in an intensive care setting is of the utmost importance.

- Monitor the following parameters/signs:
  - Mucous membrane color, capillary refill time, respiratory rate, blood pressure
  - Dyspnea, urine output
  - Recovery of body temperature, pulse, thoracic auscultation

- Analgesic therapy is indicated in animals with pain (see Chapter 6 for discussion of postoperative analgesia).
- Some surgeons treat routinely with furosemide (1–2 mg/kg) during the preoperative and immediate postoperative periods. This may be guided by the preoperative status, course of surgery, patient size, and operative fluid balance. If preoperative medical management was instituted, continue it postoperatively until clinical signs resolve.
- Perform frequent intermittent evacuation of the thorax (e.g., q2h) if a tube was left in place. Remove the thoracic tube when negative pressure is achieved or fluid or air production has subsided.
- Limit fluid therapy but maintain a sterile intravenous catheter for 24 hours.
- Auscultate the heart postoperatively for persistent murmur. A systolic murmur of mitral insufficiency, caused by left ventricular dilation, may be present. This murmur generally abates within 10 days. There should be no diastolic murmur if ligation was successful.

Long Term

- Reevaluate heart sounds at 2 weeks when sutures are removed, at 6 months, and then yearly thereafter to detect the uncommon occurrence of recanalization.
- Recanalization of the PDA occurs rarely (1–2% of cases) and is treated by relegation or division of the ductus and oversewing of the cut ends.
- PDA ligation has excellent long-term results if ligation is complete.

Chapter

156 Shock

Eric R. Schertel

▼ ***Key Point*** Shock is the clinical state resulting from an inadequate supply of oxygen to the tissues or an inability of the tissues to utilize oxygen properly.

Shock involves numerous physiologic disturbances and pathologic changes that affect multiple organ systems in different ways. Veterinarians often are alerted to the presence of shock in their patients by the physical findings of depressed mentation, pale mucous membranes, tachycardia, and weak pulse pressure. These clinical signs are the manifestations of a complex process and do not represent the full extent of the problem. The objective of this chapter is to provide a simplified approach to the diagnosis, monitoring, and treatment of shock. Information on the various manifestations, mechanisms, and temporal patterns of shock is beyond the scope of this book, but nonetheless is considered important to appropriate and successful therapy. Therapy for shock caused by acute heart failure is discussed in Chapter 147. See appropriate chapters for discussion of specific diseases that can cause shock.

ETIOLOGY AND CLASSIFICATION

Shock generally is classified by etiology because each cause of shock may produce distinct primary and secondary pathophysiologic changes and temporal patterns. Shock etiologies can be organized into those forms that result from:

- An abnormality or inadequacy of the vehicle of oxygen transport (blood)
- An abnormality of the transport system (cardiovascular system)

Hypovolemia and hypoxemia (anemic, hypoxic) are examples of the first category (Table 156-1). Diseases that disrupt the cardiovascular system and its control mechanisms (circulatory control mechanisms) also cause shock. The three important circulatory control mechanisms regulate:

- Blood pressure and blood flow distribution
- Blood volume distribution
- Cardiac function

Shock may also develop from the presence of one or more of these conditions.

- Sepsis is an example of a condition in which shock is caused by a loss of control of blood flow distribution.
- Endotoxemia and gastric dilatation-volvulus also cause shock by interfering with the distribution of blood volume, but via different mechanisms.
- Heart failure creates shock due to inadequate cardiac function (see Table 156-1).

CLINICAL SIGNS

Mental Attitude

Depressed mentation often is the most apparent physical finding in a patient with shock. This parameter is subjective and may be complicated by head injury.

- *Causes:* Decreased cerebral blood flow and oxygen delivery, circulating toxins, or head injury.

Arterial Pulse Pressure

A weak pulse is common but not necessary for shock to exist. The pulse feels weak at mean arterial pressures <60 to 70 mm Hg. Below 40 mm Hg, the pulse may not be palpable.

- *Causes:* Low cardiac output or low peripheral vascular resistance.

Mucous Membrane Color

The color may be pale, gray (muddy), cyanotic, brick-red, or normal.

- *Causes:* Pale mucous membranes reflect hypovolemia or anemia. Gray or cyanotic mucous membranes generally indicate severe cardiovascular compromise or arterial hypoxemia. Brick-red mucous membranes are common in septic shock. Mucous membrane color may be normal.

Table 156-1. CLASSIFICATION AND COMMON ETIOLOGIES OF SHOCK

Shock Involving Normal Circulatory Control Mechanisms
Hypovolemia
Hypoxemia
Anemia
Hypoxia
Shock Involving Abnormal Circulatory Control Mechanisms
Blood flow maldistribution
Sepsis
Trauma—surgical and accidental
Blood volume maldistribution
Endotoxemia
Anesthesia
Neurogenic shock
Anaphylactic shock
Gastric dilatation-volvulus
Impaired cardiac function
Systolic functional failure
Cardiomyopathy
Valvular heart disease
Myocardial ischemia
Myocardial contusion
Arrhythmias
Diastolic functional failure
Pericardial disease—tamponade
Myocardial disease—decreased diastolic compliance

Body/Extremity Temperature

Hypothermia (<99°F) and cold extremities are common. Patients that are septic may be hyperthermic (>103°F) with warm extremities.

- *Causes:* Decreased cardiac output, oxygen delivery, and ambient temperature. Cold extremities result from severe vasoconstriction. Hyperthermia results from the increased metabolic rate that commonly accompanies sepsis. Warm extremities reflect peripheral vasodilatation.

Capillary Refill Time

Capillary refill time typically is prolonged (>2 seconds), but may be normal.

- *Causes:* Prolonged capillary refill time reflects hypovolemia and poor peripheral blood flow.

Heart Rate

Heart rate is commonly elevated: >140 beats per minute (bpm) in large-breed dogs, >160 bpm in small-breed dogs, and >180 bpm in cats. Begin monitoring with electrocardiography (ECG) if an irregular rhythm is detected.

- *Causes:* Hypotension, hypovolemia, pain, stress, and fever may cause tachycardia. Irregular rapid heart rhythms result from ventricular tachycardia and atrial tachyarrhythmias, including atrial fibrillation (see Chapter 145).

Respiratory Rate

Increased respiratory rate (tachypnea) is common, but may be due to excitement or fever.

- *Causes:* Hypoxemia, metabolic acidosis, pain, fever, and excitement.

Urine Output

Urine output is decreased (normal range is 1 to 2 ml/kg/hr).

- *Causes:* Urine formation virtually ceases when mean arterial pressure is <60 mm Hg. Blood pressure may be normal in mild to moderate hypovolemia.

MONITORING AND TREATMENT

Goals

The goal for managing the shock patient is to optimize the functions of the cardiovascular system. Employ monitoring techniques that provide accurate information about functional parameters, such as blood volume, cardiac output, arterial blood pressure, and oxygen delivery.

Cardiac output, arterial blood pressure, and oxygen delivery are dependent on blood volume. When blood volume is expanded these other parameters commonly return to normal.

▼ ***Key Point*** Blood volume is the most important parameter to optimize and monitor in shock patients.

Monitoring

Blood Volume

- Physical signs and findings do not accurately reflect blood volume.
- Central venous pressure (CVP) is the simplest measurement that reflects blood volume. It may be obtained via a jugular catheter positioned so that its tip is within the thorax (see Chapter 3). CVP is approximately equivalent to the right atrial pressure and reflects the function of the systemic circulation and the right heart (Fig. 156-1).
- CVP is easily measured by a water manometer attached to the jugular catheter (see Chapter 3).
- Normal CVP ranges from 0 to 5 cm H_2O. In shock, CVP usually is −3 to 2 cm H_2O but may be as low as −5 cm H_2O. The goal of fluid therapy in shock is to optimize blood volume by administering fluid in an amount that increases CVP to between 5 and 12 cm H_2O.
- Plasma proteins, particularly albumin, maintain plasma volume. Assess total plasma proteins prior to fluid therapy and frequently during treatment to ensure that values remain above 4.0 g/dl (albumin >1.5 g/dl).

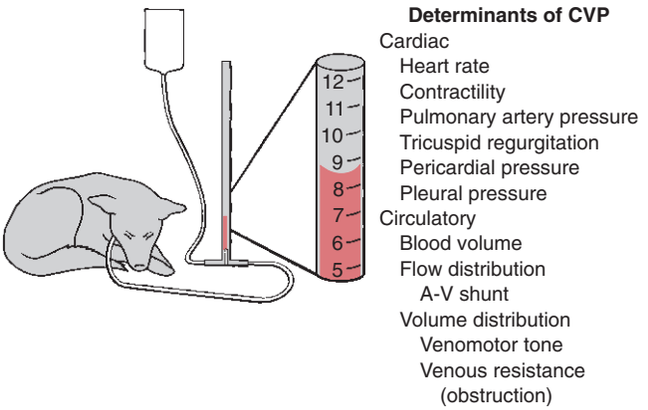

Figure 156-1. Determinants of central venous pressure (CVP).

Arterial Pressure

- Digital palpation may be used to assess mean arterial pressure (MAP). Strong pulse pressure usually reflects a MAP of >70 mm Hg. A weak pulse is detected when MAP is <70 mm Hg. When MAP is <40 mm Hg, the pulse is difficult or impossible to palpate.
- Arterial pressure also may be assessed using Doppler or oscillometric methods. These techniques are noninvasive and are generally accurate, except when arterial pressure is low.

Cardiac Output

- Capillary refill time, body temperature, and mentation are the physical findings that best reflect cardiac output. However, these are not always accurate.
- Urine output is a good indicator of cardiac output. When cardiac output is reduced, sympathetic nervous system activity may maintain blood pressure within normal limits but may decrease renal blood flow. Consequently, urine output will be decreased (<1 ml/kg/hr). However, other causes of reduced urine formation must be considered.
- Cardiac rhythm influences cardiac output and can be monitored by ECG.

Oxygen Delivery

- Oxygen delivery is determined by cardiac output as assessed above; pulmonary function is assessed by arterial oxygen pressure (Pao_2) or oximetry; and hemoglobin is assessed by hematocrit.
- Mucous membrane color, mentation, body temperature, and respiratory rate are the physical findings that best reflect oxygen delivery.
- Obtain blood samples for hematocrit measurement prior to treatment for shock. Repeat measurements frequently during aggressive fluid therapy (e.g., q1–2h). Maintain hematocrit >20%; in severe shock, it should be >30%.

Treatment

Preliminary Measures

- Establish an airway and ventilate if necessary. Administer 100% oxygen via an endotracheal tube, mask, nasal tube, or tracheal catheter.
- To evaluate the patient for the cause of shock, obtain a history and perform a physical examination. The time allotted for these efforts depends on the condition of the patient.
- Place and secure a large-gauge intravenous (IV) catheter, preferably jugular. The jugular catheter should be long enough to reach the thoracic cavity.
  - Jugular catheterization has the advantages of allowing the use of a large-gauge catheter even in small patients, ease of placement, access for blood sampling, rapid fluid administration, CVP measurement, and catheter security. The major disadvantage is that jugular catheters are slightly more expensive.
- Obtain blood for storage in ethylenediaminetetraacetic acid (EDTA) and clot tubes. Measure hematocrit and total protein, serum electrolytes, serum creatinine, blood glucose, and a complete blood count.

Optimize Blood Volume

- Initially, administer sodium-rich isotonic crystalloid fluids (e.g., 0.9% NaCl, lactated Ringer's solution) at a rate of 60 to 90 ml/kg/hr (Table 156-2). To ensure effective plasma volume expansion, maintain the sodium concentration of the isotonic fluid at >130 mEq/L.
- Administration of 7% NaCl (hypertonic saline) is an alternative resuscitation regimen in patients that are not hydrated. Deliver the initial dosage of 4 to 6 ml/kg over 5–10 minutes (Table 156-3). The hypertonic saline may be combined with 6% dextran 70 or hetastarch and given at the same dosage. Supplement this form of initial treatment by giving isotonic crystalloid fluids at a minimum rate of 20 ml/kg/hr.
- The goal of the initial rapid rate of fluid administration is to establish a normal arterial pressure and optimize blood volume. An adequate arterial pressure is easily determined by palpation of pulse pressure. Physical signs, including pulse pressure, may be normal despite continuing tissue hypoxia and less than optimal or unstable blood volume.
- Blood volume is optimized when CVP is 5 to 12 cm H_2O.
- To treat hypoproteinemia, fresh or frozen plasma may be administered at a dosage of 10 to 20 ml/kg/day IV.
- Alternatively, synthetic colloids may be used to treat hypoproteinemia. Those useful in small animal patients include 6% dextran 70 and 6% hetastarch. The dosages are similar to those for plasma

Table 156-2. TREATMENT OF SHOCK

Therapeutic Goal	Therapy	Specific Objectives	Dosage Recommendations
Optimize blood volume	Crystalloids Isotonic Hypertonic Colloids Whole blood	CVP 5–12 cm H_2O Wedge pressure 7–20 mm Hg Total protein >4.0 g/dl Albumin >1.5 g/dl Normal skin turgor	Isotonic fluids: 0.9% NaCl or LRS; 60–90 ml/kg/hr to effect IV Hypertonic saline/dextran: 7% NaCl or 7% NaCl in 6% dextran 70, 4–6 ml/kg slowly IV Plasma: 10–20 ml/kg IV 6% Dextran 70: 10–20 ml/kg/day IV 6% Hetastarch: 10–20 ml/kg/day IV Whole blood: 20–30 ml/kg IV
Optimize blood flow	Fluids Inotropic agents	Urine output >1 ml/kg/hr CRT <2 sec P_{VO_2} >35 torr Cardiac index 150–200 ml/min/kg	See Optimize Blood Volume in text Dopamine: 2–10 µg/kg/min IV Dobutamine: 2–15 µg/kg/min IV
Optimize oxygen delivery and consumption	Fluids Whole blood Packed red cells O_2 supplementation Mechanical ventilation Respiratory care	P_{aO_2} >70 torr P_{VO_2} >35 torr Hct >25 Pink mucous membranes Patient bright, alert, responsive	See Optimize Blood Volume in text Packed red cells: 10–20 µl/kg IV F_{IO_2}: 40–100%
Optimize blood pressure	Fluids Vasopressors	Arterial pressure: Systolic, 100–160 mm Hg Mean, 70–120 mm Hg Diastolic, 50–100 mm Hg Strong pulse	See Optimize Blood Volume in text Dopamine: 5–10 µg/kg/min IV Epinephrine: 0.1–0.3 µg/kg/min IV Phenylephrine: 0.01–0.1 µg/kg/min IV Methoxamine: 0.2 µg/kg IV
Optimize heart rate/rhythm	Fluids Antiarrhythmics	70–160 bpm Sinus rhythm	See Optimize Blood Volume in text Lidocaine: 1–2 mg/kg bolus IV, 25–75 µg/kg/min IV Procainamide: 15–20 mg/kg IM
Correct acid-base imbalance	$NaHCO_3$	pH >7.3 and <7.5	Sodium bicarbonate: 0.5–5.0 mEq/kg IV or mEq = 0.3 × base deficit × kg
Optimize urine output	Fluids	1–2 ml/kg/hr urine production	Furosemide: 2–4 mg/kg IV Mannitol (20%): 1–2 g/kg IV
Control sepsis	Antibiotics Surgery Culture and sensitivity	Negative culture Wound/infection management	Cephalothin: 20 mg/kg IV q6h Ampicillin: 20 mg/kg IV q6h Gentamicin: 2 mg/kg IV q8h
Optimize blood glucose	Glucose Insulin	Blood glucose 60–120 mg/dl	Dextrose 5% in maintenance fluids Dextrose 50%: 0.5–2.0 g/kg/hr Insulin (regular): 0.5–2 units/kg q2–6h IV (if hyperglycemic)
Immune/inflammatory modulation	Corticosteroids	Same as Therapeutic Goal	Dexamethasone sodium phosphate: 1–2 mg/kg IV Prednisolone sodium succinate: 10–20 mg/kg IV

CRT, capillary refill time; CVP, central ventral venous pressure; F_{IO_2}, inspired oxygen fraction; Hct, hematocrit; LRS, lactated Ringer's solution; P_{aO_2}, arterial oxygen partial pressure; P_{VO_2}, venous oxygen partial pressure.

Table 156-3. HYPERTONIC SALINE AND SYNTHETIC COLLOID THERAPY*

	Sodium Chloride Solutions			Synthetic Colloids	
	3% NaCl	5% NaCl	7% NaCl	6% Dextran 70	6% Hetastarch
Approximate osmolality (mOsm/kg)	1000	1800	2400	N/A†	N/A
Maximum dosage range (ml/kg IV)	20	6–10	4–8	10–20	10–20
Maximum infusion rate (ml/kg/min IV)	2	1	1	1	1
Available products	3% NaCl	5% NaCl	7% NaCl	Gentran 70	Hespan
Manufacturers	Baxter, Kendall McGaw	Baxter, Abbott, Kendall McGaw	Butler	Baxter	DuPont

*Indications: hypovolemia, traumatic shock, endotoxemia, septicemia, gastric dilatation-volvulus. Contraindications: dehydration, hypernatremia, hyperosmolality, heart/renal failure.
†N/A: not applicable.

(10–20 ml/kg/day) and commonly are divided into 5 to 10 ml/kg slow IV infusions (over 10–20 minutes).

- Fresh or stored blood may be given to optimize blood volume if the hematocrit and total protein are decreased below acceptable levels. Blood collected from the abdominal or thoracic cavity may be autotransfused if other, more acceptable sources are unavailable. This blood must be free of bacterial and neoplastic contamination; administer via a blood administration set (including filter). Autotransfused blood will have decreased platelets, clotting factors, and fibrinogen concentration.

Optimize Blood Flow

- Cardiac output increases and is often optimized as a result of aggressive volume expansion.
- If volume expansion has increased the CVP to 5 to 12 cm H_2O but urine output and other physical signs reflecting cardiac output are not normalized, evaluate cardiac function with ECG.
- If the ECG is normal, administer a positive inotropic agent. Dobutamine (Dobutrex, Lilly) and dopamine (Intropin, DuPont) are inotropic drugs (see Chapter 146) that are commonly used to enhance cardiac function in shock patients.
  - Dobutamine produces dose-dependent increases in contractility when administered at a dosage of 2 to 15 µg/kg/min IV (Fig. 156-2).
  - Epinephrine administered at dosages of 0.05 to 0.2 µg/kg/min IV improves contractility and increases cardiac output and peripheral vascular resistance, causing renal and mesenteric arterial vasoconstriction.
- Cardiac arrhythmias may contribute to low cardiac output. Consider causes of arrhythmias (myocardial hypoxia, myocardial contusion, and electrolyte disturbances) and correct them if possible (see Chapter 145). Ventricular arrhythmias are the most common and may be treated with lidocaine administered IV at 1 to 2 mg/kg or as a continuous infusion of 25 to 75 µg/kg/min (see Chapter 146) (Fig. 156-2).

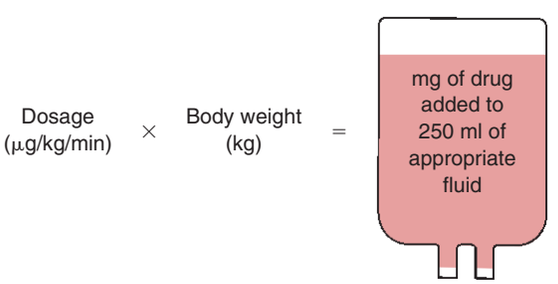

Figure 156-2. Simplified method of dosage formulation for continuous-infusion drugs. Once formulated, administer at 15 ml/hr or 1 drop/4 sec from a 60-drop/ml administration set to achieve desired dosage.

Optimize Blood Pressure

- Arterial blood pressure often is returned to normal by fluid therapy.

▼ ***Key Point*** When arterial blood pressure is <40 mm Hg (pulse weak or not palpable), increase blood pressure immediately.

- In cases of severe shock, epinephrine may be needed to increase peripheral vascular resistance and cardiac output until fluid therapy can be initiated and blood volume expanded.
  - The IV dosage of epinephrine for cardiac arrest is 0.02 to 0.2 mg/kg (0.02–0.2 ml/kg of 1:1000 dilution).
  - When the primary problem is severe hypotension, not cardiac arrest, administer epinephrine continuously at a dosage of 0.1 to 0.3 µg/kg/min IV (see Table 156–2).
  - Once blood volume is expanded and cardiac output and mean arterial pressure are restored, discontinue epinephrine.
- Use of an abdominal wrap or "belly band" to augment arterial blood pressure and to tamponade abdominal bleeding may be dangerous and is not recommended. Any increase in arterial resistance (arterial pressure) created by an abdominal wrap may be counteracted by obstruction of the vena cava and portal vein and by decreased venous return. Furthermore, the abdominal wrap may compromise respiratory function, exacerbate diaphragmatic hernia, and lead to hypotension when it is removed.
  - Manage uncontrolled intra-abdominal hemorrhage by aggressive fluid replacement, and perform surgical exploration if the condition fails to stabilize.

Optimize Oxygen Delivery

- Optimal oxygen delivery is often attained by aggressive volume replacement.
- Hemodilution or pre-existing anemia may limit oxygen delivery. Red blood cell (RBC) replacement (whole blood, packed red cells) is necessary when hematocrit is <20%. Administer whole blood at a dosage of 20 to 30 ml/kg and packed RBCs at 10 to 20 ml/kg (see Chapter 22).
- Administration of corticosteroids (e.g., prednisolone sodium succinate, 10–20 mg/kg) before transfusion minimizes the risk of severe transfusion reaction and improves the RBC function of stored blood.
- Oxygen supplementation improves arterial blood oxygen content and may be administered via mask, nasal catheter, oxygen cage, or transtracheal catheter and is particularly crucial when the patient is anemic (see Chapter 3).
- In cases of severe lung injury, provide ventilatory assistance. This requires anesthetizing the patient

and placing an endotracheal tube. Alternatively, a tracheostomy may be performed (see Chapter 3).

Correction of Acid-Base and Electrolyte Disturbances

- The metabolic acidosis that results from shock that is mild or of short duration often can be managed effectively by fluid replacement therapy.
- The degree of metabolic acidosis that develops in shock depends on the severity and duration of the oxygen delivery deficit. If blood gas analysis can be performed, the milliequivalent (mEq) dosage of $NaHCO_3$ required to correct the acidosis may be calculated by the following formula:
- $NaHCO_3$ (mEq) = 0.3 × body weight (kg) × base deficit
- If blood gas analysis is not available, an estimate of the base deficit may be made based on the severity of the shock state and its duration. Mild, moderate, and severe shock may be treated with $NaHCO_3$ dosages of 1.0, 3.0, and 5.0 mEq/kg of body weight, respectively (see Chapter 5 for more information on treatment of acidosis).
- Hyperkalemia is the most common serum electrolyte concentration abnormality observed in shock. Hyperkalemia generally responds to aggressive volume replacement, increased urine output, and improvement of metabolic status. Glucose and $NaHCO_3$ infusions facilitate reduction of serum potassium concentration (see Chapter 5).
- Hypokalemia often occurs after aggressive volume replacement. Once maintenance fluids are started, they should contain 15 to 20 mEq/L of KCl (see Chapter 5).

Corticosteroid Therapy

- Corticosteroids may be of benefit for most forms of shock, but are not recommended for septic shock. Administer early in the course of therapy to derive maximum benefits.
- Use water-soluble drugs, including dexamethasone sodium phosphate (Azium-SP, Schering), 1 to 2 mg/kg IV, and prednisolone sodium succinate (Solu-Delta-Cortef, Upjohn), 10 to 20 mg/kg IV.

Miscellaneous Treatments

- Broad-spectrum antibiotics are indicated in most forms of severe shock, particularly septic shock.
- Surgical management of a septic focus should be performed as soon as cardiorespiratory stability is established.
- IV glucose can provide some of the caloric requirements of the shock patient. Maintenance fluids should contain 5% dextrose. This treatment is helpful over the short term, but supplies only a fraction of the caloric requirements. More complete caloric supplementation may be achieved by administration of 50% dextrose at an hourly dosage of 0.5 to 2.0 g/kg.

Chapter

157 Cardiopulmonary Cerebral Resuscitation

William W. Muir III

Resuscitation is the restoration of life after apparent death. Cardiopulmonary resuscitation (CPR) includes therapy to restore heart and lung function to normal. Most resuscitative techniques incorporate methods to maximize and maintain cerebral blood flow and clinicians have redefined CPR as cardiopulmonary cerebral resuscitation (CPCR). Preparedness and early recognition of the signs of sudden death are the major factors that determine long-term outcome (Tables 157-1 and 157-2).

CPCR is divided into three phases:

- *Phase 1,* basic life support (BLS), consists of establishing an airway (A), breathing (B), and circulatory support (C).
- *Phase 2,* advanced life support (ALS), incorporates the use of drugs (D), electrocardiography (E), and methods to convert ventricular fibrillation or asystole (F) to sinus rhythm.
- *Phase 3,* prolonged life support (PLS), includes measures that focus on treating the causes of cardiac arrest and deciding whether to continue resuscitative efforts. Gauging (G) (monitoring of patient trends), hypnogenesis (H) (use of sedation, anesthesia, and pain control), utilization of methods to restore cerebral function, and intensive care (I) oriented toward preventing multiorgan failure are also elements of PLS.

BASIC LIFE SUPPORT: AIRWAY, BREATHING, AND CIRCULATORY SUPPORT

Airway

▼ ***Key Point*** Establishing a patent functional airway should be accomplished as soon as possible.

Establishing an Airway

Mouth to Endotracheal Tube

To pass a cuffed endotracheal tube of appropriate size place the patient on the sternum, open the mouth widely, and maximally extend the head and neck. Expose the larynx (using a laryngoscope if necessary) and proceed with intubation.

Tracheotomy

A tracheotomy may be necessary in animals with upper airway obstruction, brachycephalic animals, or in dogs and cats that are successfully resuscitated, regain consciousness, and object to oral-tracheal intubation. (Tracheotomy is described in Chapter 3.)

Mouth to Muzzle

Tightly cup hands around the muzzle of small dogs and cats, or place mouth directly over the patient's muzzle. Blow exhaled air into the animal's lungs.

Mouth to Mask

A variety of masks have been developed for use in dogs and cats for the delivery of oxygen or inhaled anesthetics.

▼ ***Key Point*** Mouth-to-muzzle and mouth-to-mask methods do not secure the airway but may be useful when equipment is limited. Distention of the stomach with air may limit lung expansion and predisposes to regurgitation.

Proper Endotracheal Tube Placement

Correct placement of the endotracheal tube can be verified by:

- Clearing and securing an airway.
- Direct observation of the tube positioned through the larynx (most reliable technique).
- Palpation of the endotracheal tube in the trachea.
- The appearance of water vapor on clear endotracheal tubes.
- The inability of the animal to vocalize.
- Gas exiting the endotracheal tube during exhalation. This sign, which frequently is used clinically, should not be the only method used to ensure proper endotracheal tube placement.

Table 157-1. SIGNS OF CARDIOPULMONARY ARREST

Evaluations	Clinical Signs and Observations
Effort, rate, and rhythm of breathing	Dyspnea (abdominal breathing) Gasps (gurgling sounds) Tachypnea Bradypnea Altered patterns of breathing: Cheyne-Stokes Agonal
Heart rate and rhythm	Tachycardia Bradycardia Irregular rhythm
Pulse	Peripheral arterial pulse is difficult or impossible to palpate at systolic BPs < 40–50 mm Hg
Heart sounds	Heart sounds are inaudible at BPs < 40–50 mm Hg
Bleeding	Absence of bleeding Change in color of blood from red to blue during surgical procedure
Peripheral perfusion	Change in mucous membrane color: Pale or white Blue or cyanotic—5 g/dl of reduced Hb imparts bluish discoloration to mucous membranes; anemic animals (<5 g/dl Hb) do not demonstrate cyanosis
Pupils	Pupils dilate within 1–2 min after cardiac arrest
Mental state	Altered consciousness Coma

BPs = arterial blood pressures; Hb = hemoglobin.

Air or Oxygen Delivery Systems (Fig. 157-1, *top*)

- *Self-refilling bags* connected to oxygen (Ambu bag) can be used to provide an air or oxygen source during controlled breathing.
- *Demand valves*, which are oxygen-powered, manually triggered ventilatory devices, permit both the initiation and termination of ventilation.
- *Anesthetic machines* are the most readily available source of oxygen in most hospitals.
- *Automatic pressure- or volume-cycled ventilators* can be used to assist (control volume) or control (control rate and volume) breathing. Most ventilators do not function properly during thoracic compression.
- In *translaryngeal or tracheal insufflation* (see Fig. 157-1, *bottom*), place an over-the-needle catheter (Surflo, Terumo Medical Corp.) (17-14 gauge) in the trachea and attach to a three-way stopcock, venous extension tubing, and oxygen supply.

Breathing

A ventilator, delivering 50% to 100% oxygen, can be used to assist or control breathing. The resuscitator's exhaled air, which contains 16% to 18% oxygen, may be expelled into a properly placed endotracheal tube and is adequate for maintaining Pao_2 if large tidal volumes are used.

- Detect and immediately treat:
  - Tension pneumothorax
  - Hemothorax
  - Open chest wound
  - Flail chest
  - Cardiac tamponade

Maximal oxygenation of arterial blood with minimal hemodynamic impairment can be obtained by:

- Providing adequate oxygenation (inspired $O_2 > 50\%$)
- Proper placement of an endotracheal tube
- Slow (1–2 sec) inflation of the lungs
- Providing adequate (14–20 ml/kg) tidal volume
- Providing adequate (25–30 cm H_2O) but not excessive inspiratory pressure
- Inflation of the lung with an excessive volume of gas impairs venous return and cardiac output during closed-chest CPCR. Therefore, be careful not to overinflate the lung.
- Sedation and/or anesthesia may be necessary to control ventilation in conscious or semiconscious patients (see Chapter 2) that resist placement of an endotracheal tube.
  - Diazepam, 0.2 to 0.5 mg/kg IV
  - Propofol, to effect: 3 to 4 mg/kg IV; 0.1 to 0.4 mg/kg/min
  - Isoflurane, 1 to 2%
- Positive end-expiratory pressure (PEEP; 5 cm H_2O) helps to prevent small airway closure, thereby improving gas exchange.

Circulation: Closed Chest Compression

The early re-establishment of normal or near-normal hemodynamics, particularly cerebral blood flow, is vital to long-term survival. Closed chest compression should begin immediately when the pulse is lost or it is determined that the existing pulse is not providing adequate tissue perfusion and oxygenation. Closed chest compression should only be interrupted by the establishment of a patent airway.

▼ ***Key Point*** External chest compression is effective in restoring blood flow to the systemic circulation and brain if proper techniques are utilized.

One-Rescuer CPCR with Intermittent Positive Pressure Ventilation (IPPV)

Perform one-rescuer chest compression (80–100 compressions/min) by placing the animal in lateral recumbency and manually compressing the thorax from side to side, using the thumb and first two forefingers for animals less than 5 kg and the heels of the hands for larger animals (Fig. 157-2). Ventilate the lungs after each set of 15 chest compressions.

Table 157-2. ESSENTIAL EQUIPMENT TO PERFORM CPCR*

1. Assortment of cuffed endotracheal tubes with inside diameter of 2–15 mm
2. Oxygen supply source
   a. Ambu bag and oxygen source
   b. Small animal anesthetic machine
   c. Demand valve
   d. Oxygen hose to deliver nasal oxygen
   e. Respirator (pressure or volume cycled)
   f. Oxygen chamber
3. Fluid and drug administration equipment
   a. Assortment of intravenous needles and catheters
      (1) Needles—18–25 gauge
      (2) Over-the-needle or through-the-needle catheters—17–22 gauge
   b. Assortment of syringes—1, 3, 6, 12, and 60 ml
   c. Solution administration sets
      (1) Standard solution administration sets (10 drops/ml) for animals over 5 kg
      (2) Mini-drop solution administration sets (60 drops/ml) for animals <5 kg and to deliver drugs that must be administered by infusion
   d. Venous extension tubing to prolong the time until drug effect, by increasing distance between fluids and patient
   e. Three-way stopcocks and catheter injection plugs
4. Fluids
   a. Balanced electrolyte solutions to be administered IV in most emergency situations; rate of fluid administration is determined by circumstances (see text for dosages):
      (1) 20 ml/kg/hr during hypotension
      (2) 40 ml/kg/hr following acute cardiac arrest
      (3) 90 ml/kg/hr following circulatory collapse due to hemorrhage
   b. Other solutions
      (1) 5% dextrose in water to supply volume and additional calories and dilute plasma potassium concentration
      (2) Normal saline (0.9% NaCl) to supply volume and dilute plasma potassium concentration
      (3) Colloid solutions (6% dextran 70; hetastarch) to supply volume and oncotic value
      (4) Mannitol (20% Osmotrol) to be used as an osmotic diuretic and as an oxygen free radical scavenger
   c. Special solutions
      (1) Hypertonic saline solutions (usually 3 or 7%) to restore vascular volume; the appropriate quantity of NaCl may be mixed in 6% dextran 70; 7% NaCl in 6% dextran 70 can be administered IV, 4 ml/kg, over 1–2 min
      (2) Blood substitute (Oxyglobin, Biopure), 10–30 ml/kg/hr IV, to maintain tissue oxygenation following acute hemorrhage or in severe anemia
5. Drugs (see text for dosages)
   a. Anticholinergics (atropine or glycopyrrolate)
   b. Epinephrine (1:1000 and 1:10,000)
   c. Dopamine or dobutamine
   d. Calcium chloride
   e. Lidocaine (2%)
   f. Injectable procainamide
   g. Glucocorticosteroids (dexamethasone, prednisolone sodium succinate)
   h. Furosemide
   i. Mannitol
   j. Diazepam, thiobarbiturate (thiopental), phenytoin
   k. Oxymorphone, other opioids
   l. Doxapram
6. Surgical instruments
   a. Scalpel and several #10 blades
   b. Mosquito and Kelly hemostats
   c. Rib retractors
   d. Thumb forceps
   e. Metzenbaum and Mayo scissors, needle holders
7. Bandage material (1, 2, and 4 inch)
   a. Sterile 4-inch × 4-inch gauze sponges
   b. Cotton bandage
   c. Elastic bandage
   d. Tape
8. Other equipment
   a. Clippers
   b. Leg splints (tongue depressors can be used in animals under 10 kg)
   c. Water circulating heating pad
   d. Electrocardiographic machine
   e. Electrical defibrillator
   f. Aspiration or suction device and tubing
   g. Assortment of suture material

*This material should be kept in one place, preferably on an emergency cart or in a large tool chest.

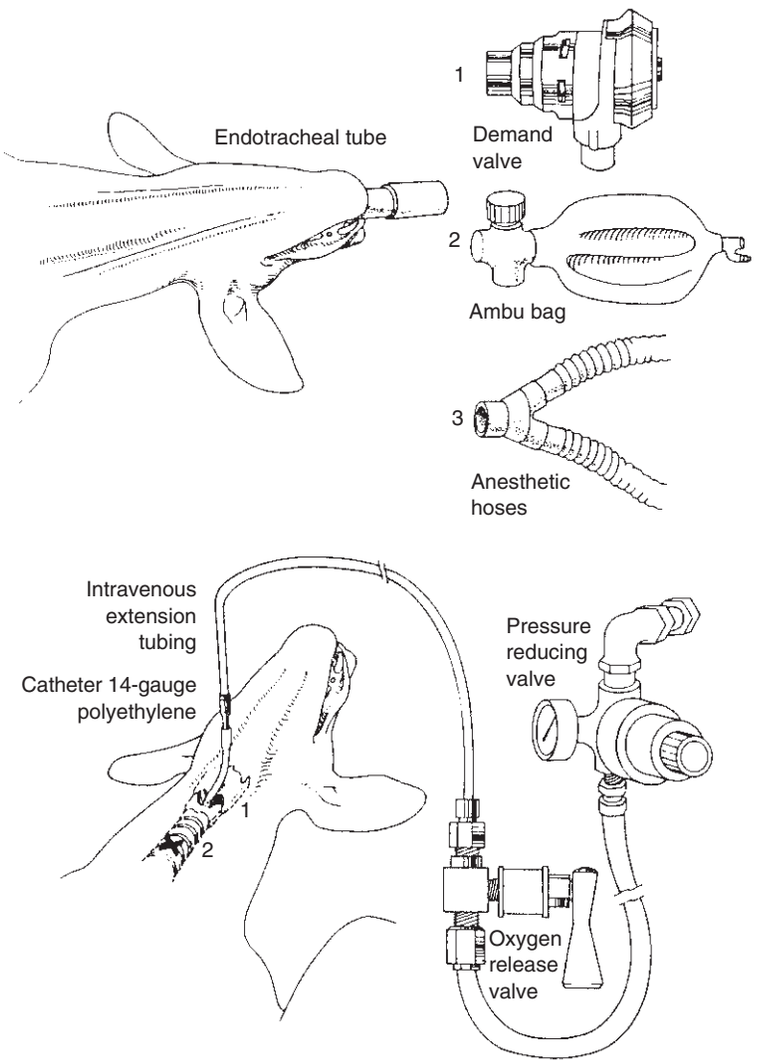

Figure 157-1. Methods of endotracheal oxygen administration *(top);* transtracheal oxygen administration *(bottom)* via catheter placement through the cricothyroid notch (1) or between tracheal rings (2). (Modified from Sherding RG: Medical Emergencies. New York: Churchill Livingstone, 1985.)

Figure 157-2. Chest compression in the dog *(left, middle);* chest compression in the cat *(right).*

Two-Rescuer CPCR with IPPV

The technique for compressing the chest is identical to that in one-rescuer CPCR (see above). Ventilate intermittently without slowing the rate of chest compression (1 breath for each set of 15 chest compressions) or simultaneously with chest compression (SVC or simultaneous compression ventilation–CPCR). Take care not to overinflate the lungs (use <30 cm H_2O), in order to prevent or minimize pulmonary barotrauma and pneumothorax.

Three-Rescuer CPCR with IPPV and Abdominal Pressure

Applying steady or intermittent abdominal pressure during CPCR or SVC-CPCR may augment carotid arterial pressures and cerebral and myocardial blood flow.

- The palm of the hand (third rescuer) may be used to compress the abdomen against the backbone for periods of 5 to 10 seconds. Repeat this procedure 2 to 3 times per minute.
- An elastic bandage can be tightly wrapped around the rear legs to prevent venous pooling and to promote venous return.

ADVANCED LIFE SUPPORT

The primary purpose of advanced life support techniques is to restore adequate spontaneous circulation. Open-chest CPCR is considered an advanced life support technique. Antiarrhythmic, inotropic, and antishock drugs (e.g., glucocorticosteroids, free radical scavengers) are used in conjunction with fluid therapy to restore supernormal hemodynamics.

Drug Therapy

Drugs and fluids are preferably administered intravenously (see Table 157-3 for dosages and side effects; also see Chapter 146 for additional details regarding the pharmacologic actions of cardiovascular and antiarrhythmic drugs). Place a large-bore catheter (18–14 gauge) in the cephalic or jugular vein. Placement of an IV catheter may require a "cutdown" or placement of an intraosseous needle (20 or 18 gauge), because the veins collapse shortly after cardiac arrest (see Chapter 3).

Epinephrine

▼ ***Key Point*** Epinephrine is the drug of choice for the treatment of cardiac arrest regardless of cause (Table 157-4).

- Large doses of epinephrine (0.2 mg/kg IV) produce dramatic increases in heart rate, arterial blood pressure, and cerebral blood flow in dogs and cats suffering from severe bradycardia (<30 beats/min) with hypotension, but may induce ventricular arrhythmias and ventricular fibrillation in animals that are in sinus or idioventricular rhythms.
- Initial doses of 0.01 mg/kg IV are adequate in most patients with hypotension or bradycardia and may be adjusted upward according to the patient's response (see Table 157-4).

Lidocaine

Lidocaine is the first choice antiarrhythmic for the treatment of ventricular arrhythmias in dogs and cats.

- It is the drug of choice for the treatment of cardiac arrhythmias induced by catecholamines and digitalis glycosides, and ventricular arrhythmias produced by myocardial contusion, inhalation anesthetics, and thiobarbiturates.
- Initial IV bolus dosages should not exceed 4 mg/kg in dogs and 1.0 mg/kg in cats. A lidocaine infusion (40–60 µg/kg/min) produces a sustained antiarrhythmic effect. A solution containing 1 mg (1000 µg) of lidocaine per ml is made by mixing 25 ml of 2% lidocaine in 500 ml of lactated Ringer's solution (infuse 0.5 ml/10 kg/min). Potassium (K^+) may be added to the fluid (15–20 mEq) to enhance lidocaine's effects (do not exceed 0.5 mEq/kg/hr). Occasionally procainamide may be effective (6–20 mg/kg; 40–60 µg/kg/min) when lidociane is ineffective.

▼ ***Key Point*** Lidocaine is relatively ineffective in hypokalemic patients and should never be administered to patients with complete (third-degree) AV block.

Sotalol

Sotalol is an antiarrhythmic drug used for long-term therapy of ventricular arrhythmias (see Chapter 146).

- Initial dosages range from 1 to 2 mg/kg PO and are titrated to effect.

Sodium Bicarbonate

Sodium bicarbonate administration helps to combat the development of metabolic acidosis and, more specifically, lactic acidosis produced by anaerobic metabolism secondary to circulatory arrest.

- The initial dose of sodium bicarbonate (1 mEq/kg IV) is not required until after 10 to 15 minutes of arrest and may be repeated (0.5 mEq/kg IV) every 10 to 15 minutes until resuscitative efforts are successful or terminated.

Anticholinergics

Atropine (0.01–0.02 mg/kg IV) or glycopyrrolate (0.005–0.01 mg/kg IV) is effective for the treatment of bradyarrhythmias (sinus bradycardia, high-grade

Table 157-3. THERAPEUTIC MANAGEMENT OF PROBLEMS ASSOCIATED WITH CARDIAC ARREST

Problem	Treatment	Trade Name or Device	Dosage	Side Effects or Contraindications
Hypovolemia	Crystalloid	Lactated Ringer's	50–90 ml/kg/hr IV	Hypervolemia, pulmonary edema, hypoproteinemia
Fluid loss	Hypertonic saline (7%)	Generic	5 ml/kg IV	Hypokalemia, hypernatremia, acidosis, arrhythmias
Plasma loss	Colloid expanders	Gentran 70	10–20 ml/kg IV	Hypervolemia, pulmonary edema, allergic reactions
		Hetastarch	10–20 ml/kg IV	
Blood loss	Whole blood		10–40 ml/kg IV	Hypervolemia, allergic reactions
	Blood substitute	Oxyglobin	15–30 ml/kg IV	Hypervolemia, pulmonary edema
Hypotension	See Hypovolemia			
	Phenylephrine	Neo-Synephrine	10–50 µg/kg IV	
	Epinephrine	Adrenalin	3–5 µg/kg IV	Hypertension, tachycardia, arrhythmias
	Dopamine	Intropin	3–10 µg/kg/min IV	
	Dobutamine	Dobutrex	3–10 µg/kg/min IV	
Cardiac arrhythmias				
Bradycardia	Atropine	Atropine	0.01–0.02 mg/kg IV	Tachycardia
	Glycopyrrolate	Robinul	0.005–0.01 mg/kg IV	Tachycardia
Tachycardia	Propranolol	Inderal	0.05–0.1 mg/kg IV	Bradycardia, cardiac failure
Atrial arrhythmias	Quinidine	Quinidine gluconate	4–8 mg/kg/10 min IV	Hypotension
	Diltiazem	Cardizem	0.5–2.0 mg/kg PO q8h; 5–10 µg/kg/min	Hypotension, AV block
Ventricular arrhythmias	Lidocaine	Xylocaine	2–4 mg/kg IV dogs; 1 mg/kg IV cats 40–60 µg/kg/min IV	CNS excitement
	Procainamide	Pronestyl	6–20 mg/kg/10 min IV	Hypotension
Acute heart failure	Calcium chloride		1 ml 10%/10 kg IV	
	Epinephrine	Adrenalin	3–5 µg/kg IV	Hypertension, tachycardia, cardiac arrhythmias
	Dopamine	Intropin	3–10 µg/kg/min IV	
	Dobutamine	Dobutrex	3–10 µg/kg/min IV	
Respiratory failure				
Hypoxia	O_2 nasal catheter; oxygen cage		2–4 L/min	
	Ventilation		Tidal volume = 14 ml/kg	Decreased venous return, respiratory alkalosis
Hypercarbia	Doxapram	Dopram V	1–2 mg/kg	CNS excitement
	Ventilation		Tidal volume = 14 ml/kg	Decreased venous return, respiratory alkalosis
Dyspnea	Tracheostomy			
	Chest tube			
	Ventilation		Tidal volume = 14 ml/kg	Decreased venous return, respiratory alkalosis

Sepsis	Surgery (if indicated)			
	Gentamicin	Gentocin	1–3 mg/kg q6–8h IM, IV	Muscle weakness, renal toxicity
	Kanamycin	Kantrim	10 mg/kg q6h IM	Muscle weakness, renal toxicity
	Ampicillin	Omnipen	10 mg/kg q6h IV	
	Cephalothin	Keflin	20–30 mg/kg IV q6h	Phlebitis, myositis
Metabolic acidosis	Sodium lactate*		Bicarbonate dose = base deficit × 0.3 × wt (kg) or 0.5 mEq/kg/ 10 min IV to effect	Metabolic alkalosis, hyperosmolarity, CSF acidosis hyperkalemia, hypocalcemia
	Sodium acetate*			
	Sodium bicarbonate			
Hyperkalemia	Sodium bicarbonate		0.5–2.0 mg/kg IV	As above
	NaCl 0.9% solution		10–40 ml/kg/hr IV	Hypervolemia, hypoproteinemia
	Calcium gluconate		0.5 ml/kg of 10% solution IV	Tachycardia
	Hyperventilation		Tidal volume = 14 ml/kg	Decreased venous return, respiratory alkalosis
Hypoglycemia	Dextrose 50%		1–2 ml/kg IV 0.5–1.0 g/kg/hr, 10% glucose	Hyperosmolarity
Renal ischemia	Fluids	Lactated Ringer's solution	10–40 ml/kg/hr IV	Hypervolemia, hypoproteinemia, pulmonary edema
	Mannitol 20%	Osmitrol	0.5–2.0 g/kg IV	Hyperosmolality
	Furosemide	Lasix	1.0–2.0 mg/kg IM, IV	Decreased cardiac output
Hypothermia (<36°C)	Fluids	Lactated Ringer's solution	10–40 ml/kg/hr, warmed to 37°C	Hypervolemia, hypoproteinemia, pulmonary edema
	H_2O-filled heating pad		Warmed slowly to 38°C	
Disseminated intravascular coagulation	Correct hypotension	Lactated Ringer's solution	10–40 ml/kg/hr, IV	Hypervolemia, hypoproteinemia, pulmonary edema
	Correct hypoxemia	Nasal catheter	2–4 L/min	Decreased venous return, respiratory alkalosis
		Ventilation	Tidal volume = 14 ml/kg	
	Correct acidosis	Sodium bicarbonate	0.5–1.0 mg/kg IV	
	Heparin		Dog: 500 U/kg SC q8h for 24 hr Cat: 250–400 U/kg Sc q8h for 24 hr	Bleeding
Cellular ischemia	Fluids	Lactated Ringer's solution	10–40 ml/kg/h IV	Hypervolemia, hypoproteinemia, pulmonary edema
	Mannitol	Osmitrol	0.5–2.0 g/kg IV	
	Oxygen	Nasal catheter	2–4 L/min	
	Dexamethasone sodium phosphate	Azium	4–6 mg/kg IV	
	Prednisolone sodium succinate	Solu-Delta-Cortef	>10 mg/kg IV	

Modified from Muir WW, Bonagura JD: Cardiovascular emergencies. *In* Sherding RG, ed.: Medical Emergencies. New York: Churchill Livingstone, 1985, p 52.
*Questionable efficacy during severe low-flow states.

Table 157-4. EMERGENCY DOSES OF EPINEPHRINE

Route	Dose	Comments
Intravenous		
Arrest/ventricular fibrillation	0.01–0.1 mg/kg	Dose determined by heart rate: begin at low dose
Bradycardia	0.01–0.1 mg/kg	
Intracardiac	0.01–0.02 mg/kg	Potentially arrhythmogenic
Intratracheal	0.1 mg/kg	Dilute with 0.9% NaCl (1 ml/5 kg body weight), ineffective during cardiac arrest/fibrillation

second-degree and third-degree AV block) produced by increases in vagal tone.

▼ ***Key Point*** Do not administer anticholinergics unless indicated. Anticholinergics can produce sinus tachycardia and predispose to cardiac arrhythmias and ventricular fibrillation in hypotensive patients.

Calcium Chloride

Calcium chloride and calcium gluconate have the potential to increase the force of myocardial contraction and thereby increase cardiac output and peripheral blood flow.

- IV administration of calcium chloride (1 ml/10 kg of a 10% solution) is indicated for the treatment of hyperkalemia, hypocalcemia, and inhalation anesthetic or calcium antagonist (e.g., verapamil, diltiazem) overdose.
- Do not use calcium routinely during the initial phases of CPCR because calcium-mediated cardiac injury (calcium overload) can occur.

Parenteral Fluids

Fluid therapy is mandatory during cardiac arrest in order to treat the hypovolemia and hypotension and to establish diuresis. The basic principles of IV administration of drugs described previously also apply to parenteral fluid administration. See Chapter 5 for a comprehensive discussion of fluid therapy.

▼ ***Key Point*** Administer fluids cautiously with close monitoring in traumatized patients when there is a suspicion of ongoing hemorrhage. Rapid fluid administration may facilitate uncontrolled hemorrhage and pulmonary edema, and increase mortality.

Crystalloids

- A minimum of 15 to 20 ml/kg of crystalloids to effect (e.g., lactated Ringer's solution) is needed to reverse the relative blood loss due to venous pooling and vasodilation caused by cardiac arrest.
- Replace blood loss by administering at least three times as much crystalloid as blood lost (3:1) and guide fluid therapy by changes in the packed cell volume (PCV), total protein concentration, and central venous pressure when appropriate.

▼ ***Key Point*** Do not dilute the PCV < 20% or the total plasma protein < 3.0 g/dl with crystalloids.

Colloids

Colloids (e.g., 6% hetastarch) provide colloid osmotic pressure and produce marked improvement in cardiac output and arterial blood pressure while helping to prevent blood sludging and capillary microembolization.

- Colloids are relatively confined to the intravascular fluid compartment and are used to replace blood loss in a ratio of 1:1 (thereby producing less hemodilution than crystalloids). Colloids are administered up to 5 ml/kg IV to a total volume of 20 ml/kg.

Hypertonic Saline

- Hypertonic sodium chloride solutions (3% and 7%) are extremely effective in drawing interstitial fluid into the vascular compartment, thereby increasing cardiac output and arterial blood pressure and restoring peripheral perfusion following hemorrhage in dogs and cats.
- The effects of hypertonic saline solutions can be prolonged by mixing 7% hypertonic saline with 6% hetastarch. A 7% solution of hypertonic saline in 6% hetastarch is produced by adding 70 mg of sodium chloride to each ml of 6% hetastarch. The dose of 7% sodium chloride mixed with either colloid is 5 ml/kg IV.

Blood

- Blood replacement therapy is indicated whenever hemorrhage is severe (>25 ml/kg), the PCV is <20%, or the total plasma protein is <2.5 g/dl.
- Like colloids, blood replacement therapy is administered in a ratio of 1:1 with blood loss.

Blood Substitute

- The blood substitute Oxyglobin (Biopure) is an oxygen-carrying oncotic solution and plasma expander that does not require cross-matching and has a 2-year shelf life.
- Administer 10 to 30 ml/kg/hr IV in dogs; 5 to 10 ml/kg/hr in cats, for tissue oxygenation that is equal to or better than that of blood.

Electrocardiography

Electrocardiography (ECG) can be used to detect changes in heart rate and rhythm, particularly

asystole and ventricular fibrillation (Fig. 157-3; Table 157-5).

Treatment of Bradycardia

▼ ***Key Point*** Bradycardia produced by hypoxemia or anesthetic overdose may be very difficult to treat and may require large doses of epinephrine (0.2 mg/kg IV).

- Isoproterenol (5 µg/kg IV; 1–3 ug/kg/min) may be temporarily effective in some cases of bradycardia (third-degree atrioventricular block).
- Long-term therapy is best accomplished by transvenous placement of a cardiac pacemaker.

Treatment of Ventricular Fibrillation

▼ ***Key Point*** The only consistently effective method for treating ventricular fibrillation is electrical defibrillation.

- Both external and internal techniques for converting ventricular fibrillation to sinus rhythm are successful in healthy patients that unexpectedly develop ventricular fibrillation (Table 157-6).
- The prior administration of epinephrine and lidocaine helps to reduce the energy required for defibrillation and the possibility of post-defibrillation ventricular arrhythmias, respectively.
- Use extreme care to avoid electrical injury to personnel.

Open-Chest Cardiac Massage

Open-chest direct cardiac massage may be the only way to provide adequate coronary and systemic blood flow, particularly in barrel-chested dogs and animals with penetrating chest trauma, broken ribs, pneumothorax, hemothorax, pericardial effusion, or thoracic masses.

- Consider open-chest direct cardiac compression within the first 5 minutes if closed chest compressions and IV epinephrine are ineffective.

Technique

1. After minimal skin preparation, make a skin incision at the fourth or fifth intercostal space on the left side.
2. Make a small hole in the pericardium near the apex of the heart and reflect the pericardium dorsally.
3. Compress the heart between the thumb and forefingers or in the heel of the hand, concentrating effort on the left ventricle. The usual compression rate is 60 to 80 per minute.
4. Administer epinephrine (5–10 µg/kg) into the apex of the heart (left ventricular chamber) to initiate or strengthen contractions. Much larger doses of epinephrine may be required to initiate an effective contraction in dogs and cats that have bradyarrhythmias and cardiovascular collapse produced by hypoxic arrest or anesthetic overdose. This technique can also be used during ventricular fibrillation prior to electrical defibrillation.

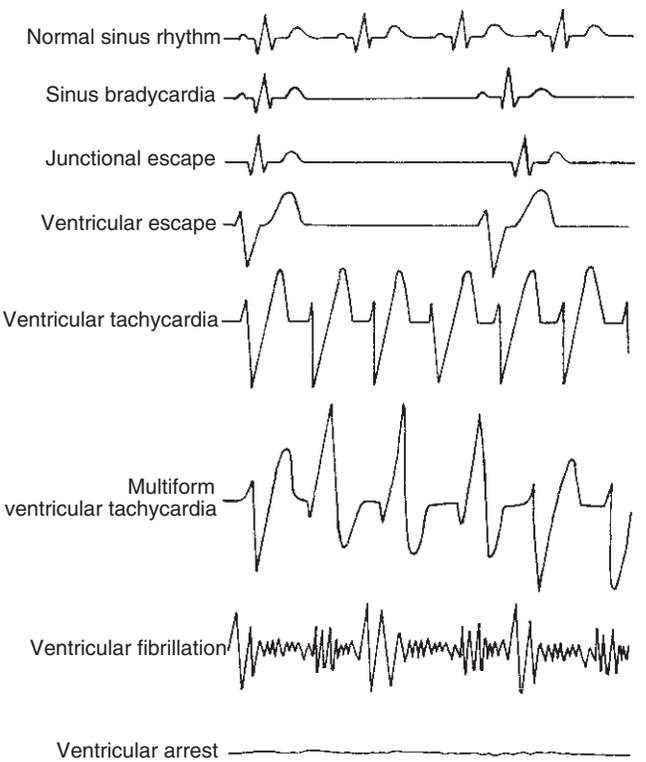

Figure 157-3. Significant cardiac rhythm patterns during cardiopulmonary cerebral resuscitation. (From Muir WW, Bonagura J: Cardiac emergencies. In Sherding R (ed): Medical Emergencies. New York: Churchill Livingstone, 1985, pp 37–93.)

PROLONGED LIFE SUPPORT

Prolonged life support incorporates all the medical and surgical methods necessary to prevent central nervous system and multiple organ failure following cardiac arrest (Table 157-7).

▼ ***Key Point*** Adequate tissue oxygenation is vital to long-term survival. Patients may require supplemental oxygen (nasal or tracheal O_2; O_2 cage) for several days following successful resuscitation. Maintain PCV <20%.

Drug Therapy

Catecholamines

Dopamine and Dobutamine

These produce dose-dependent increases in cardiac output and peripheral perfusion. Try to maintain

Table 157-5. DISTINGUISHING CHARACTERISTICS OF SEVERAL TYPES OF CARDIAC FAILURE AND ARREST

Cause	Peripheral Pulse	Auscultation of Heart Sounds	ECG	Visual Observation
Ventricular tachycardia	Weak, rapid, pulse deficit	Muffled; may be variable intensity	Wide QRS-T complexes; absence of P-QRS, large T wave relationship (see Fig. 157-3)	Disorganized, rapidly beating heart
Ventricular fibrillation	None	None	Absence of QRS-T complexes; fibrillation waves (see Fig. 157-3)	Fine to coarse rippling of ventricular myocardium
Bradycardia	Slow; may be irregular	Normal or muffled; infrequent	Infrequent or irregular P-QRS-T complexes; junctional or ventricular escape complexes (see Fig. 157-3)	Infrequent coordinated ventricular contractions
Ventricular asystole	None	None	Absence of QRS-T complexes; straight-line ECG	No cardiac improvement
Pulseless electrical activity	None or weak	None or muffled	Normal or near-normal P-QRS-T complexes	Feeble or absent cardiac contractions; systolic arterial BP < 50 mm Hg

Modified from Muir WW, Bonagura JD: Cardiovascular emergencies. *In* Sherding RG, ed.: Medical Emergencies. New York: Churchill Livingstone, 1985, p 80.

Table 157-6. DEFIBRILLATION TECHNIQUES

Ventricular Tachycardia with Severe Hypotension or Ventricular Fibrillation
Direct current fibrillators: 0.5–2.0 ws/kg internal; 5–10 ws/kg external
  Small patient (<7 kg):
    5–15 ws internal
    50–100 ws external
  Large patient (>10 kg):
    20–80 ws internal
    100–400 ws external
Alternating current defibrillators
  Small patient:
    30–50 V internal
    50–100 V external
  Large patient:
    50–100 V internal
    150–250 V external

Unresponsive Ventricular Fibrillation
Evaluate ventilation
Evaluate chest or cardiac compression
Repeat epinephrine 0.02 mg/kg (see Table 157-4)
Repeat sodium bicarbonate administration every 10 min
Administer lidocaine
Repeat electrical defibrillation (direct current; see above)

Modified from Muir WW, Bonagura JD: Cardiovascular emergencies. *In* Sherding RG, ed.: Medical Emergencies. New York: Churchill Livingstone, 1985, p 90.
ws = watt seconds; V = volts.

systolic arterial blood pressure (ABP) greater than 80 mm Hg.

- The IV infusion rate varies from 1 to 5 ug/kg/min but may be increased to 15 to 20 ug/kg/min, depending on the patient's response.
- Administer dopamine to produce heart rates ranging from 120 to 160 beats/min. Administer dobutamine or dopamine to sustain systolic blood pressure (by Doppler) >100 mm Hg.
- Dobutamine is less likely than dopamine to produce tachycardia and is preferred in patients with preexisting sinus tachycardia or supraventricular arrhythmias.
- Vasopressin has been recommended as an alternative to epinephrine, dopamine, and dobutamine to support arterial blood pressure in patients that remain hypotensive. The clinical efficacy of vasopressin in hypotensive dogs and cats with naturally occurring disease has not been validated.

Diuretics

Furosemide and Bumetanide

These highly potent loop diuretics are used to treat edema (e.g., pulmonary edema), promote diuresis, and mobilize fluids.

- The dosage of furosemide is 1 to 2 mg/kg IV.
- The dosage for bumetanide is 0.005 to 0.01 mg/kg IV.

Table 157-7. BRAIN-ORIENTED RESUSCITATION

Problem	Therapy/Drug	Dose
Hypotension	Lactated Ringer's solution	35–70 ml/kg IV
	6% Hetastarch	5 ml/kg IV
	7% NaCl	5 ml/kg IV
	7% NaCl in 6% Hetastarch	5 ml/kg IV
	Dopamine	2–5 µg/kg/min IV
	Dobutamine	1–3 µg/kg/min IV
Seizures	Pentobarbital	1–3 mg/kg IV
	Propofol	1–3 mg/kg IV
	Phenytoin	10–20 mg/kg IV
	Diazepam	0.1–0.2 mg/kg IV
Cerebral edema or increased intracranial pressure	Ventilation	$Paco_2$ 25–35 mm Hg
	Oxygenation	Pao_2 60 mm Hg
	Furosemide	1 mg/kg IV
	Mannitol	0.5–1.0 g/kg IV
	Methylprednisolone sodium succinate	5–10 mg/kg IV
Toxic cellular products*	Dimethyl sulfoxide	250–500 mg/kg IV
	Allopurinol	10 mg/kg PO

Modified from Muir WW: Brain hypoperfusion post-resuscitation. Vet Clin North Am [Small Anim Pract] 19:1151, 1989.
*These therapies await clinical verification of efficacy.

Mannitol

Mannitol (osmotherapy) produces an osmotic gradient that causes tissue dehydration and diuresis. Use mannitol (0.5–1.0 g/kg IV) if the period of cardiac arrest exceeds 3 minutes. This dose can be repeated at approximately 2 to 4 hours.

Glucocorticosteroids

Therapy with dexamethasone (Azium; 3–5 mg/kg IV) or prednisolone sodium succinate (Solu-Delta-Cortef; 10–20 mg/kg IV) has multiple benefits. These drugs can:

- Stabilize lysosomal membranes
- Reduce and prevent histamine release
- Protect against increases in capillary membrane permeability
- Cause vasodilation and inhibit phospholipase A_2 breakdown of arachidonic acid to prostaglandins and leukotrienes
- Impart a feeling of well-being

Calcium Entry Blockers

Calcium entry blockers, or calcium antagonists, are potentially beneficial in preventing reperfusion and reoxygenation injury, thereby limiting the detrimental effects of platelet aggregation and the vasoactive and membrane damaging effects of prostaglandins, leukotrienes, and other ischemia-induced (reperfusion injury) cascades.

- Diltiazem can be given at 0.5 to 2.0 mg/kg/q8h PO or 5 to 10 ug/kg/min IV for 10 minutes.
- Calcium solutions (chloride, gluconate) can be used to antagonize the negative inotropic actions of any of the calcium entry blockers.

Free Radical Scavengers

Dimethyl sulfoxide (DMSO) (250–500 mg/kg, IV) and allopurinol (10 mg/kg, PO), are experimental drugs potentially useful as oxygen–free radical scavengers. Mannitol (see previous discussion) is also an oxygen–free radical scavenger.

Heparinization

The administration of 100 IU/kg SC q6–8h of heparin is of questionable value in the post-arrest period (once hemorrhage has been controlled); it may limit the clotting cascade and microcirculatory plugging.

Sedation

- Dosages of pentobarbital (1–3 mg/kg IV) are adequate to reduce cerebral oxygen requirements and prevent seizures in most dogs and cats.
- Propofol, to effect: 3 to 4 mg/kg IV; 0.1 to 0.4 mg/kg/min.
- Phenytoin, 15 mg/kg IV, may be used for the same purpose.
- Diazepam or midazolam, 0.1 to 0.3 mg/kg IV, or an infusion, 2 to 10 µg/kg/min, is an excellent alternative to pentobarbital and produces less CNS depression.

Antibiotics

The choice of antibiotics is based on the potential for efficacy (see Table 157-3).

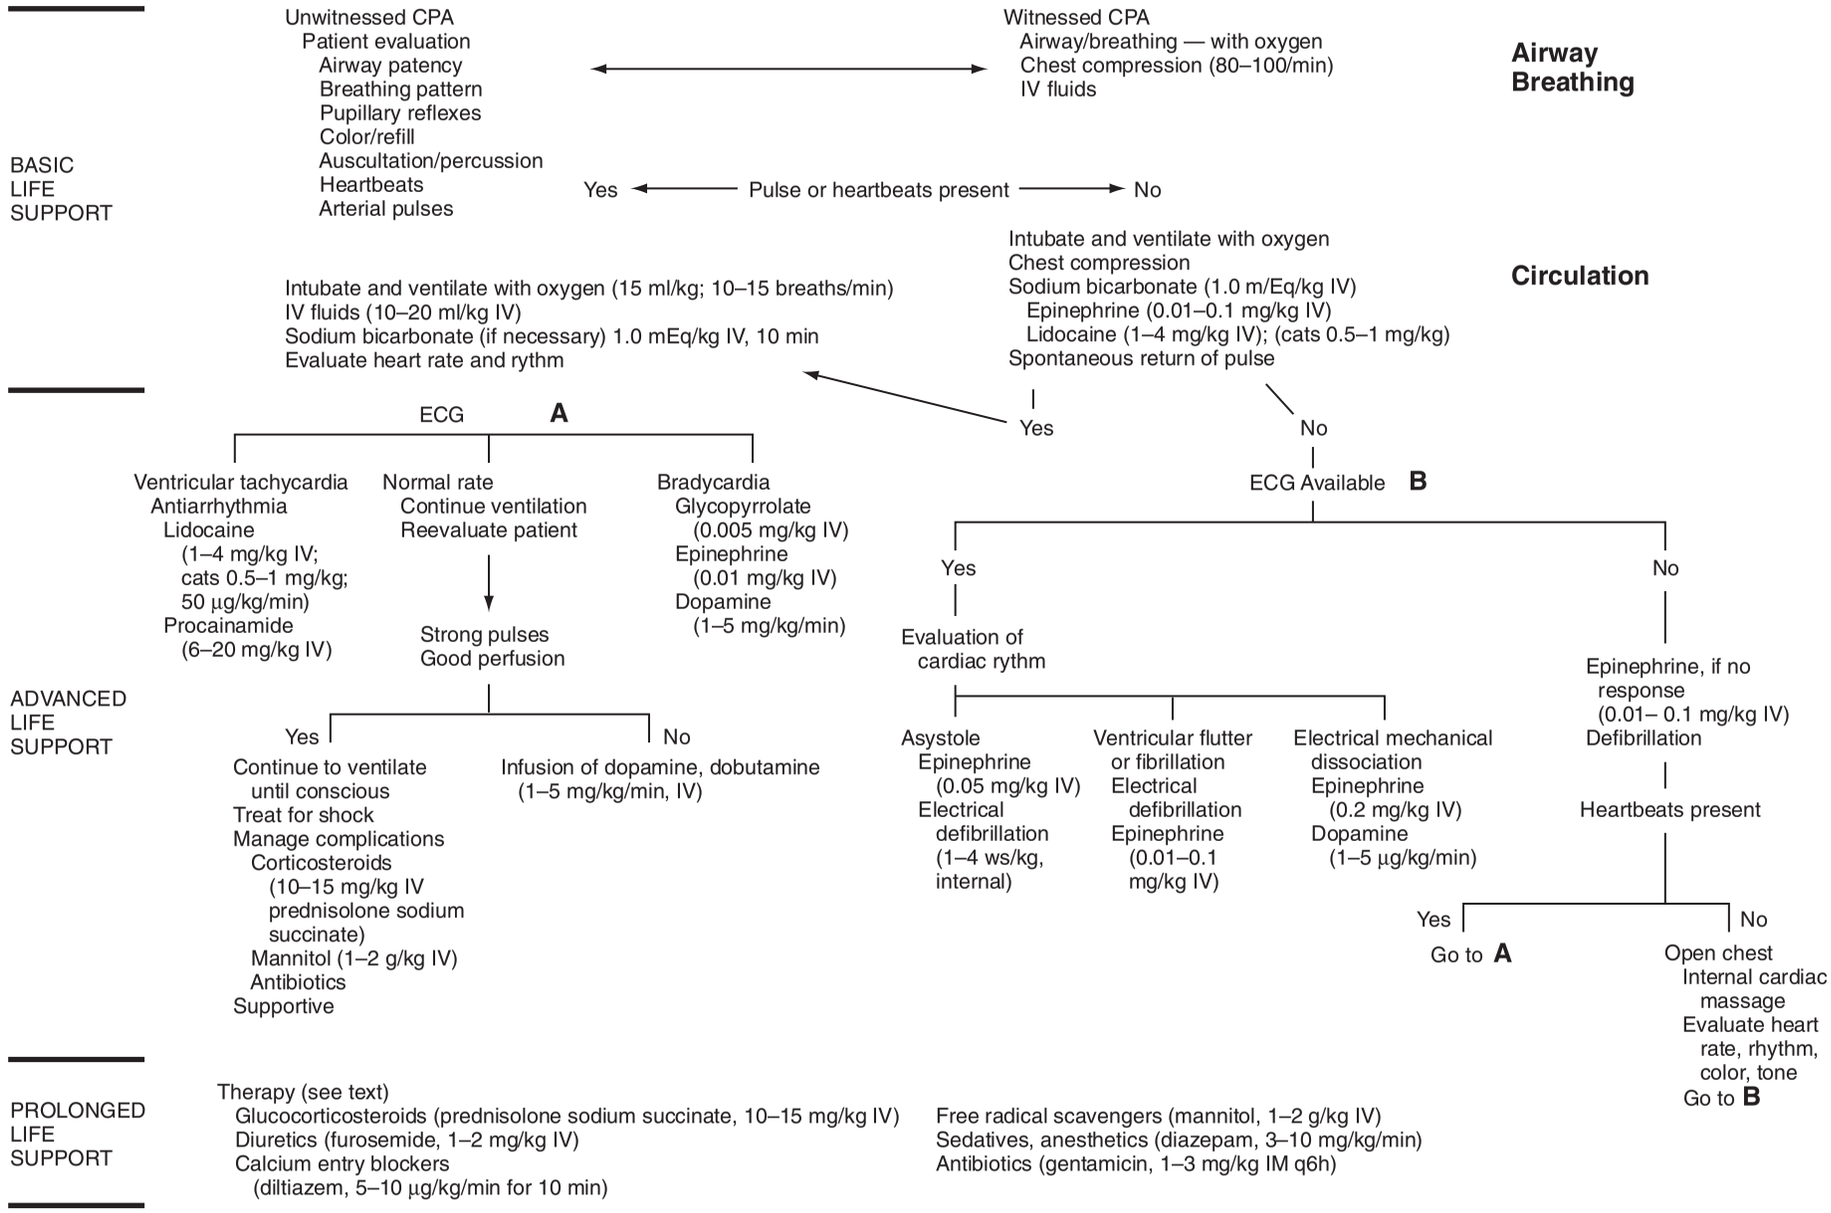

Figure 157-4. Flow chart for decision making during cardiopulmonary resuscitation. CPA: cardiopulmonary arrest.

PREDICTING OUTCOME

- Rapid recovery of eye (corneal) reflexes, upper airway reflexes including swallowing and sneezing, and spontaneous breathing are good prognostic signs.
- Continued unconsciousness, unresponsive pupils, persistent hypotension, hypothermia, and progressive deterioration of responses to physical stimulation after initial partial recovery are poor prognostic signs.

A simple algorithm for CPCR is illustrated in Figure 157-4.

Chapter

158 Diagnostic Methods in Respiratory Disease

Larry Berkwitt / James C. Prueter

This chapter briefly considers some of the more important diagnostic methods used in the recognition and assessment of respiratory disease with the goal of reminding the clinician of potential studies that may be of use in the diagnosis of upper and lower respiratory tract diseases.

UPPER RESPIRATORY TRACT

Nasal Cavity Diseases

Sneezing and nasal discharge are the principal clinical problems associated with nasal cavity and sinus diseases. A number of infectious diseases can be responsible (see Chapter 163 for additional information and diagnostic pointers). Inflammation, parasites, exudate, foreign bodies, or tumors may extend into the nasopharynx leading to gagging, reversed sneezing, or stertor. Diagnosis can be simple or highly challenging.

History

When taking the history, include:

- The chronology, progression, and duration of clinical signs, such as sneezing
- Type of nasal discharge
- Site of involvement (unilateral or bilateral)

Sneezing

- *Acute paroxysmal sneezing* typically is associated with viral rhinitis, nasal foreign body, allergic rhinitis, or trauma.
- *Chronic sneezing* suggests neoplasia, parasites, prolonged infection or inflammation (e.g., fungal rhinitis), chronic foreign body, or trauma with secondary infection or osteomyelitis.
- *Reversed sneezing* is a sign of disease or inflammation in the nasopharynx. Mites, post-nasal drip, foreign bodies, follicular rhinitis, and neoplasms are associated with this sign. When no lesions are evident, it is likely that (idiopathic) nasopharyngeal spasm is the cause.

Nasal Discharge

- Serous discharge typically is associated with acute foreign body, allergy, and viral infection.
- Mucopurulent and/or serosanguineous discharge typically is associated with viral infections (complicated by bacteria); bacterial, mycotic, and parasitic infections; long-term foreign body; neoplasia; and lymphocytic-plasmacytic inflammation.
- Hemorrhagic discharges suggest trauma, neoplasia, coagulopathy, and prolonged infection.
- Foodstuffs in the discharge suggest a communicating congenital defect (cleft palate) or acquired oro-nasal fistula.

Duration of Clinical Signs

- Sudden onset of signs suggests foreign body, viral infection, trauma, or coagulopathy.
- Chronic signs are associated with neoplasia, infection, foreign body, parasite infection, chronic inflammation, or congenital defect.

Site of Involvement

- Unilateral discharge suggests early neoplasia, foreign body, early infection, dental disease, or trauma.
- Bilateral discharge suggests chronic infection or inflammation, chronic foreign body with resulting infection/osteomyelitis, advanced neoplasia, coagulopathy, pneumonia, parasites, allergy, or trauma.

Physical Examination

A complete physical examination includes a thorough evaluation of the oral cavity, mucous membranes, tonsils, hard and soft palate, retropharyngeal area, regional lymph nodes, and teeth. Heavy sedation and/or anesthesia are generally required if the nasal cavity, nasopharynx, or larynx will be examined (see below).

- Identify swelling and asymmetry of the face, palate, or eyes (exophthalmos) that might suggest neoplasia, fungal infection, or trauma.

- Identify areas of pain that may localize the disorder.
- Evaluate for loss of patency of one or both nasal passages.
- Note ocular discharge that may be associated with nasolacrimal duct inflammation and/or obstruction secondary to inflammation or neoplasia.
- Identify cracked, loose, and infected teeth.

Complete Blood Count (CBC), Serum Chemical Profile, and Coagulation Screen

These evaluations are important when systemic diseases may be an underlying cause of signs. Although clotting disorders can cause epistaxis, it is far more commonly associated with platelet disorders such as immune-mediated thrombocytopenia, von Willebrand's disease, thrombocytopathia (drug-related or from hyperglobulinemia), or ehrlichiosis.

Serology

- Serologic tests such as immunodiffusion and enzyme-linked immunosorbent assay (ELISA) for aspergillosis and penicilliosis antibodies and for cryptococcal capsular antigen can be used for diagnosis of mycotic rhinitis. However, false-negative results are common, limiting the usefulness of serology. Molecular methods of diagnosis, confined to reference laboratories, are used for agents such as *Bartonella* spp.
- Direct observation, cytology, culture, and biopsy are more reliable than serology for identifying nasal fungi.

Radiography

- General anesthesia is essential for proper positioning and for prevention of motion artifacts.
- Include the following radiographic views (see Chapter 4):
  - Open-mouth ventrodorsal projection
  - Intraoral (occlusal)
  - Rostral-caudal frontal skyline
  - Lateral
  - Oblique skull views, particularly if dental arcade problems are suspected

Computed Tomography (CT) and Magnetic Resonance Imaging (MRI)

- Use CT of the nasal cavity and skull to delineate the extent of masses, loss of turbinates, bony lysis, midline shifts, or accumulation of fluid.
- Use MRI for better definition of brain involvement from invading nasal tumors (see Chapter 125).

Nasal Flushing for Cytology and Biopsy of Nasal Tissue

Nasal cytologic evaluation is often of little or no value unless it is performed with aggressive nasal flushing or by rhinoscopic visualization with the animal under anesthesia. Biopsy samples can be obtained under direct visualization, or by a blind method, guided by results of clinical examination and imaging. Retrograde rhinoscopy is needed to biopsy caudal masses or lesions extending into the nasopharynx.

- Perform aggressive nasal flushing with a polypropylene (rigid) male urinary catheter. Measure the length (nares to medial canthus) prior to insertion to avoid penetrating past the cribriform plate.
  - Perform intermittent flushing and suctioning via syringe to obtain as much nasal fluid and/or tissue fragments as possible.
  - Place gauze sponges in the nasal pharynx to catch any tissues that may be extracted during the flushing procedure.
  - Submit samples for culture, cytology, and histopathology.
- Small and medium-sized clamshell forceps can be used to obtain biopsy samples with or without benefit of rhinoscopy.

Rhinoscopy

Rhinoscopic examination under anesthesia allows visualization of mucosal lesions, masses, or foreign bodies. Biopsy and procurement of specimens for cytology, culture, and sensitivity can be guided by direct visualization. Different instruments are often used to evaluate the nostrils and cranial nasal cavity versus the posterior choane and nasopharynx (the passage located dorsal to the hard and soft palate). A flexible scope is superior for retrograde rhinoscopy, though it may be possible to evaluate the nasopharynx with a dental mirror, spay hook (to pull the soft palate cranioventrally), and a bright light. Polyps in cats are often visible simply by pulling the soft palate forward. Instrumentation for rhinoscopy can include any of the following:

- A flexible cytoscope or rhinoscope with an outer diameter of 2 mm is preferred.
- An otoscope with bright light source may be used for antegrade rhinoscopy.
- An arthroscope or cystoscope with an outer diameter of 1.9 to 5 mm will be useful in larger dogs.
- A bronchoscope with an outer diameter of 2.9 to 5 mm will be useful in larger dogs.
- Flexible pediatric bronchoscope.

Surgical Biopsy

- Exploratory rhinotomy with removal of a bone flap (see Chapter 160) provides complete exposure of the nasal cavity for biopsy, foreign body retrieval, culture, and debridement of diseased tissue.
- Drainage tubes can be placed at the time of surgery for treatment of bacterial and/or fungal infections.

Laryngeal Diseases

History

Clinical signs of laryngeal disease often are slowly progressive, and the owner may have noted them for an extended period of time. Laryngeal paralysis is common in a number of breeds (see Chapter 161).

- The owner may report hoarseness, progressive changes in voice, or complete loss of voice.
- Noisy respirations characterized by high-pitched inspiratory stridor or by mild, raspy, or fluid-sounding noise are common.
- Choking, gagging, and coughing may be observed, particularly while the animal is eating and/or drinking. This often worsens as the disease progresses or if there is concurrent pharyngeal disease.
- Exercise intolerance, cyanosis, and syncope may be observed in patients with laryngeal obstruction (e.g., laryngeal collapse, paralysis, foreign body, or neoplasia). Problems are exacerbated in high heat and humidity.

Physical Findings

- The most common physical findings in laryngeal disease are inspiratory dyspnea and stridor. Auscultation can detect upper respiratory inspiratory stridor ("wheeze") or lower-pitched obstructive sounds centered over the larynx.
- Palpation of the laryngeal area may detect the site of pain, fractures, and subcutaneous emphysema in cases of trauma and asymmetry due to neoplasia, granulomas, laryngitis, or unilateral muscle atrophy.
- The gag reflex may be decreased in some cases of laryngeal paralysis.

Laryngoscopy/Bronchoscopy

- Perform direct visualization under a *light* plane of anesthesia for evaluation of pharyngeal structures, soft palate, and laryngeal motor function. Tiletamine HCl/zolazepam HCl (Telazol) can cause laryngeal paralysis, so another form of sedation should be used. Propofol also depresses laryngeal motion. The use of doxapram has been advocated to stimulate the respiratory center to decrease the number of false positive examinations.
- Observe laryngeal (arytenoid) movement during both phases of respiration. Often asymmetry is observed between the left and right arytenoids and vocal folds. Be certain not to confuse passive abduction during expiration with active movements.
- A bronchoscope allows the best evaluation of the pharynx and the subglottic area for masses, infiltrates (areas of discoloration), granulomas, and polyps. In cats, laryngeal paralysis is often related to invasion by a neoplasm.
- Aspiration or brush cytology and endoscopic biopsy may be performed at the time of examination, if appropriate. Following laryngeal biopsy, the patient should be closely observed, as postsurgical edema or hemorrhage at the biopsy site may result in airway obstruction.

Radiography and Ultrasound

- A lateral radiograph of the larynx is rarely diagnostic but may demonstrate:
  - Dilated lateral saccules in cases of paralysis
  - Soft tissue swelling and/or asymmetry caused by neoplasia or trauma
  - Fractures, dislocations, or subcutaneous air caused by trauma
  - Elongated soft palate
  - Collapsed or ruptured trachea
- Thoracic radiographs may reveal chronic pulmonary or cardiac disease associated with upper respiratory diseases.
- Ultrasonography has been effective in the recognition of laryngeal disease and paralysis.

Electromyography

Abnormal electromyographic studies of the laryngeal muscles may be associated with neuromuscular, immune-mediated, and hypothyroid-related laryngeal disorders.

Thyroid Function Testing

Uncommonly patients with acquired laryngeal paralysis may have subnormal levels of triiodothyronine (T3), thyroxine (T4), and free T4 as well as abnormal results of TSH assay.

Histopathology

Histopathology of any abnormal growth or mass is important in order to differentiate chronic granulomatous disease and neoplasia and may also be useful in a generalized case of polyneuropathy.

Tracheal Diseases (see also Chapter 161)

History

- Usually there is a chronic, nonproductive, dry "honking" cough with intermittent attacks of dyspnea, particularly elicited with excitement, exercise, drinking, eating, or tracheal pressure (e.g., digital pressure or collar).
- Dyspnea and occasionally cyanosis may be demonstrated.
  - Inspiratory dyspnea and stridor develop if the cervical or extrathoracic trachea collapses.
  - Expiratory dyspnea is evident with intrathoracic tracheal collapse.

- Both phases of ventilation, especially expiration, are abnormal if the entire trachea is involved.

Physical Examination

- Tracheal palpation may demonstrate "sharp" edges or angles of the collapsible margins of the trachea.
- Cardiac examination is important to differentiate tracheal disease from primary cardiac disease and for evaluation of coexisting chronic cardiac disease (see Chapter 142).
- Auscultate the entire respiratory tract to localize primary abnormalities and to differentiate tracheal disease from lower respiratory tract disease (see Chapter 163).

Radiography

Radiographic examination (ventrodorsal and lateral views) is mandatory for routine evaluation of the cervical and thoracic trachea (see Chapter 159).

- Careful positioning avoids artifactual deviations of the trachea.
- Obtaining both inspiratory and expiratory films identifies an intermittently collapsing trachea or bronchus (this may be difficult or impossible in small-breed dogs).
- Survey radiography has limited sensitivity and specificity for diagnosis.
- Fluoroscopy may permit evaluation of dynamic tracheal functions and intermittent tracheal or principal bronchus collapse.

Transtracheal Wash

Perform an endotracheal wash (via a sterile endotracheal tube) for cytology, fluid analysis, and microbiologic evaluations to identify initiating or complicating factors that may be important in the treatment regimens. The procedure is discussed below.

Tracheoscopy

Tracheoscopy can be used to visualize anatomic lesions, tracheal collapse, hypertrophy of dorsal tracheal ligament, parasitic granulomas, foreign bodies, or neoplasia. Extreme care must be taken because of the potential of worsening airway collapse by trauma and iatrogenic irritation. In toy breeds with obvious tracheal collapse, the procedure is rarely needed except to guide surgery or stent placement. Tracheoscopy is very helpful for uncertain diagnoses or for those cases in which there is concern for a neoplastic or polypoid mass lesion, congenital defects, or concurrent mainstem bronchial collapse. As the patient must be extubated for diagnosis, supplemental oxygen should be supplied either through or around the endoscope proximally (with a small, flexible tube) during this examination. See "Bronchoscopy" in the bronchopulmonary section for further discussion of this procedure.

BRONCHOPULMONARY AND PLEURAL DISEASES

The diagnosis of diseases of the respiratory tract and pleural space depends on information obtained from a thorough history, a physical examination, and a series of ancillary tests that are well conceived and organized so as to limit the patient's discomfort and stress.

When evaluating the dyspneic patient, use sound clinical judgment in selecting tests that will aid in the diagnosis but will not place the patient in further respiratory distress. Often these patients must be stabilized, based on the physical examination, history, and dorsoventral thoracic radiograph, prior to performing other tests.

History

Coughing, tachypnea, dyspnea, and exercise intolerance are the principal signs associated with bronchopulmonary and pleural disease.

- Determine the patient's signalment, because certain breeds or age groups are more susceptible to particular diseases. For example, small and toy breed dogs are more susceptible than large breed dogs to lower respiratory disease secondary to a collapsing trachea. Cocker spaniels are prone to chronic bronchitis.
- Note the client's complaint. Determine if the patient's problem is acute or chronic and if it is improving, unchanging, or progressive.
- When evaluating a cough, determine the time of day of the cough. Cardiac coughs are usually nocturnal, whereas an infectious cough will occur throughout the day.
  - Determine the quality of the cough, such as dry hacking (nonproductive) or moist (productive).
- Note prior medical and travel history.
  - It is imperative to know what medications have been given previously and what medical response was obtained.
  - Consider geographically distributed diseases (e.g., systemic mycoses) in pets that travel or have lived in various locations.
  - Determine the patient's recent exposure to other pets that might be a source of infectious disease (e.g., in a kennel or grooming situation).
- Note the patient's current medical history. Do not overlook routine history questions about water consumption, appetite, and eliminations, because this information can give insight into the diagnosis of a systemic disease with pulmonary manifestations (e.g., hyperadrenocorticism leading to thromboembolism).

Physical Examination

Perform a complete physical examination.

- It is important to evaluate each body system, because key diagnostic physical findings may be present and pulmonary complications of heart disease may be evident. For example:
  - A remote lesion, such as a rectal carcinoma, may be the source of metastases that cause dyspnea and abnormal lung sounds.
  - In a coughing patient, skin lesions in endemic areas and lymphadenopathy suggest a diagnosis of blastomycosis.
  - A potbellied appearance, endocrine alopecia, and acute dyspnea may lead to a diagnosis of hyperadrenocorticism.
- Physical examination of the lower respiratory system and pleural space includes observation, auscultation, palpation, and percussion (see also Chapter 142).

Observation

Observe the patient's rate and pattern of breathing. Certain diseases cause inspiratory versus expiratory dyspnea.

- Note whether the patient is barrel-chested or overweight.
  - Barrel chest may indicate chronic obstructive pulmonary disease.
  - Pickwickian-type syndrome in obese animals may account for breathing problems.
- Slow, deep breathing with inspiratory difficulty can be due to large upper airway obstructive disease.
- Short, shallow breathing may be associated with restrictive disease.

Pulmonary Auscultation

Pulmonary sounds usually are classified as normal or vesicular, bronchial, or bronchovesicular (see Chapter 142). Adventitious sounds include crackles (rales), wheezes, stridor, rhonchi, and rubs.

- As air travels through the lung, it produces vesicular or bronchovesicular sounds. Depending on the medium through which the air travels (e.g., fluid or mucus) or if there are changes in diameter of diseased airways, the sound is modified (e.g., crackles, rhonchi, wheezes).
- Identification of crackles (small airway or parenchymal disease), rhonchi (airway disease or exudate), and wheezes (airway obstruction) indicates a need for additional diagnostic studies.

Percussion

The lungs and thoracic cavity emit a specific resonance when percussed by striking the second phalanx (p) of the middle finger positioned on the chest with the knuckle joint (p1–p2) fully extended (see Chapter 142).

- Dull resonance is associated with increased density (fluid or mass lesion) within the underlying pleural space or lung.
- Increased resonance (drum-like) is associated with increased air within the pleural space or lung.

As an example of incorporating all parts of the physical examination, consider the patient that has a mammary mass with louder or adventitious lung sounds on auscultation and dull percussion on the left side of the thoracic wall. This patient may have pleural effusion associated with metastatic disease. If dull percussion is present without lung sounds, suspect a consolidating mass lesion.

Thoracic Imaging—Radiograph, Ultrasound, and CT (see also Chapter 159)

Standard radiographic views include inspiratory lateral and ventrodorsal views.

- To evaluate for metastatic lung disease, right and left lateral projections with the ventrodorsal view may be helpful, and are strongly recommended.
- In a dyspneic, unstable patient, a single dorsoventral view is recommended to avoid unnecessary stress and to enable the clinician to initiate stabilizing therapy prior to further evaluation.

Evaluation of Radiographs

- Good-quality radiographs are important because excess motion or underexposure may result in false information regarding the pulmonary interstitium (see Chapter 4). Expiratory films may cause the pulmonary interstitium to have an increased density that can be mistaken as abnormal.
- To evaluate thoracic radiographs:
  - Determine the type of radiographic infiltrative pattern present, such as interstitial, alveolar, bronchial, vascular, or combinations of these.
  - Characterize the location of the infiltrate as localized or diffuse; cranial or caudal; and ventral, dorsal, or hilar.
  - Pleural effusion is indicated by blunted costophrenic angles, pleural fissure lines, and ventral scalloping of the lungs on the lateral projection.
- Thoracic ultrasound is valuable for detection of small amounts of fluid, for visualization of consolidated areas of lung and for larger mass lesions, and for identification of mediastinal mass lesions. This method, which requires advanced training for optimal use, can also guide tissue sampling.
- Computerized tomography is helpful for the detection of smaller pulmonary and pleural lesions, including metastatic lesions of the lung and pleural space, and of the presence or absence of hilar lymphadenopathy. The study may help to distinguish pulmonary mass lesions from mediastinal or esophageal

mass lesions. This is a referral examination in most cases.

Complete Blood Count

The CBC may be helpful in evaluation of respiratory disease. For example:

- Leukocytosis can indicate infection or inflammation.
- Polycythemia is associated with chronic hypoxemia.
- Eosinophilia may suggest a parasitic or allergic disease.
- Nucleated red blood cells may indicate acute hypoxemia.

Serum Chemistry Profile

No single segment of the standard automated serum chemistry profile is pathognomonic for respiratory system disease; however, this study is useful as a baseline to evaluate other organ systems. For example:

- If a patient has a localized anterior ventral alveolar infiltrate, calcification of the airways, neutrophilic leukocytosis, lymphopenia, and eosinopenia with elevated alkaline phosphatase and cholesterol levels, a tentative diagnosis of bacterial pneumonia secondary to hyperadrenocorticism might be made pending confirmatory tests.
- D-dimers may be elevated with pulmonary thromboembolic disease. The test is not specific, but a negative test argues against a diagnosis of thromboembolic disease.

Arterial Blood Gas (ABG) Analysis and Pulse Oximetry

The ABG specimen usually is drawn from the femoral artery, dorsal pedal artery, or an indwelling arterial catheter. ABG arterial analysis evaluates the patient's ability to oxygenate arterial blood. Pulse oximetry is a measure of the functional status of the patient in terms of hemoglobin saturation. Patients with saturations below 90% require immediate attention; this typically correlates to a partial pressure of oxygen of <70 mm Hg.

- In the normal patient breathing room air, the partial pressure of oxygen should be >95 mm Hg. In recumbent patients the values often are lower, but should still be >85 to 90 mm Hg.
- When the level is <60 mm Hg, respiratory failure is present.
- Elevations in CO_2 indicate ventilatory failure and contribute to respiratory acidosis. If a patient has decreased Pao_2 and increased Pco_2 the prognosis is guarded to poor.
- Alveolar-arterial oxygen difference ($A\text{-}aDO_2$; normal 4–17 mm Hg) is a parameter of gas exchange efficiency calculated as (150—$PaCO_2$)—PaO_2 when breathing room air at sea level, or using the standard full formula.

Serology and Molecular-based Tests

Specific serologic- and molecular-based evaluations aid in the diagnosis of fungal, rickettsial, and obligate intracellular microorganisms, as well as some immune-mediated diseases.

Fecal Examination

To establish the diagnosis of parasitic lung disease, evaluate fecal specimens by direct smear, flotation, and sedimentation techniques (available from commercial laboratories). Fecal sedimentation is an important tool for the detection of lungworm larvae (e.g., *Filaroides, Aelurostrongylus*) that otherwise could be overlooked if flotation is used.

Transtracheal Washing

Tracheal washing is a simple, inexpensive procedure in which warm sterile saline is instilled in the lower respiratory tract and then retrieved. Use this technique to obtain specimens for cytologic and microbiologic evaluation of the lower respiratory tract to aid in the diagnosis of bronchopulmonary disease.

Technique

1. In *dogs,* insert a long through-the-needle catheter (12 or 18 inches) percutaneously under local anesthesia between the tracheal rings or through the cricothyroid membrane and then advance it into the lower airway. Alternatively, an endotracheal wash can be performed under general anesthesia by placing a sterile urinary catheter through a sterile endotracheal tube. This approach is better for cats, small dogs, or animals with primary tracheal diseases.
2. In *cats,* use an open-end urinary catheter placed through a sterile endotracheal tube or adapt a 3-way stopcock or syringe adaptor directly to the endotracheal tube.
3. The catheters ideally should extend to the level of the tracheal bifurcation.
4. Inject warm sterile saline (6 ml in cats and small dogs; up to 20 ml in large dogs) through the catheter.
5. After instillation of the fluid, induce coughing by gently slapping the rib cage bilaterally (in awake patients).
6. Retrieve the fluid from the airway by aspiration with a syringe. In anesthetized patients, continual suction with a mucous trap provides the best results.
7. Prepare samples of the lavage fluid for cytology, culture, and sensitivity testing.
8. Any fluid remaining in the airways is harmless because it is rapidly absorbed by the pulmonary lymphatics.

Bronchoalveolar Lavage and Bronchoscopy

Bronchoalveolar Lavage

This is an effective method for retrieving diagnostic material from the lung and is particularly useful in alveolar-interstitial lung diseases and in tachypnea/dyspnea when prominent cough is absent. Proper performance of this study and bronchoscopy require advanced training.

Technique

1. Advance a flexible fiberoptic bronchoscope into the bronchial tree.
2. Visually locate the diseased area and wedge the bronchoscope within the bronchus.
3. Instill 20–30 ml of warm saline (for a 15 kg dog) through the bronchoscope channel and then retrieve it. Thoracic coupage may facilitate fluid retrieval.
4. Prepare samples for cytology, quantitative cell counts, culture, and sensitivity testing.

Bronchoscopy

Bronchoscopy allows direct visualization of the lower airway to the level of the third, fourth, or fifth bronchial divisions, depending on the size of the patient and the length and diameter of the bronchoscope.

- Bronchoscopy is a valuable alternative when no diagnostic material is obtained using the tracheal wash procedure. This can occur because there is not enough cellular material present within the airway, because the catheter is too short to retrieve any material, or because the disease is unilateral.
- Diseased areas can be directly visualized, and the exudate or tissue can be removed for cytology or histopathology.
- If there is no visible material present, bronchial brushing or bronchoalveolar lavage can retrieve cells that may aid in a diagnosis.
- Direct biopsy of visible lesions can be performed through the bronchoscope as well as through transbronchial lung biopsy, which is described in the following section.

Lung Biopsy

When the cause of diffuse lung disease cannot be determined using one of the methods described previously, consider a lung biopsy. The types of lung biopsy procedures performed in small animals include:

- Fine-needle aspiration
- Bronchoscopy
- Ultrasound- or CT-guided biopsy
- Mini-thoracotomy
- Thoracoscopy (referral centers)

Fine-Needle Aspiration

The simplest, most cost-effective procedure is fine-needle aspiration. This is usually performed on diffuse or large, superficial lesions within the parenchyma or pleural space. Peripheral lesions well visualized with ultrasound are best suited for this procedure.

Technique

1. Clip and surgically prepare the thoracic wall and instill a local anesthetic at the site. In a fractious patient, a light plane of anesthesia is preferable.
2. Attach a 22-gauge needle to a short extension set and 6cc. syringe. A spinal needle is preferred because of its length.
3. Visualize the lesion with ultrasound. Place the needle into the lesion, and with multiple short strokes take a sample each time.
4. Use the syringe to empty the sample onto a slide. This same procedure can be used to obtain samples from other organs with ultrasound guidance.

Bronchoscopic Biopsy

A lung biopsy can be obtained utilizing the bronchoscope. This method is used with deeper, more central lesions and ideally should be performed under fluoroscopy. The endoscopic biopsy forceps are passed through the bronchial wall into the pulmonary parenchyma.

Keyhole Lung Biopsy

The most invasive type of biopsy is performed via a mini-thoracotomy.

Technique

1. Make an incision 3 to 7 cm long between the ninth and tenth ribs.
2. Bring the lung tissue into the incision, place a ligature or staple around the affected area of lung, and remove the sample.
3. Inspect the stump for hemorrhage or air leak.
4. Thoracic tube should be placed, and the patient observed for 24 hours.
5. Remove the tube after obtaining negative aspirations.

Potential Risks of Biopsy

Because of the risk of hemorrhage and pneumothorax with each of these procedures, postbiopsy monitoring is essential.

- Open-lung biopsy decreases the risk of pneumothorax because the biopsy site is visualized and all leakage can be controlled.

- In fine-needle aspiration, withdrawal of infectious material can contaminate the pleural space and cause pyothorax.

Thoracocentesis

The diagnosis of pleural effusion generally depends upon analysis of pleural fluid obtained by thoracocentesis (see Chapter 3 and Chapter 164 in this section). Thoracocentesis can also be therapeutically beneficial. Perform the procedure with minimal stress to the patient.

Electrocardiography and Ultrasonography

Often, it is difficult to determine whether a patient's problem is respiratory or cardiovascular.

- With pulmonary hypertension secondary to thoracic disease, the electrocardiogram may show P-pulmonale evidenced by p waves >0.4 mV and deep s waves in leads I, II, III, and aVF.
- When pulmonary hypertension is suspected, pulmonary artery pressure and flow velocity should be measured with Doppler echocardiography.
- Ultrasonography can identify specific cardiac abnormalities and masses within the mediastinum, pleural space, and pulmonary parenchyma (see Chapters 4 and 159). Echocardiography can help to rule out cardiac disease as a cause of respiratory signs.

Other Specialized Diagnostic Tests

Other useful tests include thoracoscopy, bronchography, lymphangiographic studies for evaluation of chylothorax, computed tomography, magnetic resonance imaging, vascular and radioisotopic studies to identify pulmonary thromboembolism, and pulmonary function testing. These procedures, if necessary, are performed at referral centers.

Chapter

159 Diagnostic Imaging in Respiratory Disease

Valerie F. Samii

INDICATIONS FOR RADIOGRAPHIC EVALUATION

Radiography is commonly used for evaluating respiratory disease in small animals. Thoracic examinations can be performed rapidly and noninvasively, often without the need for patient sedation. Serial evaluations of the thoracic cavity are often performed to monitor resolution or the advancement of pathological processes. Although radiography is a sensitive method for detecting respiratory disease, changes are often nonspecific, and similar radiographic findings may be seen in different disease processes.

▼ ***Key Point*** Radiographic findings need to be assessed in light of the patient's clinical and physical examination findings.

RADIOGRAPHIC ANATOMY

- Radiographic evaluation of the nasal cavity and nasopharynx is best accomplished with the patient under general anesthesia. The open-mouth, ventrodorsal view of the maxilla is the best view for assessing disease within the nasal passages. Mirror image symmetry between the right and left nasal passages, on either side of the nasal septum, should be observed. Nasal turbinates appear as thin, lacy mineralized structures surrounded by air. Occasionally, deviation of the nasal septum is seen as a variation of normal. The frontal sinuses are typically underdeveloped in dogs with congenital hydrocephalus or with a domed cranium conformation (e.g., Chihuahua).
- Radiographic evaluation of the upper airways, to include the nasopharynx, oropharynx, larynx and trachea, is best accomplished with the patient in lateral recumbency. The soft palate and epiglottis are well outlined by air. The larynx is ventral to the first two cervical vertebrae. The bones of the hyoid are easily identified and should not be mistaken for foreign bodies. Mineralization of the laryngeal and tracheal cartilages is a common finding, particularly in older dogs and chondrodystrophic breeds. The normal larynx is slightly wider than the trachea.
- The trachea should be uniform in diameter throughout its length. The trachea is typically positioned to the right of midline in the cranial thorax. The cartilaginous tracheal rings are incomplete dorsally in the dog. Calculation of the ratio of tracheal diameter to thoracic inlet diameter is one way used to assess tracheal size. The normal ratio in non-brachycephalic breeds is 0.20 ± 0.03. The ratio is slightly smaller in brachycephalic breeds.

▼ ***Key Point*** The dorsal trachealis muscle may relax and protrude into the tracheal lumen at the level of the thoracic inlet in normal dogs.

- The following structures should be visible on a normal thoracic radiograph: the cardiac silhouette, pulmonary arteries and veins, caudal vena cava, descending aorta, trachea, primary bronchi, diaphragm, and (in young animals) the thymus.
- The following structures are often not seen on a normal thoracic radiograph: the cranial vena cava; aortic arch; brachycephalic trunk; esophagus; secondary and tertiary bronchi; and the mediastinal, tracheobronchial, and sternal lymph nodes. It is not uncommon to see small amounts of gas in the cranial to mid-thoracic esophagus, particularly in a sedated or aerophagic animal. It is also not uncommon to see a small amount of fluid (soft tissue opacity) in the caudal thoracic esophagus, particularly when the animal is in left lateral recumbency.
- Radiographically the pulmonary vessels account for the majority of the pulmonary patterns observed on normal films. The pulmonary arteries and veins should be matched in size.
  - On the lateral thoracic radiograph, the artery lies dorsal to its corresponding vein. On the dorsoventral (DV) or ventrodorsal (VD) radiograph, the artery lies abaxial to its corresponding vein. Hence,

*The author would like to acknowledge the contributions to this chapter made by Dr. C. Wendy Myer, Diplomate ACVR.

veins are central and ventral relative to their corresponding arteries.
  - On the lateral radiograph, the diameter of the cranial lobar vessels should be roughly the width of the fourth rib as it crosses that rib. The diameter of the caudal lobar vessels should be roughly the width of the ninth rib as it crosses that rib. Vessels should be linear, soft tissue opacities that taper toward the periphery of the lung.
- The bronchi are thin-walled structures that appear as paired, soft tissue opaque lines running parallel to vessels in the longitudinal plane, and as thin-walled doughnuts in the cross-sectional plane. Bronchial wall mineralization may be seen in older animals.

TECHNICAL CONSIDERATIONS

Two orthogonal radiographic views of the thorax should be obtained. Standard views include either a right or left lateral and VD or DV radiographs. The cross-bars of the collimator should be positioned just caudal to the scapula.

Thoracic radiographs should be made using a high kVp and a low mAs to increase image latitude. Exposure times should be fast, not longer than $^{1}/_{60}$ second, to diminish the effects of cardiac and respiratory motion. In tachypneic or panting animals, temporarily holding or blowing into the animal's nose may briefly cease respiratory motion.

▼ ***Key Point*** Thoracic radiographs should be exposed at peak inspiration using proper technique to evaluate the pulmonary parenchyma. Poorly aerated or underexposed lung will appear diffusely increased in opacity and may be misinterpreted as interstitial disease.

- Inspiratory and expiratory radiographs with the patient in lateral recumbency may be used to demonstrate dynamic tracheal or bronchial collapse if fluoroscopic imaging is unavailable.
- Inspiratory and expiratory radiographs with the patient in DV or VD positioning may be used to demonstrate diaphragmatic paralysis if fluoroscopic imaging is unavailable.
- For animals with moderate to severe pleural effusion, if a VD is tolerated, it is preferred to the DV radiograph to better assess the cardiac silhouette and pulmonary parenchyma. Pleural effusion will increase the overall opacity of the pulmonary structures due to summation. Also, pulmonary opacity will increase due to lung underinflation secondary to fluid in the pleural space.

Effect of Gravity on the Dependent Lung

When an animal is placed in lateral recumbency, the lung closest to the cassette becomes partially atelectatic and receives more blood volume and less air than the 'up' lung. This decreases contrast resolution in the dependent lung and the lung will have an increased soft tissue opacity. Therefore, pulmonary pathology that might be readily apparent on other radiographic views may be difficult to see when in the dependent lung. This is particularly apparent in portions of lung that are adjacent to or summate with the mediastinum, cardiac silhouette, or diaphragm. Thus, soft-tissue opaque pulmonary structures are best seen radiographically when they are in the better aerated, nondependent, 'up' lung. For this reason, both right and left lateral views of the thorax are commonly taken to screen for pulmonary metastatic disease.

Follow-Up Studies

▼ ***Key Point*** When performing recheck examinations, it is important to use similar radiographic techniques and positioning to facilitate the comparison of studies.

This is especially critical in animals with unilateral pulmonary disease (i.e., lobar pneumonia, primary pulmonary neoplasia) because pathological changes in the dependent lung may not be well appreciated on the lateral radiographic views. Accurate assessment of pleural fluid volume is also difficult when comparing DV and VD projections, even when the two radiographs are taken during the same examination. Depending on the initial thoracic pathology and the degree of resolution or advancement, additional radiographic exposures using modified techniques may be helpful.

RADIOGRAPHIC ABNORMALITIES OF THE NASAL CAVITY

- Rhinitis and neoplasia may cause focal or diffuse increases in radiographic opacity of the nasal passage. Turbinate destruction is often present in animals with neoplasia or erosive rhinitis. Most cases of bacterial or foreign body rhinitis involve the rostral and middle portions of one or both nasal passages. Most nasal neoplasms originate from one nasal passage but may extend into the other.
- Fungal rhinitis, such as aspergillosis, often causes osteomyelitis with a productive osseous component, most notably involving the frontal sinuses. There may be a diffuse *decrease* in radiographic opacity of the nasal passages due to the complete destruction of turbinates, which is followed by the animal sneezing them out. Fungal rhinitis often involves the entire nasal cavity.
- Neoplastic processes often appear more destructive than rhinitis. The mass effect caused by some neoplasms may result in displacement of normal nasal structures and distortion of anatomical structures.

Definitive diagnosis of nasal disease is generally not possible radiographically. Rhinoscopy with biopsy, cytology, and/or culture is necessary.

RADIOGRAPHIC ABNORMALITIES OF THE NASOPHARYNX, OROPHARYNX, AND LARYNX

- Upper airway diseases such as brachycephalic upper airway obstruction syndrome, laryngeal paralysis, and laryngospasm are best evaluated using visual examination externally or endoscopically.
- Masses, such as neoplasia, nasopharyngeal and oropharyngeal polyps, abscesses, and granulomas, may appear radiographically as soft tissue opacities within the airways. These masses may or may not have internal mineralization.
- Masses outside the larynx or pharynx are more difficult to identify because they are not surrounded by gas. These lesions may be identified based on their encroachment of air-tissue interfaces.

RADIOGRAPHIC ABNORMALITIES OF THE TRACHEA (Fig. 159-1)

- Tracheal hypoplasia is a congenital disorder seen most commonly in brachycephalic breeds, particularly English Bulldogs. The tracheal diameter is diffusely decreased and in severe cases, the ratio of tracheal diameter to thoracic inlet diameter may be reduced to less than 0.10.
- Tracheal displacement by regional soft tissues is a reliable sign of mass lesions once positioning artifacts and breed characteristics have been considered.
- Except for tracheobronchial and mediastinal lymphadenopathy and severe cardiomegaly, lesions causing significant attenuation of the tracheal lumen usually originate within the trachea.

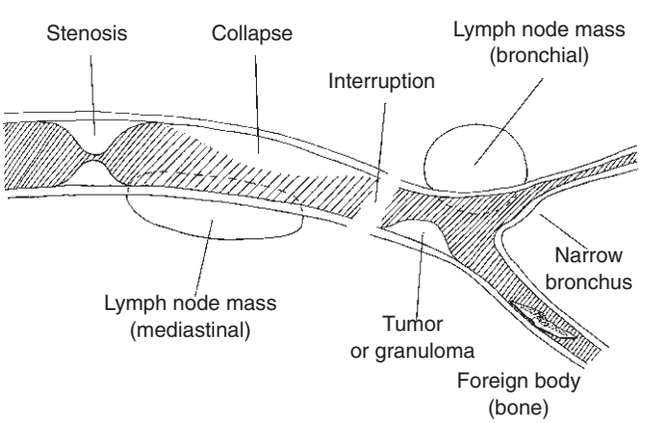

Figure 159-1. Schematic representation of various causes of tracheobronchial disease.

- Masses, such as neoplasia, polyps, abscesses, granulomas, and foreign bodies, may appear radiographically as soft tissue opacities within the airways. These masses may or may not have internal mineralization. Tracheal neoplasia is rare in small animal patients.
- Tracheitis, secondary to upper airway inflammation, may cause transient luminal narrowing due to tracheal mucosal swelling and must not be incorrectly diagnosed as tracheal hypoplasia.
- Tracheal perforation usually occurs in the thoracic inlet portion of the trachea and results in subcutaneous emphysema, pneumomediastinum, and often pneumoretroperitoneum. Occasionally, a pneumomediastinum may progress to a pneumothorax.
- Complete tracheal rupture is an uncommon, life-threatening event. In addition to severe peritracheal air accumulation, discontinuity of the tracheal wall is seen with separation of the tracheal rings. This is best assessed on the lateral radiographic view. This occurs most commonly in cats just cranial to the heart base.
- Focal tracheal stenosis is most commonly secondary to previous trauma (i.e., dog fight, prolonged overinflation of endotracheal tube cuff) with resultant stricture.
- Tracheal collapse is usually dynamic in nature, resulting in variation of tracheal diameter relative to the phase of the respiratory cycle. Tracheal collapse is often exacerbated during periods of excitement or during coughing. This is most commonly seen in toy breed dogs prone to loss of structural rigidity of the trachea and mainstem bronchi secondary to chondromalacia. To adequately assess tracheal dynamics, lateral thoracic radiographs are needed. These should be taken during peaks of inspiration and expiration, and should include the caudal neck. The cervical and thoracic inlet portions of the trachea collapse during inspiration, whereas the intrathoracic portion of the trachea and mainstem bronchi collapses during expiration.

▼ ***Key Point*** Superimposition of the esophagus over the dorsal aspect of the trachea is a common finding that may lead to the misdiagnosis of tracheal collapse in a normal dog. This appearance does not change during respiration unlike an animal with true tracheal collapse.

RADIOGRAPHIC ABNORMALITIES OF THE EXTRAPLEURAL SPACE

- The extrapleural space communicates with many of the fascial planes of the body via the thoracic inlet. It can be divided into two areas:
  - The potential space between the parietal pleura and the body wall
  - The potential space within the mediastinum

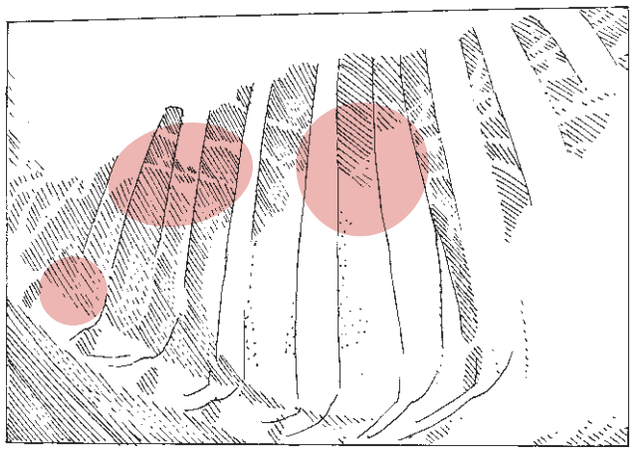

Figure 159-2. Location of thoracic lymph nodes.

- Conditions affecting the extrapleural space include abscesses, hematomas, granulomas, and neoplasms.
- Radiographically, most extrapleural diseases appear as relatively spherical, smoothly marginated masses that have a convex border facing the lung with tapering or concave cranial and caudal margins (the *extrapleural sign*).
- Thymic masses, mediastinal lymphadenopathy, and rib tumors with osteolysis are common extrapleural lesions.

Thoracic Lymph Nodes (Fig. 159-2)

The thoracic lymph nodes are located in three areas within the mediastinum:

- Dorsal to the second sternabra (sternal lymph nodes)
- Dorsal aspect of the cranial thorax (mediastinal lymph nodes)
- Hilar area of lung surrounding the bifurcation of the mainstem bronchi from the trachea (tracheobronchial lymph nodes)

▼ ***Key Point*** The thoracic lymph nodes are usually not visible in a healthy animal. When enlarged, they appear as soft-tissue opaque masses in these locations.

- Cranial mediastinal lymphadenomegaly may cause apparent widening of the cranial mediastinum on the DV or VD radiographic view, and dorsal displacement of the trachea on the lateral radiographic view.
- Enlargement of the tracheobronchial lymph nodes may compress the mainstem bronchi abaxially and ventrally. On the VD or DV radiographic view, this *splaying* of the mainstem bronchi can mimic the radiographic appearance of left atrial enlargement. However, on the lateral radiographic view, tracheobronchial lymphadenomegaly causes *ventral* displacement of the mainstem bronchi, whereas left atrial enlargement would cause dorsal deviation of the mainstem bronchi.
- The sternal lymph nodes receive afferent vessels from the abdominal wall and serosa as well as the thymus, thoracic wall, and mammary glands. Hence, abdominal disease should be suspected when sternal lymphadenomegaly is seen, particularly if thoracic disease is not identified.

Mediastinal Shift

A mediastinal shift occurs as a result of a unilateral decrease (ipsilateral shift) or increase (contralateral shift) in lung volume. Other intrathoracic masses may also cause a contralateral mediastinal shift.

▼ ***Key Point*** A mediastinal shift can only be identified on straight VD and DV radiographic views.

Cranial Mediastinal Masses

Thymoma and lymphoma are the most common neoplasms. In the cat, lymphoma frequently causes a large cranial thoracic mass that is non-compressible on physical examination. Other lesions that may cause a mass effect in the cranial mediastinum are branchial cysts, abscesses, and granulomas (most commonly the result of esophageal perforation).

▼ ***Key Point*** Obese animals and brachycephalic breeds may contain a large amount of fat in the cranial mediastinum, mimicking the appearance of a mass. Hence, it is important to recognize the radiographic differences between fat and soft tissue opacity to make this differentiation. Fat will be less opaque than soft tissue.

Concurrent pleural fluid may mask the presence of a cranial mediastinal mass. Thoracocentesis prior to radiography and/or horizontal-beam positional radiography (patient standing erect) is recommended.

Mediastinal Fluid

Mediastinal fluid is of soft-tissue radiographic opacity and may be difficult to distinguish from a mass. Horizontal-beam positional radiography may be helpful in differentiating a mediastinal mass from fluid.

Common causes of mediastinal fluid accumulation include hemorrhage (coagulopathy or trauma-induced), esophageal perforation, and feline infectious peritonitis (FIP).

Pneumomediastinum

Pneumomediastinum (i.e., air within the mediastinum) may result from a perforating injury of the esophagus, trachea, or bronchus near the hilus, usually in association with penetrating wounds of the cervical soft tissues or thoracic inlet.

This condition enables radiographic identification of the normally invisible mediastinal structures such as the esophagus, cranial vena cava, brachiocephalic artery, and other mediastinal vessels.

Because the cranial mediastinum communicates with the fascial planes of the body, extensive subcutaneous emphysema and/or pneumoretroperitoneum are common complications of this condition.

Pneumothorax may occur secondary to pneumomediastinum; however, the reverse does not occur.

RADIOGRAPHIC ABNORMALITIES OF THE PLEURAL SPACE

The normal pleural space is not visible radiographically. Filling of this space with air, fluid, or viscera (diaphragmatic hernia) will cause the space to enlarge and become apparent radiographically.

Pneumothorax

In animals with pneumothorax, the pleural space appears widened and radiolucent, the lung appears smaller than normal and increased in interstitial opacity (atelectatic), and the heart appears dorsally deviated from the sternum on the recumbent lateral radiographic view, due to shifting of the heart from midline. Pneumothorax may be classified as open or closed.

Open Pneumothorax

In an open pneumothorax, there is a defect in the body wall and air enters the thoracic cavity from the environment. Air will enter the thoracic cavity until the pleural pressure equals the atmospheric pressure.

Closed Pneumothorax

In a closed pneumothorax, there is a rent in the visceral pleura and the free pleural air comes from the lung. A closed pneumothorax may be further divided into simple and tension forms.

Simple Closed Pneumothorax

This is caused by a puncture wound or laceration of the lung that allows free movement of air through the defect during both inspiration and expiration. There is rapid equilibration between the lung and pleural cavity, and the severity of the condition depends on the dimensions of the injured area.

Tension Pneumothorax

This occurs when pleural space pressure exceeds atmospheric pressure during inspiration and expiration. Often, a flap-like defect, acting as a one-way valve, is the cause. Air can enter the pleural space during inspiration but closes and does not allow air to leave during expiration. Thus, pressure inside the pleural space may continue to increase, and progressive pulmonary atelectasis and cardiovascular compromise may develop. This condition is a medical emergency. Radiographically, tension pneumothorax is characterized by flattening of the diaphragm, severe progressive pulmonary atelectasis, and microcardia.

Pleural Effusion

- Pleural effusion is characterized by increased soft-tissue opacity within the pleural space that changes in distribution depending on patient positioning. It is not possible to radiographically determine the type of effusion within the pleural space; thus, thoracocentesis with fluid analysis is necessary to reach a definitive diagnosis.
- Radiographically, the pleural space appears widened and radiopaque and the lungs appear smaller and separated by the pleural soft-tissue opacity.
- The ease with which pleural effusion can be detected depends on the quantity and distribution of fluid. Pleural fluid gravitates to the dependent portions of the thorax. On the DV radiographic view, pleural fluid will result in an overall haziness to the internal thoracic structures, obscuring the outline of the ventrally positioned cardiac silhouette and the diaphragmatic cupula. On the VD radiographic view, pleural fluid will surround retracted lung lobe margins dorsally and the cardiac silhouette and diaphragmatic cupula are less obscured because they are adjacent to aerated lung
- Horizontal-beam positional radiography is helpful in distinguishing pleural effusion from an intrathoracic mass.

▼ ***Key Point*** If fluid accumulation is limited to one hemithorax or if peripheral lobar margins are excessively rounded, restrictive pleuritis secondary to chronic pyothorax or chylothorax should be considered.

Pleural Thickening

Pleural thickening is characterized by thin, soft-tissue opaque fissure lines between lung lobes and cannot be differentiated from small volumes of pleural effusion. Pleural fissure lines are often seen as an incidental finding in healthy dogs.

RADIOGRAPHIC ABNORMALITIES OF THE DIAPHRAGM

The normal diaphragm is a thin, soft tissue structure that silhouettes with the liver and is not distinctly visible radiographically. Radiographic evidence of diaphragm pathology is nonspecific and changes observed most frequently include general or focal outline loss of the tho-

racic diaphragmatic surface and changes in diaphragmatic shape and position.

- The position of the diaphragm changes during inspiration and expiration.
- Cranial displacement of the diaphragm is most commonly associated with abdominal disease or generalized diaphragmatic paralysis.
- Caudal displacement of the diaphragm is most commonly associated with respiratory disease (e.g., feline asthma), pneumothorax, or pleural effusion.
- During extreme inspiration, particularly for animals in respiratory distress, the thoracic surface of the diaphragm may have a scalloped appearance on the VD and DV radiographic views. This is often referred to as *tenting* of the diaphragm.
- An asymmetrical shape to the diaphragm may occur with hemiparalysis.
- Suspected diaphragmatic paralysis may be confirmed using fluoroscopy.

Diaphragmatic Hernia

Most diaphragmatic hernias are traumatic in origin, although congenital hiatal, peritoneal-pericardial, and true hernias also occur.

- The radiographic appearance of a diaphragmatic hernia varies, depending on the size and location of the defect and the amount and type of herniated viscera. The most obvious radiographic signs are discontinuity of the diaphragm and herniation of the gastrointestinal tract (gas filled viscus) or other abdominal viscera into the thorax. The lungs, heart, and mediastinum often will be shifted cranially and laterally. The heart and portions of the diaphragm may be obscured owing to their contact with herniated viscera or with pleural effusion (hemorrhage), which are almost always present in cases of trauma.
- Herniation of abdominal viscera through small diaphragmatic rents may result in strangulation and secondary serosanguineous pleural effusion.
- Although gas is often present within a herniated small intestine or stomach, administration of a small amount of barium (1.0 ml/kg orally), followed by repeat thoracic radiographs 30 minutes later, may be helpful to verify the herniation of a portion of the gastrointestinal tract.
- Herniation of the stomach may result in acute gastric dilation and become a potential source of life-threatening cardiovascular compromise.

Positive-Contrast Peritoneography

If the diagnosis of a diaphragmatic hernia is uncertain, positive-contrast peritoneography may be helpful to assess diaphragmatic integrity. Prior to peritoneography, pleural and peritoneal effusions should be removed. Effusions will dilute the positive contrast, making it less visible.

Procedure

Administer 1–2 ml/kg of a sterile aqueous tri-iodinated contrast agent such as that used for intravenous (IV) excretory urography. Warm the contrast agent to body temperature.

- Shave, surgically prepare, and locally anesthetize a small area just to the right of the umbilicus. Pass a needle-catheter combination into the abdomen, avoiding trauma to the spleen, urinary bladder, or intestine. Perform aspiration to verify that there has been no perforation of a hollow viscus or laceration of a blood vessel.
- Slowly introduce the warmed contrast medium into the peritoneal cavity, remove the needle, and gently roll the animal to facilitate distribution of contrast medium. If the animal is stable, positioning the animal with the hind end elevated for 5 to 10 minutes may promote cranial distribution of the contrast medium.
- Obtain radiographs immediately; if findings are inconclusive, repeat in 15 to 20 minutes.
- Optimally, obtain all four radiographic views centered on the diaphragm (right and left laterals, VD and DV). However, if the clinical state of the animal is compromised and only limited views can be taken, place the area of suspected rent dependently (i.e., left lateral and DV views for a suspected ventral, left-sided tear).
- In an animal with an intact diaphragm, the contrast medium will coat the abdominal surface of the diaphragm. Discontinuity of the diaphragmatic silhouette or extension of contrast medium into the thorax indicates a diaphragmatic tear.

RADIOGRAPHIC ABNORMALITIES IN PULMONARY DISEASE

Principles of Interpretation

A number of different methods have been used to describe the radiographic findings associated with pulmonary disease. One common technique uses a pattern approach that is based on the microscopic pathologic changes involved in the disease process.

▼ ***Key Point*** The radiographic patterns of pulmonary disease are alveolar, interstitial, bronchial, and vascular. Mixed pulmonary patterns may also be seen.

When making a radiographic differential diagnosis, evaluate the extent of the lesion (diffuse or focal), the location of the lesion within the lung, the opacity of the lesion, the size and shape of the lesion, and any associated abnormalities of other thoracic structures. Two radiographic signs important in the evaluation of pulmonary disease are the silhouette sign and summation.

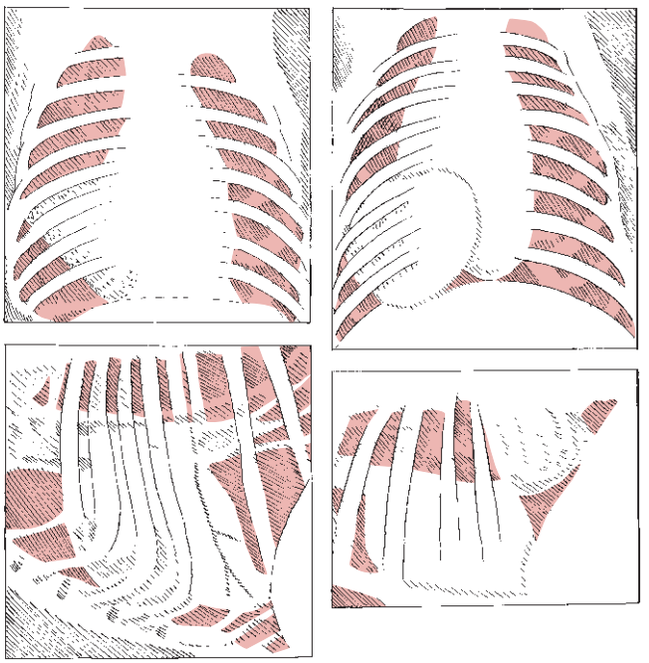

Figure 159-3. Representation of silhouette sign *(left, top and bottom)* and summation *(right, top and bottom).*

Silhouette Sign

The silhouette sign occurs when two objects of the same radiographic opacity contact one another and are oriented in such a way that there is a gradual, rather than abrupt, change in thickness at their borders (Fig. 159-3, *left, top and bottom*).

- Radiographically these objects appear to blend together and the borders between them are obscured. Therefore, it is not possible to perceive where one object ends and the other begins.
- This sign is most commonly seen in the thorax when abnormal fluid opacity within the lung or pleural space contacts the heart or diaphragm and the borders of these structures become indistinct.

Summation

Summation occurs when two objects are superimposed in such a way that there is an abrupt change in thickness at the border where these structures overlap or when they are separated by material of a different radiopacity (Fig. 159-3, *right, top and bottom*).

This occurs when a soft tissue opaque mass is within a well-aerated portion of lung and is superimposed over the heart or diaphragm. In this case the heart and mass are separated by air and the opacities of the mass and heart will be additive.

Thus, the margin where the two objects overlap is enhanced and the mass appears more opaque than it actually is.

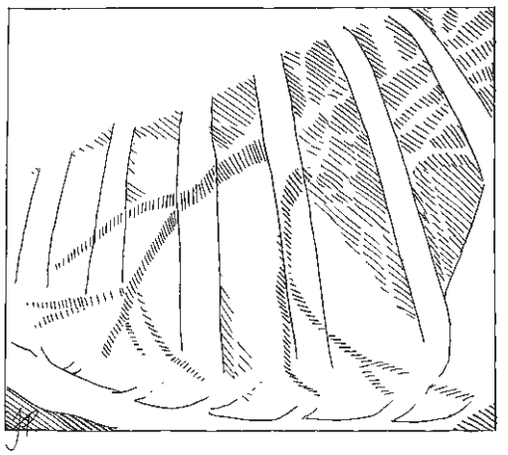

Figure 159-4. Alveolar lung consolidation with air bronchograms (shaded areas in ventral lung).

Alveolar Pattern

The alveolar pattern of pulmonary disease is seen when there is decreased air within the lung secondary to alveolar collapse or filling of the alveolar air spaces with fluid or cellular infiltrate. It is not possible to determine radiographically what type of fluid is present in the alveoli. Often there is a lag period, both at the beginning and at the end of the disease process, when radiographic signs do not correlate with the severity of clinical signs. Thus, the patient history, signalment, and other clinical information are extremely important in arriving at a definitive diagnosis.

Characteristics of Alveolar Disease

- Patchy, ill-defined areas of infiltration that fade into adjacent normal lung.
- The tendency for these lesions to coalesce, leading to lobar consolidation.
- Air bronchogram pattern and the silhouette sign (*lobar sign*).

Air Bronchogram

In an air Bronchogram, the air within the bronchus provides excellent contrast with the fluid-filled lung, and the bronchus appears as a tubular, branching, radiolucent structure within an abnormally soft tissue opaque lung lobe (Fig. 159-4). The normally seen soft tissue opaque pulmonary vessels and bronchial walls are not seen because of the silhouetting of these structures with the infiltrated lung (these signs distinguish the alveolar pattern from the bronchial pattern).

▼ ***Key Point*** The air bronchogram sign characterizes alveolar disease (the sign typically looks something like black, branching tree limbs in a snow storm).

Associated Disease Processes

Common disease processes that cause an alveolar pattern include bronchopneumonia, pulmonary edema (cardiogenic and non-cardiogenic), and pulmonary hemorrhage/contusion. The distribution of the alveolar pattern in the lung may be helpful in the differential diagnosis of these conditions.

Bronchopneumonia

- Bronchopneumonia can be divided into two categories: inhalation pneumonia (secondary to inhaled pathogens) and aspiration pneumonia (secondary to the aspiration of gastric contents). Both types typically result in focal or diffuse alveolar infiltration of the cranioventral *(dependent)* portion of the lung. The right middle lobe is one of the most commonly affected lobes. Air bronchograms and lobar consolidation are common findings in patients with bronchopneumonia.
- Soft tissue opaque inhaled foreign bodies, such as plant awns, are usually diagnosed by the infiltrate they stimulate around the bronchus rather than by direct visualization. The right caudal lung lobe is the most common site of bronchial foreign bodies in the dog.
- Hematogenous pneumonia refers to the systemic spread of bacteria, fungi, or other infectious agents. Unlike bronchopneumonia, hematogenous pneumonia often has a diffuse or caudodorsal pulmonary distribution.

Pulmonary Edema

- Pulmonary edema, whether cardiogenic or non-cardiogenic, usually has a dorsal or caudodorsal distribution.
- Edema due to anaphylaxis, left-sided congestive heart failure, or electrocution usually is most severe in the hilar area of the lung.
- Initially, pulmonary edema usually results in an increased interstitial pattern, secondary to fluid build-up in the pulmonary interstitium. Eventually, the excess fluid in the interstitium may spill over into the alveoli, leading to an alveolar pattern.
- Air bronchograms may not be a consistent feature of cardiogenic edema secondary to mitral insufficiency, possibly because of the slow onset and chronic nature of this type of heart failure. Animals with acute onset of pulmonary edema from any cause are more likely to have air bronchograms because of the rapid accumulation of pulmonary fluid. Alveolar infiltrate predominance in the right caudal lung lobe is observed in some cases of heart failure.
- Edema secondary to seizures or head trauma (neurogenic) tends to affect the more peripheral portions of the caudal lung lobes.
- Acute upper airway obstruction is a relatively uncommon cause of pulmonary edema. When it occurs, it is often similar in distribution to cardiogenic edema.

Interstitial Pattern

The interstitium surrounds and supports the pulmonary vessels, lymphatics, bronchi, and alveoli; therefore, diseases of these structures may be reflected in the interstitium. The interstitial pattern can be subdivided into structured (nodular) and unstructured patterns.

Nodular Interstitial Pattern

The nodular interstitial pattern is one of the most common pulmonary patterns. The ease of detection of pulmonary nodules depends on their size, number, parenchymal distribution, margination, and opacity. Soft tissue opaque nodules less than 0.5 cm in diameter are extremely difficult to detect unless they are numerous, mineralized, and located in the peripheral portions of the lung lobes where summation with other soft tissue structures of the thorax is at a minimum.

Smooth Versus Indistinct Nodules

- Nodules with smooth, well-defined borders suggest a slowly progressive process with minimal involvement of the surrounding alveoli. Examples include primary and metastatic neoplasia and chronic (inactive) pulmonary granulomas and abscesses.
- An indistinct nodular margin suggests a more active process that extends into the adjacent alveoli or is causing associated edema, inflammation, or hemorrhage. Highly aggressive neoplasms, active granulomas, and pulmonary abscesses often appear irregular or indistinct in margination.

Differentiating Nodules from Vessels

- On-end pulmonary vessels can be differentiated from nodules because they are:
  - More numerous in the hilar area.
  - Consistently more radiopaque than the adjacent vasculature.
  - Associated with a longitudinal vessel of which they are a branch.
  - Progressively less numerous and smaller in the periphery of the lung.
- In contrast, pulmonary nodules are:
  - Randomly distributed throughout the lung (i.e., small nodules may be seen centrally and large nodules peripherally.
  - Often less radiopaque or have the same opacity as the pulmonary vasculature.
  - Frequently *not* associated with a vessel of similar or greater size.

▼ ***Key Point*** Pulmonary osteomas (benign osseous metaplasia) are small, irregularly margined mineral opacities seen as an incidental finding in some dogs, particularly the collie breeds. These should not be confused with pulmonary nodules.

Granulomas

- Granulomas, such as those secondary to *Paragonimus kellicotti*, may be solitary or multiple, cavitated, and may occur anywhere in the lung.
  - Radiographic appearance varies from lesions that are almost entirely cystic to those that are primarily granulomatous with only a small cystic cavity.
  - Spontaneous pneumothorax may occur secondary to the rupture of air-filled cysts.
- Immune-mediated, eosinophilic, and lymphomatoid pulmonary granulomatosis are typically associated with hilar lymphadenopathy.

Neoplasia

- Primary lung tumors are relatively uncommon and are usually carcinomas.
  - Bronchogenic carcinoma is usually hilar in location and occurs most commonly as a large, irregularly marginated soft tissue mass in the caudal lung lobes, most commonly on the right side.
  - Cavitation is uncommon but may develop in large necrotic tumors.
  - Primary lung tumors may metastasize to other regions of lung.
  - Although pulmonary carcinomas commonly metastasize to hilar lymph nodes, these metastases generally are not large enough to be evident radiographically.
- Metastatic neoplasia generally appears as multiple, variably sized nodules randomly distributed throughout the lung. When small, it may be difficult to distinguish pulmonary nodules from end-on pulmonary blood vessels.

Unstructured Interstitial Pattern

This pattern is one of the most difficult to diagnose because it is commonly mimicked by poor radiographic technique secondary to respiratory motion, pulmonary underinflation, and radiographic underexposure. The lung generally appears more radiopaque than normal (Fig. 159-5). Diseases causing diffuse, unstructured interstitial infiltration have a widespread or caudodorsal distribution.

▼ ***Key Point*** A key radiographic feature of an unstructured interstitial pattern is a blurring of the vascular markings.

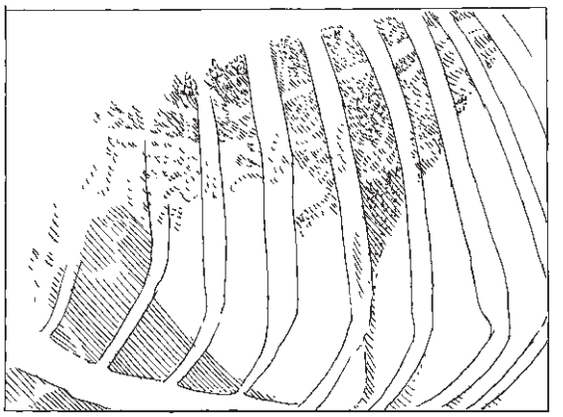

Figure 159-5. Diffuse dorsal caudal interstitial pattern.

Pulmonary Edema

Initially, pulmonary edema, both cardiogenic and noncardiogenic, usually appears as an interstitial pattern. As the disease progresses, fluid extends farther into the alveoli, resulting in an alveolar pattern.

▼ ***Key Point*** Lymphosarcoma may cause a diffuse interstitial pattern secondary to thoracic lymphatic occlusion by tumor emboli that results in fluid build up in the pulmonary interstitium.

Pneumonitis

- Interstitial pneumonia of fungal, parasitic, and especially viral etiology typically causes a diffuse increase in interstitial opacity of the dorsal and hilar lung regions. Hematogenous pneumonia, unlike bronchopneumonia, also tends to have a more caudodorsal-to-diffuse pulmonary distribution.
- Interstitial pulmonary disease secondary to metabolic or toxic disturbances, such as uremia, pancreatitis, smoke inhalation, or paraquat poisoning, are often diffuse.
- Interstitial pulmonary disease secondary to allergies often has a peribronchial distribution *(peribronchial cuffing).*

Pulmonary Fibrosis

- Lung fibrosis is a very common cause of diffuse interstitial opacity, especially in older dogs. It has been recognized as a congenital disorder in certain dog breeds (West Highland White Terriers) and may cause decreased lung compliance in severe cases.

Neoplasia

- Most neoplastic processes of the lung tend to be nodular; however, in some neoplasms there is a less

structured and more diffuse increase in interstitial pulmonary opacity. These neoplastic cells may reach the lung via the lymphatics (e.g., pulmonary lymphoma) or hematogenously (e.g., scirrhous mammary adenocarcinoma, scirrhous bronchogenic adenocarcinoma). Differentiation of this type of neoplastic infiltration from other causes of diffuse interstitial opacity is difficult.

- Clinically affected animals may present with a degree of respiratory distress disproportionate to the degree of pulmonary infiltration.
- Fine-needle aspiration of the lung, bronchoalveolar lavage, and/or lung biopsy may be needed for diagnosis.

Vascular Pattern

The vascular pattern of pulmonary disease is primarily determined by the size of the pulmonary arteries and veins.

Hypovascularity

Pulmonary underperfusion results in a decreased size to both the arteries and veins. Potential causes of pulmonary hypovascularity include:

- Congenital shunting of blood in a right-to-left direction, thus bypassing the lungs (e.g., tetralogy of Fallot, reverse patent ductus arteriosus).
- Acquired circulatory problems such as acute blood loss, shock, and cardiac tamponade.
- Decreased vascular diameter may be seen secondary to pulmonary thromboembolism. Affected portions of lung may appear hyperlucent.

Hypervascularity

- Hypervascularity can refer to the enlargement of both the arteries and veins, the arteries alone (pulmonary arterial hypertension), or the veins alone (venous congestion).
- Enlargement of both the pulmonary arteries and veins usually is associated with overhydration, secondary to over-zealous intravenous fluid administration, or with some type of congenital cardiac left-to-right shunt, resulting in pulmonary overcirculation (e.g., patent ductus arteriosus, ventricular septal defects).
- High-output states such as hyperthyroidism also may produce prominent pulmonary vascularity.
- Severe left-sided heart failure due to cardiomyopathy or chronic mitral valve insufficiency with long-standing venous congestion and secondary pulmonary hypertension also may lead to enlarged arteries and veins.

Acquired Pulmonary Arterial Hypertension

- In the dog, this condition most commonly is the result of heartworm disease.

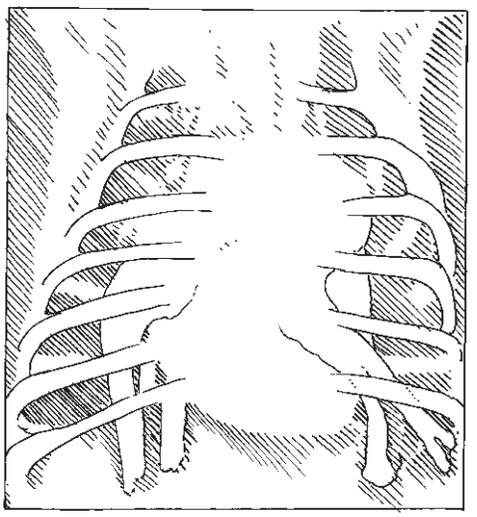

Figure 159-6. Radiographic appearance of heartworm disease. Note large, truncated lobar arteries.

- In early heartworm disease, there is right heart enlargement and a mild to moderate increase in interstitial opacity in the dorsal lung lobes.
- As the condition progresses, the right ventricle becomes more rounded, giving a "reversed D" shape to the cardiac silhouette on the radiographic view, and the main pulmonary artery segment and peripheral pulmonary arteries become enlarged and tortuous (Fig. 159-6).

▼ ***Key Point*** In advanced cases of heartworm disease, truncation or abrupt termination of the peripheral vessels, also called the *pruned tree* effect, is commonly seen in the caudal lobar vessels.

- Focal areas of pulmonary infarction appear as patchy alveolar opacities, primarily around the caudal lobar vessels.
- Pulmonary arterial hypertension also occurs in the cat and may be due to heartworm disease or aelurostrongylosis.

Venous Congestion

- Venous congestion, characterized by enlarged pulmonary veins, usually is associated with left heart failure from congenital or acquired cardiac disease.
- Early interstitial edema, which in the dog is usually restricted to the hilar area, causes a symmetric increase in interstitial opacity of the hilar area of the lung, with blurring of the veins on radiographs.
- As the pulmonary edema progresses, alveolar infiltrates become evident in the caudal lobes.
- In the cat, pulmonary edema is somewhat less predictable in its distribution and may appear more focal and asymmetric than that in the dog.

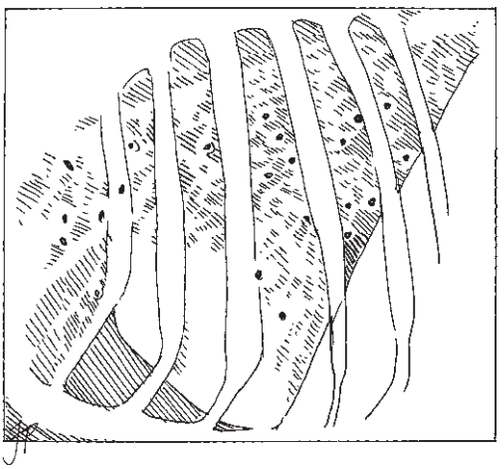

Figure 159-7. Bronchial pattern.

Bronchial Pattern

- Increased bronchial prominence in the dog may occur as a normal aging change or may be secondary to chronic bronchial inflammation.

▼ ***Key Point*** Bronchial wall mineralization, *without airway wall thickening,* may be seen as a normal aging change in dogs.

- Radiographic changes in animals with acute bronchitis may be absent or restricted to pulmonary overinflation or air trapping (e.g., feline asthma)
- As the disease progresses, the bronchial walls tend to appear thickened. This often results in a relative decrease in luminal diameter and is best appreciated on cross-sectional views in which the bronchi appear as thick-walled doughnut-like structures (Fig. 159-7). Airway inflammation may extend into the peripheral bronchial interstitium (bronchointerstitial pattern).
- When viewed longitudinally, the bronchial walls appear as paired, nearly parallel linear opacities (like tram lines) extending into the lung periphery.
- Bronchial mineralization is a common sequela of chronic bronchitis, especially in cases with an allergic or immune-mediated etiology.

Bronchial Prominence in Cats

- This pattern in cats is most commonly associated with bronchitis or feline asthma, although infection with *Aelurostrongylus abstrusus* may occasionally cause this appearance.
- Cats presenting with acute respiratory distress generally show evidence of thoracic overexpansion with a flattened diaphragm and a barrel-shaped thorax in addition to bronchial prominence.
- Asymptomatic animals may appear radiographically normal unless the disease is chronic and the animal has had several acute episodes of dyspnea.
- Some cats with chronic bronchitis have chronic consolidation or atelectasis of the right middle lung lobe, the result of mucus plugs in the middle lobe bronchus, chronic fibrosis, and volume loss in this lobe.

▼ ***Key Point*** Fluid-filled or mucus-filled bronchi, imaged in cross-section, may be mistaken for a nodular interstitial pattern.

Bronchiectasis

- Bronchiectasis, or *irreversible* bronchial dilation, generally occurs secondary to chronic bronchial disease.
- The bronchial dilation may be varicose, cylindrical, or saccular in shape, and on cross-sectional views the affected bronchi have prominent walls that appear relatively thin compared with the enlarged bronchial lumen.
- Animals with bronchiectasis are prone to secondary bronchopneumonia because of poor mucociliary pulmonary clearance.

Mixed Patterns

Although the pattern approach to pulmonary evaluation is helpful in arriving at a differential diagnosis, many disease processes result in a mixture of the aforementioned patterns. These patterns often vary depending on the stage of the disease process during which the animal is evaluated. Diseases commonly causing a mixed pattern include heartworm disease (interstitial—vascular), left-sided heart failure and pneumonia (interstitial—alveolar), and chronic bronchitis and pneumonia (bronchointerstitial).

Pulmonary Hyperlucency

- Abnormal pulmonary radiolucency is probably easiest to recognize when it is focal.
- Thin-walled, air-filled bullae or blebs often occur secondary to pulmonary trauma. They are generally subpleural in location and usually resolve spontaneously.
- Congenital bullae, cysts, and pneumatoceles may be located anywhere in the pulmonary parenchyma.

▼ ***Key Point*** Spontaneous rupture of a bullae, bleb, cyst, or pneumatocele may lead to a pneumothorax.

- Thicker-walled cavitary lesions may be the result of parasitic cysts (e.g., *Paragonimus kellicotti*), congenital bronchial cysts, cavitated abscesses, neoplasms, and granulomas. These may be single or multiple, and their location within the lung is variable.
- Horizontal beam radiographs may be helpful in determining if fluid or cellular debris is present in the cystic areas.

Emphysema

- Emphysema may occur as a compensatory change following surgical removal of a lung lobe or volume loss in one of the lung lobes; it also can be the result of aging or of true histologic breakdown of the alveolar septa. True emphysema, as seen in humans, is relatively uncommon in dog and cats.
- True emphysema with rupture and confluence of alveoli must be differentiated from causes of reversible hyperinflation including asthma or tracheobronchial obstruction (e.g., foreign body).
- Radiographically, hyperinflation is recognized by:
  - Relative pulmonary hyperlucency.
  - Flattening or tenting of the diaphragm.
  - Increased separation of the heart and diaphragm (widened cardiophrenic angle).
  - Apparent decreased size of the pulmonary vessels.
  - A barrel-shaped chest.
  - Decreased differences in diaphragmatic excursion between inspiratory and expiratory films.
- Radiographic overexposure and severe hypovascularity are other causes of apparent pulmonary hyperlucency but usually are not accompanied by the other radiographic signs seen in generalized emphysema.

ALTERNATE IMAGING MODALITIES

Ultrasound

It is not possible to image structures located beneath air-filled regions because of the large acoustic mismatch between the air and soft tissue. Air produces a reverberation artifact whereby spurious echoes are reflected back and forth between gas and the ultrasound transducer.

- Abnormal accumulations of fluid (e.g., pleural effusion), superficial soft tissue masses (e.g., laryngeal, tracheal), or peripheral pulmonary masses may be imaged sonographically.
- In animals with pleural effusion, the lung is displaced away from the body wall, allowing assessment of the character of the pleural fluid to determine if it is cellular or noncellular. Pleural fluid can serve as a window to imaging regions of atelectatic or diseased, non-aerated lung.
- Focal areas of pulmonary infiltration may be evaluated as long as they extend to the pulmonary periphery.
- Mediastinal masses may be imaged if they abut the thoracic wall or are surrounded by fluid rather than aerated lung.
- Mediastinal masses may be solitary or multiple; solid, vascular, or cystic; mineralized or non-mineralized. They may or may not invade regional vasculature. These masses are typically imaged via an intercostal or thoracic inlet approach.
- Ultrasonography has been used to evaluate for diaphragmatic hernia but a negative ultrasound exam does not rule out a rent in the diaphragm. Radiography +/− positive contrast peritoneography are still considered more sensitive than ultrasound in diagnosing diaphragmatic tears, particularly when organ displacement is not present.

▼ ***Key Point*** Ultrasound is quite useful for guiding aspirate and biopsy sampling.

Nuclear Medicine

- Nuclear medicine is rarely used in animals and is mostly limited to referral centers.
- Perfusion-ventilation studies are commonly done in humans and were first used in dogs to evaluate the effects of heartworm disease.
- Special aerosol masks and trapping mechanisms are used to deliver the radioactivity for the ventilation portion of the study.
- The perfusion part of the study involves IV administration of technetium 99m macroaggregated albumin (MAA). Because this agent is trapped in the capillary network of the lung on the first pass following an IV injection, it can be used to detect areas of decreased pulmonary perfusion, as with pulmonary thromboembolism.
- Distal intratracheal instillation of technetium 99m sulfur colloid has been used to evaluate for ciliary dyskinesis in the dog. In normal animals, the radiopharmaceutical will be swept proximally up the trachea by the functional cilia. In dogs with amotile cilia, the radiopharmaceutical will stay at the point of instillation. Affected dogs typically present with a history of chronic, recurrent bronchitis from birth.

Computed Tomography

Whereas conventional radiography produces summed images of an object, tomographic scanners rotate to divide the object and to organize it into spatially consecutive, parallel image sections. In computed tomography (CT), a computer stores x-ray attenuation data and generates a matrix of values, depicted in various shades of gray. Images can be reconstructed into multiple planes. Compared to radiographs, CT produces images with superior spatial and contrast resolution that are free from superimposition by overlapping structures.

Nasal Cavity

- General anesthesia is a requirement for CT scanning.
- Where available, CT has all but replaced radiography of the nasal cavity.
- CT is superior to radiography in defining the extent of disease processes and in differentiating infectious rhinitis from neoplasia.

- Features commonly recognized with nasal neoplasia include a soft-tissue dense-mass effect and bony lysis.
- Features commonly seen with rhinitis include turbinate thickening early on and then turbinate atrophy and lysis later in the disease process.
- Features particular to fungal (aspergillosis) rhinitis include severe turbinate loss, soft tissue dense plaque formation along the walls of the nasal passage, and productive bone formation secondary to fungal osteomyelitis when the frontal sinuses are involved.
- Radiodense, foreign bodies may be identified and are most typically found in the caudoventral nasal passages.
- Erosion of the cribriform plate with extension into the calvarial vault may occur with neoplasia or fungal (aspergillosis) rhinitis but is seldom seen in other cases of rhinitis.
- CT is useful in identifying nasopharyngeal polyps as soft-tissue–dense, pedunculated, poorly contrast-enhancing structures.
- It is important to acquire pre- and post-IV contrast images to differentiate a fluid density from a vascular soft-tissue dense mass.

Pleural Space, Mediastinum, and Lung

- CT of the thoracic cavity is usually performed following radiography to better define an abnormality identified on survey radiographs (Fig. 159-8).
- CT is more sensitive than radiographs at detecting discrete pulmonary metastases and is often recommended prior to removal of the primary tumor (e.g., limb amputation for osteosarcoma).
- CT is more sensitive than radiographs at discriminating mediastinal masses from cranial pulmonary masses.

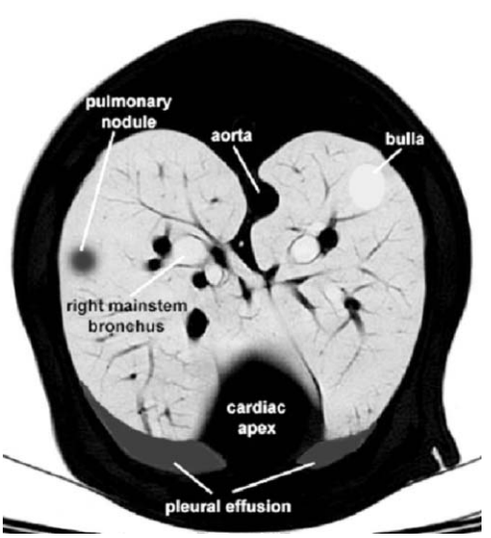

Figure 159-8. Transverse image of the thorax caudal to the bifurcation of the mainstem bronchi from the trachea.

- Pleural fluid will distribute to the dependent portion of thoracic cavity allowing better evaluation of aerated lung for pathology masked by effusion on survey radiographs.

▼ ***Key Point*** CT is quite useful for guiding aspirate and biopsy sampling.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a cross-sectional imaging modality that relies on computer generation of an image from returning signals. MRI signal intensity is a complex function of hydrogen concentration (proton density), the rates at which the nuclei realign along the magnetic field and lose synchronization with each other's spins, and blood movement. The relative weight of these components in the signal is dependent on the pulsing sequence used. Images may be acquired in multiple planes of a section.

- General anesthesia is a general requirement for MRI scanning.
- MRI has been used to evaluate nasal disease in small animal patients and is considered equally as sensitive as CT.
- Because MRI is extremely sensitive to motion, there are severe limitations to thoracic imaging due to cardiac and respiratory motion.

Chapter

160 Surgery of the Nasal Cavity and Sinuses

Cheryl S. Hedlund

Signs in dogs and cats with chronic nasal and paranasal sinus disease may include nasal discharge, epistaxis, sneezing, gagging, stertorous breathing, nasal discomfort, and nasal deformity. Causes of nasal cavity and paranasal sinus diseases can be difficult to identify, but most cases are traumatic, infectious, inflammatory, mechanical, neoplastic, or parasitic in origin. Hemostatic abnormalities may lead to epistaxis. Most of these nasal diseases can be diagnosed and treated without surgery. However, rhinotomy may be necessary to arrive at a definitive diagnosis and may facilitate treatment of some diseases.

ANATOMY

Nasal Cavity

- The nasal cavity extends from the nostrils to the nasopharyngeal meatus and is divided into two chambers by the nasal septum. The rostral portion of the nasal septum is cartilaginous and difficult to evaluate radiographically.
- The rostral nasal chambers are occupied by the dorsal and ventral nasal conchae (turbinates) (Fig. 160-1).
- The caudal nasal chamber is filled with ethmoidal conchae (turbinates). The ethmoidal conchae extend into the frontal sinus, forming narrow communicating ostia between the frontal sinus and the nasal cavity (see Fig. 160-1).
- In the cat, the nasal cavity is shorter, the ethmoidal conchae are larger, and the nasal conchae are smaller than in the dog.
- The cribriform plate is a sievelike partition between the nasal and the cranial cavities (see Fig. 160-1). It articulates with the frontal bones dorsally and the presphenoid bones ventrally and laterally.
- The blood supply to the nasal cavity originates from the external carotid arteries via branches of the maxillary artery, including the sphenopalatine, ethmoid, greater palatine, dorsal nasal, lateral nasal, and maxillary labial arteries.

Paranasal Sinuses

- The paranasal sinuses enlarge with age and vary in size depending on the breed of the animal.
- The frontal sinus extends roughly from the medial canthus of the eyes to the temporal line. In dogs (but not in cats), it is divided into rostral, lateral, and medial compartments (see Fig. 160-1). The frontal sinus varies more in size than other cavities in the skull. The lateral compartment is particularly large in dolichocephalic breeds. Brachycephalic breeds have small lateral compartments, and the medial compartment may be absent.
- The maxillary sinus or recess is found dorsal to the roots of the third and fourth premolars and medial to the infraorbital canal. The maxillary recess in the cat is very narrow.
- Cats have a small sphenoid sinus. Dogs do not have a sphenoid sinus.

PREOPERATIVE CONSIDERATIONS

Disease Conditions

- Signs of chronic nasal disease can include unilateral or bilateral nasal discharge, epistaxis, sneezing, nasal discomfort, gagging, reverse sneezing, stertorous breathing, ocular discharge, and facial or nasopharyngeal distortion. Neurologic signs are seen if the disease extends into the cranium.
- The most frequent causes of chronic nasal and paranasal sinus disease are neoplasms, infections, and foreign bodies.
- Other causes include parasites *(Pneumonyssoides caninum, Capillaria aerophila, Linguatula serrata),* dental disease, trauma, lymphocytic-plasmacytic inflammation, and congenital anomalies. Nasal polyps, which are benign lesions, occur rarely.

Tumors

- Tumors of the nasal cavity and paranasal sinuses account for approximately 1% of all neoplasms in cats and dogs.

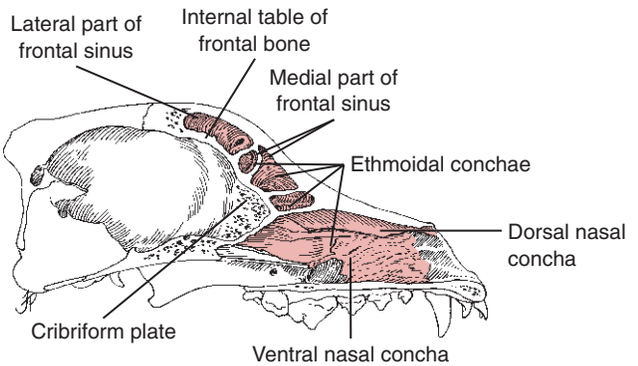

Figure 160-1. Sagittal section of the skull illustrating the anatomy of the nasal cavity and paranasal sinuses in relationship to the cranium. (Redrawn with permission from Evans HE [ed]: Miller's Anatomy of the Dog, 3rd ed. Philadelphia: WB Saunders, 1992.)

- Most intranasal tumors are diagnosed in older dogs and cats (>8–10 years) and in large-breed dogs.
- Tumors in the nasal cavity are usually found in the caudal third of the nasal passages.
- Most intranasal tumors are malignant (80%). Adenocarcinomas are most common, but squamous cell carcinoma, fibrosarcoma, chondrosarcoma, osteosarcoma, lymphosarcoma, hemangiosarcoma, undifferentiated sarcomas or carcinomas, and mast cell and transmissible venereal tumors also occur.
- The prognosis for malignant nasal neoplasms is guarded because of rapid local invasion and recurrence after therapy. Typically, these tumors do not metastasize until late in the course of the disease.
- Therapies that may help control some tumors include radiotherapy, immunotherapy, cryotherapy, and chemotherapy (see Chapter 26). These modalities are sometimes combined with surgical debulking of the lesion.

Infections

- Infections, especially those caused by fungal organisms, frequently cause nasal and paranasal cavity disease.
- Systemic diseases such as distemper, feline upper respiratory viral infections, and Rocky Mountain spotted fever can also cause acute or chronic rhinitis.
- Primary bacterial rhinitis is uncommon and usually is associated with foreign bodies, immunosuppression (feline leukemia virus [FeLV], feline immunodeficiency virus [FIV]), or dental disease.

Fungal Rhinitis

- The most commonly reported pathogenic fungi are *Aspergillus* and *Penicillium* species in dogs and *Cryptococcus neoformans* in cats. Other reported pathogens are *Rhinosporidium* and *Alternaria alternata.*
- Dogs with fungal rhinitis due to *Aspergillus* or *Penicillium* are usually young (1–7 years).
- Patients with fungal rhinitis generally do not have facial distortion but may exhibit ulceration of the nares and more nasal discomfort than dogs with nasal neoplasia.
- Treatment of fungal rhinitis is primarily medical, although surgery may be necessary for definitive diagnosis or creating ports for medical therapy.
- Medical therapy may be systemic (itraconazole, ketoconazole, or thiabendazole), topical (enilconazole or clotrimazole administered directly into the nasal cavity), or both (see Chapter 163 for details).
- If indicated, perform topical therapy by placing fenestrated balloon catheters via endoscopy or rhinoscopy, placing indwelling fenestrated tubes into the frontal sinuses and nasal cavity, or creating a nasal stoma for nasal irrigation or swabbing.
- Nasal rhinosporidiosis is treated by surgical excision of the lesion.

Diagnosis

Follow a standard protocol of evaluation, including a thorough history and physical examination, for all dogs and cats presenting with chronic nasal disease. Besides a complete blood count (CBC), serum chemistry profile, and urinalysis, consider a coagulation profile, radiography, enzyme-linked immunosorbent assay (ELISA) for FeLV and FIV in cats, computed tomography (CT) or magnetic resonance imaging (MRI), fungal serology, antegrade and retrograde rhinoscopy, and nasal biopsy.

History

The clinical history can provide important diagnostic clues.

- Suspect a destructive process if the discharge changes from unilateral to bilateral.
- Sneezing suggests involvement of the midnasal and rostral nasal chambers.
- Gagging or reverse sneezing suggests nasopharyngeal involvement or postnasal drainage.
- Reverse sneezing suggests nasal parasites *(Pneumonyssoides caninum)* in endemic areas.
- A history of trauma or dental disease suggests an oronasal fistula.

Physical Examination

- Facial or palatal deformity suggests neoplasia.
- Mouth breathing indicates nasopharyngeal obstruction.
- An ocular discharge may indicate nasolacrimal duct erosion.
- A small midline opening at the junction between the nasal planum and the skin suggests a nasal dermoid sinus cyst.
- Neurologic signs may indicate disease extension into the brain.

Laboratory Studies

- A CBC, serum chemistry profile, and urinalysis can assess the patient's overall status.
- A coagulation profile is indicated if exploratory rhinotomy is planned. If epistaxis is a major clinical sign, perform a cross-match for blood transfusion.

Diagnostic Imaging

Radiography

Obtain radiographs of the thorax in the conscious patient, and obtain radiographs of the nasal cavity and paranasal sinuses with the patient under general anesthesia.

- Include lateral, ventrodorsal, rostrocaudal, and rostroventral-caudodorsal open-mouth or occlusal radiographic views (see Chapter 4).
- The two most useful radiographic views are the ventrodorsal view of the maxilla using intraoral radiographic film and the rostrocaudal projection highlighting the frontal sinuses.

▼ ***Key Point*** To avoid iatrogenic fluid densities within the cavities, schedule radiography before performing any rhinoscopic, flush, or biopsy procedures.

Computed Tomography or Magnetic Resonance Imaging

Although costly, CT or MRI should be performed when possible to localize lesions more accurately than is possible with radiography. (See Chapter 4 for an overview of these imaging modalities.)

Rhinoscopy

Perform rhinoscopy in the anesthetized patient following skull imaging. The nasal mucosa is very sensitive to manipulation, and exposure can be obliterated by hemorrhage. Therefore, use gentle manipulation, lavage, and suction techniques.

- The rostral aspect of the nasal cavity may be seen with an otoscope, cystoscope, or small fiberoptic scope. A flexible pediatric bronchoscope or 2- to 3-mm diameter rigid telescope facilitates examination of the remainder of the cavity and allows retropharyngeal examination of the choanae for lodged foreign bodies, nasal mites, mucosal invasion (mycoses), or extruding nasal tumors.
- It may be impossible to perform a rhinoscopic examination on very small dogs and cats because of the size discrepancies between the scope and the nasal passages. However, examine the pharynx and choanae in these animals.
- Use rhinoscopy to obtain specimens for biopsy, cytology, and culture.

Biopsy

During the rhinoscopic procedure, lesions can be biopsied using endoscopic biopsy instruments. Biopsy the nasal mucosa even if no obvious lesions are found.

Other Diagnostic Procedures

- Perform *nasal flushing* or coring procedures with the patient still under anesthesia if endoscopic biopsy was not possible or successful.
  - In this procedure, slide a stiff plastic tube (e.g., the plastic cover of a Sovereign [Sherwood Medical, Ireland] indwelling catheter) vigorously in and out of the nasal passages (inserted through the nares and not extending beyond the medial canthus) while flushing and aspirating saline.
  - Premeasure the catheter to avoid trauma to or beyond the cribriform plate.
  - Pack gauze sponges in the nasopharynx and be sure the endotracheal tube cuff is adequately inflated prior to flushing.
  - Collect the lavage fluid and debris and examine for tissue fragments, foreign bodies, and parasites.
- *Nasal swabs* for culture or cytologic evaluation are of limited value. Positive fungal cultures can be obtained in about 40% of normal dogs, so diagnosis should also rely on identifying characteristic mucosal lesions grossly and on histopathology. Occasionally, cryptococcosis organisms are identified by examining a stained, direct smear.
- *Serologic evaluation* for *Aspergillus* and *Penicillium* species is useful, but false-positive results are possible. Latex agglutination test for *Cryptococcus neoformans* is useful in cats.
- Perform *rhinotomy* as a diagnostic procedure if a diagnosis is not achieved by other means.

Anesthesia

- Begin preemptive analgesia such as placing a fentanyl patch 8 to 12 hours prior to surgery to enhance postoperative analgesia. (*Note:* Prevent ingestion of the patch.) See "Appendix" for dosage recommendations for fentanyl patches.
- Induce and maintain routine general anesthesia for diagnostic and surgical procedures (see Chapter 2).
- Prior to extubation, examine and suction the nasopharyngeal area. Leave the endotracheal tube cuff partially inflated to prevent tracheal aspiration of blood clots, fluid, and debris.

SURGICAL PROCEDURES

Objectives

- Obtain sufficient tissue samples to achieve a definitive diagnosis for the patient's chronic rhinitis or sinusitis.

- Completely remove or debulk the lesion.
- Facilitate administration of adjuvant therapy.
- Minimize blood loss.
- Maintain a cosmetically acceptable appearance.

Equipment

- Standard general surgical pack and suture
- Umbilical tape, vascular tape (Vas-Tie, Sil-Med Corp., Taunton, MA), or bulldog vascular clamps for temporary carotid occlusion
- Periosteal elevator
- Oscillating saw, air drill, pins and pin chuck, and/or osteotome and mallet to create bone flap
- Gelpi retractor
- Bone curette, rasp, bur, rongeur, and trephine
- Fenestrated, indwelling tubes or balloon catheters to facilitate application of topical medications
- Synthetic mesh to span the bony defect (usually not needed)

Temporary Bilateral Carotid Artery Occlusion

This procedure is performed prior to entry into the nasal cavity or paranasal sinuses if major surgery such as rhinotomy and turbinectomy is to be performed. Carotid artery occlusion decreases blood loss and improves exposure during rhinotomy. *Not all surgeons choose to use this technique.*

Technique

1. Place the dog in dorsal recumbency with the front legs secured caudally and a rolled towel placed under the neck.
2. Clip and aseptically prepare the ventral neck from the caudal aspect of the mandibles to the manubrium.
3. Incise the skin and subcutis on the ventral cervical midline from the larynx to the midtrachea.
4. Separate the paired sternohyoideus muscles to expose the ventral trachea.
5. Bluntly dissect lateral to the trachea and palpate the carotid pulse.
6. Exteriorize the carotid sheath and separate the external carotid artery from the vagosympathetic trunk and internal jugular vein (Fig. 160-2).
7. Occlude the carotid artery with a vascular tie, umbilical tape, or vascular clamp (see Fig. 160-2).
8. Repeat the procedure on the opposite carotid.
9. Appose the separated sternohyoid muscles and skin in two layers with simple continuous suture patterns.
10. Cover the surgical site with sterile draping material and, if necessary, reposition the patient for rhinotomy.
11. Following rhinotomy, reexpose the carotids and release occlusion. Lavage the area and routinely close in three layers (muscle, subcutis, and skin).

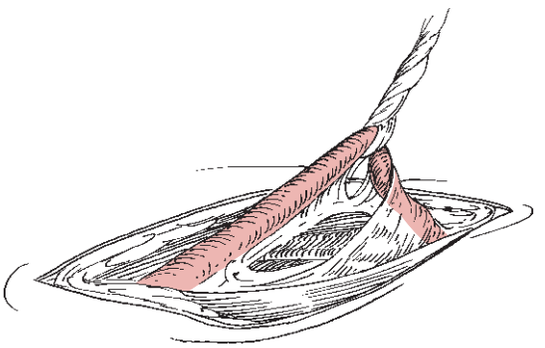

Figure 160-2. Exteriorize and incise the carotid sheath located lateral to the trachea, separate the common carotid artery *(top)* from the vagosympathetic trunk and internal jugular vein *(bottom)* and occlude.

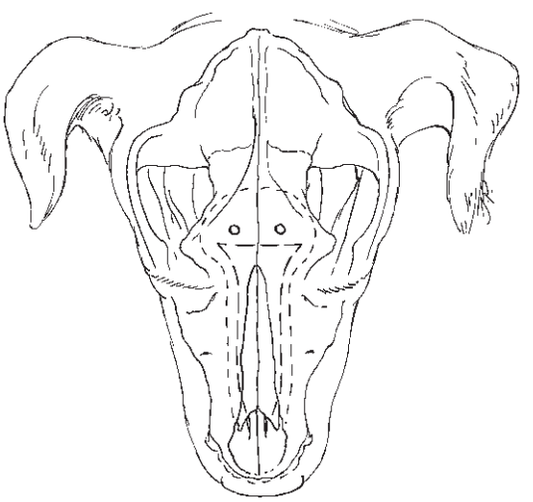

Figure 160-3. Dorsal rhinotomy. The outer dotted line delineates the approximate extent of the nasal cavity and frontal sinuses. The inner dashed lines delineate the bone flap for a unilateral or bilateral approach. The holes over the frontal sinuses indicate the site for insertion of drains. (Redrawn with permission from Bojrab MJ [ed]: Current Techniques in Small Animal Surgery, 3rd ed. Philadelphia: Lea & Febiger, 1990.)

Dorsal Rhinotomy

Following carotid occlusion, expose the nasal cavity and frontal sinuses for exploration and biopsy.

Technique

1. Position the patient in ventral recumbency insuring that the head is straight and not twisted to one side.
2. Prepare the nasal and frontal sinus areas for aseptic surgery.
3. Incise the skin and subcutis along the dorsal midline (Fig. 160-3).
4. Elevate the dense fascia and periosteum with a periosteal elevator and retract these tissues laterally with Gelpi retractors.

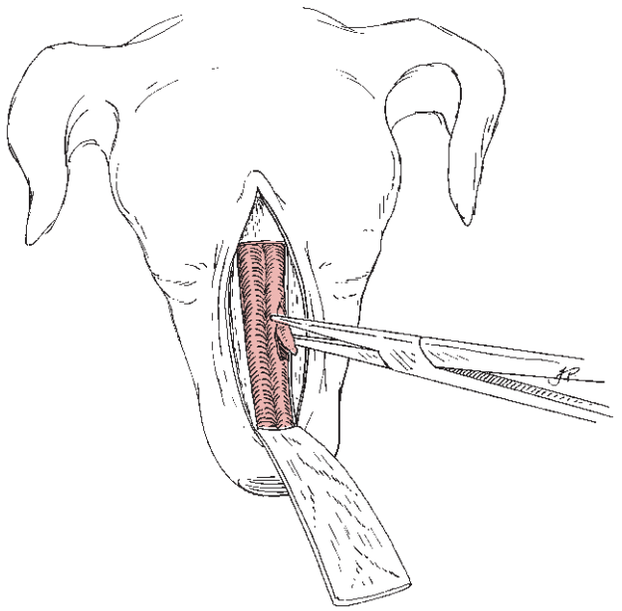

Figure 160-4. Reflect the bone flap rostrally or remove it. Perform turbinectomy using forceps, scissors, and curettes. (Redrawn with permission from Bojrab MJ [ed]: Current Techniques in Small Animal Surgery, 3rd ed. Philadelphia: Lea & Febiger, 1990.)

5. Create a unilateral or bilateral bone flap with an oscillating saw or drill. Bevel the edges of the bone flap so that the dorsal surface is slightly wider than the ventral surface if the flap is to be replaced after rhinotomy.
   a. Alternatively, make holes (drill or pin chuck) at the edges of the proposed bone flap and connect them with an osteotome and mallet.
   b. Another method is to make a hole into the nasal cavity with a trephine or pin and chuck; rongeur adjacent bone and discard.
6. Elevate the flap to expose the nasal cavity and the rostral portion of the frontal sinus for complete exploration (see Fig. 160-4).
7. Remove or debulk the lesion and involved conchae (turbinates), using forceps, Metzenbaum scissors, and/or a bone curette (Fig. 160-4). Save all tissues for culture and histologic evaluation.
8. Remove exudate from the frontal sinus, curette the lining to remove all diseased tissue, and enlarge the ostia to facilitate drainage.
9. Lavage and suction the nasal cavity and sinuses thoroughly with copious amounts of saline to dislodge debris and blood clots.
10. If required for adjuvant therapy or to minimize subcutaneous emphysema, place a fenestrated, indwelling tube (e.g., Brunswick feeding tube) into the frontal sinus and extending into the nasal cavity. Create the opening in the frontal sinus with a trephine, drill, or intramedullary pin.
11. To replace the non-diseased bone flap, drill holes in the bone flap and rhinotomy margins and place non-metallic sutures through adjacent holes to secure the flap (Fig. 160-5). Alternatively, discard the bone flap and proceed with soft tissue closure.
12. Close using continuous suture patterns in the fascial and periosteal layer, subcutaneous tissues, and the skin. When the defect is large and cosmetic appearance is critical, implant a synthetic mesh (e.g., Marlex mesh) across the bony defect and secure with non-absorbable, monofilament sutures.
13. The skin edges may be secured directly to the margins of the bony defect, creating a stoma into the nasal cavity to facilitate topical therapy or to prevent subcutaneous emphysema (Fig. 160-6).

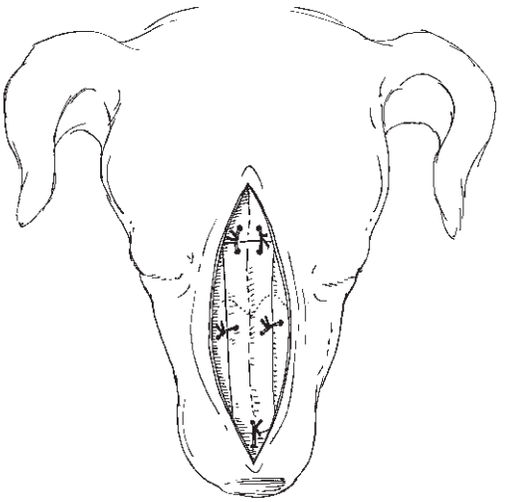

Figure 160-5. Replace the bone flap by placing sutures through holes drilled in the flap and margins of the defect. (Redrawn with permission from Bojrab MJ [ed]: Current Techniques in Small Animal Surgery, 3rd ed. Philadelphia: Lea & Febiger, 1990.)

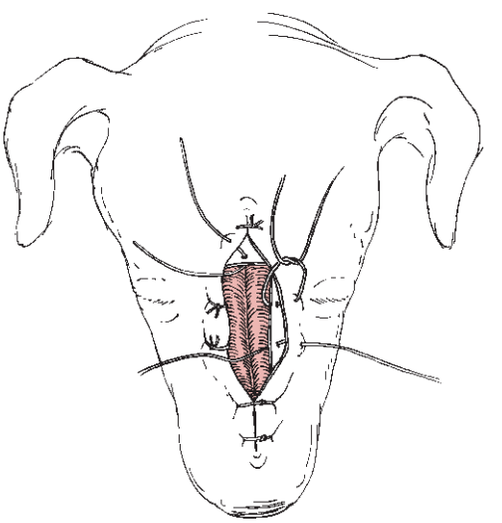

Figure 160-6. If a stoma following rhinotomy is desired, drill holes in the margins of the defect and pass sutures through these holes and the skin.

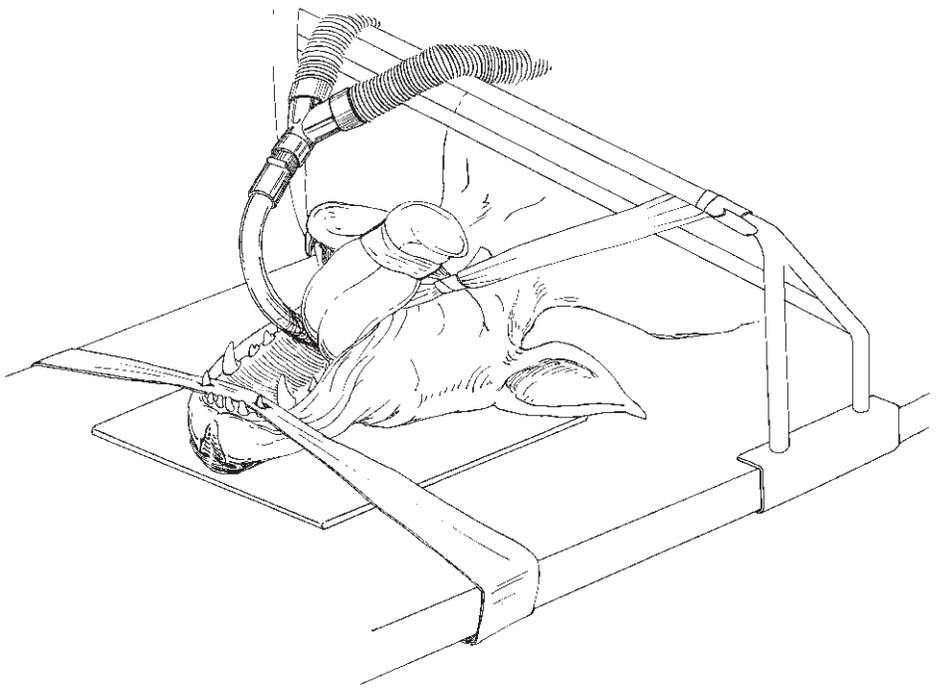

Figure 160-7. Positioning for ventral rhinotomy. (Redrawn with permission from Slatter DH [ed]: Textbook of Small Animal Surgery. Philadelphia: WB Saunders, 1985.)

14. If the stoma is small, it may heal by second intention; otherwise, following conclusion of medical therapy, debride, undermine, and appose the skin edges.
15. Dogs tolerate rhinotomy very well. Aggressive rhinotomy in cats can be associated with a higher rate of morbidity and mortality.

Ventral Rhinotomy

The nasal cavity and nasopharynx can be explored using a ventral approach. With this technique, evaluation of the frontal sinuses is limited to the rostral half.

Technique

1. Position the patient in dorsal recumbency with the oral cavity exposed by hanging and securing the mandible in a wide, open-mouth position (Fig. 160-7).
2. Cleanse the oral cavity, dental arcade, and nasopharyngeal area with a mild antiseptic solution (dilute chlorhexidine or povidone-iodine).
3. Incise the mucoperiosteum of the hard palate on the midline from the level of the canine teeth caudally to the fourth premolar or continue through the mucosa of the soft palate if the lesion extends into the nasopharyngeal area (Fig. 160-8).
   a. Alternatively, use a U-shaped mucoperiosteal incision parallel to the dental arcade (see Fig. 160-8).
4. Bilaterally reflect and retract the mucoperiosteum.
5. Identify and preserve the major palatine arteries. They penetrate the hard palate near the caudal aspect of the fourth premolar and run parallel to the course of the dental arcade about midway between it and the midline of the hard palate (see Fig. 160-8).
6. Create a window into the nasal cavity by removing a flap of hard palate with an oscillating saw, air drill, or osteotome and mallet (Fig. 160-9). Enlarge the window with a rongeur, if necessary.

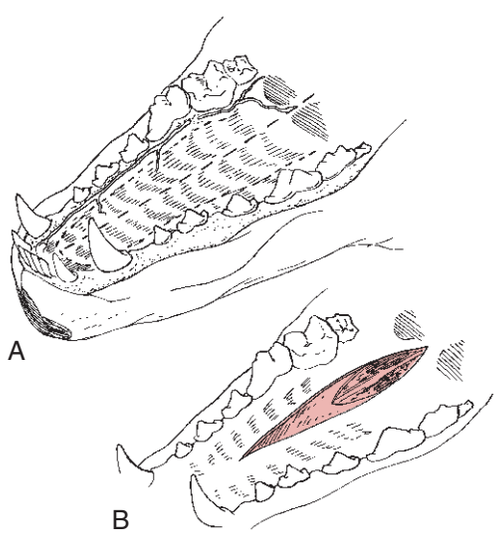

Figure 160-8. Ventral rhinotomy. Incise the mucoperiosteum on the midline or in the shape of a U, which parallels the dental arcade *(A)*. The incision may extend into the soft palate to expose lesions extending into the nasopharynx *(B)*.

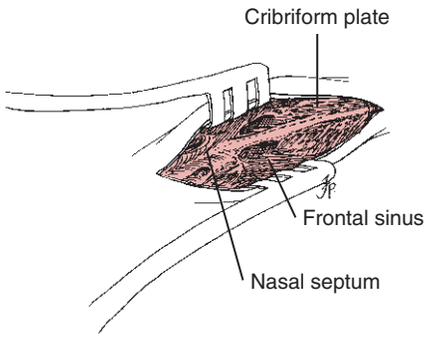

Figure 160-9. Exposure using ventral rhinotomy: cribriform plate, frontal sinus, remnant of nasal septum. (Rostral is to the left.)

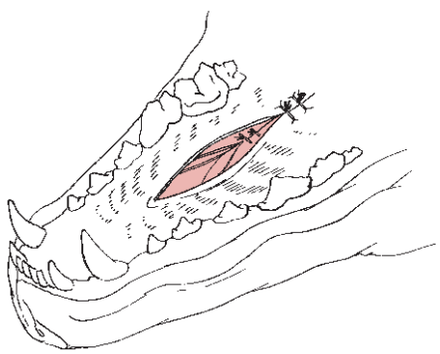

Figure 160-10. Following ventral rhinotomy, appose the mucoperiosteum with simple interrupted sutures. Appose the soft palate using two or three layers of simple interrupted or simple continuous sutures.

7. Remove the lesion and involved conchae (turbinates) with forceps and curettage.
8. Lavage and suction blood clots and debris from the area with copious amounts of saline.
9. Replace or discard the bone flap as for dorsal rhinotomy.
10. Close the mucoperiosteum with simple interrupted sutures. If possible, close the soft palate incision in two or three layers (nasal mucosa, muscle and connective tissue, pharyngeal mucosa) (Fig. 160-10).

Frontal Sinus Procedures

Chronic rhinitis or sinusitis (especially in cats) generally recurs in a variable period of time with either of the following procedures.

Technique for Sinus Flushing

1. Insert indwelling tubes for repeated frontal sinus flushing by first trephining a hole into the sinus.
2. Make an incision in the soft tissues and trephine a hole in the bone just lateral to the midline on a line connecting the rostral margins of the supraorbital processes.

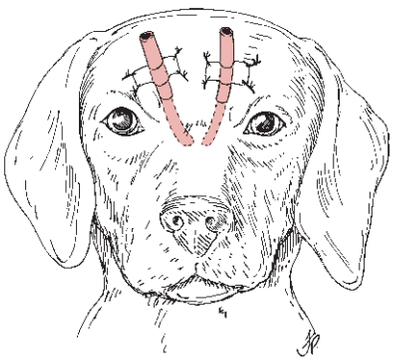

Figure 160-11. Position of tubes inserted into the frontal sinus and nasal cavity for topical treatment of chronic rhinitis and sinusitis. (Redrawn with permission from Slatter DH [ed]: Textbook of Small Animal Surgery. Philadelphia: WB Saunders, 1985.)

3. Collect biopsy and culture specimens.
4. Insert the fenestrated tube into the sinus and secure it to the skin (Fig. 160-11).
5. Following tube removal, allow the openings to heal by second intention.

Technique for Sinus Obliteration

1. Create a bone flap to expose the frontal sinuses and caudal nasal cavity.
2. Remove the compartment divisions and mucosal lining of the frontal sinus and aperture with a pneumatic bone bur. Complete removal of the lining is aided by the use of a dissecting or operating microscope.
3. Cover the aperture of the frontal sinus into the nasal cavity with a free fascial or muscle patch.
4. Lavage the area and fill the sinus with fat harvested from a secondary site (e.g., falciform ligament).
5. Close the periosteum, subcutaneous tissue, and skin.

POSTOPERATIVE CARE AND COMPLICATIONS

Patient Care

- Following rhinotomy, place the patient in a slightly head-down position and remove the endotracheal tube with the cuff slightly inflated to help remove fluid and debris.
- Give postoperative analgesics such as morphine (0.2–0.4 mg/kg IM or SC), fentanyl (1–5 µg/kg/hour continuous rate infusion), or buprenorphine (Buprenex, Norwich Eaton) (0.005 mg/kg IM or IV) for the first 24 hours and then as needed.
- Chewing on hard objects is forbidden if the bone flap from the hard palate is discarded.
- Prior to creating a nasal stoma, graphically describe to the client the postoperative appearance of the patient (optimally by viewing pictures of other

patients). Many clients are initially reluctant to accept their pets' appearance following rhinostomy.
- Following rhinotomy, discharge patients from the hospital within 2 to 3 days unless complications or adjuvant therapy dictates longer hospitalization.

Complications

- Expect sneezing and mild epistaxis for several days.
- Breathing sounds are harsh and resonant, often sounding "hollow."
- Appetite may be depressed for several days. Give cats diazepam or oxazepam to stimulate appetite if necessary.
- A serous to serosanguineous nasal discharge occurs for several days to weeks, depending on the primary disease condition and the effectiveness of adjuvant therapy. This discharge may continue indefinitely.
- Inward and outward movement of the skin flap may be observed with inspiration and expiration, respectively, if the bone flap is discarded, but this movement is usually temporary.
- Subcutaneous emphysema may occur. It is usually localized to the head and resorbs without treatment. If emphysema is excessive, place a tube in the frontal sinus to vent the air and aspirate the subcutaneous air.
- If carotid artery occlusion is not employed, blood loss during surgery may be excessive, requiring transfusions and vigorous fluid therapy.
- Airway obstruction is rare but may occur due to failure to mouth breath, mucosal edema, and anxiety. Sedate these animals and provide supplemental oxygen in a quiet, cool environment. Give corticosteroids to reduce mucosal edema.
- Disease erosion of the cribriform plate or curettage may result in exposure of the brain and cerebral edema. Treat brain edema with rapid-acting water-soluble IV corticosteroids, osmotic agents (mannitol), hyperventilation, hyperbaric oxygen, calcium channel blockers, and antioxidants.
- Indwelling catheters can be dislodged by the patient; therefore, some surgeons create temporary rhinostomies to facilitate topical therapy.
- Nasocutaneous or oronasal fistulas may form if healing is interrupted.
- Replaced bone flaps may sequestrate secondary to infection or radiation therapy.
- Chronic rhinitis or sinusitis and its causative agents will persist or recur if rhinotomy and turbinectomy (excision of nasal conchae) are performed without appropriate medical therapy (see Chapter 163). Exceptions may include nasal disease caused by foreign bodies or *Rhinosporidium* organisms.
- The chronic nasal discharge may persist because it is not possible to remove all diseased tissue during turbinectomy, and the epithelium may have undergone squamous metaplasia.

Prognosis

- Survival following various combinations of therapy for nasal neoplasms ranges from 4 to >24 months.
- Fungal rhinitis is refractory to antifungal agents currently available in about 50% of the cases. Antifungal agents are usually given for 6 to 8 weeks orally or repeated topically 1 to 3 times depending on the agent used. See Chapter 163 for medical treatment of infectious rhinitis and sinusitis.

Chapter

161 Obstructive Upper Airway Disorders

Roger B. Fingland

Obstructive upper airway diseases typically are insidious in onset and result in progressively worsening respiratory stridor and dyspnea. The dimensions of the upper airway play a fundamental role in the efficiency of breathing and progression of disease. In narrowed regions of the upper airway, air velocity is higher and pressure is lower than elsewhere (Bernoulli effect), which tends to narrow susceptible regions of the upper airway still more.

ETIOLOGY

Congenital obstructive upper airway diseases are diagnosed so commonly in brachycephalic dogs that they are referred to collectively as the brachycephalic syndrome. Most other obstructive upper airway diseases are acquired and are diagnosed in middle-aged and older dogs. Obstructive upper airway diseases are diagnosed less frequently in cats.

Brachycephalic Syndrome

The brachycephalic syndrome consists of stenotic nares, elongated soft palate, and everted laryngeal saccules.

- Tracheal hypoplasia is a generalized narrowing of the tracheal lumen diameter diagnosed commonly in English bulldogs and, less commonly, in other brachycephalic breeds.
- Stenotic nares and elongated soft palate are congenital conditions diagnosed quite frequently in brachycephalic dogs.
- Laryngeal saccule eversion is a consequence of chronic upper airway obstruction.

Laryngeal Collapse

Laryngeal collapse is recognized most commonly in brachycephalic dogs with chronic obstructive upper respiratory disease (brachycephalic syndrome). Loss of the supporting function of the laryngeal cartilages results from pressure changes within the larynx induced by obstruction rostral to the rima glottidis. Laryngeal collapse is considered a progressive, end-stage disease. However, some dogs have a mild to moderate form of the condition and can do reasonably well with medical management.

Laryngeal Paralysis

This condition is seen primarily in old, large-breed, and giant-breed dogs. Interruption of the innervation to the intrinsic muscles of the larynx, particularly the cricoarytenoideus dorsalis muscle, results in failure of the arytenoid cartilages and vocal folds to abduct during inspiration. The condition is a congenital anomaly in some breeds, such as the Bouvier des Flandres, Siberian husky, and dalmatians. Laryngeal paralysis also has been associated with hypothyroidism (see Chapter 31) and diffuse polyneuropathies in dogs (see Chapter 129). In many cases laryngeal paralysis is idiopathic.

Nasopharyngeal Polyps

These inflammatory masses arise from the epithelium of the nasopharynx, auditory canal, or tympanic cavity (see Chapters 59 and 61).

- Polyps commonly occur in cats and may be congenital in young cats.
- Masses that arise from or involve the nasopharynx result in upper airway obstruction. Although nasopharyngeal polyps are rare in dogs, upper airway obstruction related to soft tissue proliferation can develop in dogs with hyperprogesteronism secondary to drug administration or excessive hormone production in the bitch.

Tracheal Collapse

This condition is seen primarily in old toy-breed dogs. Occasionally it is diagnosed in young dogs and may be congenital.

- The etiology of tracheal collapse is not known, but most likely it is multifactorial and related to changes in airflow dynamics due to primary small airway or upper airway disease. Potential etiologic factors include the following:
  - Predisposition in small-breed dogs
  - Obesity

- Degeneration of tracheal cartilages
- Chronic bronchitis

Tracheal Stenosis

Tracheal stenosis is usually a sequela of traumatic tracheal disruption. Animal bite wounds, traumatic intubation or extubation, and cervical gunshot wounds are common causes of tracheal injury.

Intraluminal Foreign Bodies

Tracheal foreign bodies rarely cause complete obstruction; large items usually are retained at the carina, whereas small ones often pass into the bronchi, leading to bronchial obstruction and pneumonia.

Primary Tracheal Neoplasia

These tumors are uncommon in dogs and rare in cats.

- Primary tracheal tumors reported in dogs include osteosarcoma, osteochondroma, chondrosarcoma, leiomyoma, mast cell tumor, adenocarcinoma, and squamous cell carcinoma.
- Primary tracheal lymphoma and adenocarcinoma have been reported in cats.

Extraluminal Compression of the Trachea

Segmental tracheal stenosis can be caused by compression from extraluminal masses such as parasitic granulomas *(Oslerus [Filaroides] osleri),* thyroid carcinoma (see Chapter 31), hilar lymphadenopathy (see Chapter 165), left atrial enlargement (see Chapter 149), mediastinal lymphoma (see Chapter 27), and mediastinal lipoma.

CLINICAL SIGNS

Stertor and Stridor

These signs of obstructive upper respiratory disease are so common in brachycephalic dogs that owners frequently do not recognize noisy breathing as abnormal.

- Stridor is a high-pitched inspiratory sound generated from obstruction of laryngeal airflow.
- Dogs with an elongated soft palate often have characteristic stertorous, or snoring, respiratory sounds that result from occlusion of the rima glottidis by the excessively long soft palate.
- Stridor and voice change are common in cats with nasopharyngeal polyps and in dogs with laryngeal paralysis. Dogs with laryngeal collapse can exhibit either stertor or stridor.

Dyspnea

Dyspnea is observed in most animals with obstructive upper respiratory disease.

- Inspiratory dyspnea, expiratory dyspnea, or a combination may be present, depending on the location and severity of obstruction.
- Collapse of the cervical segment of the trachea results in primarily inspiratory dyspnea, whereas collapse of the thoracic segment of the trachea often is associated with expiratory dyspnea.
- Animals with fixed upper respiratory obstruction such as tracheal stenosis and laryngeal collapse usually are continually dyspneic. Dyspnea may be intermittent and exacerbated by exercise, stress, or high ambient temperature in dogs with tracheal collapse or laryngeal paralysis.

Cough

Coughing is common in dogs with tracheal collapse and, less frequently, in dogs with tracheal stenosis or laryngeal paralysis.

- Approximately 50% of dogs with tracheal collapse have a characteristic "goose honk" cough associated with vibration in the collapsing segment. Other dogs with tracheal collapse do not have a characteristic cough, and some do not cough.
- Dogs with tracheal collapse rarely cough continuously. The cough may be intermittent, and paroxysms usually are exacerbated by stress, excitement, and mechanical stimulation of the trachea.

Decreased Exercise Tolerance

Occasionally, decreased exercise tolerance is observed in dogs with laryngeal paralysis, laryngeal collapse, tracheal stenosis, or brachycephalic syndrome.

Voice Change

This may be an early clinical sign in dogs with laryngeal paralysis. It is also common in cats with nasopharyngeal polyps.

Hyperthermia

Symptoms of laryngeal paralysis frequently are not apparent until the animal is exposed to high ambient temperature; some dogs with laryngeal paralysis are presented with profound hyperthermia.

▼ ***Key Point*** Evaluate laryngeal function in large-breed dogs requiring treatment for hyperthermia.

Gagging

Occasionally, gagging is observed early in the course of obstructive upper airway diseases such as laryngeal paralysis and elongated soft palate.

Dysphagia

Dysphagia may occur in cats with nasopharyngeal polyps and, rarely, in dogs with laryngeal paralysis.

Syncope

Fainting associated with exercise (overexertion), excitement, or coughing spells occurs in some dogs with tracheal collapse.

DIAGNOSIS

History

- Animals in the early stages of obstructive upper airway disease typically are asymptomatic at rest.
- Excitement, exercise, or stress leads to varying degrees of coughing, dyspnea, and stridor.
- Clinical signs may progress to constant, severe coughing and dyspnea.
- Some animals with severe obstructive upper respiratory disease are presented with a history of cyanosis or syncope.

Physical Examination

The physical examination often is unremarkable in dogs with obstructive upper respiratory diseases.

- Distinct lateral tracheal borders may be identified on cervical palpation in dogs with tracheal collapse. Gentle tracheal palpation may cause paroxysms of coughing.
- An ear discharge occasionally is identified in cats with nasopharyngeal polyps. Otoscopic examination may reveal polypoid masses within the external ear canal.
- Stenosis of the external nares may be evident in brachycephalic dogs.

Oropharyngeal Examination

A thorough oropharyngeal examination under light general anesthesia is diagnostic for most obstructive upper airway diseases.

Brachycephalic Syndrome

- The soft palate overlaps the tip of the epiglottis.
- Everted laryngeal saccules are identified as oval mucosal masses projecting into the ventral rima glottidis, lateral to the vocal folds.
- Enlarged tonsils and edematous pharyngeal mucosa are common.

Laryngeal Paralysis

- Animals with laryngeal paralysis are unable to abduct the arytenoid cartilages and vocal folds during inspiration.

▼ ***Key Point*** Use *light* anesthesia for evaluation of laryngeal function. A surgical plane of anesthesia will obliterate normal laryngeal reflexes and possibly result in a false-positive diagnosis.

- Slight, asynchronous abduction of the arytenoids may be observed in some cases.
- The majority of dogs with laryngeal paralysis have bilateral dysfunction of the cricoarytenoideus dorsalis muscle. Unilateral laryngeal paralysis (hemiplegia) is identified infrequently, perhaps because animals with unilateral involvement remain asymptomatic.
- Laryngeal edema and inflammation also may be seen.
- Evaluate arytenoid abduction during inspiration. Do not consider passive *expiratory* opening of the glottis and arytenoids as evidence of normal function.

Laryngeal Collapse

- The corniculate and cuneiform processes of the arytenoid cartilages are apposed or overlap, causing collapse of the airway.
- Abduction of the arytenoids is not observed.

Nasopharyngeal Polyp

- With the animal in dorsal recumbency, expose the polyp by gently retracting the soft palate ventrally and rostrally.

Radiography

Obtain radiographs of the pharyngeal, cervical, and thoracic regions.

- A soft tissue density cranial to the pharynx or an increased radiodensity of one of the osseous bullae may be identified on skull radiographs of cats with nasopharyngeal polyps. Computed tomography (CT) scan is also useful in identifying tympanic bulla changes in cats with polyps.
- The soft palate may appear thickened and lengthened in dogs with an elongated soft palate. Normally, the soft palate does not extend beyond the tip of the epiglottis.
- Narrowing of the tracheal diameter may be evident on lateral cervical and thoracic radiographs in dogs with tracheal collapse. Collapse occurs most commonly at the thoracic inlet. Tracheal collapse is a dynamic disease, especially in the early stages. Obtain full inspiratory and expiratory views because the trachea may not be collapsed during all phases of respiration. A normal or near-normal tracheal diameter on plain film radiographs does not rule out tracheal collapse.
- Tracheal stenosis is identified on a lateral cervical or thoracic radiograph as a focal reduction of the tracheal lumen diameter. Radiographs usually are adequate to establish a diagnosis of tracheal stenosis because of the static nature of the condition.
- Aspiration pneumonia is an infrequent sequela of obstructive upper respiratory disease. Aspiration pneumonia typically is characterized by a mixed alveolar-interstitial density in the dependent portions of the cranial and middle lung lobes (see Chapter 163).

Fluoroscopy

Fluoroscopy allows continual assessment of the tracheal lumen diameter during all phases of the respiratory cycle. In dogs suspected of having tracheal collapse, evaluate the entire trachea and both main stem bronchi during quiet respiration and induced coughing.

Tracheoscopy

Tracheoscopy is beneficial in assessing the location and severity of stenotic tracheal lesions. Perform tracheoscopy under general anesthesia and pay close attention to patient oxygenation.

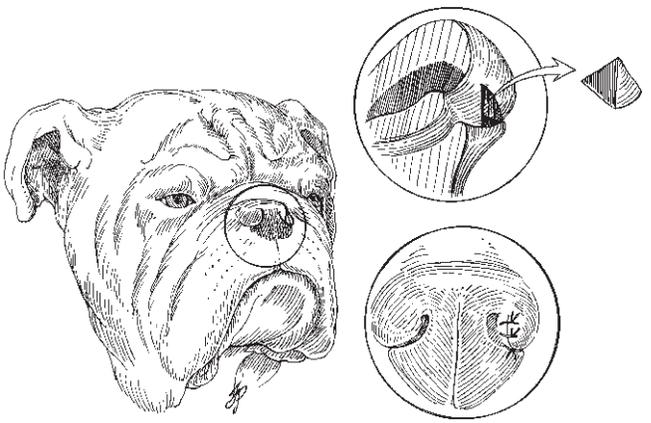

Figure 161-1. Wedge resection of the alar fold for stenotic nares.

TREATMENT

Brachycephalic Syndrome

Nasal Wedge Resection

Surgical Anatomy

In the dog, the nasal vestibule is occupied by the end of the ventral nasal concha, called the alar fold.

Preoperative Considerations

- Administer oxygen through a face mask for 3 to 5 minutes prior to induction (preoxygenation). Minimize stress to the patient.
- Consider temporary tracheostomy in brachycephalic dogs undergoing upper respiratory tract surgery.
- Rapid induction of anesthesia and control of the airway is essential. Mask induction is discouraged.
- Thoroughly evaluate the upper airway in animals with stenotic nares. Staphylectomy (soft palate excision) and laryngeal sacculectomy probably will be necessary.

Surgical Procedure

Objective

To increase the cross-sectional area of the nasal vestibule

Equipment

- #15 or #11 blade
- 4-0 or 5-0 monofilament nylon or polypropylene suture material
- Standard minor surgery pack

Technique

1. Excise a vertical triangular or elliptical wedge of tissue extending from the wing of the nostril caudally to include part of the alar cartilage. The base of the wedge should include one-third to one-half of the free edge of the nostril (Fig. 161-1).
2. Close the incision with 4-0 or 5-0 nylon or polypropylene suture material in a simple interrupted pattern.
3. If the cross-sectional area of the nasal vestibule has not been increased adequately, remove the sutures and excise more tissue. Remove the same amount of tissue on each side to ensure symmetrical nostrils.

Postoperative Care and Complications

- Carefully monitor the dog during recovery and for several hours after surgery.
- Incisional hemorrhage may occur but resolves with direct pressure.
- Signs of respiratory obstruction persist following nasal wedge resection if concurrent obstructive upper respiratory diseases have not been managed properly.

Staphylectomy (Correction of Elongated Soft Palate)

Surgical Anatomy

- The soft palate is a valve-like partition composed of mucosal and muscular layers.
- The free edge of the soft palate should appose or slightly overlap the epiglottis.

Preoperative Considerations

- See preceding discussion under "Nasal Wedge Resection."
- Just prior to beginning the procedure, administer dexamethasone sodium phosphate (0.2 mg/kg IV) to reduce tissue edema and inflammation associated with the surgery.

Surgical Procedure

Objectives

- To shorten the soft palate so that the free edge apposes or barely overlaps the epiglottis

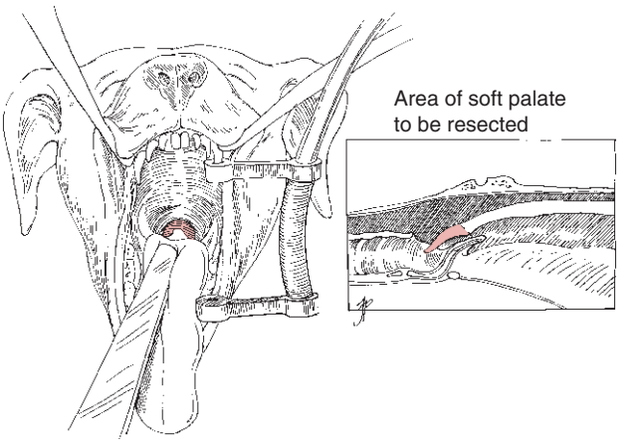

Figure 161-2. Staphylectomy for elongated soft palate. The area of soft palate to be resected is in red.

- To minimize pharyngeal and laryngeal edema by using an atraumatic technique

Equipment

- Standard instrument pack and suture
- Babcock forceps

Technique

1. Position the dog in ventral recumbency with the mouth held open with an oral speculum or adhesive tape sling.
2. Determine the portion of the soft palate that is excessive (Fig. 161-2) by placing it adjacent to the epiglottis. Alternatively, excise that portion of the soft palate that extends beyond an imaginary line across the *caudal* pole of the tonsils.
3. Place traction sutures of 4-0 absorbable suture material in the lateral aspect of the soft palate adjacent to the point at which the epiglottis touches the soft palate.
4. Grasp the center of the free border of the soft palate with Babcock forceps and retract it rostrally.
5. Incise approximately one-half the width of the soft palate with curved Metzenbaum scissors. Suture the incised mucosal edges with 4-0 absorbable suture material in a simple continuous pattern. The nasal mucosa tends to retract caudally.
6. Continue the "cut-and-sew" technique (Fig. 161-3) until the palate is resected and closure is complete.
7. Avoid using crushing clamps and electrocautery.

Postoperative Care and Complications

- Laryngeal edema is a common postoperative complication in brachycephalic dogs that have had surgery on the upper respiratory tract.

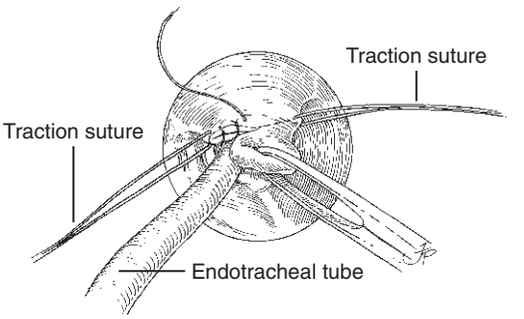

Figure 161-3. "Cut-and-sew" procedure for soft palate resection.

▼ ***Key Point*** Excessive resection of the soft palate may allow aspiration of food postoperatively because the shortened palate is unable to close the nasopharynx during swallowing.

- Clinical signs may persist if resection of the palate was inadequate.

Laryngeal Sacculectomy

Surgical Anatomy

Laryngeal saccules are small, mucosa-lined outpouchings that lie lateral to the vestibular folds.

Preoperative Considerations

See discussion under "Nasal Wedge Resection" and "Staphylectomy (Correction of Elongated Soft Palate)."

Surgical Procedure

Objective

To remove the everted laryngeal saccules and thereby relieve the obstruction

Equipment

- Metzenbaum scissors
- Babcock or Allis tissue forceps

Technique

1. Position the dog in ventral recumbency with the mouth held open with an oral speculum or adhesive tape sling.
2. Grasp the saccule with Babcock or Allis tissue forceps and retract it rostrally.
3. Amputate the saccule at its base with Metzenbaum scissors.
4. Use direct pressure to control hemorrhage. The cuff of the endotracheal tube can be used to apply pressure.

Postoperative Care and Complications

See discussion under "Staphylectomy (Correction of Elongated Soft Palate)."

Laryngeal Paralysis

Surgical Anatomy

- The larynx is supported by the cricoid and thyroid cartilages.
- Left and right arytenoid cartilages covered with mucous membrane are located at the rostral end of the larynx and form the dorsal part of the glottal cleft. The corniculate and cuneiform processes of the arytenoid cartilages project into the glottal cleft.
- The vocal folds form the ventral part of the glottal cleft.
- The cricoarytenoideus dorsalis muscles are innervated by the recurrent laryngeal nerves and are the only abductors of the arytenoid cartilages and vocal folds.

Preoperative Considerations

- Medical therapy for hyperthermic dogs in acute cyanotic crisis includes oxygen administration, alcohol or ice water baths, IV fluid therapy, and corticosteroids (prednisolone sodium succinate, 2.5 to 5.0 mg/kg IV, and dexamethasone, 0.5 mg/kg IV).
- Sedation may be necessary (e.g., acepromazine) to calm hyperthermic animals.
- Temporary tracheostomy (see Chapter 3) may be necessary for animals that do not respond to initial conservative treatment.
- Evaluate thyroid function (see Chapter 31). Also, perform a neurologic examination to evaluate the animal for polyneuropathy.
- Preoxygenate the dog and gain control of the airway rapidly during induction of anesthesia (i.e., via tracheal intubation).
- Prepare for tracheostomy tube insertion.

Surgical Procedure: Arytenoid Lateralization

Objective

To increase the diameter of the rima glottidis by lateralizing the arytenoid cartilages, which is also known as a tie-back procedure.

Avoid excessively lateralizing the arytenoid, which could predispose to aspiration pneumonia.

Equipment

- Standard surgical pack and suture
- Narrow malleable retractors
- Gelpi or Weitlaner retractors

Arytenoid lateralization involves freeing the arytenoid cartilage from its cartilaginous attachments and placing a non-absorbable suture to permanently abduct the cartilage, thus increasing the diameter of the rima glottidis. The procedure should be performed unilaterally, since that is usually successful in alleviating clinical signs.

Advantages

Advantages of arytenoid lateralization over other techniques, such as arytenoidectomy, are as follows:

- Intraoperative hemorrhage and postoperative edema are less compared with intraoral procedures.
- Postoperative laryngeal scar formation is uncommon.
- Voice change is minimal because a ventriculocordectomy is not performed.
- Temporary tracheostomy is seldom needed.

Technique

1. Prepare the ventral and lateral cervical region for aseptic surgery.
2. Place the dog in dorsolateral recumbency with the neck extended over a small, rolled towel. Approach either the right or the left side of the larynx, depending on the preference of the surgeon.
3. Make a paramedian incision adjacent to the larynx, approximately in the jugular furrow.
4. Continue the incision through the superficial muscle and subcutaneous fat, and identify the thyropharyngeus muscle.
5. Grasp the dorsal edge of the thyroid cartilage through the thyropharyngeus muscle. Rotate the thyroid cartilage ventrally.
6. Transect the thyropharyngeus muscle along the dorsal edge of the thyroid cartilage (Fig. 161-4).
7. Elevate the exposed dorsal edge of the thyroid cartilage and incise the articulation of the thyroid and cricoid cartilages. The intrinsic muscles of the larynx are exposed. Identify the cricoarytenoideus dorsalis muscle.
8. Transect the cricoarytenoideus dorsalis muscle near its insertion on the muscular process of the arytenoid cartilage (Fig. 161-5). Preserve a section of the muscle for histologic analysis.
9. Retract the remainder of the cricoarytenoideus dorsalis muscle rostrally and identify the cricoarytenoid articulation.
10. Separate the cricoarytenoid articulation with Mayo scissors.
11. Retract the arytenoid cartilage laterally.
12. Pass Mayo scissors between the arytenoid and the cricoid cartilages and transect the arytenoid-arytenoid articulation on the dorsal midline of the larynx. Some surgeons chose not to transect this articulation, and adequate arytenoid lateralization still results.

▼ ***Key Point*** Wound infection and postoperative stricture formation are more likely if the laryngeal mucosa is incised during this procedure.

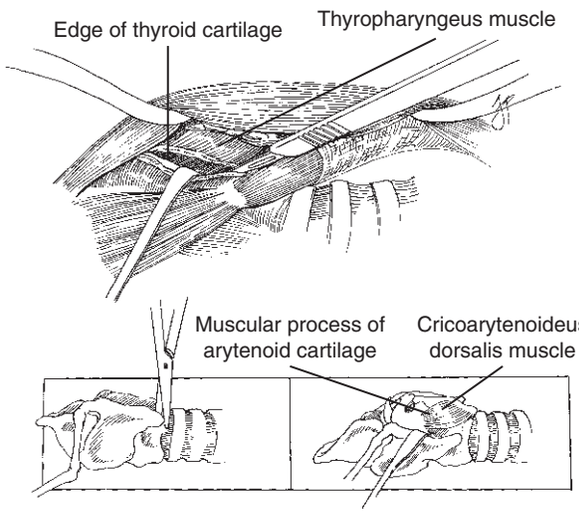

Figure 161-4. Arytenoid lateralization. Transect the thyropharyngeus muscle and expose the arytenoid cartilage. *Below left,* Transect the cricothyroid articulation. *Below right,* expose the arytenoid cartilage by retracting the thyroid cartilage.

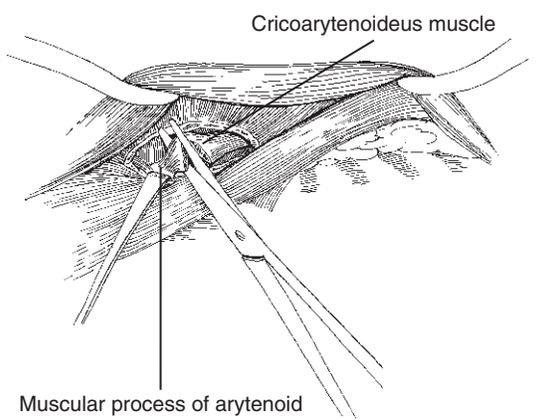

Figure 161-5. Arytenoid lateralization. Transect the cricoarytenoideus dorsalis muscle.

13. Pass a monofilament non-absorbable suture (0 nylon or polypropylene) from the muscular process of the arytenoid cartilage to the caudodorsal portion of the thyroid cartilage (Fig. 161-6). Alternatively, pass the suture from the muscular process of the arytenoid cartilage to the caudodorsal aspect of the cricoid cartilage (see inset in Fig. 161-6).
14. Temporarily extubate the patient and have an assistant perform an oral examination to evaluate the degree of arytenoid lateralization. Temporary extubation is not necessary if anesthetic gases are being delivered through an endotracheal tube passed through a temporary tracheostomy.
15. Tighten the suture as an assistant evaluates the position of the arytenoid cartilage. Knot the suture at the point of maximal abduction.

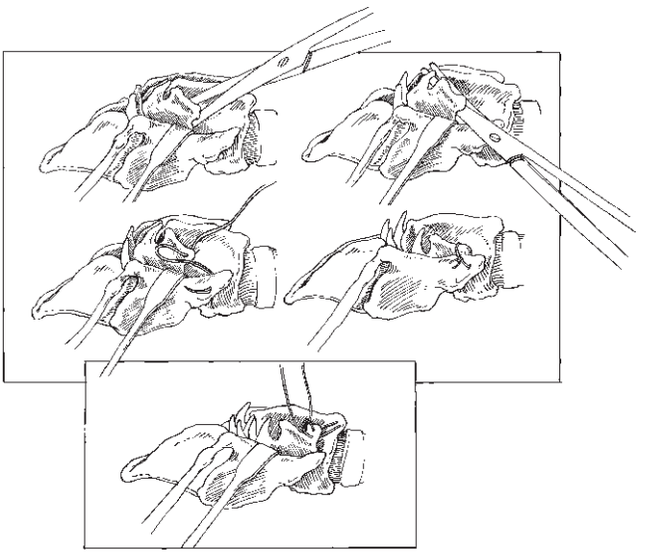

Figure 161-6. Arytenoid lateralization-suture adduction. *Top,* Transect the arytenoid-cricoid articulation *(left),* then the arytenoid-arytenoid articulation carefully *(right),* avoiding incising the laryngeal mucosa. Suture the muscular process of the arytenoid cartilage to the caudodorsal portion of the thyroid cartilage. *Inset,* In the alternative LaHue approach, suture from the muscular process of the arytenoid to the dorsocaudal aspect of the cricoid.

16. Replace the endotracheal tube if it was removed.
17. Close the thyropharyngeus muscle with 3-0 absorbable suture in a simple continuous pattern.
18. Close the subcutaneous and skin layers routinely.

Postoperative Care and Complications

- Laryngeal edema is a common sequela of laryngoplasty. Carefully monitor postoperative laryngoplasty patients that do not have a tracheostomy tube for signs of upper respiratory obstruction. Administer corticosteroids and supplemental oxygen if laryngeal edema develops. Be prepared for emergency tracheostomy.
- Manage tracheostomy tubes meticulously. Clean the tube as needed (at least every 2 hours). Double-cannula tracheostomy tubes are ideal (see Chapter 3).
- Laryngeal scar formation resulting in cranial glottic stenosis is a potential complication of arytenoidectomy, especially when excision of the vocal folds or arytenoid cartilages extends into the dorsal or ventral commissures; however, the lateralization procedure avoids this complication.
- Failure to open the rima glottidis adequately may result in recurrence or persistence of clinical signs after surgery.
- Consider lateralization of the contralateral arytenoid cartilage if signs recur or persist after unilateral arytenoid lateralization.
- Consider arytenoidectomy (Fig. 161-7) only as a last resort when bilateral lateralization fails.

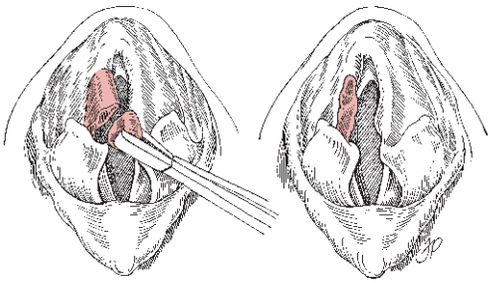

Figure 161-7. Partial arytenoidectomy for laryngeal paralysis.

- Bilateral arytenoidectomy or excision of excessive arytenoid tissue during partial arytenoidectomy may result in laryngeal dysfunction or excessive enlargement of the lumen characterized by episodes of aspiration pneumonia and gagging. Surgical amelioration of this condition is unlikely. Permanent tracheostomy can be performed as a salvage procedure.

Laryngeal Collapse

Treat the predisposing factors, such as stenotic nares, everted laryngeal saccules, and elongated soft palate. Also, recommend an integrated program of medical therapy consisting of weight control, prevention of hyperthermia, and intermittent use of sedatives (e.g., acepromazine) and corticosteroids as needed. If clinical signs persist, reevaluate the respiratory tract. Persistence of clinical signs after appropriate medical and surgical management of predisposing factors may necessitate a permanent tracheostomy.

Permanent Tracheostomy

Preoperative Considerations

- Permanent tracheostomy is a salvage procedure that usually is indicated for treatment of end-stage laryngeal disease. Permanent tracheostomy can be performed following laryngectomy for laryngeal neoplasia.
- Detailed client communication is vital prior to performing permanent tracheostomy. Explain the procedure, potential postoperative complications, and activity restrictions (see below).
- Make certain the segment of the trachea distal to the proposed tracheostomy site is normal. Tracheoscopy or fluoroscopy is preferable; however, inspiratory and expiratory cervical and thoracic radiographs may be adequate to evaluate the integrity of the distal trachea.
- Use an endotracheal tube with a high-volume, low-pressure cuff that has been checked for leaks. Place the cuff distal to the proposed tracheostomy site.

Surgical Procedure

Objective

To create a permanent stoma in the cervical segment of the trachea

Equipment

- Standard surgical pack and suture
- Tracheostomy tube with a high-volume, low-pressure cuff (tube must be long enough to allow positioning of the cuff in the caudal cervical trachea)

Technique

1. Place the dog in dorsal recumbency with the neck extended over a rolled towel. Prepare the ventral cervical region for aseptic surgery.
2. Make a ventral cervical midline incision through the skin and subcutaneous tissues, beginning at the larynx and extending caudally approximately 10 cm. Center the incision over the proposed tracheostomy site.
3. Separate the paired sternohyoideus muscles, exposing the trachea.
4. Bluntly dissect the cervical fascia from the entire circumference of the trachea between the second and the sixth tracheal cartilages.

▼ ***Key Point*** Identify and avoid the recurrent laryngeal nerves when dissecting the cervical fascia from the trachea.

5. Preplace two horizontal mattress sutures (2-0 polydioxanone) between the sternohyoideus muscles, passing *dorsal* to the trachea where the cervical fascia was dissected.
6. Tie the horizontal mattress sutures. This apposes the sternohyoideus muscles dorsal to the trachea, decreasing tension on the mucocutaneous anastomosis by deviating the trachea ventrally to the level of the skin.
7. Make a partial-thickness rectangular incision in the tracheal wall. Make the segment to be excised three tracheal cartilages long (include the third, fourth, and fifth cartilages) and approximately one-third the width of the tracheal circumference (Fig. 161-8).

▼ ***Key Point*** Do not make a full-thickness incision in the tracheal wall. Incise the tracheal wall to the level of the mucosa.

8. Bluntly elevate the tracheal cartilages and annular ligaments from the tracheal mucosa inside the boundaries of the rectangular incision. Remove the cartilages and annular ligaments, leaving the mucosa intact.
9. Excise a rectangular section of skin adjacent to the stoma bilaterally. Make each section equal to the

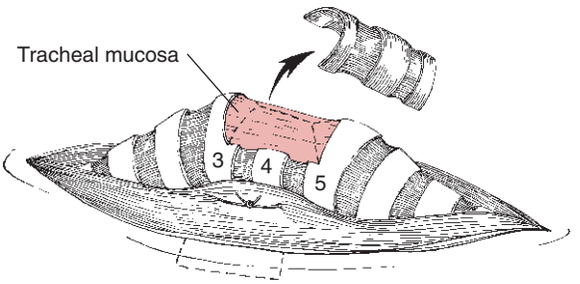

Figure 161-8. Permanent tracheostomy. Remove the segment of ventral trachea with remaining mucosa intact *(red)*. The dotted line indicates the area of mucosa and skin to be incised to complete the stoma.

length and approximately one-half the width of the tracheal stoma (see Fig. 161-8).

10. Secure the skin to the trachea by placing simple interrupted sutures (2-0 polyglycolic) between the dermis (not the skin edge) and the fascia on the lateral aspect of the trachea.
11. Check the endotracheal tube position and make certain that the cuff is inflated. The cuff should be positioned approximately 2 cm distal to the stoma.
12. Incise the tracheal mucosa, as shown in Figure 161-9.
13. Place simple interrupted sutures (4-0 monofilament nylon) 2 mm apart between the skin and the tracheal mucosa. Precise apposition is important.

▼ ***Key Point*** Make certain that there is no tension on the mucocutaneous sutures. Tension predisposes to dehiscence and stenosis.

14. Close the skin incision cranial and caudal to the stoma.
15. Gently suction the tracheal lumen proximal to the cuff to remove clotted blood.

Postoperative Care and Complications

- Clean the stoma every 4 to 6 hours for 48 hours after surgery. Cleaning is needed less frequently after 48 hours. Instruct the owner to clean the stoma once a day.
- Protect the stoma from self-trauma. Elizabethan collars are not recommended. Rarely, rear-limb hobbles are necessary to keep the animal from scratching the surgery site.
- Apply petroleum jelly to the skin around the stoma once a day for approximately 2 weeks to prevent irritation from dried secretions. This usually is not necessary after hair regrows. Avoid putting petroleum jelly in the stoma.
- Trim the hair around the stoma frequently.
- Dirty, dusty environments and swimming must be avoided.
- Skin fold occlusion of the stoma resulting in episodes of respiratory distress is the most common postoperative complication. Excision of redundant skin may be necessary, especially in brachycephalic breeds.
- Approximately 60% of dogs and cats are unable to bark or purr after permanent tracheostomy.
- All tracheostomies stenose approximately 20% to 40%. The degree of stenosis is variable and can be minimized by meticulous surgical technique.
- Closure of the stoma rarely is indicated. Closure is accomplished by resection of the stomal segment and primary anastomosis (see discussion under "Tracheal Resection and Anastomosis").

Nasopharyngeal Polyp

Surgical Anatomy

- The auditory (eustachian) tube extends from the nasal pharynx to the rostral portion of the tympanic cavity. The pharyngeal opening of the auditory tube is an oblique, slit-like opening that lies on the lateral

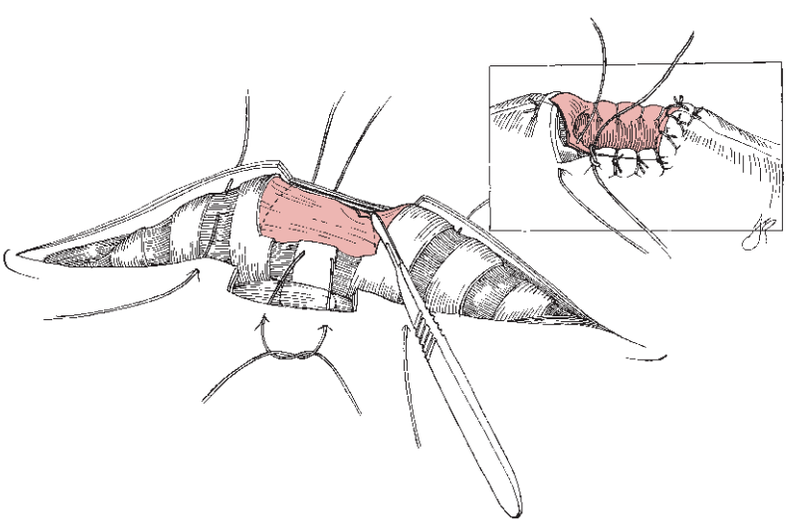

Figure 161-9. Permanent tracheostomy. After the mucosa is incised and reflected laterally, suture the skin directly to the peritracheal fascia and the annular ligament. Complete the stoma by closing the mucosa and skin with simple interrupted sutures *(inset)*.

wall of the nasal pharynx above the middle of the soft palate.
- The tympanic bulla is a smooth bulbous enlargement of the temporal bone, located between the retroarticular and the jugular processes.

Preoperative Considerations

- Obtain skull radiographs or a CT scan preoperatively. Evaluate the tympanic bulla and petrous-temporal bone for evidence of middle ear infection, including osseous bulla thickening, increased density within the tympanic cavity, and sclerosis of the petrous-temporal bone.
- Be prepared to perform a ventral bulla osteotomy in cats with radiographic signs or clinical signs of otitis media.

Surgical Procedure

Objective

To remove the polyp from the pharynx and bulla

Equipment

- Standard surgical pack and suture
- Atraumatic spay hook
- Allis tissue forceps
- Steinmann pin
- Rongeur
- Curette

Technique

1. If a ventral bulla osteotomy is indicated, position the cat in dorsal recumbency and prepare the ventral cervical region for aseptic surgery.
2. Perform a ventral bulla osteotomy (see Chapter 62) on the side with radiographic evidence of otitis media. If the cat is affected bilaterally, perform the osteotomy on the side of origin of the polyp. If the side of origin cannot be determined, perform the osteotomy on the side with the most pronounced radiographic changes.
3. Expose both the dorsomedial and the ventrolateral compartments of the tympanic cavity and carefully remove all inflammatory tissue. Submit tissues for histologic analysis. Avoid curettage of the dorsomedial aspect of the tympanic cavity.
4. Submit material from the bulla for bacterial culture and sensitivity testing.
5. Place a small rubber drain in the bulla that exits from an opening in the skin adjacent to the primary incision.
6. Place the cat in sternal recumbency with the mouth held open by a mouth speculum or adhesive tape sling.
7. Retract the soft palate cranially and ventrally with an atraumatic spay hook.
8. Grasp the nasopharyngeal polyp with an Allis tissue forceps and apply slow, steady traction until the mass is removed. A long stalk should be attached at the base.
9. Submit the excised tissue for histologic evaluation.

Postoperative Care and Complications

- Observe for laryngeal edema.
- Horner syndrome is a common complication of bulla osteotomy in cats. Clinical signs typically resolve within 4 weeks.
- Leave the drain in the bulla osteotomy site for 3 to 5 days.
- Administer antibiotics based on results of culture and sensitivity testing.

▼ ***Key Point*** Nasopharyngeal polyps may recur as a result of incomplete excision of inflammatory tissue. Failure to perform a bulla osteotomy in cats with middle ear involvement is a common cause of recurrence.

Tracheal Collapse

Application of Extraluminal Prostheses

Surgical Anatomy

- Individual C-shaped cartilage rings provide structural rigidity for the trachea.
- The space left by failure of the cartilage rings to meet dorsally is spanned by the transversely oriented trachealis muscle and connective tissue, collectively referred to as the dorsal tracheal membrane.
- The left recurrent laryngeal nerve lies on the left lateral or dorsolateral aspect of the trachea.
- The trachea is supplied by the cranial thyroid, caudal thyroid, and bronchoesophageal arteries. These arteries are enmeshed in delicate sheets of connective tissue on the lateral aspects of the trachea called lateral pedicles. Small, transversely oriented branches penetrate between tracheal rings and arborize in the tracheal submucosa.

Preoperative Considerations

- Consider surgical management on initial presentation only in dogs that are experiencing life-threatening dyspnea or syncope. Treat other dogs medically (Table 161-1) for approximately 4 weeks before considering surgical management. Dogs with mild to moderate tracheal collapse that respond well to medical management may not require surgery.
- Perform a tracheal wash, preferably bronchoscopically, and submit samples for routine cytology and bacterial culture and sensitivity testing.

- Identify the location of collapse using radiography or bronchoscopy.
- Anesthesia (see Chapter 2 for details on drug dosages):
  - Choose an endotracheal tube that is long enough to reach the thoracic inlet. Test the cuff.
  - Premedicate with diazepam.
  - Administer a *light* dose of thiobarbiturate.

▼ ***Key Point*** Always evaluate laryngeal function in dogs with tracheal collapse.

  - Induce anesthesia and rapidly gain control of the airway by passing an endotracheal tube.
  - Prepare for mechanical ventilation.
  - Administer cefazolin (25 mg/kg IV) at induction of anesthesia and 2 hours after the first dose.

Table 161-1. MEDICAL TREATMENT OF TRACHEAL COLLAPSE

Patient Management

Avoid airborne irritants or allergens.
Identify and then minimize exacerbating factors. Excitement, stress, extremes of air temperature, and humidity should be avoided.
Control daily activity. Minimize fatigue, episodes of exercise-induced cough, or dyspnea.
Provide nutritional counseling. Correct overweight body condition.
Schedule routine preventive dental care. Dental prophylaxis reduces bacterial contamination of the pharynx and upper airway.
Prevent dehydration. Adequate hydration maintains low viscosity of airway secretions and thereby promotes clearance.
Promote clearance of airway secretions. Liquefy secretions using humidifier or vaporizer treatments (probably more effective than expectorant drugs), and then facilitate their removal using physiotherapy (light exercise, coupage, or percussion).
Prevent infectious tracheobronchitis (kennel cough complex). Vaccination for parainfluenza, adenovirus, and *Bordetella* is preventive.

Drug Therapy

Antibiotics. If complicating bacterial airway infections are suspected, use amoxicillin-clavulanate cephalosporins, trimethoprim-sulfa, quinolones, or others as guided by tracheobronchial cultures; aerosol administration (gentamicin, 50 mg q12h for 5–7 days) may be more effective for eliminating *Bordetella* from the airways.
Reduce airway inflammation. Use an oral corticosteroid (prednisone, 1–2 mg/kg/day for 1–2 weeks; if improvement is noted, then continue with alternate-day maintenance.
Bronchodilator therapy. See Chapter 162 for a table of drug dosages. Administer drugs such as aminophylline, theophylline, oxtriphylline, or terbutaline, although the reversibility of lower airway obstruction in canine bronchitis and tracheobronchitis may be limited.
Antitussive therapy. See Chapter 162 for a table of drug dosages. Administer drugs such as hydrocodone to control a cough that is distressful to the owner or that causes exhaustion or episodic collapse in the animal; use cautiously and only intermittently if possible, because suppression of the cough reflex may be detrimental to clearance of airway secretions in chronic bronchitis.

Surgical Procedure

Objective

To provide rigid support for the collapsed tracheal segment and maintain function of the mucociliary system

Equipment

- Spiral- or ring-shaped prostheses made from the case and barrel of a 3-ml polypropylene syringe case (Fig. 161-10)
- 4-0 polypropylene suture material with a tapercut needle
- Standard instrument pack and suture
- Small Gelpi retractors

Technique

1. Place the dog in dorsal recumbency with the neck extended over a small, rolled towel.
2. Prepare the ventral cervical region for aseptic surgery.
3. Incise the skin on the ventral cervical midline from the larynx to the manubrium.
4. Separate the paired sternohyoideus and sternothyroideus muscles on the midline and retract the muscles laterally with Gelpi retractors. Partially myotomize the sternocephalicus muscles at the manubrial attachment.
5. Identify the left recurrent laryngeal nerve.
6. Beginning approximately 2 cm caudal to the larynx and preserving the caudal thyroid artery, dissect the lateral pedicle from the left side of the trachea to the level of the thoracic inlet.
7. Make a 5-mm window in the right lateral pedicle 2 cm caudal to the larynx, preserving the caudal thyroid artery.
8. Place a right-angle forceps dorsal to the trachea through the window in the right lateral pedicle; grasp the spiral prosthesis and direct the prosthesis around the trachea.
9. Rotate the prosthesis onto the trachea, making a small window in the right lateral pedicle where the

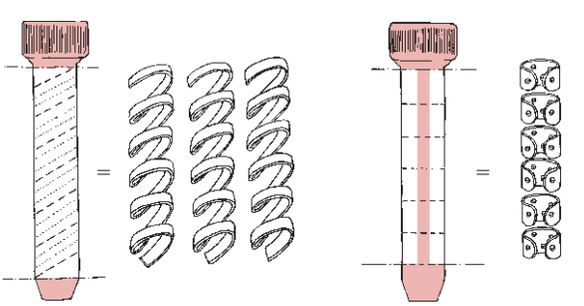

Figure 161-10. Extraluminal prosthesis. The barrel of a 3-cc polypropylene syringe case can be used to make spiral or ring-shaped tracheal prostheses.

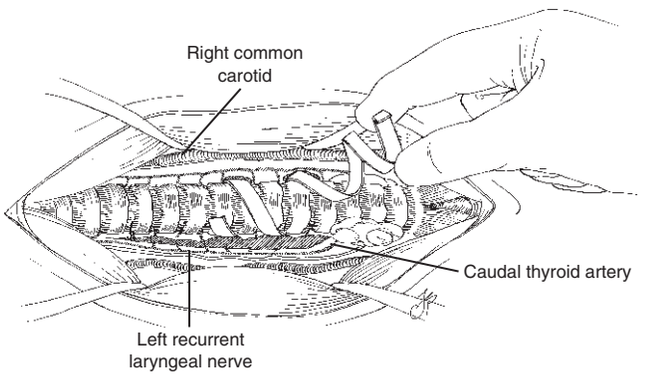

Figure 161-11. Extraluminal prosthesis. Rotate the prosthesis onto the trachea.

prosthesis passes around the right lateral aspect of the trachea. Place the prosthesis over the collapsed segment of the trachea (Fig. 161-11).

10. When applying total-ring prostheses (C-shaped rings), simply make small windows through the right and left lateral pedicles to allow placement of the rings.
11. Deflate the endotracheal tube cuff and reposition the tube either cranial or caudal to the prosthesis. Reinflate the endotracheal tube cuff.
12. Suture the prosthesis to the trachea with 4-0 polypropylene suture material placed in simple interrupted fashion. Place a row of sutures laterally, ventrally, and dorsally, including the dorsal tracheal membrane. All sutures enter the tracheal lumen (Fig. 161-12).
13. Apply additional prostheses caudally as needed. Gentle cranial traction on the cervical trachea affords limited exposure to the segment of the trachea in the thoracic inlet.
14. Deflate the endotracheal tube cuff and gently move the tube in the trachea to ensure that sutures have not been placed through the endotracheal tube cuff. Reinflate the cuff.
15. Appose the sternocephalicus, sternohyoideus, and sternothyroideus muscles. Close the subcutaneous tissue and skin in a routine manner.
16. The intrathoracic segment of the trachea can be supported by performing a right third intercostal thoracotomy (see Chapter 167) and applying prostheses, as described above.

Postoperative Care and Complications

- Leave the endotracheal tube in place with the cuff inflated until the dog has a strong swallowing reflex. Deflate the cuff prior to removing the tube.
- Administer supplemental oxygen postoperatively as needed.
- Administer corticosteroids immediately postoperatively and at 6 hours postoperatively to minimize tracheal mucosal swelling. See discussion under "Staphylectomy (Correction of Elongated Soft Palate)" for drugs and dosages.
- Continue antibiotic therapy for 14 days after surgery.
- Continue antitussive and bronchodilator therapy as needed to control coughing (see Table 161-1).
- Observe the dog for subcutaneous emphysema and signs of tracheal obstruction for 5 days after surgery.
- Ischemic necrosis of the trachea resulting from dissection of the lateral pedicles occurs in a limited number of cases. Gentle tissue handling and minimizing dissection of the lateral pedicles reduces the incidence of this complication.

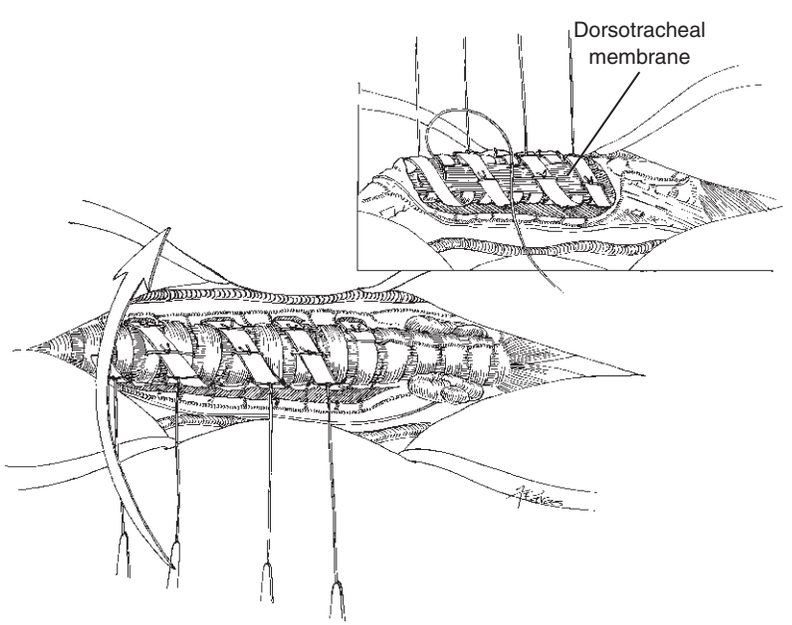

Figure 161-12. Extraluminal prosthesis. Suture the prosthesis to the trachea laterally, ventrally, and dorsally. All sutures enter the tracheal lumen.

Placement of an Intraluminal Prosthesis

Recent reports have indicated successful placement of intraluminal tracheal prostheses, or stents, in some dogs with tracheal collapse. Stent placement requires specific materials, endoscopic equipment, and an experienced clinician. Complications, such as stent migration and infection, have been reported. Refer the patient to a specialist for this procedure.

Tracheal Foreign Body Retrieval

Tracheal foreign bodies often can be removed with a fiberoptic endoscope. Various transendoscopic retrieval devices are available for flexible and rigid endoscopes.

Technique

1. General anesthesia is required for this procedure. Attach a Y-shaped swivel adapter that has a self-sealing port for passage of the endoscope (Fiberoptic Scope/Suction Catheter Adapter with Swivel, Portex; Wilmington, DE) to the endotracheal tube. This allows simultaneous tracheoscopy and inhalation anesthesia in dogs intubated with a tube with an inner diameter of >7.5 mm.
2. Anesthetize small dogs and cats with an intravenous anesthetic and pass the endoscope directly into the trachea.
3. Place the animal in sternal recumbency with the head elevated.
4. Insert an oral speculum to prevent the animal from biting and damaging the endoscope.
5. Carefully insert the endoscope into the trachea. Examine the larynx, trachea, and bronchi and locate the foreign body.
6. Critically evaluate the type and position of the foreign body before attempting to remove it. Foreign bodies that are embedded in the tracheal mucosa or that have sharp edges may not be amenable to transendoscopic removal.
7. Pass the retrieval instrument through the operative port of the endoscope. Position the retrieval instrument either cranial (forceps) or caudal (basket device) to the foreign body.
8. Grasp the foreign body and *gently* retract the endoscope and foreign body together. Tracheotomy or tracheal resection and anastomosis may be necessary if the foreign body is firmly lodged in the trachea.

▼ ***Key Point*** Excessive traction on a foreign body firmly lodged in the trachea may cause severe tracheal trauma.

9. After the foreign body has been removed, replace the endoscope and perform a thorough, systematic inspection of all accessible parts of the trachea and bronchial tree.

Postoperative Care and Complications

- Complications are rare after transendoscopic removal of a tracheal foreign body.
- Moderate coughing from tracheal irritation is common but transient.
- If the foreign body was firmly lodged in the trachea and removal was difficult, closely monitor the animal for signs of tracheal trauma (e.g., subcutaneous emphysema) for 48 to 72 hours.

Segmental Stenosis

Tracheal Resection and Anastomosis

Tracheal resection and anastomosis is indicated for treatment of tracheal stricture and tracheal neoplasia and, rarely, for removal of a tracheal foreign body. Meticulous surgical technique is imperative to minimize postanastomotic stenosis.

Surgical Anatomy

- Review surgical anatomy in the tracheal collapse section.
- The tracheal cartilages are joined ventrally and laterally by 1-mm-wide fibroelastic bands called annular ligaments.

Preoperative Considerations

- Identify the extent of the stenotic lesion radiographically and/or endoscopically.
- Anesthesia:
  - Gain control of the airway by rapidly passing an endotracheal tube. Mask induction is not advisable.
  - Endotracheal intubation may be difficult or impossible when the cranial cervical segment of the trachea is stenotic. Be prepared to perform a tracheostomy for delivery of anesthetic gases.
  - Administer cefazolin (25 mg/kg IV) at induction of anesthesia and 2 hours after the first dose.

Surgical Procedure

Objective

To remove the stenotic segment of the trachea and create an airtight anastomosis under minimal tension.

Equipment

- Standard surgical pack and suture
- Gelpi retractors
- 2-0 and 3-0 polypropylene suture material with a tapercut needle

Technique

Many techniques for tracheal resection and anastomosis have been described. The split-cartilage technique is

ideal because the technique is easy to perform and results in more precise anatomic alignment with less luminal stenosis compared with other anastomotic techniques.

1. Patient positioning and surgical approach are the same as for application of tracheal prostheses.
2. Dissect the right and left lateral pedicles from the stenotic segment of the trachea.
3. Place stay sutures one cartilage cranial and one cartilage caudal to the stenotic segment to prevent retraction and facilitate manipulation of the incised ends.
4. Reposition the endotracheal tube so that the cuff is distal to the stenotic segment. Perform the resection and anastomosis over the endotracheal tube if possible. Do not manipulate the distal segment with the endotracheal tube cuff inflated.
5. Using a #10 blade, circumferentially split in half one tracheal cartilage at each end of the stenotic segment. Incise the stenotic segment longitudinally and remove it. Submit the diseased segment for histologic evaluation.
6. Preplace four to six simple interrupted, tension-relieving sutures with 2-0 polypropylene suture material between the cranial and the caudal tracheal segments. Pass each suture around the second or third tracheal cartilage cranial and caudal to the anastomotic site.
7. Bring the cranial and caudal segments into apposition by tying the tension sutures.
8. Place 8 to 12 simple interrupted sutures, encompassing the split tracheal cartilage at the end of the cranial and caudal segments. Penetrate the tracheal lumen and tie knots on the outside of the trachea. Make certain that the edges of the dorsal tracheal membrane are apposed.

Postoperative Care and Complications

- Leave the endotracheal tube in place with the cuff inflated until the dog has a strong swallowing reflex. Deflate the cuff and then carefully remove the tube.
- Observe for signs of tracheal obstruction. Mucosal swelling rarely is a problem after resection and anastomosis.
- Discourage extension of the neck if the resected segment was large (i.e., more than five tracheal cartilages).
- Obtain cervical radiographs 1, 2, and 3 months after surgery. Follow-up tracheoscopy to assess healing is ideal.
- Postanastomotic stenosis is the most common complication. Excessive anastomotic tension usually is the cause. Complications such as air leakage, infection, mucostasis, and dehiscence occur rarely.

Chapter

162 Bronchopulmonary Disease

Lynelle R. Johnson

Diseases of the tracheobronchial tree and pulmonary parenchyma are very common in canine and feline patients and are responsible for substantial morbidity in the pet animal population. Determining the underlying disease responsible requires an understanding of clinical signs, interpretation of laboratory and radiographic findings, and collection and analysis of airway samples. Individualized therapy will be most likely to lead to amelioration of signs. Many respiratory tract diseases are chronic in nature, and the goals of therapy become controlling clinical signs and avoiding progression of disease.

CLINICAL SIGNS

Coughing, respiratory distress, abnormal breathing, and exercise intolerance are the presenting complaints most commonly observed in cats and dogs with diseases involving the respiratory tract.

- Early in the course of disease, disorders of the conducting airways primarily cause cough.
- As disease progresses, shortness of breath and decreased ability to exercise may become more evident. Parenchymal disorders usually are associated with abnormal respiratory rate and effort as well as exercise intolerance and signs of systemic illness.
- In chronic airway disease or parenchymal lung disorders, complications such as syncope and cyanosis may arise from progressive respiratory disease.

Overview in Dogs

A wide variety of infectious, inflammatory, degenerative, and neoplastic diseases cause clinical signs referable to the respiratory tract in dogs.

- Common causes of respiratory disease in dogs include tracheal or bronchial collapse, chronic bronchitis, and infectious or inflammatory lung disease. Clinical signs of cough and exercise intolerance are common to all three conditions, and further diagnostic testing is needed to further define the underlying disorder. Isolated cervical tracheal collapse may be suspected by the observation of a high-pitched, honking cough in a small breed dog in combination with inspiratory difficulty; however, lower-airway inflammatory disease may complicate the clinical picture and will be easily missed unless a full evaluation is completed. Additionally, some dogs with tracheal collapse have concurrent laryngeal paralysis, detected by the presence of dramatic stridor over the larynx along with voice change. Chronic bronchitis is a very common disease of small-breed dogs; however, large breed dogs are equally affected.
- Acute respiratory distress, characterized by extreme tachypnea, cyanosis, or collapse, may be observed in animals with decompensated chronic tracheobronchial or interstitial disease. This should be distinguished from other causes of acute respiratory signs such as pulmonary edema (cardiogenic and noncardiogenic), pulmonary thromboembolism, and disease of the pleural space (pneumothorax or pleural effusion).
- Hemoptysis is relatively uncommon in dogs and cats, but this finding may be observed with pulmonary infiltrates with eosinophils, *Paragonimus* infection, heartworm disease, pulmonary hypertension, pulmonary neoplasia, anticoagulant rodenticide toxicity, and pulmonary foreign body.

Overview in Cats

Cats may present with a history of acute or chronic respiratory disease. Cats with chronic respiratory disease may present emergently with acute signs of respiratory discomfort because stress can lead to rapid physical decompensation.

- The most common cause of respiratory signs in cats is lower-airway inflammatory disease (chronic bronchitis and asthma). These airway diseases have many features that parallel the same disorders in people, including spontaneous airflow limitation, airway inflammation, and bronchial hyper-responsiveness.
- Cats are susceptible to pulmonary infection with bacteria, although bacterial infection of feline airways is a relatively uncommon phenomenon. Similarly, aspiration pneumonia, which is common in the dog, occurs relatively uncommonly in the cat. Isolation of *Mycoplasma* spp. from the lower airways of a cat

should be considered indicative of infection since this organism is not found in the lower airways of healthy cats. This is important to recognize because isolation requires special culture techniques, and, in some studies, this organism is the most common cause of primary lung infection in the cat. *Yersinia pestis,* the cause of bubonic and pneumonic plague, is an additional primary pathogen to consider in cats from New Mexico (see Chapter 19).

- Other infectious agents to consider as causes of respiratory signs in cats include systemic mycoses (particularly cryptococcosis, blastomycosis, and histoplasmosis), parasites (lungworms and heartworm), viruses (calicivirus, herpesvirus, feline infectious peritonitis), and protozoa (toxoplasmosis).
- Additional causes of cough that should be considered are tracheobronchial foreign body, tracheal neoplasm, and chylothorax. Other differential diagnoses for cats with primarily shortness of breath include pleural effusion (chylothorax, pyothorax, hydrothorax, hemothorax), pneumothorax, pulmonary thromboembolism, neoplasia, and cardiac failure.

TRACHEAL COLLAPSE

Etiology

- Hypocellular tracheal cartilage with deficient production of glycosaminoglycans and chondroitin sulfate has been found in some dogs with tracheal collapse. These metabolic deficiencies cause a reduction of bound water within tracheal cartilage and result in decreased turgidity of the ring structure. The abnormalities in chondrogenesis that result in tracheal collapse may be congenital or inherited, or may be related to dietary deficiencies.
- Collapse may be present in the cervical region, intrathoracic region, or both. In some dogs, collapse of smaller airways supported by cartilage can be seen. Collapse may be found solely at rest, or it may be dynamic, varying with the phases of respiration. In these situations, cervical collapse is found on inspiration, while intrathoracic collapse occurs on expiration. Inflammation within the airways may exacerbate airway collapse.
- In cats, tracheal collapse has been associated with masses that obstruct the upper airway.

Pathophysiology

- Loss of structural support in the cartilage of the tracheal ring allows fluctuations in airway diameter in association with changes in airway pressure that occur during respiration or cough.
- The trachea generally collapses in a dorsoventral orientation. Tracheal rings become flattened, leading to narrowing of airway diameter, elongation of the dorsal tracheal membrane, and prolapse into the airway. Concussive trauma between the dorsal tracheal membrane and the ventral epithelial surface of the trachea results in airway injury, mucus production, and perpetuation of cough. Reduction in the radius of the airway increases the resistance to airflow, which necessitates an increase in driving pressure to maintain normal air movement into and out of the lungs. Increased airflow can perpetuate airway inflammation and injury.
- Collapse is isolated to the cervical trachea in some dogs, but many dogs also have disease in the intrathoracic region.

Cervical Tracheal Collapse

Cervical tracheal collapse occurs on inspiration. During inspiration, intrapleural pressure drops, leading to a decrease in intrathoracic airway pressure and airflow from the glottis into the region of gas exchange in the lung. The cervical trachea is exposed to atmospheric pressure, and a pressure drop also occurs from the glottis down the airway. Dogs that lack rigidity in the cervical trachea will experience collapse on inspiration and will exhibit clinical signs of inspiratory distress. Inspiratory wheezing may also be evident. In dogs with concurrent upper-airway obstruction (everted laryngeal saccules, elongated soft palate, laryngeal paralysis), a larger pressure gradient develops in the cervical trachea and this increases the tendency of the airway to collapse and perpetuates upper-airway inflammation. Prolapse of the dorsal tracheal membrane into the airway lumen accentuates mechanical trauma to the wall of the trachea, leading to further mucosal irritation, inflammation, and cough.

Intrathoracic Tracheobronchial Collapse

Intrathoracic tracheal collapse or collapse of the mainstem bronchi is encountered on expiration when intrapleural pressure exceeds intra-airway pressures, and poorly supported airways tend to close. In some dogs, generalized airway collapse is encountered. It is unclear whether cartilaginous deficiency underlies this disease as it does with tracheal collapse. Airway collapse can be seen in conjunction with chronic bronchitis or airway inflammatory disease, perhaps because of irritation caused by cough or because of changes in the pressure gradients within the lung associated with obstruction of smaller airways. In addition, airway inflammation stimulates a cough, which can exacerbate signs related to airway collapse.

Clinical Signs

Signalment

Small-breed dogs are typically affected with tracheal collapse, and an increased prevalence is generally seen in the Yorkshire terrier, poodle, Pomeranian, and chihuahua. Any breed of dog can be affected by lower-

airway collapse, although typically smaller breed dogs are affected. Animals of any age may present with signs related to tracheal and/or lower-airway collapse.

History

A long-term history of chronic, intermittent cough is typically reported with or without episodes of respiratory distress. These signs have often been present since the patient was young. Stress, heat, humidity, eating, drinking, or external pressure on the trachea can all trigger clinical signs of disease.

- Coughing, gagging, and retching can be reported with tracheal collapse and may be mistaken for vomiting. Owners might also suspect a tracheal foreign body or "kennel cough" as a cause for signs.
- Paroxysms of coughing often occur and may lead to cough syncope. In general, cough and respiratory distress progress over time until the animal becomes debilitated or unable to function.
- Animals with tracheal collapse can have long periods of normalcy between episodes of apparent acute disease. Exacerbations of clinical signs may be associated with any additional respiratory-related complication including inflammation or infection (bronchitis or pneumonia), upper-airway obstruction (laryngeal paralysis or everted saccules), or congestive heart failure (CHF). A common cause for exacerbation of disease is intubation for a procedure under anesthesia. Finally, weight gain appears to worsen clinical signs of disease in affected animals.

Physical Examination

- Obesity is very common in dogs with tracheal and airway collapse. Hepatomegaly has also been reported, which may be a result of fat deposition in the liver.
- Dogs with tracheal collapse can appear normal at rest. Excitement induces a honking cough, and in more severe cases can result in airway obstruction and respiratory distress. Animals typically have marked tracheal sensitivity, and even gentle palpation can precipitate a crisis.
- High-pitched inspiratory noises are sometimes heard over the narrowed trachea in animals with cervical collapse. The presence of stridor indicates that concurrent laryngeal paralysis should be considered.
- An end-expiratory snap may be heard over the thorax with collapse of the intrathoracic trachea or mainstem bronchi.
- Auscultation of wheezes or crackles suggests the presence of concurrent bronchitis or interstitial lung disease.

Diagnosis

The presence of a honking cough in a small-breed dog is often considered diagnostic of tracheal collapse. Consider a full diagnostic workup in order to identify and treat all coincident disorders that complicate the clinical presentation.

Radiography

- Inspiratory and expiratory lateral views and a ventrodorsal view are recommended to evaluate tracheal luminal diameter, pulmonary infiltrates, and cardiac size.
  - The cervical trachea may be collapsed on inspiration.
  - It may be possible to confirm collapse of the intrathoracic trachea or mainstem bronchi on expiration.
- The trachea can appear radiographically normal in more than 50% of cases, and false-positive results are also common. Performing fluoroscopy during the induction of a cough can be used to aid in the diagnosis, although even this technique cannot identify all cases of collapsed trachea.
- Ultrasound of the cervical trachea has been reported as a modality for confirming trachea collapse by identifying the abnormal shape of the tracheal lumen.

Airway Sampling

Obtain respiratory samples for cytology and culture to rule out infectious or inflammatory conditions (pneumonia, bronchitis, or fibrosis) that can accentuate clinical signs. Endoscopy (bronchoscopy) offers the most complete evaluation of the respiratory tract and has the benefit of confirming the presence or absence of tracheal and airway collapse. Evaluate upper airway structure and function in all animals sedated for tracheal wash or bronchoscopy.

- Evaluate samples for cytologic abnormalities that might suggest inflammation or infection. Bacterial culture and special culture for *Mycoplasma* spp. are recommended (see discussion under "Chronic Bronchitis").

Transtracheal Wash

- Use sedation and oral intubation when performing a tracheal wash on a patient with tracheal collapse. To avoid tracheal irritation, use a sterile endotracheal tube of small diameter. Lidocaine gel applied lightly to the tube can lessen induction of cough. It is not necessary to expand the inflatable cuff during the short procedure, and this can also lessen the tendency for worsening of cough after the procedure.
- After intubation, pass a sterile polypropylene urinary catheter or feeding tube to the level of the carina (the fourth intercostal space), and inject sterile nonbacteriostatic saline (4–5 ml), and then aspirate back into the syringe. Stimulating a cough and performing coupage during aspiration will increase the return of fluid as will a sterile mucus trap system attached to a controlled suction device. Only 1 to 2 ml

of fluid are required for sample processing (cultures and cytology), and a second and third aliquot can be instilled if the sample recovered is inadequate. Alternatively, culture can be performed using a guarded swab passed through the endotracheal tube. This system will not be contaminated by the tip of the endotracheal tube.

Bronchoscopy

- When available, bronchoscopy is useful both for collection of airway samples and for grading the extent and severity of tracheal collapse. In small dogs, a bronchoscope with a diameter smaller than 5 mm diameter is most useful for assessing the airways. Flexible bronchoscopy has an advantage over rigid bronchoscopy because of the ability to assess lower airways as well. Bronchoscopy can confirm the presence of isolated cervical tracheal collapse and can identify passive or dynamic collapse of lower airways. Determining the extent of disease is important when deciding whether surgical correction or placement of an intraluminal stent is feasible.
- Bronchoalveolar lavage can be used to collect lower-airway samples. Culture can be obtained from the lavage fluid or from a guarded endoscopic microbiology brush. Veterinarians performing respiratory endoscopy and bronchoscopic-guided airway lavage should be intimately familiar with respiratory tract anatomy and trained in the procedures of bronchoscopy. Particular attention must be paid to coordinating the airway examination with anesthesia methods, and assuring sufficient ventilation and delivery of oxygen during the procedure.

Treatment

General

- Weight loss is beneficial for most patients. Reducing the amount of fat on the thoracic cage improves chest wall compliance and decreases the work of breathing. Many dogs will experience substantial reduction in cough and improvement in respiratory health with weight loss alone.
- Efforts should be made to limit exposure to environmental stressors such as high humidity and heat during exercise. A harness should be used in place of a collar.
- Sedatives may be required during periods of high stress. Acepromazine (0.05–0.25 mg/kg SC or IM) or butorphanol (0.05–0.2 mg/kg SC or IM) may be used alone or in combination. Use reduced dosages when the two drugs are used in combination.

Antitussives

Cough suppressants are needed at some stage in most cases of tracheal collapse to break the cycle of cough-induced airway injury.

- Opiates such as hydrocodone (0.2 mg/kg PO q6–12h) or butorphanol (0.5–11 mg/kg PO q6–12h) are most effective. The dosing regimen must be sufficiently flexible to control cough without inducing nausea or excessive sedation.
- Over-the-counter dextromethorphan-containing compounds are occasionally effective.

Bronchodilators

Dogs that have intrathoracic airway collapse and evidence of small airway disease may benefit from the use of bronchodilators (Table 162-1). Bronchodilators have no clinically significant effect on the large airways and do not result in an increased diameter in the tracheal lumen. Instead, these drugs act primarily on small airways, making it easier for air to flow out of the lungs and lessening the tendency for dynamic collapse of large airways.

Anti-Inflammatory Drugs

Treat concurrent chronic bronchitis as described in the next section. Occasionally, tracheal inflammation may require a short course of therapy with glucocorticoids for resolution of airway injury; 5 to 7 days of prednisone, 0.25 to 0.5 mg/kg PO q12–24h followed by rapid tapering of the dose is usually sufficient to treat inflammation.

Antibiotics

It is uncommon for clinically significant bacterial infection to complicate the course of tracheal collapse. When a bacterial infection is documented, the choice of antibiotics should be based on culture and sensitivity results.

- Before cultures become available, antibiotics with efficacy against oral bacteria, including *Mycoplasma* are recommended. Doxycycline and enrofloxacin both provide a good spectrum of activity and are efficacious against most of the bacteria typically encountered.

Surgical Stabilization

- Surgical placement of tracheal ring prostheses has been successful in reducing clinical signs in dogs with focal cervical tracheal collapse. The surgery is technically demanding and is associated with occasionally serious complications. However, most owners report that the surgery is beneficial in improving the quality of life for their pet (see Chapter 161).
- Placement of intraluminal stents has resulted in alleviation of clinical signs in dogs with severe tracheal collapse that failed to respond to medical management. Stents made from a nitinol metal alloy are placed fluoroscopically. Once placed, stents are generally not removable. Complications associated with obstruction of a principal bronchus, device fracture, and granuloma formation have been reported.

Table 162-1. BRONCHODILATORS COMMONLY USED IN CANINE AND FELINE BRONCHOPULMONARY DISEASE.

Drug	Dosage	Side effects
Methylxanthines		
Sustained-release theophylline	Dog: 10 mg/kg PO q12 h Cat: 10 mg/kg PO q24 h (PM)	Multiple drug interactions, gastrointestinal upset, tachycardia
Beta agonists		
Terbutaline	Dog and cat: 0.01 mg/kg SC, IV Dog: 1.25–5.0 mg/dog PO q12 h Cat: 0.625 mg PO q12 h	Tachycardia, hypotension
Terbutaline MDI	200 μg/puff q12 h by aerosol	
Albuterol	Dog: 50 μg/kg PO q12 h	
Albuterol MDI	90 μg/puff q12 h by aerosol	
Epinephrine	20 μg/kg IV, IM, SC, IT	Cardiac arrhythmias, hypertension, vasoconstriction

MDI, metered dose inhaler

Prognosis

Dogs with tracheal collapse generally have irreversible disease. The goals of preventive and acute therapy are to minimize clinical signs, prevent worsening of bronchopulmonary disease, and improve the overall quality of life.

CHRONIC BRONCHITIS

Etiology

The etiology of chronic bronchitis in the dog is unknown; however, it is likely that chronic mucosal irritation or immunologic stimulation is responsible for airway inflammation and clinical signs of disease.

- Smoking remains the major cause of chronic bronchitis in people, and exposure to air pollution or particulate matter may play a role in the canine disease.
- In addition, some dogs may suffer from chronic aspiration of small-volumes of gastrointestinal content sufficient to trigger airway inflammation.

Pathophysiology

- Chronic airway inflammation results in characteristic changes in lower-airway structure and function. Neutrophilic infiltration of the airway results in release of proteases and oxidant species that damage the mucosa, stimulating a chronic cycle of injury and repair of the epithelium.
- Chronic bronchitis is characterized by hypertrophy and hyperplasia of mucous glands and goblet cells. These changes result in accumulation of mucus within the airway with obstruction of airflow, leading to clinical signs of cough and exercise intolerance.
- Histopathologic changes reported in dogs with chronic bronchitis include inflammatory cells in the lamina propria, goblet cell proliferation, enlargement of mucous glands, epithelial erosion with healing by basal cell proliferation, and squamous metaplasia. Mild emphysema, characterized by increased alveolar air space and loss of interalveolar septae is occasionally seen, although dogs do not display clinical manifestations of emphysema.

Clinical Signs

Signalment

Most dogs with chronic bronchitis are middle aged to older. Both large and small breed dogs are affected, and often the animal is overweight or obese.

History

- The characteristic historical finding in chronic bronchitis is the presence of a chronic cough for at least 2 months' duration, in the absence of other disorders that can cause cough. An acute exacerbation of disease may cause the owner to seek veterinary attention, but often it is discovered that the dog has coughed for years when a careful history is obtained.
- The cough associated with chronic bronchitis can be a dry hacking cough or may be reported as moist or harsh. Swallowing or licking the lips after a cough suggests that the cough is productive, which is probably due to excessive mucus production.
- Exercise intolerance, fatigue, or increased panting may be reported in addition to cough, however, the typical dog with bronchitis is not systemically ill. This characteristic helps distinguish chronic bronchitis from other causes of cough including infective pneumonia, CHF, and thoracic neoplasia.

Physical Examination

- Animals with chronic bronchitis are often overweight.

- Chronic bronchitis is classified as an obstructive airway disease that classically results in a slow, deep respiratory pattern in order to decrease the work of breathing. When observed carefully, animals severely affected by chronic bronchitis may show prolonged expiration and an expiratory push. These animals may also be intermittently cyanotic or syncopal. Dogs with chronic bronchitis may also pant or appear short of breath when excited or agitated during an examination.
- Tracheal sensitivity is usually present but this is a nonspecific finding associated with airway inflammation. Concurrent tracheal or airway collapse is commonly present and may be detected by the characteristic goose-honk cough or as a snapping sound over the thoracic cage when intrathoracic airways collapse on expiration.
- The presence of normal lung sounds does not rule out the diagnosis of chronic bronchitis. Stimulating a large inspiration by causing breath holding or inducing a cough will increase the detection of abnormal lung sounds in many cases.
- Adventitious lung sounds are often found in dogs with chronic bronchitis. Coarse or harsh, diffuse crackles are reported along with expiratory wheezes.
- Cardiac auscultation may reveal concurrent mitral-valve insufficiency in older, small-breed dogs. Heart rate and rhythm may be helpful in ruling out CHF as a cause of cough, because these dogs typically exhibit a regular sinus rhythm or sinus tachycardia, whereas dogs with respiratory disease usually have a normal to slow heart rate, often with sinus arrhythmia due to increased vagal input from pulmonary disease.
- Determining the etiologic cause of cough in a dog with cardiomegaly, left atrial dilation, and collapse or compression of the mainstem bronchus can be challenging. In some dogs, increased left-atrial volume, causing compression of the bronchus is the primary problem, whereas in others, primary loss of cartilaginous support of the airway is the principal pathology resulting in cough. Some dogs might also suffer from airway inflammation that induces cough in conjunction with cardiac or airway structural abnormalities.

Diagnosis

The history of a long-term cough in an otherwise bright and healthy dog is suggestive of chronic bronchitis, which is largely a diagnosis of exclusion. Pneumonia and pulmonary neoplasia can cause similar signs. Also, dogs often have separate or concurrent cardiopulmonary conditions such as tracheal collapse, bronchial collapse, bronchial compression, or heart failure. A complete diagnostic workup assesses the role each condition might play in the generation of clinical signs and aids in developing a therapeutic plan. Laboratory evaluation (complete blood count [CBC], chemistry panel, urinalysis) should be done to evaluate systemic health, although there are no typical abnormalities for chronic bronchitis. The diagnosis is based on the history, clinical findings, chest radiographs, and airway sampling to rule out other pulmonary causes of cough.

Radiography

▼ ***Key Point*** Normal-appearing thoracic radiographs are common with chronic bronchitis. This does not rule out bronchitis as a diagnosis.

- Generalized peribronchial infiltrates are considered typical of chronic bronchitis. This pattern is usually characterized by "doughnuts" (end-on bronchi) or "tram lines" (airways seen in longitudinal section), which represent airway walls thickened by inflammation. In comparison to age-matched control dogs, dogs with bronchitis have thickening of bronchial walls and increased numbers of airway walls visible on chest radiographs. However, some older dogs demonstrate radiographic features of bronchial thickening without evident clinical signs of chronic bronchitis.
- Alveolar infiltrates are not typically found in chronic bronchitis and would suggest a diagnosis of pneumonia or pulmonary edema.
- Pulmonary infiltrates may be obscured by fat overlying the thoracic cage in obese animals. Obesity also leads to decreased thoracic compliance, which restricts expansion of the thorax and can lead to an apparent reduction in lung volume.
- Heart size can be difficult to interpret in patients with chronic bronchitis. True right-sided cardiomegaly may be seen in severely affected patients that develop pulmonary hypertension or cor pulmonale. However, many chondrodysplastic breeds will appear to have cardiomegaly due to breed conformation. Also, obesity can cause an enlarged cardiac silhouette as a result of intrapericardial deposition of fat. A vertebral heart score is a good method for objectively estimating heart size in many dogs (see Chapter 143).

Airway Sampling

Cytologic characterization and culture of the cellular infiltrate within the airways can identify or exclude infectious causes of cough and allows development of a rational therapeutic plan. Samples may be obtained through endotracheal or transtracheal wash or with bronchoscopy.

Transtracheal Wash

- An endotracheal wash through a sterile endotracheal tube can be performed as described under "Tracheal Collapse."

- A transtracheal wash can be performed by passing the needle of a jugular catheter between the tracheal rings (I prefer a puncture as low on the trachea as possible), and then threading a sterile catheter down the airway. Alternately, a through-the-needle catheter can be used to access the lower airways. After placement of the catheter and withdrawal of the needle, sterile tubing is passed through the catheter in order to collect the wash sample.
- A sterile preparation is performed in the site desired. Local anesthetic block can be achieved with SC infiltration with 2% lidocaine at the site of entry in the skin and in the trachea.
- The needle is placed into the skin several rings below the site where the trachea will be entered. By drawing the skin upward before penetrating the trachea, a SC tunnel will be created that lessens accumulation of air after the procedure. When the trachea has been entered, a slight "pop" is felt and the animal will usually cough. The catheter is threaded through the needle to the level of the carina (the fourth intercostal space).
- If a jugular catheter is used, the needle is withdrawn from the neck at this time, and the guard secured over the needle-catheter junction.
- When performing a transtracheal wash, the catheter should never be withdrawn back into the needle after the trachea has been entered, as this increases risk of shearing the catheter off into the airway.
- Tracheal washing is performed with one to three aliquots of 4 to 6 ml of sterile, non-bacteriostatic saline. Stimulation of a cough or coupage of the chest during aspiration can enhance recovery of fluid. Only 1 to 2 ml is necessary for sample processing.

Bronchoscopy

- Bronchoscopy is extremely useful in the diagnosis of chronic bronchitis, particularly in cases that lack typical radiographic findings. The procedure allows visualization of airway changes, localization of disease, collection of more specific airway samples, characterization of dynamic changes in airway caliber, and the opportunity to identify and biopsy lesions.
- Dogs with chronic bronchitis have variable degrees of airway hyperemia and a roughened appearance to the mucosa. The majority of dogs have increased mucus in the airways. Animals with long-standing bronchitis can have nodular proliferations of fibrous tissue protruding into the airway. These nodules are usually of varying size and are found throughout the airway. In some cases these must be differentiated from the nodules produced by the parasite *Oslerus osleri,* which are typically found on the floor of the airway just cranial to the carina.
- Bronchoalveolar lavage is performed as described under "Tracheal Collapse."

Tracheobronchial Cytology

- Healthy dogs have primarily ciliated, columnar epithelial cells in tracheal wash fluid. Rare inflammatory cells or macrophages from the lower airway are seen.
- Dog with bronchitis typically have elevated numbers of non-degenerate neutrophils in airway cytologic preparations. Increased mucus may be seen in airway fluid and occasionally Curschmann's spirals are seen, which represent bronchial casts of airway mucus.
- A large number of epithelial cells on cytology suggests sloughing of the airway mucosa. Squamous metaplasia also may be noted.
- Healthy dogs have 5% to 6% neutrophils, 5% to 6% eosinophils, 5% to 6% lymphocytes, and 75% to 95% macrophages in bronchoalveolar lavage fluid. An increased number or percentage of neutrophils is seen in most dogs with chronic bronchitis. This is usually a reflection of inflammation within the airway and does not indicate a septic process. However, the presence of toxic neutrophils or intracellular bacteria indicates that infection is likely.
- A smaller percentage of patients will have a predominance of eosinophils in airway washings, which may be a reflection of the generalized immune response, or in some cases may suggest a hypersensitivity response or parasitic infection. Further workup should be considered in these patients (see "Other Laboratory Tests").

Tracheobronchial Culture

- Airway samples should be submitted for aerobic culture and susceptibility testing and for Mycoplasma culture. Specialized transport media may be required to isolate Mycoplasma, and individual laboratories should be consulted.
- The lumina of the trachea and large airways are not sterile environments, and a variety of oral contaminants or commensal bacteria may be found in tracheal wash or bronchoalveolar lavage samples, despite careful attention to technique. Interpretation of positive culture results must take into account cytologic abnormalities.
- The presence of oral contaminants on cytology, such as squamous cells or *Simonsiella* bacteria, makes a positive culture result of questionable importance (Table 162-2).
- Quantitative aerobic culture of bronchoalveolar lavage fluid yielding large numbers of bacteria and detection of intracellular bacteria on cytology are most helpful in determining that true bacterial infection is present. Most animals with bronchitis have very small numbers of bacteria on culture and lack intracellular bacteria.
- In rare animals with chronic bronchitis, aspiration of oral bacteria may occur during episodes of coughing or panting, and these bacteria may overwhelm host

Table 162-2. BACTERIA RETRIEVED FROM THE AIRWAYS OF HEALTHY DOGS AND CATS

Dogs	Cats
Bordetella bronchiseptica	*Acinetobacter*
Corynebacterium spp.	*Bordetella bronchiseptica*
Escherichia coli	*Corynebacterium*
Enterobacter	*Enterobacter*
Klebsiella	*Flavobacterium*
Pasteurella	*Klebsiella*
Pseudomonas	*Pasteurella*
Staphylococcus	*Staphylococcus*
Streptococcus	*alpha-Streptococcus*

defenses. Previously stable bronchitic patients that develop an exacerbation of disease may be experiencing true bacterial infection or secondary bronchopneumonia.

Other Laboratory Tests

- Nonspecific abnormalities on the minimum database, such as a stress neutrophilia or eosinophilia, may be seen in animals with chronic bronchitis. The presence of neutrophilia with a left shift, neutropenia, or monocytosis indicates that other conditions such as pneumonia or bronchiectasis should be considered.
- Animals with eosinophilic airway washes should be screened for airway parasites and larval migration through appropriate fecal exams (see Chapter 158). Heartworm disease must be ruled out.
- An electrocardiogram often shows an exaggerated sinus arrhythmia and may give an indication of right atrial enlargement ($P > 0.4$ mV) or infrequently of right-sided cardiomegaly (S-waves in leads I, II, III, aVF).
- Pulse oximetry is useful as a screening test for detection of hypoxemia. If the S_pO_2 is less than 95%, an arterial blood gas should be performed.
- Arterial blood gas analysis may exhibit mild to moderate hypoxemia. Hypercarbia is not detected unless respiratory failure ensues or the dog is sedated and hypoventilating. In one study, nuclear ventilation scans confirmed the existence of patchy areas of deficient ventilation in dogs with chronic bronchitis.
- Tidal breathing flow volume loops in dogs with chronic bronchitis have shown reductions in expiratory flow and loop shapes similar to those seen in humans with chronic bronchitis.

Treatment

General

- Obesity worsens clinical signs in dogs with chronic bronchitis by decreasing thoracic wall compliance, increasing the work of breathing, and increasing abdominal pressure on the diaphragm. Gradual weight loss should be stressed for all overweight animals. Increasing amounts of exercise also can be useful in encouraging weight loss.
- Animals with concurrent tracheal collapse or marked tracheal sensitivity may benefit from using a harness instead of a collar.
- Environmental stressors, such as cigarette smoke, dust, pollutants, heat, and low humidity should be avoided whenever possible.
- Some patients may benefit from intermittent airway humidification via steam inhalation or nebulization. Owners should be instructed to coupage the chest after nebulization or encourage gentle exercise to facilitate clearance of secretions.
- Rarely, dogs with chronic bronchitis are also affected with chronic atopic-type skin allergies. The value of desensitization on bronchitis signs has not been evaluated clinically in dogs. Other aspects of treatment, such as introduction of a novel-protein diet can be considered as part of the overall treatment plan. Attention to diet may also benefit weight control, which is often a problem in dogs with chronic airway diseases.
- When airway cytology reveals a preponderance of eosinophils, consideration should be given to empiric deworming with a broad-spectrum drug such as fenbendazole.

Anti-Inflammatory Drugs

Airway inflammation is the cause of clinical signs of chronic bronchitis. This can be ameliorated by treatment with glucocorticoids. It is essential that infectious diseases have been ruled out and that concurrent abnormalities, such as severe dental disease or CHF, have been successfully treated prior to initiation of anti-inflammatory treatment.

- Prednisone or prednisolone is generally safe and effective in dogs with uncomplicated bronchitis. The dosage regimen should be tailored to the individual, with the severity of signs, chronicity of infection, and systemic health playing a role in decisions regarding treatment.
  - Dogs often require initial dosages of prednisolone of 0.5 to 1.0 mg/kg q12h for 5 to 7 days to induce remission of clinical signs. When the cough has reduced to a satisfactory level, the dosage should be decreased by half every 5 to 7 days until the lowest possible dose is achieved. Long-term therapy (2–3 months) should be expected in most cases.
  - Alternate-day use of steroids or possible discontinuation of medication should be the goal of therapy. Some clinicians attempt to reduce dependence on systemic corticosteroids by initiating treatment with inhaled fluticasone during the period of dose tapering (see "Feline Asthma"). The efficacy and

adverse effects of such treatment in dogs has not been studied critically, and such therapy is relatively expensive, but the approach merits consideration in dogs that experience substantial side effects but still require chronic therapy for control.
  - Animals that do not respond to steroids alone may benefit from addition of a bronchodilator (see "Bronchodilators").
  - Exacerbation of disease in the early stages of treatment requires returning to the higher dose of glucocorticoid that controlled clinical signs. It is very common for dogs to suffer recurrence of clinical signs throughout life. Repeated episodes require additional workup when complicating infections or other cardiopulmonary diseases contribute to illness.
- Owners should be instructed to monitor response to therapy closely and should understand that the goal of therapy is to control cough, not eliminate cough, since most dogs remain variably symptomatic. Failure to respond to glucocorticoids indicates that the diagnosis of non-infective, chronic bronchitis should be reconsidered.

Bronchodilators

Bronchodilators may be helpful in reducing clinical signs in dogs with bronchitis that do not show complete response to glucocorticoids. Bronchoconstriction is likely not a component of chronic bronchitis in the dog; however, bronchodilator therapy may provide a multitude of beneficial effects such as reducing airway inflammation, reducing work of breathing, and stimulating mucociliary clearance.

- The clinical effects of methylxanthine derivatives probably result from adenosine inhibition. Extended-release theophylline dosed at 10 mg/kg PO q12h has been shown to achieve predictable plasma levels in dogs that approximate the human therapeutic range (see Table 162-1).
  - Adverse effects reported with use of methylxanthines include gastrointestinal signs, nervousness, and hyperexcitability.
  - Theophylline metabolism is affected by a multitude of factors, including fiber in the diet, smoke in the environment, CHF, and other factors. Drug therapy must be tailored to the individual because there is a wide variation in the dose that causes side effects. In overweight dogs, it is prudent to begin at half the recommended dosage, then increase the dose if needed and if the dog tolerates the drug.
  - Enrofloxacin inhibits metabolism of theophylline. Use of the two drugs concurrently could result in toxic plasma levels of theophylline. At least a 30% reduction in theophylline dose is recommended when enrofloxacin is required to treat coincident infection.
- Beta-2 agonists are likely to provide more profound bronchodilation than methylxanthine derivatives due to direct relaxant effects on airway smooth muscle. Terbutaline and albuterol have been used successfully in cases of chronic bronchitis. Adverse effects include hyperexcitability, tremors, nervousness, and gastrointestinal signs.

Antitussives

Coughing serves an essential function in clearance of the viscid secretions associated with chronic bronchitis. However, chronic coughing can lead to repeated airway injury and may be responsible for syncopal events. Cough suppressants (e.g., hydrocodone or butorphanol) have an important role in management of chronic bronchitis after infection has been ruled out and after the majority of inflammation has resolved (see "Tracheal Collapse" for dosage).

Antibiotics

Antibiotic treatment is warranted when infection has been documented through appropriate culturing technique and cytologic findings. In general, infection is not a major component of the syndrome of canine chronic bronchitis; however, bronchitis can result in an abnormal environment in the airways and disrupt normal host defenses by altering mucociliary clearance and disrupting the mucosal barrier. Therefore, every animal should be screened for concurrent infection and treated if needed. In particular, *Mycoplasma* and *Bordetella bronchiseptica* should be excluded.

- Antibiotics should be based on culture and sensitivity results when possible. Chosen drugs should have a broad spectrum of activity against bacteria commonly found in the conducting airways, should be lipophilic in order to facilitate penetration of the airway, and should be relatively free of side effects. When possible, I prefer use of doxycycline or possibly chloramphenicol. Potentiated sulfa drugs can also be efficacious. Potentiated penicillin drugs can be used, but have no efficacy against *Mycoplasma*. Enrofloxacin should not be used in uncomplicated bronchitis; it should be reserved for cases with pneumonia.
- Infection plays a predominant role in cases that have concurrent bronchiectasis (see next section). In these patients, long-term antibiotic therapy is indicated.

Prognosis

Owners should be informed that bronchitis is a chronic disease. The goals of therapy should be to (1) control the degree of inflammation present, (2) diagnose and treat infection when it occurs, (3) limit clinical signs, and (4) prevent worsening airway disease that might lead to debilitating sequellae such as bronchiectasis and cor pulmonale.

BRONCHIECTASIS

Etiology

- Bronchiectasis is characterized by irreversible dilation of the airways and is typically accompanied by concurrent suppuration.
- Possible etiologies include chronic inflammation due to uncontrolled bronchitis, chronic infection due to unresolved pneumonia or a bronchial foreign body, or as a sequela to an airway insult such as smoke inhalation. Bronchiectasis can also be encountered in association with primary ciliary dyskinesia or with eosinophilic lung disease.
- Bronchiectasis occurs more commonly in dogs than in cats and is associated with more dramatic clinical manifestations of disease.

Pathophysiology

- Proteases and elastases released from neutrophils during a chronic inflammatory or infectious process destroy the support structure of the bronchial walls. The negative pressure in the surrounding pulmonary tissue pulls the airways open, resulting in dilation.
- Dilated airways lack normal mucociliary clearance and trap secretions distally. Airflow is obstructed by airway secretions, and mucus-laden airways stimulate a productive cough. Chronic recurrent pneumonia can develop because the bronchial environment is primed for continual bacterial growth.
- Because bronchiectasis is difficult to recognize clinically, proper therapy is often delayed. As a result, it is common for airway changes to have progressed beyond the reversible stage by the time of diagnosis.

Clinical Signs

Signalment

- Bronchiectasis is a disease primarily affecting dogs; it is rarely documented pre- or postmortem in cats. Cocker spaniels have an increased reported prevalence of bronchiectasis.
- Animals with primary ciliary dyskinesia are typically young when the condition is diagnosed and have a history of chronic nasal discharge or airway infection. Other animals are generally older on presentation, with a history of pulmonary disease, typically chronic bronchitis.

History

- A chronic, productive cough and recurrent pneumonia are the primary historical complaints. Failure to respond to standard therapy for chronic pulmonary disease, along with frequent and serious exacerbations of disease, seem to be characteristic of patients with bronchiectasis.
- In some dogs, hemoptysis may be reported.

Physical Examination

- Animals often display systemic signs resembling pneumonia, such as fever, cachexia, and tachypnea. A noxious oral odor may be noted.
- Tracheal sensitivity is usually marked, and animals often expectorate and swallow mucus. Lung sounds are generally abnormal. Loud bronchial noises can sometimes be heard over dilated airways. Loud crackles may be ausculted in mucus-filled air spaces. Lobar consolidation may result in a region of absent lung sounds.

Diagnosis

Laboratory Evaluation

The CBC may show signs that reflect the chronic nature of the inflammatory process. Neutrophilia, monocytosis, anemia, and hyperglobinemia may be present.

Radiography

- Radiography may be confirmatory, but it is generally insensitive for detecting dilation of the airways. Bronchography was previously used in human medicine but has been replaced by thin-section computed tomography (CT).
- Ventral consolidation of the lung is seen when airways are obstructed with mucus or purulent secretions. Dilated airways are more visible when a pneumonic infiltrate is present.
- CT reveals focal or diffuse regions of increased airway space in conjunction with thickened airway walls. Pneumonic processes are generally more visible on CT.

Bronchoscopy

Bronchoscopy can be very useful in documenting dilation of the airways in dogs. In addition, foreign bodies can be identified and removed, bacterial cultures can be obtained, and the extent of disease can be assessed.

- Bronchiectasis often results in reddening of the mucosa and accumulation of a large amount of yellow to green viscid mucus. Airways lose the normal elliptical shape when bronchiectasis develops, airway bifurcations become very thinned, airways are dilated, and some airways can be obstructed with mucus.
- Bronchoalveolar lavage fluid is characterized by a preponderance of neutrophils. Cells should be assessed for the presence of intracellular bacteria. Blood-tinged fluid may be recovered or macrophages may contain hemosiderin as an indicator of previous alveolar hemorrhage.
- Both aerobic and anaerobic cultures should be obtained because suppuration can support growth of bacteria in an anaerobic environment. In veterinary patients, occult (culture negative) infections may also

occur, a finding that can complicate decisions regarding therapy.

Other Laboratory Tests

Electron microscopy on biopsies of ciliated airway epithelium (nasal or tracheal samples) can be used to document primary ciliary dyskinesia.

Treatment

General

- When present, foreign body removal greatly assists in resolution of clinical signs of disease. However, focal bronchiectasis can result, which then serves as a source of chronic reinfection or recurrent signs. In these patients, lobectomy should be considered as part of treatment.
- Nebulization, chest coupage and postural drainage assist in the removal of secretions from the airway. Maintenance of systemic and airway hydration through oral intake, intravenous fluids, or nebulization should be used when necessary.
- Cough suppressants should be avoided in virtually every instance because failure to remove infectious and inflammatory secretions will perpetuate disease.

▼ ***Key Point*** Antibiotics are the mainstay of therapy, and long-term or lifelong therapy may be required.

Antibiotics

Choose antibiotics based on culture and sensitivity results. The occurrence of occult infection makes it difficult to choose specific therapy in some cases. Use broad-spectrum antibiotics that penetrate the pulmonary tissue.

- Fluoroquinolones are useful agents; however, resistance by streptococcal species poses a serious concern and these drugs have no efficacy against anaerobes. Therefore a second drug must be used in conjunction.
- Chloramphenicol, doxycycline, and clindamycin have been used with success.
- Trimethoprim-sulfa would most likely be useful, although side effects preclude long-term use of this drug.
- Azithromycin is a useful drug when susceptibility has been proved and this drug is well tolerated long term.
- When long-term (6 months to lifelong) antibiotics are required, a monthly rotation of several drugs should be considered to avoid development of resistant species.

Prognosis

Bronchiectasis associated with a foreign body may be partially resolved by retrieval of the material and with aggressive antibiotic treatment, but most cases of bronchiectasis are at continued risk for infection and worsening lung disease.

FELINE BRONCHIAL DISEASE

Etiology

- Feline bronchial disease appears to result from the initiation of an inflammatory process within the airways that results in mucosal edema, smooth muscle hypertrophy, hypertrophy of mucous glands with increased bronchial mucus, and reversible bronchoconstriction.
- Triggers of the inflammatory condition in spontaneously diseased cats have not been identified and it is likely that individual susceptibility to the induction of airway inflammation and hyper-responsiveness is quite variable.
- Environmental conditions or infectious agents have not been proven to cause bronchial disease; however, they may be responsible for exacerbation of preexisting disease. Some studies have found an association with *Mycoplasma* airway infection in asthmatic cats.
- The lungworm *Aelurostrongylus abstrusus* and the heartworm *Dirofilaria immitis* have been proposed as causes of hypersensitivity lung disease, but are present in just a fraction of affected cats.

Pathophysiology

- Current research suggests that cats with bronchial disease have hyper-responsive airways, analogous to asthma in humans. Human asthma is associated with an accumulation of inflammatory cells and mediators within the airway.
- Degranulation of mast cells with release of histamine and serotonin is associated with an acute inflammatory response within the airways. Release of inflammatory mediators aids in recruitment and activation of T lymphocytes and eosinophils.
- T lymphocytes contribute to airway inflammation through production of cytokines including interleukin-5, which enhances expression of leukocyte adhesion molecules and facilitates the ingress of eosinophils.
- The products of eosinophils are likely contributors to the pathology seen in feline bronchial disease. Major basic protein, eosinophil-derived cationic protein, eosinophil peroxidase, and eosinophil-derived neurotoxin are released from eosinophil granules. Major basic protein is particularly damaging to the airway, causing ciliostasis, epithelial cell death, and bronchoconstriction.
- Inflammatory injury to the mucosal lining exposes sensory endings in the lung, resulting in enhanced neural responsiveness to noxious stimuli. Thus, inflammation leads to a perpetual state of airway hyperexcitability and potential hyper-responsiveness.

Clinical Signs

Cats of all ages and of either sex are affected. There is a suggestion of an increased incidence and severity of disease in the Siamese cat.

History

- Cats with bronchial disease may have a long-term history of coughing, gagging, and decreased activity levels, suggesting chronic disease. Occasionally owners will report noisy breathing or wheezing. Another subset of cats will develop respiratory distress and cyanosis acutely and require emergency care, typical of an acute asthmatic attack.
- Feline bronchial disease can be misdiagnosed as a vomiting disorder because cats tend to retch and bring up bronchial secretions during a cough.
- Signs of upper respiratory tract infection can precede the onset of bronchial signs. This may be similar to viral-induced asthmatic symptoms in susceptible human patients.

Physical Examination

- Physical examination and thoracic auscultation are normal in some cats, whereas others exhibit adventitious lung sounds ranging from subtle wheezes to harsh crackles. Expiratory sounds are expected since asthma is classified as an obstructive airway disease of small airways. Pulmonary function testing has shown prolonged expiratory times in most cats examined. This can be observed in some cats at rest; however, excitement induced in the exam room often leads to tachypnea or panting.
- Cats with bronchial disease usually have increased tracheal sensitivity, and post-tussive crackles can be ausculted.
- Decreased thoracic compliance may be detected due to hyperinflation of the lungs.
- Open-mouthed breathing with or without cyanosis occurs in some cats and represents a medical emergency.

Diagnosis

The history and physical examination are helpful in establishing a presumptive diagnosis of bronchial disease. The remainder of the diagnostic workup may elucidate a primary cause of underlying airway hyperreactivity, such as lungworm, heartworm, or *Mycoplasma* infection, and it can rule out complicating conditions.

Laboratory Evaluation

- Peripheral eosinophilia is present in some cats with bronchial disease. Neutrophilia and monocytosis may reflect the chronicity of disease.
- Fecal examination, by zinc sulfate centrifugation-flotation and Baermann procedure, are useful in detecting parasitic infection. Heartworm testing (antibody, antigen, and echocardiography of the pulmonary arteries) should be considered in endemic areas when radiographs suggest pulmonary vascular disease and should also be considered in the cat that presents with both coughing and vomiting as clinical signs.
- Hyperglobulinemia may be present but is a nonspecific finding.

Radiography

- Normal chest radiographs do *not* rule out the diagnosis of bronchial disease.
- An interstitial peribronchial pattern with "doughnuts" and increased linear markings is considered classic for feline bronchial disease. Animals presenting in respiratory distress may show hyperinflation of the lungs with caudal displacement of the diaphragm and evidence of aerophagia.
- Occasionally a larger airway retains a mucus plug, resulting in atelectasis of the lobe supplied by that bronchus. This most commonly occurs in the right-middle lung lobe due to its dependent position; however, this is found in a minority (10%) of cats. Excessive mucus accumulation and plugging of more peripheral airways can result in a patchy alveolar pattern that must be distinguished from pneumonia, pulmonary edema, or neoplasia.
- CT can reveal thickened airway walls, mucus plugging, and emphysematous change with asthma or bronchitis.

Airway Sampling

Evaluation of airway washings through transoral (endotracheal) wash or bronchoscopy is recommended for patients that are stable enough to undergo the procedure. Anesthetic protocols that include ketamine are generally safe and effective for the procedure. Pretreatment with terbutaline prior to the anesthetic procedure can reduce the likelihood of bronchoconstriction. The drug can be given orally (0.625 mg PO q12h) or by injection (0.01 mg/kg sSC).

Airway Evaluation

- Bronchoscopy can reveal viscid mucus accumulation, mucus plugging, and nodular irregularities of the airways. Hyperemia is not a prominent finding.
- Cytologic findings in feline bronchial disease can include eosinophilic, neutrophilic, or mixed inflammatory responses. Normal feline airways are rich in eosinophils, and it is not uncommon for healthy cats to have greater than 25% eosinophils in an airway wash. Increased numbers or percentages of eosinophils or neutrophils are consistent with the diagnosis of feline bronchial disease and the level of inflammation correlates with the severity of disease. This can be helpful in determining therapy.

Table 162-3. ANTI-INFLAMMATORY AGENTS USED IN THE TREATMENT OF FELINE ASTHMA

Drug	Dosage	Mechanism of Action
Glucocorticoids:		Decrease influx of inflammatory cells, stabilize lysosomal membranes, decrease capillary permeability.
Prednisolone	1–2 mg/kg PO, IM q12–48 h	
Methylprednisolone acetate	10–20 mg/cat IM every 2–8 weeks	
Prednisolone sodium succinate	50–100 mg/cat IV	
Fluticasone proprionate (MDI)	110 µg/puff by aerosol q12–6 h	
Cyproheptadine	1–2 mg/cat PO q12 h	Blockade of serotonin receptor
Cyclosporine	10 mg/kg PO q12 h (adjust dosage to produce trough levels in the blood >500 ng/ml)	T-cell inhibition

MDI, metered dose inhaler.

- Studies have reported that 25–42% of airway cultures are positive for bacteria or *Mycoplasma*. When cytologic findings suggest airway infection, these positive cultures likely represent true infection, but a large percentage of healthy cats have positive airway cultures. Also, bacteria may establish temporary residence in the respiratory tract of cats with bronchial disease during episodes of respiratory distress without causing true infection.

Other Laboratory Tests

Pulmonary function tests can be performed in certain referral institutions. Anesthesia is required for measurement of airway resistance and lung compliance. Cats with bronchial disease exhibit higher airway resistance due to bronchoconstriction. Administration of terbutaline decreases resistance in some cats indicating partial reversibility of smooth muscle contraction.

Treatment

Emergency Therapy

▼ ***Key Point*** Minimization of stress is one of the most important aspects in management of the cat in acute respiratory distress. Provide a quiet, cool environment with supplemental oxygen.

Cats often benefit from concurrent administration of a bronchodilator such as terbutaline or albuterol, which are smooth muscle relaxants and generally provide rapid bronchodilation. A near immediate response to bronchodilator therapy is supportive of a clinical diagnosis of bronchial asthma.

- The suggested dose of terbutaline is 0.01 mg/kg SC. Monitor the cat for improvement in respiratory rate and effort for 15 minutes after administration. If no alterations are seen, give a second dose.
- Though often available, parenteral aminophylline is a poor substitute for terbutaline, as bronchodilatory effects are relatively minimal. Aminophylline is painful when administered by SC or IM injection, and agitation may occur following IV injection.
- An alternative approach used in many emergency practices involves administration of one or two puffs of albuterol from a metered dose inhaler delivered into a pediatric or feline spacer. The face mask attached to the spacer should be appropriate for a feline face and create a good seal; the mask should be maintained in place for 6 to 10 breaths.
- In cases of life-threatening bronchoconstriction, epinephrine can be administered cautiously if terbutaline is not available. Beta-2 agonist effects will produce reliable bronchodilation; however, cardiovascular stimulatory actions can cause side effects.
- If treatment with terbutaline, albuterol, or epinephrine fails to improve effort of breathing, the diagnosis of reactive bronchial disease is less likely. However, many cats with chronic bronchial disease show signs mainly as a consequence of inflammation so that the use of short-acting parenteral corticosteroids will often result in a relatively rapid improvement in clinical signs (Table 162-3).
- Signs of successful therapy result in reductions of respiratory rate, expiratory effort, and cyanosis.

Chronic Management

- Anti-inflammatory agents are the mainstay of therapy. Oral or inhaled steroids are the most commonly used agents and are generally successful in alleviating clinical signs (see Table 162-3). Prednisolone is the preferred anti-inflammatory agent, using a high dose initially (1–2 mg/kg PO q12h) for 3 to 10 days, and then tapered according to clinical response. Approximately 50% of cats can be stabilized and medication can be discontinued.
- Cats that cannot be medicated orally can be treated with long-acting steroid injections; however, this is a

less desirable method of treatment and leads to a number of systemic side effects. In these patients, the use of inhaled medications is preferred, either alone or preferably after stabilization and during the tapering of oral medication. Administer Flovent (fluticasone proprionate) 110 µg/puff q12h using an aerosol chamber or spacer device (AeroKat or Optichamber) and mask. Following one actuation of the metered dose inhaler into the chamber, cats should inhale 6 to 8 breaths to receive an adequate amount of drug.

- Alternate anti-inflammatory agents occasionally used in animals that cannot tolerate corticosteroids include cyproheptadine, a serotonin blocker, which is effective in vitro, and cyclosporine, an inhibitor of T cells (see Table 162-3). Side effects associated with cyclosporine limit its use to severe and refractory cases.
- Bronchodilators may help control clinical signs and decrease the dosage of corticosteroids required. Terbutaline, a beta-agonist, and extended release theophylline, a methylxanthine derivative, can be used. Individual cats will react differently to the drugs available. If the initial response to terbutaline is not adequate or if pills can be given only once daily, substitute a theophylline derivative. Consider prescribing inhaled albuterol by metered dose (see "Emergency Therapy") for use in the home setting for emergency management of asthmatic attacks.
- Some cats suffer exacerbation of disease in dusty or polluted environments, in response to cigarette smoke, or when they encounter specific noxious elements or stressful situations. Recognition and elimination of these triggers can reduce the frequency of attacks of respiratory distress or coughing episodes. Use of HEPA filters in the home may benefit indoor cats.

Contraindications

- Cats have significant sympathetic innervation to the airway. Blockade of beta receptors with propranolol (a nonselective beta blocker) or atenolol (a selective beta-1 blocker) can result in bronchoconstriction and respiratory distress in cats with bronchial disease. These drugs should be avoided.
- Diuretics and anticholinergic agents should not be used. There are no primary indications for these classes of drugs, and they have the negative effects of dehydrating the mucus layer and increasing mucus trapping.

Prognosis

Feline bronchial disease can be a chronic disorder and cats often exhibit either chronic persistent signs or recurrent episodes of clinical disease. Owners should be informed of this probability, encouraged to follow anti-inflammatory therapy closely, and to pursue regular communication with their veterinarian for follow-up care.

INTERSTITIAL LUNG DISEASE

Etiology

The etiopathogenesis of interstitial lung diseases is unknown, and the origin of disease is most likely multifactorial.

- Hundreds of inhaled agents, drugs, chemicals, and chronic infection or inflammation have been shown to lead to interstitial pneumonias or pulmonary fibrosis in humans. It is likely that chronic exposure to any of these substances could lead to similar conditions in dogs and cats.
- Genetic factors may play a role in the development of interstitial lung disease since West Highland white terriers and other terrier breeds seem more likely to develop this condition.

Pathophysiology

- Exposure to a variety of insults can lead to the release of inflammatory mediators in the lung, which initiate a chronic progressive inflammatory disease in the interstitium. Accumulation of the inflammatory products and cellular components of neutrophils and macrophages causes thickening of the alveolar wall and destruction of alveolar architecture.
- The presence of cellular debris within the alveoli and the formation of enlarged, dysfunctional alveolar units result in mismatching of ventilation and perfusion with subsequent hypoxemia.
- Interstitial lung disease results in a thickened barrier to diffusion for gas exchange. Diffusion impairment leads to hypoxemia during exercise and in severe cases can cause clinical signs at rest.
- Lung compliance is decreased by fibrosis causing increased work of breathing and tachypnea. End-stage restrictive lung disease develops.

Clinical Signs

Signalment

Terrier-type dogs, particularly the West Highland white terrier, and perhaps other small-breed dogs seem to be at increased risk for development of interstitial lung disease. Males and females are equally affected. Any age is susceptible; however, animals are usually older on presentation, perhaps because of prolonged exposure to inciting agents or due to compensatory mechanisms that preserve pulmonary function. A similar disease resulting in pulmonary dysfunction has been reported in cats.

History

- The classic history in an animal with interstitial lung disease is shortness of breath and exercise intolerance. Owners may attribute easy fatigability to advanc-

ing age and fail to recognize the presence of respiratory disease.
- Syncope can result from hypoxemia, pulmonary hypertension, or inappropriate baroreceptor responses following coughing or excitement.
- In cats, findings of respiratory distress and cough mimic those seen in feline bronchial disease.

Physical Examination

- Patients may appear relatively normal at rest, but develop shortness of breath and possibly cyanosis on exertion. Most animals are tachypneic and may exhibit respiratory distress.
- Pulmonary auscultation may be relatively unremarkable; however, the hallmark of pulmonary fibrosis is the presence of diffuse inspiratory crackles across the thorax. Crackles may be fine and localized or may be diffusely present and audible without a stethoscope.
- In patients that have developed pulmonary hypertension, cardiac auscultation may reveal a prominent pulmonic component to the second heart sound, a split S_2, or a murmur of tricuspid regurgitation.

Diagnosis

Definitive diagnosis of interstitial lung disease requires an open-lung biopsy. However, exclusion of other diseases that result in shortness of breath and crackles (e.g., pneumonia, bronchitis, CHF), along with failure to respond to standard treatment for bronchitis, is suggestive of the diagnosis.

Radiography

- Radiographs may be relatively normal, particularly in view of the degree of respiratory distress present in the patient. Classically, a generalized, diffuse interstitial pattern is detected.
- True cardiomegaly in these patients is characterized by right-sided cardiomegaly, and this may be an indicator of pulmonary hypertension. Artifactual cardiomegaly can be present due to breed conformation, decreased inspiratory volume, or reduced lung expansion.
- CT is valuable in documenting and characterizing the interstitial lung diseases in humans and further use of this modality may improve diagnostic capabilities in affected animals.

Airway Sampling

- Bronchoalveolar lavage will show an increase in the percentage of neutrophils, usually to greater than 25% (normal 5–6%). It is not possible to differentiate interstitial lung disease from chronic bronchitis based on cytologic findings alone; however, absence of increased bronchial mucus or anatomic changes at bronchoscopy argues against a diagnosis of chronic bronchitis.
- Cultures are usually negative unless infection complicates the disease.
- Pathologic assessment of affected lungs in cats reveals interstitial fibrosis, alveolar epithelial metaplasia and alveolar interstitial smooth-muscle metaplasia. In affected West Highland white terriers, expansion of the extracellular matrix with collagen rather than fibroplasia leads to thickening of the alveolocapillary barrier. Inflammation does not appear to be a substantial component of this disease.

Other Laboratory Tests

- Arterial blood gas analysis can show extreme hypoxemia at rest, while other animals may be normoxemic at rest.
- Doppler echocardiography may be used to document pulmonary hypertension when either tricuspid regurgitation or pulmonic insufficiency is present.

Treatment

General

- Exposure to identifiable inhaled or ingested risk factors should be minimized.
- Weight control is desirable to improve thoracic compliance.
- In general, animals diagnosed with interstitial lung disease respond poorly to treatment and have a poor prognosis. Underlying neoplasia may be present in some animals.

Anti-inflammatory Drugs

- Animals that will benefit from steroid therapy should show a response after 2 to 3 weeks of treatment with prednisone or prednisolone at 1 to 2 mg/kg PO q12h. High-dose therapy may result in continued improvement over 1 to 2 months, but the risk of severe immunosuppression and other complications must be considered.
- Variable success has been found in human patients when cytotoxic agents are used alone or in combination with glucocorticoids. The risk of systemic side effects related to immunosuppression or myelosuppression increases dramatically when cyclophosphamide is used. Anti-fibrotic drugs have not proved successful in human medicine and have unacceptable side effects in dogs. While interferon-gamma had initial success in treatment of humans, further studies have not supported its use.

Bronchodilators

- It is reasonable to consider a trial on bronchodilators in animals suspected of having an interstitial lung disease. Theophylline or beta-2 agonists may reduce respiratory distress and improve cardiac and respiratory muscle function in some patients (see Table 162-1).

Prognosis

- The prognosis for control of disease is guarded. Some animals can be made relatively comfortable for variable amounts of time, but respiratory distress typically worsens.
- Patients with pulmonary fibrosis are at risk for pulmonary hypertension and cor pulmonale.

PULMONARY INFILTRATES WITH EOSINOPHILS

Etiology

- Eosinophils accumulate in the canine airway in response to infection with heartworm, lungworms *(Filaroides hirthi, Capillaria aerophila),* or with parasitic bronchitis *(Oslerus osleri, Paragonimus kellicotti)*. Larval migration can also result in an eosinophilic pulmonary infiltrate.
- Hypersensitivity or an immune directed reaction can trigger eosinophil deposition in the airway and idiopathic eosinophilic lung disease. This condition is called eosinophilic bronchopneumopathy by some authors.
- Pulmonary eosinophilia has also been observed in cases of neoplastic-associated hypereosinophilic syndrome (see Chapter 22), in pulmonary fungal infections (see Chapter 20), and in dogs with pulmonary granulomatosis.

Pathophysiology

- Eosinophils in the airway release effector molecules such as major basic protein and eosinophil-derived cationic protein, which normally act to kill parasites or to combat an immunologic insult. The products of eosinophils damage cells of the respiratory system, resulting in ciliary paralysis and erosion and sloughing of the mucosa.
- Eosinophils stimulate release of preformed mediators from mast cells such as histamine and serotonin, and increase circulating levels of leukotrienes and platelet activating factor. These substances increase the permeability of the epithelium, increase secretion of mucus, and may also mediate smooth muscle contraction, causing bronchoconstriction.
- Eosinophil activation causes an increase in airway mucus, leading to increased resistance to air flow and subsequent hypoxemia.

Clinical Signs

History

The most common clinical complaint is a cough that is unresponsive to antibiotic treatment. Hemoptysis may be present in dogs with pulmonary infiltrates with eosinophils. Dogs are often short of breath, anorexic, and exhibit exercise intolerance.

Physical Examination

- The animal may be bright and alert or show variable degrees of depression and weight loss. Occasionally, severe systemic signs are present.
- Loud bronchial noises can be heard along with diffuse coarse crackles. Marked tracheal sensitivity is often present.

Diagnosis

Laboratory Evaluation

- The CBC often shows leukocytosis with eosinophilia and basophilia; however, peripheral eosinophil numbers may be normal despite significant pulmonary involvement.
- Heartworm disease must be ruled out with an occult heartworm test, and animals should have multiple fecal examinations (zinc sulfate centrifugation-flotation or Baermann procedure) performed to detect possible lungworm infection.

Radiography

- Thoracic radiographs typically show a mixed infiltrative pattern with bronchial, interstitial, and alveolar densities. Young animals with larval migration have a primarily caudodorsal distribution of infiltrates.
- *Paragonimus* infection may show the characteristic thick-walled cystic structures on radiographs. Occasionally, rupture of a cyst can lead to pneumothorax.
- Heartworm infection is characterized by a prominent right ventricle and enlarged pulmonary arteries.

Airway Sampling

- High numbers of eosinophils are seen on cytology from tracheal wash fluid or on bronchoalveolar lavage. Cytology preparations should be carefully searched for parasite eggs and larvae.
- Bronchoscopy generally reveals markedly hyperemic airways. Yellow-green mucus, polypoid proliferations on the epithelium, bronchiectasis, and airway collapse are variably seen.

Other Laboratory Tests

- Intradermal skin testing might be considered in an attempt to identify an offending allergen, but has never been well correlated to spontaneous canine lung diseases.

Treatment

- Removal of an offending allergen can result in resolution of clinical signs, but most animals also require glucocorticoid therapy.
- In dogs with suspected eosinophilic lung disease, empiric therapy for lungworm infection or larval migration could be considered in animals that are

stable. In that case, Fenbendazole is recommended at 50 mg/kg PO q24h for 10 days. Specifically identified parasitic infections and larval migration should be treated with appropriate anthelminics.

- The primary treatment for eosinophilic infiltration of the airways or pulmonary parenchyma is based on immunosuppression with glucocorticoids. Prednisone is used initially at 1 mg/kg PO q12h for 5 to 10 days. The dose is slowly tapered as signs resolve and the drug can often be discontinued in 4 to 6 months. Too rapid tapering of drug can result in failure to eliminate signs or early recurrence, and recurrence of clinical signs requires a return to the higher dose of steroid. Some dogs require sustained treatment.

GRANULOMATOUS PULMONARY DISEASES

Etiology

- In endemic regions, granulomatous pulmonary disease is commonly seen with systemic fungal infections (histoplasmosis, blastomycosis, and coccidioidomycosis; see Chapter 20).
- Noninfectious granulomatous lung diseases are uncommonly encountered in the dog and cat.
  - Eosinophilic pulmonary granulomatosis is a nodular lung disease that has been linked to occult heartworm infection in the majority of cases.
  - Pulmonary lymphomatoid granulomatosis has been described in dogs and is similar to a neoplastic condition in humans characterized by proliferation of T lymphocytes. Some animals with lymphomatoid granulomatosis have had a history of heartworm disease.

Pathophysiology

- Fungal elements typically incite a type IV hypersensitivity immune response with infiltration of macrophages and lymphocytes.
- Eosinophilic granulomatosis may be induced by an immune reaction to heartworm antigens, dirofilarial immune complexes, or other unidentified stimuli. Characteristics of type III and type IV hypersensitivity reactions are present, with proliferation of epithelioid cells, macrophages, and eosinophils within the parenchyma.
- Histopathologic lesions are typically described as an angiocentric infiltrate of mononuclear cells, lymphocytes, plasma cells, mast cells, and occasionally eosinophils.

Clinical Signs

Signalment

Any age or breed of animal may develop granulomatous pulmonary disease, although young to middle-aged, large-breed dogs and young cats are more commonly affected.

History

These diseases often result in a chronic course of disease with signs present from 1 to 12 months prior to diagnosis.

- Respiratory signs include a nonproductive cough, abnormal breathing, respiratory distress, and exercise intolerance.
- Systemic signs such as fever, anorexia, and weight loss are often present.
- A relentless course of disease is typical, and treatment with glucocorticoids results in worsening disease in the case of fungal disease or minimal improvement with granulomatous disease. These disorders are also unresponsive to antibiotic treatment.

Physical Examination

- Systemic involvement is indicated by the generally debilitated state of the patient. Additional organs are often affected in cases with systemic mycoses (see Chapter 20) but not in primary granulomatous pulmonary diseases.
- Respiratory abnormalities include an elevated respiratory rate, increased tracheal sensitivity, harsh coarse crackles, and loud bronchial wheezing noises.

Diagnosis

Laboratory Evaluation

- The CBC typically shows a leukocytosis with variable degrees of neutrophilia, monocytosis, eosinophilia, or basophilia. Hyperglobulinemia may be present in association with chronic antigenic stimulation.
- Occult heartworm testing and fungal titers are recommended in suspected cases. Positive titers for histoplasmosis and blastomycosis may reflect only exposure to disease.

Radiography

- Fungal disease typically results in a nodular pattern on chest radiographs, with a homogeneous population of small or large nodules, depending on the type and duration of fungal infection.
- The presence of multiple pulmonary masses varying in size is suspicious for a granulomatous disease, metastatic neoplasia, or malignant histiocytosis. Pulmonary masses ranging from 1 to 7 cm and lobar consolidation have been reported in eosinophilic and lymphomatoid granulomatosis.
- Hilar lymphadenopathy is present in virtually all granulomatous lung diseases and can be severe. Partial obstruction of a main stem bronchus often occurs due to enlargement of hilar nodes.

Airway Sampling

- In myocotic infections, fungal elements may be seen on transtracheal wash, bronchoalveolar lavage, or on fine-needle aspiration of the lung.
- Definitive diagnosis of nonfungal granulomatous disease is based on characteristic histopathologic findings from biopsy of a lung mass. Eosinophils are commonly encountered on cytology of eosinophilic granulomatosis and may also be seen in lymphomatoid granulomatosis.

Treatment

- Treat pulmonary mycosis as described in Chapter 20.
- Therapy for eosinophilic or lymphomatoid granulomatosis should begin with treatment of heartworm disease, when present. Treatment for the granulomatous component of disease requires the use of immunosuppressive and cytotoxic drugs. Prednisone along with cyclophosphamide or cyclophosphamide/vincristine has been used with some success; however, prognosis is guarded for these conditions. A remission rate of less than 25% has been reported in one series of advanced canine patients.

NON-CARDIOGENIC PULMONARY EDEMA

Etiology

Non-cardiogenic pulmonary edema can be categorized as high-pressure edema or permeability edema. High-pressure edema may be more amenable to therapeutic intervention.

- **High-pressure edema** results from overexpansion of the extracellular fluid volume by overzealous administration of fluids, from decreased oncotic pressure, or in association with pulmonary overcirculation, which may occur with pulmonary thromboembolism.
- **Permeability edema** can result from pulmonary insults such as aspiration of acidic gastrointestinal contents, near drowning, and smoke inhalation, or from extrapulmonary insults such as pancreatitis, disseminated intravascular coagulation, sepsis, and anaphylaxis. A number of these conditions activate the systemic inflammatory response syndrome (SIRS), a disorder known to predispose to noncardiogenic pulmonary edema,
- Combination of these two types of noncardiogenic pulmonary edema may result from electric cord shock, upper airway obstruction, or in re-expansion pulmonary edema (i.e., after alleviation of chronic atelectasis due to long-standing pleural effusion or chronic diaphragmatic hernia).

Pathophysiology

- Noncardiogenic pulmonary edema is not associated with primary cardiac insufficiency. In high-pressure edema, overexpansion of plasma volume or decreased oncotic pressure leads to fluid accumulation in the lung due to a disruption of Starling forces.
- Damage to the alveolocapillary membrane results in permeability edema and allows protein-rich fluid to flood the alveoli. This results in refractory hypoxemia, decreased pulmonary compliance, and eventual hyaline membrane formation. In humans, the severest form of this condition is known as acute (or adult) respiratory distress syndrome (ARDS).

Clinical Signs

Dogs or cats with serious systemic illness that develop signs of refractory respiratory distress or tachypnea should be suspected of having non-cardiogenic pulmonary edema and/or pulmonary thromboembolism. Typically, animals with non-cardiogenic pulmonary edema are poorly responsive to conventional therapy.

History

The history usually reveals an acute or chronic pulmonary or multisystemic illness requiring significant supportive care. Non-cardiogenic edema may be associated with chronic vomiting syndromes. Respiratory abnormalities noted include tachypnea, respiratory distress, and cyanosis.

Physical Examination

- Thoracic auscultation reveals tachypnea and often the fine crackles of pulmonary edema. Underlying lung disease may result in coarse crackles or absence of lung sounds due to lobar consolidation.
- The remainder of the physical examination may provide clues to the inciting event, such as electric cord burns, peripheral edema, neurologic abnormalities, stridor, abnormal abdominal palpation, or other physical exam abnormalities.

Diagnosis

The history of a precipitating catastrophic event or trigger for systemic inflammation along with acute onset of respiratory distress is highly suggestive of the diagnosis. Alternative considerations should include pneumonia, pleural effusion, and pulmonary thromboembolism. Refractory hypoxemia despite aggressive supportive care increases the index of suspicion for non-cardiogenic pulmonary edema.

Radiography

- Patchy interstitial and alveolar densities are found, particularly in the periphery or caudodorsal lung lobes. The pattern of distribution helps distinguish this type of pulmonary edema from cardiogenic edema in the dog. Typically, with non-cardiogenic pulmonary edema, the infiltrate is severe and bilat-

eral rather than perihilar in distribution, and it fails to clear with diuretic therapy.
- Radiographic signs of aspiration pneumonia such as cranioventral alveolar infiltrates or consolidation of middle lung lobes may be present in some cases.

Arterial Blood Gas

Arterial blood gas analysis is helpful in following the course of disease and in determining prognosis. Animals are hypoxemic, there is an increased alveolar to arterial gradient, and oxygen responsiveness is minimal.

Treatment

Use aggressive therapy to correct the primary disease. Acid-base imbalances and electrolyte abnormalities are identified and normalized early in the course of disease. Prognosis is guarded in most cases.

High Pressure Edema

In cases with high-pressure edema, *discontinue* intravenous fluid support as soon as the problem is identified. Overhydration can usually be resolved with diuretic therapy. Oncotic pressure may be elevated transiently through infusion of plasma or dextrans, and this may clear the pulmonary infiltrate.

Permeability Edema

Animals that develop non-cardiogenic pulmonary edema due to increased permeability in the alveolocapillary membrane often have more severe derangements in gas exchange and are more difficult to stabilize.

- Unfortunately there is no specific therapy for non-cardiogenic pulmonary edema and many cases require short-term ventilation support to survive.
- Use oxygen therapy to increase the pO_2.
- Use sedation (butorphanol, 0.1–0.2 mg/kg IM) to reduce anxiety.
- Administer IV fluids *very* cautiously to avoid alveolar flooding; generally fluid therapy will exacerbate the edema. This relationship can create real problems when there is a need for fluid resuscitation, but the clinician should understand that large volume infusions will likely precipitate a need for ventilator therapy.
- Use diuretic therapy cautiously because it can deplete intravascular fluid volume and lead to hypotensive shock while failing to clear pulmonary congestion. Reducing capillary hydrostatic does lower the tendency towards edema formation, but this point must be weighed against the loss of cardiac filling and tissue perfusion.
- Plasma infusion can be helpful by replacing proteins lost through the alveolocapillary membrane and maintaining oncotic pressure; however, colloid not maintained within the vascular space may worsen the edema.
- There is no clear evidence that corticosteroids are efficacious in patients with non-cardiogenic pulmonary edema. Steroids may be useful in rare cases of non-cardiogenic pulmonary edema associated with shock or anaphylaxis.
- Bronchodilators are of uncertain value. Long-acting theophylline might increase the strength of respiratory muscles but at the risk of anxiety and gastrointestinal disturbances. Terbutaline in dogs has been shown to reduce lung water in experimentally induced permeability edema.
- Positive inotropic support may be helpful in certain cases to maintain blood pressure, especially when fluid intake is restricted.
- Progressive respiratory distress, desaturation despite oxygen therapy, hypercarbia and other signs of respiratory failure, or obvious respiratory fatigue require tracheal intubation and mechanical ventilation.

Chapter

163 Respiratory Infections

John D. Bonagura

The respiratory system is a common portal of entry for infectious agents of all varieties, with many of these infectious agents have been identified as respiratory pathogens (Table 163-1). The purpose of this chapter is to emphasize clinical aspects of common respiratory infections in dogs and cats. For details concerning specific infectious diseases, the reader is referred to Chapter 11 for respiratory virus and chlamydia infections of the cat, Chapter 12 for bordetellosis and viral tracheobronchitis of the dog, Chapter 13 for canine distemper, Chapter 20 for the systemic mycoses, and Chapter 21 for toxoplasmosis. Diagnostic procedures relevant for respiratory infections are summarized in Table 163-2 and are discussed in Chapters 158 and 159. Management of noninfective bronchopulmonary diseases and of chronic bronchitis in the dog and cat are described in Chapter 162. Management of pleural infections is described in Chapter 164.

- The nasal cavity, nasopharynx, larynx, and the trachea are normally inhabited by a variety of microorganisms. Aspirated bacteria from the upper respiratory tract intermittently populate the tracheal-bronchial tree. Thus the potential for *secondary* opportunistic infection is high when underlying pulmonary injury is present or when the host is immunologically compromised. In addition, the clinician can expect to culture microorganisms such as *Pasteurella* spp. from the upper airways when performing diagnostic studies. These results must be interpreted with care.
- Many infectious agents are *primary* pathogens of the respiratory epithelium, pulmonary interstitium, or pleural space. This is particularly true of upper respiratory infections caused by viral agents or bacteria like *Bordetella bronchiseptica.*
- The respiratory system also may be involved in *multisystemic* infections. This is common with the systemic mycoses, *Blastomyces dermatitidis* and *Histoplasma capsulatum.*
- Certain infectious agents, such as *Bartonella* spp., are emerging as potential causes of respiratory infection at multiple levels. Some of these agents are intracellular, others very difficult to culture. Diagnosis of these infections relies increasingly on molecular laboratory methods.
- It is helpful to identify the principal *anatomical site(s)* of infection, as many infectious agents produce a characteristic pattern of respiratory disease. This approach may help the clinician in the differential diagnosis and in directing appropriate laboratory studies. Good examples of localized respiratory disease are the viral upper respiratory infections of cats and canine infectious tracheobronchitis. Because clinicians generally speak in terms of the anatomic diagnosis—rhinitis, sinusitis, laryngitis, tracheitis, bronchitis, pneumonia, pleuritis, or mediastinitis—respiratory infections will be discussed using this classification (see Tables 163-1 and 163-2).

▼ ***Key Point*** Because many respiratory infections are secondary to another condition, consider the possibility of *underlying* respiratory disease or the possibility of host immunosuppression.

- The subject of infectious disease is extensive. For more detailed information on specific infections, the reader is directed to other sources such as *Greene's Infectious Diseases of the Dog and Cat.*

RHINITIS AND SINUSITIS OF INFECTIOUS ETIOLOGY

Infections of the nasal cavity and paranasal sinuses are common, and clinical signs may also involve the nasopharynx. Acute rhinitis is frequently caused by viral and bacterial pathogens that directly invade the nasal mucosa. Chronic rhinitis often can be traced to another predisposing problem such as immunosuppression, foreign body, or tumor. Because the nasal cavity is not sterile, standard culture and sensitivity tests are of little value in diagnosis and management of these diseases.

Etiology

- Infections of the nasal cavity and nasal sinuses are not uncommon, especially those associated with acute, contagious viral infections in dogs and cats. Etiologic agents are summarized in Table 163-1.

History

- Cardinal signs of upper airway infection are sneezing, nasal discharge, and often a dry cough. Involvement

Table 163-1. CLASSIFICATION OF COMMON RESPIRATORY INFECTIONS BY ANATOMIC LOCATION

Rhinitis and Sinusitis

Herpesvirus (rhinotracheitis) [F][†]
Calicivirus [F][†‡]
Chlamydia psittaci
Parainfluenza virus [C][†]
Canine distemper virus [C][†‡]
Adenovirus-2 [C][†‡]
Salmon poisoning rickettsial agent [C]
Bordetella bronchiseptica [C,F][†‡]
Secondary bacterial infection (find predisposing cause)
Aspergillus flavum [C]
Penicillium spp. [C]
Rhinosporidium seeberi [C]
Cryptococcus neoformans [F]
Cuterebra and other grubs
Pneumonyssus (Pneumonyssoides) caninum [C]
Eucoleus boehmi [C]

Tracheitis

Upper respiratory virus (see above)
Bordetella bronchiseptica [C][‡]
Osleri (Filaroides) osleri [C]

Bronchopulmonary Infections[§]

Some upper respiratory viruses (see above)
Canine influenza virus
FIV infection—can cause alveolitis in cats
Bacteria bronchopneumonia—both gram-positive and gram-negative infections
Bordetella bronchiseptica [C, F]
Gram-negative bacteria: *Escherichia coli, Klebsiella* spp., *Pseudomonas* spp., *Pasteurella* spp.
Gram-positive bacteria: *Streptococcus* spp., *Staphylococcus* spp.
Mycoplasma spp. [F > C]
Parasitic infections [F, C]
Aelurostrongylus abstrusus [F]
Paragonimus kellicotti [C, F]
Capillaria aerophilia [C, F]
Osleri (Filaroides) infection *(F. milksi, F. hirthi)* [C]
Aspergillosis (endobronchial infection)
Viral infections: feline calicivirus; canine distemper virus
Chlamydia psittaci [F]
Rickettsial infections (*Ehrlichia canis;* Rocky Mountain spotted fever) [C >> F]
Toxoplasma gondii [F > C]
Hematogenous bacterial infection
Nocardia spp., *Actinomyces,* anaerobes[¶]
Leishmania donovani [C]
Systemic mycoses: *Histoplasma encapsulatum, Blastomyces dermatitidis, Coccidioides immitis, Cryptococcus neoformans* [C > F]
Response to parasitic infection: migrating nematodes [C]
Dirofilaria immitis [C > F]
Lungworms and flukes [F, C]

Pleuritis and Pleuropneumonia

Feline infectious peritonitis
Anaerobic bacteria
Aerobic bacteria (*Pasteurella* spp., *E. coli,* etc.)
Nocardia asteroids
Actinomyces spp.
Blastomyces dermatitidis [C >> F]
Toxoplasma gondii [F >> C]

*This list is not comprehensive; important clinical conditions are indicated with the most commonly affected species designated as [C] = canine; [F] = feline.
[†]Infection commonly extends to the larynx and trachea.
[‡]Infection commonly extends to the bronchi and may cause pneumonia.
[§]Alveolar involvement may develop in some cases of interstitial pneumonia.
[¶]Pulmonary abscess, pleuropneumonia, and pyothorax may develop with these agents.

of or discharge into the nasopharynx may cause reversed sneezing or gagging.

- Contagion is an issue with some causes of upper respiratory infections, especially with agents associated with the feline upper respiratory infections (see Chapter 11).
- Acute viral rhinitis is usually self-limiting within 1 to 2 weeks.
  - Persistence of viral or bacterial rhinitis or sinusitis can occur in immunocompromised cats infected with feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV).
  - In addition, feline herpesvirus persists in a latent subclinical carrier form in recovered cats, and this occasionally recrudesces to result in episodic or persistent rhinitis (or conjunctivitis).
- Primary bacterial rhinitis and sinusitis are uncommon (except with *Bordetella bronchiseptica*); however, secondary bacterial infection can develop as a sequel to mucosal injury or obstructed nasal passages caused by upper respiratory viral infection, foreign body, periodontal disease and root abscesses, oral-nasal fistula or cleft palate, trauma (sequestrum), allergic rhinitis, lymphocytic-plasmacytic rhinitis, congenital ciliary dyskinesia (including the Kartagener syndrome), polyps, neoplasia, and fungal infection.
- *B. bronchiseptica* infection can lead to significant rhinitis as well as tracheobronchitis.
- Chronic bronchitis or lobar pneumonia can predispose to sinusitis, and vice versa. It is likely that a sinubronchial route of migration reinforces each infection.
- Bacterial isolates in rhinitis/sinusitis are variable and typify bacteria normally encountered in the nasopharynx, including gram-positive, gram-negative, and anaerobic organisms. Recently *Bartonella* spp. has been incriminated as a possible cause of nasal cavity discharge, including epistaxis, in dogs.
- Fungal infection of the nasal cavity or sinuses (see Table 163-1) can also be associated with immunosuppression; however, this immunodeficiency may be difficult to demonstrate in dogs. *Aspergillus flavus,* for example, is a normal inhabitant of the nasal cavity, but may invade respiratory epithelium in dogs with altered immunity or preexistent inflammation (e.g., lymphocytic-plasmacytic rhinitis, foreign body, or trauma).
- Nasal parasites, such as the nasal mite, *Pneumonyssus (Pneumonyssoides) caninum,* and the nasal nematode, Eucoleous, are uncommon in most localities, but are a potentially treatable cause of upper nasal/nasopharyngeal signs; this should be considered, especially in young dog with rhinitis and reversed sneezing.

Clinical Signs

- Sneezing, nasal discharge, and gagging or retching from postnasal drip are the typical signs of infectious rhinitis and sinusitis.

Table 163-2. DIAGNOSIS OF RESPIRATORY INFECTIONS

Nasal Cavity and Paranasal Sinuses

Signalment (age, breed, sex), vaccination status, history
Physical examination (emphasis: head, eyes, nose, oral cavity, regional lymph nodes, skin)
Auscultation
Serologic tests (aspergillosis, FeLV, FIV, and cryptococcus)
Skull, dental, and nasal radiographs
CT or MRI of the nasal cavity and paranasal sinuses
Examination of the teeth, oral cavity, oropharynx, and tonsils under anesthesia (inspection, palpation, examination with dental probes and mirrors)
Rhinoscopy (nasal cavity and retroflex rhinoscopy of the nasopharynx and posterior choanae)
Nasal culture (bacterial, fungal)
Aspiration biopsy/cytology (swab or nasal flush) of nasal exudate
Mucosal biopsy of the nasal cavity
Fine-needle aspiration biopsy/cytology of enlarged regional lymph nodes or mass lesions
Surgical exploration of the nasal cavity and paranasal sinuses for culture, biopsy, and debridement
Virology: Immunocytologic identification of viruses (e.g., immunofluorescence for canine distemper, feline herpes) and virus isolation (e.g., feline calicivirus)

Larynx

Ultrasonography of larynx
Visual examination of the larynx during light anesthesia
Radiography

Trachea

Radiography (cervical and thoracic)
Fluoroscopy
Tracheoscopy (endoscopy)
Cytologic examination of tracheal lesions (brush cytology of the tracheal mucosa)

Bronchopulmonary Diseases

History and physical examination (observation, auscultation, percussion of the thorax)
Thoracic radiography
Complete blood count
Heartworm (HW) tests (enzyme-linked immunosorbent assay [ELISA] antigen tests for dogs and cats, microfilaria tests for dogs, HW antibody test for cats)
Fecal examinations (flotation and Baermann sedimentation to detect lung parasites)
Serologic testing
(e.g., immunodiffusion or other tests for systemic mycoses, IgM ELISA for toxoplasmosis)
Arterial blood gas
Pulse oximetry
Bronchoscopy
Culture of tracheobronchial secretions
(transtracheal wash, endotracheal approach using a guarded culture swab, or aspiration through sterile tubing advanced through a sterilized endoscopic port)
Cytologic examination of the bronchi or lower airways
- Transtracheal wash of tracheobronchial secretions
- Endotracheal aspiration cytology
  - Via a catheter placed in the trachea or bronchial tree
  - Via an endotracheal tube (method sometimes used in cats and very small dogs)
- Brush cytology of the bronchial mucosa
- Bronchial aspiration cytology (selective, via a bronchoscope catheter)
- Bronchoalveolar lavage with a wedged bronchoscope

Fine-needle aspiration (FNA) of the lung or a mass lesion
Lung biopsy
Pulmonary function testing

Diseases of the Pleural Space

History and physical examination (observation, auscultation, percussion of the thorax)
Thoracic radiography (pre- and post-thoracentesis)
Thoracentesis
Cytology of pleural effusate
Culture and sensitivity of pleural effusate
Serological testing when appropriate (FIV, FIP)
Biochemical tests (e.g., serum/pleural effusion triglyceride concentration)
Ultrasound examination
Computed tomography (CT) or magnetic resonance imaging (MRI) of thorax
Lymphangiography

Diseases of the Mediastinum

History and physical examination (observation, auscultation, percussion of the thorax)
Thoracic radiography
Ultrasound examination
CT or MRI of mediastinum
FNA of mediastinal masses
Barium swallow and esophagram
Tracheoscopy/bronchoscopy

- Reversed sneezing (violent, inspiratory movements against a closed glottis) may occur with nasopharyngeal irritation from any source.
- Involvement of the ocular conjunctiva is not uncommon with contagious causes of rhinitis. Corneal involvement may suggest herpesvirus infection. Chorioretinitis may develop consequently to infectious canine distemper virus or cryptococcosis.
- Cough may indicate postnasal drip with pharyngeal irritation or concurrent involvement of the larynx, trachea, or bronchial tree.
- Some dogs retch and expectorate secretions that have accumulated in the pharynx.
- A serous discharge is typical of acute viral disease, whereas mucopurulent nasal exudate suggests a bacterial or fungal component.
- Other clinical findings such as fever, enlargement of the tonsils, bony swelling, regional lymphadenopathy, oral ulceration, and ocular or neurological involvement may be evident depending on the underlying causes of disease.

Diagnosis

- The differential diagnosis of upper respiratory infections is extensive (Table 163-3), including primary infectious diseases, secondary infections, and a large number of non-infective disorders. The age, vaccination status, history, and physical examination tend to focus the diagnostic considerations in most cases. The diagnostic studies chosen depend on the presumptive diagnosis and response to initial therapy (see Table 163-2).
- Primary infectious diseases, nasal mites, and foreign bodies with secondary infection are the important cause of rhinitis and sinusitis in younger dogs and cats. Older pets (older than 8 years of age) tend to be afflicted with nasal tumors complicated by secondary nasal infection.
- The poorly understood, idiopathic, lymphocytic-plasmacytic rhinitis of dogs and cats is a very common biopsy diagnosis that may be associated with allergy or infection. This disorder may allow for opportunistic secondary mucosal invasion by bacteria or fungi.
- Suppurative rhinitis is a less common biopsy diagnosis of the nasal mucosa. Primary and secondary bacterial infection may be involved; infection by *Bartonella* spp. should be considered.
- Infections caused by *Aspergillus* spp. and *Penicillium* spp. require histologic examination of nasal tissue, sometimes with special staining (e.g., silver stains) to detect hyphae. A positive agar gel immunodiffusion (AGID) test may also be supportive of the diagnosis. Routine culture is nonspecific because these fungi can be normal inhabitants of the nasal cavity.

▼ ***Key Point*** Because bacteria and fungi can be cultured normally from the nasal cavities, a careful exclusion of an underlying condition is essential and over-interpretations of positive cultures must be avoided.

- The typical *canine work-up* for signs of nasal disease requires general anesthesia. Routine laboratory tests can be obtained including a complete blood count (CBC) and serologic tests for aspergillosis and polymerase chain reaction (PCR) for *Bartonella*. Regional lymph nodes can be aspirated if enlarged, and routine thoracic films exposed to exclude concurrent bronchopulmonary infection. However, most diagnoses are made under general anesthesia.
  - At a minimum, diagnostic imaging should include an open mouth radiograph of the nasal cavity. Abnormal findings include focal or multifocal lesions, increased soft tissue or fluid density, loss of turbinate detail, nasal septal deviation, and boney destruction. These findings are not diagnostic of any specific condition, and each is compatible with some form of chronic infection.
  - Optimally computed tomography (CT) of the nasal cavity, paranasal sinuses, and nasopharynx should be done and interpreted by an expert in this form of imaging.
  - After radiological procedures, initiate anesthetic examination with careful inspection of the oral cavity, oropharynx, tonsils, and larynx. Follow this with antegrade rhinoscopy via the nostrils and retrograde rhinoscopy across the nasopharynx using a retroflexed endoscope.
    Unfortunately, rhinoscopy is limited in small dogs (and cats) related to availability of appropriate sized endoscopes.
    Visual findings of disease may include abnormal mucosal color (hyperemic, white); plaque formation (fungus or lymphocytic-plasmacytic rhinitis); puff ball (rhinosporidiosis) or nasal mites; and destruction of turbinate structure or friable mucosa. An obvious foreign body or mass lesions may be observed in some cases. Hemorrhage may obscure the examination field.
  - Then undertake mucosal biopsy of the nasal cavity, preferably guided by findings at endoscopy or radiography/CT.
    Blind biopsy based on location of clinical signs is also appropriate.
    In some cases of chronic rhinitis, large chunks of nasal turbinate bone may be obtained during this procedure. Request special stains (e.g., silver stains) for suspected cases of fungal rhinitis.
- At the end of the procedure the nasal cavity is flushed bilaterally with cooled saline (ensure that the endotracheal tube is inflated and the caudal airways packed with sponges; put the nose "down" to prevent aspiration and swallowing of fluid). Inspect the collection sponges at the conclusion of the procedure for any foreign material or tissue that may be appropriate for cytologic or histopathologic examination.

Table 163-3. DIFFERENTIAL DIAGNOSIS OF UPPER AIRWAY INFECTIONS

Causes of Nasal Discharge

Infectious causes of nasal discharge in dogs and cats (see Table 163–1)
Inflammatory causes of nasal discharge
  Lymphocytic plasmacytic rhinitis
  Idiopathic, including "allergic" rhinitis
  Postinflammatory scars at posterior choanae
Congenital diseases predisposing to nasal discharge
  Ciliary dyskinesis
  Congenital—cleft palate
  Imperforate posterior choanae openings
  Immunodeficiency disease (IgA)
Physical disorders leading to nasal discharge
  Foreign body
  Acquired—oro-nasal defect
  Trauma leading to nasal bleeding or fracture/sequestrum
  Abnormal drainage from the nasal cavity due to inflammatory or congenital webs, tumors, or polyps
Neoplastic causes of nasal discharge

Dogs—Malignant Tumors

Adenocarcinoma (most common)
Chondrosarcoma
Fibrosarcoma
Mast cell tumor
Osteosarcoma
Squamous cell carcinoma
Transmissible venereal tumor

Cats—Malignant Tumors

Squamous cell carcinoma
Adenocarcinoma
Lymphoma

Benign Tumors (Dogs and Cats)

Polyps (more common in cats)
Adenoma
Fibroma

Causes of Epistaxis

Thrombocytopenia from any cause
Thrombocytopathia
Ehrlichiosis
Hyperglobulinemia or other hyperviscosity syndromes
Polycythemia (serous discharge or epistaxis)
Hypertension (including pheochromocytoma)
Coagulopathy with normal platelets (not typical; usually due to platelet problems)
Neoplasms
Foreign bodies
Violent sneezing from any cause
Some chronic infections

Other Upper Airway Disorders

Inflammatory polyps
Disease of the tonsils
Laryngeal edema consequent to inflammation, trauma, or increased work of breathing
Unilateral or bilateral laryngeal paresis
Inflammatory nodules on the vocal folds
Eversion of the laryngeal saccules
Airway obstruction
Collapse of the glottic opening
Congenital tracheal lesions (segmental lesions)
Tracheal collapse
Relentless barking
Foreign body or foreign material
Swallowing disorders, esophageal masses, or megaesophagus
Trauma leading to hematoma, edema, fracture, perforation, laceration, or disruption
Iatrogenic injury (traumatic intubation, excessive cuff inflation)
Mass lesions: granulomas, tumors, and neoplastic conditions

Other Respiratory Disorders

Mediastinal lymphadenopathy or heart base tumors causing airway compression
Primary bronchial collapse
Left main bronchus compression by an enlarged left atrium
Primary chronic bronchitis (noninfectious)
Heartworm disease
Lungworms
Pulmonary neoplasm
Granulomatous disease

- Positive fungal cultures for aspergillosis are not necessarily diagnostic for the disease, but invasion of nasal mucosa with hyphae or a positive immunodiffusion or enzyme linked immunosorbent assay (ELISA) test are supportive of the diagnosis.
- Mucosal biopsies can be cultured for bacteria. A positive culture is more likely to be significant when compared to a flush or swab (superficial) culture, but results must be interpreted carefully.
  - Rarely, surgical exploration of the nasal cavity and paranasal sinuses is needed for definitive diagnosis.
- The typical *feline work-up* for signs of nasal disease is often completed in two stages:
  - Initially, submit a CBC and feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), and Cryptococcus ELISA tests to the laboratory.
  - Obtain a chest radiograph if the condition is chronic or there are lower airway signs.
  - Send a swab of nasal discharge to the lab with specific instructions to stain the smear for Cryptococcus neoformans.
  - Submit advanced virus diagnosis tests (immunofluorescence; PCR) for herpesvirus infection.
  - Following this first set of treatments, treat the cat empirically with a single course of antibiotics (amoxicillin, clavulanate, or doxycycline with food) and lysine (for possible herpesvirus infection) while awaiting the test results. Clients are instructed to provide good home nursing care and a stress-free environment for the cat.
  - If these studies fail to yield a diagnosis and empiric therapy is not curative, then anesthetic procedures

including nasal cavity imaging, rhinoscopy, and biopsy are needed, as described above for the dog.

- When clients cannot pursue advanced imaging and rhinoscopy, an "intermediate" and less costly (but more superficial) approach can be taken using a very short period of general anesthesia.
  - Premedicated the cat with butorphanol (0.25 mg/kg, IM) with acepromazine (0.1 mg/kg, unless contraindicated), accomplish IV anesthetic induction, and intubate the cat with a cuffed endotracheal tube.
  - If permitted, obtain one open-mouth radiograph of the nasal cavity.
  - Use a warmed dental mirror and a strong focal light source to evaluate the retropharyngeal space to rule out a polyp or obvious foreign body. Pull the soft palate in a rostral and ventral direction using a spay hook, and place the mirror in the caudal oropharynx to direct reflected light into the nasopharynx.
  - Then obtain two or three empiric nasal mucosal biopsies from the affected side(s) using 2- to 3-mm biopsy forceps.
  - At the conclusion of the procedure, flush the nasal cavity gently with sterile saline using a soft red-rubber tube to dislodge accumulated secretions or foreign material. The glottis should be protected by inflation of the cuff, packing with clean sponges (inspect at end of procedure), and by keeping the cat in a nose-down position so that most fluid exits the pharynx via the mouth.

Treatment of Viral and Bacterial Rhinitis

- Treatment of *acute upper respiratory infection* depends on the underlying condition. In cases of viral rhinitis, supportive nursing care, maintenance of hydration, and prevention of secondary bacterial infections by administration of a broad-spectrum antibiotic represent a typical therapy (avoid tetracyclines in puppies, enrofloxacin in growing animals, and chloramphenicol in cats). Ophthalmic medications may be useful for conjunctivitis or in cases of herpesvirus associated corneal ulcers (avoid corticosteroids).
- Dogs or cats with respiratory infection caused by bacterial infection may respond to doxycycline. This is especially true for *B. bronchiseptica* or *Bartonella* infections, which may be primary. Tetracyclines should not be used in pregnant bitches or in young dogs or cats if permanent teeth have not yet erupted (as staining will occur). Because *B. bronchiseptica* is an inhabitant of the mucosal brush-border, it can be difficult to eradicate infection with systemic antibiotics. In well-defined cases, empiric therapy with nebulized gentamicin can be considered (for details, see "Infectious Tracheobronchitis").
- For cats with chronic bacterial rhinitis of uncertain cause, a recurring cycle of intermittent antibiotics may be needed. Amoxicillin-clavanalate, doxycycline (5–10 mg/kg PO daily, always followed by food), and a 5-day course of azithromycin (5–10 mg/kg daily for 5 days; thereafter 10 mg/kg q72h) may provide symptomatic relief. A course of clindamycin also may be considered as it has some efficacy against *Mycoplasma* spp. Lysine (250 mg/day once or twice daily, crushed in food) can be tried if herpesvirus is thought to be a predisposing cause.
- Treat immunosuppressed cats with secondary bacterial rhinitis with broad-spectrum antibiotics if clinical signs worsen or if lower respiratory infection develops. For cats with FIV or FeLV viral-related immunosuppression, the empiric use of diluted human interferon alpha 2a (30 units, PO for 7 days, every other week) or of recombinant feline alpha interferon has been advocated, but more studies are needed. Cats do form antibodies against human interferon, which may limit effectiveness long term.
- In bacterial rhinitis associated with tooth root abscesses, management of the dental disease, along with a long-term course of antibiotics, may be curative. Any oronasal fistula should be closed.

Treatment of Fungal Rhinitis

A variety of treatments have been suggested for well-defined *fungal rhinitis/sinusitis*. Treatment recommendations depend on the specific agent, and protocols can be complicated and, in many cases, unsuccessful.

- General principles of therapy
  - Patients with fungal rhinitis represent complicated cases, and the clinician should consult detailed textbooks or current literature before embarking on any course of therapy for these serious conditions. It may be helpful to discuss options with an internist or a surgical specialist.
  - Oral medical therapy with an azole antimicrobial represents the least complicated approach to treatment. However, the drugs are expensive and many patients will not respond. Furthermore, these drugs may have significant adverse effects, such as hepatotoxicity, that must be discussed with the client.
  - The use Foley-type balloon catheters or red-rubber tubes, placed by endoscopy or by surgery, allows for instillation of antifungal medication. Some imidizoles are available in liquid form and can be infused directly into the nasal cavity and frontal sinus.
  - Surgical debridement may be considered a possible adjunct to therapy. Non-surgical debridement can be done via an endoscope or with devices used for dental cleaning (Water-pik) dislodge infected material.

- *Rhinosporidiosis* is associated with "puff-ball granulomas" in the nose. These can be treated by surgical extraction.
- *Aspergillus flavus* and *Penicillium* spp. are most commonly treated with nasal tubes placed by endoscopy or surgery.
  - The endoscopic method involves general anesthesia; placement of two infusion catheters in the nasal cavity (or frontal sinus if visible); multiple Foley or balloon catheters within the nostrils rostrally and in the cranial soft palate (via the nasopharynx); and infusion of antifungal medication with the dog placed in varying recumbent positions during the procedure. Before treatment, the balloons are inflated to create a nearly sealed nasal cavity. A one-time treatment of liquid enilconazole is administered (1% or 10 mg/ml, enilconazole) or clotrimazole (approximately 120 ml of a 1% solution) for 1 hour. A slow, constant infusion process maintains continual filling of the space and contact with the mucosa. This may be preceded by debridement of affected tissues (controversial). Enilconazole is also effective as a vapor, which may enhance its local effect.
  - One-treatment cures with enilconazole and clotrimazole have been reported. In one study of 24 dogs an 80% response rate was observed. In another study of 36 dogs, almost 95% responded to local treatment of enilconazole (about 55% responded to a single treatment). A second treatment 3 to 4 weeks later provided a positive outcome for most dogs that did not respond to a single infusion. One study of 60 dogs treated with clotrimazole reported about a 90% response rate.
  - An alternative method is placement of nasal tubes in the frontal sinus either surgically or by use of an endoscope to instill enilconazole (10 mg/kg, in 10 ml of solution divided between each nasal cavity) for 10 to 14 days. This approach is more labor intensive and may have a higher success rate, but has largely been supplanted by the endoscopic method.
  - Oral therapy of nasal aspergillosis may be attempted as a primary treatment or as a supplement to local therapy. A number of drugs have been used with varying success.
    Itraconazole at 5 mg/kg PO q12h for 2 to 3 months.
    Thiabendazole, which is less effective (40–50% positive response) and is more hepatotoxic, but can be administered at a dose of 10 to 20 mg/kg PO q12h with food (start at lower dose) for 6 to 8 weeks. The main advantage is a lower drug cost.
    Ketoconazole (Nizoral 5–10 mg/kg PO q12h for 6–8 weeks) is about as effective as thiabendazole.
- *Cryptococcus neoformans* infection of the upper airways is treated with fluconazole, itraconazole, ketoconazole, or amphotericin B (alone or in combination with flucytosine). Fluconazole seems to be useful at 50 mg total dose per cat q24h for 2 to 4 months. Itraconazole at 5 mg/kg q12h may be an alternative and needs to be continued even after the control of nasal discharge. Occasionally, higher doses are needed.

INFECTIOUS TRACHEOBRONCHITIS

General Points

- Acute tracheobronchitis refers to an inflammation of the trachea and bronchial tree of recent onset and short duration.
- Canine infectious tracheobronchitis (ITB), also known as the kennel cough complex, refers to a group of acute contagious infections in dogs that cause inflammation of the larynx, trachea, and bronchi. ITB is discussed in Chapter 12.
- Feline upper respiratory infection (URI) complex refers to a group of acute contagious upper respiratory diseases in the cat that may also involve the trachea or bronchial tree (see Chapter 11). In some cases the lung is involved as well.
- The clinical signs of tracheobronchitis typically include a paroxysmal, harsh, dry cough that can last for days to weeks.
- The condition may be accompanied by other signs of upper respiratory infection such as nasal discharge and sneezing (which are typical in cats and may be noted in dogs with *Bordetella* infection). In many cases, signs are isolated to the tracheobronchial tree.
- Common canine infectious agents include *B. bronchiseptica,* canine parainfluenza virus, canine adenoviruses (types 1 and 2), canine distemper virus, canine reoviruses (types 1 and 2), and canine herpesvirus. *B. bronchiseptica* is the most common bacterial infection, and canine parainfluenza virus is the most common viral isolate noted in the dog with canine infectious tracheobronchitis (ITB).
- Recently a new canine influenza virus, mutated from an equine strain, has been identified in dogs. This virus can cause signs identical to those of other "kennel cough" agents.
- In cats, feline herpesvirus and calicivirus are considered the most common causes of contagious upper respiratory disease. Calicivirus is more likely to involve the lower airways. Mycoplasma infection and bordetellosis should also be in the differential diagnosis for lower airway disease in cats.
- Many of these infectious diseases are very contagious and associated with high-density populations. The infectious agents can be transmitted by aerosol or fomite. Incubation periods are typically between 3 and 10 days. Vaccinations confer partial to complete protection against many of the ITB agents in most cats and dogs.
- In addition to infectious (contagious) causes, other conditions may *predispose* to tracheobronchial infection or inflammation. Some of these include:

- Abnormal local immunity
- Boarding kennels/catteries
- Racetracks
- Ciliary dyskinesis (rare)
- Contagious diseases
- Debilitation/poor nutrition
- Drying of the mucous membranes
- General anesthesia (intubation; aspiration)
- Poor vaccination history
- Recurrent or chronic bronchial disease

- Acute tracheobronchitis indicates an inflammatory reaction. The usual consequences of this inflammation are variable increases in tracheobronchial secretions and cough. If respiratory clearance mechanisms or immunity is insufficient, pneumonia may develop from the primary agent (e.g., bordetellosis) or from secondary bacterial invaders.

Diagnosis of Tracheobronchitis

- In general, one diagnoses feline upper respiratory infections and canine infectious tracheobronchitis from the history and physical examination. The long list of potential causes of signs of acute tracheobronchitis includes the conditions listed in the lower portion of Table 163-3.
- Some conditions (e.g., noninfective bronchitis, neoplasia) are more likely in mature animals and should be excluded initially by examination and thoracic radiography.
- The duration of signs and the response to supportive treatment will largely determine which diagnostic considerations are pursued. In classic kennel cough with no constitutional signs, diagnostic studies are generally negative and are not indicated. Poor responders should be worked up.

Diagnostic Tests

- Routine hematologic tests and radiographs are usually unremarkable; however, the client must understand that a number of other conditions can lead to similar clinical signs and should be prepared to support further examinations if indicated. If the patient is very ill, or if the clinical course of expected improvement is not met, additional tests are indicated.
- A CBC and serum chemistry panel (especially renal function, glucose) is appropriate for sick animals.
- Fecal flotation and empiric deworming with pyrantel is recommended for puppies and kittens.
- If significant ocular signs such as photophobia or anisocoria are noted, stain the cornea for ulcers; if results are positive, give antibiotics (without steroids).
- In previously untested cats, perform FeLV and FIV tests to screen for immunosuppressive diseases.
- Radiography of the thorax is probably the most indicated of studies and can be justified to rule out bronchiopneumonia and other causes of acute cough. The right middle lung lobe is predisposed to secondary infection in upper respiratory diseases, and pulmonary involvement is best seen on a VD or DV projection.
- Culture and cytology of the tracheobronchial airway secretions are indicated in unresponsive cases or those with confounding bacterial pneumonia. A transtracheal wash in cooperative dogs or an endotracheal wash in puppies or cats can be used to obtain a diagnostic sample.
- Other diagnostic tests may be considered in ruling out the differential diagnosis. These are indicated in Table 163-3.

Therapy of Infectious Tracheobronchitis

- The viral causes of these diseases are usually self-limiting, and often no treatment is necessary. This is especially true in mild, uncomplicated cases with minimal constitutional signs (i.e., animals that are without fever, still eating, and not acting sick).
- Specific supportive, symptomatic, and antimicrobial therapy for infectious tracheobronchitis is described in Chapters 11 (cats) and 12 (dogs).

Prevention of ITB

- Vaccination in dogs can be performed routinely with the following antigens: *B. bronchiseptica*, canine parainfluenza virus, canine adenovirus type 2, and canine distemper virus (see Chapter 7). Cats can be vaccinated against herpes-, calici-, and panleukopenia (parvo) viruses and bordetellosis (see Chapter 7).

BRONCHOPNEUMONIA

Etiology

- Pulmonary infections are common in dogs and in cats. Bacterial pneumonia is an important cause of morbidity and mortality in dogs and cats.
- Though numerous infectious agents (viruses, rickettsia, and systemic mycoses) can cause interstitial pneumonia, most cases of bronchopneumonia are bacterial in origin. Common microorganisms responsible for pneumonia are indicated in Table 163-1.
- The route of infection is typically inhalation.
- Hematogenous spread of bacterial pneumonia to the lungs is less common and can be very difficult to treat.
- The clinician should appreciate possible risk factors and predisposition for pneumonia, including:
  - Contagious upper respiratory infection (e.g., infective tracheobronchitis after boarding)
  - Preexistent bronchopulmonary disease (including noninfectious bronchitis, lung contusion, heartworm disease, smoke inhalation, pulmonary atelectasis, thromboembolic disease)

- Inhalation or aspiration of pharyngeal or gastric fluid or contents (due to anesthesia, swallowing disorders, megaesophagus, neuromuscular disease, laryngeal paralysis, posterior fossa lesion, stupor, vomiting, prolonged recumbency), or opiates and postoperative sedatives
- Oro-nasal sources of infection (sinusitis, dental disease)
- Immunosuppression caused by another virus (FeLV, FIV, canine distemper, parvovirus) or disease (e.g., hyperadrenocorticism, diabetes mellitus, generalized demodecosis)
- Immunosuppressive drug therapy (glucocorticoids, anticancer chemotherapy)
- Abnormal respiratory defense mechanisms (Cushing's disease, chronic bronchitis, ciliary dyskinesia, neutrophil dysfunction syndromes)
- Bronchial foreign body
- Foreign body aspiration pneumonia (e.g., food, mineral oil in cats)
- Debilitation, hospitalization, nosocomial infection

- Sedation with opiates.
  - Indwelling intravenous catheter sepsis (hematogenous spread)
  - Contaminated endotracheal tube, tracheostomy tube, or bronchoscope
  - Aspiration or inhalation of liquid foreign material during diagnostic or therapeutic procedures (barium sulfate, medications, mineral oil, nutritional supplements)
  - Following thoracic surgery
- Prompt recognition and treatment of bronchopneumonia is important. It is equally important to identify the predisposing cause so that further episodes can be prevented or anticipated.

Clinical Signs

- The history often indicates a predisposing factor for bronchopneumonia.
- Tachypnea, respiratory distress, productive cough, and fever are typical findings.
- Constitutional signs—depression, anorexia, and listlessness—may be observed as the only features of disease.
- Mucopurulent nasal exudate may be present.
- Pulmonary adventitious sounds—especially rhonchi and crackles—may be ausculted; however, loud or asymmetric bronchial sounds can be the only auscultatory finding.

Diagnosis of Bacterial Bronchopneumonia

▼ ***Key Point*** Point Clinical signs, radiography, and the CBC are usually sufficient to make a presumptive diagnosis of bacterial pneumonia.

- Thoracic radiographs are key to the diagnosis of bronchopneumonia.
  - The typical findings are increased lung density that is most commonly alveolar in nature leading to border effacement (silhouetting) of the heart. The lobe may become consolidated, producing a fluid density lobar sign.
  - The right middle lung lobe is most prone to bacterial infection; the cranial lobes also are frequently involved. In contrast, dorso-caudal pulmonary infiltrates are very unlikely to be associated with bacterial infection of the lung with the exception of atypical microorganisms (mycoplasmas, fungal infections, mycobacteria), or hematogenous pneumonia (from sepsis), which is diffuse, beginning as an interstitial pattern and progressing to alveolar.
  - A cranioventral distribution of bacterial bronchopneumonia is typical.
  - With some foreign bodies, the intermediate lobe may be involved.
  - Lung consolidation may occur, leading to an eventual loss of air bronchograms except in the most proximal portion of the lobe.
- *Radiographic differential diagnosis* is important.
  - Hilar or sternal lymphadenopathy is uncommon with bacterial infection.
  - Nodular densities are more typical of fungal disease, granulomatosis, or pulmonary neoplasia.
  - The combination of bronchopneumonia with concurrent septic pleural effusion (pyothorax) is very uncommon in dogs and cats. These findings are suggestive of an atypical infectious agent such as *Nocardia asteroides* or actinomycosis, presence of a foreign body, concurrent malignancy, or pulmonary embolus.
  - Pneumonia caused by viral, protozoal (e.g., toxoplasmosis), rickettsial, or fungal infection is typically interstitial in distribution. Fungal and *Toxoplasma* infections produce granulomatous lesions in the lung, and with systemic mycoses, hilar lymphadenopathy can be pronounced.
  - Esophageal air or dilatation may indicate simple air swallowing or a more serious condition such as megaesophagus or myasthenia gravis.
- *CBC*—Leukocytosis, left shift, and monocytosis are typical abnormalities on the CBC; however, the magnitude of change is not consistently related to the extent of infection. Overwhelming fulminant bacterial pneumonia may cause a neutropenia with degenerative left shift.
- *Serology*—Infected cats also may be FIV or FeLV positive. FIV infection has also been associated with nonbacterial alveolitis and interstitial pneumonia.
- *Airway cytology and culture* can confirm the diagnosis.
  - Transtracheal or endotracheal aspiration cytology demonstrates neutrophilic inflammation, often with degenerative PMNs and intracellular bacteria.

- Cocci are usually streptococcus, and rods are usually gram-negative bacteria.
- The culture is typically positive for bacterial growth (see Table163-1).
- Special media are needed for effective culturing of Myocoplasma spp.; mycoplasma culture should be requested in most cases, and especially in cats.
- While a fine-needle aspiration of a collapsed lung can provide diagnostic tissue, in general, one should avoid percutaneous needle aspiration of a consolidated lung in order to prevent inoculation of the pleural space.

▼ ***Key Point*** Bronchopneumonia is typically a complication related to another disorder, general anesthesia, or medical or surgical treatments. The precipitating cause should be identified.

Treatment of Bacterial Bronchopneumonia

- Keep the patient well hydrated and warm. Fluid therapy is often required to prevent dehydration and inspissated respiratory secretions.
- Perform thoracic coupage 4 to 6 times daily. Once the patient feels better, brief walks, followed by coupage, help to mobilize tracheobronchial secretions.
- Airway humidification may assist in expectoration of secretions. Expectorants like guaifenesin are of uncertain merit and are not usually prescribed.
- Bronchodilator therapy (sustained release theophylline at 10–20 mg/kg PO q12h for dogs) is of unproven efficacy but may reverse irritative bronchoconstriction and strengthen respiratory muscle effort in dyspneic animals.

▼ ***Key Point*** Cough suppressants are *contraindicated* in bronchopneumonia.

- Humidified oxygen should be administered to dyspneic, cyanotic, or hypoxemic animals.
- Antibiotics should be prescribed *for at least 3 weeks.* The duration of therapy may be longer pending clinical results and radiographs.
- Antibiotic choice should be based on culture and sensitivity (obtained by transtracheal or endotracheal washing) and with consideration of current or prior antibiotic therapy. Request a Gram stain on expectorated material or a cytoprep from an airway washing.
- *Initial/Empiric antibiotic therapy* is initiated when culture results are pending, when cultures are reported as "no growth," or when airway culture is simply unavailable. An extended or broad-spectrum antibiotic is generally indicated in dogs and in cats. The choice depends on a number of factors including the species, age of the patient, severity of pneumonia radiographically, respiratory status (oxygen saturation, respiratory rate and depth), previous antibiotic therapy, and suspected source and type of microorganism. In cases of nosocomial (hospital-acquired) infection, a more aggressive antibiotic protocol may be indicated. There is no one best choice for antibiotic therapy in pneumonia, and the best approach is to culture fluid from the lung and target a specific microorganism based on sensitivity testing.
  - Cephalosporins and amoxicillin-clavulanic acid are generally effective with activity against gram-positive and gram-negative bacteria, as well as against anaerobes. They are generally well tolerated by dogs and cats, including most young animals. Rapid IV administration of cefazolin can cause vomiting. These drugs do not demonstrate significant activity against *mycoplasma* spp.
  - Sulfadiazine-trimethoprim is a reasonable drug for first-line therapy of bronchopneumonia in dogs.
  - Azithromycin is increasingly used for treatment of infections in dogs and cats, and is proabably a good drug for empiric therapy of pneumonia. There is demonstrated activity against *mycoplasma* spp.
  - Fluoroquinolones (enrofloxacin or orbifloxacin) are broad-spectrum drugs available for both parenteral and oral use. These antibiotics should not be used for trivial infections. There is some activity against *mycoplasma* spp.
- Resistant or complicated bronchopneumonia
  - Doxycycline is an excellent choice for unresponsive pneumonia, in part related to strong activity against bordetellosis and myoplasma infection. However, the overall spectrum is limited and it is not generally chosen as a single drug for empirical therapy. In resistant pneumonia in cats, doxycycline is a good choice because of the high probability of *mycoplasma* infection.
  - In cases of life-threatening or poorly responsive pneumonia, the spectrum of a cephalosporin or amoxicillin-calvulanic acid can be extended with parenteral amikacin, once daily (provided hydration and renal function are satisfactory). This combination does not affect *mycoplasma* spp.
  - In cases of pulmonary consolidation, a combination of a fluoroquinolone combined with clindamycin, metronidazole, or amoxicillin is a reasonable choice.
  - In life-threatening bronchopneumonia, consider a combination of IV enrofloxacin plus IV amoxicillin or a third generation cephalosporin.
- Management of bacterial pyothorax requires thoracostomy tube drainage and antibiotics. Because anaerobic organisms are commonly involved in pyothorax, treatment with penicillin (20,000–40,000 units/kg PO or IV q6–8h), alone or in combination with sulfadiazine-trimethoprim, or clindamycin is recommended.

Follow-Up

- Obtain thoracic radiographs to ensure resolution of infection. Areas of lobar consolidation may take 2 to 6 weeks to become totally clear. Failure of steady clinical and radiographic improvement indicates a need to reevaluate the patient and to consider a tracheal wash or bronchoscopy with bronchial fluid aspiration.
- Recurrent pneumonia also is common, particularly in those animals with persistence of predisposing factors, including swallowing disorders, chemotherapy, ciliary dyskinesis, and acquired or congenital immune deficiencies. Infrequently, an unresponsive or refractory single lobe infection requires surgical lobectomy for resolution of the problem. Surgery is also indicated in cases of lung abscess or pneumonia due to a foreign body that cannot otherwise be retrieved. Surgical results are generally rewarding in this clinical situation.

RESPIRATORY PARASITES

Etiology

- A number of respiratory parasites have been identified in dogs and cats. The life cycle of some respiratory parasites is complex and involves intermediate and transport hosts. Some of the more important infections include:
  - *Aelurostrongylus abstrusus* is a parasite of cats. This nematode requires a snail or slug as an intermediate host. Cats are often infected by eating transport hosts including birds, small mammals, and reptiles.
  - *Paragonimus kellicotti* is a fluke parasitic to dogs and cats. Infection follows ingestion of an intermediate host (crayfish, aquatic snail) or a transport host (e.g., raccoon).
  - *Capillaria aerophilia* is a nematode parasite of the dog and cat that has a direct life cycle. Pathogenic potential appears very low.
  - *Crenosoma vulpis,* the fox lungworm, infrequently infects dogs.
  - *Osleri/Filaroides* spp. are nematodes that invade the respiratory tract of the dog. Transmission is direct, often from bitch to pups. Three related species have been associated with respiratory disease, *O. osleri* (found in granulomas near the tracheal bifurcation), *F. milksi* (a bronchopulmonary parasite), and *F. hirthi* (a lung parasite of importance to research colonies).
  - *Dirofilaria immitis* infects the pulmonary arteries, causing secondary pulmonary injury (see Chapter 152).
  - *Toxoplasma gondii* is a protozoan capable of multisystemic infection that is usually subclinical, but occasionally can cause pneumonia (see Chapter 21). Immunosuppression predisposes to toxoplasmosis.
- Parasites of the nasal cavity include cuterebra and other grubs, the microscopic nematode *Eucoleus boehmi,* nasal mite *Pneumonyssus (Pneumonyssoides) caninum,* and the gapeworm *(S. ierei).*

Clinical Signs

- Signs depend on the specific parasite, site and severity of infection, and the magnitude of the host reaction.
- Mild cases are asymptomatic and only detected if ova are identified during routine fecal examination.
- Clinically apparent infections occur most often in younger animals (<2 years) that are heavily infested.
- Sneezing, nasal discharge, and reversed sneezing are signs of nasal mite infestation.
- A chronic cough is typical of *O. osleri* infection; some dogs develop marked reactions to the parasites, leading to productive coughing of white foam and even airway obstruction from tracheal granulomas.
- Coughing is the most common sign of lower respiratory parasitic infections. Exercise intolerance and weight loss also may occur.
- Fever and tachypnea are typical of toxoplasmosis but not of other respiratory parasites. Multisystemic disease may be present in toxoplasma infection including neurological signs, anterior uveitis, chorioretinitis, and hepatitis.

Diagnosis

- Diagnosis of respiratory parasites is made following clinical examination, endoscopy, radiography, or identification of either ova or larvae in fecal samples or respiratory secretions.
- Eosinophilia is not uncommon in lungworm or fluke infections.
- Diagnosis of nasal mites or other nasal parasites is by direct visualization, often using a retroflexed bronchoscope. Diagnosis of *E. boehmi* requires mucosal biopsy or identification of the ova on a fecal examination.
- Diagnosis of *O. osleri* usually requires tracheoscopy, identification of nodules (which contain small, filamentous worms), or biopsy of a granuloma. There are no obvious radiographic changes unless soft tissue granulomas proximal to the carina are observed within the air-filled trachea. Occasionally, larvae may be obtained via tracheal washings.
- Radiographs are helpful in the recognition of advanced lungworm infections.
  - *Aerulostrongylus* causes an indistinct interstitial-nodular pattern in the lung. Distribution of infiltrates varies but caudal lung lobes are typically involved.
  - *Paragonimus* generally causes a granulomatous interstitial reaction with appearance of air-filled cystic structures (especially in the dog).

  - *Filaroides* infections can cause a diffuse interstitial infiltrate ranging from severe *(F. milksi)* to mild. *F. hirthi* seldom leads to clinical disease.
  - *Toxoplasma* when manifested in the lung leads to a mixed interstitial-alveolar infiltrate.
- Fecal flotation can identify ova from some parasites (double-operculated *Capillaria* ova, single-operculated *Paragonimus* ova) or larvae of *Aelurostrongylus* or *Osleri/Filaroides* spp. Baermann fecal sedimentation techniques may be required to identify larvae.
- Transtracheal washing or aspirations of tracheobronchial secretions may demonstrate parasitic ova or larvae. In some cases, ova are scarce. An eosinophilic pulmonary infiltrate with accompanying neutrophilia is typical.
- Diagnosis of pulmonary toxoplasmosis depends on clinical signs and serological evaluation.

Treatment

- Treatment of respiratory parasites involves destroying the infective organism, reducing parenchymal reaction, and instructing the owner about the prevention of further infection. A number of drugs (at varying dosages) have demonstrated efficacy against respiratory parasites, though treatments for some parasites are difficult.
- Fenbendazole (Panacur) is generally the safest antiparasitic drug. In cases of severe eosinophilic pulmonary reaction, adjunctive therapy with prednisolone (0.5 mg/kg, orally, once or twice daily for 7–14 days) may be quite helpful.
- Nasal parasites are treated by manual removal of large parasites or by treatment with oral injectable ivermectin (consult a parasitologist or specialist). Nasal mites may require high-dose ivermectin for control (800 mcg/kg SC single dose) or topical selemactin (6–24 mg/kg topically every 2 weeks for 3 total doses), or extra-label use of milbemycin (1 mg/kg PO every 10 days for 3 total doses). Dogs treated in these ways must be heartworm and microfilaria negative; do not use in collies.
- Aelurostrongylosis is treated with fenbendazole (Panacur, 50 mg/kg, orally, once daily for 10 days).
- Paragonimiasis is treated with either fenbendazole (as above), praziquantel (Droncit, 25 mg/kg, orally, q8h for 2 days), or albendazole (25–50 mg/kg orally q12h for 10–20 days).
- *Filaroides* spp. are treated with fenbendazole, albendazole, or oral ivermectin (200 µg/kg/wk for 3 doses or 400 µg/kg once; do not administer to collies).
- Capillaria infection is often asymptomatic but can be treated as per *Filaroides* infection.
- The prognosis for recovery and elimination of signs is generally good unless severe granulomatous disease has developed, in which case, residual cough may occur.

Chapter

164 Pleural Effusion

Robert G. Sherding / Stephen J. Birchard

Pleural effusion is an abnormal accumulation of fluid within the pleural space and is a clinical manifestation of conditions such as pyothorax, feline infectious peritonitis, congestive heart failure, intrathoracic neoplasia (e.g., lymphoma, thymoma, pulmonary neoplasia, mesothelioma), chylothorax, heartworm disease, hemothorax, hypoalbuminemia, lung lobe torsion, and diaphragmatic hernia. Pleural effusion is usually suspected from clinical signs and physical findings and is confirmed by thoracentesis or thoracic radiography.

ETIOLOGY

Pleural effusion occurs when one or, more often, a combination of the factors that determine pleural fluid dynamics are altered so as to increase fluid formation, decrease fluid absorption, or both. For example, pleural effusion is often associated with congestive heart failure (CHF) because increased capillary hydrostatic pressure results in increased pleural fluid formation. Extreme hypoalbuminemia may lower systemic colloidal osmotic pressure sufficiently to cause increased formation and decreased absorption of pleural fluid. Inflammation of the pleura may increase the formation of pleural fluid because of increased blood flow (hydrostatic pressure) and permeability of the pleural capillaries along with increased intrapleural colloidal osmotic pressure due to a higher concentration of protein in the fluid. Pleural effusion may also result from lymphatic insufficiency caused by thoracic duct obstruction, intrathoracic neoplasia, pleural thickening, or lymphatic hypertension secondary to CHF. The major causes of pleural effusion in dogs and cats are listed in Table 164-1.

CLINICAL SIGNS

- Dyspnea and exercise intolerance (inactivity) are the most consistent presenting signs of pleural effusion. Dogs and cats generally accommodate to small to moderate increases in the volume of intrapleural fluid by gradually decreasing their level of activity. Thus the signs of early pleural effusion are subtle and often imperceptible to the owner. As the accumulation of intrapleural fluid becomes substantial, however, tachypnea and respiratory distress become apparent during mild exertion and eventually even at rest.
- To facilitate breathing, the animal may prefer a sitting or crouched sternal posture, with the head and neck extended and the elbows abducted away from the thorax. An anxious facial expression and open-mouth breathing with forceful abdominal efforts during inspiration may be observed. Cyanosis may be seen in severe cases.

▼ ***Key Point*** Any struggling or increased distress during examination procedures may worsen dyspnea and induce respiratory arrest because of limited respiratory reserve.

- Other clinical signs associated with pleural effusion depend on the underlying cause but may include anorexia, depression, weight loss, dehydration, pallor, fever, hypothermia, or cough. Cough in animals with pleural effusion may indicate tracheal compression by a mediastinal mass (lymphoma, thymoma), intrapulmonary involvement (e.g., lung tumor, pulmonary edema, heartworm disease, pneumonia), or the presence of pleuritis.

DIAGNOSIS

Suspect pleural effusion on the basis of clinical signs and physical findings. Confirm pleural effusion by thoracentesis (see Chapter 3) or thoracic radiography (see Chapter 159). The cause is often determined through analysis of pleural fluid obtained by thoracentesis, in conjunction with post-thoracentesis radiographs. Depending on the suspected etiology, consider other diagnostic procedures such as laboratory evaluations, cardiac evaluations, ultrasonography, and specialized imaging procedures (contrast radiography, scintigraphy, computed tomography [CT]). Rarely, exploratory thoracotomy is required for definitive diagnosis.

Table 164-1. CAUSES OF PLEURAL EFFUSION AND CRITERIA FOR DIAGNOSIS

Causes of Pleural Effusion	Distinguishing Radiographic Findings	Fluid Patterns	Other Diagnostics
Common Diseases			
Pyothorax	Effusion may be unilateral or encapsulated; rounded or collapsed lung lobes (constrictive pleuritis)	Septic exudate	CBC; fluid culture
Feline infectious peritonitis	Concurrent abdominal effusion in some cases; rounded or collapsed lung lobes (constrictive pleuritis)	Nonseptic exudate (pyogranulomatous)	Fluid protein electrophoresis; Serology; PCR, immunostain
Congestive heart failure	Cardiomegaly; pulmonary edema and venous congestion; dilated caudal vena cava; abdominal effusion (rare)	Pure transudate; modified transudate; chylous effusion	Echocardiography; electrocardiography; angiocardiography
Heartworms (dirofilariasis)	Prominent pulmonary arteries; right-sided heart enlargement	Modified transudate; chylous effusion	Heartworm tests; echocardiography
Mediastinal neoplasia (lymphoma, thymoma)	Mediastinal mass (widened mediastinum; dorsally displaced trachea; caudally displaced heart and carina; esophageal compression)	Neoplastic: modified transudate; nonseptic exudate; chylous effusion	Ultrasound; fine-needle aspiration cytology
Bronchopulmonary neoplasia (carcinoma)	Pulmonary mass or infiltration	Neoplastic (variable): modified transudate; nonseptic exudate; chylous effusion; hemorrhage	Ultrasound; fine-needle aspiration cytology; thoracotomy
Chylothorax	Rounded or collapsed lung lobes (constrictive pleuritis); effusion may be unilateral	Chylous effusion	Fluid triglyceride; lymphangiogram; evaluate for underlying causes
Uncommon Diseases			
Diaphragmatic hernia	Other signs of thoracic trauma; loss of diaphragm shadow; displaced abdominal organs; concurrent abdominal effusion	Modified transudate; nonseptic exudate	Ultrasound; contrast peritoneography
Hemothorax	Other signs of thoracic trauma	Hemorrhage	If nontraumatic: coagulation tests; evaluate for underlying causes
Lung lobe torsion	Opaque lung lobe (right middle or either cranial lobe)	Nonseptic exudate; hemorrhage	Ultrasound, bronchoscopy; thoracotomy
Hypoalbuminemia	Concurrent abdominal effusion	Pure transudate	Evaluate kidneys, liver, and GI tract
Mesothelioma	No distinguishing characteristics	Neoplastic (variable): modified transudate; nonseptic exudate	Ultrasound; fine-needle aspiration cytology; thoracotomy
Thymic branchial cyst	Mediastinal mass (similar appearance to mediastinal neoplasia)	Modified transudate; nonseptic exudate	Ultrasound; thoracotomy
Pancreatitis	Concurrent abdominal effusion	Nonseptic exudate	Abdominal ultrasound; serum pancreatic lipase immunoassay
Pulmonary thromboembolism	Hypovascularity of lung; blunted pulmonary arteries; right-sided heart enlargement	Modified transudate; nonseptic exudate	Angiography; pulmonary perfusion scan

Physical Examination

Thoracic Auscultation and Percussion

- Auscultation generally reveals muffled or inaudible heart and lung sounds ventrally, while breath sounds are preserved dorsally.
- On percussion, pleural effusion causes the thorax to sound dull and hyporesonant, and a horizontal fluid line may be demonstrable.

Other Physical Findings

- Fever suggests an inflammatory, infectious, or neoplastic process.
- Jugular venous distention or pulsations and auscultation of murmurs, gallops, and arrhythmias are signs suggestive of cardiogenic pleural effusion. Pleural effusion can be associated with congestive heart failure in cats with hyperthyroidism; thus, palpate the thyroid region for the presence of thyroid gland nodules or enlargement.
- Decreased compressibility of the cranial thorax is suggestive of a mediastinal mass, usually lymphoma or thymoma. Mediastinal lymphoma can also compress the esophagus, causing signs of dysphagia and regurgitation; it also can impinge on the sympathetic innervation of the eye, causing Horner syndrome.
- Animals with pleural effusion should also be thoroughly examined for evidence of a tumor in any location, since extrathoracic neoplasms may metastasize to the lungs or pleural cavity and cause pleural effusion (e.g., mammary adenocarcinoma).
- Ophthalmoscopy may reveal lesions of chorioretinitis in cats with feline infectious peritonitis (FIP).
- External signs of trauma may indicate hemothorax or diaphragmatic hernia.

Thoracic Radiography

Routine thoracic radiography is generally effective for confirming pleural effusion.

▼ ***Key Point*** If the animal is in extreme respiratory distress, perform pleural drainage to stabilize the patient before radiography. Otherwise, the stress of restraint and manipulation during radiography could prove fatal.

The radiographic signs of pleural effusion include separation of the lung lobes from the parietal pleura and sternum by extrapulmonary fluid density (i.e., compression of lung lobes by a pleural fluid density), fluid-filled interlobar fissures producing a scalloped appearance to the edges of the lungs, and obscuring of the cardiac and diaphragmatic shadows, which is referred to as the silhouette sign (see Chapter 159). There is also widening of the mediastinum and blunting or filling of the costophrenic angles by intrapleural fluid density on a ventrodorsal view. In addition, the various causes of pleural effusion may be associated with other radiographic findings of diagnostic significance (see Table 164-1).

- A rounded contour to the caudal lobar borders, often accompanied by atelectasis of the cranial and middle lobes, is suggestive of a chronic fibrosing reaction of the visceral pleura that is exerting a constrictive and restrictive effect on the lung lobes (especially in cats with chronic chylothorax). Atelectatic lobes may be mistaken for pulmonary masses, hilar masses, or lung lobe torsion.
- Although most pleural effusions are bilateral, unilateral effusion is seen occasionally. This is most suggestive of pyothorax because the natural walling-off response to septic suppuration can cause extensive pleural thickening, which may seal off the mediastinum and limit the effusion to one side. Pleural thickening associated with chylothorax can also result in unilateral effusion. In addition to pyothorax and chylothorax, unilateral effusion is occasionally observed in traumatic hemothorax, diaphragmatic hernia, pulmonary neoplasia, and lung lobe torsion.
- Pleural effusion is sometimes found in combination with ascites. Simultaneous pleural and peritoneal effusions (dual-cavity effusion) occur most often in cats with FIP but also in dogs or cats with severe hypoalbuminemia, diaphragmatic hernia, widely disseminated neoplasia, pancreatitis, and CHF.

▼ ***Key Point*** Because many intrathoracic structures are obscured by the presence of pleural effusion, obtain radiographs *after* the removal of pleural fluid to facilitate visualization of such abnormalities as mediastinal mass, cardiomegaly, intrapulmonary lesions (masses, infiltrates, vascular changes), lung lobe torsion, or diaphragmatic hernia (see Table 164-1).

- Both right and left lateral radiographic views of the thorax may be indicated when a unilateral lesion is suspected (e.g., focal fluid accumulation, pulmonary mass or focal density, lung lobe torsion). Horizontal beam radiography (e.g., standing lateral view) can be used to confirm small-volume effusions, to demonstrate fluid encapsulation, and to facilitate visualization of thoracic structures by shifting fluid away from the structures of interest.

Thoracentesis and Fluid Analysis

In most animals with pleural effusion, the combination of radiographic findings and fluid analysis establishes the diagnosis or determines the direction for additional diagnostic evaluations. Drainage of the pleural fluid also provides therapeutic benefit and may be lifesaving in patients with hypoxemia.

Thoracentesis

- Thoracentesis is a safe and generally effective method for removal of fluid from the pleural space.

See Chapter 3 for a description of thoracentesis techniques.

- Following the collection of diagnostic specimens, enough fluid should be aspirated to relieve respiratory distress. In some animals it may be difficult to obtain an adequate volume of fluid if the fluid is compartmentalized within the pleural space by adhesions or if it is viscid and full of fibrin or debris. In this case, or if repeated pleural drainage is anticipated, place a thoracostomy tube (see Chapter 3).

Pleural Fluid Analysis

Perform the following analyses on the pleural fluid.

- Perform cytologic examination of direct smears and centrifuged cell concentrate smears stained with routine hematologic stains. In scanty aspirates, smears for cytologic examination are the first priority.
- Measure total nucleated cell count (differentiates transudates from exudates).
- Determine physical and biochemical characteristics, such as color, turbidity (correlates with nucleated cell count in non-chylous fluids), odor (foul odor suggests pyothorax), specific gravity and total protein concentration (differentiates transudates from exudates), viscosity and clot formation (indicates fibrinous exudate as in feline infectious peritonitis [FIP]), and presence of chylomicrons (tests for triglyceride indicate chylous effusion).
- Consider non-routine chemical analyses; e.g., pH (<6.9 in pyothorax), glucose (<10 mg/dl in pyothorax), lactic dehydrogenase (>200 IU/L in exudates), adenosine deaminase (elevated in inflammatory exudates), and fibronectin (elevated in neoplastic effusion).
- If infection is suspected, consider Gram stain, acid-fast stain, culture and sensitivity testing for aerobic and anaerobic bacteria, and, in some cases, culture for fungi.
- If FIP is a possibility, set aside an aliquot of fluid in case protein electrophoresis and a polymerase chain reaction test are later warranted based on preliminary findings (see under Feline Infectious Peritonitis).

Classification of Pleural Fluid Patterns

On the basis of these analyses, pleural effusions are generally classified into one of several patterns: transudate, modified transudate, nonseptic exudate, septic exudate, chylous effusion, or hemorrhage (Table 164-2). In addition, any of these can be subcategorized as neoplastic versus non-neoplastic depending on whether or not neoplastic cells are present on cytologic evaluation. There can be considerable overlap between these various categories; nevertheless, they are helpful for understanding the pathogenesis and determining the cause of pleural effusions.

Transudate

Transudative effusions are generally associated with alteration of capillary hydrostatic pressure caused by CHF or decreased plasma colloidal osmotic pressure caused by hypoalbuminemia. The typical features of a pure transudate are low protein concentration and low cell count consisting predominantly of mesothelial cells; this is comparable to the characteristics of normal pleural fluid.

Modified Transudate

Long-standing transudative effusions often become modified transudates, as they acquire greater cellularity and protein content. Modified transudates and nonseptic exudates can be very similar.

Table 164-2. PLEURAL FLUID ANALYSIS PATTERNS*

Fluid Category	TP	WBC/μl	Disease Associations
Transudate	<1.5	<1,000	CHF (early); hypoproteinemia
Modified transudate	2.5–5	1,000–7,000	CHF; neoplasia (e.g., lymphoma); diaphragmatic hernia; pulmonary thromboembolism
Nonseptic exudate	3–6	5,000–20,000	FIP; neoplasia; diaphragmatic hernia; lung lobe torsion; pancreatitis; pulmonary thromboembolism
Septic exudate	3–7	5,000–300,000	Septic pleuritis (pyothorax)
Chylous effusion	2.5–6	1,000–20,000	CHF; lymphoma; thoracic lymphangiectasia; heartworms; jugular vein thrombosis (catheter-induced); diaphragmatic hernia; lung lobe torsion
Hemorrhage	>3.0	5,000–20,000	Trauma, coagulopathy, neoplasia, lung lobe torsion

TP, total protein (g/dl).
*The six basic fluid patterns and their most frequent clinical associations are indicated. Any of these can be subcategorized as neoplastic if neoplastic cells are present on cytologic evaluation.

Septic Exudate

Septic exudates are purulent effusions consisting of numerous degenerating neutrophils, usually in association with intra- and extracellular bacteria. The fluid usually has marked turbidity, high protein concentration, and a foul odor, whereas the color is variable. The presence of a septic exudate within the pleural space indicates septic pleuritis (pyothorax) and is an indication for culture and Gram stain of the effusion (see under Pyothorax).

Nonseptic Exudate

Nonseptic inflammation and disorders that cause lymphatic or venous obstruction, such as neoplasia, diaphragmatic hernia, lung lobe torsion, pulmonary infarction, and thymic branchial cysts may result in a nonseptic exudative effusion that is difficult to distinguish from a modified transudate. Some clinicians subclassify such effusions as neoplastic effusions if neoplastic cells are evident cytologically.

- *Feline infectious peritonitis* causes a nonseptic pyogranulomatous exudate that has fairly distinctive characteristics—yellow and translucent in appearance with a viscous consistency, high protein concentration (approximating serum levels), high fibrin content, and low-to-moderate cellularity consisting mostly of non-degenerate neutrophils and macrophages (see under Feline Infectious Peritonitis; see also Chapter 10). If FIP is suspected, consider performing protein electrophoresis of the fluid. If gamma globulin is greater than 32% of the protein in effusates, FIP is strongly considered; conversely, if more than 48% of protein is albumin or if the albumin-to-globulin ratio is greater than 0.81, FIP is unlikely.
- *Eosinophilic effusion* (>10% eosinophils) can be either an exudate or modified transudate. The most frequent cause has been intrathoracic neoplasia (e.g., systemic mastocytosis, lymphoma). Eosinophilic pleural effusion has also been associated with heartworm disease, allergy, bronchointerstitial lung disease, eosinophilic granulomatosis, and trauma.

Chylous Effusion

Chylous effusions are caused by extravasation or leakage of intestinal lymph (chyle) from an obstructed or ruptured thoracic duct. Chylothorax in dogs and cats may be idiopathic or associated with trauma, thoracic lymphangiectasia, intrathoracic neoplasia, heart disease, heartworms, venous thrombosis, diaphragmatic hernia, or lung lobe torsion (see under Chylothorax). The milky white opaque fluid contains mostly lymphocytes accompanied by variable numbers of neutrophils, depending on the duration of the effusion and the extent of the resulting pleuritis (see Table 164-2). Chylous effusions are confirmed by the presence of chylomicrons, which can be demonstrated by the ether clearance test, by the presence of a cream layer on refrigeration, and microscopically by the presence of Sudan-positive orange fat droplets, but these are relatively insensitive methods.

▼ ***Key Point*** The most reliable test for chylous effusion is the comparison of the triglyceride and cholesterol concentrations measured simultaneously in the fluid and serum. Chylous effusion is characterized by a high triglyceride concentration (usually >300 mg/dl) compared with that of serum and a pleural fluid cholesterol-to-triglyceride ratio of less than 1. The fluid cholesterol concentration is less than or equal to that of serum.

Hemorrhagic Effusion

Hemorrhage into the pleural space may be associated with trauma, hemostatic abnormalities, or neoplasia. The physicochemical and cytologic features of the effusion are similar to those of defibrinated peripheral blood. The presence of erythrophagocytosis by macrophages confirms that the hemorrhage is not merely the result of a traumatic collection.

Laboratory Evaluations

Various laboratory evaluations may provide useful diagnostic information depending on the suspected underlying cause of pleural effusion.

- The complete blood count may reveal a neutrophilia with a left shift in pyothorax, FIP, lung lobe torsion, and neoplasia. Lymphopenia is common in animals with chylothorax, but it can also be a nonspecific manifestation of stress. Anemia and various other hematologic abnormalities may be associated with lymphoma and feline leukemia virus (FeLV).
- Serum protein determinations may reveal hypoalbuminemia, a cause of transudation, or hyperglobulinemia, a common finding in FIP and other conditions of chronic immune stimulation. Severe proteinuria would be expected on the urinalysis of a dog or cat with hypoalbuminemia and transudation associated with nephrotic syndrome.
- Diagnostic testing may be indicated for infectious and parasitic diseases that have been associated with pleural effusion, such as FeLV, feline immunodeficiency virus (FIV), FIP, heartworm disease, and aelurostrongylosis. Specific aspects of these various diagnostic tests are described in the appropriate chapters elsewhere in this book.
- In cats with cardiogenic pleural effusion, the serum concentrations of thyroxine and taurine may be indicated for the diagnosis of hyperthyroid cardiomyopathy and taurine-deficient cardiomyopathy, respectively (see Chapter 150).

Cardiac Evaluations

- Echocardiography is the most useful procedure for diagnosis of cardiogenic causes of pleural effusion such as cardiomyopathy (idiopathic, taurine deficiency, hyperthyroidism), pericardial diseases (pericarditis, neoplasia), congenital heart defects, and heartworm disease.
- Angiocardiography is also helpful for determining the underlying cardiac abnormality in selected cases of cardiogenic pleural effusion. A detailed discussion of cardiac evaluation is found in Chapters 142 and 143.

Ultrasonography

The inability of ultrasound to penetrate air-filled structures limits the diagnostic usefulness of ultrasound examination of the lungs; however, in animals with pleural effusion, ultrasonography can provide meaningful information because the pleural fluid provides an "acoustic window" for transmission. Thoracic ultrasonography is possible when an air-filled lung is collapsed, displaced (by fluid, mass, or herniated abdominal viscera), replaced (by neoplastic tissue), or consolidated. Because the presence of pleural fluid actually enhances ultrasound transmission, it is preferable to perform the procedure prior to evacuation of the pleural fluid.

- Pleural fluid usually appears as an anechoic or hypoechoic space between the thoracic wall or diaphragm and lung. The fluid in pyothorax and hemothorax may contain internal echoes.
- In addition to confirming pleural effusion, ultrasonography is helpful for the diagnosis of pulmonary, mediastinal, and pleural neoplasms; pulmonary abscesses associated with pyothorax; lung lobe torsion; cardiac abnormalities; and diaphragmatic hernia.
- Ultrasonography can also be used to guide needle placement accurately for fine-needle aspiration or biopsy of pleural, mediastinal, and pulmonary masses.

Specialized Imaging Techniques

Depending on the suspected etiology of the pleural effusion and the results of other diagnostic evaluations, specialized imaging techniques may be indicated, such as contrast radiographic procedures (contrast peritoneography for the diagnosis of diaphragmatic hernia, contrast lymphangiography for the diagnosis of chylothorax, contrast pleurography), lymphoscintigraphy, and CT.

Positive Contrast Peritoneography

When diaphragmatic hernia is suspected but cannot be confirmed on routine thoracic and abdominal radiographs, ultrasonography should be the next approach; however, if ultrasound is unavailable, positive contrast peritoneography is an alternative method for diagnosis of diaphragmatic hernia. Inject an aqueous contrast iodide (Renovist; 1 ml/kg) into the peritoneal cavity, and roll the animal from side to side for several minutes to distribute the contrast agent. Obtain radiographs to determine whether the contrast agent has entered the pleural space through a defect in the diaphragm.

Lymphangiography

Positive-contrast lymphangiography is used to evaluate the thoracic duct lymphatic channel in dogs and cats with unexplained chylous effusion. This is usually done by catheterizing an intestinal lymphatic just prior to, and in preparation for, surgical ligation of the thoracic duct to treat chylothorax. The reader is directed to surgical clinical literature and texts for a technical description of this procedure.

SPECIFIC DISEASES

Pyothorax (Septic Pleuritis)

Pyothorax is the accumulation of purulent exudate (pus) within the pleural space as a result of intrapleural bacterial infection (septic pleuritis) or, rarely, mycotic infection.

Etiology

Microorganisms

A diversity of microorganisms has been isolated from the pleural fluid of dogs and cats with pyothorax; mixed bacterial infections composed mostly of obligate and facultative anaerobes are found most consistently.

- In many cases, the infection consists entirely of anaerobic bacteria. The most frequent isolates are *Bacteroides* spp., *Clostridium* spp., *Peptostreptococcus* spp., *Fusobacterium* spp., *Pasteurella multocida,* and *Actinomyces* spp. The isolates from cats with pyothorax and their relative frequency closely resemble those found in subcutaneous cat bite abscesses and mirror the normal oropharyngeal flora of the cat.
- Other bacteria found sporadically include *Pseudomonas* spp., *Escherichia coli, Klebsiella* spp., *Proteus* spp., *Streptococcus* spp., *Staphylococcus* spp., *Corynebacterium pyogenes, Nocardia* spp., *Borrelia* spp., *Eubacterium* spp., and mycoplasmas.
- Fungi, such as *Cryptococcus neoformans, Blastomyces dermatitidis,* and *Candida albicans,* are rare causes.
- In addition, pleuritis has been reported as a rare manifestation of infection with Aelurostrongylus abstrusus, the feline lungworm.

Source of Infection

The source of infection is not identified in most dogs and cats with pyothorax. Microorganisms may poten-

tially enter the pleural space through penetrating chest wounds (e.g., bite wounds), perforations of mediastinal structures (i.e., esophagus, trachea, bronchi), migrating pleural foreign bodies (e.g., grass awns), and direct extension from the lung in bacterial pneumonia (parapneumonic effusion). Mediastinitis, pleuritis, and pyothorax are frequent complications of esophageal perforation caused by esophageal foreign bodies, especially those with irregular sharp edges, such as plastic, glass, wood, and bone. Iatrogenic esophageal rupture can occur during endoscopic foreign body retrieval or during balloon dilation of esophageal strictures. Intrapleural infection can also result from hematogenous or lymphatic spread from distant infection sites.

Clinical Signs

Dyspnea is the most consistent sign of pyothorax. Cough is observed in some cases. In addition, nonspecific systemic signs are common, including inactivity, exercise intolerance, fever, depression, anorexia, dehydration, weight loss, and pallor. Advanced cases may present in a moribund state with endotoxic shock and hypothermia.

Diagnosis

- Physical findings (auscultation and percussion) and radiographic findings in pyothorax are typical of pleural effusion. In some animals with pyothorax, the pleural fluid may become encapsulated or compartmentalized by fibrinous adhesions and fibrosis (walling-off process), producing radiographic signs of unilateral or non-gravitating effusion and rounded lobar edges.
- The hematologic findings in pyothorax are typical of a serious septic inflammatory process and support the diagnosis. A neutrophilic leukocytosis with a left shift and with toxic-appearing neutrophils are found in most cases, while a neutropenia with a degenerative left shift may develop terminally. The hemogram also usually reveals a mild to moderate nonregenerative, normochromic, normocytic anemia of chronic infection.
- Confirm the diagnosis of pyothorax with pleural fluid analysis, which indicates septic inflammatory (purulent) exudate. The fluid is usually malodorous and cloudy or opaque, with color varying from red to brown to yellow. The fluid also may contain a flocculent sediment of fibrinous and cellular debris. The total protein concentration generally exceeds 4.5 g/dl and there are usually 50,000 to 100,000 or more nucleated cells/µl, consisting of mostly (greater than 85%) degenerating neutrophils. Cytologic examination usually reveals abundant intra- and extracellular bacteria.
- Culture the pleural fluid for confirmation of the diagnosis and for determination of optimal antibacterial therapy. In most cases, a mixed infection (see earlier, under Etiology) involving primarily anaerobic bacteria is found. If only routine aerobic culture techniques are used, only the aerobic component of the infection will be identified, and because some dogs and cats with pyothorax have an exclusively anaerobic infection, there may be no growth at all. Thus, perform both aerobic and anaerobic cultures.
- Because retroviral status may influence prognosis, test cats with pyothorax for FeLV (see Chapter 8) and FIV (see Chapter 9).

Treatment

Treat pyothorax with systemic antibiotics, closed-chest drainage, and lavage by means of an indwelling chest tube thoracostomy (see elsewhere for thoracic tube placement). The chest tube provides for repeated drainage and irrigation of the pleural space.

Antibiotics

Start antibiotic therapy intravenously and then continue orally at home for at least 4 to 6 weeks. Until the results of culture and sensitivity of the effusion are available, assume that a mixed anaerobic and aerobic infection is present (see earlier, under Etiology). Most isolates are susceptible to antibiotics of the penicillin family, such as penicillin G, ampicillin, amoxicillin, or amoxicillin with clavulanate; thus, standard dosages of any one of these are a good initial choice (see Table 164-3), although approximately 20% of anaerobes may be resistant to the penicillin-ampicillin group. Other effective antibiotics for anaerobic infections include clindamycin and metronidazole (see Table 164-3). For gram-negative infections, add an aminoglycoside (amikacin), enrofloxacin, or trimethoprim-sulfadiazine. Trimethoprim-sulfadiazine is indicated for *Nocardia* spp.

Pleural Drainage and Lavage

Place a thoracic drainage tube to drain purulent material from the pleural space and allow lavage of the pleural cavity. Although some animals with severe effusion may require continuous chest drainage, intermittent drainage is adequate for most patients.

- Perform thoracic drainage at least twice daily. For pleural lavage use sterile isotonic saline or lactated Ringer's solution warmed to body temperature. Prior to each irrigation procedure, evacuate any fluid that has accumulated since the previous lavage and record the quantity. Warm the irrigation solution to body temperature and infuse 10 to 20 ml/kg body weight slowly over about 5 minutes through the chest tube. If respiratory distress occurs, stop the infusion.
- Leave the solution in the thorax for 5 to 10 minutes while the animal is gently rolled to enhance distribution; then aspirate as much as possible. A return of 75% or more of the irrigation solution is expected, which can sometimes be facilitated by repositioning

Table 164-3. USEFUL ANTIBIOTICS FOR TREATMENT OF PYOTHORAX

Antibiotic	Trade Name	Dosage	Indications
Penicillin G	generic	20,000–40,000 U/kg q6–8h IV IM	anaerobes,* *Pasteurella, Actinomyces*
Ampicillin	Omnipen	20 mg/kg q6–8h IV IM SC	anaerobes,* *Pasteurella* and some other gram negatives
Amoxicillin	Amoxi-Tabs	20 mg/kg q8–12h PO	anaerobes,* *Pasteurella* and some other gram negatives
Amoxicillin/clavulanate	Clavamox	20 mg/kg q12h PO	anaerobes,† *Pasteurella* and many other gram negatives
Chloramphenicol	Chloromycetin	50 mg total/cat q12h IV SC PO	anaerobes,† gram-positive and gram-negative aerobes
Clindamycin	Antirobe	10 mg/kg q12h PO	anaerobes†
Metronidazole	Flagyl	10–15 mg/kg q8–12h PO IV	anaerobes†
Enrofloxacin§¶	Baytril	*Dogs:* 5 mg/kg q12h PO, IV, SC; *Cats:* 5 mg/kg q24h PO, IV, SC	most gram-negative and gram-positive aerobes
Trimethoprim-sulfadiazine	Tribrissen	15 mg/kg q12h PO	*Nocardia*
Amikacin‡	Amiglyde-V	10 mg/kg q8–12h IV IM SC	gram negatives§
Cefoxitin	Mefoxin	20–30 mg/kg q8h IV IM	anaerobes,† gram-negatives
Ticarcillin	Ticar	30–50 mg/kg q6h IV IM	anaerobes,† gram-negatives, *Pseudomonas*

*Excluding Bacteroides fragilis.
†Including most penicillin-resistant strains of Bacteroides fragilis.
‡Caution: uncorrected dehydration may potentiate aminoglycoside nephrotoxicity.
§Enrofloxacin and aminoglycosides are ineffective against anaerobes; thus, always use in combination with penicillin or other antibiotic with activity against anaerobes when treating pyothorax.
¶Doses exceeding 5 mg/kg daily are retinotoxic in cats and may cause blindness.

the animal or rolling it from side to side during aspiration.

- If the animal is initially dehydrated, rehydration should be accomplished before, or simultaneous to, the first lavage; otherwise, much of the instilled fluid will be absorbed from the pleural space with very little returned on aspiration.
- Obtain samples of interlavage fluid for cytologic examination on a daily basis and examine for disappearance of microorganisms and degenerative neutrophils. Remove the chest tube once the interlavage pleural fluid becomes characteristic of a modified transudate (clear in appearance and free of microorganisms and degenerative neutrophils) and the quantity that accumulates is small and can be accounted for merely by the presence of the drain itself (i.e., up to 2–3 ml/kg/day). There should also be radiographic resolution of pleural effusion.
- The duration of the pleural drainage phase of therapy in most cases is 4 to 7 days. Monitor serum proteins and electrolytes (especially potassium) because depletion can occur with prolonged lavage. Evaluate thoracic radiographs about 1 week following tube removal to ensure resolution, and continue systemic antibiotics for a minimum of 4 to 6 weeks.

Complications

Adverse sequelae to pyothorax may include restrictive pleuritis, pleural adhesion formation, and pulmonary abscessation. Occasionally, adhesions render closed-chest drainage and lavage ineffective. In such cases, perform a thoracotomy (see Chapter 167) to manually break down adhesions, drain pockets of exudate, remove debris, and place a drainage tube in the most favorable location for postoperative thoracic lavage. In addition, thoracotomy may be necessary if a migrating pleural foreign body is suspected.

Chylothorax

Etiology

Chylothorax results from the leakage or extravasation of chylomicron-laden intestinal lymph (chyle) into the pleural space from an obstructed, ruptured, or anomalous thoracic duct or its collateral branches. The cause of chylothorax is frequently not apparent; however, chylous pleural effusions in dogs and cats have been associated with lymphangiectasia of intrathoracic lymphatics (resulting from obstruction of thoracic duct inflow into the cranial vena cava), traumatic rupture of the thoracic duct, intrathoracic neoplasia (mediastinal lymphoma, thymoma), heart disease (cardiomyopathy, heartworms, hyperthyroidism, pericarditis), diaphragmatic hernia, peritoneopericardial diaphragmatic hernia, lung lobe torsion, and vena caval thromboembolism (iatrogenic from indwelling jugular venous catheterization). Idiopathic chylothorax has a predilection for Afghan hounds, Smiba Inus, and Oriental cat breeds (Siamese, Himalayan).

Clinical Signs

In addition to typical signs of pleural effusion, such as dyspnea and tachypnea, it is noteworthy that dogs and cats with chylothorax often present with coughing.

Diagnosis

- Confirmation that pleural fluid is chyle depends on demonstration of the presence of chylomicrons. The most reliable criteria for chyle are an increased concentration of triglycerides in the fluid compared with serum and a fluid cholesterol-to-triglyceride ratio of less than 1 (see under Classification of Pleural Fluid Patterns).
- In the veterinary literature, many milky effusions have been called pseudochylous (which implies lipid in the form of cholesterol and lecithin derived from degenerating cells) when, in fact, if triglyceride analysis had been performed, these effusions would probably have been true chyle.
- The predominant cell in chyle is usually the small lymphocyte. However, over time the irritant effect of chyle results in an influx of inflammatory cells, especially neutrophils.
- Once chylothorax is confirmed, use routine radiography and other clinical evaluations (e.g., ultrasonography, echocardiography, heartworm testing) to search for underlying causes, such as heart disease, heartworms, neoplasia, or diaphragmatic hernia.

Medical Treatment

- If an underlying cause is identified, treatment is directed toward the underlying primary disorder. In the rare case when there is a history of recent thoracic trauma, conservative medical management may be tried for a 2-week period in hopes of spontaneous healing of the injured lymphatic. This consists of (1) pleural drainage by either periodic thoracentesis or continuous chest tube drainage, and (2) decreasing thoracic duct flow by exercise restriction (cage rest).
- A fat-restricted diet supplemented with medium-chain triglycerides (MCTs) has been recommended in the past; however, this has not been effective clinically, and in normal dogs it has been shown experimentally that altering dietary fat content or using MCTs does not significantly affect thoracic duct lymph flow and that orally administered MCTs are carried in thoracic duct lymph.
- Anecdotal reports have indicated some success with the administration of a benzopyrone compound, Rutin (50mg/kg PO q8h). The proposed mechanisms of action of rutin include reducing leakage from blood vessels, increasing protein removal by lymphatic vessels, increasing the macrophage phagocytosis of chyle, increasing tissue macrophage numbers, and increasing proteolysis and removal of protein from tissues. However, clinical results from the use of this drug for dogs and cats with chylothorax have been inconsistent.

Surgical Treatment

- If no underlying medically treatable cause of chylothorax is found, surgical intervention is indicated. The surgical approach to treatment of chylothorax involves ligation of the thoracic duct at the level of the diaphragm in association with evaluation of the thoracic duct and intrathoracic lymphatics by pre- and immediate postoperative contrast lymphangiography. Lymphangiography is performed by cannulating a mesenteric lymphatic vessel via a flank abdominal approach. After delineating the thoracic duct and its branches with the dye study, the duct is ligated via a 10th intercostal space thoracotomy (right side in dogs, left side in cats). Ligate the duct as close to the diaphragm as possible, and be sure to occlude all branches. Postligation lymphangiography then confirms complete occlusion of the thoracic duct system. The details of these procedures are provided in Chapter 167.
- The reported success rate of this procedure varies from 20% to 60% in cats and 55–60% in dogs. Commercially available pump devices (e.g., Hakim-Cordis ventricular-peritoneal catheter, Cordis Corporation, Miami, FL; double-valve Denver peritoneal-venous catheter, Denver Biomaterials Inc., Evergreen, CO) are available for active pleuroperitoneal shunting of chylous effusion in refractory chylothorax. Disadvantages of shunt devices are that they are expensive, they are easily occluded, they require considerable owner compliance, and the complication rate is high.
- Recent clinical studies have shown improved results of surgical treatment when thoracic duct ligation is combined with partial pericardectomy. Although the reason for treatment successes with pericardectomy are unclear, subtle changes in thoracic venous and/or lymphatic pressures could account for the cessation of effusion due to improved flow through thoracic duct lymphatics. The authors currently create a pericardial window in conjunction with thoracic duct ligation for chylothorax in dogs and cats.
- When chylothorax is unresponsive to thoracic duct ligation or shunt procedures, pleurodesis using intrapleural instillation of a sclerosing agent such as tetracycline or sterile talc may be palliative. Pleurodesis is intended to reduce or stop pleural effusion by causing diffuse adhesions between the parietal and visceral pleura. It is an effective technique in humans but has not been efficacious in dogs, either with experimental or spontaneous effusion.

Complications

Chronic diffuse fibrosing pleuritis is a sequela of chylothorax that may cause constriction and collapse of lung lobes and restrict the expandability of the lungs. Radiographically, fibrosing pleuritis is indicated by rounded lung lobe borders and atelectasis of cranial or middle lobes. The atelectatic lobes may be mistaken for pulmonary masses, hilar masses, or lung lobe torsion. In order to avoid excessive pleural fibrosis, surgical

intervention in animals with chylothorax, especially cats, should not be delayed. Surgical removal of the layer of fibrin and fibrotic reaction covering the visceral pleura, a process called decortication, is difficult in cats and usually results in significant laceration of underlying lung tissue that requires continuous pleural drainage for postoperative pneumothorax and effusion.

Feline Infectious Peritonitis

Etiology

Feline infectious peritonitis is a highly fatal chronic progressive coronaviral infection of cats characterized by widespread immune complex-mediated vasculitis and pyogranulomatous inflammation (see Chapter 10 for a comprehensive description of the disease). In the effusive form of FIP, exudative peritonitis or pleuritis may occur.

Clinical Signs

Pleural involvement is manifested as dyspnea and by other signs of pleural effusion, often accompanied by nonspecific signs such as anorexia, depression, fever, and pallor. Pericardial effusion due to fibrinous pericarditis may accompany pleural FIP and is detectable by echocardiography, but only rarely is this extensive enough to cause cardiac tamponade.

Diagnosis

- The diagnosis can usually be established by analysis of a specimen of pleural fluid obtained by thoracentesis. The fluid of FIP is a nonseptic exudate, often described as pyogranulomatous or fibrinous. It is typically pale yellow to golden in color, is nearly translucent because of its relatively low cell count (usually 1,000–10,000 nucleated cells/μl), and is foamy because of its high protein content. The fluid of FIP may seem viscous, tenacious, and sticky, and it may contain flecks, strands, or clots of fibrin. The concentration of protein often approaches that of serum, ranging from 4 to 10 g/dl. Fluid protein electrophoresis is a reliable diagnostic indicator of FIP when gamma globulin composes more than 32% of the protein, albumin is less than 48% of the protein, and the albumin-to-globulin ratio is less than 0.81. A somewhat distinctive mixture of inflammatory cells characterizes the pyogranulomatous nature of FIP exudate, with non-degenerate neutrophils and macrophages predominating, but also including plasma cells and lymphocytes.
- Ancillary laboratory findings that may support the diagnosis of FIP include neutrophilic leukocytosis, neutropenia, lymphopenia, normocytic-normochromic nonregenerative anemia, and hyperglobulinemia.
- A high serum titer of anti-coronaviral antibody indicates the possibility of FIP but is not a confirmatory test. A polymerase chain reaction (PCR) test for coronavirus in pleural fluid is a useful diagnostic aid (low sensitivity but high specificity) providing that a validated assay is used. Also use fluid immunostaining.

Treatment

In general, the results of treatments for FIP have been disappointing, and the prognosis is considered poor. Nevertheless, occasional remissions have been obtained with immunosuppressive therapy and with drainage of the intrapleural exudate (see Chapter 10).

Congestive Heart Failure

Etiology

Pleural effusion can be a manifestation of CHF in dogs and cats (Chapter 147). It is most commonly associated with cardiomyopathy (see Chapter 150), but also occurs with cardiac arrhythmias, congenital cardiac defects, pericardial diseases, heartworm disease, and hyperthyroid cardiomyopathy. Although pleural effusion is considered primarily a sign of right-sided CHF, animals with severe or chronic left-sided failure also develop pleural effusion.

Clinical Signs

In animals with pleural effusion due to heart disease, presenting signs often include tachypnea, dyspnea, depression, inactivity, and weakness. Anorexia and vomiting may also be observed. Physical findings that may indicate a cardiogenic cause for pleural effusion include:

- Signs of low cardiac output, such as pallor, hypothermia, cold extremities and pinnae, and weak femoral pulses
- Jugular venous distention, jugular pulsation, or positive hepatojugular reflex
- Concurrent hepatomegaly (due to hepatic congestion) or ascites (although, unlike dogs, cats rarely develop significant ascites from CHF)
- Abnormalities of cardiac auscultation, such as murmurs, diastolic gallops, or arrhythmias
- Ophthalmoscopic lesions of taurine-deficient retinopathy in cats (see Chapter 138)
- A palpable thyroid nodule in hyperthyroid cats

Diagnosis

The diagnosis of cardiogenic pleural effusion can be difficult because the effusion may muffle the heart sounds on auscultation and obscure the cardiac silhouette on thoracic radiographs.

- Radiographic findings that suggest pleural effusion is associated with CHF include cardiomegaly, pulmonary infiltrates (edema), pulmonary venous distention, distended caudal vena cava, and hepato-

megaly. In many cases, these findings are more apparent on radiographs taken after fluid has been drained from the pleural space.
- Pleural fluid analysis may determine the effusate to be a transudate, modified transudate, or chylous effusion, the predominant cells being erythrocytes, mesothelial cells, and small lymphocytes.
- Echocardiography is often and sometimes angiocardiography, may be necessary to confirm and assess cardiac disease. Cardiac arrhythmias and conduction disturbances are evaluated electrocardiographically.

Treatment

The treatment options for CHF as described in Chapter 147 are used for control of cardiogenic pleural effusion.

Intrathoracic Neoplasia

Etiology

Intrathoracic neoplasia is one of the most common causes of pleural effusion in dogs and cats. Causes of neoplastic pleural effusion include mediastinal lymphoma and thymoma, primary and metastatic pulmonary neoplasia (see Chapter 165), and malignant pleural mesothelioma. The mechanism of pleural effusion in these conditions generally involves hemolymphatic obstruction.

Diagnosis

- Use radiography (both right and left lateral views) and ultrasonography to characterize or identify the location of an intrathoracic mass (see Chapter 159).
- The fluid can vary from modified transudate to nonseptic exudate to chylous effusion. Lymphoma is usually diagnosed cytologically. Confirmation of nonlymphomatous intrathoracic neoplasia can be a diagnostic challenge requiring biopsy by thoracoscopy or thoracotomy. Clumps of reactive mesothelial cells exfoliate into all pleural effusions and are easily mistaken for neoplastic cells, especially carcinoma cells. Ideally, similar-appearing cells should be aspirated from pulmonary or intrathoracic masses before a definitive diagnosis of neoplasia is made. Conversely, many primary and metastatic tumors do not exfoliate cells into pleural fluid; thus, an absence of neoplastic cells in pleural effusion does not necessarily exclude neoplasia as the cause.

Treatment

Chemotherapy for mediastinal lymphoma is discussed in Chapter 27. The surgical aspects of intrathoracic neoplasia (thoracotomy, lobectomy) are discussed in Chapter 167.

Hemothorax

Etiology

- Hemothorax, the accumulation of blood within the pleural space, may be associated with any form of thoracic trauma that lacerates the lung parenchyma or ruptures intrathoracic vessels (see Chapter 166). It can also be caused by disorders of hemostasis (see Chapter 23) or by intrathoracic neoplasms that rupture or erode into vessels. Lung lobe torsion and pulmonary infarction are rare causes.
- The seriousness of hemothorax depends on the rate and volume of blood loss. Bleeding from the venous circulation or the low-pressure pulmonary arterial circulation is usually self-limiting, whereas bleeding from high-pressure systemic arteries, such as the intercostal or bronchoesophageal arteries, may be more severe. Hemorrhage due to injury of the heart or great vessels results in massive hemothorax that is rapidly fatal.
- The two major consequences of hemothorax are shock due to loss of circulating blood volume into the pleural space and ventilatory impairment due to fluid compression of the lung. As a general rule, in rapidly developing hemothorax, fatal circulatory failure (exsanguination) occurs before the volume of pleural fluid that accumulates is sufficient to cause serious respiratory compromise. However, blood or fluid replacement therapy in the presence of continued bleeding may lead to greater accumulation of intrapleural fluid, resulting in severe lung compression and ventilatory failure.

Clinical Signs

Clinical signs of hemothorax are attributed to shock and pleural effusion—dyspnea, tachypnea, weakness, pallor, and weak femoral pulses.

Diagnosis

- The heart and lung sounds are usually muffled, and percussion of the ventral thorax may be hyporesonant. In the trauma victim, this is distinguished from the hyperresonance of pneumothorax.
- Confirm intrapleural fluid radiographically.
- Definitive diagnosis is made by aspiration of defibrinated (non-clotting) blood from the pleural space. Blood clots rapidly (within 45 minutes) in the pleural space; thus, unless there is ongoing or very recent bleeding, the aspirated hemorrhagic effusion will not clot or contain platelets.

Treatment

The treatment of hemothorax involves treatment of shock with intravenous fluids or blood, as well as relief of respiratory distress via thoracentesis if necessary. See

Chapter 166 for more details on treatment of hemothorax.

Lung Lobe Torsion

Etiology

Torsions of either the right middle lung lobe or the right or left cranial lung lobe have occasionally been found in dogs and cats with pleural effusions. The mechanism of lung lobe displacement that culminates in torsion is poorly understood. Lung lobe torsion can occur secondary to pleural effusion, or it can be the cause of a serosanguineous effusion.

Clinical Signs

The signs usually include dyspnea, tachypnea, depression, anorexia, and weight loss.

Diagnosis

- The diagnosis of lung lobe torsion is suggested by visualization of a consolidated cranial or middle lung lobe on post-thoracentesis radiographs. Radiographic differential diagnoses for lobar consolidation should include pneumonia, edema, hemorrhage, atelectasis, and neoplasia.
- The pleural fluid may be nonspecific (i.e., nonseptic exudate), or it may reflect the underlying disease state (i.e., chylous, septic, or neoplastic effusion).
- Ultrasonography is helpful for identifying lung lobe torsion in some animals with pleural effusion.
- Confirmation of lung lobe torsion can only be made by thoracotomy in many cases.

Treatment

The treatment is lung lobectomy of the affected lobe (see Chapter 167).

Thymic Branchial Cysts

Branchial cysts develop from vestiges of the fetal branchial arch system. These are rare, but when they develop in the thymus they produce an encapsulated, multilobulated, multicystic mass in the cranial mediastinum that compresses adjacent structures and usually cause pleural effusion. Pleural fluid is blood-tinged and characteristic of a modified transudate (obstructive pattern) or nonseptic exudate. On the basis of their radiographic appearance, thymic branchial cysts must be differentiated from other cranial mediastinal masses such as lymphoma and thymoma (see under Intrathoracic Neoplasia). Because of their cystic nature, branchial cysts should be distinguishable from solid mediastinal masses by ultrasonography. Treat branchial cysts by surgical resection.

Diaphragmatic Hernia

Pleural effusion can be a complication of diaphragmatic hernia, especially when the liver or omentum is incarcerated in the hernia. The effusion can complicate the radiographic diagnosis of diaphragmatic hernia. The pleural fluid is usually a modified transudate, but in some cases it may be blood or chyle. Diaphragmatic hernia is discussed further in Chapter 166.

Pancreatitis-Associated Effusion

Mild transient pleural effusion has occasionally been associated with acute pancreatitis. Accompanying peritoneal effusion may also be present. Pleural effusion is a well-known complication of pancreatitis in humans; the pathogenesis is not fully understood, but it has been attributed to chemical pleuritis associated with toxins and activated pancreatic enzymes such as lipase reaching the pleural cavity via intercommunicating lymphatics. Generalized vascular injury and increased vascular permeability associated with acute pancreatitis may also play a role. The pleural effusion is usually a small volume and self-limiting with resolution of the pancreatitis; thus, no specific treatment is necessary. See Chapter 73 for further discussion of pancreatitis.

Pulmonary Thromboembolism

Pleural effusion can occur in association with pulmonary thromboembolism whenever it is extensive enough to produce infarction and ischemic necrosis of the lung and inflammation of adjacent pleura.

- *Clinical signs* are unresponsive dyspnea and signs of right-sided heart failure.
- Underlying causes of pulmonary thromboembolism include heartworm disease, pulmonary neoplasia, and hypercoagulability caused by septicemia, amyloidosis, hyperadrenocorticism, and immune-mediated hemolysis.
- The effusion is usually a modified transudate or nonseptic exudate, but secondary infection of the infarcted lung can result in a septic effusion.
- Radiographically, blunted pulmonary arteries, hypovascularity of the affected lung, and evidence of right-sided heart enlargement or failure suggest pulmonary thromboembolism; however, the diagnosis can be difficult to document because radiographic abnormalities may be absent or very subtle.
- Specialized procedures such as right ventricular and pulmonary artery pressure measurements, angiography, and radionuclide lung perfusion scan may be required for definitive diagnosis.
- *Treatment* is based on resolving the underlying cause of the thromboembolism (see Chapter 153), providing pleural drainage as needed, supplemental oxygen therapy, and control of secondary bacterial infection.

Chapter

165 Respiratory Neoplasia

Marcia A. Carothers / Francisco J. Alvarez

Neoplasms of the respiratory tract are relatively uncommon in small animals representing 4% to 5% of all neoplasms in the dog and cat. More than 80% of respiratory tract tumors are malignant. In addition to primary tumors affecting the respiratory tract, the lungs are common sites of metastatic neoplasia.

NEOPLASMS OF THE NASAL PASSAGES AND PARANASAL SINUSES

- Neoplasms of the nasal cavity are more common in dogs than in cats and constitute approximately 75% of the respiratory tract tumors in dogs.
- The prevalence of nasal tumors has been reported to be 0.3% to 2.4% in dogs and 4.2% in cats. Approximately 80% of primary nasal tumors are malignant.
- Nasal tumors are likely to originate in the caudal two-thirds of the nasal passages and often invade the sinuses.
- Local invasion of the surrounding tissues is typical of these tumors. Paraneoplasic syndromes are rare and include hypercalcemia (associated with adenocarcinoma) and polycythemia (associated with fibrosarcoma).

Tumor Types

- Histologically, epithelial tumors are most common, representing 60%–75% of all nasal tumors in the dog.

▼ ***Key Point*** Of the tumors that occur most frequently in the dog, adenocarcinomas, squamous cell carcinomas, and undifferentiated carcinomas comprise approximately 66% of intranasal neoplasms. Chondrosarcomas, fibrosarcomas, and osteosarcomas comprise the remaining 33%.

- Nasal transmissible venereal tumors are uncommon, but the presence of such a tumor should always be considered in the differential diagnosis where the disease is endemic.
- Plasma cell tumors, mast cell tumors, and benign tumors are rarely seen in the dog.
- Although nasal tumors are locally invasive and the metastatic rate at the time of diagnosis is generally low, approximately 40% to 50% of patients have distant metastasis at the time of necropsy.
  - Mesenchymal tumors have the lowest rate of metastasis, whereas neuroendocrine tumors and neuroblastomas have the highest rate (80–100%).
  - Regional lymph nodes, brain, lung, and liver are the most common sites of metastasis.
- *In the cat* nasal and paranasal lymphoma are the most common types of malignancies, followed by adenocarcinoma and squamous cell carcinoma. Benign *nasopharyngeal inflammatory polyps* are more common in the cat than in the dog.

Table 165-1 lists tumors of the nasal passages and paranasal sinus occurring in dogs and cats.

▼ ***Key Point*** Malignant nasal tumors usually are locally invasive, with metastasis occurring late in the course of the disease.

Signalment

- Nasal tumors are more common in older animals. Mean ages range from 7 to 12 years in dogs, with chondrosarcomas having the lower mean (7 years) and neuroendocrine tumors having the higher mean (12 years). Cats have reported mean ages of 8 to 10 years.
- There is no sex predilection; however, in one study (Patniak, 1989), male canines had a slight higher predilection (1.8:1.0) than female canines.
- Dolichocephalic and medium- to large-breed dogs are predisposed to developing nasal neoplasms. Canine breeds reported to be at high risk for the development of nasal neoplasms include the Airedale Terrier, Bassett Hound, Old English Sheepdog, Scottish Terrier, Collie, German Shepherd, Keeshond, and German Short-haired Pointer.

History

- The average duration of clinical signs prior to diagnosis is approximately 3 months.

Table 165-1. NEOPLASMS OF THE NASAL PASSAGES AND PARANASAL SINUSES*

Malignant Tumors in Dogs	*Malignant Tumors in Cats*
Adenocarcinoma	Lymphoma
Squamous cell carcinoma	Squamous cell carcinoma
Chondrosarcoma	Adenocarcinoma
Osteosarcoma	Undifferentiated carcinoma
Fibrosarcoma	Neuroblastoma
Lymphoma	Fibrosarcoma
Histiocytic sarcoma or malignant histiocytosis	*Benign Tumors in Dogs and Cats*
Neuroendocrine tumors	Polyps (more common in cats)
Neuroblastoma	Adenoma
Transmissible venereal tumor	Fibroma
	Chondroma

*Listed in decreasing order of frequency.

- Sneezing, nasal discharge, epistaxis, and epiphora are the most common presenting signs.
- A partial response to antibiotic therapy can be observed initially; however, intermittent and progressive signs continue.

Clinical Signs

- Unilateral or bilateral nasal discharge (hemorrhagic, serohemorrhagic, or mucopurulent) and/or ocular discharge are the most common signs noted.
- Sneezing, snoring, or reverse sneezing may also been reported by the owner.
- Facial deformity (e.g., exophthalmos and nasal swelling) is common in dogs with skeletal neoplasms and may occur late in the curse of other types of nasal tumors.
- Seizures, blindness, and behavioral changes may result from invasion of the central nervous system (CNS) by direct extension. CNS involvement has been reported in 20% of the cases and is more common in neuroendocrine tumors and neuroblastomas than in other tumors.

▼ ***Key Point*** Chronic nasal discharge unresponsive to antibiotic therapy is likely to be caused by neoplasia.

Diagnosis

Diagnostic Imaging

- Plain radiographs (occlusal, dorsoventral, open mouth ventrodorsal, lateral, frontal sinuses, and ventrodorsal views) may demonstrate loss of trabecular pattern, increase in soft tissue density, septal destruction or deviation, facial bone destruction, frontal sinus opacification, and/or periosteal bone formation (see Chapters 4 and 159). The open-mouth view is the most useful for evaluating the nasal cavity.
- Computed tomography (CT) or magnetic resonance imaging (MRI) are useful for evaluating the extent of the tumor and for planning radiation therapy.
- Thoracic radiographs are necessary to determine the possibility of distant metastasis to the lungs.

Cytologic and Histopathologic Studies

- Cytologic and/or histopathologic confirmation is diagnostic. Procedures (and their specific uses) include:
  - Antegrade rhinoscopy, often performed with a cystoscope or an arthroscope, can be used for viewing the tumor and for acquiring tissue for cytology, histopathology, and culture.
  - Retrograde rhinoscopy, using a retroflexed endoscope or dental mirror, can demonstrate tumors extending caudal to the posterior choane.
  - Nasal flushes can be used for cytologic identification (see Chapter 160 for technique)
  - Blind biopsy procedures, using a biopsy needle, alligator biopsy forceps, catheter, or polypropylene tube, can be used to obtain diagnostic specimens for cytology-histopathology (see Chapter 160)

▼ ***Key Point*** Premeasure nasal biopsy devices to avoid penetration of the cribriform plate.

- Rhinotomy and nasal exploratory surgery can be used for direct exposure of the tumor and to obtain larger biopsy specimens.
- Transnasal curettage (through nostril) can be used to obtain tissue specimens for cytology and histopathology.
- Lymph node aspirates helps to determine the possibility of metastasis to regional lymph nodes.

Treatment

Radiation Therapy

With radiation therapy, the entire nasal cavity, including the bone, can be treated (cobalt, linear accelerator). The dose and fractionation often used is 40 to 54 Gray (Gy) delivered in 10 to 18 fractions over 2 to 4 weeks.

- Radiation has been shown to increase survival times in dogs and cats with nasal tumors. Orthovoltage (due to low tissue penetration) may be effective only when combined with surgical cytoreduction.
- Brachytherapy (intracavitary radiation), using iridium-192, has been reported to treat nasal tumors. Potential problems are associated with this type of treatment and lower survival times are achieved compared with other forms of radiation.

Complications

The following post-treatment complications have been reported:

- Rhinitis and mucositis may be severe but usually subside within 2 months.
- Nasal discharge and sneezing may persist.
- Ulcerative dermatitis may occur at the irradiated site but generally resolves with topical treatment.
- Ocular complications may include keratoconjunctivitis sicca, corneal ulcers, uveitis, retinal degeneration, and cataract formation.

▼ ***Key Point*** To maximize survival times and reduce complications of radiation therapy, include CT or MRI with radiation therapy to provide optimal treatment fields and minimize exposure to normal tissues (e.g., eyes and brain)

Surgical Cytoreduction

Surgical cytoreduction alone or followed by radiotherapy has been reported, but a high rate of acute and chronic morbidity is also associated. In addition, because survival times for animals treated with surgical cytoreduction alone are similar to that for untreated animals, surgical cytoreduction is rarely indicated.

- Rhinotomy (nasal flap) with curettage or turbinectomy is the most common procedure (see Chapter 160)
- Radiation therapy after surgery is recommended.
- Surgery is the treatment of choice for nasal polyps.

Chemotherapy

- Chemotherapy may be effective in certain tumor types (see Chapter 26 for discussion of chemotherapy).
- Platinum drugs (cisplatin, carboplatin) have been shown to benefit some dogs with nasal carcinoma (response rate <25%), but with short median survival times.
- Single-agent therapy with dactinomycin, doxorubicin, and mitoxantrone has had variable results, but in general are not effective for adenocarcinomas.
- A combination COP protocol (vincristine, cyclophosphamide, prednisone), followed by a maintenance protocol is recommended after radiation therapy for nasal lymphoma in cats and dogs.
- Vincristine, as a single agent, is the treatment of choice for transmissible venereal tumors.

Prognosis

Prognostic factors include histologic type and tumor size. Survival times of 3 to 5 months have been reported for animals with no treatment.

- Prognosis for nasal polyps is good, but recurrence is possible.
- Median survival time for nasal tumors treated with radiation ranges from 8 to 25 months, with 1-year survival from 20% to 80% of the cases and 2-year survival from 10% to 48% of the cases.
- Dogs with chondrosarcomas treated with radiation therapy have longer median survival times than dogs with adenocarcinomas.
- Shorter survival times are reported for squamous cell carcinomas and undifferentiated carcinomas.
- Larger and more extensive tumors have a poorer prognosis than smaller tumors.
- In cats with nasal lymphomas, it has been reported that more than 40% can achieve 1 year and approximately 15% can achieve 2 years of survival.

NEOPLASMS OF THE LARYNX

Table 165-2 lists the types of laryngeal neoplasms seen in dogs and cats. These tumors are uncommon and are usually locally invasive; however, distant metastasis has been reported.

- Malignant neoplasms are more common than benign tumors.
- Oncocytomas, which are usually benign tumors, are the second most common laryngeal neoplasm in dogs. There is speculation that oncocytomas may be a form of rhabdomyoma.
- Feline laryngeal tumors include lymphoma, squamous cell carcinoma, and adenocarcinoma.

Table 165-2. NEOPLASMS OF THE LARYNX

Primary Malignant Tumors in Dogs
Squamous cell carcinoma
Lymphoma
Osteosarcoma
Melanoma
Mast cell tumor
Adenocarcinoma
Chondrosarcoma
Metastatic Tumors in Dogs
Thyroid carcinoma
Lymphoma
Pharyngeal rhabdomyosarcoma
Primary Malignant Tumors in Cats
Lymphoma
Squamous cell carcinoma
Adenocarcinoma
Benign Tumors in Dogs and Cats (Uncommon)
Unilateral polyps, generally inflammatory in origin
Oncocytoma* and rhabdomyoma
Leiomyoma

*The second most common laryngeal tumor in dogs. See text for description.

Signalment

- Laryngeal tumors occur in middle-aged to older animals (5–15 years) with the exception of oncocytomas or rhabdomyomas, which occur in young to middle-aged dogs (2–8 years).
- Males appear to be at increased risk.

History

- Noisy breathing and respiratory distress are the most common complaints reported.
- Exercise intolerance, change in voice, and loss of bark or purr may be noted by the owner.

Clinical Signs

- Inspiratory dyspnea and cyanosis usually occur when the animal is stressed. Laryngeal stridor is common on inspiration.
- Coughing due to aspiration pneumonia may occur secondary to laryngeal dysfunction.
- Palpable laryngeal masses are uncommon except for those patients with rhabdomyomas.

▼ ***Key Point*** Inspiratory dyspnea is the most common sign of laryngeal obstructive disease. Neoplasia must be differentiated from laryngeal paralysis, foreign body, or other upper airway disorder via laryngoscopy.

Diagnosis

- The history and physical findings may suggest laryngeal disease.
- Radiography may demonstrate laryngeal distortion, increased soft tissue density of the larynx, and decreased laryngeal space. Ultrasonography may be useful for identifying mass lesions or secondary functional problems such as laryngeal paralysis.
- Laryngoscopic evaluation (using a laryngoscope or endoscope) may reveal a laryngeal swelling or mass. Differential diagnosis for a mass on the vocal fold includes an inflammatory polyp.
- Biopsy for histopathology provides a definitive diagnosis. Biopsy with alligator biopsy forceps, needle biopsy instruments, or bronchoscopic biopsy forceps is usually successful in obtaining a diagnosis.

Treatment

Surgery

- Surgical excision may be curative if the tumor is benign, but is only palliative for malignant disease.
- Complete laryngectomy with a permanent tracheostomy (see Chapter 161) has been done rarely in veterinary medicine because of associated complications.

Radiation Therapy

Radiation may be beneficial in the treatment of some laryngeal tumors (e.g., mast cell tumor and lymphoma).

Chemotherapy

- Lymphoma usually responds to combination therapy (see Chapter 27) but little information is available concerning laryngeal lymphoma.
- Other tumors may respond to chemotherapy (mast cell tumors, some carcinomas, and grade 2 and 3 sarcomas).

Prognosis

The prognosis for most laryngeal tumors is guarded because advanced disease usually is present at the time of diagnosis. However, if tumors are benign (e.g., polyps, oncocytomas, or rhabdomyomas) the prognosis is good with surgical excision.

NEOPLASMS OF THE TRACHEA

Tracheal tumors are rare in dogs and cats. See Table 165-3 for common types of tumors.

Signalment

- Young animals are at higher risk for osteochondromas; these usually are benign.

▼ ***Key Point*** Tracheal tumors are rare. Consider them malignant in older animals.

History

- Exercise intolerance, panting, and cough may be present for weeks before presentation.

Table 165-3. NEOPLASMS OF THE TRACHEA

Malignant Tumors in Dogs
Osteosarcoma
Chondrosarcoma
Lymphoma
Mast cell tumor
Adenocarcinoma
Malignant Tumors in Cats
Adenocarcinoma
Lymphoma
Squamous cell carcinoma
Benign Tumors in Dogs and Cats
Osteochondroma (dogs)
Leiomyoma
Polyps
Eosinophillic granuloma (cats)
Nodular amyloidosis (dogs)

Clinical Signs

- Cough, usually non-productive, is the most common sign.
- Stridor, usually inspiratory, may be noticed during exercise or panting.
- Tumors located at the carina cause both inspiratory and expiratory respiratory distress.
- Cyanosis, dyspnea, and collapse may occur with severe obstruction.

Diagnosis

- Radiography may demonstrate a soft tissue density within the tracheal lumen or decrease in lumen size.
- Tracheoscopy/bronchoscopy may be needed to reveal a tracheal mass.
- Biopsy and histopathology are diagnostic.
- In young dogs, consider Oslerus (Filaroides) osleri in the differential diagnosis.

Treatment

Surgical Excision

Surgery is the primary treatment for tracheal masses (see Chapter 161)

- Benign lesions may be cured with surgical resection.
- Tracheal resection and end-to-end anastomosis are usually the most appropriate surgical treatments (see Chapter 161).

Chemotherapy

- Local laryngeal lymphoma in dogs and cats can be treated with surgery or radiation therapy followed by a chemotherapy protocol.

Prognosis

- Benign tumors respond well to surgical excision.
- Complete remission can be achieved with tracheal lymphoma using chemotherapy with or without radiation or surgery.

NEOPLASMS OF THE LUNG

Primary pulmonary neoplasms represent approximately 1.2% and 0.5% of all tumors in the dog and cat, respectively. Primary lung tumors may metastasize to bronchial lymph nodes, lung, brain, bone, and pleura via lymphatics, airways, blood vessels, and transpleural space. Metastatic neoplasms to the lungs are more common than primary pulmonary tumors in the dog and cat.

Paraneoplastic syndromes are rarely recognized in dogs and cats.

- Hypertrophic osteopathy is the most common paraneoplastic syndrome associated with lung masses and has been reported in 3% to 15% of animals with pulmonary neoplasia.
- Leukocytosis (neutrophilia or eosinophilia) is a paraneoplastic syndrome that may be related to some types of pulmonary carcinoma.
- Other paraneoplastic syndromes include neuromyopathy, hypercalcemia, and secretion of adrenocorticotropic hormone resulting in clinical signs of hyperadrenocorticism.

Table 165-4. PULMONARY NEOPLASMS

Primary Tumors in Dogs
Carcinoma
Bronchoalveolar adenocarcinoma
Squamous cell carcinoma
Bronchogenic carcinoma
Anaplastic carcinoma
Sarcoma
Fibrosarcoma
Hemangiosarcoma
Osteosarcoma
Round cell tumors
Lymphoma
Malignant histiocytosis or histiocytic sarcoma
Benign
Lymphomatoid granulomatosis
Eosinophilic granuloma
Adenoma
Fibroma
Primary Tumors in Cats
Carcinoma
Adenocarcinoma
Squamous cell carcinoma
Bronchogenic carcinoma

Hemangiosarcoma
Fibrosarcoma
Round cell tumors
Lymphoma
Malignant histiocytosis or histocytic sarcoma
Benign
Bronchial adenoma
Hemangioma
Metastatic Tumors in Dogs and Cats
Mammary carcinoma
Osteosarcoma
Thyroid carcinoma
Transitional cell carcinoma
Melanoma
Hemangiosarcoma
Squamous cell carcinoma

▼ ***Key Point*** Pulmonary neoplasia is the most likely diagnosis in dogs with hypertrophic osteopathy.

Tumor Types (see Table 165-4)

Primary Pulmonary Neoplasm

Carcinomas are the most common primary lung tumors in dogs, being bronchial, bronchoalveolar and alveolar, and they are graded as differentiated and undifferentiated.

- Differentiated carcinomas have a lower rate of metastasis than undifferentiated carcinomas and squamous cell carcinomas.
- The rate of metastasis at the time of diagnosis is approximately 50% for undifferentiated carcinomas and 80% for squamous cell carcinomas.
- In one report (Hahn, 1997), feline lung tumors had a metastatic rate of 75%.

Metastatic Pulmonary Neoplasms

These tumors are more common than primary pulmonary neoplasms. Metastasis occurs by the spread of tumor emboli via lymphatics or blood vessels.

- Because of the capillary network in the lungs, these tumor emboli are trapped and may proliferate and form nodules.
- See Table 165-4 for a list of common metastatic tumors.

Pulmonary Lymphomatoid Granulomatosis

- This is a condition that affects young to middle-age dogs. The etiology is unknown.
- The disease responds to immunosuppressive drugs and, in general, has a better prognosis than primary lung tumors.
- The most consistent laboratory finding is leukocytosis, eosinophilia, and/or basophilia.
- Eosinophilic granulomas have a good prognosis using immunosuppressive drugs.

Signalment

- Pulmonary neoplasms occur in older animals (>10 years), except lymphomatoid granulomatosis, which occurs in young dogs (1–6 years).
- Most studies do not recognize a breed or sex predilection.
- Larger dogs (>10kg) may be at increased risk.

History

History may vary depending on the tumor type, size, and doubling time. Many dogs are asymptomatic, and pulmonary nodules are discovered during a medical workup.

Clinical Signs

- Approximately 25% of dogs have no clinical abnormalities.
- Cough (harsh, nonproductive) is one of the most common presenting signs in symptomatic patients. The duration is usually chronic. Occasionally, hemoptysis is also present.
- Dyspnea, tachypnea, and cyanosis may be present and associated with pleural effusion and/or diffuse disease.
- Decreased exercise tolerance is usually related to respiratory compromise.
- Less common signs include anorexia, fever, weight loss, dysphagia, vomiting, regurgitation, and hemoptysis.
- Halitosis may be noted by the owner or during clinical examination.
- Lameness may be associated with hypertrophic osteopathy or with skeletal muscle and/or bone metastasis.
- Cats may present with multiple swollen digits and lameness associated with metastasis from primary pulmonary tumors (adenocarcinomas and squamous cell carcinoma).

Diagnosis

Diagnostic Imaging

Routine thoracic radiographs usually establish the diagnosis of a mass lesion(s). However, approximately 11% of pulmonary neoplasms are missed in survey radiographs because of:

- The small size of the lesions (<5–10mm).
- Lack of tumor contrast with pulmonary parenchyma or tumor site in a hidden location (e.g., the subpleural space or paraspinal recesses).
- The presence of pleural fluid.
- Atelectasis of one or more lung lobes.

▼ ***Key Point*** The evaluation of three radiographic views (ventrodorsal, right, and left lateral) of the thorax is recommended when primary or metastatic pulmonary neoplasia is suspected. MRI or CT scans may allow the detection of occult masses or lymph node enlargement.

Radiographic Pattern

- The most common radiographic pattern seen in dogs and cats with primary lung tumors is a well-demarcated spherical or smooth-edged mass that usually is solitary. However, metastatic lesions can be seen as a single nodule.
- Other, less common patterns that can be seen in primary lung masses, but are more common in metastatic disease, are multiple circumscribed nodules, interstitial disseminated reticulonodular pattern, mixed disseminated alveolar pattern, and homogeneous lobar consolidation.

Other Diagnostic Signs

- Radiographic changes associated with pulmonary tumors include: pleural effusion, pleural thickening, and thoracic lymphadenopathy.
- Calcification and cavitation of masses have been associated with adenocarcinomas.
- The caudal lung lobes are the most common locations of primary pulmonary neoplasms.

Other Diagnostic Evaluations

- Percutaneous transthoracic fine-needle aspiration for cytologic evaluation can be useful in peripheral masses, but it is common to have a nondiagnostic sample. Transthoracic needle aspiration biopsy for histopathologic evaluation may provide a diagnosis in more than 50% of the cases, but an approximate mortality rate of 10% was reported in one study.
- Cytologic evaluation of tracheal wash fluid, bronchoalveolar lavage fluid, and pleural fluid may detect neoplastic cells in some cases.
- Bronchoscopy may be valuable in perihiliar masses that extend into the bronchus, permitting tissue biopsy.
- Exploratory thoracotomy (see Chapter 167) and biopsy provide a definitive diagnosis and aid in staging the tumor. Lobectomy may be curative for an isolated mass lesion without lymphatic metastasis.
- Thoracoscopy may be used for obtaining a diagnosis in the case of multiple pulmonary lesions.

Treatment

Surgical Excision

- Surgical excision by lobectomy is the treatment of choice for solitary lung tumors (see Chapter 167).
- Biopsy samples from regional lymph nodes can be obtained when possible.
- Adjunctive chemotherapy may improve survival in some cases in which metastasis or local invasion is present or when complete clean margins have not been achieved.
- Metastectomy is recommended in some circumstances (e.g., complete control of the primary tumor for a long period of time [>300 days], no other metastatic sites, slow doubling time, and less than three metastatic lesions).

▼ ***Key Point*** Always submit lung tumors for histopathologic evaluation to establish diagnosis and prognosis.

Chemotherapy

- Chemotherapy may be beneficial in some tumors, mainly if used as an adjunctive therapy.
- Lymphomatoid granulomatosis may respond to combination chemotherapy with prednisone, vincristine, and cyclophosphamide. Eosinophilic granulomas may respond to immunosuppressive doses of prednisone alone.
- Carboplatin and gemcitabine are two drugs used for adjunctive therapy for excised primary pulmonary tumors.
- Malignant pleural effusion can be treated with intrapleural chemotherapy. 5-fluoruracil is an inexpensive drug that can be used safely in dogs. Cisplatin is other drug that can be used in dogs but is nephrotoxic. Cisplatin and 5-fluoruracil are fatal if used in cats.
- Some metastatic tumors that are responsive to chemotherapy include hemangiosarcoma (VAC protocol; vincristine, doxorubicin, and cyclophosphamide), lymphoma (COP with or without doxorubicin or L-asparaginase), and some malignant histiocytosis (lomustine with prednisone). Specific protocols for these types of tumors are described in the literature.

Prognosis

- Factors that decrease survival time include large tumor burden, thoracic lymph node involvement, and other metastases. Absence of lymphatic invasion by the lung tumor has been associated with increased survival times.
- Small (<5cm), solitary primary lung tumors without metastasis or malignant effusion are associated with prolonged survival (>1 year). Even large lobar masses can be removed successfully with a reasonable (>6 months) survival time.
- In cats, based in the histologic grade, poorly differentiated tumors have a median survival time of 2.5 months and those tumors that are moderately differentiated without evidence of metastasis have a median survival time of 23 months after surgery.
- Following treatment, monitor with routine thoracic radiographs every 1 to 3 months.

Chapter

166 Thoracic Trauma

Dale E. Bjorling

Thoracic trauma in dogs and cats most often is the result of automobile accidents. The lack of apparent external injuries may be misleading; the diaphragm, thoracic wall, heart, or lungs may be severely damaged with little apparent damage to the overlying skin. Evaluate animals presented for treatment of thoracic trauma thoroughly but rapidly; if necessary, institute treatment prior to completing a full patient assessment. Animals with thoracic trauma may suffer concurrent abdominal or skeletal injuries.

Surgical correction of injuries associated with thoracic trauma may be required on an emergency basis; however, in general veterinary practice it is preferable to avoid emergency surgery of animals suffering thoracic trauma unless absolutely necessary.

This chapter discusses the major disorders caused by thoracic trauma: pulmonary and myocardial contusions, pneumothorax, rib fractures and flail chest, hemothorax, and diaphragmatic hernia; see Chapter 164 for discussion of chylothorax.

Injuries to abdominal viscera are discussed in respective organ-system chapters.

ETIOLOGY

Blunt Trauma

- Blunt trauma to the thoracic cavity usually is the result of automobile accidents. It may also be the result of being kicked by a human or farm animal (horse, cow), being struck by a heavy object, or falling from heights (e.g., falling from a window of a high-rise building).
- The severity of injury depends on the mass of the object delivering the blow, the velocity of the object, and the area to which the blow is delivered. It has been shown experimentally that when a blow equivalent to that delivered by a car is administered to the thorax of anesthetized dogs, the thoracic viscera may be compressed until the opposing parietal pleural surfaces underlying the ribs may almost be brought into contact. The ribs of young animals are pliable and tend to fracture less often than those of older animals.
- Blunt trauma can cause pneumothorax, hemothorax, pulmonary contusions, fractured ribs, or any combination of these.

Penetrating Trauma

- Penetrating trauma usually is the result of a gunshot. It may also result from a sharp instrument (e.g., a knife, screwdriver, stick, or arrow) or from deep bite wounds inflicted by a big dog on a smaller dog or cat.
- Consider the type of projectile, point of entry, and path of the penetrating object when attempting to diagnose thoracic trauma, even if wound entry is distant to the thoracic cavity. The path of a projectile may be altered if it strikes bony structures.
- It is often unclear whether thoracic injuries have resulted from penetrating wounds. Depending on the extent of injury, signs of cardiovascular collapse or respiratory distress may develop more slowly in patients suffering penetrating injuries of the thorax.
- In at least one study, mortality subsequent to bite wounds only occurred with thoracic or abdominal trauma, and exploratory thoracotomy failed to improve survival.

CLINICAL SIGNS

- *Tachypnea or dyspnea* (difficulty breathing) is a typical presenting sign in dogs and cats that suffer thoracic trauma. The animal may have an anxious or distressed appearance. The owner may or may not have observed the injury. Clinical signs of thoracic trauma may be delayed in onset, especially those associated with diaphragmatic hernia.
- *Hypovolemic shock* may result from internal or external hemorrhage or accumulation of fluid within tissue spaces. An animal suffering from hypovolemic shock has an increased heart rate, weak peripheral arterial pulses, cold extremities, and pale mucous membranes, and it often appears depressed or stuporous (see Chapter 156 for further discussion of shock).
- *Gastrointestinal signs* (diarrhea or vomiting due to obstruction) may be observed if a portion of the gastrointestinal tract has been displaced into the tho-

racic cavity through a diaphragmatic hernia. These signs are not commonly present immediately after the injury has occurred.

DIAGNOSIS

▼ ***Key Point*** Treatment of hypovolemic shock or other life-threatening disorders takes precedence over patient evaluation.

History

- Attempt to identify recent or past traumatic episodes.
- Question the owner regarding the onset and progression of the current clinical signs.
- Take the history while initial evaluation of vital signs is in progress so that life-threatening injuries (e.g., tension pneumothorax) can be detected and treated immediately.

Physical Examination

After initially determining the animal's vital signs (e.g., heart rate, respiratory rate, mucous membrane color and refill, temperature, and level of consciousness), examine the respiratory system using the following:

- Observation (of breathing)
- Palpation
- Auscultation
- Percussion
- Radiography

Observation

- Observe the rate, depth, and effort of respirations.
- Rapidly developing dyspnea usually is the result of pneumothorax, pulmonary contusion, or hypovolemia.
- Rapid, shallow, choppy breathing can result from restriction of the thoracic wall because of painful rib fracture.
- Paradoxical motion of the chest wall is caused by collapse of a portion of the rib cage on inspiration when multiple rib fractures create an unstable flail chest wall.
- Decreased hemithorax movement (fixation) can be seen on the side into which abdominal viscera have herniated through a ruptured diaphragm.
- Herniation of the lung into the intercostal space countercurrent with each respiration indicates torn intercostal muscles.

Palpation

- Palpate the thoracic wall for rib fractures, unstable (flail) segments, hematomas (usually adjacent to rib fractures), subcutaneous emphysema (crepitus), intercostal muscle tears (usually under intact skin), and abnormal location of the cardiac apex beat (displaced by herniation of abdominal viscera).
- Also palpate the abdominal cavity for concurrent intra-abdominal injuries. The absence of viscera suggests their displacement into the thoracic cavity.

Auscultation

- Carefully auscultate the entire thoracic cavity to determine whether breath sounds can be identified throughout the thoracic cavity. The absence of respiratory sounds strongly suggests displacement of the lungs by air, fluid (e.g., blood), or abdominal viscera. Crackles suggest intrapulmonary fluid accumulation.
- Auscultate the heart as well. A change in the location or pitch of heart sounds suggests displacement of the heart by air, fluid, or viscera. Ventricular arrhythmias may occur as the result of traumatic myocarditis or myocardial ischemia; however, their onset is more frequently observed 24 to 48 hours after the traumatic episode.
- See also Chapter 142.

Percussion

- Perform percussion of the thoracic wall to determine increased or decreased resonance. By placing one hand flat on the thoracic wall and tapping the knuckle of the middle finger with a percussion hammer or the tips of the fingers of the opposite hand, a sound of consistent frequency is produced in normal animals.
- In animals with air or air-filled viscera underlying the thoracic wall, the pitch is deeper and more resonant, whereas the sound produced in animals with fluid or solid viscera immediately under the thoracic wall is dull and less resonant.
- Percussion aids detection of pneumothorax, pleural effusion (e.g., hemothorax and chylothorax), diaphragmatic hernia, and consolidation of lung lobes.
- Skilled use of this technique requires frequent practice on normal animals to allow a distinction between normal and abnormal sounds.
- See also Chapter 142.

Fractures

- Thoracic injuries may occur in more than 30% of dogs and cats sustaining traumatic fractures.
- Examine the animal for the presence of fractures; do not be distracted by the obvious presence of broken bones but continue searching for evidence of more serious internal injuries.
- If spinal fractures are suspected, handle the animal with great care until these have been stabilized or it is determined radiographically that the spine is intact.
- The presence of fractures suggests that trauma of sufficient force to inflict injury to the thorax and its con-

tents has occurred. A survey of dogs injured in motor vehicle accidents found that more than 50% of animals with intrathoracic injuries also had fractured bones.

Surface Wounds and Abrasions

- Clip hair from the thoracic wall area as necessary to identify abrasions, bruises, or wounds that may point to likely sites of intrathoracic injury.
- Open wounds that freely communicate with the pleural space can cause progressive pneumothorax; unless the animal is stable, seal these immediately.

Thoracic Radiography

Take radiographs to evaluate the heart, lungs, pleural space, and thoracic wall (see Chapters 143 and 159 for a discussion of thoracic radiography).

- It is sometimes advisable to delay thoracic radiography of the injured animal until after higher priority conditions such as shock have been stabilized by emergency treatment. Pulmonary contusion, characterized by hemorrhage and fluid accumulation within the lungs, may not reach its greatest extent for 6 to 12 hours and then often may not appear radiographically to be improved for 7 to 10 days after injury.

▼ ***Key Point*** The full severity of pulmonary contusions may not be apparent on thoracic radiographs made within 1 to 2 hours of injury.

- A narrowed cardiac silhouette may suggest hypovolemia.
- Evaluate the pleural space carefully for fluid, air, or abdominal viscera, and evaluate the integrity of the diaphragmatic outline.
- Look for radiographic evidence of fracture or dislocation of skeletal structures and subcutaneous emphysema, which indicates leakage of air into the subcutaneous space from the environment, the thoracic cavity, or a major airway.
- Pneumomediastinum is seen as air outlining the mediastinal contents and is indicative of tracheobronchial rupture.
- If the animal's condition does not preclude this, obtain two radiographic projections.
- Often it is difficult to identify a diaphragmatic hernia on thoracic radiographs, particularly if obscured by accumulation of fluid within the pleural space. If a large quantity of pleural fluid is present, remove it and repeat the radiographs (see Chapter 159) or obtain an ultrasound examination, if readily available.
- Observations suggesting a diaphragmatic hernia include cranial displacement of the stomach, the loss of the caudal outline of the liver, and the presence of gas-filled viscous organs within the thoracic cavity.
- If a diaphragmatic hernia is suspected but unconfirmed by plain radiographs, consider positive-contrast celiography or abdominal ultrasonography (see Chapter 4).

Thoracocentesis

If indicated, perform thoracocentesis to obtain a sample of pleural fluid or to drain air from the pleural space (see Chapter 3 for technique).

- Analyze the fluid for the presence and concentration of red blood cells (RBCs) and plasma protein. The fluid may be whole blood, or it may be a combination of transudate, exudate, chyle, and blood, depending on the severity and duration of injury and the organs affected.
- Centrifuge an aliquot of the fluid and examine the cellular portion microscopically for degenerative neutrophils, bacteria, and organic matter (see Chapter 164). These findings may suggest a severe inflammatory process and possibly perforation of the esophagus or gastrointestinal tract.
- On rare occasions, the biliary tract may be ruptured in the presence of diaphragmatic hernia, and this can be identified by determining the concentration of bilirubin within pleural fluid. Biliary-pleural fistula has also been reported secondary to gunshot in a dog.

Blood Samples

- Draw blood and store the sample in anticoagulant and serum tubes (preferably before initiating treatment), unless analyzed immediately.
- Although these samples may not be needed, it is often helpful to determine the biochemical status of the animal at the time of hospital admission when attempting to distinguish between preexistent disease and that which has developed acutely after injury. These same considerations apply to the collection and storage of urine samples.

Packed Cell Volume and Plasma Protein Concentration

- Determine the packed cell volume (PCV) and plasma protein concentration (PPC) as soon as possible after the initial examination.
- It is critical to record these values because the diagnosis of continuing hemorrhage often relies on comparison of serial determinations of PCV and PPC.
- If hemorrhage is ongoing, these two values continue to decline at a similar rate. If, however, hemorrhage has ceased, it is not uncommon for the PPC to stabilize while the PCV continues to decline.
- The administration of IV fluids may further decrease these values; consider this when evaluating these parameters.

Arterial pH and Blood Gas Tensions

- These values give an indication of ventilatory function and gas exchange.
- Satisfactory oxygenation of the blood by the lungs requires adequate cardiac output, and decreased cardiac output caused by hypovolemic shock or depressed cardiac function may profoundly affect blood gas values.

Electrocardiography

- If available, obtain serial electrocardiograms to check for arrhythmias associated with myocardial injury.
- If electrocardiography is not available, closely monitor the animal's heart rate and rhythm and the occurrence of pulse deficits.

TREATMENT

Modify treatment to suit the individual needs of each trauma patient. Place and maintain at least one IV catheter for administration of fluids and drugs early in the course of treatment. In severely traumatized animals, place two IV catheters (one may be a central venous line) to allow more rapid infusion of IV fluids.

When confronted with a seriously injured animal, it is often difficult to develop a logical, disciplined treatment plan. The airway, breathing, and circulation (ABC) approach is a consistent, comprehensive plan for initial treatment of animals with thoracic trauma.

Airway, Breathing, and Circulation Approach

Airway

Be sure that the animal has a patent airway.

- Remove debris from the trachea and bronchi by forceps or suction or by passing an endotracheal tube.
- If the pharynx, larynx, or cranial portion of the trachea is severely damaged, consider performing a tracheostomy (see Chapter 3).

Breathing (Spontaneous or Assisted) and Oxygen Therapy

Restore thoracic wall integrity by sealing open ("sucking") chest wounds with an occlusive dressing and stabilizing flail segments so that the animal can ventilate effectively. Fluid and air should be removed from the pleural space. If the animal is not able to ventilate satisfactorily, institute assisted breathing.

- Assisted breathing requires an endotracheal or tracheostomy tube and may necessitate anesthetizing the animal or giving neuromuscular blocking drugs to paralyze the animal (see Chapter 2).
- Supplemental oxygen may be provided by an incubator or oxygen cage, face mask, nasal catheter (see Chapter 3), transtracheal cannula or catheter, or endotracheal or tracheostomy tube.
- When supplemental oxygen is administered to the animal in such a manner that it does not pass through the nasal passages, prewarm and humidify the air.
- A transtracheal catheter may be placed using a large-gauge (12–18) jugular catheter passed between the rings of the trachea.
- Secure the catheter to the skin and attach to the oxygen source. Deliver oxygen via the transtracheal catheter at an initial rate of 10 to 20 ml/kg/min.

Circulation

If myocardial function is satisfactory, administer IV fluids as needed to increase the circulating blood volume and cardiac output.

- In most cases of hypovolemic shock, administer a blood volume of IV fluids (90 ml/kg in dogs and 65 ml/kg in cats) as rapidly as gravity flow allows.
- In the presence of significant ongoing hemorrhage, fluid bags may be pressurized to increase the rate of administration.
- After the rapid infusion of a bolus of IV fluids equivalent to one blood volume, reassess the status of the patient and determine the need for ongoing fluid administration.
- If signs of hypovolemic shock have abated and hemorrhage has ceased, continue to administer fluids at a rate of 30 to 50 ml/kg q24h (see Chapter 156).
- If the animal's condition does not stabilize, continue rapid fluid administration.
- Auscultate the lungs for evidence of pulmonary edema and carefully monitor for other signs of edema (e.g., tachypnea, chemosis, tearing, tissue swelling, decreasing PCV and PPC).
- If necessary, monitor the central venous pressure (CVP) to determine the ability of the right side of the heart to eject the volume of blood presented to it (see Chapter 3 for CVP techniques). The relative change in CVP is more significant than the absolute value, and an increase of 7 to 10 cm of water indicates that the rate of fluid administration should be slowed.
- Because the low oncotic pressure of crystalloid fluids may contribute to fluid loss into the tissue space, a general rule for replacement of blood loss by crystalloid fluids is as follows:
  - For every 1 ml of blood lost, administer 3 ml of crystalloid fluid.

Pleural Space Drainage

- The pleural space may be drained intermittently by thoracocentesis using a hypodermic needle.
- If continuous or prolonged pleural drainage for removal of fluid or air is required, place a thora-

costomy tube (see Chapter 3 for thoracic drainage techniques).
- Attach thoracostomy tubes to a three-way stopcock to allow intermittent aspiration of the tube (e.g., q2–4h) or to a continuous suction device.
- If continuous suction is used, carefully control the negative pressure; it should not be less than −5 to −10 cm of water.
- Alternatively, attach the thoracostomy tube to a Heimlich one-way flutter valve.
  - If using this valve, carefully monitor the animal for complications.
  - Be aware that if the valve becomes cracked or the valve's diaphragm becomes wet, the one-way function of the valve may be lost and severe pneumothorax may develop.
  - This valve is available in two sizes, and animals weighing <10 kg frequently may be incapable of activating the larger valve, resulting in continued accumulation of air within the thoracic cavity.
- If fluid or air cannot be aspirated from the thoracostomy tube, the pleural space may be completely evacuated or the tube may be obstructed by a fibrin clot or by the tube bending on itself. Obtain thoracic radiographs and flush the tube with sterile saline to confirm patency.

Tube Removal

- Remove the tube when it is no longer needed.
- An indwelling thoracostomy tube results in continued production of a small volume of fluid (at least 3 ml q24h in a dog weighing 25 kg).
- It also is possible that a small volume of air may continue to accumulate within the pleural space due to air migration along the external surface of the chest tube or through leaks in the tubing.
- Therefore, it is often not possible to wait until there is no air or fluid accumulation within the thorax to remove the thoracostomy tube, and the tube usually is removed when the volume of air and fluid removed has reached insignificant amounts.

Treatment of Pneumothorax

Pneumothorax can be closed or open; in *closed* pneumothorax, the most common type, air escapes from the injured lung or airway into the pleural space; in *open* pneumothorax, air enters the pleural space through an open wound in the chest wall (e.g., bites, sharp objects, and projectiles).

Simple Pneumothorax

Accumulation of air in the pleural space that is not progressive is termed *simple pneumothorax* and is a common complication of thoracic trauma.

- Conservative treatment with thoracic drainage and cage rest usually is adequate. The air leak usually seals itself within hours, and residual intrapleural air is reabsorbed within a few days.
- Occasionally, oxygen therapy may be needed as initial treatment in animals that are severely dyspneic on presentation until the pleural space can be evacuated.
- Simple pneumothorax frequently is accompanied by other thoracic problems, such as pulmonary contusions and rib fractures, that can combine to cause serious problems with ventilation.

Tension Pneumothorax

Laceration of the lung, bronchus, or trachea may result in *tension pneumothorax,* the progressive accumulation of air in the pleural space that results in positive intrapleural pressure.

▼ ***Key Point*** Animals with tension pneumothorax need immediate life-saving thoracic drainage via a needle or thoracostomy tube to prevent lung collapse, decreased systemic venous return to the heart, and rapid death. This reestablishes negative intrapleural pressure and allows lung reexpansion.

- Intermittent thoracic drainage may not be adequate to allow proper ventilation, and continuous suction drainage frequently is necessary. In this case, connect the thoracic tube to a suction drainage unit such as Pleur-Evac (Deknatel, Fall River, MA).
- Consider exploratory thoracotomy (see later discussion in this chapter; also see Chapter 167) if the patient's condition fails to stabilize.

Treatment of Pulmonary Contusions

A pulmonary contusion is analogous to a bruise, with disruption of the tissues and capillaries resulting in extravasation of blood and accumulation of fluid within the pulmonary parenchyma. As mentioned previously in the discussion of IV fluid administration, aggressive fluid therapy may result in fluid accumulation within the lungs. This most likely is the result of decreased plasma oncotic pressure. IV infusion of the equivalent of one blood volume of crystalloid fluids over the course of 1 hour does not increase the extent of experimentally created pulmonary contusions in dogs. It is unlikely that IV fluid administration will increase fluid accumulation within pulmonary contusions unless the PPC is <3.0 g/dl or the plasma albumin concentration is <1.5 g/dl.

- Transfusions of plasma or whole blood or administration of colloid (hetastarch) helps maintain plasma oncotic pressure.
- Corticosteroids (2–4 mg/kg of dexamethasone phosphate or 30 mg/kg of methylprednisolone sodium succinate) may be useful in limiting the severity of pulmonary contusions if administered soon after injury.

- Diuretics have been recommended to remove excess water and limit the severity of contusions; however, diuretics may act to reduce total body fluid when volume expansion is critical to resuscitate the patient.
- Administer antibiotics to animals with pulmonary contusions to minimize the potential for development of bacterial pneumonia (antibiotic therapy for patients with thoracic trauma is discussed at the end of this chapter).
- In animals that are recumbent, frequent repositioning may help prevent hypostatic congestion, atelectasis, and pneumonia.
- Administer oxygen to treat or prevent hypoxemia.
- Bronchodilators (e.g., aminophylline at a dosage of 6–10 mg/kg q8h PO, IM, or IV in dogs and 6.6 mg/kg q12h PO in cats) may improve ventilation by keeping airways open.
- Closely monitor animals with moderate to severe contusions. If deterioration of respiratory function continues despite the above-mentioned measures, positive-pressure assisted ventilation may be necessary.

Treatment of Myocardial Contusions

Administration of corticosteroids as described for treatment of pulmonary contusions may be beneficial in the treatment of myocardial contusions, but the efficacy of any form of treatment is uncertain.

- Monitor ventricular arrhythmias (see Chapter 145) that develop as a result of traumatic myocarditis by continuous electrocardiography and treat initially with IV administration of lidocaine (2 mg/kg boluses to a maximum of 8 mg/kg/hour).
- If lidocaine therapy is effective but a constant infusion is required, administer lidocaine at a rate of 50 to 80 µg/kg/minute. Adjust the rate to achieve the desired effect.
- Procainamide may also be given (8–20 mg/kg q8h IM, 10–20 mg/kg q6h PO, or 20–50 mg/kg q8h extended release PO).
- See Chapter 145 for treatment of cardiac arrhythmias.

Treatment of Hemothorax

Hemothorax (blood accumulation in the pleural space) occurs secondary to any form of trauma that causes laceration of blood vessels, heart, lung, or thoracic wall (diseases other than trauma can cause hemothorax and are discussed in Chapter 164). Hemothorax causes two major problems: hypovolemic shock and impairment of ventilation. Massive hemorrhage from rupture of the heart or one of the great vessels usually causes rapid death.

- Treatment of traumatically induced hemothorax involves aggressive and rapid supportive care consisting of IV fluids and/or blood transfusions and pleural drainage (see Chapter 156 for details of treatment of hypovolemic shock).
- Consider autotransfusions for animals with significant hemothorax not complicated by an infectious or neoplastic process in the thorax.
- Aseptically collect the blood via a chest tube and return to the patient using a blood administration set.
- Closely monitor the patient's vital signs, PCV, and PPC.
- Consider exploratory thoracotomy for animals that fail to stabilize (see subsequent discussion in this chapter). However, surgical treatment of hemothorax may be unsuccessful because the source of hemorrhage is sometimes not identifiable.

Stabilization of Rib Fractures and Flail Chest

▼ ***Key Point*** Stabilization of rib fractures is required when a gross deformity has occurred, displacement of the fragments results in ongoing damage to the underlying viscera, or displacement or instability of the fragments interferes with ventilation (e.g., flail chest).

- Potential complications of rib fractures include the following:
  - Pneumothorax (from lung laceration by the sharp end of a fragment)
  - Pulmonary contusions
  - Hemothorax (bleeding from torn intercostal vessels, lacerated lung, or exposed rib marrow cavity)
  - Unstable chest wall (flail chest)
- *Flail chest* occurs when two or more adjacent ribs are fractured or dislocated both dorsally and ventrally, resulting in paradoxical movement of a segment of the thoracic wall during respiration. This may diminish lung volume and damage underlying viscera as the flail segment is displaced during respiration.
- Rib fractures may be stabilized by open fixation using pins and wires.
- Alternatively, secure the ribs to an external frame by percutaneous placement of sutures around the ribs (this procedure has been used successfully to stabilize flail chest).
- Place a frame made of malleable rodding used to construct splints and contour to the normal curvature of the thoracic wall. Bars pass over the dorsal and ventral aspects of the flail segment. Place at least two sutures around the ribs of the flail segment, dorsally and ventrally, and tie to the frame to displace the flail segment in a lateral, or outward, direction (Fig. 166-1). Alternatively, tongue depressors or other stiff materials of sufficient length to span the flail segment can be used to stabilize the damaged ribs.
- Damage to the underlying lung tissue usually does not occur during passage of the suture needle around the rib because of the presence of pneumothorax.

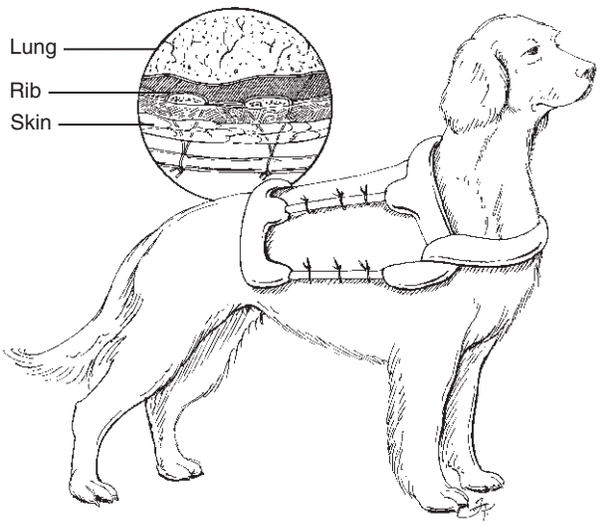

Figure 166-1. Fractured ribs can be secured to an external frame contoured to the body wall. Place sutures around the ribs dorsally and ventrally and tie them around the bars of the frame. (Redrawn from Bjorling DE, DeNovo RC, Kolata RJ: Flail chest: Review, clinical experience, and new method of stabilization. J Am Anim Hosp Assoc 18:269, 1982.)

Minimize the risk of potential damage to the underlying lungs by grasping a rib with a towel forceps and retracting the flail segment laterally.

- Keep the frame in place for at least 3 weeks.
- Do not apply tight bandages for stabilization of rib fractures because this displaces the ribs medially, resulting in continued damage to the underlying viscera and in healing of the ribs in such a position that lung volume is permanently decreased.
- Adjunctive therapy for rib fracture includes analgesia and intercostal nerve blocks to control pain (see Chapter 6), thereby promoting uninhibited cough and deeper, less restrictive breathing that helps prevent hypoventilation, atelectasis, retained secretions, and pneumonia.

Treatment of Open Chest Wounds

- Immediate treatment of open chest wounds consists of minor cleansing of the wound and application of a bandage to restore continuity of the chest wall.
- The defect in the chest wall should not be closed without treating associated pneumothorax with thoracocentesis or chest tube.
- Allow small penetrating wounds to heal as an open wound (if air is not leaking into the pleural space), or they may be explored, debrided, and sutured. Surgically explore, debride, and close large open wounds of the thoracic wall.
- It may be necessary to remove ribs that are devoid of musculature and vascular supply.
- Up to four adjacent ribs can be removed and the thoracic wall can be closed by apposing the remaining ribs.
- Larger defects require implantation of synthetic mesh (e.g., polypropylene) to compensate for the tissue lost.

Diaphragmatic Hernia Repair

Some hernias remain undetected for months or years before signs of pleural effusion, weight loss, gastrointestinal dysfunction, or jaundice occur (see Chapter 159 for radiographic diagnosis of diaphragmatic hernia).

- Minor perforations of the diaphragm usually seal without treatment.
- Surgically repair diaphragmatic defects (most can be closed by suture) that result in displacement of viscera into the thoracic cavity (see "Technique"). The liver, spleen, omentum, and gastrointestinal tract commonly are herniated.
- Timing of diaphragmatic hernia repair depends on the patient's condition.
- It is preferable to delay diaphragmatic hernia repair until the patient has stabilized; however, if respiratory function cannot be stabilized despite aggressive supportive care, it may be necessary to repair the diaphragmatic hernia on an emergency basis.

▼ ***Key Point*** Acute dilatation of herniated stomach or strangulation of herniated bowel requires emergency correction of a diaphragmatic hernia.

Surgical Procedure

Objectives

- Maintain pulmonary function by positive pressure ventilation during anesthesia and surgery.
- Replace viscera to the abdomen cavity.
- Inspect lungs, other thoracic viscera, and abdominal viscera for evidence of trauma.
- Repair the diaphragmatic defect with a monofilament absorbable suture.

Equipment

- Standard general surgical instrument pack and suture (plus various sizes of polydioxanone PDS)
- Long-handled instruments for deep-chested dogs
- Balfour and malleable retractors
- Thoracic drain tube and connectors

Technique

1. Keep the animal on mechanical ventilation throughout the repair.
2. Approach the diaphragm through a ventral midline abdominal incision.
3. Initially, it may be necessary to enlarge the diaphragmatic rent to reduce the herniated viscera. If so, make the incision ventrally to simplify repair.
4. Chronic diaphragmatic hernias are more commonly associated with formation of adhesions between

abdominal and thoracic viscera, and it has been observed that it may be necessary to perform a caudal median sternotomy to free abdominal viscera of adhesions from the lungs, mediastinum, and visceral pleura. If adhesions are extensive, a portion of the lungs or liver may have to be resected to allow repair of the hernia.

5. Following reduction of displaced organs and examination of the lungs and pleural space, close the rent with synthetic absorbable or monofilament nonabsorbable suture (simple continuous or horizontal mattress pattern).
6. Begin with the most dorsal aspect of the hernia and work ventrally to close the repair.
7. Grasp large "bites" of the abdominal wall musculature or ribs when suturing a diaphragm that has avulsed from the ventrolateral body wall. Identify and avoid the caudal vena cava.
8. If large portions of diaphragm have been destroyed, repair the defect with synthetic mesh or transposition of a transversus abdominis muscle flap, although this is rarely required.
9. Place a thoracostomy tube to remove air and fluid after surgery prior to closure of the diaphragmatic defect.

Postoperative Care and Complications

- Remove the thoracostomy tube when it is no longer needed.
- Advise the owner to limit the patient's activity for 2 to 4 weeks.
- Complications are rare and the prognosis usually is good.
- Reexpansion pulmonary edema rarely develops (more often in cats) and is characterized by fulminant pulmonary edema immediately after reexpansion of the lung lobes. Treat with diuretics and oxygen.

Exploratory Thoracotomy

Thoracotomy for treatment of ongoing hemorrhage or air leakage on an emergency basis is difficult and may be unrewarding. Exploratory thoracotomy failed to improve survival of dogs that sustained thoracic bite wounds. The animal is at significant risk due to the effects of anesthesia, and often it is difficult to identify and effectively treat the site of hemorrhage or air leakage.

- Before undertaking an exploratory thoracotomy, be sure that adequate equipment and personnel are available to successfully complete the procedure.
- Perform exploratory thoracotomy for treatment of traumatic injuries of the thoracic cavity only after aggressive medical therapy and thoracic drainage have failed to stabilize the animal's condition.
- If the site of injury can be identified, a lateral thoracotomy approach may be used (see Chapter 167). Unfortunately, this rarely is possible.
- A median sternotomy approach (splitting the sternum) allows exploration of both sides of the thorax (see Chapter 167).

Antibiotic Therapy

- Administer antibiotics to prevent the following:
  - Development of bacterial pneumonia resulting from traumatic injuries of the lungs
  - Wound infection as a result of disruption of the thoracic wall
- Initially give antibiotics intravenously to establish satisfactory tissue concentrations. This can be followed by oral administration of antibiotics.
- Prophylactic antibiotic treatment for pulmonary injuries should provide broad-spectrum antibacterial activity. A satisfactory combination is cefazolin (20 mg/kg q8h IM or IV) and gentamicin (2–4 mg/kg q12h or 4–8 mg/kg q24h SC, IM, or IV) or ampicillin (20 mg/kg q8h IM or IV) and enrofloxacin (5–10 mg/kg q12h PO or IM).
- Wound infections due to contamination of tissues with dirt most often are caused by gram-positive bacteria. Cephazolin or other cephalosporin antibiotics have good activity against the most common organisms involved.

Chapter

167 Principles of Thoracic Surgery

Stephen J. Birchard / Eric R. Schertel

Thoracic surgery frequently is performed in small animals for a variety of disorders, especially in referral centers. Thoracotomy is commonly performed to correct routine cardiovascular defects such as patent ductus arteriosus and to evaluate and correct respiratory diseases such as pulmonary neoplasia. Exploratory thoracotomy may be indicated to determine the extent of diseases such as neoplasia and diffuse infection and to obtain biopsies to help establish a definitive diagnosis. It is important to be well versed in the anatomy and physiology of the thoracic cavity and its major structures and to be familiar with the principles of anesthetic management of the thoracic surgery patient.

Recently, minimally invasive thoracic exploratory (thoracoscopy) has become an alternative to traditional methods of thoracic surgery in veterinary medicine. Thoracoscopy requires specialized instrumentation and expertise, generally limiting its users to surgical specialists. Refer to the clinical literature and appropriate texts if more information on thoracoscopy is desired.

This chapter discusses surgical anatomy and physiology of the thorax, thoracic surgical technique, and patient care before, during, and after thoracic surgery.

SURGICAL ANATOMY

Bony Structures

- The bony structures of the thorax usually consist of 13 pairs of ribs and costal cartilages, 13 vertebrae, and 8 sternebrae.
- The first 9 ribs, called the sternal ribs, articulate with the sternum. The last 4 ribs are called the asternal ribs. The costal cartilages of ribs 10 to 12 make up the costal arch. The 13th pair of ribs is also called the floating ribs.
- The manubrium is the most cranial aspect of the sternum, and the xiphoid is located caudally. The xiphoid cartilage is the caudal extension of the xiphoid. Intersternebral cartilages are located between each sternebra. The sternebrae are very narrow structures, making midline division somewhat difficult. The sternebral midline is characterized by a slight bony ridge.

Soft Tissues

Muscles

- The external and internal intercostal muscles are located between each rib.
- Other surgically important muscles of the lateral thoracic wall are the serratus ventralis and serratus cranialis dorsalis, the scalenus, and the external abdominal oblique. The latissimus dorsi, a large, fan-shaped muscle extending from the ribs to the forelimb, is the first major muscle encountered during lateral thoracotomy.

Vessels and Nerves

- The intercostal arteries, veins, and nerves are located on the caudal aspect of each rib. The internal thoracic artery and veins run horizontally just lateral to the sternum, within the thorax.
- The cutaneous and muscular branches of the thoracodorsal artery are frequently encountered during lateral thoracotomy.

PREOPERATIVE CONSIDERATIONS

History, Physical Examination, and Diagnostic Tests

- Review the animal's history and perform a thorough physical examination.
- Give special consideration to the patient's cardiopulmonary status (mucous membrane color and refill time, heart rate and rhythm, pulse rate and character, heart and lung sounds, ventilation, thoracic palpation and percussion).
- Review diagnostic tests already performed and repeat if necessary.
- Evaluate thoracic radiographs and other diagnostic images to become familiar with the animal's disease and to plan the surgical approach. Thoracic ultrasound may assist in planning the surgical approach. Advanced imaging (computed tomography, magnetic resonance imaging) may be of benefit in selected cases.

- Evaluate blood tests, such as the complete blood count (CBC) and serum chemistry profile, to establish the patient's baseline before surgery. If the condition is severe, blood gas analysis may be helpful to further evaluate the patient's respiratory status.

Preoperative Treatment and Stabilization

General Supportive Care

- Closely observe the patient's condition. The clinical states of animals with thoracic disease may change rapidly.
- Administer appropriate medical therapy that will stabilize the animal and reduce the level of anesthetic and surgical risk.
  - For example, if a dog with patent ductus arteriosus is in congestive heart failure, treat with the appropriate drugs to improve cardiopulmonary function before anesthesia and surgery.
  - Correct fluid and electrolyte deficiencies.
- Maintain the animal's nutritional status. Consider placing a nasogastric, esophagostomy, or percutaneous endoscopic gastrostomy (PEG) tube if the animal will not eat and is becoming debilitated (see Chapter 3).

Thoracic Drainage

- If pleural fluid or air is present, perform thoracentesis before anesthesia to allow better ventilation (see Chapter 3).
- Place an indwelling thoracic drainage tube if fluid or air accumulation is recurrent (see Chapter 3).
- Use intermittent or continuous suction drainage.
- Quantify the amount of fluid or air recovered to establish a baseline before surgery.

Oxygen

- Administer oxygen to severely dyspneic or cyanotic animals.
- Place the animal in an oxygen cage with a 40% to 50% concentration or place a nasal oxygen tube to raise the concentration of inspired oxygen (see Chapter 3).
- If possible, analyze blood gases before and after oxygen administration to establish its effectiveness. Pulse oximetry may be useful as well.

Prophylactic Antibiotics

- Use prophylactic antibiotics if the planned operation will be a clean-contaminated, contaminated, or "dirty" procedure.
- Thoracotomy to open and/or resect a portion of the respiratory tract is considered a clean-contaminated procedure. However, we use prophylactic antibiotics only if there is a strong suspicion that contamination of the surgical field will occur (e.g., foreign bodies, abscess, necrotic tumor, or bacterial pneumonia). Thoracotomy for drainage and resection of the pericardium for pericarditis is an example of an indication for preoperative use of antibiotics.
- Administer the prophylactic antibiotic immediately before surgery to ensure sufficient blood concentrations of the drug at the time of surgery. Discontinue antibiotic administration 24 to 48 hours postoperatively unless evidence of infection is present.
- Choose an antibiotic that is effective against the suspected contaminant and that reaches therapeutic concentrations in the target tissues.

Blood

- Cardiac surgery or removal of large, vascular neoplasms may be associated with significant blood loss.
- Ensure that a blood donor or packed cells are available if significant blood loss is anticipated.
- Cross-match or type the donor's blood if multiple transfusions are anticipated.

Client Communication

Risks

- Major cardiac and respiratory surgery is associated with a high incidence of morbidity and mortality.
- Review the incidence of complications and death associated with the planned procedure and discuss this information with the client.

Cost

Thoracic surgery and patient care may be quite expensive. Discuss the cost of preoperative diagnosis and therapy, anesthesia and surgery, and postoperative intensive care with the client.

ANESTHETIC CONSIDERATIONS

The general principles of anesthesia described in Chapter 2 apply to thoracic surgery patients. Special considerations for thoracic surgery patients are outlined in this section.

Premedication

- Consider placing a transdermal fentanyl patch on the animal 12 hours prior to surgery for analgesia (see Chapter 6).
- Generally avoid phenothiazines such as acepromazine because of possible side effects of hypotension and myocardial depression. However, at low doses (up to 0.1 mg/kg SC or IM), they may be beneficial for calming animals with respiratory compromise but normal cardiac function. Acepromazine can be combined with one of the opiates (e.g., butorphanol) as an effective preanesthetic treatment (see Chapter 2).

- Diazepam (Valium) is a safe drug that can be used as a premedicant (0.2 mg/kg IV). It has minimal effects on the cardiovascular and respiratory systems.
- Xylazine (Rompun, Miles) causes undesirable cardiac and respiratory depression, making it a poor choice for thoracic surgery.
- Avoid using anticholinergics (e.g., atropine) because they increase viscosity of respiratory secretions, can increase anatomic dead space, and may induce cardiac arrhythmias.

Induction

- Diazepam, 0.2 mg/kg IV, followed by administration of a thiobarbiturate (e.g., thiopental), 6 to 10 mg/kg IV, provides relatively safe and rapid, smooth induction that allows immediate intubation and control of ventilation.
- The combination of ketamine and diazepam (1:1 mixture; 1 ml of mixture per 10 kg) also can be used for thoracic surgery patients. Hemodynamics is minimally compromised by this combination. However, ventilatory support may be necessary.
- Propofol is another choice for induction of anesthesia. See Chapter 2 for indications and dosage.

Maintenance

- Any of the commonly used inhalation anesthetics can be used successfully for thoracic procedures. Isoflurane is preferred because of less myocardial depression, although hypotension commonly occurs.
- Avoid nitrous oxide in patients with respiratory disease, pneumothorax, anemia, or hypoxia.
- Provide positive pressure ventilation by manual compression of the bag or with a mechanical ventilator (see Table 167-1 for ventilation guidelines).

▼ ***Key Point*** Adequate positive pressure ventilation in the thoracic surgery patient is essential for preventing hypoxia, respiratory acidosis, and atelectasis.

Table 167-1. GENERAL GUIDELINES FOR CONTROLLED VENTILATION

Physiologic Parameter	Value
Respiratory	8–12 breaths/min
Tidal volume	15–20 ml/kg of ideal body weight
Peak airway pressure	15–20 cm H_2O—closed 20–30 cm H_2O—open
Inspiratory time	1–1.5 sec
Expiratory time	2–3 sec
Inspiratory-to-expiratory ratio	1:2–1:4

Modified from Faggella AM, Raffe MR: Anesthetic management of thoracotomy. Vet Clin North Am 17:480, 1987.

Fluids

- Thoracotomy diminishes the functional reserve of the heart by decreasing effective filling pressures. This may be compensated for, in part, by fluid therapy.
- Place one or two intravenous catheters for fluid administration.
- Administer balanced electrolyte solutions at a surgical maintenance rate of 10 to 20 ml/kg/hour.

Monitoring

Cardiovascular

- The standard methods of cardiovascular monitoring (e.g., heart rate, color, pulse quality, and capillary refill) are very important, because alterations due to the disease or surgical manipulations are common.
- Electrocardiography (ECG) is helpful to monitor heart rate and detect arrhythmias.
- Blood pressure measurements obtained with an arterial catheter or a Doppler unit with a pneumatic cuff placed over an accessible artery (e.g., metatarsal artery) help monitor circulatory status during the anesthetic period.

Respiratory

- Carefully monitor the respiratory rate and depth. In the patient with respiratory compromise, be especially aware of spontaneous respirations before thoracotomy and immediately after closure of the thorax.
- Monitor blood gas analysis or pulse oximetry to determine respiratory status; make necessary adjustments.

Other

- Use standard techniques for monitoring depth of anesthesia (see Chapter 2).
- Ensure good communication between anesthetist and surgeon, which is essential for a smooth and successful procedure. Indicate to the anesthetist when major manipulations of the heart and lungs are imminent, and point out when problems arise such as atelectasis, due to inadequate ventilation, or acute blood loss. The anesthetist should keep the surgeon informed of the patient's overall status.

SURGICAL PROCEDURES

Instruments

A standard general pack is needed. See Table 167-2 for additional instruments that are particularly useful in thoracic surgery.

Table 167-2. SPECIAL INSTRUMENTS RECOMMENDED FOR THORACIC SURGERY

Scissors
Long-handled Metzenbaum
Potts

Needle Holders
Mayo-Hegar (long-handled)
DeBakey
French eye

Tissue Forceps
DeBakey general thoracic

PDA, patent ductus arteriosus; PRAA, persistent right aortic arch.

Lateral Thoracotomy

Indications

This is the standard approach to most intrathoracic structures. See Table 167-3 for the locations of structures exposed through intercostal thoracotomy.

Objective

Gain access to the right or left hemithorax to expose the heart, lungs, or other structures.

Equipment

See Table 167-2 for specific instruments useful in thoracic surgery.

Technique

1. Place the animal in lateral recumbency. Place a towel or small pillow under the thorax to slightly arch the contralateral thoracic wall, making the surgical approach easier. Prepare the lateral thorax for aseptic surgery.
2. Count the intercostal spaces to approximate the location of the incision.
3. Incise the skin, subcutaneous tissues, and cutaneous trunci muscle, from dorsal to ventral, from the costovertebral junction to the sternum.
4. Incise the latissimus dorsi muscle from ventral to dorsal (Fig. 167-1).
5. Recount the intercostal spaces (by palpating underneath the latissimus dorsi muscle) from cranial to caudal unless the incision is located in the caudal thorax.
6. Incise through the remainder of muscles: serratus ventralis (can be bluntly separated rather than incised), scalenus, external abdominal oblique, and external and internal intercostals (Fig. 167-2). Penetrate the pleura (instruct the anesthetist to stop pos-

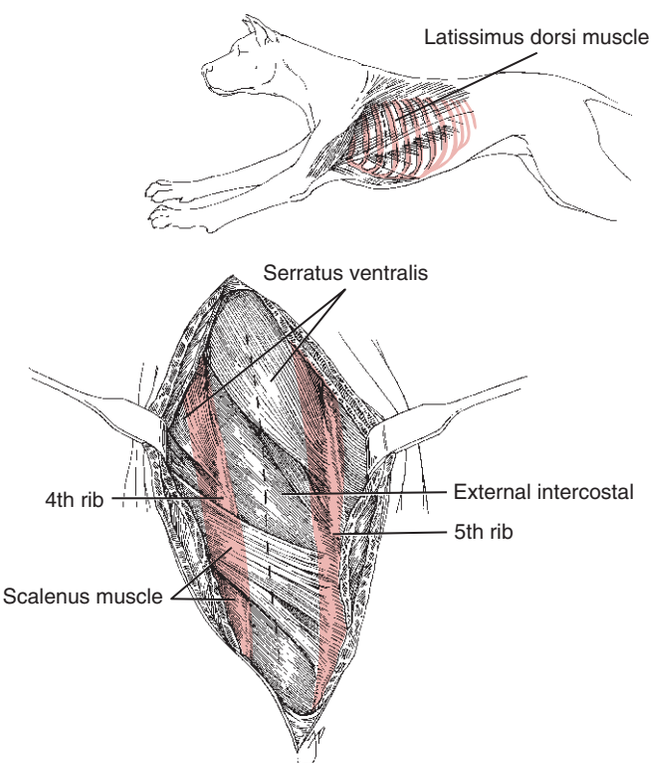

Figure 167-1. Thoracotomy technique. *Top,* Incise the skin at the intercostal space between rib 4 and rib 5 *(dotted line). Below,* Cut the latissimus dorsi muscle and retract to expose the serratus ventralis, dorsalis, scalenus, and external intercostal muscles.

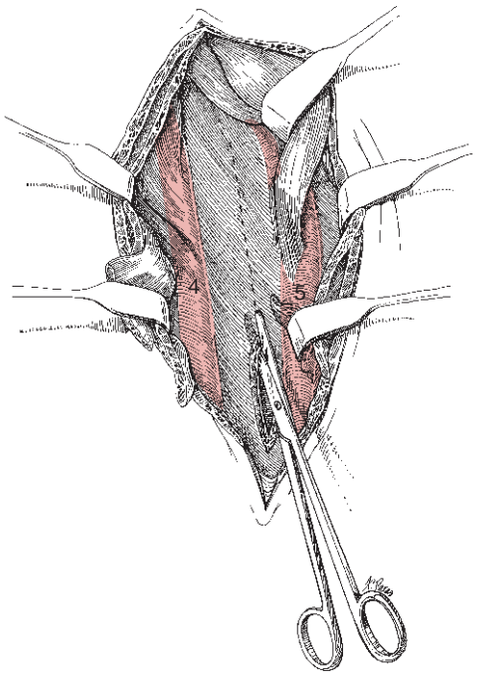

Figure 167-2. Cut or separate the serratus and scalenus muscles between rib 4 and rib 5 so that an incision can be made in the intercostal muscles and the pleura.

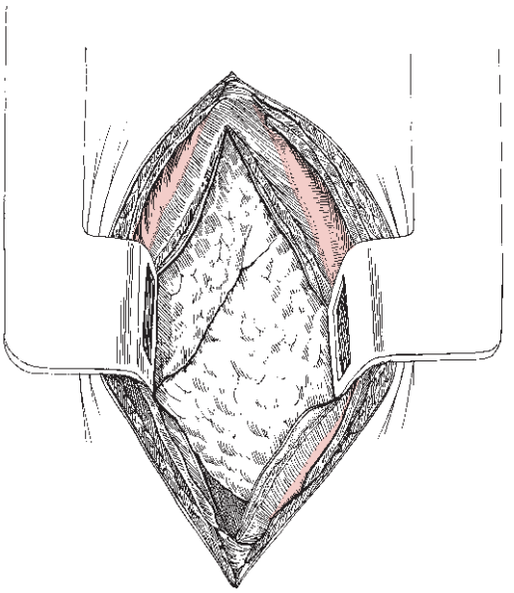

Figure 167-3. After the intercostal muscles and pleura are cut, retract the ribs to expose the lung.

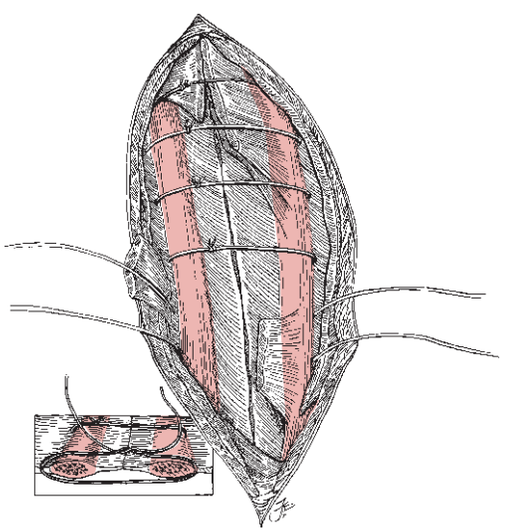

Figure 167-4. For lateral thoracotomy closure, place sutures around ribs 4 and 5 and secure each with a surgeon's knot.

itive pressure ventilation before introducing sharp instruments into the thorax), and incise the pleura dorsally and ventrally with Metzenbaum scissors. Avoid trauma to the internal thoracic artery when incising ventrally.

7. Protect the ribs and muscle tissue with moistened sponges and insert a self-retaining rib retractor (e.g., Finochietto) to expose the thoracic viscera (Fig. 167-3).
8. Closure
   a. Preplace a thoracic drain tube one to two intercostal spaces caudal to the thoracotomy.
   b. Perform an intercostal nerve block by injecting bupivacaine (Marcaine) adjacent to two rib heads on each side of the incision (administer a total dose of 1 mg/kg).
   c. Preplace several large (2-0, 0, or 1) absorbable sutures around the ribs. Hug the caudal rib during suture passage to avoid damage to the intercostal vessels and nerve. Avoid puncture of intrathoracic structures during needle passage around the ribs.
   d. While an assistant approximates the ribs by placing traction on the preplaced sutures, tie the rib sutures using a surgeon's knot (Fig. 167-4).
   e. Close the deep muscles in one layer (serratus, scalenus, external abdominal oblique, and intercostal muscles) in a simple continuous pattern (use absorbable suture for all layers except the skin).
   f. Close the latissimus dorsi muscle in a simple continuous pattern (Fig. 167-5).
   g. Close the cutaneous trunci muscle and subcutaneous tissues in the next layer in a simple continuous pattern; then close the skin routinely, using the pattern of your choice.
   h. Perform thoracocentesis using the thoracic tube to evacuate air or fluid.
   i. Place a light, loosely fitting bandage over the incision and thoracic tube.

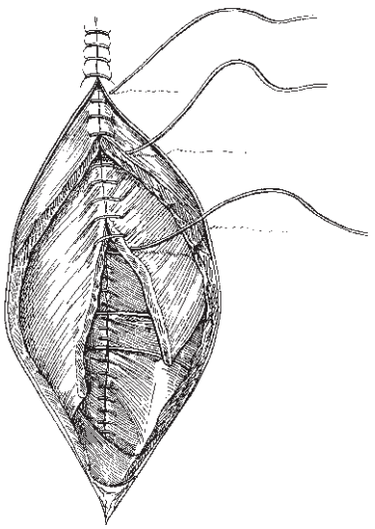

Figure 167-5. Close the latissimus dorsi muscle (simple continuous suture), the subcutaneous tissue (simple continuous suture), and the skin (simple continuous or interrupted suture).

Median Sternotomy

Indications

Median sternotomy is indicated when bilateral exposure of the thorax is necessary. Examples are as follows:

- Multiple lung lesions (e.g., multiple emphysematous bullae)
- Pericardiectomy
- Mediastinal tumors (e.g., thymoma)
- Alternate approach to the pulmonic valve or for other cardiac procedures
- Hepatic surgery
- Complicated diaphragmatic hernia or other diaphragmatic surgery

Objectives

- Obtain bilateral exposure of the thorax
- Achieve stable closure of the sternum to minimize postoperative complications

Equipment

See Table 167-2 for special equipment needed for thoracic surgery.

- Oscillating bone saw for medium to large dogs (an alternative is the Lebsche sternal knife; however, the saw is preferred)
- Osteotome and mallet
- Orthopedic wire (0.028–0.035 gauge) for medium to large dogs, wire cutters, and a wire-twisting instrument
- Electrocautery

Technique

1. Place the animal in dorsal recumbency.
2. Prepare the sternum and ventral half of the thorax for aseptic surgery.
3. Incise the skin and subcutaneous tissues from manubrium to xiphoid.
4. Divide the muscular attachments to the sternum along the thin, white fascial raphe to expose the sternum. This is best performed using electrocautery (Fig. 167-6).
5. Score the sternebrae precisely on the ventral midline with a scalpel or electrocautery (see Fig. 167-6).
6. Cut two-thirds of the thickness of the sternebrae with the bone saw. Finish the cut with an osteotome and mallet, being careful not to injure the heart or internal thoracic vessels.

▼ ***Key Point*** When performing sternotomy, make the sternal cut exactly on the midline to facilitate secure closure with full cerclage wire.

7. If possible, leave at least one sternebra uncut (e.g., cranial or caudal extent) to counteract sheer forces on the sternum after closure.
8. Protect the sternum with moistened sponges and retract with a rib retractor (e.g., Finochietto).
9. Closure
   a. Place a thoracic drain tube through an intercostal space lateral and dorsal to the sternotomy.
   b. Preplace cerclage wire or a heavy suture (e.g., 0 or 1 polypropylene in a cat or small dog) around each sternebra using hemostatic forceps (Fig. 167-7). Stay close to the bone to avoid the internal thoracic vessels. Tighten the wire using wire-holding forceps. If insufficient bone is present to wire the sternebrae directly, place the wires in a figure-eight pattern around the ribs where they attach to the sternum.
   c. Close the muscle tissue using an absorbable suture in a simple continuous pattern.
   d. Close the subcutaneous tissue and skin in a routine fashion.
   e. Perform thoracocentesis using the thoracic tube to evacuate air and fluid.
   f. Loosely place a lightly padded bandage over the incision and thoracic tube.

Lung Lobectomy

Indications

- Neoplasia
- Abscesses or granuloma of the lung
- Lung lobe torsion or severe trauma
- Irreversible atelectasis
- Bronchoesophageal fistula
- Emphysematous bulla
- Refractory lobar pneumonia

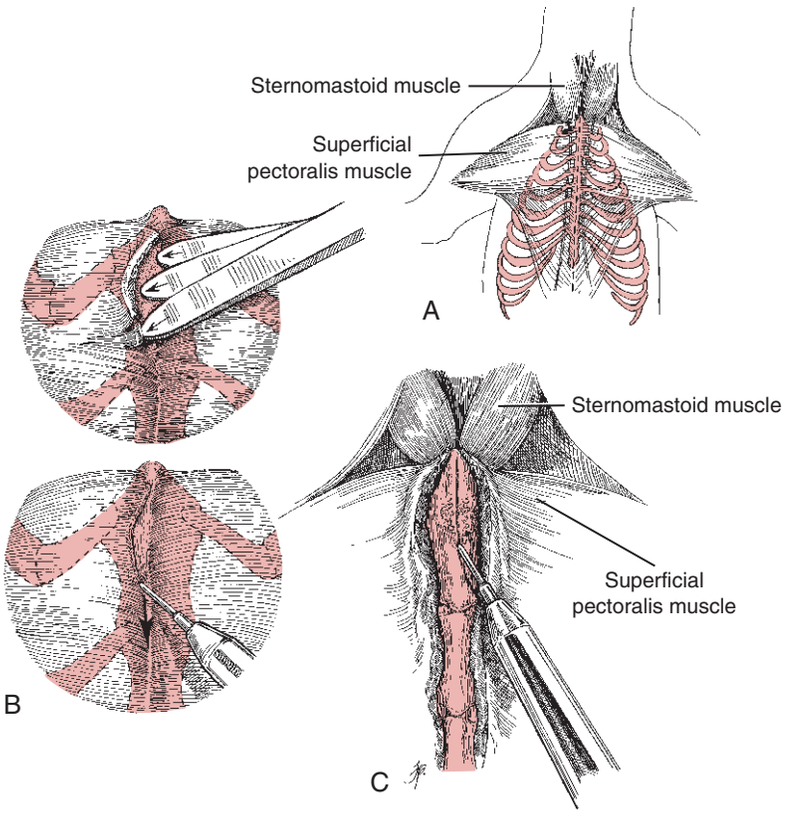

Figure 167-6. Technique for median sternotomy. *A,* Determine the middle of the sternum and associated muscle attachments. *B,* Bluntly dissect muscle off the sternum *(upper),* or incise muscle attachments with electrocautery *(lower). C,* Score the exposed periosteum on the midline.

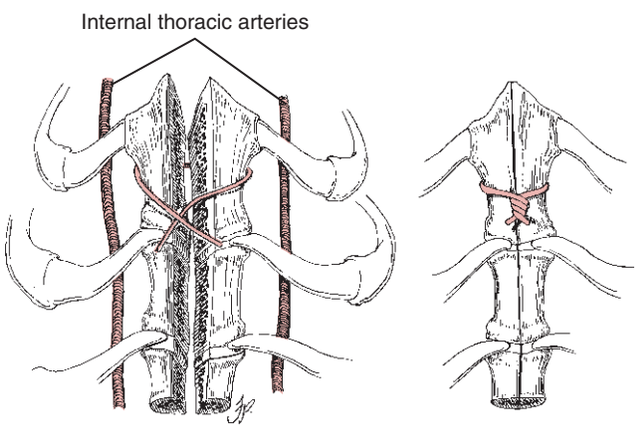

Figure 167-7. Close each sternebra with full cerclage wire twisted with a needle holder or wire twister.

Objectives

- Remove part or all of a lung lobe
- Maintain good hemostasis, especially of the major pulmonary blood vessels
- Establish an airtight seal of the bronchus and/or lung parenchyma
- Leave adequate pulmonary tissue to avoid compromise of the patient's cardiopulmonary status

Equipment

Use the same equipment as for lateral thoracotomy or median sternotomy, plus the following:

- Babcock tissue-holding forceps
- Small suture with swaged needle (e.g., 4-0 nylon or polypropylene)
- Tissue stapling device (30, 55, or 90 Thoracoabdominal Autosuture stapler; U.S. Surgical, Norwalk, CT) (optional)

Technique

1. See the preceding surgical techniques (lateral thoracotomy, median sternotomy) for descriptions of approaches to the lung lobes.
2. Explore the thorax and determine the extent of disease and which lobes are involved.
3. Determine which bronchus or bronchi supply the affected lobe(s).
4. Mobilize the lobe.
   a. For the caudal lung lobe, incise the pulmonary ligament that attaches the caudal aspect of the lobe to parietal pleura.
   b. Incise the pleural attachments between the affected lobe and the adjacent lobes.
   c. Gently incise or dissect adhesions between the lobe and the surrounding tissues (especially a problem in pulmonary neoplasia).

5. Partial lobectomy
   a. Place a non-crushing clamp (e.g., Satinsky) between the lesion and the hilus and incise distally to the clamp with scalpel or scissors.
   b. Close the remaining lung lobe parenchyma with 4-0 or 5-0 nylon or polypropylene in a continuous horizontal mattress pattern. Oversew the incised tissue with a simple continuous pattern to prevent air leakage.
   c. Alternatively, place the Thoracoabdominal Autosuture stapler between the lesion and the hilus. Staple the lung, incise distal to the stapler, and remove the diseased tissue.
   d. Check for hemostasis. Check for air leakage by flooding the lung incision with sterile saline, inflating the lung by positive pressure inspiration, and observing for bubbles. Place additional sutures if necessary to control leaks.
6. Complete lobectomy
   a. Dissect the pulmonary artery and vein free from the adjacent bronchus.
   b. Triple-ligate each vessel with silk or chromic catgut.
   c. Divide each vessel among the ligatures, leaving two ligatures with the animal.
   d. Place two clamps (e.g., Satinsky) across the bronchus and divide it between the clamps. Remove the lung lobe.
   e. Close the bronchus with monofilament nylon or polypropylene, using a horizontal mattress pattern followed by a simple continuous pattern.
   f. Alternatively, use the stapling device previously mentioned to close the hilar vessels and bronchus.

POSTOPERATIVE CARE AND COMPLICATIONS

Thoracic Drain Tubes

- If a thoracic tube has been placed, leave it in as long as necessary, depending on the animal's condition and production of air or fluid (see Chapter 3 for details on thoracic tube management).
- In routine procedures in patients without risk of recurrent pneumothorax or effusion, pull the tube as soon as negative pressure has been reestablished after completion of surgical closure.
- After pulmonary resection, consider leaving a thoracic tube in place for a minimum of 24 hours even if no air or fluid is recovered. Otherwise, leave the tube in until insignificant amounts of air or fluids are being recovered (<2 ml/kg/day).
- Obtain thoracic radiographs prior to removal of the thoracic tube to ensure that there is no significant pleural air or fluid.

Pain

- Thoracic surgery is associated with postoperative pain that causes discomfort and can inhibit ventilation by making the animal reluctant to expand the thorax.
- Be careful when handling the animal, especially around the thoracotomy site. Unilateral forelimb lameness is common after lateral thoracotomy but should resolve within several days.
- Local analgesia can be used as a method of decreasing postoperative discomfort. See lateral thoracotomy closure earlier in this chapter for intercostal nerve block technique.
- Systemic analgesia can also be used for those animals exhibiting significant pain. See Chapter 6 for discussion of postoperative analgesia.

Pneumothorax

- Small amounts of residual air in the pleural space are common after thoracic surgery and rarely cause a clinical problem.
- Persistent postoperative pneumothorax can be a serious problem after surgery of the lung or airways if continuing leakage occurs at the site of incision or excision.
- If pneumothorax causes respiratory compromise and a thoracic tube is not already present, tap the animal's chest with a butterfly needle, syringe, and stopcock (see Chapter 3). Place a thoracic tube and consider performing thoracic radiography if improvement in the animal's condition does not occur or if the pneumothorax is recurrent. Evaluate the heart, lungs, pleural space, and location of the thoracic tube.

Hemothorax

- Postoperative hemothorax can occur after any thoracic surgery but is more common after major cardiac or vascular surgery or after removal of large, highly vascular tumors. This can be a difficult complication to manage because reoperation does not usually reveal the source of bleeding.
- If large quantities of bloody fluid are aspirated from the thorax, obtain a packed cell volume (PCV) assay of the fluid. If the fluid is consistent with whole blood and the animal is losing considerable volume (i.e., clinical evidence of shock or PCV < 20), use supportive care to replace volume (isotonic or hypertonic fluids). A steadily declining PCV in evacuated pleural fluid is a good indicator of pending hemostasis.
- Perform autotransfusion if the blood is not contaminated with bacteria or neoplastic cells. Give whole blood from a donor dog if autotransfusion is not pos-

sible. (See Chapter 22 for more information on blood transfusions.)
- Monitor peripheral PCV and total protein until the animal's condition is stabilized.
- As a general rule, some surgeons recommend reexploration of the thorax if blood loss is >2 ml/kg/hour for 3 to 4 hours and unresponsive to conservative therapy.

Ventricular Arrhythmias

Cardiac arrhythmias are not uncommon and may develop 24 to 48 hours postoperatively (see Chapter 145).

Infection

- Postoperative infection after thoracotomy is uncommon but may occur if bacterial contamination occurs during the surgery or may be associated with the indwelling thoracic tube.
- Treat pleural infection with appropriate antibiotics (based on culture and sensitivity of the pleural fluid) and thoracic drainage (see Chapter 164). Rarely, thoracic lavage with fluids is necessary.

Chapter

168 Avian Techniques

Barbara L. Oglesbee

RESTRAINT

For General Physical Examination (Fig. 168-1)

- Hold the bird's head firmly with one hand, placing the thumb and second finger under the mandibles and the first finger on the crown.
- With the other hand, grasp the bird with a towel wrapped securely around the body.

For Radiography

- Anesthesia with isoflurane may be necessary and reduces stress from the procedure.
- Use an acrylic positioning board (Silverdust, El Granada, CA).

Dorsoventral View (Fig. 168-2*A*)

- Lock the head in an acrylic shield.
- Extend the wings fully and place masking tape proximal to the carpus and on the primary feathers.
- Tape the legs in full extension.
- Align the keel bone over the spinal column.

Lateral View (Fig. 168-2*B*)

- Position the bird with the right side down.
- Lock the head in an acrylic shield.
- Pull the wings dorsally and tape with masking tape proximal to the carpi.
- Tape the legs caudally, with the right leg slightly anterior to the left leg.
- Restrain the tail with masking tape.

OPENING THE MOUTH

- A mouth speculum (Lafeber Co., Odell, IL) can be used to keep the mouth open (Fig. 168-3*A*).
- This procedure can cause cracking of the beak in some birds.
- Alternatively, loops of gauze can be used (Fig. 168-3*B*).
- Restrain the bird in a towel with one hand (see Fig. 168-1); with the other hand, pull down on a gauze loop placed over the upper beak.
- Instruct an assistant to pull a second gauze loop over the upper beak.

FORCED ALIMENTATION (GAVAGE FEEDING)

- Hold the bird in an upright position, using towel restraint if necessary (see Fig. 168-1).
- Hold the mouth open with a speculum or gauze loops (see Fig. 168-3).

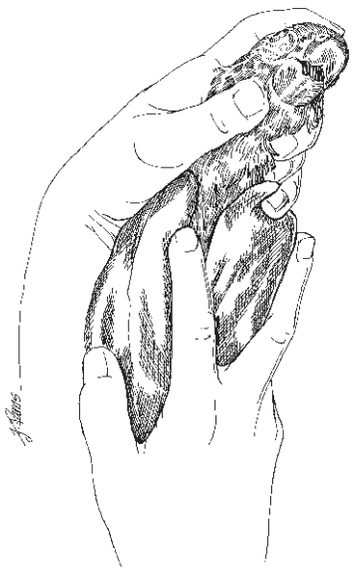

Figure 168-1. Restraint of parrot using a towel.

- Gently pass a rigid feeding tube (Lafeber Co., Odell, IL) or soft rubber catheter with an attached, gruel-filled syringe from the right side of the mouth into the crop (Fig. 168-4).
- Palpate the tube within the crop to check its position.
- Expel the contents of the syringe while monitoring the pharynx for reflux of food.
- Withdraw the tube and immediately release the bird.
- The volume of gruel to be administered varies with the size and age of the birds. Suggested volumes are budgerigar, 1 to 3 ml; cockatiel, 3 to 6 ml; Amazon parrot, 15 to 35 ml; and macaw 35 to 60 ml.
- The same procedure may be used to perform a *crop wash* for diagnostic sample collection. In place of gruel, instill 0.5 to 1 ml of sterile saline into the crop, then aspirate immediately.

SUBCUTANEOUS FLUID INJECTION

- Use a 25-gauge needle.
- Always use warmed fluids, 0.9% NaCl or lactated Ringer's solution (98°F).
- Divide volume of fluid into two equal injections in the groin area (Fig. 168-5).
- Approximately 1 to 2 ml of fluids per 100 g of body weight (BW) may be administered; the larger volume is given to smaller birds.

COLLECTION OF SAMPLES FOR CULTURE

Via the Choana (Fig. 168-6*A*)

- Hold the bird upright and open its mouth with a speculum or gauze loops (see Fig. 168-3).

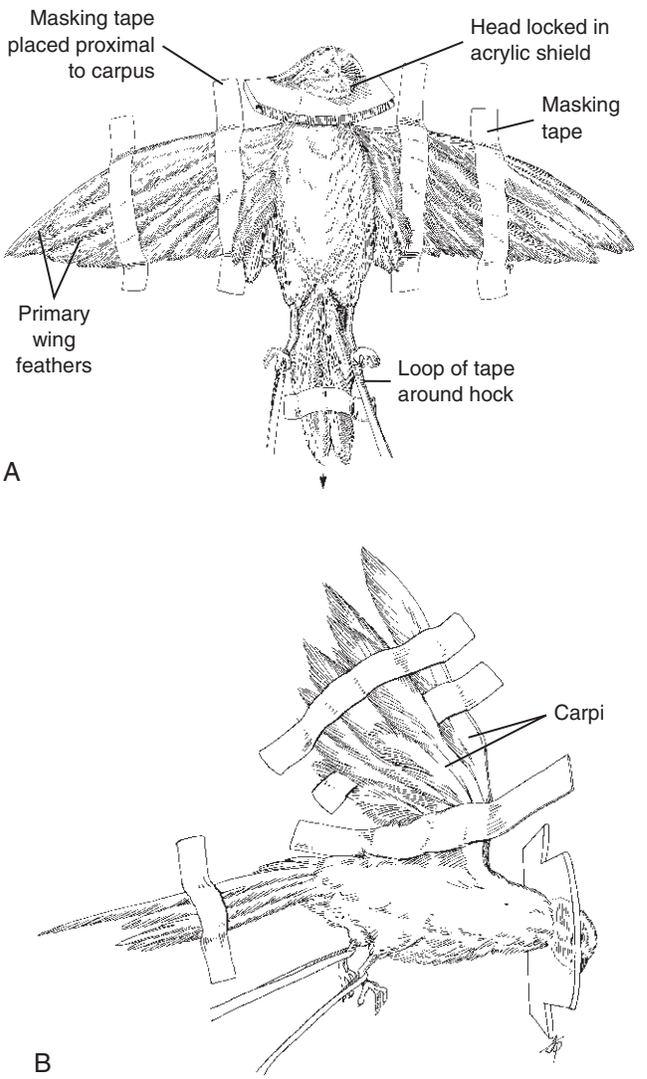

Figure 168-2. Restraint and positioning for radiography: *A,* dorsoventral view. *B,* lateral view.

- Insert a cotton-tipped swab into the most rostral portion of the choana.

Via the Cloaca (Fig. 168-6*B*)

- Restrain the bird in a towel.
- To avoid trauma to the mucosa, moisten the cotton-tipped swab with transport media or sterile saline solution before insertion into the cloaca.

VENIPUNCTURE SITES

▼ ***Key Point*** To prevent hematoma formation, always apply firm pressure after venipuncture.

The following sites are recommended for blood collection and infusion of bolus fluids.

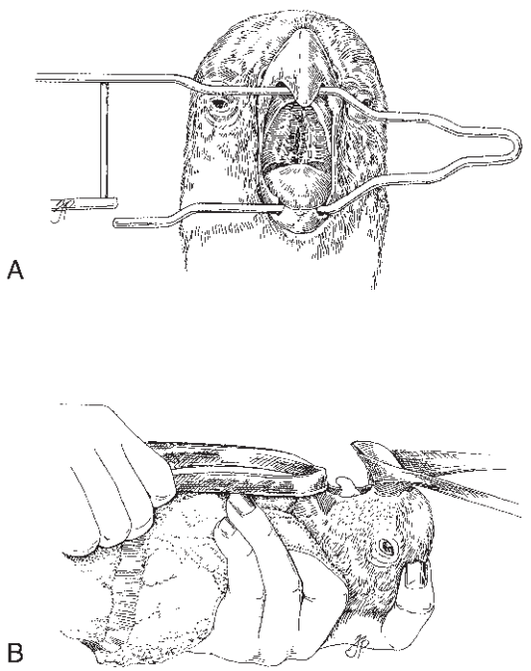

Figure 168-3. Opening the mouth using *(A)* a mouth speculum and *(B)* loops of gauze.

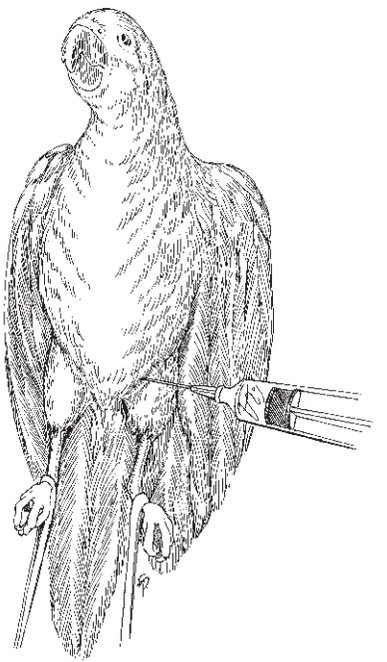

Figure 168-5. Subcutaneous fluid injection sites: interscapular region.

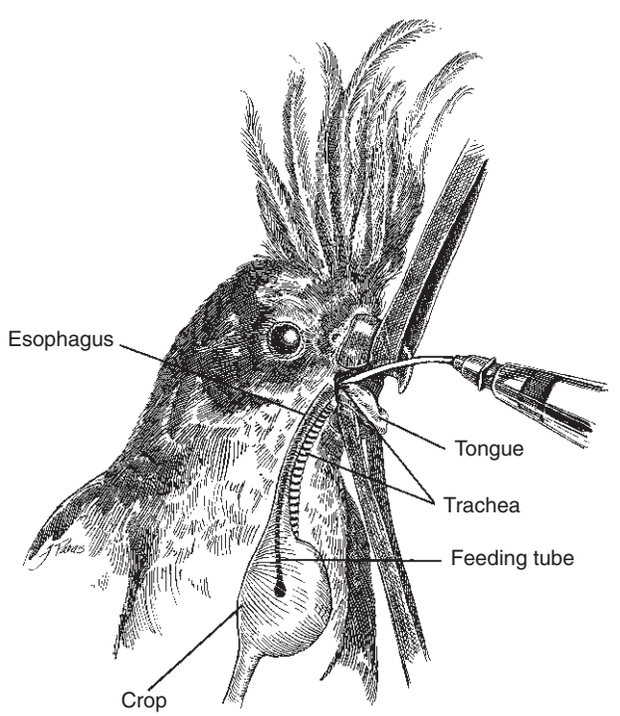

Figure 168-4. Forced alimentation.

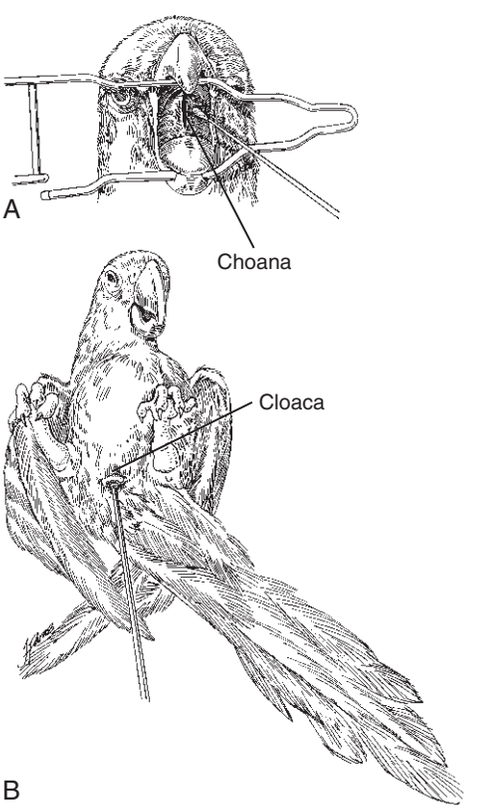

Figure 168-6. Collection of culture samples from *(A)* the choana and *(B)* the cloaca.

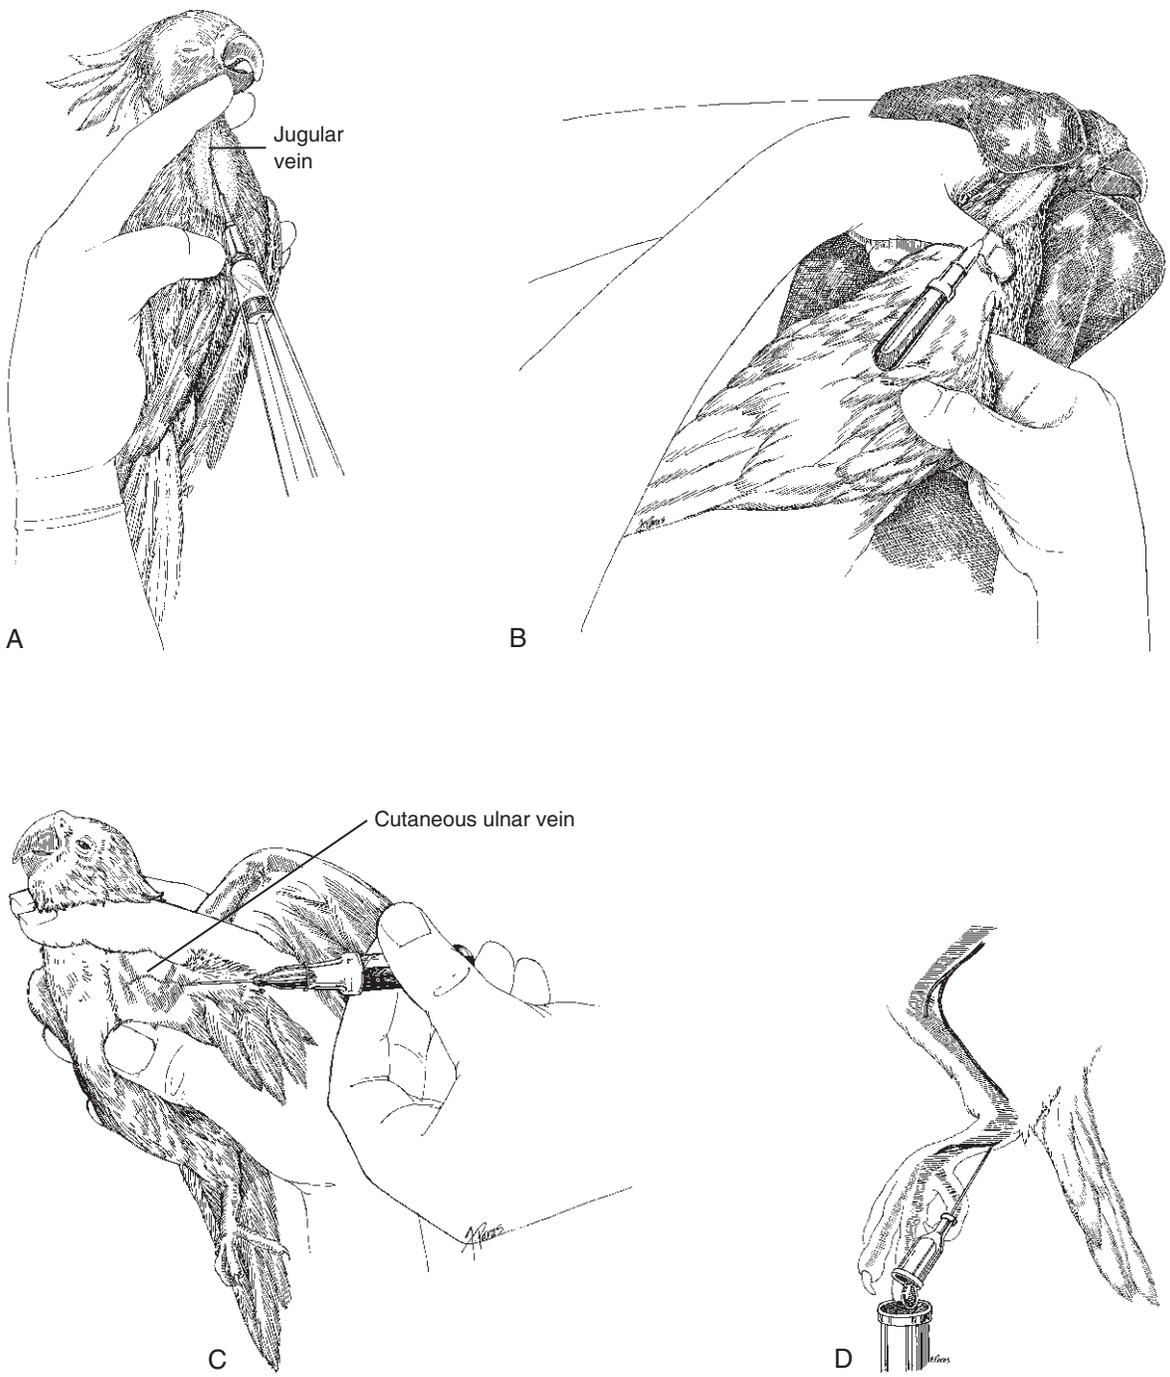

Figure 168-7. Venipuncture sites: *A,* jugular vein, birds weighing less than 200 g. *B,* jugular vein, larger birds. *C,* cutaneous ulnar vein. *D,* caudal tibial vein.

The volume of blood that may safely removed from a healthy bird for diagnostic sample collection is approximately 1% of BW (e.g., 1 ml of blood per 100 g of BW).

Jugular Vein

This venipuncture site is preferred for psittacine birds because of the relatively large size of the vessel and decreased tendency toward hematoma formation.

Birds Under 200 g (Fig. 168-7*A*)

- Use a hypodermic needle (25 or 27 gauge) and syringe (1 ml) for blood collection.
- The jugular vein is highly movable; make sure that the neck is in full extension.

Larger Birds (Fig. 168-7*B*)

- If an assistant is not available, larger birds (e.g., parrots) may require anesthetization with isoflurane.
- With the right hand, the assistant holds the feet and the right wing pulled caudally; with the left hand, he or she restrains the bird's head.
- Using a larger needle (22–27 gauge) and syringe (3 ml) for blood collection, apply firm pressure to the right jugular vein at the thoracic inlet.

Cutaneous Ulnar Vein (Fig. 168-7*C*)

- The cutaneous ulnar vein crosses the ventral surface of the humeroradioulnar joint.
- To collect blood, cannulate the vessel with a 25-gauge needle and aspirate with a 1-ml syringe.
- This vein is prone toward significant hematoma formation.

Caudal Tibial Vein (Fig. 168-7*D*)

- The caudal tibial vein passes on the medial side of the tibiotarsus just above the tarsal joint.
- To collect blood, cannulate vessel with a 25-gauge needle and allow blood to flow into a microcollection tube (Microtainer; Becton-Dickinson, Rutherford, NJ).
- Apply firm pressure for several minutes until bleeding stops.

INTRAMUSCULAR INJECTION (Fig. 168-8)

- If necessary, use towel restraint (see Fig. 168-1).
- Inject into the superficial pectoral muscles on either side of the keel bone. Alternate sides with subsequent injections.

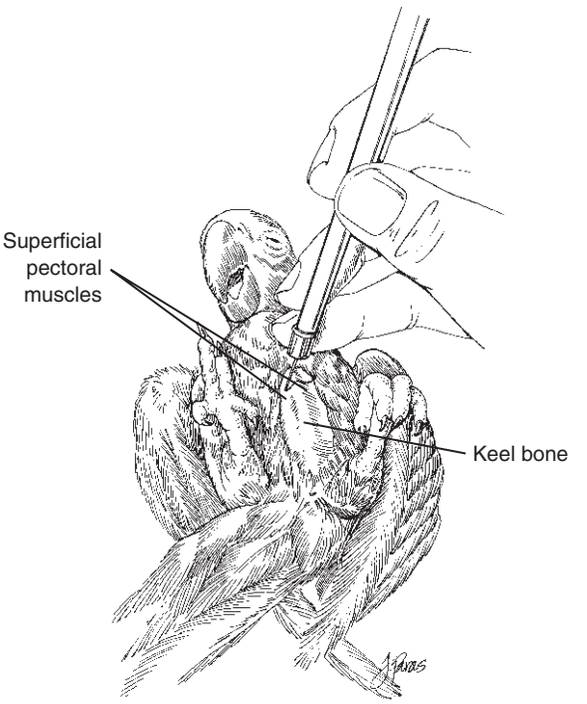

Figure 168-8. Intramuscular injection.

SINUS INJECTION OR FLUSH

Sinus Injection or Aspirate (Fig. 168-9*A*)

- Restrain the bird in a towel.
- Restrain the head firmly in a normal upright position.
- Insert the needle percutaneously into the sinus slightly above the commissure of the beak, midway between the upper beak and the medial canthus of the eye.

Sinus or Nasal Flush (Fig. 168-9*B*)

- Restrain the bird in a towel over a sink or collection bowl.
- Position the head so that it is slightly lower than the body, and restrain firmly.
- Press the syringe (without needle) against the naris opening.
- Inject 3 to 10 ml (depending on the size of the bird) of saline solution-antibiotic mixture into the nares with light pressure.
- If the flushing procedure is successful, the mixture will flow freely from the choana.
- Perform alternate flushes into each naris until all the mixture is used and/or no further exudate is produced.

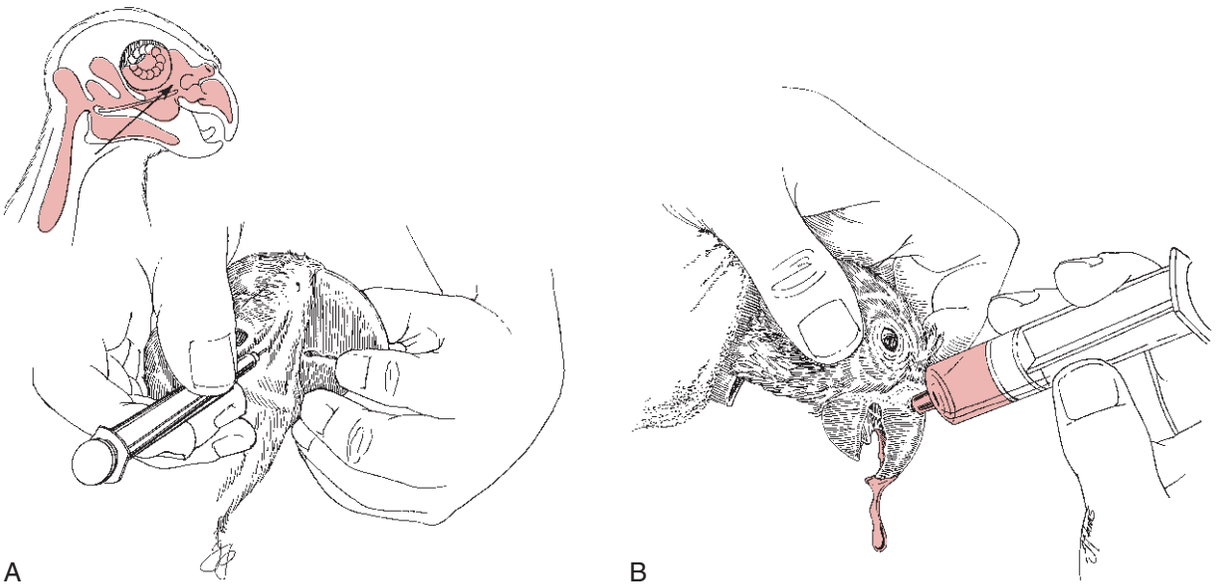

Figure 168-9. *A,* Sinus injection; *inset,* diagram of sinuses showing injection site *(arrow). B,* Sinus flush.

Figure 168-10. Tracheal injection or wash.

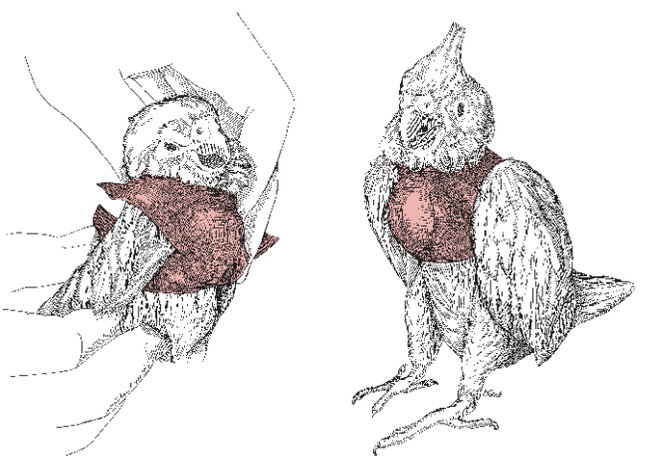

Figure 168-11. Crop supporter.

TRACHEAL INJECTION OR WASH (Fig. 168-10)

- Restrain the bird firmly.
- For tracheal injection, the bird may be held with the face upward, if desired.
- For tracheal wash, hold the bird in an upright position.
- Open the bird's mouth, using gauze loops or a speculum (see Fig. 168-1).
- Insert an open-ended tomcat catheter with attached syringe into the tracheal opening:
  - For tracheal injection—Inject medication.
  - For tracheal wash—Inject 1.0 to 2.0 ml of 0.9% NaCl/kg BW into the trachea, and then aspirate immediately.
- This method also may be used for tracheal endoscopy.

CROP SUPPORTER (Fig. 168-11)

- Cut the Vetrap longitudinally on each end.
- Position the longitudinal cuts above and below each wing.
- Secure in the back with tape.

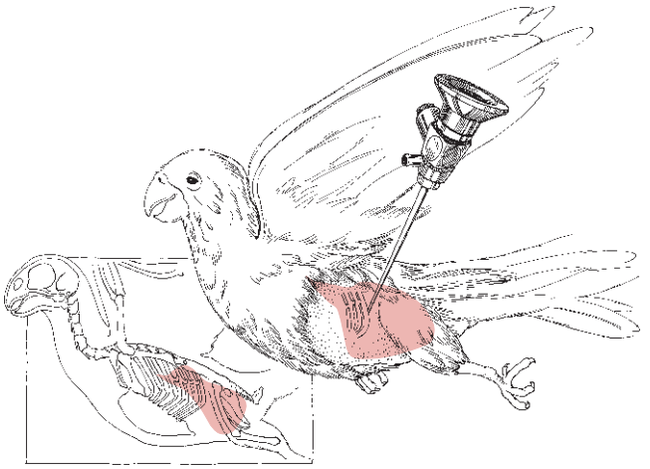

Figure 168-12. Preparation for endoscopy of the abdominal air sac; *inset,* trocar or cannula site.

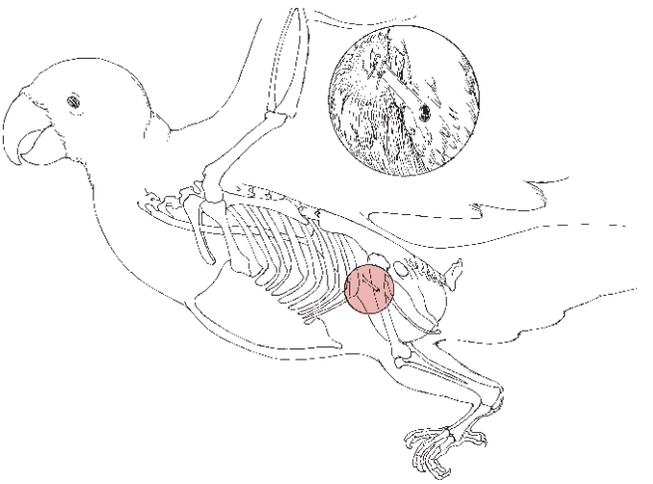

Figure 168-13. Abdominal breathing tube placement; *inset,* enlargement of placement site.

- When applying the Vetrap, maintain slight pressure inward to aid crop emptying.

PREPARATION FOR ENDOSCOPY OF THE ABDOMINAL AIR SAC (Fig. 168-12)

- Anesthetize the bird with isoflurane.
- Place the bird in lateral recumbency, right side down.
- Extend the wings out over the back; have an assistant hold them in this position.
- Pull the left leg as far caudally as possible.
- Push the right leg under the body to aid in maintaining true lateral recumbency.
- Pluck the area anterior to the proximal one-third of the femur free of feathers, and perform a sterile scrub.
- Apply clear drapes (3M, St. Paul, MN) over the area.
- Make a stab incision with a #15 scalpel blade through the skin anterior to the proximal one-third of the femur and caudal to the last rib.
- Bluntly separate the underlying musculature and peritoneum, using straight mosquito forceps.
- Introduce the trocar or cannula through the opened musculature to visualize the air sacs.

PLACEMENT OF ABDOMINAL BREATHING TUBE (Fig. 168-13)

- Enter the abdominal air sac using the technique described for endoscopy. Once the air sac is entered, the bird will begin breathing normally through the opening.
- Hold open the abdominal musculature or peritoneum with the inserted mosquito forceps.
- Place a 1- to 2-inch piece of a sterilized rubber catheter or shortened endotracheal tube in the opening and suture it in place with non-absorbable suture material.
- The catheter can be left in place for up to 2 weeks. If obstruction with mucus or exudate occurs, flush with a 0.9% saline solution.

Chapter

169 Avian Infectious Diseases

Don J. Harris / Barbara L. Oglesbee

ASPERGILLOSIS

Aspergillosis is an infectious but not contagious disease of pet and wild birds that is caused by the ubiquitous soil saprophyte *Aspergillus*. Infection generally occurs via inhalation of spores, resulting in primary lesions in the thoracic and abdominal air sacs and in the large airways (syrinx). Dissemination to other organ systems often occurs. Two forms of the disease, acute and chronic, commonly are seen.

- The acute form, which is seen most often in wild birds or psittacine birds under poor sanitary conditions, occurs after inhalation of an overwhelming number of spores. Severe dyspnea may result, with rapid progression to death.
- The chronic form, seen most often in psittacines, usually follows a stressful event or immunosuppressed state. Signs are often nonspecific and depend on the location of the infection and the immune status of the bird.
- The most common species isolated is *Aspergillus fumigatus*. *A. flavus, A. niger,* and other species play a lesser role.

▼ ***Key Point*** Aspergillosis is an opportunistic disease, requiring predisposing immunosuppressive factors such as stress, malnutrition, and environmental factors.

Etiology

Predisposing factors include the following:

- *Stress,* as may occur in shipping, quarantine, or movement to an unfamiliar environment. Stress also may result from a prolonged illness, such as chlamydiosis, or after a traumatic event, such as an injury or smoke inhalation.
- *Malnutrition* or vitamin deficiencies, especially hypovitaminosis A, often occur in birds on diets consisting of seed only.
- *Prolonged antibiotic or corticosteroid use* may cause underlying immunosuppression. For example, aspergillosis may occur after treatment for chlamydiosis owing to the immunosuppressive effects of tetracycline in conjunction with the debilitated state of a diseased bird.

▼ ***Key Point*** Suspect aspergillosis when clinical signs do not respond to or worsen with antibiotic treatment.

- Environmental factors:
  - Poor ventilation in conjunction with damp litter (especially corn-cob litter) soiled with feces promotes spore formation.
  - Poor sanitation, such as when nest boxes and incubators are cleaned inadequately, can predispose birds to aspergillosis.

Clinical Signs

Acute Form

- Signs include anorexia, dyspnea, and cyanosis.
- Sudden death may occur without signs.

Chronic Form

The onset is insidious, and signs vary depending on the location of the infection.

Respiratory System

Signs depend on the area affected. Respiratory signs will only occur if lesions impede airflow, for example, aspergillus granuloma formation in the syrinx, air sac thickening, and exudate accumulation in the air sacs.

Upper Respiratory Tract Signs

- Signs include a change in voice, reluctance to talk, and a respiratory click that can be heard when lesions involve the main airways, especially the syrinx.
- Severe, life-threatening dyspnea often occurs if the lesions are large enough to occlude the trachea or syrinx. In some cases, these may be the only lesions present.
- Mucoid to mucopurulent nasal discharge occurs in birds with *Aspergillus rhinitis* or *sinusitis*.
- Erosion of the nasal conchae and misshapened nares are seen in advanced cases of nasal aspergillosis.

▼ ***Key Point*** Suspect aspergillosis when the owner describes the bird as having "laryngitis."

Lower Respiratory Tract Signs

- With mild to moderate aspergillus airsacculitis, the air sacs are usually able to function normally (i.e., inflate and deflate to move air through the lungs). In these birds, respiratory signs are mild or absent, especially in birds that are sedentary.
- Dyspnea or exercise intolerance is seen in birds with extensive pneumonia or air sac involvement. Air sacs may become thickened or filled with caseous exudate, inhibiting their ability to move air.
- Respiratory signs are more likely to occur earlier in birds that are permitted to fly, as oxygen demand is greater in these birds.

▼ ***Key Point*** Birds with lower respiratory tract involvement often do not exhibit respiratory signs until disease is extensive. The most common clinical signs in birds with lower respiratory tract aspergillosis are nonspecific, such as weight loss, depression, and poor feathering.

Liver and Kidneys

Diarrhea, anorexia, and polyuria may be seen. Green discoloration of the urates (biliverdinuria) and hepatomegaly occasionally are seen.

Nervous System

Ataxia, torticollis, and paralysis may indicate central nervous system (CNS) involvement. Compression of the sciatic nerve by a granulomatous *Aspergillus* lesion has resulted in unilateral paralysis.

Nonspecific Signs

These are the most common signs. Weight loss, muscle wasting, depression, lethargy, and poor feathering often are the only clinical signs.

Diagnosis

History

- The history may identify an underlying environmental or immunosuppressive factor.

Physical Examination

- Examine the mouth and nares for mucus, exudates, or deformation of the nares. Take samples from the trachea or choana for fungal culture.
- Palpate the breast muscles and weigh the bird for evidence of weight loss and muscle wasting.
- Palpate the abdomen for evidence of organomegaly.
- Auscultate the trachea and chest for abnormal respiratory sounds and a respiratory click.

Laboratory Tests

- A severe leukocytosis often ranging from 25,000 to 100,000 white blood cells (WBCs) per microliter is often present.
- The differential count usually reveals heterophilia, monocytosis, lymphopenia, and anemia of chronic disease. Occasionally, the complete blood count (CBC) is normal.
- Increased serum total protein with an increased beta or gamma globulin portion is seen on plasma protein electrophoresis (EPH) in birds with chronic disease.
- Aspartate aminotransferase (AST), lactate dehydrogenase (LDH), and creatine phosphokinase (CPK) levels usually are increased, especially with hepatic involvement.

Endoscopy

▼ ***Key Point*** Endoscopy is invaluable for the diagnosis of aspergillosis.

- When there are episodes of severe dyspnea, tracheal endoscopy may reveal a single lesion occluding the syrinx.
- If a thick, white discharge or plaque is seen in the trachea, obtain a sample for cytologic examination and culture on Sabouraud's dextrose agar.
- Endoscopy of the abdominal air sacs may reveal diffuse cloudiness or white to yellow plaques. These plaques may become covered with a green-gray pigmented mold; obtain samples for culture and cytology.
- Samples for culture and cytology may sometimes be obtained by performing an air sac wash.

Radiography

- Radiographic changes may not be visible in early cases.
- Radiographs are generally not sensitive for defining tracheal granulomas, although if a soft tissue mass is seen within the trachea, aspergillosis should be suspected.
- In birds with nasal or sinus aspergillosis, perform cranial imaging such as skull radiographs, computed tomography (CT), or magnetic resonance imaging (MRI) to assess for the presence of granulomatous or caseated masses. Skull radiographs are less sensitive for picking up small lesions but are more readily available than CT or MRI.
- In advanced disease, radiographic abnormalities can include loss of definition of the air sacs, asymmetry of the air sacs due to air sac collapse or hyperinflation, and focal densities in the lungs or air sacs.
- Hepatomegaly or renomegaly may be visible radiographically when there is involvement of these organs.

Treatment

Treatment is most successful with early lesions confined to the nares or syrinx and when aggressive treatment is instituted early. A combination of topical treatment such as tracheal injection, sinus flush or nebulization (depending on the site of infection), systemic treatment, and debridement are usually necessary for successful outcome. Treatment is prolonged, requiring weeks to months of outpatient therapy. Continue treatment until clinicopathologic changes normalize and radiographic and endoscopic lesions resolve.

Antifungal Agents

- For birds with severe infections, administer amphotericin B (Fungizone, Squibb), 1.5 mg/kg q8h IV, for 3 to 7 days. Mask the bird with isoflurane anesthesia, and maintain an IV catheter for each injection.
- In birds with syringeal lesions, administer amphotericin B by intratracheal injection, using a tomcat urinary catheter (Sherwood Medical) at a dosage of 1 mg/kg q12h for up to 1 month.
- For nasal aspergillosis, a solution of 0.05 mg of amphotericin B per milliliter of sterile water may be used to flush the nares.
- For mycotic airsacculitis, make a solution of 1 mg of amphotericin B per milliliter of sterile water and nebulize q12h for 15 minutes. Alternatively, nebulize with clotrimazole (10 mg/ml in polyethylene glycol).
- Amphotericin B is potentially nephrotoxic and may cause bone marrow suppression. Monitor serum uric acid concentration to detect toxicity.
- Administer itraconazole (Sporanox, Janssen), 10 mg/kg q12h (with food) alone, in conjunction with, or following amphotericin B treatment. Usually at least 6 to 8 weeks of treatment are necessary; some birds may require treatment for months. Obtain a plasma biochemistry profile every 2 to 4 weeks to monitor for hepatotoxicity during treatment. African grey parrots appear to be more sensitive to the hepatotoxic effects of itraconazole. Use with caution, and discontinue use if anorexia occurs.
- Alternatively, administer fluconazole (Diflucan, Roerig), 15 mg/kg q24h PO, for up to 6 weeks with or after amphotericin B. Fluconazole is usually not as effective as itraconazole, but it may be better tolerated by some species, especially African grey parrots.
- Terbinafine (Lamisil, Novartis), 10 mg/kg q12h, PO has been anecdotally used to successfully treat aspergillosis in birds.
- 5-Fluorocytosine (Ancobon, Roche Labs), 50 to 150 mg/kg q12h PO, in conjunction with or after amphotericin B treatment has been used to treat aspergillosis in raptors. Give the higher dosage for active infections; use the lower dosage, often prophylactically, for 10 to 14 days in high-risk patients.

Antibiotic Therapy

- Antibiotic treatment based on culture and susceptibility testing may be necessary if a secondary bacterial infection is present.

Surgical Treatment

- Surgical removal of large accumulations of caseous material from air sacs in conjunction with systemic treatment and nebulization is often necessary for successful treatment.
- Surgical debridement of devitalized material from the upper airways and sinuses may facilitate topical therapy.

Supportive Care

- Fluid therapy, forced alimentation (see Chapter 168), and a warm environment are required for debilitated birds.

Prognosis

- The prognosis is poor to grave, depending on the severity of the disease.

Prevention

- Because *Aspergillus* is an opportunistic pathogen, attempt to reduce predisposing immunosuppressive factors such as stress and malnutrition.
- Treat birds with prolonged antibiotic therapy or other birds at risk with 5-fluorocytosine prophylactically (as previously described).

▼ ***Key Point*** To avoid inhalation of an overwhelming number of *Aspergillus* spores, house birds in a well-ventilated area. Do not use organic materials as bedding in nest boxes.

CHLAMYDIOSIS

Avian chlamydiosis is known as psittacosis when occurring in psittacine species and ornithosis when occurring in passerine species. The incidence in pet birds is high and is reportedly 15% to 30% of those tested.

Etiology

Avian chlamydiosis is caused by the obligate intracellular bacteria *Chlamydophila psittaci*. The organism infects many species of wild, domestic, and exotic birds, domestic mammals, and humans. Manifestation of this disease varies from subclinical to fatal, depending on the strain of *C. psittaci* involved and the species of bird affected.

▼ ***Key Point*** Chlamydiosis is potentially zoonotic and a reportable disease in many states. A valuable resource for practicing veterinarians, the compendium of psittacosis control is updated yearly by the Association of Public Health Veterinarians and is available at www.avma.org/.

Life Cycle and Transmission

Chlamydophila have a biphasic life cycle.

- Infectious, extracellular elementary bodies are shed in oral or nasal secretions and feces and may survive outside the host for a month or longer. Dissemination may occur via shared food dishes or aerosolized fecal dust.
- Elementary bodies are inhaled or ingested and enter host cells, where they undergo cellular rearrangement to form *reticulate bodies,* the replicating form of the organism.
- After replication, initial bodies reorganize to form *infectious* elementary bodies, which are released on rupture of the host cell. Elementary bodies then may be disseminated to cells of the liver, spleen, lungs, intestines, kidneys, gonads, and CNS.

Clinical Signs

▼ ***Key Point*** Clinical signs vary greatly, depending on the organ system affected, virulence of the organism, and immune status of the host.

- *Inapparent carriers* are common. These may be birds that have recovered from clinical illness or that may have never shown signs. High numbers of organisms may be shed intermittently from the feces or nasal or oral secretions, putting other pet birds and humans at risk.
- Clinical signs may develop in these carriers when they are stressed or otherwise immunocompromised.

Acute Form

- The acute form of the disease is seen more often in young or immunosuppressed birds. Signs may include the following:
  - Liver or gastrointestinal (GI) signs, such as inappetence, green-gray diarrhea, biliverdinuria (lime-green urates), and occasionally vomiting or regurgitation
  - Respiratory signs, including serous to purulent nasal or ocular discharge, labored breathing, blepharitis, and conjunctivitis
  - Nonspecific signs, including ruffled feathers, weight loss, and depression
- Without treatment, signs may progress over a few weeks, leading to prostration and death.

Chronic Form

- Nonspecific signs such as muscle wasting, poor feathering, lethargy, and inappetence may be the only signs. These signs are most often seen in birds with chronic hepatopathy.
- Recurrent conjunctivitis and mild respiratory signs are often seen.
- Occasionally, CNS signs (e.g., torticollis, seizures, and rear limb paresis or paralysis) may be seen alone.

Diagnosis

History

- Recently acquired birds may be at higher risk because of the increased exposure and stress associated with transport.

▼ ***Key Point*** Recently acquired birds are not the only ones at risk; birds may harbor the disease for months and even years before manifestation of clinical signs.

Physical Examination

- Findings may be normal in inapparent carriers.
- Suspect chlamydiosis in birds with poor feathering, weight loss, or signs of GI or respiratory disease.

▼ ***Key Point*** Lime-green urates are highly suggestive of chlamydiosis.

Laboratory Tests

- Leukocytosis, often >40,000 WBC per microliter demonstrating heterophilia with toxic heterophils, usually is seen in acute disease. Relative monocytosis and reactive lymphocytes and basophilia are often present.
- The WBC count may be normal in subclinical cases.
- A low packed cell volume is common in both acute and chronic disease.
- Serum protein usually is elevated as a result of chronic inflammatory stimulation. Plasma protein electrophoresis may demonstrate hypergammaglobulinemia and hypoalbuminemia.
- AST, LDH, bile acids, creatine kinase, and/or uric acid levels may be elevated, depending on the organ system affected.

Radiography

- Hepatosplenomegaly is the most common radiographic feature.
- Diffuse clouding of the air sacs may be present with airsacculitis.
- Often, no radiographic abnormalities are seen with chronic disease.

Antigen Capture

Immunoassay

- An immunoassay (IDEIA antigen system, California Avian Laboratories, Citrus Heights, CA) may be used to detect chlamydial antigen in naso-ocular discharges, pharyngeal swabs, and feces. The chlamydial organisms do not have to be viable for antigen to be detected.
- Shedding of organisms is often intermittent, producing false-negative results.
- Shedding is inhibited temporarily in birds tested within 1 to 2 weeks of treatment with erythromycin (e.g., Ornacyn, available in pet stores), doxycycline, tetracyclines, penicillins, chloramphenicol, tylosin, and quinolones.
- False-positive results also are common owing to cross-reactivity with some gram-negative bacteria. Confirm positive results using another method of testing.

Serology

Complement Fixation

- In the complement fixation (CF) test (Texas Veterinary Medical Diagnostic Laboratory, College Station, TX), single serum samples are of value if the titer is sufficiently high.
- Titers up to 1:8 are considered negative, 1:16 to 1:32 is suspicious, and >1:64 is positive. A fourfold rise in titer over a 4-week period is considered most significant. Titers may remain high following successful treatment.
- Young birds, budgerigars, cockatiels, canaries, and finches with chlamydiosis may not produce antibody titers high enough to be detectable by CF, making negative results unreliable in these birds.
- False negatives may occur when birds are tested early in the course of the disease, before sufficient antibody formation.

Latex Agglutination

- This test detects serum immunoglobulin M (IgM), which indicates a current infection.
- False-negative results are common in cockatiels, lovebirds, budgerigars, and some young birds, as well as in later stages of the disease.

Elementary Body Agglutination (Texas Veterinary Medical Diagnostic Laboratory)

- This test primarily detects IgM and is more sensitive than latex agglutination.
- IgM appears in the early phase of infection and wanes after approximately 3 weeks.
- False positives are rare, but false negatives are common.
- An elementary body agglutination titer of 80 suggests an active infection. Titers of 10 to 40 may be seen with low-grade infections, exposure, or recently treated infections.

Immunofluorescent Antibody

- This test primarily detects IgG, which appears in later stages of infection.
- False positives are more common than with other tests.

DNA Probe

- A highly sensitive and specific DNA probe for the detection of *Chlamydophila* infection is commercially available. Samples may be taken from blood, the oropharynx or cloaca.
- A positive result indicates an active infection, as false positives are unlikely.
- For *Chlamydophila* organisms to be detected in oropharyngeal secretions or cloacal swabs, the bird must be actively shedding organisms. Therefore, false-negative results are possible. However, a DNA probe is significantly more sensitive for detecting shedding than any other available method.
- For *Chlamydophila* organisms to be detected in blood samples, the bird must be bacteremic. Therefore, false-negative results are possible.
- To increase the likelihood of detecting infection, submit samples from the oropharynx, cloaca, and blood simultaneously.

Isolation on Culture

- Isolation requires live *Chlamydia* organisms.
- Success is highly dependent on proper transport medium, transport conditions, and previous antibiotic treatment.
- The chlamydial agent may be propagated in tissue culture, mice, or embryonated chicken eggs. Obtain postmortem samples from the spleen, liver, or air sacs.
- Isolation may be possible from antemortem exudate or fecal samples; however, shedding often is intermittent. This is the most reliable postmortem confirmation.

▼ ***Key Point*** False-negative results are common when testing for *Chlamydophila* organisms owing to intermittent shedding, administration of inhibitory antimicrobials, and production of low antibody titers in the face of active disease. Base the diagnosis of chlamydiosis on a combination of DNA probe and serologic testing, clinical signs, hematology, serum biochemical profile, plasma protein electrophoresis, and radiography.

Treatment

Tetracyclines are the most effective antibiotics against *Chlamydophila*.

▼ ***Key Point*** Tetracyclines must be administered for 45 days to be effective in eliminating infection. Client compliance is often a problem, especially when once- or twice-daily oral administration is prescribed. Treat clinically ill birds by a parenteral or direct oral route. Use food- and water-based dosage regimens in stable birds only. Monitor these birds to ensure that the treated food or water is being appropriately consumed.

- *Doxycycline* (Vibramycin, Pfizer) is the drug of choice for treatment of *Chlamydophila*. It is available in an oral (suspension, solution, or capsules) or IV form in the United States. The IV form should *not* be injected IM or SC.
  - The dosage of doxycycline varies, depending on the species. Administer 25 mg/kg q24h to macaws and cockatoos and 35 to 50 mg/kg q24h to African grey parrots, cockatiels, and Amazon parrots. Senegal parrots require 30 mg/kg q12h. Some birds will regurgitate on higher doses. Doxycycline may be mixed with a small amount of a favorite food, as long as that food is immediately and completely consumed.
  - For cockatiels and budgerigars, doxycycline may be added to a mixture of *hulled* millet seed and oats. Lightly coat the seed-oat mixture with sunflower oil, and add doxycycline at a rate of 300 mg/kg of seed mix. Feed birds this mix exclusively for 45 days. Use this route only in stable birds. Monitor birds to ensure that they are eating this diet.
  - Doxycycline for IM injection (Vibravenos, Pfizer) is available in countries outside of the United States and may be imported for use in birds. Administer 75 to 100 mg/kg IM every 7 days for 6 weeks.
  - Doxycycline may be effective for some birds when added to the drinking water. Use this route only in stable birds, and carefully monitor the birds to ensure that the water is palatable and that water consumption is normal. Birds may overconsume water during hot, dry periods or while on dry or pelleted diets, resulting in overdosage. Underdosage, resulting in treatment failures and possibly dehydration, may occur if birds refuse to drink treated water. Species that normally consume very little water, such as budgerigars *cannot* be effectively treated using water-based medication. Dosages are available for a limited number of species and include 300 to 400 mg/L water for cockatiels, 400 mg/L water for Goffin's cockatoos, and 600 to 800 mg/L water for African grey parrots.
- Secondary mycotic or bacterial infections owing to alterations of the normal enteric flora, stress, and immunosuppression are a common problem in birds treated with doxycycline.
- Thoroughly clean the environment following treatment to remove chlamydia organisms and prevent reinfection.
- Treat all birds sharing the same air space as birds diagnosed with *Chlamydophila* for 45 days.

Supportive Care

- Many birds with acute chlamydiosis are seriously ill and require supportive care such as fluid therapy, forced alimentation (see Chapter 168), and heat, as well as antibiotic therapy if secondary bacterial infection is present.

Prevention

- Because inapparent carriers are common and an accurate screening test is not available, it is difficult to prevent the introduction of *Chlamydia* organisms into a flock when purchasing new birds. A combination of serology and DNA probe to screen for chlamydiosis is recommended, with repeated yearly testing.

PSITTACINE VIRAL DISEASES

Psittacine Circovirus: Psittacine Beak and Feather Disease

Psittacine beak and feather disease (PBFD) is an infectious, sometimes fatal disease characterized by feather loss, feather dystrophy, occasional beak deformity, and destruction of the thymus and bursa. Originally believed to affect only white and pink cockatoos and a few other South Pacific psittacine birds, the disease has been reported in more than 30 species of Asian and South Pacific psittacine birds and is believed to be capable of causing disease in many others. Occurrence in Central and South American psittacine birds is rare. Death is attributed to secondary bacterial, viral, or mycotic infections or to general debilitation.

Etiology

- PBFD is caused by a non-enveloped, single-stranded DNA virus (PBFDV) that is structurally similar to the porcine circovirus and chicken anemia agent.

Transmission

- Virus may be recovered in the feces, crop secretions, and feather dust of infected birds. Being non-enveloped, PBFDV is thought to be extremely stable in the environment and may be resistant to many disinfectants.
- Infection may occur by inhalation or ingestion of the virus.
- PBFDV is believed to spread throughout the body of an infected bird via circulating WBCs. There is evidence that inapparent carriers may exist.

▼ ***Key Point*** Feather dust is a major method of transmission and environmental persistence of PBFDV. Feather dust may be dispersed through natural air flow and may contaminate food dishes, cages, bird carriers, insects, and human clothing.

Clinical Signs

PBFDV may cause peracute, acute hematologic, acute dermatologic, or chronic disease.

Peracute Form

This form is seen in neonates, most often cockatoos and African grey parrots, and may be associated with crop stasis, pneumonia, diarrhea, weight loss, and rapid death. There are few feather lesions.

Acute Hematologic Form

This form is seen almost exclusively in African grey parrots and on occasion in other African species.

- Patients usually present near or just after weaning age with severe weakness and depression.
- The primary hematologic feature is a marked pancytopenia, with WBCs sometimes absent and the hematocrit dropping to as low as 4%.
- Recovery is rare but has occurred with supportive care.

Acute Dermatologic Form

This form is seen in birds as young as 30 days of age, when feathers begin to replace neonatal down.

- Feather lesions include fractures, necrosis, hemorrhage, curvature, and premature shedding of affected feathers.
- GI signs include diarrhea, crop stasis, and anorexia. There may be few feather lesions, especially in young cockatoos, lovebirds, and African grey parrots.
- Death may follow the onset of clinical signs within days to several weeks.

Chronic Form

This form usually is recognized in psittacines younger than 3 years of age but has been reported in birds as old as 20 years of age. Birds may live for months to years before succumbing to secondary infections or chronic debilitation.

- Progressive feather abnormalities may be accompanied by beak lesions.
- Feather lesions include retained feather sheaths, bleeding within the pulp cavity, fractured feathers, clubbed feathers, circumferential constrictions within the feather shaft, curled or deformed feathers, and stress lines within feather vanes.
- Feather loss typically begins with powder down feathers. Contour, crest, wing, and tail feather loss is roughly symmetrical and progresses with each molt. Some birds become completely bald and remain so until death (months to years).
- Beak lesions often occur in galahs and Moluccan and sulfur-crested cockatoos but are not routinely seen in other species. Lesions may include oral ulceration and elongation and fractures of the beak, often accompanied by secondary mycotic or bacterial infections. Beak lesions usually occur after chronic feather loss but also can occur in birds with mild feather lesions. In cockatoos, the beak may appear shiny and black because of the absence of powder that settles on the beak during preening.

Diagnosis

Histopathology

- In affected feathers, typically there are ballooning degeneration and necrosis of epithelial cells in the epidermal collar and in the epidermal basal and intermediate zones of the developing rachis.
- Non-suppurative inflammation, characterized by perivascular accumulations of heterophils, plasma cells, lymphocytes, and macrophages, is the primary lesion seen in the feather pulp.
- Beak lesions histopathologically are similar to those seen in the feather shafts.
- The thymus and bursa typically are atrophied, with focal areas of necrosis and degeneration. These lesions are thought to cause immunosuppression.

Hematoxylin and Eosin Stain

- Basophilic intranuclear and intracytoplasmic inclusion bodies may be seen with hematoxylin and eosin (H&E) staining in the feathers, pulp, and follicular epithelium. These were once considered diagnostic for PBFDV; however, other viruses (e.g., avian polyomavirus) may induce similar intranuclear inclusion bodies.

DNA Probe

- A highly sensitive and specific viral DNA probe for the detection of PBFDV infection is commercially available (Infectious Diseases Laboratory, University of Georgia, Athens, GA). Birds latently infected can be detected by submitting 0.2 to 0.5 ml of whole unclotted blood. This test allows veterinarians to screen for birds subclinically infected with PBFDV.
- Birds testing positive on a blood DNA probe for PBFDV with *no* feather lesions should be retested in 90 days. If negative, the bird has cleared the virus and is likely immune. Birds continuing to test positive after 90 days are subclinically infected and may develop feather lesions at a later date.
- Birds testing positive on a blood DNA probe for PBFDV *with* feather lesions have an active infection. It is still possible that DNA-positive birds will mount

an immune response, clear the infection, and become blood DNA negative. However, keep birds with feather lesions strictly isolated until all feathers become normal. Abnormal-appearing feathers and their feather dust should be considered infectious. Monitor these birds for the development of normal feathers.
- Birds with feather lesions that continue to test positive and continue to grow abnormal feathers are unlikely to recover and will continue to be infectious to other birds as long as abnormal feathers are present.

▼ ***Key Point*** Keep all birds with abnormal feathers strictly isolated. Birds may become blood DNA negative before all affected feathers are molted. However, as long as abnormal feathers and their associated feather dust are present, the bird is continuing to shed virus and should be considered contagious.

Treatment

- There is currently no effective treatment for PBFDV.
- Provide supportive care (e.g., good nutrition, debridement of lesions, beak trimming, and heat) and antimicrobial therapy for secondary bacterial and fungal infections for chronically infected patients.

Prevention

▼ ***Key Point*** Using the DNA probe, test all birds for PBFDV prior to admission to the aviary.

- Isolate all birds testing positive for PBFDV to prevent contact with non-infected birds.
- Isolate all birds with feather lesions caused by PBFDV from direct or indirect contact with other birds until all abnormal feathers have been replaced with normal feathers.
- Exercise care to prevent feather or fecal dust from infected birds contaminating non-infected birds, particularly psittacine neonates.
- Viral particles, which are resistant to practically all disinfectants, may remain viable for more than 3 years in a contaminated environment.

Polyomavirus

Etiology

Polyomavirus is responsible for major economic losses in commercial budgerigar aviaries (budgerigar fledgling disease, BFD). Polyomavirus also has been reported to cause clinical disease in nearly all species of large psittacine birds and in passerine birds.

Budgerigars that survive BFD infection may develop feather abnormalities commonly referred to as "French molt." The lesions of French molt, however, also may be caused by psittacine circovirus.

Transmission

- Polyomavirus may be present in feces, feather dust, and oronasal and oral secretions. These contaminated materials may be inhaled or ingested by susceptible birds.
- Infected hens may pass the virus to offspring through the egg.
- Latent infections are common in budgerigars and are believed to be responsible for spread of this virus. Clinically normal parents may transmit polyomavirus to their offspring, some of which also become inapparent carriers.
- There is currently no evidence to support the existence of persistent infections in larger psittacine birds. However, some psittacine birds may become infected without demonstrating clinical signs and shed virus before eliminating the infection. Thus, birds with subclinical infections may be responsible for viral outbreaks, especially in pet stores and breeding facilities where susceptible neonates are exposed.

Clinical Signs

Hatchling Budgerigars <15 Days Old

- Signs include abdominal enlargement, delayed crop emptying, subcutaneous hemorrhage, retarded growth, and abnormal feathers.
- Sudden death is common. Reported mortality rates vary from 30% to 100% of affected hatchlings.

Budgerigars >15 Days Old

- Signs are similar to those described for hatchlings; however, the mortality rate is much lower.
- Fledglings may produce deformed primary flight feathers that break off at the base, leaving the birds unable to fly thus called "runners."

Neonatal Parrots

Non-budgerigar psittacine neonates are extremely susceptible to polyomavirus and are likely to develop clinical signs.

- Clinical signs usually develop at the time of weaning but may be seen anywhere from 14 to 150 days of age.
- Sudden death with and without clinical signs is common; birds that develop clinical signs usually die within 12 to 48 hours.
- Signs include diarrhea, delayed crop emptying, depression, anorexia, widespread hemorrhage, polyuria, and posterior paresis and paralysis.
- Unless immunosuppressed, adult non-budgerigar psittacine birds demonstrate mild or no clinical signs and eventually eliminate the virus. However,

these birds are likely to shed virus before recovery and thus serve as a source of environmental contamination.

Diagnosis

- Gross pathologic changes include hydropericardium, cardiomegaly, pale kidneys, ascites, hepatomegaly, splenomegaly, and diffuse petechial and ecchymotic hemorrhages in the subcutis, intestines, myocardium, epicardium, and serosal surfaces.
- Histopathologic demonstration of karyomegaly with basophilic intranuclear inclusion bodies in the kidneys, liver, spleen, heart, or feather follicles suggests polyomavirus.
- Confirmatory diagnosis requires the identification of viral antigen using virus-specific antibodies or the detection of viral nucleic acid using virus-specific DNA probes.
  - Highly specific and sensitive viral DNA probes (Infectious Diseases Laboratory, University of Georgia, Athens, GA or Avian Research Associates Laboratory, Milford, OH) can detect polyomavirus in infected tissue, cloacal swabs, and fresh feces of birds shedding virus. Identify birds that are shedding the polyomavirus by submitting a cloacal swab for testing. False-negative results may occur if the bird is not shedding virus at the time of testing.

Treatment

- Provide supportive care, as described for PBFD.

Prevention

▼ ***Key Point*** Quarantine all new birds for 30 days before entrance into an aviary. Perform DNA probe testing on all birds before entrance into an aviary. Isolate birds testing positive.

- Do not keep budgerigars in the vicinity of unvaccinated neonatal parrots.
- Do not mix neonates from different sources or return a neonate to the nursery after exposure to other birds.
- Disinfection with chlorine solution (50 ml/L of water) or prolonged contact with iodophors inactivates the virus.

Vaccination

A United States Department of Agriculture (USDA) approved inactivated avian polyomavirus is considered safe and effective (Biomune, Lenexa, KS). Administer the vaccine subcutaneously. Mild injection site reactions have been reported but should resolve within 3 to 6 weeks after injection. Follow vaccination guidelines provided by the manufacturer.

Pacheco's Disease

Also known as *herpes hepatosplenitis,* Pacheco's disease causes an acute, necrotizing hepatosplenitis that usually is rapidly fatal. The hallmark of Pacheco's disease is sudden death in birds that appear clinically normal until just before death. All species of psittacines of all ages, both imported and domestically raised, are susceptible.

Etiology

- Several strains of antigenically unrelated herpesvirus may cause Pacheco's disease; herpesvirus persists by inducing latent disease, with periodic reactivation and shedding. Clinical disease is dependent on the virus serotype, the species, and the immune status of the infected bird.

Transmission

- Although the exact route of Pacheco's disease virus transmission is unknown, this virus is present in high numbers in the feces and pharyngeal secretions of symptomatic and asymptomatic carrier birds. Thus, direct-contact contaminated aerosols and fecal-oral routes are the most likely routes of virus transmission.
- Herpesvirus is an enveloped virus and is relatively unstable in the environment. Anecdotal reports suggest that humans can serve as vectors, even with relatively long intervals between bird exposure. An incubation period of 3 to 7 days is common.

▼ ***Key Point*** Asymptomatic carriers of viruses that cause Pacheco's disease are common and often are incriminated in disease outbreaks. Any psittacine bird that has been exposed to or recovered from herpesvirus infection may potentially become a carrier.

Clinical Signs

- Sudden death without premonitory signs has been reported most frequently in Amazon parrots, cockatoos, lovebirds, Pionus parrots, and parakeets.
- Nonspecific signs include lethargy, anorexia, vomiting, diarrhea (sometimes hemorrhagic), biliverdinuria, naso-ocular discharge, and occasionally CNS signs.
- Signs often progress to death within several days; however, recovery has been reported in some birds with clinical signs consistent with Pacheco's disease virus.

Diagnosis

Antemortem Diagnosis

- Virus isolation from feces may reveal infection; however, viral shedding may be intermittent, making it ineffective for the detection of carrier birds.

- A reliable serologic test is not commercially available.
- A DNA probe is currently available that theoretically detects all known herpes serotypes affecting pet birds. Evidence suggests that the oral cavity or the cloaca is a highly reliable site for the collection of samples. To detect virus, birds must be shedding virus at the time the sample is taken, so false negatives are possible. The significance of a positive test is currently unclear at the time of this writing. A positive test result indicates that the bird is shedding a herpesvirus; however, what type of clinical disease, if any, that the detected herpesvirus may cause is unknown.

Postmortem Diagnosis

- Gross lesions may include hepatomegaly, splenomegaly, hemorrhagic enteritis, sinusitis, pneumonia, airsacculitis, and congestion and hemorrhage in the spleen, liver, and kidneys. Gross lesions may not be apparent in birds with peracute death.
- Histopathologic lesions often include hepatic and splenic necrosis.
- Virus may be isolated from liver, spleen, small intestine, and pancreas.

▼ ***Key Point*** Basophilic and eosinophilic Cowdry type A inclusion bodies, often present in the liver, spleen, kidneys, and pancreas, suggest herpesvirus infection.

Treatment

- Oral administration of acyclovir (Zovirax, Burroughs Wellcome) (80 mg/kg q8h × 7d) or the IV form given IM (40 mg/kg q8h) has been reported to decrease morbidity and mortality during Pacheco's disease outbreaks.
- Supportive care, including fluids, heat, assisted alimentation, and antibiotic therapy for secondary infections, may be of some benefit.

Prevention

- Do not mix susceptible birds with suspected carriers.
- Sanitation is critical in disease prevention because viral spread within an aviary occurs primarily by contact with contaminated feces and pharyngeal secretions.
- Thoroughly clean water and feed dishes followed by treatment with a disinfectant. Herpesvirus typically is inactivated by desiccation and through contact with most disinfectants.
- Instruct all aviary personnel to practice sound hygiene by washing and disinfecting hands before entering the aviary and after handling individual birds or cages.
- Reduce stress to help prevent shedding and spread of the virus.

Vaccination

Licensed Pacheco's disease virus vaccine is currently available (Biomune, Lenexa, KS). Two vaccinations subcutaneously in the inguinal area 4 to 8 weeks apart followed by yearly boosters are recommended. The vaccine is not effective against all avian herpesvirus serotypes.

Other Herpesviruses

Thirteen different herpesviruses are known to affect birds. The pathogenicity, host spectrum, and relation of these viruses largely are unknown.

- The only herpesvirus of known clinical significance in psittacine birds (besides those that cause Pacheco's disease) is Amazon tracheitis virus.
  - This virus causes a pseudomembranous tracheitis, pharyngitis, and sinusitis.
  - Signs include dyspnea, change or loss of voice, abnormal respiratory signs, and occasionally hemoptysis.
  - Base diagnosis on virus isolation or typical Cowdry type A inclusion bodies in the tracheal mucosa at necropsy.
  - Treatment is similar to that discussed for Pacheco's disease virus.
  - Based on histologic findings, another herpesvirus has been reported as the suspected etiology of wart-like lesions occurring on the feet of cockatoos.
  - Limited success has been reported in these cases with treatment with topical application of acyclovir cream.

Poxviruses

Poxvirus is commonly seen in canaries, pigeons, and wild birds. It is rarely seen in pet psittacine birds due to recent restrictions on importation of these birds.

Two forms of clinical disease caused by avian poxviruses commonly are encountered:

- Dry, or cutaneous, pox is characterized by discrete nodules on unfeathered skin.
- The more common wet, or diphtheritic, pox is characterized by fibronecrotic lesions in the respiratory system, conjunctiva, and pharynx.

The type of disease that develops may depend on the strain of infecting virus, route of infection, and the species, age, and condition of the host.

Etiology

- Avipoxviruses replicate in the cytoplasm of epithelial cells, inducing characteristic intracytoplasmic, lipophilic inclusion bodies called *Bollinger bodies*.
- Host susceptibility and virulence of the virus varies with the strain of avipoxvirus. Most poxvirus strains are relatively host specific.

Transmission

- Poxvirus is incapable of penetrating intact epithelium. Entrance into the host is gained through preexisting traumatic lesions or often is introduced into a flock via mosquito vectors.
- Virus is shed in epithelial crusts and exudates during active infection and in feces, skin, and feather quills during recovery and in latent infections.
- Virus transmission may occur through direct contact with affected birds or through contact with contaminated soil, food, or cages.
- Poxviruses are very resistant to desiccation, humidity, and light and may survive up to 1.5 years in the environment.
- Recurrence of poxvirus lesions has been reported in some species.
- It is postulated that asymptomatic carriers of poxvirus may exist.

Clinical Signs

Diphtheritic (Wet) Pox

- Yellow to gray-brown fibronecrotic plaques may occur on the mucosa of the mouth, choana, beak, esophagus, and trachea.
  - Multiple plaques may coalesce, forming tightly adherent diphtheritic membranes, which, if forcibly removed, leave a raw, hemorrhagic surface.
- Respiratory epithelium may be affected, with resulting dyspnea, rales, serous to purulent naso-ocular discharge, lethargy, and anorexia.
- Death due to secondary bacterial bronchopneumonia is common.

Cutaneous (Dry) Pox

- Signs include papules, pustules, and scabs on the unfeathered portions of the skin.
  - Secondary bacterial and fungal infections are common and may result in swelling or abscessation.
  - If no secondary bacterial infection occurs, the lesions may resolve without scarring in 10 to 14 days.
- In canaries and finches, wart-like lesions are common on unfeathered skin.

Diagnosis

- Clinical lesions suggest the diagnosis.
- Epithelial hyperplasia with ballooning degeneration and intraepithelial vesicles seen on histopathologic examination suggest avian pox.
- Intracytoplasmic lipophilic Bollinger bodies are pathognomonic.

Treatment

- Treatment of secondary fungal or bacterial infections is based on culture and susceptibility testing.
- Birds often have systemic illness, and mortality rates are high.
- Provide supportive care such as supplemental heat, fluid therapy, and assisted alimentation, if mouth lesions are present.
- Prophylactic administration of systemic broad-spectrum antibiotics may prevent secondary bacterial infections.

Prevention

Vaccination

Vaccines are available for canaries, pigeons, and domestic fowl. Use of these vaccines is restricted to high-risk populations, such as recently imported birds or birds exposed to large numbers of mosquitoes. Adverse reactions, including sudden death, have been associated with the vaccine.

Disinfection

Effective disinfectants include 1% potassium hydroxide (KOH), 2% sodium hydroxide (NaOH), and 5% phenol.

- To control an outbreak, replace all wood items in the aviary and clean and disinfect all equipment, nets, cages, and breeding containers.

Reoviruses

There are 11 avian serotypes of reoviruses that are antigenically distinct from each other and from reoviruses isolated from mammals. Of the common pet birds, African grey parrots have historically been the most severely affected.

Etiology

- Avian reoviruses have been isolated or identified by electron microscopy from asymptomatic psittacine and passerine birds.

Transmission

- Both horizontal and egg transmissions of reovirus occur in chickens. However, little is known about transmission in psittacine birds; horizontal transmission through oral and respiratory routes is believed to occur.
- The incubation period in experimental studies is 2 to 15 days. After natural exposure, replication of the virus occurs in the GI mucosa, followed by viremia (24–48 hours) and spread to other organ systems.

Clinical Signs

- Severity of the disease, and thus clinical signs, varies, depending on the age of the host, the virulence of the virus, the route of infection, and the presence or absence of secondary infections.

- Signs include anorexia, depression, yellow-orange urates, diarrhea, dyspnea, and occasionally paresis, hind limb paralysis, and bloody nasal discharge.

Diagnosis

- Gross pathologic changes include hepatosplenomegaly with pale yellow mottling and multifocal gray-white foci.
- The typical histologic lesion is disseminated or focal coagulative, necrotizing hepatopathy.
- A tentative histologic diagnosis may be confirmed by isolating the virus in cell culture from feces, liver, or spleen.

Treatment

- Supportive care is the only treatment currently available.

Prevention

- There currently is no serologic test or commercial vaccine available for reoviruses affecting pet birds.
- Strict quarantine of newly arrived birds, especially birds of African descent, may help prevent flock exposure. However, epidemiologic evidence suggests the existence of an asymptomatic carrier state.
- Viral infectivity can be reduced by prolonged contact with phenols, aldehydes, ethanol, halides, a 0.5% iodine solution, and a temperature of 158°F.

Adenoviridae

Adenovirus infections have been associated with depression, diarrhea, anorexia, and acute death in budgerigars, Amazon parrots, macaws, cockatoos, lovebirds, and parakeets. Adenovirus infections typically produce eosinophilic and basophilic intranuclear inclusion bodies.

Adenovirus infections in psittacines commonly are referred to as *inclusion body hepatitis* or *inclusion body pancreatitis,* depending on the predominant organ system involved.

Clinical Signs

- Signs generally are nonspecific and vary with the organ system affected. Signs include lethargy, depression, fluffed feathers, yellow urates, diarrhea, anorexia, and sudden death.

Diagnosis

- An enlarged, friable liver is the most consistent feature recognized on gross necropsy examination.
- Base definitive diagnosis on histologic examination of affected tissues from necropsy specimens. Histologically, there is diffuse necrosis of parenchymatous organs with eosinophilic and basophilic intranuclear inclusion bodies.

Treatment

- There is no specific treatment.
- General supportive care may be beneficial (warmth, fluids, forced alimentation, and antibiotic therapy for secondary infection).

Prevention

- Disinfect cages and supplies with an aldehyde disinfectant (requires 1 hour of contact) to prevent spread of the disease.
- Quarantine all new birds and strictly isolate affected birds.

Newcastle Disease Virus (Paramyxovirus-1)

Newcastle disease virus (NDV) is of extreme economic importance to the poultry industry. Legally imported birds are placed in USDA quarantine stations for 30 days. These were created to prevent the introduction of virulent forms of this virus into the United States.

▼ ***Key Point*** Smuggling of birds into the United States is the main source of NDV-infected birds. NDV should not be a problem for the serious aviculturist who does not expose an aviary collection to birds of questionable origin. NDV is a reportable disease.

Etiology

- There are nine serotypes of avian paramyxovirus (PMV). The most significant pathogens are virulent serotypes of PMV-1, which has been isolated from most species of domestic, aviary, and wild birds.

Transmission

- The respiratory and oral routes of transmission are equally important.
- Fecal contamination of eggshells may lead to viral spread. The virus infects the red blood cells and then is spread throughout the body.
- The incubation period typically is 4 to 7 days.

Clinical Signs

- Clinical signs depend on the virulence of the strain of virus involved.
- Predominant clinical signs in psittacine birds include fluffed feathers, conjunctivitis, and CNS signs (e.g., ataxia, wing and head tremors, and paralysis of extremities).
- The mortality rate is 22% to 55% of affected birds.
- Chronic NDV infection may develop in survivors. Virus has been isolated from oral and cloacal swabs 84 days to 1 year after exposure.

Diagnosis

- Serologic testing using hemagglutination inhibition, agar-gel immunodiffusion, or enzyme-linked immuno-

sorbent assay can indirectly diagnose avian PMV infection. However, serology is less effective in diagnosing infections than viral isolation. Antibodies typically appear 8 days after infection.
  - Hemagglutination inhibition is not specific for PMV-1 (crossreaction may occur with other PMVs); however, suspect NDV in birds demonstrating high titers.
- Base definitive diagnosis on virus isolation from feces or oral secretions of live birds or from infected organs at necropsy.

Treatment

- No treatment is available. Inform the USDA of any birds positively diagnosed with NDV.

Prevention

All birds legally presented for importation into the United States are placed in a USDA-approved quarantine station for 30 days, at which time samples are taken to detect hemagglutination viruses, including PMV and influenza. Birds with isolates of hemagglutination viruses that are pathogenic to chickens are refused entry.

▼ ***Key Point*** The best prevention against NDV in psittacine birds is avoidance of contact with birds that may have been smuggled into the country.

- No vaccine is available for psittacine birds.

SUSPECTED VIRAL DISEASES

Proventricular Dilatation Disease

Other names for this disease include myenteric ganglioneuritis, infiltrative splanchnic neuropathy, and macaw wasting disease. The disease originally was seen only in macaws but has been reported in almost all psittacine species. Both ultrastructural findings and epidemiologic evidence suggest that proventricular dilatation disease (PDD) has a viral etiology. The disease appears to have a protracted course, with low virulence and extended incubation periods. The potential mode of transmission is unknown at this time.

Clinical Signs

- Signs include intermittent regurgitation, diarrhea, polydipsia or polyuria, depression, passage of undigested food, progressive weight loss, abdominal distension, and central and peripheral neurologic signs.
- In birds with a severely dilated proventriculus, secondary aspiration pneumonia may develop after repeated bouts of regurgitation.

▼ ***Key Point*** Once signs of PDD develop, the disease is usually fatal.

Diagnosis

Antemortem Diagnosis

- A presumptive diagnosis may be based on clinical signs and radiographic identification of an enlarged proventriculus, and it may be made by ruling out all other possible causes of proventricular dilatation.
- Contrast radiography is usually necessary to positively identify a dilated proventriculus.
- Rule out other causes of regurgitation, proventricular dilatation, or passage of undigested food, such as GI foreign bodies, proventricular outflow obstruction (e.g., tumors and granuloma), heavy metal toxicity, proventriculus, enteritis, crop disorders, impaction, pancreatitis, and liver and kidney disease.
- Definitive diagnosis requires the identification of typical histopathologic lesions on biopsy specimens. A biopsy of the crop is relatively non-invasive and may provide a diagnosis. When obtaining a biopsy, be certain to include mucosal blood vessels in the sample. This will increase the likelihood of obtaining a nerve, thus demonstrating histologic lesions. False-negative results are likely if nervous tissue is not obtained or if lesions are absent in the crop but are present in other areas of the GI tract.
- The CBC may demonstrate a leukocytosis and nonregenerative anemia.
- The serum biochemical profile may reveal increased CK and hypoproteinemia.

Postmortem Diagnosis

The diagnosis is made by identification of characteristic lesions on necropsy.

- Gross pathologic changes include proventricular dilatation, ventricular ulcers, and undigested food in the lower GI tract.
- Confirmation of the diagnosis requires identification of accumulated lymphocytes and plasma cells in the nerves of the GI tract, brain, or spinal cord.
  - GI lesions include endoventriculitis, muscle atrophy, lymphocytic leiomyositis, and smooth muscle degeneration.
  - Lesions may be found in the brain and peripheral nerves. Peripheral nervous tissue is affected most often, and lesions include lymphocyte and plasma cell infiltrates in the mesenteric plexus ganglia and in the intrinsic and extrinsic nerves of the proventriculus and ventriculus and intranuclear and intracytoplasmic eosinophilic inclusion bodies in nerve cells of intestinal ganglia.
  - Other, less frequently encountered nervous tissue lesions include multifocal lymphocytic encephalitis with gliosis; neuronophagia and perivascular cuffing in the cerebellum, medulla oblongata, brain stem, cerebrum, spinal cord, and meninges; visceral ganglioneuritis; and lymphocytic poliomyelitis.

Treatment

- There are some reports of prolonged survival with supportive care, a soft gruel diet, and nonsteroidal anti-inflammatory drugs (NSAIDs). In most cases, however, PDD eventually is fatal.
- The use of NSAIDs has alleviated clinical signs and prolonged life in mild to moderately affected birds. Drugs used include meloxicam (Metacam, Merial), 0.1 to 0.5 mg/kg PO q24h, or celecoxib (Celebrex, Pfizer), 10 mg/kg PO q24h, for 6 to 12 weeks.
- It is currently unknown whether, but entirely possible that, birds treated with NSAIDs may continue to be infectious, even after resolution of clinical signs. Continue to isolate birds definitively diagnosed with PDD.

Prevention

- Because an etiologic agent, its transmission mode, and the incubation period have not been identified, prevention is difficult.
- Strictly isolate birds with confirmed PDD from direct or indirect contact with other birds.
- Quarantine birds exposed to confirmed cases for at least 6 months.

▼ ***Key Point*** Do not euthanize birds with radiographic evidence of proventricular dilatation unless a definitive, histologic diagnosis of PDD has been obtained. Rule out other causes of proventricular dilatation.

Papillomatosis

Papillomas are proliferative, wartlike lesions that may occur on mucosal surfaces of the intestinal tract, including the oral cavity, esophagus, crop, proventriculus, and cloaca. Lesions are most commonly identified on the cloacal mucosa. Some birds develop internal papillomatous disease, which results in multiple papillomas throughout the GI tract, and, in some cases, neoplasia of the liver or GI tract. The most common neoplasia associated with internal papillomatous disease is bile duct adenoma or adenocarcinoma. South and Central American birds such as Macaws, Amazon parrots, and conures are the species most frequently affected. Clinical signs have not been reported in South Pacific and African parrots (cockatoos, cockatiels, parakeets, lovebirds, and African grey parrots).

Etiology

- A viral etiology is suspected because papillomas often appear to spread through groups of birds. Currently, evidence suggests that a psittacine herpesvirus similar to that causing Pacheco's disease may be at least in part responsible for this condition. In one study, all birds with cloacal papillomas tested positive for psittacine herpesviruses. Psittacine herpesvirus has also been isolated from hepatic and GI tract neoplasia in birds with papillomas.

Clinical Signs

Clinical signs vary with the location of the lesions. Clinical signs have only been reported in Central and South American parrots.

- Signs of cloacal papillomas include straining to defecate, flatulence, malodorous and bloody stools, persistent enteric bacterial infections, and reduced fertility.
  - Cloacal papillomas may resemble granulation tissue and can be difficult to distinguish from cloacal prolapse.
- Oral papillomas may cause wheezing, dyspnea, excessive salivation, dysphagia, and persistent oral bacterial infections.
- Signs of esophageal, crop, and proventricular papillomas are less common and include vomiting, regurgitation, and weight loss.
- Birds with hepatic or GI tract neoplasia exhibit weight loss, lethargy, or signs referable to the space-occupying effects of the mass.

Diagnosis

- Base the diagnosis on the appearance of the lesions, biopsy, and histopathology.

Treatment

In some cases, the size and appearance of lesions wax and wane without treatment. Treatment is indicated when clinical signs are evident or, in the case of cloacal papillomas, if self-mutilation occurs.

- Cloacal papillomas may be gradually removed with chemical cauterization with silver nitrate sticks. Evert the papilloma from the cloaca, and roll a silver nitrate cautery stick onto the papilloma, taking extreme care not to cauterize normal mucosa. Rinse thoroughly with water. This procedure can be painful; therefore, anesthetize with isoflurane.
- Remove surgically by ligation and resection, electrocautery, or cryosurgery. The technique used depends on the extent of the lesion.
  - Circumferential lesions of the cloaca may require more than one procedure.
  - Take care to avoid the development of postoperative strictures.
- Treat secondary bacterial infections before surgical removal.
- Although a psittacine herpesvirus has been associated with papillomas, treatment with acyclovir is not effective.

Prevention

- Because papillomas may be caused by an infectious agent, carefully examine the cloaca and mouth of all birds being added to a collection for the presence of papillomas. Those with lesions should be denied entry.
- It may be difficult to detect birds that have had papillomas surgically removed. It is likely that a carrier state exists if a herpesvirus is the cause of lesions.
- Until a greater understanding of the relationship between psittacine herpesviruses and papillomas exists, avoid exposure of non-infected birds to birds diagnosed with herpesviruses.

BACTERIAL DISEASES

Gram-Negative Infections

Bacterial infections requiring treatment commonly are encountered in avian medicine, especially in birds that have been stressed, are on a poor nutritional plane, or are housed in unsanitary conditions. Normal intestinal flora in most pet bird species consist primarily of gram-positive bacteria. Although small numbers of gram-negative bacteria may normally be found in healthy birds, many gram-negative bacteria are primary or potentially opportunistic pathogens. Normal psittacine flora includes *Lactobacillus, Bacillus,* non-hemolytic *Streptococcus, Micrococcus, Staphylococcus, Corynebacterium,* and *Streptomyces* species and *Pasteurella gallinarum.*

Etiology

Commonly encountered gram-negative pathogens include *Escherichia coli; Enterobacter, Klebsiella, Pseudomonas, Salmonella, Proteus,* and *Campylobacter* species; and *Pasteurella multocida.*

Clinical Signs

Clinical signs depend on the organ system affected.

- Respiratory, GI, or nonspecific signs such as inappetence, lethargy, and ruffled feathers may be seen alone or concurrently.
- Septicemia, especially from invasion of enteric pathogens, is extremely common in pet birds.
  - Suspect septicemia in any severely depressed bird.

Diagnosis

- If a bacterial cause of illness is suspected, perform a Gram stain and culture on samples collected from sites of infection.
- CBC usually demonstrates leukocytosis, with a relative heterophilia. Toxic heterophils are often seen. With chronic disease, the serum protein electrophoresis may demonstrate a hypergammaglobulinemia. The serum biochemical profile may be helpful in identifying hepatic or renal involvement.

Respiratory System

- The rostral-most portion of the choana is a readily accessible site for collecting specimens from the upper respiratory system.

▼ ***Key Point*** Microbiologic analysis of samples from the choana is only significant if visible pathology is present or if clinical signs of respiratory disease are evident.

- Other techniques for isolation of respiratory microbial agents include aspiration of the sinuses and tracheal washing (see Chapter 168).
- Direct culture of the air sacs or air sac flushing may be performed via laparoscopy.

Gastrointestinal System

- Readily accessible sites for isolation of microbial agents include the crop, cloaca, and fresh feces.
- In large birds, the proventriculus and ventriculus may be cultured directly using a rigid endoscope or small flexible endoscope.

Other Organ Systems

- Organ systems such as the urogenital tract and liver, both common sites of bacterial infection, are accessible only by more invasive techniques, such as laparoscopy or exploratory laparotomy.
- Septicemic birds often are severely depressed and are unable to withstand invasive procedures. Aggressive empirical treatment with antibiotics is often indicated for these birds.

Treatment

Treatment is indicated when potentially pathogenic bacteria are isolated from a bird with system-specific signs or signs of septicemia.

▼ ***Key Point*** Identification of gram-negative organisms on samples taken from clinically healthy birds does not usually warrant treatment. Monitor these birds for clinical signs and shifts in bacterial flora.

Selection of Antibiotics

Whenever possible, select antibiotics based on culture and susceptibility testing.

Kirby Bauer Susceptibility Test

- Bacterial isolates are classified as susceptible based on serum concentrations of antimicrobial agents that are achievable in humans.

Table 169-1. ANTIBIOTICS FOR USE IN AVIAN PATIENTS

Generic Name	Product Name (Manufacturer)	Dosage	Comments
Amikacin (250 mg/ml)	Amiglyde (Bristol)	10–20 mg/kg q12h IM	Potentially nephrotoxic Synergistic with penicillins
Piperacillin (injectable)	Pipracil (Lederle)	100–200 mg/kg q6–8h IM, IV	Effective against most gram-negative bacteria Synergistic with aminoglycosides Freeze after reconstitution until use Good activity against gram-negative bacteria
Cefotaxime	Claforan (Hoechst-Roussel)	75 mg/kg q6–8h IM	Broad-spectrum, low toxicity Good against gentamicin-resistant gram-negative isolates
Ceftiofur	Naxel (Pharmacia & Upjohn)	75–100 mg/kg q6–8h IM, IV	Synergistic with aminoglycosides Reconstituted drug lasts 12 weeks in freezer, 10 days in refrigerator Broad-spectrum, penetrates into CNS
Enrofloxacin	Baytril (Bayer)	10–20 mg/kg q24h IM, PO	Broad-spectrum, little toxicity Irritating when injected IM—do not use for >3–5 days
Metronidazole	Flagyl (Searle)	50 mg/kg q12h	Effective against many anaerobic bacteria
Trimethoprim-sulfamethoxazole (suspension)	Bactrim (Roche)	100 mg/kg q12h PO	Good against many gram-negative and gram-positive isolates Excellent for hand-feeding neonates May cause emesis in some birds, especially macaws

CNS, central nervous system; IM, intramuscularly; IV, intravenously PO, orally (per os).

- Because it may not be possible to achieve these high levels in pet birds, this test may not accurately predict the efficacy of the antibiotic chosen in vivo.
- Determining the minimum inhibitory concentration (MIC) of antibiotics allows a more accurate assessment of antimicrobial efficacy in pet birds; however, this test is not readily available. For this reason, the Kirby Bauer test still is commonly used.
- When choosing an antibiotic based on standard Kirby Bauer testing check the following:
  - The bacterial isolate should be susceptible to the antibiotic.
  - The antibiotic preferably should be bactericidal, known to penetrate into the site of infection, and effective at very low serum concentrations.
- Antibiotics and dosages commonly used in pet birds are listed in Table 169-1.

Route of Administration

Oral Administration

- Direct oral administration of medications often is used in pet birds, especially for palatable solutions or suspension. However, this method is difficult for some owners. Instruct owners on the proper restraint techniques. Even after this, birds sometimes spit out the medication, and aspiration is a possibility.
- Addition of medications to a small amount of favorite food is a stress-free method and generally effective as long as the entire portion is readily consumed.
- Administration of antibiotics via drinking water is the least preferred method because most antibiotics are unpalatable and are not water soluble and because ingestion of the medication is sporadic and effective concentrations at the site of infection are rarely achieved.
- When a bird is hospitalized and the intestinal tract is functioning properly, oral medications may be administered via gavage tube.

Parenteral Administration

- Many antibiotics commonly used in avian medicine are poorly absorbed when given orally, necessitating parenteral administration.
- Use injectable antibiotics in the following cases:
  - When a bird is unwilling to take oral medications
  - When GI motility is altered
  - In critically ill or septicemic birds
- The advantages of this method include precise dosing, rapid development of therapeutic serum concentrations, and relatively stress-free administration.
- Some practitioners teach their clients to administer IM injections to their pets (the technique for IM injection is described in Chapter 168).

Monitoring

Assess antibiotic effectiveness by monitoring the resolution of clinical signs, serial hemograms, cytology, and culture. Serial fecal or cloacal Gram stains during and after antibiotic administration are important because development of secondary infections, especially candidiasis or aspergillosis, are common.

Gram-Positive Infections

Gram-positive infections occur less frequently in pet birds. Pathogens include beta-hemolytic *Streptococcus, Staphylococcus aureus,* and *Clostridium* spp. Follow the same principles for diagnosis and treatment as outlined previously for gram-negative infections.

Avian Tuberculosis

Etiology

Tuberculosis in psittacines, unlike that in mammals, usually is a primarily alimentary disease.

- Although a few cases of *Mycobacterium tuberculosis* and *M. bovis* have been reported in pet birds, the causative agent usually is *M. avium.*
- These gram-positive, acid-fast granulated rods are capable of causing disease in birds, pigs, guinea pigs, rabbits, and humans.
- Brotogeris parakeets (especially gray-checked parakeets) are particularly susceptible, followed by Amazon parrots, budgerigars, and Pionus parrots.

Transmission

- Transmission occurs primarily by ingestion of fecal-contaminated food, water, or soil; an aerosol route or wound contamination also is possible. The organism is capable of surviving in soil for up to 2 years.
- After ingestion, the organisms penetrate the GI mucosa and colonize under the serosa.
- A primary bacteremia occurs (usually without clinical signs), and the organisms are phagocytized (but not killed) by mononuclear phagocyte cells of the liver, spleen, and bone marrow. Multiplication within these cells causes a local reaction by the cell-mediated immune system and the formation of nodules, which may calcify with time.
- Release of the organisms from the liver results in a secondary bacteremia, with localization in lungs, kidneys, gonads, and intestines. Tubercles in the intestinal wall may open into the intestinal lumen, resulting in shedding of large numbers of organisms in the feces.

Clinical Signs

- Clinical signs include chronic weight loss (often despite a good appetite), depression, chronic diarrhea, polyuria, and poor feathering.
- Abdominal distension due to hepatomegaly and dilated, fluid-filled, thickened intestines is common.
- Subcutaneous and periorbital masses may be seen.
- Lameness due to endosteal bone proliferation occasionally is reported.
- Signs often are nonspecific and slowly progressive.

Diagnosis

Hematology and Serum Biochemistry

- Severe leukocytosis (>20,000) with marked heterophilia and monocytosis is common.
- Anemia and polychromasia usually are present.
- AST levels usually are elevated with hepatic involvement.

Histopathologic Lesions

- On postmortem examination, in addition to the grossly visible nodules previously described, diffuse infiltration of epithelioid or giant cells may result in a grossly thickened firm intestine, hepatomegaly, or splenomegaly.
- Histologically, the intestinal villi may be club shaped, swollen, and filled with epithelioid cells containing acid-fast rods.
- Definitive diagnosis is based on identification of acid-fast rods and epithelioid cells on biopsy or postmortem slide preparations. The liver is generally the most reliable source.
- Acid-fast staining or culture of feces also may demonstrate the organism, although false-negative results are common owing to intermittent shedding of organisms.
- Cultures require 3 to 6 weeks for results.
- Indirect diagnosis with intradermal tuberculin and slide agglutination tests also frequently produce false-negative results.

Treatment

- Euthanasia often is recommended because of the potential human health hazard, especially to immunocompromised owners.
- Successful treatment of pet birds with *M. avium,* mimicking human treatment protocols, has been reported.

Chapter

170 Avian Dermatology

Tia B. Greenberg

Skin and feather disorders are common in companion avian species. Since many of these disorders have a psychological basis, either as the primary cause or as a contributing component, diagnosis and treatment can often be frustrating. A detailed history, physical examination, and assessment of a wide range of diagnostic tests are generally required for diagnosis.

ANATOMY

A basic understanding of normal structure and function of the skin is important.

- The avian skin consists of the epidermis, dermis, and subcutis tissue.
- The epidermis is composed of three layers: the basal or germinative layer, the intermediate layer, and the cornified layer.
- The dermis consists of the superficial layer and the dermal layer.
  - The dermal layer varies in thickness depending on its location on the body. For example, the face is a non-feathered area and therefore is thicker than feathered areas.
  - During breeding season, females and some males will develop dermal thickening and neovascularization in the ventral abdominal area. This area is referred to as the *brood patch* or *incubation patch* since it contributes to egg incubation. The area should not be confused with an area of feather loss and is a normal finding.
- The subcutis is composed of the fascia superficialis, the superficial layer, and the favia profunda.
  - The subcutis is a very thin layer and therefore not amenable to suturing.
  - Because this layer is so thin, it can be difficult to maintain a needle in the subcutaneous space while administering subcutaneous injections.

GUIDELINES FOR HEALTHY SKIN AND FEATHERS

Provide the bird owner with information on proper nutrition and husbandry guidelines to keep the bird's skin and feathers healthy.

- Provide a balanced diet including a wide variety of fresh fruits and vegetables, a pelleted diet, and limited access to seeds.
- Allow exposure to unfiltered natural sunshine daily, if possible.
- Bathe or mist feathers daily with water to help promote healthy skin and feathers.

GENERAL HISTORY AND EXAMINATION

History

A complete, detailed history is essential to the diagnosis of birds presenting with dermatologic disorders. Include questions such as the following:

- How long have you owned the bird, and where was it acquired?
- Are there any new birds in the house? If so, are they sick?
- Has this bird had any contact with other birds?
- Has anything changed in the bird's environment?
- What type of cage is used, and where is it located?
- What diet is normally fed and, of this, what does the bird actually consume? Have there been any changes in the diet?
- Has appetite or water consumption changed?
- Are there any behavioral changes?
- Is there any change in droppings?
- What is the bird's reproductive status?
- Have the bird's feathers changed in the past 6 months?
- Does the bird seem itchy?
- When was the onset of the presenting complaint? Has the problem progressed?
- Has the bird been examined by or treated by another veterinarian?
- Has there been any previous illness?
- Is the bird currently on any medications, including over-the-counter medications?

Physical Examination

Perform a thorough physical exam.

- Notice the distribution and severity of skin or feather lesions.

Table 170-1. COMMON DERMATOLOGIC CONDITIONS IN SPECIFIC SPECIES

Canaries
Knemidokoptes
Feather cysts
Scaly leg syndrome
Genetic baldness
Papilloma virus
Chlamydophila
Mites

Budgerigars
Knemidokoptes
Lipomas
Fibrosarcomas
Feather cysts
Uropygial gland problems
Polyfollicilitis

Cockatiels
Giardia
Genetic baldness
Feather cysts
Conures
Feather picking
Self-mutilation

Amazons
Amazon foot necrosis
Lipomas
Feather picking

Cockatoos
Feather picking
PBFDV
Papillomas

Rose-Breasted Cockatoos
Lipomas

Macaws
PBFDV
Feather picking

Lovebirds
PBFDV
Feather picking
Ulcerative dermatitis

PBFDV, psittacine beak and feather disease virus.

- Determine to which of four categories the problem belongs: lack of feather growth, abnormal feather growth, feather destruction, or pseudoproblems (normal changes presumed by the owner to be a problem) (Table 170-1).

DISORDERS OF THE SKIN AND SUBCUTANEOUS TISSUES

Infectious Diseases

Ectoparasites

Knemidokoptes pilae (Scaly Leg and Face Mites)

Etiology

- These mites are most commonly seen in budgerigars, canaries, and finches. They are occasionally reported in cockatiels, Amazon parrots, and other parakeets.
- Transmission is direct; the entire life cycle is on the bird.
- Infestation can be subclinical until the bird becomes immunosuppressed, similar to demodicosis in mammals.
- Clinical disease is often associated with periods of stress or malnutrition.

Clinical Signs

- Lesions begin on the featherless skin of the face, eyelids, cere, beak, and feet.
- Lesions begin as hyperkeratosis, crusting, and flaking, eventually progressing to characteristic honeycomb-like encrustations.
- If left untreated, infestation can deform the beak and nails.

Diagnosis

- Gross appearance of characteristic honeycomb lesions is usually diagnostic.
- If in doubt, perform a gentle skin scraping to confirm the presence of mites.

Treatment

- Give ivermectin at 0.2 mg/kg SQ, PO, or topically every 2 to 4 weeks for three to four treatments.
- Do not administer ivermectin by an IM route.
- For birds weighing <100 g, applying diluted ivermectin (1 mg/ml) topically to the featherless tract of skin overlying the jugular vein may also be effective.
- If proliferative lesions are excessive, gently debride with a cotton-tipped swab and a small amount of mineral oil.
- Corrective beak or nail trimming may be necessary in birds with chronic infestation.
- Correct underlying nutritional deficiencies, environmental stress, or disease.
- Treat all cage mates.

Dermanyssus gallinae (Red Mites)

Etiology

- Red mites affect canaries and are usually only a problem in large breeding operations.
- The mites feed on blood at night and may cause high mortality rates, especially among nestlings.

Clinical Signs and Diagnosis

- Birds are often uncomfortable, pruritic, and restless at night.
- Sometimes signs of anemia can be seen on physical examination.
- Mites usually feed on the bird during the night and live in the environment during the day. Covering the cage with a white cloth overnight and removing it in the morning may facilitate finding the mite. Mites appear as small red dots or may leave small trails of blood on the cloth.

Treatment

- Lightly dust the environment, including nest boxes, with pyrethrins or carbaryl powders.
- Disinfect the entire cage and eliminate crevices in which the mites can hide.
- Provide supportive care for anemic birds.

Biting Lice

- Biting lice that rarely infest pet birds include *Neopsittaconirmus, Psittaconirmus, Eomenopon,* and *Pacifimenopon*.
- These lice can cause a mild to moderate pruritus and hyperkeratosis.
- Identification of lice or eggs on the feathers is diagnostic.
- Pyrethrin sprays and powders can be used but have little residual effect.
- Repeat treatments every 2 weeks to kill newly hatched lice.

Viral Diseases

Herpesvirus

- Hyperkeratotic, papilloma-like lesions on the surface of the feet are relatively common in cockatoos and macaws. Lesions are believed to be caused by a herpesvirus, based on histologic evidence of characteristic inclusion bodies or identification of virus on electromicroscopy.
- Affected birds are clinically normal except for wart-like lesions on their feet.
- The diagnosis is based on physical examination and histologic examination of biopsy specimens.
- Lesions are usually self-limiting. Rubbing a small amount of a gentle moisturizing agent, such as aloe vera, into the feet daily helps loosen and remove hyperkeratotic tissue.

Avian Poxvirus

- Avian pox can cause lesions on the unfeathered skin that can appear ulcerative or as crusts, scabs, or proliferative lesions.
- Systemic or respiratory signs are usually more clinically significant than cutaneous lesions. A detailed description of diagnosis and management of avian poxviruses is discussed in Chapter 169.

Papillomavirus

- Wart-like lesions on unfeathered areas of the skin have occasionally been reported. Histologically, these lesions resemble those caused by papillomaviruses in other species. However, papillomavirus has only rarely been demonstrated to be the causative agent, and other viruses, such as herpesviruses, can cause similar lesions.
- Diagnosis is based on histologic examination and identification of the virus when possible.
- Lesions are benign but may become large or widespread in non-feathered areas. Surgical excision is indicated when possible.

Bacterial Diseases

Primary bacterial skin infections are uncommon. Most infections are secondary to trauma, including self-mutilation or other disease processes. The low incidence of primary pyoderma is thought to be due to high body temperatures and keratinocyte-derived lipids that inhibit bacteria growth.

Bacterial Folliculitis

Etiology

- Primary bacterial folliculitis is unusual in pet bird species. Folliculitis secondary to the trauma caused to the follicle by feather picking may be more common.
- Bacterial pathogens reported include *Staphylococcus* spp and *Aeromonas* spp.

Clinical Signs

- Clinical signs include erythema and swelling around feather follicles.
- If secondary to feather picking, feather loss and occasionally feather malformation may be seen.
- With severe, generalized infection, lesions may progress to erosions with scab formation.
- Pruritus may occur and occasionally may be severe enough to cause self-mutilation.
- Bacterial folliculitis is a rare cause of feather picking but may exacerbate picking if the bird is pruritic.

▼ ***Key Point*** Folliculitis generally does *not* cause feather picking and only rarely occurs as a consequence of feather picking.

Diagnosis

- Examine the skin underlying the feathers for lesions.
- Obtain one or more small skin biopsy specimens that include an affected follicle. When obtaining a biopsy specimen, keep in mind that avian skin and subcutis are extremely thin as compared with that of mammals. Submit biopsy specimens for histologic examination and culture and susceptibility testing.
- In some cases, samples for culture can be obtained via sterile aspiration of perifollicular swelling.
- If the feather pulp is infected, plucking an affected feather and expressing the pulp for cytologic examination and culture may sometimes reveal the causative agent.

Treatment

- Administer antimicrobial therapy based on culture and susceptibility results.
- Correct the underlying cause in birds with secondary folliculitis.

▼ ***Key Point*** Do not use topical antibiotic ointments, especially combination products containing corticosteroids, in birds. Oils from these products will be spread onto the feathers during preening, interfering with normal feather function. Birds can be extremely susceptible to the immunosuppressive effects of corticosteroids, even when applied topically.

Chronic Ulcerative Dermatitis

This syndrome is characterized by ulceration, hyperemia, feather loss, and self-mutilation in a localized area of the dermis. Lesions may be seen alone or may be associated with other diseases.

Etiology

- The cause is unknown but has been anecdotally associated with giardiasis in cockatiels, an unidentified virus in lovebirds, and hypovitaminosis E in other species. Environmental, behavioral, and hormonal factors may also play a role.
- *Staphylococcus* species are usually isolated on culture of lesions but are likely a secondary infection. Many other potential bacterial pathogens, including *Pseudomonas* species, may be cultured.

Clinical Signs

- Disease is most commonly seen lovebirds, cockatiels, grey-cheeked parakeets, Quaker parrots, Amazons, and cockatoos.
- Lesions usually are found in the ventral wing web area and lateral body wall underneath the wing or around the neck, but they can be seen in any area.
- The disease is usually associated with extreme pruritus; self-mutilation may occur.
- Skin may appear thickened, ulcerated, exudative, and hyperemic. Scabs and crusts may form over healing ulcers.

Diagnosis

- Base the diagnosis on clinical signs and the location of lesions.
- Obtain a complete blood count (CBC) and plasma chemical profile to rule out underlying disease.
- Obtain a skin biopsy for histologic examination.
- Perform bacterial and mycotic culture and susceptibility testing to direct antimicrobial therapy.
- Obtain a fresh fecal sample to rule out *Giardia* or other intestinal parasites.

Treatment

- Aggressive systemic antibiotic treatment is usually warranted. Sepsis may occur in untreated birds. Base selection on results of culture when possible. Pending culture, administer broad spectrum antibiotics that are effective against *Staphylococcus* spp., such as enrofloxacin (Baytril, Bayer), 7.5 to 15 mg/kg PO or IM q12h, or ceftazidime (Fortaz, Glaxo), 75 to 100 mg/kg IM q6–8h. Treatment for 4 to 6 weeks may be necessary.
- In some birds, especially cockatiels, lesions respond well to empirical treatment with metronidazole (Flagyl, Searle), 10 to 30 mg/kg PO q12h for 10 days. Treatment success may be due to underlying giardiasis or may be the result of the antimicrobial or anti-inflammatory effects of metronidazole.
- Apply topical silver sulfadiazine 1% cream (Silvadene, Marion Merrell Dow) or mild topical astringent such as Domeboro solution.
- Prevent self-mutilation. In severe cases, application of an Elizabethan collar may be necessary. With milder cases, control self-mutilation by administering antihistamines such as hydroxyzine (Atarax, Roerig), 2.2 mg/kg PO q8h, or anti-compulsive medications.

Avian Tuberculosis

- Cutaneous mycobacteriosis is unusual in pet birds. Lesions are usually caused by mycobacterium avium and can be an extension of systemic disease.
- Lesions usually appear around the head and neck. Most appear as subcutaneous swellings but may appear wart-like or ulcerated.
- Perform a skin biopsy or cytologic examination with acid-fast staining or polymerase chain reaction to identify mycobacterium.
- Inform owners of zoonotic potential.
- See Chapter 169 for a discussion of the diagnosis and treatment.

Fungal Diseases

- *Trichophyton flavis, Microsporum gypseum,* and *Malassezia* spp. are rare causes of dermatitis.
- Diagnosis is based on repeated isolation on culture and identification of organisms on histopathologic examination.
- Treat with appropriate antifungals.
- Warn owners about zoonotic potential.

Neoplasia

Cutaneous neoplasms occur with relative frequency in companion birds. Most diagnostic and treatment protocols have been extrapolated from mammalian medicine. Refer to the corresponding chapters on mammalian neoplasia for details (see Section 3).

Squamous Cell Carcinoma

This is the most common malignant tumor found on pet birds and has been reported in a variety of species.

Clinical Signs

- The most common sites affected include the back, uropygial gland, and wings. Oral mucosa, including the crop and esophagus, can also be affected.
- Tumors are locally invasive and readily metastasize.
- Tumors appear raised, irregular, and proliferative, and they may or may not ulcerate.

Diagnosis

- Perform an exfoliative cytologic exam, fine-needle aspirate, or excisional biopsy to diagnose.

Treatment

- Excise the mass with complete margins, when possible. Consider radiation therapy.
- Intralesional carboplatin and cisplatin, and cryotherapy, have also been attempted.

Lipoma

Lipomas are benign tumors of lipocytes that may grow rapidly over time. They are a common occurrence in budgerigars but can be seen in any pet species.

Etiology

- A diet high in fat and limited exercise seems to contribute to formation of lipomas. Tumors are most commonly found on obese birds. Hypothyroidism may play a role.
- There may be a genetic predisposition in budgerigars.

Clinical Signs

- Common areas affected include the ventral thoracoabdominal area, wings, back, neck, and legs.
- They may be single or multiple.
- Large tumors may interfere with movement.

Diagnosis

- Palpate for one or more well-delineated, soft, fluctuant masses. Masses may appear white or yellow through the skin.
- Perform a fine-needle aspirate or biopsy to confirm the diagnosis.

Treatment

- Many lipomas will respond to dietary changes. Place the bird on a low-fat diet, restrict the amount of food offered, and increase exercise.
- Surgery may be indicated if the masses interfere with movement, become ulcerated, or become infected or if the bird is picking at the mass. Complete excision can be difficult if the masses are large.
- Masses can be vascular, and risk of hemorrhagic can be significant.
- Do not use levothyroxine unless a diagnosis of hypothyroidism has been confirmed.

Liposarcomas

Etiology

- Malignant tumors are composed of immature adipocytes and lipoblasts.

Clinical Signs

- Liposarcomas usually appear as firm, multilobulated, poorly encapsulated, and highly vascular subcutaneous masses.
- They are usually found on the sternum or uropygial gland.
- Occasionally, they are found in the liver, skeletal muscle, and thoracoabdominal area.
- Tumors have the potential to metastasis and can be locally invasive.
- Liposarcomas have been reported in budgerigars, cockatiels, Quakers, and green-cheeked conures.

Diagnosis

- Perform a biopsy with histologic examination to confirm the diagnosis.

Treatment

- Compete excision is often difficult due to the invasiveness of the tumor.

Fibrosarcomas

Etiology

- Malignant tumors arise from mesenchymal cells and fibroblasts.
- Fibrosarcomas are commonly seen in budgerigars, cockatiels, and macaws but can occur in any species.

Clinical Signs

- Fibrosarcomas can occur anywhere on the body but usually are found on the head or limbs.
- They are locally invasive and rarely metastasize.
- Tumors appear as firm, irregular, non-movable subcutaneous masses that may ulcerate.

Diagnosis

- Perform biopsy and histopathology for diagnosis.

Treatment

- Surgery can be performed, but recurrence is common. Limb amputation may be indicated to prevent recurrence or metastasis.

- Intratumoral cisplatin and radiation have not been successful.

Xanthomas

- Xanthoma is not a true neoplasm but an accumulation of macrophages containing lipid, multinucleated giant cells and cholesterol in the dermis.
- Xanthomas are commonly seen in cockatiels, rose-breasted cockatoos, grey-cheeked parakeets, green-winged macaws, and budgerigars.

Etiology

- The etiology is unknown but may be related to high-fat diets and diets containing aromatic hydrocarbons.
- Most affected birds are obese and have been maintained on a high-fat, seed-containing diet.

Clinical Signs

- These tumors usually only become a problem if the bird picks at the area, the lesions become traumatized, or they become extremely large.
- Lesions can be diffuse or localized.
- Masses appear as areas of thickened, yellow-orange, friable skin.
- They commonly occur on the wing tips, abdomen, and thighs but may occur anywhere.

Diagnosis

- Characteristic gross appearance is often diagnostic.
- Perform a biopsy and histologic examination to confirm the diagnosis.

Treatment

- Small masses that are not traumatized may not require treatment.
- Dietary correction may prevent future occurrence.
- Attempt surgical excision. Some masses are difficult to excise due to their large size and difficulty in closing the defect. Affected dermis is very friable and does not hold suture well.
- Irradiation with low-energy x-rays or hyperthermia has been suggested for lesions not amenable to surgical excision.

Follicular Cysts

Etiology

- These are commonly referred to as feather cysts and consist of an accumulation of keratinaceous debris within a follicle. Cysts may be acquired or congenital.
- Acquired cysts may form secondary to trauma, malnutrition, or bacterial or viral infection of the follicle.
- Congenital cysts are usually seen in canaries, especially in Norwich and Gloucester. These birds are genetically bred for soft feathering, which may predisposes them to cyst formation.
- Folliculomas, benign tumors of the feather follicles, may resemble or contribute to follicular cyst formation. Differentiation is based on histologic examination following surgical excision of the cyst.

Clinical Signs

- Lesions most commonly appear on the wing or back.
- Raised yellow to beige subcutaneous masses, often freely movable, can become quite large.
- Birds may pick at these areas.
- Incision of lesions may reveal caseous keratinaceous debris or may contain an entire feather (ingrown feather).

Diagnosis

- Perform an excisional biopsy with histologic examination.
- Location and appearance of the gross lesions may be diagnostic.

Treatment

- Complete surgical excision of the entire follicle is the treatment of choice.
- Fulguration with an electrosurgery or lancing and curettage of the follicle may also be successful.
- In canaries with congenital cysts, removing the entire affected feather tract may be required.

Other Diseases of the Skin

Allergic Dermatitis

- Birds develop dermal lesions that are histologically similar to those seen in mammals with allergic dermatitis. However, little information exists on allergic response in birds.
- Anecdotal reports suggest that pruritic birds with lesions compatible with allergic dermatitis may improve when the suspected allergen is removed or antihistamines are administered.
- Intradermal skin testing has been examined in psittacine species; however, results have not been conclusive and testing cannot yet be recommended to confidently diagnose allergies in these species.
- Antihistamines reported to be effective in birds include hydroxyzine HCl (Atarax, Roerig), 2.0 to 2.2 mg/kg PO q8h, and diphenhydramine, 2 to 4 mg/kg PO q12h.
- Some birds have anecdotally improved on oral essential fatty acid therapy.

Amazon Foot Necrosis

This syndrome has been reported in all species of Amazon parrots but is most commonly seen in yellow-naped and yellow-headed Amazon parrots. Affected birds will chew on the scaled portion of their feet and hocks, sometimes to the point of tearing scales and

underlying tissue. Reappearance of lesions is often cyclic.

Etiology

- The cause of this condition is unknown.
- Proposed causes include contact hypersensitivity, poor nutrition, seasonal sexual frustration, high-fat diets, and bacterial, viral, and immune-mediated infection.
- *Staphylococcus* has been isolated from many of these birds but may represent a secondary infection.

Clinical Signs

- Birds often appear pruritic or painful around the hocks and feet. Sometimes this is a promontory sign.
- There may be areas of black and brown patching of the scales on the feet and legs prior to gross necrosis or self-mutilation.
- Lesions range from areas of dark brown or black swelling to scaling and peeling of the superficial scales to erythremia, necrosis, and sloughing or mutilation of the scales, skin, and deeper tissues.
- Secondary bacterial or mycotic infections may be present.

Diagnosis

- Obtain a detailed history, including environmental and dietary history.
- Perform a CBC, plasma biochemistry, bile acid concentration, and plasma protein electrophoresis to look for underlying disease.
- Diagnosis is usually based on the gross characteristics and distribution of lesions.
- Due to the limited amount of skin over these areas, skin biopsy is difficult to perform.
- Perform deep culture and susceptibility testing on samples from the lesions.

Treatment

- Long-term management is often required.
- Maintain strict sanitation of the environment.
- Try to eliminate contact allergens if identified.
- Administer antibiotics based on cultures and susceptibility testing.
- Administer antifungal therapy if indicated.
- Administration of hydroxyzine HCl (Atarax, Roerig) at a dosage of 2.0 to 2.2 mg/kg PO q8h may diminish pruritus and mutilation.
- Topical treatments include chlorhexidine solution or povidone-iodine solution diluted 1:10 and applied daily to the areas. Apply silver sulfadiazine 1% cream (Silvadene, Marion Merrell Dow) or topical antibiotic creams when indicated.
- Apply bandages or an Elizabethan collar as needed to prevent further mutilation.

Nutritional Disorders

Hypovitaminosis A

- This is one of the most common nutritional deficiencies seen in pet birds.
- Squamous metaplasia of epithelial cells in the oral and respiratory mucosa often progress to the formation of white, keratin-filled plaques.
- Signs are usually confined to the respiratory or oral mucosa, but occasionally white plaques are found in the subcutaneous tissues around the beak, submandibular, or periorbital regions.
- See Chapter 171 for details on diagnosis and treatment.

DISORDERS OF THE CUTANEOUS GLANDS

- Birds do not have sweat glands.
- There are four major types of cutaneous glands found in bird skin: glands of the external ear canal, meibomian eyelid glands, pericloacal glands, and the uropygial gland.

Uropygial Gland

Normal Anatomy and Function

- The uropygial gland is a bilobed gland found at the tail base of most psittacine birds. It drains into a single papilla at the base of the tail.
- Normally, the gland is easily expressed and secretes a clear, oily fluid.
- This gland is absent in Amazon parrots, some pigeons, and doves.
- The uropygial gland produces a sebaceous material containing vitamin D precursors, which are converted to the active form of vitamin D_3 when exposed to ultraviolet light. During preening, the active form of vitamin D_3 is ingested.
- Exposure to unfiltered ultraviolet light is necessary for this metabolic process to take place.
- Material produced by the uropygial gland is very important for waterproofing feathers.
- Material produced by the gland also produces antibacterial and antifungal components, which help maintain the integrity of the skin.

Disorders

There are three common uropygial gland disorders: impaction, abscessation, and neoplasia.

Impaction and Abscessation of the Uropygial Gland

- An impacted gland is a gland that does not express easily; fluid generally remains clear unless a bacterial infection is present.
- A gland that is abscessed may or may not express normally. Fluid within the gland contains purulent exudate.

- Obtain fluid from the gland via expression or fine-needle aspirate for cytologic examination and culture.
- Remove dried exudates or other debris blocking the papilla to drain an impacted gland.
- Administer antimicrobial therapy as indicated from culture and susceptibility testing.
- Surgical extirpation may be necessary for abscesses not responsive to medical therapy or for neoplastic conditions.

Uropygial Gland Tumors

- Tumors of this gland include squamous cell carcinoma, adenoma, adenocarcinoma, and fibrosarcoma.
- The most common tumor found is fibrosarcoma.
- Adenomas and adenocarcinomas are commonly found in budgerigars and canaries.
- Perform a fine-needle aspirate for cytologic examination or biopsy with histologic examination.
- Obtain radiographs to determine if metastasis has occurred and to evaluate the invasiveness of the tumor.
- Attempt complete surgical excisions if an adenoma is diagnosed.
- Adenocarcinomas and fibrosarcomas carry a poorer prognosis, especially if the tumor has invaded the pelvic bones, since complete excision is rarely possible.
- If the invasion into the pygostyle has occurred, amputation can be attempted.

DISORDERS OF THE FEATHERS

Anatomy and Function

- Feathers serve three primary functions: flight, insulation, and waterproofing.
- In addition, feathers are used to demonstrate territorial behaviors, courtship, and defense.
- Feathers are similar to hair in that they are derived from epithelium and dermal layers of the skin.
- Stress, nutrition, hormones, and diseases can affect feather growth.
- In most birds, the body surface is divided into non-feathered portions called apteria and feathered portions called pterylae.
- There are 10 major feather types:
  - Contour (vaned) feathers consist of major flight feathers of the wing and tail.
  - Semiplume feathers provide insulation.
  - Filoplume feathers are proprioceptive.
  - Powder down feathers produce powder (keratin).
  - Bristles are found around the mouth, nostrils, and eyes.
  - Coverts are arranged in rows on the wings and tail.
  - Remiges are found in the wing and are responsible for flight.
  - Retrices are the tail feathers.
  - Down feathers are small fluffy feathers used for insulation.
  - Hypopnea feathers are attached to the underside of other feathers.

Molting

- Molting is the shedding and replacement of the stratum corneum and feathers. New feathers erupting trigger the shedding of the old feather.
- This process depends on neurohormonal factors, which are regulated by stress, thyroid, gonads, photoperiod, and breeding state.
- Environmental heat and humidity promote molting; usually 60% humidity is adequate for proper molting.
- Most birds will molt once a year, but budgerigars can sometimes molt 2 to 3 times a year.
- Some psittacine birds may take up to 2 years to complete a single molt cycle.
- African grey parrots, cockatiels, and cockatoos constantly shed powder down, and this should not be considered abnormal.
- Lack of normal molting can be the cause or the result of disease.
- During the molting process, the metabolic demand on the bird is increased. A well-balanced diet should not be overlooked.
- A diet lacking protein can contribute to an improper molt.

Coloration

- A variety of pigments and structural adaptations are responsible for the colors seen in bird plumage.
- There are three principle pigments found in bird feathers: Melanin is the most common pigment and is responsible for black, grays, and browns. Carotenoids are responsible for the intense reds and yellows. Porphyrins produce a range of reds, browns, and greens.
- Birds lacking sources of dietary carotenoids (orange or dark green fruits and vegetables) may be able to maintain bright orange or yellow plumage.
- Any color abnormalities of feathers can be caused by deficiencies of one or more nutrients such as lysine; choline; protein; essential fatty and amino acids; vitamins A, D, and E; copper; zinc; and iron.

Disorders of the Feathers

Common feathering problems include broken blood feathers, abnormal-appearing feathers, lack of feather growth or regrowth resulting in feather loss, and feather picking.

Pseudoproblems

- Pseudoproblems are conditions that inexperienced owners perceive to be a problem but that are normal behavioral or physiologic changes. These problems include molting, dandruff, and bare areas.
- Molting (see the discussion above) is often confused by the owner as feather picking.
- Birds spend a significant amount of time preening their feathers, and shed feathers may be found in or around the cage. Considering a complete molt may take up to a year to complete, an owner may consider this excessive.
- New, emerging feathers, called *pin feathers* because they are partially or completely enclosed in a keratin sheath, can be found in areas where the old feathers were shed. These are often readily visible on the head, an area that solitary birds cannot easily reach to preen.
- Dandruff on the cage bottom is a common owner misperception. What are mistaken for dandruff are small pieces of the keratinaceous sheath that surrounds newly emerging feathers. Pieces of the sheath are picked off and dropped to the cage floor during normal preening; the amount of "dandruff" on the cage bottom can be considerable during a heavy molt but is normal.
- Bare areas called apteria (see above) are normal featherless areas between feather tracts. Some owners become concerned that these areas are abnormal.
- Some color mutations of cockatiels normally have a featherless area under the feather crest on the head.

Broken Blood Feathers

- Newly emerging feathers, especially large feathers on the tail and wings, contain a rich blood supply within the developing sheath. This blood supply gradually recedes as the feather grows. If the feather is broken, significant hemorrhage can occur.
- The broken feather will usually continue to bleed until action is taken. Continued hemorrhage can be fatal.
- To control hemorrhage, the feather can be carefully pulled from its base.
  - For removal, the feather should be isolated from surrounding feathers.
  - Place a hemostat around the base of the feather.
  - Firmly stabilize the wing or tail at the feather's origin.
  - Apply gentle traction until the feather is removed.
  - Apply direct pressure to the skin where the feather originated until the bleeding stops.
  - If bleeding continues, a small amount of surgical glue can be applied to the skin or a small absorbable suture can be placed.
  - Avoid applying chemical or electrical cautery on the skin where the feather was pulled. Cautery can damage the feather follicle and cause abnormal feather growth and feather cysts.
- Pulling very large tail or wing feathers on large birds such as macaws and cockatoos can sometime cause significant tearing of the skin. For these feathers, ligate the blood feather with suture material slightly proximal to the break. Monitor these birds to ensure that hemorrhage does not recur.
- Avoid applying chemical cautery to the bleeding feather shaft, since the bird can ingest it during preening.

▼ ***Key Point*** Broken blood feathers can cause significant, even fatal, hemorrhage. Treat breakage as an emergency situation.

Feather Loss without Plucking

Spontaneous feather loss or lack of feather regrowth occurs much less commonly than feather picking in pet birds.

Etiology

Feather loss without plucking can be caused by the following:

- Genetic baldness under the crest feathers in color mutation cockatiels
- Ectoparasites, especially Knemidokoptes
- Damaged follicles
- Malnutrition
- Viral diseases, especially psittacine beak and feather disease virus (PBFDV) (circovirus) or avian polyomavirus
- Hypothyroidism
- Excessive or irregular molt pattern
- Genetic factors (especially in Lutino cockatiels)
- Obesity
- Systemic disease (septicemia alopecia)

Clinical Signs

- Feather loss can occur anywhere on the body, including the head region.
- The surrounding skin may or may not appear normal.
- The owner denies ever observing the bird picking itself.

Diagnosis

- Obtain a detailed history including diet, housing, management, initial appearance of lesions, lesion progression, lesion duration, pattern of feather loss, previous treatments, and response.
- Perform a thorough physical examination; look specifically for abnormalities in emerging feathers.
- Perform a CBC, plasma chemical analysis, bile acid concentration, plasma protein electrophoresis, and possibly whole body radiographs to look for underlying disease resulting in poor feathering.

- Test for PBFDV and polyomavirus. See Chapter 169 for details on diagnosis.
- Consider obtaining a skin biopsy that contains abnormal feather follicles for histologic examination.

Treatment

- Treatment consists of correcting any underlying disease or nutritional deficiencies.
- See the discussion of infectious disease above, nutritional and endocrine diseases below, or Chapter 169 for details on treatment.

Nutritional Diseases

Nutritional excesses, deficiencies, and imbalances are common in avian patients.

Etiology

- Birds are often fed an all-seed diet, which is inadequate in essential fatty acids, zinc, copper, protein, and vitamins A, E, and B.
- Protein and amino acids are essential for hormone, enzyme, muscle, bone, and normal feather production.

Clinical Signs

- Delayed or abnormal molt
- Prolonged retention of old feathers, resulting in ragged, frayed feathering
- Dull coloration
- "Bronzing" or brown or black appearance to the tips of feathers
- "Stress bars" or lines of depigmentation on contour feathers
- Excessively scale or thickened skin on the face and feet
- Overgrowth or abnormal consistency of the beak and nails
- Signs of respiratory, hepatic, or renal disease secondary to malnutrition

Diagnosis

- Obtain a complete dietary history.
- Birds with dermatologic signs of malnutrition often have systemic manifestations as well, such as hepatic, respiratory, or renal disease.
- Perform a CBC, plasma biochemical analysis, bile acid concentration, and plasma protein electrophoresis to look for systemic disease.
- Obtain radiographs to rule out systemic disease.

Treatment

Advise owners to convert the bird to a nutritionally complete, well-balanced diet. Although species variation exists and information on what constitutes a balanced diet is incomplete, general guidelines include the following:

- Add fresh fruits and vegetables
- Add whole grains and legumes
- Feed a commercial pelleted diet
- Supplement seeds with a balanced vitamin and mineral supplement while converting to a new diet

Endocrine Causes of Feather Abnormalities

Hypothyroidism

Etiology

- Hypothyroidism can lead to symmetrical feather loss without pruritus. Many anecdotal reports exist in pet birds, especially Amazon parrots. However, only one published report, in a scarlet macaw, exists. Lack of confirmed cases may be due to the unavailability of thyroid-stimulating hormone (TSH) for stimulation testing and due to the lack of established normal T4 values for avian species.
- Budgerigars with iodine-deficiency goiter may become hypothyroid. However, the most common clinical manifestation of goiter in these species is related to the space-occupying effects of the enlarged thyroid gland.

Clinical Signs

- The plumage may appear dull, fringed, and have black tinting.
- Hyperkeratosis and thickening of the skin may occur.
- Mild to diffuse loss of contour feathers may be seen over the head and body.
- Primary feathers may be tattered and show bronzing.
- No evidence exists of molting or newly emerging feathers in bald areas.
- Affected birds may be obese.
- Poor reproductive performance may be seen.
- There may be a mild anemia and elevated serum cholesterol concentration.

Diagnosis

- In budgerigars with goiter, a positive response to supplementation may be diagnostic.
- In other species, clinical signs, history, skin biopsy, and basal T4 may be suggestive.
- Decreased basal T4 concentration alone is not diagnostic, as many factors can influence T4 concentration and normal values have not been well established.
- A positive response to exogenous L-thyroxine supplementation alone is not diagnostic. Most euthyroid birds will undergo a molt or lose weight with supplementation.
- Perform a CBC and plasma biochemical analysis.
- Obtain radiographs to rule out systemic causes for disease.
- If available, perform a TSH response test by administering 1 IU of TSH per kg IM. Obtain a presample and a 6-hour post-sample.

- A normal TSH response is a twofold increase from basal T4 concentration; failure to reach this increase is diagnostic.
- Since TSH may not be widely available, it may be necessary to base a presumptive diagnosis on clinical signs, results of the CBC and chemistry profile, basal T4 concentration, and skin biopsy and on ruling out other causes of feather loss.

Treatment

- Provide supplemental oral iodine to budgerigars.
- Administer L-thyroxine at a dosage of 0.01 to 0.02 mg/kg PO q12h. This dosage is empirically based on treatment in small animals; pharmacologic data on appropriate administration in birds does not exist. Supplement the hormone with caution and carefully monitor the bird for response to treatment and toxicity.
- Do not administer L-thyroxine in drinking water.
- Obtain a periodic serum T4 concentration to monitor response to therapy and potential toxicity.
- Serious side effects include anorexia, cardiotoxicity, hyperactivity, and death.

▼ ***Key Point*** Hypothyroidism is an unusual cause of feather loss in pet birds. Empirical supplementation of L-thyroxine in birds can have serious, life-threatening side effects. The proper dosage in birds has not been well established. Monitor carefully for signs of thyroid toxicosis such as hyperactivity, weight loss, poor feathering, anorexia, or increased appetite, and discontinue use if observed. Sudden death has also been reported.

Other Endocrine Abnormalities

- Spontaneous hypoadrenocorticism (Cushing's disease) has not been reported in pet birds. Iatrogenic hypoadrenocorticism due to exogenous steroid administration is common; however, dermatologic signs have not been observed.
- Baldness in male canaries is believed to be caused by a testosterone deficiency. An incidence of up to 60% has been anecdotally reported. Treatment with testosterone, 2.5 mg/kg IM or PO once weekly for 6 weeks, may induce feather regrowth in some affected birds.

Feather Picking and Self-mutilation (Non-behavioral)

- Feather picking and self-mutilation of feathers are extremely common problems in pet birds. Some birds pull the feathers out, whereas others will shred or mutilate existing feathers without removing them. Occasionally, mutilation of the skin and/or underlying muscle may accompany feather mutilation or may be seen alone.
- Although any species of psittacine bird can be affected, feather picking is most common in African grey parrots, cockatoos, Eclectus parrots, conures, and macaws. In these species, psychological or behavioral disorders are the most common cause of feather picking (see the discussion later in this chapter). In small birds such as budgerigars and cockatiels, an underlying disease process is more likely to cause in feather picking than psychological causes.
- Feather picking can be extremely frustrating to diagnose and treat. A wide variety of disease processes can cause or contribute to feather picking, and extensive diagnostic testing is usually required to identify the cause. In many cases, the cause appears to be behavioral. Successful treatment of behavioral feather picking varies considerably and, in some cases, remains nonresponsive to environmental, behavioral, or pharmacologic treatment.

Etiology

- Nearly every infectious and metabolic disease in birds has been reported to initiate or exacerbate feather picking in pet birds. In most cases, the mechanism of this response is unknown. Feather picking has been most commonly associated with the following:
- Endoparasitism—Especially pruritic picking in the wing web area in cockatiels with giardiasis.
- Hepatic disease
- Renal disease
- Air sac disorders or coelomic cavity granulomas—These may cause focal feather picking.
- Ingluvitis—Occasionally, this causes focal picking over the crop.
- Enteric bacterial or mycotic infection
- Allergic dermatitis—Food, contact, or environmental allergens; birds may appear pruritic or agitated.
- Neoplasia of any type
- Follicular dermatitis—This is rarely a primary cause but may occur secondary to feather picking and may exacerbate the behavior. Dermatitis may be bacterial, viral, or mycotic. Birds often appear pruritic or agitated.
- Heavy metal toxicity—Zinc or lead toxicosis has been anecdotally associated with feather picking.
- Nutritional deficiencies—Such deficiencies may cause pica and feather picking.
- Topical sprays—Many over-the-counter or homemade "remedies" for ectoparasites or for the prevention or treatment of feather picking are irritating to birds and can cause feather picking.
- Soap, shampoos, or other products used for bathing birds.
- Hypothyroidism—This does not usually cause feather picking.
- Ectoparasitism—Although rare, red mites, lice, and Knemidokoptes can contribute to feather picking.

Diagnosis

- Obtain a complete history, including duration and progression of feather picking, areas of feather loss, and any previous treatment.
- Perform a complete physical examination.
- Obtain blood for a CBC, plasma biochemical analysis, and plasma protein electrophoresis to look for underlying disease.
- Perform diagnostic testing to rule out infectious diseases such as *Chlamydophila,* PBFDV, and polyomavirus (see Chapter 169).
- Measure blood concentrations of heavy metal.
- Perform skin and feather scrapes to rule out ectoparasites when indicated.
- Perform a fecal direct smear, float, and Gram stain.
- Perform a skin biopsy, including affected feathers for histologic examination and culture.
- Obtain whole body radiographs to investigate systemic disease.
- Consider performing laparoscopy to investigate metabolic disease and determine if the bird is reproductively normal. Obtain biopsy samples of abnormal organs where indicated.

Treatment

- Identify and treat any underlying medical problems.
- Consider administration of metronidazole (50–60 mg/kg q12 PO for 7–10 days) to treat *Giardia* in any pruritic, feather-picking cockatiel, even if the fecal examination is normal, since organisms are shed intermittently. Many feather-picking cockatiels will improve with metronidazole therapy, regardless of the cause. The reasons for this positive response are not clear. Other species of birds rarely respond.
- Antihistamines may be effective if the bird appears pruritic. Administer hydroxyzine HCl (Atarax, Roerig) at 2 mg/kg orally twice daily. Some birds may become drowsy.
- Correct any dietary deficiencies.
- Apply a physical barrier to plucking, such as an Elizabethan collar or tube collar, *only* if the bird is in danger of inflicting serious harm to itself. Birds that are mutilating to the point of removing skin and underlying tissues may need a temporary barrier while the underlying disorder is treated. Applying a collar alone does not treat the cause of feather picking and causes significant stress.
- If a collar is necessary, hospitalize the bird for 24 to 48 hours for observation, and provide supportive care if needed. Some birds become severely lethargic and will not eat or drink when collared.
- Keep the bird in a space free of objects capable of entangling the collar. Birds have become seriously injured or asphyxiated due to Elizabethan collar entanglement.
- Use collars commercially manufactured for birds (Veterinary Specialty Products, Boca Raton, FL).
- New feathers will not emerge normally from their keratin sheaths if not preened regularly. Long-term collaring does not allow normal preening.
- Do not apply topical sprays, homemade or sold over the counter, to deter feather picking (such as bitter-tasting solutions). Birds are very meticulous about their feathers, and these solutions often exacerbate picking.

▼ ***Key Point*** Every attempt should be made to rule out underlying disease as a cause of feather picking before diagnosing psychological feather picking. Feather picking can sometimes be the only or most prominent sign of serious underlying disease. A thorough diagnostic evaluation, including CBC, plasma biochemical analysis, fecal testing for parasites and microflora, whole body radiography, testing for infectious diseases, skin biopsy, and exploratory laparoscopy may all be required to rule out systemic disease.

Behavioral or Psychological Causes of Feather Picking

Psittacine birds are extremely intelligent, gregarious, and social animals. Unlike pet dogs and cats, they have not had the advantage of centuries of selective breeding for a domestic temperament. Instead, most captive-bred parrots are only a few generations removed from wild birds. Captivity in most households cannot provide the exercise, free flight, mental stimulation, or complex social flock behaviors that exist in the wild. Preening and mutual grooming are important psychosocial activities and would normally occupy a significant portion of the day. Exaggeration of these activities, progressing to mutilation of feathers or skin, is the most common and disconcerting aberrant behavior seen in captive psittacine birds. Mutilation is often accompanied by other stereotypic behaviors such as repeated movements of the body or toys or screaming.

Reasons for this aberrant behavior may sometimes become clear with a careful history—for example, lack of mental or social stimulation, a change in the household routine, or other stressful events. However, even birds that are obviously well cared for, are in a stimulating environment, and are treated as a family member may feather pick or self-mutilate. In these cases, the cause is often elusive. Advise the owners that this can be a very frustrating disorder to deal with and that, in some cases, the behavior may not improve despite treatment.

Etiology

- Proposed contributing factors include boredom, frustration, nervousness, anxiety, social isolation, separation anxiety, overcrowding, environmental changes, lack of stimulation, and inappropriate housing.
- Birds spend a large portion of their time foraging for food. In captivity, food is supplied spontaneously,

denying birds the opportunity to exercise this vital mentally stimulating activity.
- Flocks in the wild are well structured with routine. Picking may result if the bird's environment has no daily routine or if the normal routine is disrupted.
- Birds are gregarious flock creatures; many do not cope well with the social isolation that occurs when left alone for prolonged periods during the day. Some birds will feather pick even if left alone at night.
- Attention-seeking behavior may contribute to feather picking. Owners often scold the bird or attempt to distract it, inadvertently providing the bird with attention and reinforcing the behavior.
- Reproductive frustration may contribute to feather picking. Affected birds often exhibit other signs of reproductive interest such as masturbation and regurgitation.
- Too many birds kept in a small area can lead to overcrowding and stress.
- Once some birds begin picking, the behavior can become a vicious cycle similar to obsessive-compulsive disorders in humans.
- Neurochemical abnormalities or inherited factors may contribute to feather picking. There appears to be a greater predilection for feather picking in species such as cockatoos, African grey parrots, Eclectus parrots, and conures. Some birds respond well to treatment with psychopharmacologic agents.

Diagnosis

- Rule out any possible underlying medical causes of feather picking.
- Obtain a detailed history, including area of feather loss, duration, progression of picking, daily routine, changes in the environment, breeding behavior, and other abnormal behaviors, if present.
- Have the owner keep a log of when and under what circumstances the bird feather picks.
- Obtain a detailed dietary history.
- Perform a careful physical examination.
- If evidence of pyoderma exists, obtain samples for cytologic exam and culture (see previous discussion in this chapter).

Treatment

▼ ***Key Point*** Attempt to identify and correct any environmental stressors or deficiencies. Often several changes in surroundings and numerous activity trials are needed before a positive response is seen. The addition of pharmacologic agents is effective in only some cases. Advise the owners that the solution is rarely simple and generally requires dedication and long-term treatment. Some birds fail to respond to any treatment.

- Provide mental and physical activity to occupy the bird during the day.
- Birds have a strong need to chew. Provide materials for the bird to shred such as perches of soft non-toxic wood, branches, paper (magazines, books), toys with multiple textures, or coconut shells.
- Provide toys that stimulate thinking and foraging behavior.
- Dedicate playtime at the same time every day.
- Move the cage to an area in which there is a lot of activity.
- Leave the television or radio on during the day.
- Continuous loop videos are commercially available containing film of birds engaging in natural behaviors. Playing these videos during the hours that the bird is alone has been beneficial in many cases.
- Advise owners to buy the largest cage possible for the bird. If possible, a large flight cage with outdoor access is most effective.
- Provide a safe hide box for the bird for security and "quiet time."
- Allow the bird 8 to 12 hours of sleep a night.
- The addition of a cage mate is helpful in some cases. However, not all birds will stop picking with the addition of a mate and may actually feather pick the mate or teach the new bird to feather pick. Addition of a mate may make the original bird less interactive with people, or the original bird may not accept the new bird and may harm it.
- Quarantine all new birds for 60 days.
- Psychopharmacologic drugs have been used with varying success; however, there is no one panacea for feather-picking birds. A therapeutic trial may be necessary with several different agents before results are achieved. Some birds do not respond to pharmacologic treatment. Suggested therapeutic agents include the following:
  - Haloperidol (Haldol, DuPont) at a dosage of 0.1 to 0.4 mg/kg PO q24h. Begin at a low dose and increase gradually every 5 to 7 days, to effect, if well tolerated. Drowsiness is the most common side effect.
  - Tricyclic antidepressants, such as clomipramine HCl (Clomicalm, Novartis) at 1.0 mg/kg PO q24h. Up to 2.0 mg/kg q24h has been tolerated and effective in some birds. Rare anecdotal reports of sudden death exist, possibly due to an underlying arrhythmia. Alternatively, try doxepin (Sinequan, Roerig) at a dosage of 0.5 to 1.0 mg/kg q12h.
  - Naltrexone (Trexan, DuPont) at a dosage of 1.5 mg/kg PO q8–12h. Naltrexone is an opioid antagonist used to counteract the release of endogenous opioids that may occur during picking or self-mutilation. Do not use in birds with liver disease.
- Serotonin-specific reuptake inhibitors (SSRIs) are rarely effective.
- Some female birds displaying sexual behaviors respond to leuprolide acetate (Lupron, TAP Pharmaceuticals) depot injection at 800 µg/kg IM every 14 days. Three doses are usually sufficient to inhibit

further egg laying. Repeat treatment may be needed if signs return. Lupron is believed to act by inhibiting the release of follicle-stimulating hormone and luteinizing hormone. The owner must also discourage all sexual behavior by removing toys or any other objects to which the bird is directing sexual behavior.
- Other treatments include the use of human chorionic gonadotropin (hCG) at 1500 IU/kg IM every 14 days to inhibit reproductive activity in female birds.
- Megestrol acetate, testosterone, and medroxyprogesterone have all been used, but due to their serious and possible lethal side effects they are strongly discouraged.
- Apply a physical barrier to plucking, such as an Elizabethan collar or tube collar, *only* if the bird is in danger of inflicting serious harm to itself. Birds that are mutilating to the point of removing skin and underlying tissues may need a temporary barrier while the underlying disorder is treated. Applying a collar alone does not treat the cause of feather picking and causes significant stress. See the discussion of Elizabethan collars above.
- Do not apply topical sprays, homemade or sold over the counter, to deter feather picking (such as bitter-tasting solutions). Birds are very meticulous about their feathers, and these solutions often exacerbate picking.
- Do not perform radical beak grinding to inhibit picking.

Oiled Birds

- In most cases, the owner has applied an oily substance to prevent the bird from picking, to attempt treatment of a dermatologic condition, or as accidental contact with oil.
- The most serious consequence is hypothermia. Oils interfere with the insulation and waterproofing functions of the feathers.
- Ingestion may cause gastritis or gastric ulceration.
- Crude oils can be toxic if ingested. Birds will vigorously preen when something is applied to their feathers.
- Administer activated charcoal to prevent further absorption.
- Wash the bird in commercial dishwashing soap such as Dawn (Procter & Gamble) to remove topical oil.
- Dry the bird well and keep it warm.
- Provide supportive care as needed.

Glue Traps

- Birds occasionally become entrapped in glue traps used for rodent pests.
- Advise the owner to leave the bird attached to the trap and bring the bird into the hospital.
- Try to manually remove small parts from the trap; if this is not possible, use Armor All Protectant (Armor All Products) automobile cleaner to assist removal.
- Once the bird is removed, wash the bird with warm water to remove any residue.
- Give supportive care as needed.

Chapter

171 Avian Respiratory System Disorders

Matthew S. Johnston

Disorders of the respiratory system are very common in birds. The unique anatomy and physiology of the avian respiratory system can make the diagnosis and treatment of disorders of the respiratory system difficult for the veterinary clinician. This chapter will focus mainly on anatomy, physiology, and clinical management of disorders of the respiratory system of pet parrots. For ease of use, the respiratory system will be discussed based on anatomy, with separation of the upper respiratory tract and lower respiratory tract. Clinical signs of many different disorders are very similar depending on the anatomic location of the disease process.

ANATOMY AND PHYSIOLOGY

Upper Respiratory Tract

- The upper respiratory tract begins at the nares, which are usually located on a fleshy mound at the base of the rhinotheca (upper beak keratin) called the cere.
- The cere may be feathered or unfeathered, depending on the species.
- The nares open on the dorsal aspect of the cere into the nasal cavity. An operculum is present just within the nasal opening in Amazon parrots (*Amazona* species) that probably functions in filtering out particulate matter.
- The nasal cavity is divided by a septum and is composed of three fairly distinct and well-vascularized conchae—rostral, middle, and caudal. The middle concha is the largest of the three in most parrots.
- The nasal cavity opens into the dorsal aspect of the oral cavity via the choanal slit. The choanal slit is normally lined by a respiratory epithelium and, grossly, sharp papillae can be seen extending into the lumen of the slit from the lateral margins. Absence of these choanal papillae is a sign of respiratory pathology.
- During breathing, the larynx abuts the choanal slit to allow close-mouthed nasal breathing in a normal parrot.
- The infraorbital sinus is the only sinus in birds, but it is quite large and convoluted, with six diverticula that can be found anatomically throughout the head and beak.
- The dorsal aspect of the infraorbital diverticulum opens into the middle and caudal nasal conchae. This dorsal opening makes drainage of the sinus difficult in a clinical setting.
- The infraorbital sinus communicates with the cervicocephalic air sacs at the base of the skull.
- The rima glottidis is not covered by an epiglottis, as is the case in mammals. Paired arytenoids cartilages form the walls of the rima glottidis.
- Compared with that of mammals, the avian trachea and rima glottidis are quite wide in diameter relative to the size of the bird. In addition, the trachea is long and often convoluted as it tracks down the neck. This convolution allows the bird full range of flexibility in the neck.
- Because of the large diameter and length of the trachea, there is a larger physiologic dead space in birds compared with in mammals. To compensate for this, birds tend to have a slower respiratory rate but a larger tidal volume.
- The tracheal rings are complete, and tracheal expansion capacity is very limited.
- At the bifurcation of the trachea (at the thoracic inlet in most parrots), the syrinx can be found. The syrinx is the sound-production organ of the bird, and it is an important anatomic structure as it is a common location of many disease processes, including inhaled foreign bodies and fungal granulomas. The syrinx is composed of a number of complex cartilages, muscles, and membranes that work together to create vibrations that can be amplified to create loud sounds.

▼ ***Key Point*** The infraorbital sinus is very complex and convoluted. It is only open to the nasal cavity dorsally, making drainage of the sinus very difficult.

▼ ***Key Point*** The trachea is formed by complete tracheal rings, which restrict expansion of the trachea, so be very cautious when using cuffed endotracheal tubes. The syrinx is the "voice box" of a parrot and is situated at the bifurcation of the trachea, an anatomic location of many disease processes.

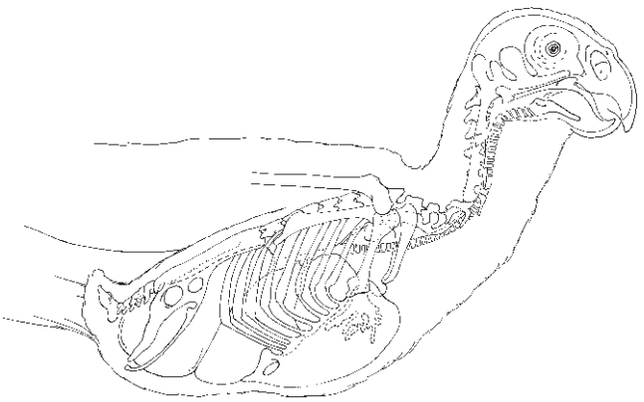

Figure 171-1. Anatomy of the air sacs.

Lower Respiratory Tract

- The lower respiratory tract consists of the lungs and air sacs (Fig. 171-1).
- The lungs are paired, non-expansible, and located against the dorsal body wall in the thoracic region of the coelom.
- The parabronchi travel throughout each lung and have extensive anastomoses with each other. The parabronchi have outpocketings throughout their length, termed atria, which further open into infundibula. The infundibula narrow in size into air capillaries, the functional equivalent of the mammalian alveoli. Gas exchange occurs throughout the anastomosing meshwork of the air capillaries, which course in immediate proximity to the blood capillaries.
- To complete a respiratory cycle, birds require two breaths. On the first inhalation, the majority of inhaled air moves into the caudal air sacs. On the first exhalation, this air then moves through the lungs, where gas exchange occurs. On the second inhalation, the air in the lungs moves to the cranial air sacs, and on the second expiration, this air is then expelled through the trachea. This unidirectional flow of air makes up the majority of respiration in pet parrots.
- Bidirectional flow also occurs in parrots, wherein a small percentage of inhaled air goes directly to the lungs and is then expelled on expiration. Because of these two systems, birds exchange gas on both inspiration and expiration.
- Birds lack a diaphragm; they rely on a system of bellows, the air sacs, to propel air throughout the respiratory tract. Pressure changes in the air sacs are a result of muscle-controlled volume changes within the thoracoabdominal coelom (see Fig. 171-1).
- Parrots have nine air sacs: paired cervicocephalic, single clavicular, paired cranial thoracic, paired caudal thoracic, and paired abdominal. The latter four sets of air sacs have connections to the lungs (termed ostia), so they are considered part of the lower respiratory tract. As discussed above, the cervicocephalic air sacs have connections to the infraorbital sinus but not the lungs.
- Histologically, air sacs are similar to peritoneum: one to two cell layers thick, relatively avascular, and composed of connective tissue stroma.
- In some species, the air sacs extend into the bones. In parrots, the only consistently pneumatic bone is the humerus, which is aerated by the clavicular air sac.

▼ ***Key Point*** Birds exchange gas on both inspiration and expiration. A complete respiratory cycle in a parrot takes two complete breaths to cycle air unidirectionally through the air sacs and lungs. The air sacs are very thin and relatively avascular, and they do not function in gas exchange.

CLINICAL SIGNS OF RESPIRATORY DISORDERS

Upper Respiratory Tract

Signs of upper respiratory tract disorders can be divided into nasal, sinus, or choanal disorders and tracheal or syringeal disorders. In many instances, diseases that affect one of these anatomic sites also affect another.

- Common historical and physical examination findings in parrots with nasal, sinus, or choanal disorders include the following:
  - Sneezing
  - Picking at the nares
  - Rubbing of the head on perches
  - Nasal discharge
  - Ocular discharge
  - Periorbital swelling
  - Facial asymmetry or focal subcutaneous facial swellings
  - Blunting of choanal papillae
  - Hyperemia of the cere
  - Lack of airflow through one or both nostrils
  - "Wet" respiratory noises auscultated over the sinuses
  - Plaque-like lesions around the choana or within the oral cavity
  - Discharge or swelling at the choanal slit
  - Inflation of the infraorbital sinus during expiration
- Common historical and physical examination findings in parrots with tracheal or syringeal disorders include the following:
  - "Coughing" (birds cannot technically cough since they lack a diaphragm)
  - Voice change
  - Stridorous breathing
  - Deep and slow respiratory pattern

- Clicking respiratory noises
- History of recent anesthesia and intubation
- Traumatic wounds to the neck
- Exercise intolerance
- Cyanosis of beak or nail beds (in parrots with unpigmented beak and skin)
- Collapse

Lower Respiratory Tract

Common historical and physical examination findings in parrots with lung or air sac disorders include the following:

- Dyspnea
- Tachypnea
- Tail bob
- Lethargy
- Decreased appetite
- Exercise intolerance
- Respiratory noise
- Cyanosis of beak or nail beds (in parrots with unpigmented beak and skin)
- Shock
- Coelomic distention

▼ ***Key Point*** Many different diseases can present with similar clinical signs based on their location within the respiratory tract.

DISORDERS OF THE UPPER RESPIRATORY TRACT

Hypovitaminosis A

This condition is seen most frequently in Amazon parrots but can occur in any species. A thorough dietary history is the most important diagnostic tool.

Etiology

- Most birds with clinical signs from hypovitaminosis A are adult birds that have been fed an unsupplemented seed diet. Hypovitaminosis A causes squamous metaplasia of epithelial cells.

Clinical Signs

- Most commonly, parrots present with chronic sinusitis due to secondary infections and blunted choanal papillae.
- In addition to upper respiratory signs, parrots may have reproductive, gastrointestinal, or urinary tract problems due to the squamous metaplasia of all epithelial cell types.

Diagnosis

- Obtain a specific dietary history of what the parrot eats, not just what it is offered.
- Perform sinus aspirates for cytology and perform culture and sensitivity (including fungal cultures) as secondary infections are common (see Chapter 169).

Treatment

- Correct the diet by recommending a formulated pelleted diet, fresh food diet, or some combination of the two. Seeds should be fed in a minute quantity if at all.
- Treat secondary infections with appropriate antimicrobials; trimethoprim-sulfa (25 mg/kg PO q12h) or enrofloxacin (20 mg/kg PO q24h) are good first-line choices until culture results are obtained.
- Give a single injection of vitamin A (10,000 IU/kg IM). Vitamin A is often available combined with vitamins D and E. Dosing should be made on the vitamin A component of this mixture. No more than two injections given 1 week apart should be recommended, as oversupplementation of vitamin A can have serious deleterious effects.
- Supplement the diet with beta carotene (one to two drops per parrot) while the bird is being converted to a healthier diet. Beta carotene is a precursor to formed vitamin A and overdosage is unlikely, as parrots will excrete what they do not need. Owners can monitor for orange or yellow discoloration of the urine, which occurs when beta carotene is being supplemented in excess. Supplementation with formed vitamin A is not recommended due to the likelihood of overdosage. Signs of hypervitaminosis A are similar to those of hypovitaminosis A.

Prognosis

- The prognosis is generally good, although some parrots are left with permanent damage to the epithelium and may need chronic treatments.

Rhinitis

Etiology

- This condition can occur in any species of parrot and is often associated with hypovitaminosis A or environmental irritants such as dust, scented cleaning products, aerosol sprays, or tobacco smoke.

Clinical Signs

- Parrots most commonly present with nasal discharge, sneezing, picking at the nares, and scratching of their beak on perches.

Diagnosis

- Obtain a thorough dietary and environmental history, paying particular attention to airborne irritants.
- Perform a nasal flush using sterile saline and collect a sample for cytologic examination and culture (see

Chapter 168). With rhinitis, cytology should demonstrate inflammatory cells and possibly bacterial or fungal agents.

Treatment

- See the section on hypovitaminosis A for good first-choice antimicrobials or a base choice on cytologic findings.
- If the diet is deficient in vitamin A, correction of the diet should be part of the therapeutic plan.
- Control environmental irritants by use of air filtration, humidification, and adequate ventilation.
- In dry climates, owners can be taught to perform nasal flushes to moisturize the upper airway.

Prognosis

- Prognosis is generally good.

Rhinoliths and Nasal Foreign Bodies

Etiology

- Rhinoliths occur most commonly in African grey parrots, while foreign bodies can occur in any species. Rhinoliths are concretions of mucous and debris that form within the nasal cavity. Any small airborne particles can become nasal foreign bodies when inhaled.

Clinical Signs

- Parrots most often present with acute onset of nasal discharge, facial discomfort, and sneezing.

Diagnosis

- Obtain a thorough environmental history, paying particular attention to humidity and inhaled particulate matter.
- Use a penlight or small fiber-optic endoscope or transilluminator to look into the nares. Rhinoliths are usually easily identifiable as mass-like, hard concretions just within the nares. Foreign objects may or may not be seen depending on how deep within the nasal cavity they are lodged. If a foreign body is suspected but not seen, the bird should be anesthetized for rigid rhinoscopy.

Treatment

- Perform a nasal flush to remove debris and moisturize the airway. Perform the flush over a container so that foreign objects can be easily identified (see Chapter 168).
- Use a hypodermic needle or cotton-tipped applicator to remove rhinoliths by gently teasing the rhinolith off of the mucous membranes. Some bleeding may occur with this technique. Significant hemorrhage can be controlled with an ice pack of the nose or topical diluted (1:100) epinephrine nasal drops.

Prognosis

- Prognosis is generally good.
- Humidification and air purification may help prevent recurrence.

Sinusitis

Etiology

- This condition can occur in any species but is seen most commonly in New World parrots. It is associated with hypovitaminosis A and environmental irritants, but it can also occur as a primary disease process.

Clinical Signs

- The most common clinical signs are asymmetrical facial swelling(s), facial discomfort, and sneezing.

Diagnosis

- Perform sinus aspirates for cytology and culture and sensitivity (including fungal culture).
- Consider testing for psittacosis (*Chlamydophila psittaci* infection) in high-risk birds. See below and Chapter 169 for details on chlamydiosis.
- Perform cranial imaging such as skull radiographs, computed tomography (CT), or magnetic resonance imaging (MRI) in advanced or recurrent cases to assess the presence of granulomatous or caseated masses (see Chapter 4). Skull radiographs are less sensitive for picking up small lesions but are more readily available than CT or MRI.

Treatment

- Some cases respond favorably to antimicrobial treatment based on culture and sensitivity, nebulization, and correction of dietary or environmental causes. Nebulization with saline is usually effective; however, some clinicians prefer to add medications to their nebulization. Commonly used nebulized medications include acetylcysteine to moisturize airways (200 mg/9 ml in sterile water), enrofloxacin for gram-negative sinusitis (10 mg/ml in sterile saline), gentamicin for gram-negative sinusitis (50 mg/10 ml in sterile saline), and clotrimazole for fungal sinusitis (10 mg/ml in polyethylene glycol). Nebulization is best performed with a nebulizer unit in a sealed cage.
- Many birds with sinusitis will not completely respond to antimicrobial medications and correction of husbandry. In recurrent cases, suspicion should be raised of caseated or granulomatous masses that may require surgical removal.

Prognosis

- The prognosis is guarded with advanced or chronic, recurrent disease.

Psittacosis

Etiology

- Caused by the organism *Chlamydophila psittaci,* psittacosis is a very important zoonotic disease of pet birds. In humans, it may cause generalized malaise and flu-like symptoms. In addition to its respiratory signs, it usually causes hepatic pathology.
- Psittacosis seems to be most prevalent in the small parrots such as cockatiels *(Nymphicus hollandicus)* and budgerigars *(Melopsittacus undulatus).* See Chapter 169.

Clinical Signs

- Clinical signs attributable to the respiratory system include sneezing, oculonasal discharge, facial discomfort, and hyperemia of mucous membranes. Other clinical signs include lethargy, biliverdinuria (green discolored urates), and anorexia.

Diagnosis

- Obtain a thorough history of exposure to other birds (boarding, pet stores, bird shows, wild birds).
- Perform a complete blood count (CBC), plasma biochemistry panel, and plasma protein electrophoresis (EPH) to check for leukocytosis characterized by a monocytosis, elevated aspartate aminotransferase and/or bile acids, or hyperglobulinemia.
- Perform polymerase chain reaction (PCR) testing of a choanal and cloacal swab.
- In larger parrots, elementary body antibody titers, complement fixation, or immunofluorescent antibody may be useful.

Treatment

- Isolate parrots with clinical signs of psittacosis from other parrots until treatment has been initiated. Research has demonstrated a cessation of shedding after 1 week of treatment with tetracycline antibiotics.
- Treat with doxycycline for a minimum of 45 days. Doxycycline can be given orally, weekly by depot intramuscular injection, in medicated water, or in medicated feed depending on the circumstances. The oral dosage for doxycycline is 25 to 50 mg/kg q24h in most parrots.
- Psittacosis is a reportable disease in most states, and you should check with your local health department in confirmed or suspected cases.

Prognosis

- Prognosis is generally good if treatment is initiated early in the course of the disease.
- Recurrence is more likely in cockatiels, budgerigars, and lovebirds.

Choanal Atresia

- Choanal atresia has been reported to occur in African grey parrots.
- Typical historical presentation is a young bird that is unable to nose-breathe and has copious mucoid nasal discharge. In some cases, the choanal slit may appear to be open, but endoscopic examination reveals a soft-tissue membrane occluding the nasal passage just dorsal to the choanal slit.
- Several treatment modalities have been attempted. The two most successful surgical corrections include stenting and laser surgical ablation of the membrane. Fatal hemorrhage is a potential complication of these surgical procedures, and some cases will reclose and require multiple surgical procedures.

Aspergillosis

Etiology

- Although traditionally thought of as a disease of the lower respiratory tract, aspergillosis (caused by *Aspergillus* species) commonly occurs in the infraorbital sinus and trachea. *Aspergillus* granulomas can form at the syrinx, leading to upper airway obstruction.
- Aspergillosis is more common in immunosuppressed parrots or in parrots that obtain a heavy burden of organisms in a short period of time.

Clinical Signs

- Clinical signs in parrots can be those of a chronic sinusitis or tracheal obstruction, including voice changes historically.

Diagnosis

- Perform a CBC and an EPH to look for a leukocytosis and/or hyperglobulinemia. Research suggests that aspergillosis should be considered a differential if the albumin-to-globulin ratio, as measured by an EPH, is markedly decreased.
- *Aspergillus* antibody and antigen testing are neither sensitive nor specific in pet parrots, so their utility as a diagnostic tool is questionable.
- Radiographs are generally not sensitive for defining tracheal granulomas, although if a soft tissue mass is seen within the trachea, aspergillosis should be suspected.
- Place an air sac cannula if tracheal obstruction is suspected to stabilize the patient prior to further diagnostics (see Chapter 168).
- Under anesthesia, perform tracheoscopy or tracheal washes to obtain samples for cytology, histopathology, and fungal culture. *Aspergillus* species are easily identified cytologically or histologically because of their

characteristic pseudohyphae and septate branching. *Aspergillus* species are common environmental contaminants and the most common contaminant of culture plates. So, interpretation of a positive culture in the face of negative cytology or histopathology should be made with caution.

Treatment

- Surgical or endoscopic removal or ablation of granulomas is necessary before medical therapy will be effective.
- Most parrots require hospitalization for several days of inpatient treatment followed by a very extensive and long-term outpatient treatment. During treatment, monitor the CBC or EPH to assess progression. Periodic tracheoscopy may be beneficial to assess the presence of granulomatous or plaque lesions. Duration of therapy ranges from 1 month to lifelong, and determining an end point of therapy can be extremely difficult if classic clinicopathologic findings are not present.
- Treat medically with nebulization and systemic antifungals. Commonly used nebulized antifungals include clotrimazole (10 mg/ml in polyethylene glycol) and amphotericin B (7 mg/ml in saline). The most commonly used systemic antifungal is itraconazole (10 mg/kg PO q24h), but this drug should be used with great caution in Africa grey patients due to their apparent sensitivity to its hepatotoxic effects. In African grey parrots, use ketoconazole (30 mg/kg PO q12h) or fluconazole (15 mg/kg PO q12h).

Prognosis

- Prognosis is generally poor, and recurrence is common.

Mycoplasmosis

- *Mycoplasma* species uncommonly cause sinusitis and blepharoconjunctivitis in pet parrots. Mycoplasmosis should be suspected in cases of sinusitis that partially respond to antibiotics but never completely resolve.
- Unfortunately, definitive diagnosis is very difficult, as culturing *Mycoplasma* species is a time-consuming and not clinically useful practice.
- Long-term, combination antimicrobial treatment is usually necessary to eradicate the organism from the host.

Tracheal Foreign Bodies

Etiology

- Parrots with tracheal foreign bodies usually present as emergencies due to upper airway obstruction.
- Cockatiels seem predisposed to aspiration of seeds, although tracheal foreign bodies can occur in any species.

Clinical Signs

- Parrots usually present with acute dyspnea attributable to the upper airway; often, a seed is aspirated during vigorous feeding, so feeding practices should be questioned when obtaining a history.

Treatment

- Place an air sac cannula to provide an open airway until definitive therapy can be provided (see Chapter 168).
- Tracheal lavage can be attempted but carries an inherent risk of drowning or forcing the foreign object further down the respiratory tract, so it is not recommended unless other treatments are not feasible. This should be performed with the bird under general anesthesia and an air sac cannula in place.
- Perform a tracheoscopy to remove the foreign body (usually a seed) in larger parrots.
- If you are unable to perform a tracheoscopy, perform a tracheotomy to allow surgical removal of the foreign object. A tracheotomy is performed at the level of the thoracic inlet unless radiographs or a tracheoscopy determine that the foreign object is further cranially.
- Begin nonsteroidal anti-inflammatory drugs (NSAIDs) and antibiotics to reduce the chance of tracheal stricture.

Prognosis

- Prognosis is good if the foreign object can be removed.

Tracheitis and Tracheal Strictures

Tracheitis and tracheal strictures appear to occur more commonly in macaws and cockatoos, possibly because in these genera the trachea narrows as it courses toward its bifurcation.

Etiology

- Most tracheitis and tracheal strictures occur as a result of a malpositioned, oversized, rigid, or cuffed endotracheal tube. Tracheal intubation is important during anesthesia, but it is very important to not inflate cuffed tubes and to make sure uncuffed tubes are not positioned so as to put pressure on the tracheal mucosa.

Clinical Signs

- Most cases have a history of recent endotracheal intubation.
- "Coughing," upper airway obstruction, and voice change are the most common clinical signs.

Diagnosis

- Take radiographs to assess for tracheal stricture as demonstrated by acute narrowing of the tracheal lumen.
- Perform tracheoscopy to confirm stricture or diagnose tracheitis.

Treatment

- Place an air sac cannula to provide a patent airway if the patient is dyspneic (see Chapter 168).
- Tracheitis will sometimes respond favorably to NSAIDs and antibiotics if diagnosed early in the course of disease, but it may lead to tracheal stricture if not addressed.
- Tracheal strictures usually require surgical removal of the strictured site, as the complete tracheal rings prevent effective bougienage or ballooning procedures.

Prognosis

- Prognosis is generally good if the stricture is treated early or if the tracheal stricture can be removed.

Extramural Tracheal Obstructions

Any mass that compresses the trachea can lead to signs of upper airway obstruction. The most common cause of this is goiter in budgerigars, but any extraluminal neoplasia can have a similar presentation.

DISORDERS OF THE LOWER RESPIRATORY TRACT

Aspiration Pneumonia and Air Sacculitis

Etiology

- This condition occurs most commonly in neonates or hand-fed chicks that are accidentally fed directly into the trachea and is almost always fatal. However, it can also occur in parrots that are regurgitating for any reason or iatrogenically in parrots that are administered fluids via crop gavage.

Clinical Signs

- The most common clinical sign is severe dyspnea.

Diagnosis

- Take radiographs to confirm lung and air sac opacities. In minor cases, thickened air sac membranes will appear as radio-opaque lines on the radiograph.

Treatment

- Most cases require hospitalization for inpatient treatment with broad spectrum antimicrobials, nebulization, and supportive care.

Prognosis

- The prognosis is guarded.

Hypersensitivity Syndrome

Etiology

- Seen most commonly in macaws, this condition is characterized by an intense inflammatory reaction within the lungs (pneumonitis) to an airborne irritant.
- Common irritants include feather dust from other parrots that produce powder down, aerosolized disinfectants and deodorizers, tobacco smoke, or dust.

Clinical Signs

- The most common clinical signs are wheezing, tail bob, and exercise intolerance.

Diagnosis

- Perform a CBC to assess the presence of polycythemia and eosinophilia. In some cases, the polycythemia can be quite severe (as high as 85%) owing to chronic hypoxia. Eosinophilia is not always present.
- Perform radiographs to assess the lung field for increased radio-opacity of the normal reticulated pattern. The avian lungs are evaluated on a lateral projection, and the normal lung has a fine reticular pattern throughout its parenchyma. Birds with hypersensitivity pneumonitis will have thickenings of the reticular pattern that appear similar to bronchial lung patterns of cats or dogs.

Treatment

- Antihistamines and NSAIDs have been used with limited success. Commonly used antihistamines include diphenhydramine (4 mg/kg PO q8h) and hydroxyzine (2.2 mg/kg PO q8h). Commonly used NSAIDs include meloxicam (0.5 mg/kg PO q12h) and carprofen (2 mg/kg PO q12h).
- Bronchodilators have been used with mixed success. Commonly used bronchodilators include terbutaline (0.1 mg/kg PO q12h) and aminophylline (4 mg/kg PO q6–12h).
- Avoid corticosteroids due to severe side effects, including immunosuppression and gastric ulceration.
- Resolution will only occur if irritants can be removed from the bird's environment by physical removal, air purification, and excellent ventilation. In some cases, even with removal of the source of irritation, birds are left with some degree of pneumonitis, although it may be easier to manage.

Prognosis

- The prognosis is guarded.

Polytetrafluoroethylene Toxicosis

Etiology

- Polytetrafluoroethylene (PTFE) (Teflon and other non-stick coatings) causes severe pulmonary hemorrhage in parrots when pans containing these non-stick coatings are overheated.

Clinical Signs

- Parrots are presented severely dyspneic or often dead; some may be coughing up blood-tinged sputum.

Treatment

- Treat immediately with oxygen, furosemide (2 mg/kg IM), and terbutaline (0.01 mg/kg IM). Minimize handling of these severely dyspneic birds or consider anesthesia and mechanical ventilation to maintain oxygenation.
- Advise owners to keep parrots as far from the kitchen as possible if the owners use non-stick cookware. Ideally, parrot owners should not use cookware coated with PTFE.

Prognosis

- Prognosis is very guarded.

Inhaled Irritants

Any inhaled irritant can cause signs of respiratory distress in pet parrots. Treatment of any of these consists of removal of the source of irritation and supportive care of the parrot. Some of the more common irritants include the following:

- Potpourri and other strongly scented deodorizers
- Tobacco smoke
- Dust or pollution
- Aerosolized sprays
- Concentrated cleaning agents (undiluted bleach or vinegar)
- Perfumes or colognes
- Oven cleaner

Aspergillosis

Etiology

- As discussed above, aspergillosis occurs mainly in immunocompromised parrots.
- Aspergillosis can occur as discrete granulomas within the air sacs or lungs or as a disseminated, fulminant air sacculitis and pneumonia.

Clinical Signs

- Clinical signs include lethargy, exercise intolerance, and dyspnea.

Diagnosis

- Perform a CBC to look for leukocytosis characterized by a heterophilia and monocytosis.
- Perform an EPH to look for a hyperglobulinemia. As discussed above, one of the more common findings in parrots with aspergillosis is a markedly decreased albumin-to-globulin ratio.
- Antibody or antigen serology is neither sensitive nor specific in parrots, so its diagnostic value is limited.
- Take radiographs to assess for granulomatous masses or air sac lines. Air sac lines are most commonly seen on the lateral projection in the normally radiolucent air sac triangle that sits just cranial to the pelvis. On the ventrodorsal projection, air sac lines may be apparent just cranial to the femurs.
- Obtain biopsies of air sacs and/or granulomas for cytology, histopathology, and fungal culture using endoscopic guidance. As discussed above, cytology or histopathology is more sensitive and specific than fungal cultures, as *Aspergillus* species are common culture plate contaminants.

Treatment

- If possible, remove granulomas surgically or with endoscopic assistance using a diode laser.
- Treat medically with nebulization and systemic antifungal agents for at least 6 weeks. See above discussion on upper airway aspergillosis for commonly used antifungal drugs.

Prognosis

- Prognosis for complete remission is poor, although some cases can be managed long term. Determination of the end point of therapy is difficult, as radiographic changes may be permanent because of scarring of the air sac membranes, and not all cases will have classic clinicopathologic findings.

Bacterial Pneumonia and Air Sacculitis

Etiology

- Although rare in parrots, primary bacterial pneumonia and air sacculitis can occur, usually as a result of gram-negative colonization of the respiratory tract.
- Bacterial pneumonia and air sacculitis occur most frequently in parrots that are immunosuppressed from concurrent diseases, poor husbandry, or chronic stress.

Diagnosis

- Perform a CBC to assess for a leukocytosis characterized by a heterophilia.

- Perform an EPH to assess for hyperglobulinemia, usually characterized by elevations of the alpha or beta globulins.
- A tracheal wash can be performed under anesthesia, or laparoscopy may be performed to obtain samples for cytology and culture and sensitivity.

Treatment

- Hospitalize for inpatient treatment with antibiotics (enrofloxacin at 20 mg/kg IM as a single dose followed by oral administration q24h pending culture and sensitivity results), oxygen therapy, nebulization, and supportive care.

Prognosis

- Prognosis is guarded.

Focal Subcutaneous Emphysema

Etiology

- Often called *air sac rupture,* this condition occurs for unknown reasons, most commonly in Amazon parrots.

Clinical Signs

- It is characterized by a focal, air-filled swelling usually around the shoulders or neck. It is caused by a ruptured cervicocephalic or clavicular air sac. Usually birds have no clinical signs except for the swelling.

Diagnosis

- Perform an aspirate of the swelling to confirm that it is air filled.

Treatment

- Treatment is often unrewarding, but stenting has showed some promise.
- Some cases will resolve without treatment.

Prognosis

- Prognosis is good for life, although some birds are left with permanent swelling.

Neoplasia

Etiology

- Neoplasia of the lungs is uncommon and appears to occur more frequently in cockatoos. Primary bronchial carcinomas are the most common tumor type.

Clinical Signs

- Frequently, the presenting complaint is a pathologic fracture or swelling of a long bone, as boney metastases are common in this disease. Many birds have no signs attributable to the respiratory system, but primary tumors are found on postmortem examination.

Treatment

- Thus far, treatment attempts have been unrewarding, but chemotherapy may be attempted.

Newcastle Disease (Exotic Newcastle Disease)

- This important agricultural disease has recently been found in pet parrots. It is a highly contagious, usually fatal disease caused by a paramyxovirus, which affects the respiratory, gastrointestinal, and neurologic systems.
- Most recently, it has been diagnosed in flocks of parrots that were illegally smuggled into the United States.
- Any birds that die with premonitory signs attributable to these systems should receive a full necropsy examination.
- This disease is reportable in all states.

Psittacosis

- Diagnostics for psittacosis and an overview of the disease have been given above and in Chapter 169.
- Be aware that psittacosis can also cause pneumonia and air sacculitis, although these presentations are unusual in pet parrots.

Sarcocystosis

Etiology

- Disease attributable to infection with *Sarcocystis falcatula* occurs most commonly in the southeastern United States. Most commonly, it affects Old World parrots, although New World species have been reported to be infected.

Clinical Signs

- Clinical signs are those of an acute pneumonitis, usually resulting in high mortality.

Diagnosis

- Diagnosis is made by the demonstration of oocysts within the lung tissue. Oocysts may also be found in striated and cardiac muscle.

Treatment

- This disease can be controlled by limiting exposure of parrots to flies and cockroaches, which serve as the transport host for the organism.

Chapter

172 Avian Digestive System Disorders

Barbara L. Oglesbee

DISORDERS OF THE BEAK

General Principles

Normal Structure and Function

- The beak includes the bones of the upper and lower jaws and their keratinized sheaths or rhamphotheca. This horny covering functionally replaces the lips and teeth of mammals.
- The shape of the beak varies, depending on how the species feed and live.
  - In psittacines, the upper beak is massive and curved, and the lower beak is small and horseshoe shaped (this is why psittacines are called hookbills).
- The beak is adapted to cracking large nuts and seeds, as well as tearing and shredding wood from trees to provide nest sites.
- Histologically, the horny beak resembles skin and consists of dermis and modified epidermis. The stratum corneum of the epidermis is very thick.
- The horny tissue of the beak is continuously replaced during normal wear and tear.

Normal Beak Growth

- Many bird owners erroneously believe that the upper beak grows only from the cere and continues to the tip (or edges), where it is then worn off (and that the process is similar in the lower beak). On the contrary, beak tissue grows continuously outward (toward the surface) over much of the beak.
- As the keratinized epithelium reaches the surface, it is worn off or may move distally a short distance before it is shed.
- Beak tissue truly moves rostrally only toward the edges and tip.

Beak Overgrowth

Many pathologic conditions can change the normal outward appearance of the beak, adversely affecting its primary functions of food gathering, prehension, preening, and protection. Regardless of the etiology, overgrowth may take various forms, the most common of which are listed here.

- The tip of the upper beak, lower beak, or both may be overgrown.
- Elongation of the upper beak, usually accompanied by subcorneal petechia and increased malleability, is commonly seen in budgerigars with underlying metabolic disease (most commonly hepatic disease).
- Malocclusion of the beak causing the upper beak to angle off to one side, while the lower beak angles in the opposite direction, is referred to as *scissors beak*. The tips and outer edges usually are overgrown owing to a lack of occlusal wear.
- The upper beak is shortened and does not extend out over the tip of the lower beak (prognathism).
- An area of the beak may appear bulged or thickened because of buildup of covering horn. This commonly is seen in birds lacking access to rough surfaces but may also been seen in birds with systemic disease or malnutrition.

Beak Trimming

- Severe malocclusions, such as scissors beak, require surgical correction. See “Supplemental Reading” at the end of this chapter.
- When the underlying condition has been identified and treated, corrective beak trimming may be necessary.
  - Mild overgrowth or a buildup of covering horn may be trimmed if it is interfering with the function of the beak. Depending on the size of the bird, use human fingernail trimmers, cuticle nippers, Roscoe nail trimmers, or an electric hobby tool (Dremel) with a coarse sanding bit.
  - Anesthesia usually is not required; however, be aware that some birds stress easily during this procedure, especially when a hobby tool is used, and deaths have been reported.

▼ ***Key Point*** Knowledge of the normal anatomy and conformation of the beak for each individual species is necessary for proper trimming. Inaccurate trimming, and especially overtrimming, can cause malocclusion, pain and potentially severe hemorrhage.

Nutritional Disorders

An *all-seed diet* is deficient in many nutrients, especially vitamin A, essential in maintaining the health and integrity of epithelial tissues. Hypovitaminosis A may cause hyperkeratosis of epithelial surfaces.

Clinical Signs

Signs include beak thickening and overgrowth. The surface of the beak is hard and thickened, and it appears flaky and chipped instead of smooth.

Diagnosis

Base the diagnosis on clinical signs and a history of a seed-based diet.

Treatment

▼ ***Key Point*** Place pet birds on a commercial pelleted diet whenever possible.

- Supplement a commercial diet with fruits, vegetables, legumes, wholegrain cereals or rice, and small amounts of lean-cooked meats or eggs.
- If the bird will not convert to a commercial diet, then use a commercial avian vitamin supplement.
- Perform beak trims as necessary.

Bacterial and Mycotic Infection

Superficial or deep bacterial and mycotic infections occasionally are seen. These usually are secondary to trauma, chronic rhinitis, or other systemic diseases. Gram-negative enteric organisms (e.g., *Pseudomonas, Escherichia coli,* and *Klebsiella* species) are the most common bacteria isolated. *Aspergillus fumigatus* is the mycotic agent most commonly identified. In budgerigars, *Knemidokoptes* mite infestation is the most common infectious cause of beak deformity.

Clinical Signs

- The surface of the beak appears brittle and crumbly instead of smooth and hard. This may involve the entire beak or may be localized. Lesions may occur externally or within the oral cavity.
- The bird is reluctant to eat, crack seeds, or play with toys. The beak may seem painful.
- Areas of localized necrosis may be found on the beak surface or on the underside of the upper beak.

Diagnosis

- Examine stained specimens from affected areas for inflammatory cells, bacteria, or fungi.
- Obtain bacterial and fungal cultures of lesions.

Treatment

▼ ***Key Point*** Bacterial and mycotic infections of the beak usually are secondary to trauma, systemic disease, or nutritional deficiencies. Whenever possible, identify and treat the primary disease.

- Debride localized necrotic areas with the bird under anesthesia.
- Base antibiotic therapy on culture and sensitivity testing. Pending culture results, begin antibiotic therapy with a broad-spectrum antibiotic such as trimethoprim-sulfa or enrofloxacin (Baytril, Haver/Diamond) (see Chapter 169 for dosages). Long-term systemic therapy usually is required in addition to local debridement.
- For localized *Aspergillus* infection, see Chapter 169 for diagnosis and treatment. Treatment for months may be required.
- The prognosis is guarded if the fungal disease is systemic.

Trauma

Beak damage from trauma can occur in all species and often is the result of aggressive behavior among individual birds housed together, flying into walls or windows, struggling after beak entrapment, or improper beak trimming. A split lower beak may result from a fall, injury from another bird, biting with excessive force, or beak trimming.

Clinical Signs

- An inability to eat and manipulate food or toys may be the only presenting signs. Thoroughly inspect the beak to identify trauma because some injuries are not obvious.
- The beak may seem painful.
- Look for hemorrhage, cracks, punctures, avulsions, or complete amputation.

Treatment

Treatment varies with the type of injury. If the bird is reluctant to eat, forced alimentation may be necessary until the beak has healed sufficiently.

Cracked Upper Beak Tip

- Remove the tip with nail clippers or grind it with a hobby tool.
- Apply ammonium sulfate or ferric subsulfate powder to control hemorrhage.

Split Lower Beak

- If the crack extends the entire length of the beak, dividing it into two movable segments, nothing can

be done to permanently fuse the pieces back together. However, most birds eventually adapt to this condition.
- Wire and dental acrylics can only temporarily repair the crack.
- Birds can eat a normal diet with this condition; cracking seed or pellets is usually not a problem.
- Occasional trimming of the lower beak segments may be necessary because of inadequate occlusion with the upper beak.

Puncture Injury Penetrating the Horny Layer

- Initially treat as an open wound and debride damaged and necrotic areas with the bird under general anesthesia.
- Administer topical and systemic antifungal or antibiotic agents, based on culture and sensitivity testing.
- Defects in the horny layer may be filled or patched with acrylic compounds once a healthy granulation bed has been established.

Beak Avulsions

- If avulsion of the distal one-third occurs, treat as follows:
  - Treat initially as an open wound (as described previously).
  - Cover the open end with acrylics as a temporary patch if necessary (see "Supplemental Reading").
  - Regeneration of the beak is possible, but the beak may never appear totally normal.
- Damage to the proximal one-third of the beak usually is not reversible.
- If the injured birds can be kept alive with forced alimentation, the damaged beak may scar over and the bird may adapt to a soft-food diet.
- Avulsion of the entire upper or lower beak is not reversible. Affected birds usually die of starvation or secondary infection, or they require euthanasia.
- Successful use of beak prosthetic devices has been reported but is rare.

Prevention

- Do not leave birds uncaged unless they are closely supervised.
- Keep apart birds that exhibit obvious aggressive tendencies toward each other. This is a common problem in breeding pairs of cockatoos. Sexually active males may attack females that are not sexually receptive, and beaks commonly are bitten. Preventive measures include the following:
  - Large flight cages
  - Clipping wings of the male but not the female bird
  - Nest boxes with two separate entrances

Neoplasia

Neoplasia of the beak is encountered infrequently, usually in older birds. Fibrosarcoma, fibroma, and squamous cell carcinoma are the most common types.

Clinical Signs

- *Fibrosarcoma* usually appears as a well-demarcated, fleshy protrusion from the horny layer.
- *Squamous cell carcinoma* appears as a focal area of hemorrhage or ulceration.
- Common signs include weight loss and inability to eat.

Diagnosis

Base the diagnosis on histologic examination of excised tissues.

Treatment

- Surgical excision or debulking of beak tumors is rarely successful.
- Cryosurgery or radiation therapy may be beneficial, but the prognosis is generally guarded.

Environmental Factors

- To maintain a normal appearance of the beak, chewing on hard objects and rasping of the outer horny layer of the beak is necessary.
- Lack of access to materials necessary for normal beak wear can result in beak overgrowth or a flaky, chipped surface.
- Provide ample amounts of wood for the bird to chew on. This may be in the form of perches, nest boxes, or wood toys.
- Other items suitable for chewing include rawhide, concrete perches, lava stones, mineral blocks, and leather.

Growth and Developmental Abnormalities

- These conditions usually are seen in preweaned or recently weaned birds. The exact causes are unknown.
- The most common presentations are as follows:
  - *Scissors beak,* a lateral deviation of the upper beak seen most often in macaws
  - *Prognathism,* which affects the architecture of the upper beak and is seen most often in cockatoos
- Treatment by construction and application of a simple, durable prosthesis allows the redirection of beak growth (see "Supplemental Reading").

DISORDERS OF THE ORAL CAVITY

Normal Structure and Function

- Because birds lack a soft palate, which separates the nasal and oral parts of the pharynx in mammals, the oral cavity and pharynx of birds form a single cavity called the *oropharynx*.
- The roof of the mouth, or hard palate, is located immediately behind the upper beak.
  - Rostrally, the palate resembles a hard, fleshy cushion against which the tongue can manipulate objects.
  - Caudally, the palate is divided into two folds containing numerous caudally directed papillae, which are referred to as the *choana*. The choana communicate directly with the nasal passageway.
- The floor of the oropharynx is occupied by the tongue and the glottis.
  - The psittacine tongue is thick, blunt, and dexterous.
  - The glottis lies on the midline directly behind the tongue.
  - Papillae are distributed over the laryngeal prominence and posterior floor of the pharynx. Birds do not have an epiglottis.
- The surface of the oropharynx is lined by stratified squamous epithelium that is keratinized in regions subject to abrasion, such as the papillae.
- *Salivary glands* are not visible grossly and are distributed over the palatine folds, base of the tongue, laryngeal prominence, and pharynx. These glands primarily produce mucus and thus often are referred to as *mucous glands*.
- Psittacine birds do not produce the large amount of watery saliva seen in mammals. Therefore, the oral mucosa is normally only slightly moist, and the tongue is dry.

▼ ***Key Point*** Diseases of the oral cavity are common in pet birds. Routinely inspect the mouth during examination.

Hypovitaminosis A

Hypovitaminosis A, which is generally the result of an unsupplemented, all-seed diet, causes squamous metaplasia of the oral epithelium and subsequent hyperkeratosis of the mucous glands. Keratin-filled cystic structures may be found on the palatine folds, base of the tongue, laryngeal prominence, and pharynx. These lesions may coalesce and become secondarily infected to form large abscesses.

Lesions are more likely to be seen in large psittacine birds (e.g., Amazon and African grey parrots, macaws, and cockatoos) than in small species (e.g., budgerigars and cockatiels).

Clinical Signs

- Signs include white or yellow cysts and abscesses in the oral mucosa.
- If the lesions become secondarily infected, anorexia, general malaise, and weight loss may be present.
- Accompanying signs include blepharitis, conjunctivitis, uveitis, rhinitis, sinusitis, and dyspnea.

Diagnosis

- The diagnosis usually is based on the history and physical examination.
- Obtain biopsy specimens to confirm the diagnosis.

Treatment

- Change the diet as previously described under "Nutritional Disorders."
- Under isoflurane anesthesia, lance and curette oral abscesses; perform a Gram stain and bacterial and fungal culture on the abscess contents.
- Administer systemic antibiotic or antifungal agents, as indicated by culture.
- Provide supportive therapy, such as forced alimentation and fluid therapy, as needed.

Prevention

- Provide a diet adequate in vitamin A or add vitamin supplementation, as described under "Nutritional Disorders."
- Dark green and yellow vegetables are good sources of vitamin A.

Psittacine Pox

See Chapter 169 in this section for discussion of this disorder.

Oral Candidiasis

Candida albicans is a secondary invader that affects the mouth, esophagus, and crop. Factors predisposing to oral candidiasis include poor sanitation, malnutrition, coexisting disease, and prolonged antibiotic therapy. Cockatiels and macaws are affected most commonly.

Clinical Signs

Clinical signs vary with the severity of the disease and include the following:

- Anorexia, general malaise, and weight loss
- Vomiting, regurgitation, and mucus evident on the feathers of the head
- Wet feathers surrounding the mouth, halitosis, and oral hemorrhage
- Poor feeding response in hand-fed baby birds

Diagnosis

- Examine the oral mucosa for lesions that typically appear as a thickening of the oral mucosa associated with a mucoid exudate.
- Lesions may progress to focal or widespread mucosal necrosis, forming diphtheritic membranes or white caseated plugs.
- Perform a Gram or Diff-Quik stain on exudate from oral lesions; look for budding yeasts.
- Perform a fungal culture of oral lesions.

Treatment

▼ ***Key Point*** Candidiasis is usually a secondary invader. Correct predisposing factors in conjunction with specific antifungal treatment.

- In mild cases, birds may respond to nystatin (Mycostatin, Bristol-Myers Squibb), 1 ml/300 g q8h, PO.
- More often, systemic therapy with one of the azole antifungal agents is necessary. Administer ketoconazole (Nizoral, Janssen), 20 to 30 mg/kg q12h, PO, or fluconazole (Diflucan, Roerig), 20 mg/kg q48h, PO.
- Continue treatment until all lesions are healed (usually 1 month or longer).

Prevention

- Provide a clean environment, including food and water. Do not leave moist foods in the cage longer than 2 hours.
- Thoroughly disinfect utensils when feeding baby birds. Soak utensils in chlorhexidine solution (Nolvasan, Fort Dodge), 2 oz per gallon of water.
- Do not save powdered baby foods once they are reconstituted beyond one feeding or overgrowth of yeast and bacterial occurs.
- If long-term antibiotic therapy is indicated (e.g., to treat chlamydiosis), give antifungal agents such as nystatin and ketoconazole prophylactically.

Bacterial Infections

Bacterial infections of the mouth are unusual and are usually caused by similar conditions that encourage the growth of *C. albicans*. Common pathogens include *E. coli* and *Salmonella, Proteus, Pseudomonas, Enterobacter,* and *Citrobacter* species.

Clinical Signs

Lesions are variable but can appear similar to those of candidiasis (e.g., mucoid exudate or abscess formation).

Diagnosis and Treatment

Perform a Gram stain and bacterial culture on any exudate found in the mouth.

- Large numbers of enteric bacteria present in clinically ill psittacines with accompanying oral lesions are significant.
- Administer systemic antibiotic therapy, based on susceptibility testing.

Prevention

- Treat underlying systemic disease.
- Provide a clean environment and offer fresh food, as described previously under "Oral Candidiasis."

Oral Papillomas

See the discussion of oral papillomas in Chapter 169 in this section.

Trichomoniasis

Trichomonas gallinae is a flagellated protozoan parasite. Trichomoniasis usually occurs in aviaries with many birds housed together and rarely is seen in individual pet birds. Infection may extend into the esophagus, crop, lungs, and oral cavity. The budgerigar is the most commonly affected pet bird. Outbreaks have been reported in neonatal Amazon parrots, conures, and cockatiels.

Clinical Signs

- White, sticky plaques may coalesce to form yellow, caseated masses on the choana, tongue, or pharyngeal mucosa.
- Common signs include anorexia and weight loss.
- Moisture around the beak and halitosis may occur.

Diagnosis

- Perform a saline wet mount of oral exudate for microscopic examination.
- Organisms are flagellated and pear shaped, and they move in a spiral motion. Thousands may be seen on one slide.
- In psittacine birds, organisms often are not present on wet mounts of oral exudates, especially in the early stages.
- High numbers of organisms are sometimes found on wet mount smears from lungs of recently deceased birds.

Treatment

Give metronidazole (Flagyl-Searle), 30 mg/kg q12h PO, for 10 days. Crush the tablets and mix with a palatable liquid.

▼ ***Key Point*** Treat birds with oral lesions that suggest trichomoniasis with metronidazole, even when this organism is not positively identified.

Prevention

In an aviary, quarantine and examine all new budgerigars for organisms in the pharynx and crop before introduction to the flock.

Trauma

Trauma to the mouth is rare, but when it occurs, lacerations or bite wounds to the tongue are most common. The next most common injury is laceration or crushing injury to the intermandibular space as a result of the bird being hooked or caught on items such as chains or toys.

▼ ***Key Point*** Hemorrhage in tongue lacerations can be profuse and life threatening. Immediate treatment is required.

Treatment

- Anesthesia may be required; use isoflurane via an endotracheal tube.
- Control hemorrhage via direct pressure or cauterization.
- Clean, debride, and suture injuries, as required.
- Administer systemic broad-spectrum antibiotics prophylactically.

DISORDERS OF THE ESOPHAGUS AND CROP

Normal Structure and Function

Esophagus

- The avian esophagus is thin walled and highly distensible. It courses down the right side of the neck, the opposite of the placement in mammals.
- The esophagus is lined by incompletely keratinized, stratified squamous epithelium, with numerous subepithelial mucous glands.

Crop

- The crop is a dilatation of the esophagus found in many (but not all) species of birds. It is prominent in psittacines birds.
- The crop is located just cranial to the thoracic inlet. It is firmly attached to the underlying skin and thus can easily be seen and palpated externally.
- The crop in parrots is oriented transversely across the neck. Food enters from the right side and exits caudally on the midline.
- When the proventriculus and ventriculus are full, food may be stored in the crop. Stored food undergoes softening and swelling, but no chemical digestion takes place.
- Food eventually is moved caudally from the crop by powerful smooth muscle contractions of the crop and the esophageal wall.
- The crop (and proventriculus) is much larger in preweaned psittacine birds than in adults to accommodate large volumes of food required for rapid growth.
- As a bird is weaned, it is not uncommon for it to lose 10% to 15% of its body weight because of shrinkage of these organs and change in diet.

Crop Stasis

Many environmental, dietary, and systemic conditions can lead to crop stasis.

- Management factors include dehydration, low ambient temperature, change in the formula or in the consistency or amounts being fed, and unsanitary feeding methods.
- Medical conditions that cause crop stasis include bacterial or fungal ingluvitis (inflammation of the crop), heavy metal toxicity, foreign bodies, tumors (including papillomas), obstruction within the alimentary tract distal to the crop, and ileus due to generalized systemic disease (e.g., polyomavirus infection or proventricular dilatation disease).
- *Sour crop* refers to crop stasis in baby birds with bacterial or yeast overgrowth.

Clinical Signs

Hand-Fed Chicks

- The crop may be enlarged and pendulous and may fail to empty or may do so extremely slowly.
- Feeding response varies from normal to absent.
- Vomiting or regurgitation may occur.
- Initially, birds are alert and active, but depression and listlessness occur as the disease progresses.
- There is failure to gain weight, or there is loss of body weight.
- The number of droppings decreases.
- There may be discoloration or necrosis of the skin overlying the crop.

Adult Birds

- The enlarged crop fails to empty or does so slowly.
- Varying degrees of weight loss, weakness, depression, and anorexia are seen.
- Vomiting may occur; expelled food may collect on feathers of the head and neck.

Diagnosis

- Question the owner regarding husbandry practices (housing, ambient temperature, humidity, and diet) and possible exposure to infectious diseases.
- Palpate the crop to determine the amount and consistency of its contents, degree of thickness, muscle tone, fibrous or necrotic areas, and abscesses.
- Examine the skin over the crop for discoloration and necrosis.

- Transillumination of the crop may reveal its contents.
- The lower esophagus extends through the thoracic inlet and cannot be examined externally.
- Examine the mouth for oral lesions, which, if present, often extend into the esophagus and crop. This is often the case with bacterial and yeast infections, trichomoniasis, and occasionally papillomas.
- Endoscopic examination of the interior of the crop and esophagus or proventriculus requires general anesthesia. Examination may be useful to identify inflammation, tumors, and foreign bodies that can cause crop stasis.
- Perform a Gram stain and culture of exudate or food material from the esophageal or crop wall. Large numbers of gram-negative bacteria and budding yeasts are abnormal, but they may represent overgrowth within putrefying food in the stagnant crop only and may not be the primary cause of crop stasis. Be sure to look for the underlying cause of crop stasis and not overinterpret Gram stains.
- Perform a complete blood count (CBC) and serum chemistry profile to rule out systemic disease.
- Obtain blood samples for determination of blood lead concentrations to rule out heavy metal toxicity.
- Radiographs (plain films or contrast studies) may reveal obstruction caused by foreign bodies, tumors, or the presence of heavy metals.
- Histopathologic examination of tissues from chicks at necropsy can be important in the management and treatment of outbreaks of disease in aviaries.

Treatment

The primary goal of therapy is to alleviate crop stasis, which, if not corrected, leads to dehydration, starvation, secondary infections, and eventually death. Treatment and management in neonates can be extremely labor intensive and time consuming. If possible, evaluate and stabilize these birds in the hospital, and then instruct the client in home treatment. Most clinics simply do not have the personnel, housing, or time to provide 24-hour nursing care.

▼ ***Key Point*** Regardless of the cause of crop stasis, do not feed affected birds solid food (adults) or formula (chicks) until crop motility returns.

Measures to Restore Crop Motility

- Add warm water or lactated Ringer's solution to the crop to break down impacted food. This may stimulate emptying of the crop.
- If crop motility does not return, manually empty the crop contents. Insert a large catheter (metal or rubber) into the crop via the mouth and aspirate the contents (see Chapter 168). Be careful not to aspirate the mucosal lining of the crop during this procedure.
- Save samples of aspirated material for cytologic examination and bacterial or fungal culture.
- Rinse the crop with several flushes of normal saline or warm water after emptying contents.
- To treat dehydration, administer subcutaneous, intravenous, or intraosseous fluids daily until crop motility returns.
- Administer oral fluids such as lactated Ringer's solution and Pedialyte (Ross Products) in place of solid food or formula until motility begins to return. Frequent dosing in small amounts is recommended so as not to stretch the crop.
  - If the crop fails to empty adequately during this time, remove the solution contents once daily to prevent putrefaction.
  - If gastrointestinal (GI) obstruction has been ruled out, administer metoclopramide (Reglan, Robins) at 0.5 mg/kg q12h, IM or IV, or cisapride (available through veterinary compounding pharmacies) at 0.5 mg/kg q8h, PO.
- As motility begins to return, add formula to the oral fluids. Begin with a very diluted solution and gradually increase the concentration until a normal consistency is achieved.
- Administer parenteral broad-spectrum antibiotic and antifungal agents as indicated by Gram staining or to prevent secondary infections. Oral preparations may be administered once crop motility returns.

Environmental Factors

- House well-hydrated birds in an incubator or brooder (95–98°F for hatchlings, 94–97°F for neonates up to 7 days old, 90–94°F for neonates up to 14 days old, and 85–90°F for chicks more than 14 days old).
- Maintain relative humidity above 50%.
- Feed birds a consistent formula type or brand. Formula temperature should be approximately 98°F to 100°F.

▼ ***Key Point*** Identification and treatment of any underlying disorders are essential in the treatment of crop stasis.

Prolonged Crop Stasis

- Overfeeding or prolonged stasis in neonates can result in a pendulous, atonic crop.
- Use a crop supporter to provide support for the crop and to facilitate emptying (see Chapter 168).

Prevention

- To prevent crop stasis in hand-fed neonates, provide a clean, warm brooder; feed a good hand-feeding formula; and practice sanitary handling techniques:
  - Clean the brooder daily; follow ambient temperature guides as previously described.
  - Use a commercial hand-feeding formula or a proven home recipe. Do not switch arbitrarily from one formula to another.
  - Feed birds on a regular schedule.

  - Feed amounts appropriate for the size of the bird; do not overfill the crop.
  - Maintain consistent formula viscosity and temperature.
  - Make fresh formula for each feeding.
  - Disinfect utensils and bowls used for food preparation and delivery after each feeding.
  - Use separate feeding syringes for each bird.
  - Instruct caretakers to wash their hands before handling each bird.
- If there is a history of candidiasis in the aviary or for an individual bird, administer nystatin prophylactically until weaning.
- Correct other predisposing factors for bacterial and fungal infections, as previously described.

Foreign Bodies

The powerful beaks and persistent chewing habits of psittacine birds can lead to ingestion of foreign bodies, which may lodge in the crop.

Clinical Signs

- Crop stasis or delayed crop emptying may be seen.
- Regurgitation or repeated attempts at regurgitation may occur.

Diagnosis

- Palpate the crop. Many rigid objects large enough to lodge in the crop are palpable externally.
- Transillumination of the crop may reveal its contents.
- A small, rigid endoscope may be used to examine the crop and remove foreign bodies.
- Radiograph the cervical area. In some cases, contrast (barium or air) radiography may be necessary to visualize the object.

Treatment

- Retrieve smaller foreign bodies by passing a forceps into the crop through the mouth or by percutaneously manipulating the object into the esophagus for removal through the mouth.
- General anesthesia with isoflurane usually is required in all birds except neonates.
- Surgical removal via *ingluviotomy* (incision into the crop) may be required to remove the object.
- Close the crop wall with 4-0 to 6-0 polydioxanone (PDS) sutures in an inverting, interrupted suture pattern.
- Close the skin using a simple interrupted suture pattern.

Goiter

Etiology

Iodine-deficient thyroid dysplasia may develop in budgerigars fed a seed diet without vitamin or mineral supplementation.

Clinical Signs

All clinical signs are attributed to the space-occupying effects of the enlarged glands; thyroid hormone concentrations are usually normal. Signs include the following:

- Regurgitation
- Crop stasis or delayed crop emptying
- Clicking noise with respiration

Diagnosis

- Base the diagnosis on the clinical signs and history.
- Enlarged thyroid glands are usually not palpable because they are contained within the thoracic cavity.

Treatment

- Inject sodium iodide (Butler), 0.02 ml/30 g, IM, if birds are severely dyspneic.
- Maintain budgerigars on oral Lugol's iodine (Strong Iodine solution, Humco) in the drinking water. Mix 2 ml of Lugol's with 20 ml of water, then add 1 drop/oz of water daily for 1 week and once weekly thereafter.

Prevention

For budgerigars, switch to a commercial pelleted diet or supplement the existing diet with a commercial avian vitamin and mineral preparation.

Thermal Burns

Crop burns in neonates are caused by feeding hand-rearing formula at a temperature greater than 105°F. History usually reveals that the formula was heated in a microwave oven and not sufficiently stirred or tested for temperature.

Clinical Signs

- Birds usually remain bright and alert and maintain a normal feeding response despite full-thickness necrosis of portions of the crop and overlying skin. Therefore, these birds usually are not presented for evaluation until the caretaker notices formula leaking from the crop fistula onto the chest feathers.
- Necrosis and fistula formation does not occur until several days after the burn occurs.

Diagnosis

Base the diagnosis on the clinical signs and history.

Treatment

▼ ***Key Point*** Do not attempt surgical debridement or removal of scabs until wound contracture is complete and the crop begins to leak. Premature debridement may cause excessive loss of viable tissue.

- After anesthetizing the bird with isoflurane, debride all necrotic edges of the skin and crop.
- Close the crop wall and skin as described for ingluviotomy under "Foreign Bodies."
- Administer prophylactic antibiotic therapy using enrofloxacin, trimethoprim-sulfa, or cefotaxime.

DISORDERS OF THE PROVENTRICULUS AND VENTRICULUS

Normal Structure and Function

Proventriculus

- The proventriculus, or glandular stomach, is continuous with the esophagus at the level of the base of the heart and contains digestive (pepsinogen-secreting) and mucous glands.
- A strong muscular sphincter separates the proventriculus from the ventriculus.

Ventriculus

- The ventriculus, or muscular stomach (also known as the "gizzard"), contains two opposing sets of muscles used for grinding food.
- The epithelium secretes keratinous fluid that hardens to provide a surface against which food may be ground. Grit within the proventriculus aids this grinding action; however, in most psittacine birds, grit is not essential for digestion of food.
- Contractions of the proventriculus and ventriculus are coordinated to provide adequate mixing and grinding of gastric contents and digestive enzymes.

Foreign Body Impaction

Ingested objects small enough to bypass the thoracic inlet may lodge in the proventriculus or ventriculus. The pyloric sphincter, a valve-like structure separating the ventriculus from the duodenum, helps restrict larger solid objects from leaving the ventriculus. Small objects tend to collect in the ventriculus owing to its blind, pouch-like relationship to the remainder of the digestive tract.

Etiology

- Unweaned chicks typically are presented for ingestion of nesting substrates such as wood chips and shavings (especially young macaws) or for accidental swallowing of feeding instruments (e.g., tubes, spoons, or gavage needles).
- In weaning-age chicks, there may be impaction of seed hulls and other food objects that have been swallowed whole.
- Adults commonly present with a history of ingesting toys, cage parts, wood from perches, or carpet fibers. Shredded wood from perches or nest boxes and commercially available braided rope toys are the most common GI foreign bodies.
- Overconsumption of grit can cause impaction. If grit is provided, a small amount (10–20 pieces) given every few months is adequate.

▼ ***Key Point*** Do not offer gravel or grit free choice to pet birds. Ill or otherwise stressed birds may overeat grit, causing impaction of the ventriculus. Do not offer whole seeds or other hard foods to weaning birds.

Clinical Signs

- Early signs include crop stasis, decreased fecal output, and regurgitation.
- If the impaction is partial, chronic regurgitation, weight loss in adults, and decreased weight gain in neonates may be seen.
- Anorexia, lethargy, depression, seizures, and death occur with complete obstruction, erosion of mucosa, perforation, and septicemia.

Diagnosis

- Rule out crop impaction and foreign bodies (described previously).
- Obtain abdominal radiographs. Some objects may be visible on plain radiographs, but contrast radiography often is necessary. Use a mixture of 72% barium sulfate suspension diluted 1:1 with water at 25 ml/kg into the crop via a gavage tube. The entire GI tract should be delineated by the barium within 2.5 hours.
- It may be possible to identify and retrieve the object via endoscopy. An incision into the crop may be needed to access the proventriculus. Insert the endoscope through the crop via an ingluviotomy at the level of the thoracic inlet and direct it through the esophagus into the proventriculus.
- In larger birds, a flexible endoscope can be inserted through the oral cavity.

Treatment

- Small, non-toxic objects lodged in but not obstructing the ventriculus may be ground down and enzymatically digested by natural processes. Limited amounts of fine gravel grit can expedite the process.
- If the object is visible via endoscopy, it usually can be removed using blunt-jawed grasping forceps.
- Gastric lavage has been used to flush out objects lodged in the proventriculus.
- Proventriculotomy may be necessary to remove larger foreign bodies.

Prevention

- In neonates, use only large, non-ingestible or, alternatively, easily digestible nesting substrates. Also, use

only long, flexible feeding tubes to allow easy retrieval if syringe disconnection should occur.
- Monitor parent-reared chicks for signs of nest box substrate ingestion.
- When chicks begin feeding on their own, do not feed them seeds. Offer only small particles of fresh, soft foods.
- Restrict adult birds from access to toys that are easily broken apart, rope toys, and soft woods if the bird has been observed swallowing these objects or has a history of GI foreign bodies.
- Avoid feeding chitinous insects to pet birds.

Proventricular Dilatation Syndrome

See Chapter 169 in this section for a discussion of proventricular dilatation syndrome.

Papillomatosis

See Chapter 169 in this section for a description of this disorder.

Candidiasis

Etiology

C. albicans is a secondary invader, primarily of the mouth, esophagus, and crop, and has been discussed previously as a cause of oral lesions and crop stasis. Overgrowth of *Candida* may also occur in the lower digestive tract, particularly in the proventriculus. Lesions usually are not found in the lower digestive tract alone but are an extension of esophageal or crop candidiasis.

Clinical Signs

Common signs include delayed crop emptying, vomiting, diarrhea, and weight loss.

Diagnosis

- Endoscopic examination of the proventriculus (described previously) may reveal rough, thickened, white mucosa characteristic of candidiasis. Similar gross lesions usually are visible in the crop.
- Perform a Gram stain and fungal culture on samples obtained from the crop and fresh feces or from the proventriculus during endoscopic examination.
  - Although *C. albicans* may be part of the normal intestinal flora, large numbers of budding yeasts on Gram stains of these samples are abnormal and warrant treatment.
- Differentiate *Candida* organisms from brewer's yeast, which is commonly seen on Gram-stained fecal samples from birds fed bread products or some pellets. Brewer's yeast is non-budding, and fungal culture results will yield no growth.

Treatment

See "Treatment" under "Oral Candidiasis."

Bacterial Proventriculitis

Common pathogens of bacterial proventriculitis include *E. coli* and *Klebsiella, Enterobacter,* and *Salmonella* species.

Clinical Signs

Signs include vomiting, regurgitation, delayed crop emptying, and weight loss.

Diagnosis

- Perform the diagnostic procedures outlined under "Oral Candidiasis."
- The CBC may demonstrate leukocytosis with heterophilia.

For further discussion of bacterial infections, see Chapter 169 in this section.

DISORDERS OF THE INTESTINES

Infectious Diseases

Bacterial enteritis, *Mycobacterium avium,* and viral enteritis are common causes of diarrhea, vomiting, and weight loss in pet birds (see Chapter 169).

Giardiasis

Etiology

The trophozoite and cyst forms of the flagellated protozoan parasite *Giardia* are found in the crop and duodenum.

- The incidence is estimated to be as high as 20% to 50% in cockatiels, budgerigars, and lovebirds in some regions of North America.
- Giardiasis occurs less frequently in conures, Amazon parrots, cockatoos, and macaws.

Clinical Signs

- Malabsorptive diarrhea, characterized by voluminous, mucus-covered feces, or the passing of undigested food may be seen.
- Weight loss may be gradual or sudden, with losses of 20% to 30% of body weight.
- In cockatiels, pruritus—especially along the wing webs, axillary region, and back—has been anecdotally associated with intestinal giardiasis. This often is manifested by feather picking and occasionally is manifested by self-mutilation.

- Although the exact relationship is unknown, a hypersensitivity reaction is believed to be responsible.
- Paresis or lameness has been reported in birds with heavy *Giardia* infections. Malabsorption of vitamin E and selenium is the suspected cause.

Diagnosis

- Perform a direct saline smear assay on fresh feces immediately after collection to identify *Giardia* trophozoites and cysts. Staining with carbolfuchsin or iodine may aid visualization of organisms.
- Zinc sulfate centrifugation may reveal trophozoites in fecal samples.

▼ ***Key Point*** Because *Giardia* organisms are shed intermittently, false-negative test results are common.

- If a direct fecal examination cannot be performed immediately, submit the feces to a laboratory specializing in avian clinical pathology for trichrome staining.
- Fecal enzyme-linked immunosorbent assay and florescent antibody testing can also be performed by laboratories specializing in avian clinical pathology. The sensitivity and specificity of these tests have not been completely evaluated.
- The CBC may demonstrate a peripheral eosinophilia.
- Hypoproteinemia may be noted on the serum biochemical profile as a result of intestinal malabsorption.

Treatment

- Give metronidazole (Flagyl, Searle), 30 mg/kg q12h, PO, for 7 to 10 days. Crush the tablets and mix with a palatable liquid.
- If lameness or paresis is present, give vitamin E or selenium (Seletoc, Schering-Plough), 0.1 mg of selenium per kilogram, IM, every 14 days.

Helminthiasis

Intestinal helminths are most frequently a problem in newly imported birds or birds in captive breeding colonies.

Etiology

- Ascarids commonly are found in cockatiels, cockatoos, budgerigars, and other Australian parakeets. Ascaridiasis can be a persistent problem in captive breeding colonies, particularly if the birds have access to a wood or concrete floor. The life cycle is direct, as in mammals.
- *Capillaria* species (intestinal threadworm) can be found in all species of pet birds but is most common in macaws, conures, and Australian birds. The worms may be found in the mouth, esophagus, and small intestines. The life cycle is direct.
- Cestodes are found primarily in Old World psittacines (e.g., cockatoos and African grey parrots). They may be responsible for hemorrhagic enteritis and chronic wasting in African grey parrots. They have an indirect life cycle, with arthropod or annelid worms as intermediate hosts.

Clinical Signs

Clinical signs are generally nonspecific, with weight loss, diarrhea, and general unthriftiness predominating.

Diagnosis

Avian helminth eggs are detected by routine salt or sugar fecal flotation, as for dogs and cats.

Treatment

- Ivermectin (Ivomec 1% solution, Merck) is effective against intestinal nematodes when given at a dose of 200 µg/kg, IM, or diluted 1:9 with water in propylene glycol and given at 0.2 mg/kg, PO, every 2 weeks.
- Levamisole (Tramisol, American Cyanamid) is effective against most intestinal nematodes when given at a dosage of 10 to 20 mg/kg, SQ, every 2 weeks or as a solution of 10 ml/gallon drinking water if treating an entire flock (use as the only source of drinking water for 1 to 3 days).
- For cestodes, give praziquantel (Droncit, Haver/Diamond) at a dosage of 10 to 20 mg/kg, PO, and repeat in 10 to 14 days.

DISORDERS OF THE LIVER

Infectious Diseases

Etiology

Infectious disorders such as chlamydiosis, viral disease, bacterial hepatitis, and occasionally *Mycobacterium avium* are common causes of liver diseases in pet birds. This is especially true in larger psittacines such as parrots, macaws, and cockatoos, although cockatiels and budgerigars also may be affected.

Diagnosis

- Indicators of liver disease include green-yellow urates (biliverdinuria), hepatomegaly (palpable or radiographically evident), and serum biochemical profile indicators such as increased levels of serum bile acids and aspartate aminotransferase (AST). AST values may be elevated with either liver or muscle damage. Concurrent elevation in serum AST and creatine kinase (CK) values indicates muscle damage. Decreased serum albumin levels often are seen with liver disease.

- Liver biopsy often is necessary for definitive diagnosis with identification of a specific etiologic agent.
- See Chapter 169 for specific diagnostic tests, treatment, and prevention of infectious disease.

Fatty Liver Syndrome

Fatty liver syndrome (FLS), or hepatic lipidosis, commonly is seen in budgerigars, cockatiels, Amazon parrots, or any bird on a high-fat (especially all-seed) diet. Accumulation of fat in the liver is usually gradual, and with severity it will cause the destruction of normal liver cells and may progress to fibrosis.

Etiology

- The etiology of FLS is unknown; however, malnutrition appears to play a major role.
- Most birds with FLS are obese and on a high-fat diet consisting primarily of seeds.
- Unlike FLS in cats, anorexia does not appear to play a role in the development of this disorder.

Clinical Signs

- Most affect birds are obese, although with chronicity significant weight loss may occur.
- The most common clinical signs are lethargy, anorexia, depression, biliverdinuria, and poor feathering. Diarrhea and/or vomiting may also be seen.
- Budgerigars frequently have overgrown, soft, friable beaks, with focal areas of hemorrhage.
- Sudden death has been reported in budgerigars, cockatiels, and Amazon parrots, with hepatic lipidosis as the only identifiable lesion on necropsy.

Diagnosis

- Obtain radiographs of the abdomen to detect hepatomegaly.
- Increased AST, bile acid, and cholesterol concentrations are usually present on the serum biochemistry profile.
- Liver biopsy is necessary to confirm the diagnosis. Grossly, the liver is enlarged, yellowish, and friable.

Treatment

- Administer intravenous or interosseous fluids to critically ill birds. If anorexic, forced alimentation with low-fat gruel is indicated (see Chapter 168).
- Place the bird on a strict low-fat diet containing at least 12% protein. Eliminate seeds from the diet.
- Ideally, a commercial avian pellet formula should make up at least 40% of the diet, with the remainder consisting of vegetables, fruits, and grains or legumes.

Hepatic Fibrosis

Etiology

- Hepatic fibrosis is a common sequela to chronic liver disease.
- The primary insult can be infectious (e.g., bacterial, viral, or chlamydial) or non-infectious (e.g., FLS). Fibrosis can persist after elimination of the primary insult.

Diagnosis

- Radiographs usually reveal a normal-sized or small liver shadow.
- Increase in serum AST concentration is variable. With severe disease, AST may be normal. Bile acid concentrations are increased.
- Liver biopsy is required for definitive diagnosis of hepatic fibrosis.
- Ascites is seen in severe (end stage) disease. Clinical signs of ascites include abdominal distention and dyspnea due to compression of air sacs.

Treatment

- Supportive care in the form of fluid therapy, nursing care, and appropriate diet are essential in the treatment of hepatic disease.
- If significant ascites is present, perform abdominocentesis.
- Colchicine has been reported to be beneficial in the treatment of chronic liver disease by interfering with collagen precursor synthesis. Doses have been extrapolated from those used in cats.
- Ursodeoxycholic acid has been used anecdotally for its immune-modulating effects, induction of choleresis, and effect on the circulating bile pool. Doses have been extrapolated from those used in cats.
- Antibiotic therapy may be indicated if bacterial hepatitis is suspected to limit inflammation and subsequent fibrosis. Common choices include doxycycline (Vibramycin, Pfizer), 25 to 50 mg/kg PO q24h, or a combination of enrofloxacin (Baytril, Bayer), 10 to 20 mg/kg PO q24h, and metronidazole (Flagyl, Searle), 50 mg/kg PO q12h.
- If hepatic encephalopathy is suspected, administer lactulose at a dosage of 0.3 to 1.0 ml/kg PO q12h; decrease the dose if diarrhea develops. Metronidazole may be added to alter colonic flora.

Aflatoxicosis

Etiology

- Avian aflatoxicosis is caused by the ingestion of toxic metabolites from molds such as *Aspergillus flavus* and *Aspergillus parasiticus*. Foods in which these molds may be found include peanuts and peanut products, cereals, breads, cheeses, beans, and meat.
- Aflatoxins frequently are hepatoxic and may be carcinogenic.

Clinical Signs

Signs generally are nonspecific and include anorexia, weight loss, and depression.

Diagnosis

- Base the diagnosis on history, clinical signs, and fungus isolation from feed or the GI tract.
- Gross and histopathologic lesions from postmortem or liver biopsy confirm the diagnosis.
  - Chronic lesions include biliary hyperplasia, cirrhosis, generalized fatty degeneration, and portal fibrosis.
  - Acute lesions include massive hepatocyte necrosis and hepatic hemorrhage.

Treatment

- No specific therapy is available. Supportive care, antibiotic, antifibrotic and Ursodeoxycholic acid may be helpful (see treatment of hepatic fibrosis above).
- Oral selenium may act as a competitive inhibitor of aflatoxins in the liver.

Hemochromatosis

Etiology

Hemochromatosis, defined as excessive deposition of iron in hepatic parenchymal cells with resultant cellular damage, is common in mynahs and toucans. Iron normally is absorbed from the intestines at a rate dependent on the body's needs and then recycled with minimal excretion from the body.

- In hemochromatosis, there is excessive uncontrolled absorption and storage of iron.
- The mechanism of this defect in iron metabolism is not understood, but affected birds absorb and store even small amounts of iron in the diet.

Clinical Signs

Signs include weight loss, dyspnea, and abdominal swelling from severe hepatomegaly and ascites.

Diagnosis

Diagnosis is based on clinical signs and confirmation on hepatic biopsy. Radiographs demonstrate hepatomegaly, sometimes with splenomegaly and cardiomegaly. Elevation in serum AST and bile acid concentrations is inconsistent.

Treatment

- For symptomatic control of ascites, periodically remove abdominal fluid and administer diuretics.
- Successful long-term treatment has been reported with weekly phlebotomies.
- Iron chelation therapy with deferoxamine mesylate, 100 mg/kg SC q24h, may help reduce serum and hepatic iron concentration.
- Change the diet to a low-iron commercial ration (20–40 ppm).
- Chronic disease may lead to fibrosis or cirrhosis. Treat as described under fibrosis above.

Prevention

- Many commercial mynah pellets contain excessively high levels of iron. Place mynahs and toucans on low-iron (20 to 40 ppm) commercial pelleted food.

Neoplasia

Primary and metastatic neoplasms have been reported in all psittacine birds; they are particularly prevalent in budgerigars and Amazon parrots.

- An increased incidence of hepatic neoplasia has been noted in birds with papillomas.
- Primary tumors seen include bile duct carcinoma, hepatocellular carcinoma, hepatoma, fibrosarcoma, and hemangiosarcoma.
- Hepatomegaly usually is palpable or visible on radiographs.
- Diagnosis is confirmed by biopsy.
- Treatment is ineffective.

DISORDERS OF THE PANCREAS

Etiology

- As in liver disease, many infectious agents (e.g., bacteria, *Chlamydia,* and viruses) may target the pancreas alone (e.g., many viral infections) or concurrently with other organ systems (see Chapter 169).
- Non-infectious causes of pancreatitis include nutritional factors; pancreatitis may be seen secondary to egg yolk peritonitis (see Chapter 173).
- In some cases, pancreatitis diagnosed at necropsy showed an intense inflammatory process without infectious etiology, especially in birds on high-fat (seed) diets.
- There is a possible correlation between hypercalcemia occurring in hens in breeding condition (serum calcium levels usually are 20 times normal before ovulation) and onset of pancreatitis (hypercalcemia is known to be a cause of pancreatitis in humans).

Clinical Signs

- Signs include anorexia, polyuria or polydipsia, diarrhea, and listlessness.

Diagnosis

- Serum amylase levels are sometimes elevated, and lipemia, hypercalcemia, and hyperglycemia may be present.
- Radiography may reveal decreased abdominal detail.
- Definitive diagnosis is based on pancreatic biopsy, obtained via laparoscopy.

Treatment

- Treatment is similar to that for dogs and cats and includes fluid therapy (nothing per os), antibiotic therapy, and maintenance on a low-fat diet (see Chapter 73).

I would like to acknowledge Scott McDonald for his contribution of this chapter to the first edition.

Chapter

173 Avian Reproductive Tract Disorders

Heather L. Bowles

Avian reproductive disorders are a result of complex combinations of hormonal, physiologic, and behavioral actions reacting to photoperiods, food availability, and availability of nest sites. Environmental influences unique to captivity may induce reproductive and hormonal activity in several ways. For instance, artificial lighting may interfere with the normal photoperiod and annual light cycles, resulting in inappropriate cycling. Food is typically available ad libitum in captivity, and it often is high-fat, calorically dense seed or foods high in simple carbohydrates, such as corn and fruit. These foods may actually stimulate reproduction. A lack of an appropriate mate may also cause reproductive problems. Most pet birds are not intended for breeding and do not have mates. As a result, some of these birds select an abnormal mate such as their human cohabitants or cage furniture. Along with all of these common environmental influences, there may be genetic factors that contribute to a lack of normal reproductive hormonal balance.

Reproductively driven birds may display instinctual territorial and mate-related behaviors. These behaviors may include but are not limited to aggression, biting, and excessive vocalization. These "undesirable" behaviors may jeopardize their value as pets, diminishing the pet-human relationship, and even result in these birds losing their homes.

Reproduction often is not desired in pet birds. Egg production and hormonal cycling may lead to diseases of the reproductive system or systemic, endocrine, and metabolic disorders. Therefore, avian practitioners have sought medical and surgical methods to limit reproductive drive and hormone production.

FEMALE REPRODUCTIVE DISORDERS

See Figure 173-1 for reproductive anatomy of the female bird.

Chronic or Excessive Egg Laying

Etiology

- Chronic egg laying in pet birds occurs when a hen lays repeated clutches or a larger-than-normal number of eggs per clutch without regard to the presence of a mate or accurate breeding season. This process often physically exhausts the reproductive tract and is a serious metabolic drain, particularly on calcium stores. These factors may predispose the hen to egg binding, yolk peritonitis, and osteoporosis.
- Commonly affected species include cockatiels, finches, and lovebirds; however, any species may be affected.

Diagnosis

Diagnosis of chronic egg laying is based on history and physical examination.

History

- Affected hens lay large numbers of eggs with or without a pause period between clutches.
- A thorough history of the environment will often reveal several reproductive stimuli and a "mate relationship" with the owner, another member of the household, or an inanimate object.

Physical Examination

- This examination may be unremarkable.
- Palpate the abdomen. An egg is sometimes palpable in the coelom. The abdomen often has a doughy consistency due to uterine distension.
- Look for other, secondary disease conditions such as a pathologic fracture secondary to osteoporosis.

Laboratory Evaluation

- Serum chemistries may reveal hypercalcemia, hypercholesterolemia, and hyperglobulinemia supportive of an ovulating hen.
- In some cases, hypocalcemia is seen if the hen's calcium stores are depleted, particularly if she is consuming a low-calcium seed diet.

Treatment

Medical therapy for chronic egg laying focuses on stopping egg production while removing predisposing stimuli and correcting any secondary diseases that may be present. Pharmacologic, behavioral, nutritional,

Table 173-1. MEDICAL THERAPY FOR REPRODUCTIVE DISORDERS

Drug	Dosage	Comments
Leuprolide acetate	150–800 µg/kg IM	Administered every 14 days; three doses are usually adequate
Human chorionic gonadotropin	250–500 IU/kg IM on days 1, 3, and 7 500–1000 IU/kg IM	Stable in refrigerator 60 days If a second egg is laid, repeat dose on day 3; if a third egg is laid, repeat dose on day 7
Levonorgestrel		Not recommended
Medroxyprogesterone		Not recommended
Arginine vasotocin	0.01–1.0 mg/kg IM	Stable in standard freezer
Prostaglandin E (Prepidil Gel)	0.1 ml/100 g 0.002–0.1 mg/kg	May freeze into aliquots and thaw Applied topically prior to administration; relaxes uterovaginal sphincter while inducing uterine contractions
Prostaglandin F-2-alpha (Lutalyse)	0.02–0.1 mg/kg IM	May not relax uterovaginal sphincter when inducing uterine contractions Topically applied to prolapsed uterine tissue to stop hemorrhage and shrink tissues

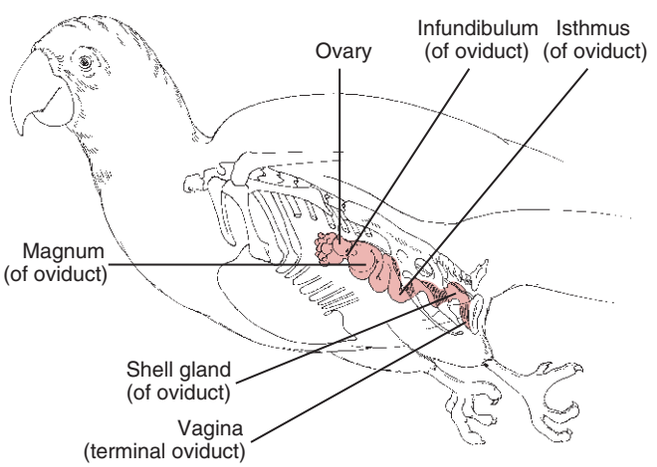

Figure 173-1. Reproductive anatomy of the female bird. The shell gland is equivalent to the uterus.

environmental, and surgical options are used alone or in combination, depending on the needs of the individual patient. Pharmacologic options have included medroxyprogesterone acetate, levonorgestrel, human chorionic gonadotropin, testosterone, and leuprolide acetate.

Pharmacologic Therapy (Table 173-1)

Leuprolide Acetate

- Leuprolide acetate (Lupron Depot, TAP Pharmaceuticals) is a long-acting gonadotropin-releasing hormone (GnRH) analogue. Principles for use of Lupron have been extrapolated from use in humans and other species and are often effective in controlling ovulation in birds.
- Administer 150 to 800 µg/kg IM every 14 days. Three doses are usually sufficient to inhibit further egg laying. Repeat treatment may be needed if signs return.

Human Chorionic Gonadotropin

- Human chorionic gonadotropin (hCG) (Pregnyl, Organon) has been used successful to inhibit egg laying with few side effects; however, it has not been consistently effective and patients may become refractory to treatment.
- Reported dosage regimens vary. Administration of 250 to 500 IU/kg IM on days 1, 3, and 7 has been effective to prevent laying. Alternatively, administer 500 to 1000 IU/kg IM after the first egg is laid. If another egg is laid, repeat the injection on day 3; if a third egg is laid, repeat the injection on day 7.

Other Hormonal Treatments

- Medroxyprogesterone acetate, although often effective, may cause serious side effects such as polyuria and polydipsia, obesity, lethargy, hepatic lipidosis, diabetes mellitus, hepatic cirrhosis, and death. Therefore, it is not recommended.
- Testosterone therapy interrupts the ovulatory cycle, but it has inconsistent results and is contraindicated in patients with liver disease.
- Norethindrone or mestranol, and tamoxifen, have been also used in a limited number of species with unreliable results.

Environmental Modification

- Decrease the photoperiod to 8 to 10 hours of daylight per day.
- Remove from the enclosure nest sites, toys, and other items toward which the bird has a sexual affinity. Pro-

hibit access to the nesting environment or materials such as a box, other dark cavities, or shredded papers.
- If the bird is showing nesting behavior and laying eggs in a designated site, leave the eggs in the "nest" for the duration of the normal incubation period for each species. Removal of the eggs may stimulate the hen to lay more eggs to replace those removed.
- Remove any perceived or actual mate from the cage or room. In some species, such as the cockatiel, both visual and auditory separation from an actual or perceived mate may be necessary.
- A "one-person bird," which has a single household person who exclusively or primarily handles and cares for it, should potentially be viewed as having a "mate relationship" with that person. This may serve as a trigger for reproductively driven behaviors. Advise this person to avoid stimulatory petting such as rubbing the pelvis, dorsum, and cloacal regions.
- Avoid feeding calorically dense diets, as mentioned previously.
- Encourage interactive behaviors that simulate a "flock relationship," such as the bird being handled by several people in the household.
- Periodically change or rotate the cage location and furniture (toys, perches, food dishes) to discourage territorial behavior and limit reproductive drive in response to a perceived "nest site."
- Correct any nutritional problems to improve the hen's overall dietary plane and reduce the severity of metabolic drain. Dietary alteration and reduction of caloric intake appears to anecdotally reduce or stop egg production. This nutritional effect often is achieved by converting the pet bird from a seed-based diet to a formulated one. The exact reason for this effect is unknown, but it is common practice in poultry to reduce feed intake to stop egg production and induce molting.

▼ ***Key Point*** Removal of environmental stimuli is essential to inhibiting ovulation in birds. Pharmacologic therapy will sometimes fail if even seemingly minor stimuli (such as access to cage papers to shred as nest material) are present.

Surgical Treatment

Salpingohysterectomy may be elected or necessary if medical therapy is not successful and if there is no intent to breed the affected hen. Laparoscopic salpingohysterectomy may be performed as a preemptive measure on juvenile birds to prevent egg production and its associated diseases.

Other Treatment

Any secondary disease conditions also should be appropriately treated.

Polyostotic Hyperostosis

Etiology

- Physiologic osteomyelosclerosis is the deposition of calcium stores in medullary bone for future use in egg production.
- Polyostotic hyperostosis differs from physiologic osteomyelosclerosis in that this condition occurs in non-laying hens and cocks as a result of pathologic conditions.
- The pathogenesis of polyostotic hyperostosis still is unclear. Many affected birds exhibit concurrent reproductive-associated activity or may suffer from reproductive-associated disease conditions.
- Hepatic disease may play a role in this condition due to the liver's role in the inactivation of estrogen. However, a recent study does not support this theory, stating that budgerigars affected by polyostotic hyperostosis had no evidence of estrogen secretion or other endocrine disease.

Diagnosis

- History and physical exam may reveal lethargy, depression, reduced appetite, and reproductively driven behaviors.
- Serum chemistries typically demonstrate hypercalcemia. The bird may be normocalcemic or hypocalcemic if on a calcium-deficient diet.
- Radiographs reveal significantly increased bone density of the long bones and occasionally the vertebrae.

Treatment

- Pharmacologic therapy and environmental manipulation to inhibit ovulation (listed above under treatment of excessive egg laying) may reduce reproductive hormone production and the subsequent effect on bone metabolism.
- Increased medullary bone density appears to resolve radiographically with resolution of reproductive drive or underlying reproductive disease.

Egg Binding and Dystocia

Definition

- Egg binding is defined as the failure of an egg to pass through the oviduct within a normal period of time.
- Most companion birds lay eggs at intervals of greater than 24 hours, and individuals may vary further.
- This variability may make it difficult to determine if there is a problem in the early stages of this disease.
- Dystocia involves the mechanical obstruction of oviposition.

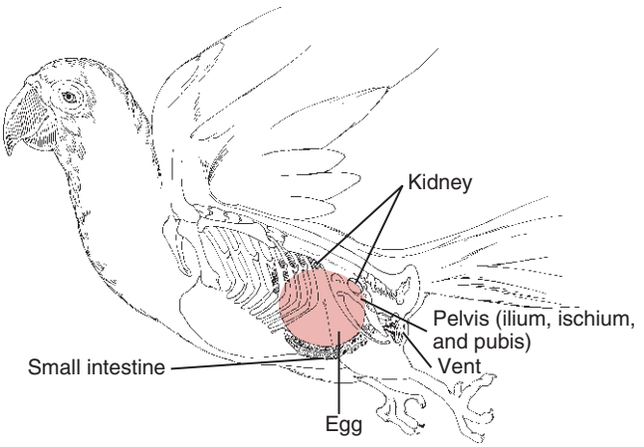

Figure 173-2. Anatomic landmarks associated with egg binding.

- The most common anatomic areas for this obstruction to occur are the distal uterus, vagina, and vaginal-cloacal junction. See Figure 173-2 for other anatomic landmarks associated with egg binding.

Etiology

- Causes of egg binding may include chronic egg laying, oviductal muscle dysfunction secondary to excessive egg laying, disorders of calcium metabolism, vitamin E and selenium deficiencies, malnutrition, obesity, inadequate exercise and muscle strength, malformed eggs, mechanical tears or damage to the oviduct, oviductal infections, systemic disease, genetic predisposition, and environmental stressors.
- Dystocia also may result when a developing egg in the distal oviduct obstructs the cloaca or causes oviductal tissue to prolapse.
- Oviductal torsion and oviductal or abdominal masses compressing the oviduct also may obstruct passage of an egg and result in dystocia. Breeding birds out of their natural season, egg-producing virginal hens, and hens with a persistent right oviduct may be predisposed to egg binding or dystocia.

Clinical Signs

- Cockatiels, canaries, and finches are most commonly affected and usually present with more severe clinical signs, possibly due to their small size.
- Clinical signs associated with egg binding and dystocia vary according to severity, size of the bird affected, and degree of secondary complications.
- Common signs include acute depression, abdominal straining, persistent tail wagging, a wide stance, pelvic limb paresis or paralysis, failure to perch, abdominal distension, urine or urate retention, dyspnea, and sudden death.

Secondary Disorders

- An egg lodged in the pelvic canal may compress the pelvic blood vessels, ureters, ischiatic nerves, and cloaca, causing pelvic limb paresis, paralysis, cyanosis, circulatory disorders, or urine or urate retention.
- Pressure necrosis of the oviductal wall may occur.
- Dystocia may cause metabolic disturbances by interfering with normal defecation and micturition, and cause ileus and renal disease, respectively.

Diagnosis

History

Diagnosis of egg binding or dystocia in a severely compromised patient may be made based on history and physical examination alone, and the patient may not be stable enough to survive other diagnostic procedures. Rapid diagnosis and therapy are crucial for a successful outcome.

▼ ***Key Point*** The severity of the patient's condition can be estimated by the degree of depression and the length of time clinical signs have been present.

Physical Examination

- Palpate the abdomen for the presence of an egg. Palpable eggs may be located within the oviduct or ectopically within the coelom. A combination of abdominal palpation, cloacal examination, radiographs, coelomic ultrasound, laparoscopy, and/or laparotomy may be required to determine the egg's position.
- Cranially located, soft-shelled, and non-shelled eggs may not be palpable.

Diagnostic Imaging

- Obtain abdominal radiographs. Shelled eggs are visible radiographically. Eggs are typically located in the distal oviduct, in the region of the uterus.
- Osteomyelosclerosis of the femurs, tibiotarsi, radii, ulnas, and/or spine may be visible. A soft tissue density suggestive of an enlarged ovary in the region of the ovary may be noted, supportive of a reproductively active hen.
- Coelomic ultrasound often will reveal an egg and may identify soft-shelled or non-shelled egg(s) that may not have been identifiable on radiographs. Again, there may be several eggs visible within the coelom. Follicles may be visible on the ovary, indicating the potential for further ovulation and egg formation.

Laboratory Evaluation

- A hematologic analysis and serum chemistries are useful to identify any predisposing and secondary diseases.

- A complete blood count may reveal a leukocytosis with a relative heterophilia if there is a concurrent inflammatory or infectious process.
- Serum chemistries may demonstrate elevated aminotransferase and creatinine phosphokinase due to skeletal muscle enzyme leakage from tissue damage or as a result of reduced food consumption and a hypermetabolic state.
- Hypercholesterolemia and hyperglobulinemia are supportive of an ovulating hen.
- Elevated total and ionized calcium and may be indicative of a cycling hen. Hypocalcemia may be observed if the hen has been consuming a calcium-poor diet or has been laying excessive numbers of eggs, resulting in depletion of her calcium stores.

Treatment

Therapy varies with history, severity of clinical signs, and diagnostic test results.

Supportive Care

- Provide supportive care, including a warm and humid environment, parenteral calcium, fluid therapy, and nutritional support.
- Administer broad-spectrum antibiotics if an infectious etiology is suspected or if the integrity of the oviduct may be compromised.
- Administer analgesics if the patient appears to be in pain or if clinical knowledge of the patient's condition suggests that pain may be a part of the pathologic state.

▼ ***Key Point*** In birds that are not severely compromised, supportive care alone often is enough to allow oviposition, although the hen should be monitored closely for deterioration of her condition, which may require further intervention.

Pharmacologic Therapy (See Table 173-1)

- Prostaglandin and hormonal therapy may be used to induce oviductal contractions. This may result in expulsion of the egg if the contractility of the oviduct is sufficient to expel the egg, the uterus is intact, the egg is within the oviduct, and there is no obstruction such as a neoplastic mass, granuloma, or egg adhered to the oviduct.
- Prostaglandin and hormonal therapy requires exogenous calcium to be effective. Because many of these patients are severely hypocalcemic due to either malnutrition or chronic egg laying, supplemental calcium may be required prior to administration of these medications.

Prostaglandin E-2

- Apply prostaglandin E-2 (PGE_2) (dinoprostone) gel (Prepidil Gel, Upjohn) topically, per cloaca, to the uterovaginal sphincter, at a dose of 0.1 ml per 100-g bird.
- PGE_2 causes relaxation of the uterovaginal sphincter while inducing oviductal contractions. These contractions usually expel the egg within 15 minutes.
- After the egg is expelled, flush the cloaca with warm water or saline to remove remaining gel, prevent further discomfort from continued uterine contractions, and minimize systemic side effects.

▼ ***Key Point*** Contact with PGE_2 gel may cause altered menses and induce spontaneous abortion in women. Therefore, it is important to flush any excess from the cloaca after egg expulsion and precaution staff and clients regarding contact with any stool and/or urine produced.

Prostaglandin F-2-alpha and Other Hormonal Therapy

- Administration of prostaglandin F-2-alpha (PGF_{2a}), oxytocin, or arginine vasotocin (AVT) will also cause powerful uterine contractions.
- These treatments are administered parenterally, rather than topically, and are more likely to cause systemic side effects such as hypertension, bronchoconstriction, and general smooth-muscle stimulation.

▼ ***Key Point*** PGF_{2a}, oxytocin, and AVT do not cause relaxation of the uterovaginal sphincter while inducing powerful oviductal contractions. This may result in reverse peristalsis, severe pain, and/or rupture of the uterus. Therefore, prior to their use determine if the uterovaginal sphincter is open.

Manual Manipulation

- If supportive care and medical therapy fail to induce oviposition, then manual manipulation may be necessary.
- Massage the abdomen and vaginal opening, which may relax the vaginal sphincter and allow passage of the egg in mildly affected birds. It may be helpful to infuse lubricants into the cloaca to moisten the urodeum and vagina.
- Apply careful digital pressure to the cranial portion of the egg, directing pressure caudally to encourage movement through the distal oviduct and cloaca. Using a cloacal speculum, dilate the vaginal opening of the oviduct by inserting a blunt probe (e.g., a lubricated cotton-tipped swab), gently advancing in a twirling motion.
- Potential complications of manual manipulation may include retroperistalsis of the egg out of the oviduct into an ectopic position within the coelom, rupture of the egg, oviductal trauma, oviductal laceration, and displacement of the egg or fragments into an ectopic position.

Ovocentesis

- Ovocentesis may be performed to facilitate passage of an egg. Aspiration may be performed through the cloacal opening if the egg is distally located or transabdominally if the egg is more cranially positioned.
- Manipulate the egg so that the shell is visible through the cloaca and insert an 18-gauge needle with syringe attached into the egg. Aspirate the contents of the egg into the syringe, while manually collapsing the shell and expelling the pieces through the cloaca.
- If the egg cannot be seen through the cloaca due to a more cranial location, perform transabdominal ovocentesis. Manually position the egg directly against the abdominal wall so that other abdominal organs are displaced and not damaged during aspiration. Insert a needle with a syringe attached through the skin and abdominal wall into the egg. Aspirate the egg contents into the syringe while manually collapsing the egg. The eggshell remnants can then be expelled through the cloaca, either naturally or with clinical assistance.
- Confirm radiographically that these eggshell pieces have been completely expelled. If these pieces are not expelled within a reasonable amount of time, approximately 36 hours, it may be necessary to irrigate the oviduct through the cloaca or laparotomy approach.
- Use medical therapy to reduce reproductive activity (as described under excessive laying above) to temporarily prevent further egg production.
- Salpingohysterectomy may be indicated if egg remnants are retained and the hen is not required for breeding. Some clinicians advocate flushing the postoviposition uterus with saline, chlorhexidine, or iodine to remove any shell fragments and decrease the incidence of metritis. Oviductal rupture, resulting in an ectopic egg, shell fragments, or yolk coelomitis, is a possible complication of ovocentesis.

Surgical Treatment

- Prostaglandin treatment, manual delivery, and ovocentesis are contraindicated in cases of ectopic eggs, oviductal rupture, oviductal torsion, and mechanical obstruction.
- Surgical intervention is indicated in birds with oviductal rupture with or without an ectopic egg, oviductal necrosis, oviductal torsion, abdominal hernia, or conditions interfering with defecation and/or micturition.
- Surgical removal of an egg may be elected as an initial treatment or if medical treatment is not successful.
- If surgical intervention is necessary, perform bacterial culture and sensitivity and histopathologic analysis on oviductal tissue samples.
- Salpingohysterectomy may be considered to prevent further reproductive complications after medical therapy, and any predisposing and secondary diseases should be corrected.

Oviductal Prolapse

Etiology

- Oviductal prolapse may occur secondary to any condition that causes chronic, excessive abdominal straining, such as physiologic uterine hyperplasia, egg laying, or dystocia. An intracoelomic, space-occupying mass also may induce prolapse of the oviduct.
- Predisposing factors may include abnormal or soft-shelled eggs, malnutrition, obesity, salpingitis, and cloacitis.

Clinical Signs

Typically, the uterus protrudes through the cloaca, often with a partial prolapse of the vagina and cloaca.

Diagnosis

- Complete blood count, serum chemistries, radiographs, ultrasonography, and laparoscopy should be included in a complete diagnostic evaluation to identify predisposing or secondary disease conditions.
- Bacterial culture and sensitivity of the prolapsed tissue should be performed to aid appropriate antibiotic therapy.

Treatment

- Rapid treatment is necessary to prevent necrosis of prolapsed tissues.
- Remove any egg, egg remnants, or debris and irrigate all exposed tissues.
- Keep tissues well moistened to prevent desiccation.
- Topical anti-inflammatories, such as dimethyl sulfoxide (DMSO) at 1 ml/kg to the affected area once, may be of benefit.
- Repair any lacerations and gently replace all tissues.
- Temporary stay sutures placed in the vent opening may be indicated to aid in preventing recurrence. Recurrence is common, and repeated replacement often is required.
- Administer broad-spectrum antibiotics and antifungals while bacterial and fungal cultures are pending.
- Administer hormonal treatment to decrease reproductive activity (described under excessive laying above) to prevent further prolapse, prevent egg formation, decrease the size of oviductal tissue, and allow the reproductive tract to rest.
- Salpingohysterectomy may be considered to prevent recurrence. Predisposing factors should be corrected to prevent recurrence and secondary diseases should be addressed.

Uterine Torsion

- Uterine torsion usually is diagnosed in the later stages of the disease.

- Birds typically present with abdominal distension secondary to coelomitis.
- Early clinical signs may include depression and anorexia following recent oviposition.
- A complete blood count often demonstrates a leukocytosis with a relative heterophilia, and serum chemistries show an elevated aspartate transferase and creatinine kinase.
- Diagnosis usually is made at exploratory laparotomy or laparoscopy. Many times, severe vascular compromise and necrosis of the oviduct is found, which requires salpingohysterectomy.

Oviductal Impaction

Etiology

- Oviductal impaction may occur following salpingitis, metritis, or cystic hyperplasia of the oviduct or dystocia.
- Substances causing impaction include excess mucin, albumin, or inspissated egg material.

Clinical Signs

Clinical signs may be vague and can include cessation of egg production, broody behavior without egg production, weight loss, anorexia, depression, constipation, diarrhea, abdominal distension, and reluctance to walk or fly.

Diagnosis

- Usually there is a history of reproductive activity.
- A leukocytosis with or without a relative heterophilia may be noted.
- Serum chemistries may be supportive of an ovulating hen.
- Radiographs and coelomic ultrasound may demonstrate a soft tissue density in the region of the oviduct, displacement of other coelomic viscera, loss of coelomic visceral detail, or coelomic fluid if there is a concurrent coelomitis.
- Definitive diagnosis of oviductal impaction often is made during laparoscopy or celiotomy, revealing an abnormal-appearing, enlarged oviduct with or without coelomitis and adhesions.
- Bacterial culture and sensitivity should be performed on specimens from the affected oviduct, and histopathologic examination should be performed on biopsy samples.

Treatment

- Provide supportive care, including parenteral fluids, nutritional support, warmth, and broad-spectrum antibiotics, pending culture and sensitivity results.
- In most cases, it is necessary to clean and repair or surgically remove the oviduct. Surgery may be complicated if coelomic fluid and/or adhesions are present.
- To prevent recurrence, begin medical therapy to reduce reproductive hormone production and reproductive activity and reduce environmental stimuli altered as discussed with chronic egg laying above.

Salpingitis and Metritis

Etiology

- Salpingitis is inflammation of the oviduct either by an infectious or non-infectious etiology, the latter being far less common. It is usually associated with air sacculitis, liver disease, pneumonia, systemic infections, and ascending infections of the oviduct from the uterus or cloaca.
- Salpingitis is most common in adult hens but occasionally may occur in young birds.
- Commonly identified pathogens include *Escherichia coli, Salmonella, Mycoplasma, Pasteurella,* and *Streptococcus* species. Newcastle disease virus also has been associated with salpingitis. In ground-nesting species such as *Anseriformes* and emus, non–lactose-fermenting, gram-negative bacteria such as *Pseudomonas aeruginosa, Proteus mirabilis,* and *Proteus vulgaris* commonly are identified.
- Non-infectious causes of salpingitis include trauma and inflammation secondary to oviposition disorders, malnutrition, and foreign bodies.
- Metritis is a localized infection or inflammatory process within the uterine portion of the oviduct. Metritis may occur secondary to dystocia, egg binding, oviductal impaction, systemic bacterial infection, and ascending infection. Salpingitis and metritis may cause abnormal shell formation and impaired uterine contractions, and it may cause infections in chicks and embryos, including embryonic death.
- Fatalities are often associated with ovulation, egg binding or dystocia, oviductal rupture, coelomitis, and septicemia.

Clinical Signs

Clinical signs of salpingitis and metritis may be vague and difficult to detect initially, and they include decreased egg production, infertility, abnormally shaped eggs, and mild depression. More advanced cases may exhibit anorexia, lethargy, abdominal distension, oviductal rupture, coelomitis, and septicemia.

Diagnosis

- Hemogram often reveals leukocytosis with a relative heterophilia. Serum chemistries may or may not be supportive of an ovulating hen.
- Radiographs and ultrasonography may reveal an enlarged oviduct. Laparoscopy may or may not identify inflammation of the serosal surface of the oviduct. The oviduct may be thin walled, be decreased in length, or have vascular congestion. The lumen may contain fluid or fibrinous exudates.

- Definitive diagnosis of salpingitis and metritis is based on cytology, bacterial and fungal culture and sensitivity, and biopsy with histopathologic analysis of a specimen from the oviduct.

Treatment

- Correct any underlying or contributing causes.
- Administer antibiotic therapy for identified or suspected bacterial organisms, pending results of bacterial culture and sensitivity.
- Initiate pharmacologic treatment and husbandry-related intervention, as discussed with chronic egg laying, to prevent further hormonal stimulation with subsequent egg production, which may perpetuate or contribute to this disease.
- Monitor patients closely, including oviductal bacterial culture and sensitivity and fertility monitoring after treatment, as many cases are difficult to resolve completely. It is important to note that bacteria isolates from the cloaca are not equivalent to oviductal infectants, and cloacal bacterial cultures should be interpreted carefully.
- Severe, refractory cases may require laparotomy to remove necrotic tissue and flushing of the oviduct with fluids and antibiotics.
- Patients suffering from severe salpingitis may require salpingohysterectomy, or this may be elected in milder cases to resolve disease and prevent recurrence if the hen is not intended for breeding.

Cystic Hyperplasia of the Oviduct

Etiology

Cystic hyperplasia of the oviduct may occur from improper formation of the left oviduct or secondary to an endocrine abnormality. In addition, the vestigial right oviduct may become cystic, and the associated ovary often has cystic changes. Cystic hyperplasia often contributes to salpingitis and egg binding.

Clinical Signs

Clinical signs may include depression, anorexia, abdominal distension, ascites, and dyspnea. A tentative diagnosis is made through history, physical examination, and supporting laboratory tests, similarly to that of salpingitis and metritis.

Diagnosis

- Radiographs may demonstrate an enlarged soft tissue density in the region of the oviduct.
- Ultrasonography may reveal an enlarged oviduct that may be filled with fluid or have obvious cysts present, with or without concurrent ovarian follicles or cysts.
- Laparoscopy may show a dilated oviduct filled with a white or brown mucoid fluid.
- Definitive diagnosis requires laparotomy with biopsy, cytology, histopathology, and bacterial culture and sensitivity.

Treatment

- Initiate therapy to stop ovulation, as outlined under excessive egg laying above, due to increased risk of rupture during ovulation and oviposition.
- If bacterial infection is suspected or documented by cytology and bacterial culture and sensitivity, begin appropriate antibiotic treatment.
- Salpingohysterectomy may be required to resolve the current problem or prevent future recurrences and should be considered if the hen is not intended for breeding, as complete resolution with medical therapy alone may be difficult.

Oviductal Rupture

Etiology

- Oviductal rupture may occur secondary to dystocia or oviductal disease.
- Administration of prostaglandins, oxytocin, vasotocin, and ovocentesis may cause traumatic rupture of the oviduct.

Clinical Signs

Clinical signs may include depression, anorexia, and abdominal distension secondary to coelomitis or deposition of egg or oviductal contents.

Diagnosis

- Radiographs and ultrasonography may reveal polyostotic hyperostosis, a soft tissue density in the region of the ovary, ovarian follicles, an enlarged or cystic oviduct, a shelled or non-shelled egg, and coelomic fluid if a concurrent coelomitis is present.
- Diagnosis is confirmed at laparoscopy or laparotomy.

Treatment

The laceration may be repaired, depending on the integrity of the tissue, or salpingohysterectomy may be performed as a therapeutic and preventative technique.

Ectopic Ovulation

Etiology

- Ectopic ovulation may result from failure of the infundibulum to retrieve an ovulated ovum, reverse peristalsis of the oviduct, or oviductal rupture.
- Ectopic ovulation does not necessarily result in coelomitis. Internal laying actually is a common occurrence in many avian species, and the ova usually are resorbed without any problems.
- Reverse peristalsis may be triggered by obstruction of the oviduct, cystic hyperplasia, neoplasia, malnutrition, trauma, and stress.

- The ectopic ova may be resorbed without incident or may induce a severe coelomitis.

Clinical Signs

Clinical signs of ectopic ovulation may include transient or persistent depression, inappetence, and abdominal distension, especially if there is an associated coelomitis.

Diagnosis

- There may be a leukocytosis with a mature heterophilia. Serum chemistries may demonstrate an ovulating hen.
- Radiographs may reveal polyostotic hyperostosis and one or multiple eggs in the abdomen.
- It may be difficult or impossible to determine if an egg is located within the oviduct or is ectopic without laparoscopy or laparotomy, depending on its location within the coelom.

▼ ***Key Point*** Incidental detection of ectopic ova by ultrasound in the absence of clinical signs may resolve on its own with no treatment, and any medical or surgical intervention may be contraindicated.

Treatment

- If an egg is not laid within a reasonable time period and/or the patient's condition is declining, an exploratory laparotomy is indicated.
- Ectopic eggs are removed by laparotomy, and any oviductal tear should be surgically repaired or a salpingohysterectomy should be performed.
- Cytology, bacterial culture and sensitivity, and histopathology should be performed in cases of oviductal rupture, cystic hyperplasia, and neoplasia.

Cystic Ovarian Disease

Etiology

Cyst development may be caused by endocrine disorders, anatomic abnormalities on the ovary itself, and neoplasia.

Clinical Signs

Clinical signs include abdominal distension and associated dyspnea, usually due to secondary coelomitis. Advanced cystic ovarian disease may cause depression, inappetence, and weight loss.

Diagnosis

- A thorough history may reveal current or previous egg production, with an abrupt halt. Owners may report chronic reproductive behavior without egg production or impaired reproductive performance in breeding hens.
- A leukocytosis with a relative heterophilia commonly is seen, as well as a peripheral hypercalcemia, hyperglobulinemia, and hypercholesterolemia.
- Radiographs may demonstrate polyostotic hyperostosis, a soft tissue density in the area of the ovary and/or oviduct, coelomic fluid, and displacement of coelomic viscera.
- Ultrasonography may reveal fluid-filled cyst(s) in the area of the ovary or simply coelomic fluid of an undetermined source. An ovarian cyst may be quite large and may actually fold onto itself as it grows. There may be normal ovarian follicles present as well.
- In birds with associated coelomitis, perform abdominocentesis to collect fluid for cytologic exam and bacterial culture and sensitivity. Abdominocentesis is often both diagnostic and therapeutic.
- Perform a laparoscopic examination to identify the ovary, and obtain biopsy specimens for histologic examination and for culture and susceptibility testing. Aspirate the contents of the cysts. Fluid is typically clear to straw colored and of low cellularity.

▼ ***Key Point*** Exercise extreme caution during a laparoscopic exam and aspiration, as fluid from the cyst or coelom may gain access to the respiratory system through the entry hole in the abdominal air sac.

- A laparoscopic exam with ovarian biopsy is especially important in the diagnosis of ovarian disease in those patients with cysts that do not resolve with medical therapy, as it is not uncommon for hens to develop ovarian cysts secondary to neoplasia and oophoritis.

Treatment

- Treatment goals include resolution of cyst(s) and associated disease conditions such as coelomitis, oophoritis, ovarian granuloma, and neoplasia.
- Perform abdominocentesis in dyspneic hens with coelomic fluid to relieve dyspnea caused by fluid compressing the air sacs.
- Initiate pharmacologic, behavioral, environmental, and dietary intervention (as described under treatment of excessive laying above) to reduce ovarian activity with production of reproductive hormones that may perpetuate ovarian cysts.
- Aspiration of cysts, salpingohysterectomy, and partial ovariectomy may be beneficial for complete resolution.
- Regularly monitor treated hens for recurrence, since long-term resolution may be difficult.

Reproductive-Associated Coelomitis

Etiology

- Reproductive-associated coelomitis includes sterile egg yolk coelomitis, ectopic ovulation-associated coelomitis, and septic coelomitis.

- Coelomitis may be found in association with other diseases such as malnutrition, metabolic disorders, and systemic infections. Cystic ovarian disease, salpingitis, metritis, cystic hyperplasia, oviductal rupture, oviductal and ovarian granulomas, oviductal rupture, septicemia, intestinal rupture, and neoplasia may cause associated coelomitis as well.

Clinical Signs

Clinical signs may include transient or persistent depression, lethargy, and inappetence. Patients with more advanced disease may suffer from weight loss, abdominal distension, and dyspnea associated with coelomic fluid and air sac compression.

Diagnosis

- Tentative diagnosis of reproductive-associated coelomitis is made through history, physical examination, and supporting laboratory tests.
- The hen may have a history of egg production, which often has abruptly stopped.
- It is important to note that not all patients with coelomitis will have identifiable fluid present.
- Leukocytosis with a relative heterophilia is usually seen, along with hypercalcemia, hyperglobulinemia, and hypercholesterolemia compatible with preovulation and immediate post-ovulation. Many birds will be hypocalcemic due to calcium depletion subsequent to malnutrition or chronic egg laying.
- Some birds may have egg yolk visible in their peripheral blood smears, as well as above the buffy coat, in separated blood samples.
- Radiographs may demonstrate polyostotic hyperostosis, soft tissue density in the region of the ovary and/or oviduct, coelomic fluid, abdominal and caudal thoracic air sac compression, or even an obvious shelled or non-shelled egg. Contrast radiography may be helpful to illustrate organ displacement and locate any suspected space-occupying mass.
- Ultrasound may reveal coelomic fluid, ovarian follicle(s), ovarian cyst(s), an ovarian mass, and oviductal masses such as granuloma or neoplasia.
- Perform abdominocentesis on hens with coelomic fluid. Cytology of coelomic fluid may demonstrate a septic or non-septic exudate, a transudate, or yolk or fat globules if such material is present. Perform bacterial culture and sensitivity on samples of coelomic fluid.
- Laparoscopy and/or laparotomy may be necessary to identify the causative etiology of coelomitis.

Treatment

- Treatment of reproductive-associated coelomitis varies with type and severity of clinical signs. Many birds respond well to supportive care alone.
- Perform abdominocentesis in dyspneic hens with coelomic fluid to relieve dyspnea caused by fluid compressing the air sacs.
- Administer broad-spectrum antibiotics to hens with suspected or confirmed septic coelomitis while waiting for sensitivity results on fluid obtained from abdominocentesis.
- Corticosteroids may be indicated in cases in which an infectious etiology has been excluded, but they should be used judiciously due to potential serious side effects.
- Initiate pharmacologic, behavioral, environmental, and dietary intervention (as described under treatment of excessive laying above) to reduce ovarian activity with production of reproductive hormones that may perpetuate this condition.
- Once the coelomic fluid has decreased and the patient is stable, it may be beneficial to perform a laparoscopic examination. This allows direct visualization of the ovary, oviduct, and other organs to help confirm underlying conditions such as a cyst, granuloma, and/or tumor.
- Obtain a biopsy on abnormal tissue for cytologic or histopathologic examination and bacterial culture and sensitivity.
- A laparotomy with or without a salpingohysterectomy may be necessary to remove a mass, cystic oviduct, or inflammatory debris from the abdomen, particularly if medical therapy alone is not effective.
- During laparoscopy or laparotomy there is a risk of fluid gaining access to the respiratory system via the incision through the abdominal air sacs, and often there are significant adhesions between the oviduct and the neighboring viscera due to chronic inflammation.

Oophoritis

Etiology

Inflammation of the ovary results from neoplastic, mechanical, or infectious causes. Infectious oophoritis often occurs as a result of spread from adjacent organs or septicemia and is frequently bacterial in origin.

Clinical Signs

Clinical signs may be vague and include anorexia, weight loss, depression, cessation of egg production, egg binding, and sudden death.

Diagnosis

- A diagnosis of oophoritis is made through history, physical examination, radiography, ultrasonography, abdominocentesis with coelomic fluid analysis, laparoscopy, laparotomy, and biopsy of the ovary with bacterial culture and sensitivity and with histopathologic analysis.

- Hematology may demonstrate a leukocytosis with a relative heterophilia.
- Radiographs and ultrasound may demonstrate an enlarged soft tissue density in the region of the ovary, ovarian follicle(s), and ovarian cyst(s), and there may be coelomic fluid present if there is a concurrent coelomitis.
- If coelomic fluid is present, abdominocentesis is beneficial both therapeutically and diagnostically. Perform cytologic analysis and bacterial culture and sensitivity on fluid recovered. Laparoscopy may demonstrate an enlarged, abnormal-appearing ovary, which may have associated hypervascularization.
- Persistent or chronic oophoritis may progress to granulomatous disease, which may be evident on ultrasound, laparoscopy, and laparotomy.
- Definitive diagnosis is based on ovarian biopsy with histopathologic examination, along with bacterial culture and sensitivity.

Treatment

- Administer broad-spectrum antibiotics, pending sensitivity results.
- Initiate pharmacologic, behavioral, environmental, and dietary intervention (as described under treatment of excessive laying above) to reduce ovarian activity with production of reproductive hormones that may perpetuate this condition.
- Repeat the laparoscopic exam, bacterial culture and sensitivity, and complete blood count until culture results are negative and any leukocytosis has resolved.
- Carefully monitor reproductive performance and general condition, as complete resolution may be difficult.
- Partial ovariectomy, usually performed with salpingohysterectomy, may be beneficial in refractory cases if the hen is not intended for breeding.

Ovarian and Oviductal Neoplasia

Etiology

- Ovarian and oviductal neoplasia most commonly is seen in the budgerigar *(Melopsittacus undulates)* and gallinaceous species.
- Lymphomatosis, adenocarcinoma, leiomyosarcoma, leiomyomas, adenomas, and granulosa cell tumors have been reported.

Clinical Signs

Clinical signs usually include abdominal distension, coelomic fluid, lameness, dyspnea, depression, inappetence, and chronic reproductive-associated behavior.

Diagnosis

- Alteration of secondary sex characteristics such as a cere color change may occur.
- Perform a complete diagnostic workup in all hens with egg binding, oviductal impaction, ovarian cysts, abdominal hernia, and coelomic fluid, since neoplasia is a common underlying cause of these conditions.
- Diagnosis is supported by history, physical examination, demonstration of enlargement in the area of the ovary or oviduct on radiographs, and ultrasound. Definitive diagnosis is based on biopsy with histopathologic examination of abnormal tissues.

Treatment

- There have been anecdotal reports of treatment with chemotherapeutic drugs such as carboplatin; however, no consistent results have been documented to date.
- Prognosis for long-term recovery is grave with no refereed reports of successful treatment.
- Salpingohysterectomy with partial or complete ovariectomy may have value in select patients.

Parasites

Etiology

- Ascarids and flukes have been reported to infect the oviduct from the cloaca by reverse peristalsis.
- Heavy infestation may cause soft-shelled and shell-less eggs and may result in salpingitis. *Anseriformes* are most commonly affected. Ascarids and small flukes reportedly have been passed in eggs.

Diagnosis

- Diagnosis is made by finding adult worms in the oviduct on laparotomy or necropsy or by finding adult worms in eggs laid by affected hens.
- Perform a fecal floatation, especially on ground-dwelling species.

Treatment

- Prophylactic anthelmintic programs may be helpful in preventing severe infestations.
- If these worms obstruct the oviduct, they require surgical removal or salpingohysterectomy.

Overproduction of Eggs

- Safe numbers of egg production for different species is not definitively documented.
- Nutrition and environmental conditions affect safe production levels. Free-ranging psittacines typically produce one to two clutches per year; however, many captive psittacines produce far more chicks than this.
- While many birds show no obvious side effects, chronically overproducing hens may develop reproductive tract disorders, as well as poor body condition and feather quality.
- To improve long-term health in producing birds, egg production should be limited to two clutches per year

in birds that show any signs of poor health secondary to overproduction.
- It also is recommended that all birds receive some rest period each year to prevent reproductive disorders from developing.

MALE REPRODUCTIVE DISORDERS

Orchitis

Etiology

Infectious orchitis may occur from ascending infections, hematogenous spread, or infected adjacent organs. Rarely, non-infectious causes are associated with inflammation of the testicles.

Clinical Signs

Early clinical signs are vague and difficult to detect, and they may include infertility, mild depression, and decreased appetite. As the disease progresses, the patient may develop lethargy, inappetence, and abdominal distension if a secondary coelomitis develops.

Diagnosis

- Leukocytosis with a relative heterophilia may be noted.
- The testicles may be enlarged on radiographs and ultrasound. There also may be notable enlargement, inflammation, and hypervascularization on laparoscopy.
- Definitive diagnosis is made by cytology, bacterial culture and sensitivity, and histopathologic examination of samples from affected testicles.

Treatment

Therapy includes broad-spectrum antibiotics, pending sensitivity results.

Testicular Neoplasia

Etiology

- Neoplasms reported include Sertoli cell tumors, seminomas, interstitial cell tumors, and lymphosarcomas. Leiomyosarcoma and carcinoma have been reported to arise from the epididymis and ductus deferens.
- Testicular neoplasia commonly has been documented in the budgerigar *(Melopsittacus undulates)* and often is unilateral.

Clinical Signs

Clinical signs include abdominal distension and one-sided paresis, paralysis, or cyanosis of the pelvic limb due to compression of the ischiatic nerve and blood vessels. Alterations of secondary sex characteristics such as cere color change from blue to brown may occur.

Diagnosis

- Often the disease is advanced once clinical signs are evident.
- Definitive diagnosis is made by testicular biopsy and histopathologic examination.
- Radiographs may reveal a soft tissue mass in the region of the testicles, air sac compression, and secondary sex changes such as polyostotic hyperostosis, even in male birds.

Treatment

Treatment includes orchiectomy. Chemotherapy has been reported if the tumor is deemed incompletely or non-resectable or if the patient is not a good surgical candidate. However, no conclusive data is available regarding the efficacy of chemotherapy to date.

DISORDERS OF THE CLOACA

Cloacal Papillomas

Cloacal papillomas have been noted in New World psittacine species. To date the cause is unknown, but a herpesvirus is strongly suspected. See Chapter 169 for a complete discussion.

Cloacal Prolapse

Etiology

Cloacal prolapse may occur secondary to chronic straining from masturbation, egg laying, space-occupying abdominal masses, and inappropriate weaning and social behavior.

Diagnosis

- History includes straining and observation of intermittent or persistent prolapsed mucosa through the vent opening. Physical examination will reveal prolapsed tissue through the vent that may be intermittent or persistent.
- Obtain samples from prolapsed tissue for cytologic examination and bacterial culture and sensitivity to aid antibiotic therapy.
- Perform a complete blood count, serum chemistries, radiographs, ultrasound, and endoscopic exam of the coelom and cloaca to determine any other predisposing cause.

Treatment

- Thoroughly clean, irrigate, and lubricate prolapsed tissue. Examine affected tissue for necrosis, and remove any adhered egg remnants.
- In birds with chronic reproductive-associated behavior and straining secondary to masturbation, initiate pharmacologic therapy and environmental manipulation (as described under excessive laying above) to decrease reproductive stimuli.
- Cloacopexy and the use of temporary stay sutures may be helpful in temporary or permanent reduction. However, those procedures interfere with movement of the cloaca and may alter defecation and micturition.
- Ventplasty may decrease the vent opening and prevent further prolapse if the vent has become flaccid.
- Clomipramine hydrochloride and phenylpropanolamine hydrochloride administration have anecdotally been reported to contract the vent orifice and assist in the resolution of prolapse of the cloaca.
- Salpingohysterectomy with partial ovariectomy or orchiectomy may be beneficial in those patients refractory to medical therapy.
- Administer broad-spectrum antibiotics pending bacterial culture and sensitivity, because primary and secondary bacterial infections are common.

Cloacitis

Etiology

- Cloacitis may result from both infectious and noninfectious processes.
- Cloacal prolapse, cloacal papillomas, cloacoliths, and bacterial infections may cause inflammation of these tissues. This may result in secondary urogenital and/or gastrointestinal disease due to their anatomic relationship to the cloaca.

Diagnosis

Obtain samples from the cloaca for cytologic examination and bacterial culture and sensitivity testing.

Treatment

- Initiate appropriate antibiotic therapy as directed by culture and sensitivity testing.
- Dimethyl sulfoxide may be used to reduce inflammation with no systemic side effects, and swabbing the cloaca with petroleum jelly will prevent fecal and urate accumulation on the cloacal surface with subsequent irritation.

Cloacolithiasis

Etiology

Cloacolithiasis is infrequently noted in pet birds. It may result from previous egg binding, infectious cloacitis, malnutrition, or neurologic disease of the cloaca.

Diagnosis

Perform cloacal cytology with bacterial culture and sensitivity.

Treatment

- Manually or surgically remove cloacoliths.
- Administer broad-spectrum antibiotics, pending culture results.
- Change the diet to improved nutrition when indicated.
- Monitor patients closely for recurrence; prognosis for return to normal breeding performance is poor.

Cloacal Neoplasia

Etiology

Cloacal carcinomas are infrequently reported in pet birds.

Diagnosis

- Perform a laparoscopic examination of the cloaca, noting patency of openings into the urodeum, proctodeum, and coprodeum.
- Definitive diagnosis is based on histopathologic analysis of biopsy samples.

Treatment

Surgically remove neoplastic masses, with caution not to damage the openings to the gastrointestinal, urinary, and reproductive tract.

Other Cloacal Diseases

- Cloacal strictures may occur due to associated cloacal disease or secondary to surgical procedures such as biopsy or cauterization of papillomas.
- These strictures may be gently manually dilated with the use of a speculum.
- Excessive feathering around the vent may cause infertility; these feathers should be removed by trimming or pulling prior to breeding season.

Chapter

174 Avian Neurologic Disorders

Anthony Pilny / Katherine E. Quesenberry

Companion and aviary birds frequently develop clinical signs associated with the peripheral or central nervous system. Although many possible causes of neurologic disease exist, certain syndromes and diseases occur commonly. Diagnosis of these syndromes is based on history, clinical signs, results of diagnostic tests, and response to therapy.

PRINCIPLES OF DIAGNOSIS

History

Several important points should be included in the general history of a bird with neurologic disease.

- Dietary history is important because nutritional deficiencies are factors in many diseases. Ask for specific details, such as the following:
  - What is the regular diet? Does the bird have dietary preferences?
  - What vitamin and mineral supplements are being given?
  - Is adequate calcium provided for egg-laying females?
- What is the home environment of the bird, especially as related to exposure to trauma or toxins?
- Is the bird always caged or is it allowed free flight in the house?
- Does the bird chew on any painted surfaces, metal objects, or plants?
- What types of toys are kept in the cage?
- Is the bird a recent purchase or a long-term pet? Is there exposure to other birds? Was the bird boarded recently with exposure to other birds?
- When was the onset of the disorder, and what has been the duration and progression of clinical signs?

Clinical Signs

Clinical signs associated with neurologic disease in birds are similar to those seen in mammals.

- The most common clinical signs are seizures, ataxia, paresis, paralysis, head tilt, circling, abnormal mentation, nystagmus, intention tremors, and visual deficits. Weakness and ataxia can be manifested as falling off the perch.
- It may be difficult to distinguish weakness secondary to severe systemic disease from that associated with neurologic disease.
- The presence or absence of other neurologic deficits may be helpful in determining which body system is involved.
- Unilateral or bilateral lameness or wing droop may indicate a peripheral nerve deficit. Rule out fractures and other musculoskeletal abnormalities as a cause.

Neurologic Evaluation

The goal of the examination is to determine if the neuropathy is focal or diffuse and to localize lesions.

- Cranial nerve function should be assessed in addition to peripheral nerve function.
  - Assess vision in each eye by slowly moving a hand or an object toward the bird from behind on each side. A bird with visual deficits does not react until the object is very close or its face is touched.
  - The pupillary light reflex is difficult to evaluate because of the presence of striated muscle in the iris. A widely dilated pupil that reacts minimally to changes in light intensity may indicate a visual deficit.
  - Check facial sensation by touching various parts of the face with hemostats. Assess the palpebral reflex as in mammals.
- Neurologic evaluation of neonates can be difficult, and comparison with clutchmates may be the best way to detect abnormalities. Useful tests include feeding responses, vocalization, use of wings for balance, and perching ability.

Diagnostic Tests

Methods of diagnosis and treatment in birds are limited by anatomic variations, patient size, and lack of reference values to interpret test results. Diagnostic test options that may be helpful in diagnosing neurologic disease are a complete blood count, biochemical profile, bile acid concentration, plasma protein electrophoresis, viral and *Chlamydophila* screening tests,

blood lead levels, radiographs, computed tomography, and magnetic resonance imaging. Neurologic tests can include electroencephalograms and auditory-evoked potentials.

PRINCIPLES OF TREATMENT

▼ ***Key Point*** Birds with neurologic disease need special nursing care in the hospital and at home.

- Keep ataxic birds or birds having seizures in cages without perches. Provide soft bedding.
- Use small, shallow, or covered water bowls to prevent accidental drowning, especially with small birds.
- Remove sharp objects, chains, and potentially dangerous toys from the cage.
- Make food easily accessible by spreading it on the floor or by providing several containers in the cage.
- *Supplemental fluids* and *gavage feeding* are necessary for anorectic birds (see Chapter 168) and birds that are unable to eat because of tremors or ataxia.
- Give *antibiotics* if bacterial disease is suspected or if a risk of secondary bacterial infection exists. If possible, use antimicrobials that cross the blood-brain barrier (e.g., trimethoprim-sulfa at 100 mg/kg PO q12h or chloramphenicol at 50 mg/kg PO q8–12h).
- Administer *antifungal* agents if fungal infection of the central nervous system (CNS) is a differential diagnosis. Fluconazole (5–15 mg/kg PO q12h) reaches therapeutic concentrations in the brain parenchyma and the cerebral spinal fluid.
- *Anti-inflammatory drugs* (corticosteroids) may be beneficial in the treatment of acute head trauma. Be conservative in administration because of the potential for adrenal suppression and immune compromise. For long-term anti-inflammatory treatment, nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., carprofen at a dosage of 2–5 mg/kg PO q12h or meloxicam at 0.2 mg/kg PO q24h) are safer.
- Give *supplemental calcium* if blood calcium concentrations are abnormally low.
- Administer *chelating agents* such as calcium ethylenediaminetetraacetic acid (Calcium EDTA, or CaEDTA) (35 mg/kg IM q12h for 5 days, off 3 days, then as needed), dimercaptosuccinic acid (DMSA) (25–35 mg/kg PO q12h for 5 days a week for 3–5 weeks), or both to birds with suspected heavy metal toxicosis, such as lead. With lead toxicosis, birds often improve clinically within 24 to 48 hours. Side effects of treatment are rare, and birds can be treated with CaEDTA and/or DMSA on an emergency basis until results of tests for blood lead concentrations are known.
- *Anticonvulsants* such as diazepam (0.5–2.0 mg/kg IV) or midazolam (1–2 mg/kg IM) are helpful in controlling seizures.
- Give parenteral *vitamins* to birds with suspected vitamin deficiencies. Vitamin D_3 is especially important in African grey parrots and birds with hypocalcemia. Give multivitamin B-complex and thiamine if birds are anorectic or thiamine deficiency is suspected. Supplement with vitamin E or selenium if muscular weakness is present.

METABOLIC OR NUTRITIONAL DISORDERS

Hypocalcemia

▼ ***Key Point*** African grey parrots on unsupplemented seed diets are predisposed to a hypocalcemic syndrome.

Hypocalcemia is associated with neurologic abnormalities, especially in African grey parrots. This syndrome is less common than in previous years, probably because more bird owners are better educated about avian nutrition and feed pelleted diets.

Etiology

- The exact cause of this syndrome is unknown. A common history in African grey parrots with hypocalcemia is an all-seed diet with little or no vitamin supplementation, suggesting that a lack of vitamin D_3 may be a factor. Abnormal parathyroid function is also possible.

Clinical Signs

- Common neurologic signs include seizures, opisthotonus, tonic extension of the limbs, incoordination, dilated pupils, and convulsions.
- Seizures are the most common clinical sign and may be triggered by sudden noise and excitement. The seizure lasts several seconds and can occur as an acute onset of tetanic spasms with extensor rigidity, wing flapping, vocalizations, focal facial seizures, and occasionally nystagmus.
- Skeletal abnormalities, including pathologic fractures and nutritional bone disease, that are usually associated with dietary calcium deficiency are rarely seen in African grey parrots.

Diagnosis

Base the diagnosis on the history, clinical signs, results of plasma biochemical analysis, and response to therapy.

- To determine proper treatment, measurement of blood calcium concentration is necessary.
  - The total plasma calcium concentration is usually low in affected birds (1.5–6.0 mg/dl).
- Obtain whole-body survey radiographs to identify soft tissue or bone abnormalities and to detect any metal

objects in the gastrointestinal (GI) tract or soft tissues that may indicate lead toxicosis.
  - The proventriculus and intestinal loops may appear dilated on radiographs. Hypocalcemia may cause decreased smooth muscle contraction and motility of the GI tract.
- Consider and investigate other potential causes for the clinical signs (e.g., lead toxicosis and systemic fungal infection).

Treatment

- Give supplemental calcium orally or parenterally.
  - In severely debilitated birds, start treatment with calcium gluconate, 50 to 100 mg/kg IM q12–24h.
  - If seizures are infrequent and the danger of aspiration during seizures is minimal, give calcium supplements orally, such as Neo-calglucon, 25 mg/kg PO q24h).
- During initial therapy, give supplemental vitamin D_3 (1000 IU of D_3 per 300 g IM) of compounded emulsion; repeat in 7 days as needed.
- Provide general supportive care and control continuous or severe seizures with diazepam or midazolam as needed.
- Correct the diet to provide adequate calcium and vitamins. Encourage use of pelleted diets. Add a liquid calcium supplement, or crush Tums or hard-boiled eggshells over food.

Prognosis

- The prognosis is good in most birds; however, African grey parrots with blood calcium concentrations less than 2.0 mg/dl may not improve with treatment. Improvement in some birds is gradual.

NEOPLASIA

Central Nervous System Neoplasia

Primary tumors of neural tissue origin are rare in psittacine birds. Meningiomas, pituitary adenomas, and glioblastomas are a few of the neoplasms that have been reported, most commonly in budgerigars and cockatiels.

Clinical Signs

- Common signs include ataxia, weakness, wide-based stance, and postural abnormalities.
- Depression, nystagmus, abnormal mentation, and visual deficits often are present.

Diagnosis

- Clinical diagnosis of a CNS tumor is extremely difficult. Static or progressive clinical signs indicating CNS involvement with failure to respond to therapy suggests neoplasia.
- Computed tomography or magnetic resonance imaging of the brain can be diagnostic.
- Diagnosis is usually determined by results of necropsy.

Treatment and Prognosis

- Anti-inflammatory therapy may be helpful in the short term. The prognosis is poor.

Paresis Secondary to Renal or Gonadal Neoplasia

▼ ***Key Point*** Tumors of renal tissue origin are common in budgerigars 4 years of age and older and are associated with progressive unilateral limb paresis.

Gonadal tumors are less common than renal tumors; clinical signs may resemble those of renal neoplasia.

Etiology

- The ischiatic nerves pass through the renal parenchyma; renal neoplasia that compresses the nerve will result in paresis.

Clinical Signs

- Progressive paresis or paralysis of the leg on the ipsilateral side develops from pressure of the tumor on the sciatic nerve.
- Muscle atrophy may be severe in the affected leg.
- Polyuria may be present.

Diagnosis

Base the diagnosis on history, clinical signs, physical examination, and radiographic or ultrasonographic findings.

- Palpate the abdomen carefully on the affected side to detect the presence of a mass.
- Obtain radiographs to identify a soft tissue mass in the area of the kidney.
  - Barium contrast radiography may reveal ventral or lateral displacement of bowel loops in the dorsal-sacral area of the kidney or gonad, suggestive of a mass.

Treatment and Prognosis

- No treatment is available.
- Budgies usually die within several months of the onset of clinical signs.

INFECTIOUS DISEASES

Viruses

Several viruses affect the avian nervous system (see Chapter 169).

- *Paramyxovirus* (PMV) causes neurologic disease in many species of wild and domestic birds.
- *Newcastle disease* (PMV-1) and other strains (PMV-3) can cause CNS disease in psittaciformes. Clinical signs can include torticollis, trembling, paresis, and opisthotonus. PMV-1 is common in pigeons in which the virus spreads to the kidneys and CNS. PMV causes torticollis, depression, and weight loss in finches. A number of PMV serotypes have been seen in mynahs and toucans. PMV-3 infections are particularly common in the *Neophema* genus of Australian grass parakeets. Head tilt, subclinical pancreatic disease, and/or CNS disease are seen with this virus infection. Diagnosis is based on symptoms, virus isolation, and serology. A vaccine is available.
- *Proventricular dilatation disease* (PDD) is suspected to be viral cause of neurologic signs in psittacine species. (See Chapter 169 for details.)
- Neurologic deficits are sometimes seen in birds with *polyomavirus*. Diagnosis is by polymerase chain reaction testing and a vaccine is available.
- *West Nile virus* is a cause of neurologic disease in many species of wild and captive birds, including psittacine and passerine species. Birds housed outdoors during mosquito season are at highest risk. West Nile virus has been identified in more than *100 species of birds* found dead in the United States. Most of these birds were identified through reporting of dead wild birds by the public.
- Other suspected viral causes of neurologic disease have been reported but are uncommon.

Bacteria and Fungi

Neurologic disease resulting from bacterial or fungal infection is sometimes seen.

- Bacterial encephalitis secondary to systemic infection can result in multifocal neurologic disease.
  - Neurologic signs are seen with fungal infections affecting the CNS or peripheral nervous system. Clinical signs vary from paralysis or paresis to generalized weakness, ataxia, or seizures. *Aspergillus* spp. are implicated most commonly, but infections with other fungi do occur (e.g., *Mucormycosis*).
- *Chlamydophila psittaci* (psittacosis) can cause CNS lesions and neurologic signs. Typical signs of psittacosis (see Chapter 169) may be present.
- Infection with *Mycobacterium* spp. can result in neurologic signs, either as a result of direct involvement of the nervous system or secondary to weakness associated with systemic disease.
- Neurologic signs secondary to salmonellosis are seen in pigeons.

Parasites

Parasitic causes of neurologic diseases are rare in birds.

- Possible causes include microfilaria, protozoa (e.g., *Plasmodium* and *Atoxoplasma* spp.), sporozoa (*Sarcocystis* and *Toxoplasma* spp.), and nematode migration.
- Diagnosis usually is based on results of necropsy and histologic examination of tissue samples.

TOXICOSES

Lead Toxicosis

Lead toxicosis is a common cause of neurologic disease in pet birds. Other aspects of lead toxicosis, as pertaining to dogs and cats, are discussed elsewhere.

▼ ***Key Point*** Sources of lead include surfaces or objects painted with lead-based paint, stained glass, mirror backing, champagne bottle foil, lead-weighted objects (curtain weights), and some ceramic or glazed dishes.

Clinical Signs

- Signs of acute lead ingestion include depression, anorexia, gastroenteritis (usually hemorrhagic), crop stasis, regurgitation, dehydration, and hemoglobinuria.
- Neurologic signs may be latent in onset. Latent signs include seizures, ataxia, weakness, paresis, and leg paralysis.

Diagnosis

Establish the diagnosis based on the history, clinical signs, diagnostic tests, and response to therapy.

- Measure blood lead concentration. Lead concentrations of 10 µg/dl or greater suggest lead toxicosis.
- Obtain radiographs to screen for metal objects in the GI tract (or soft tissues). The presence of metal in a bird with typical clinical signs suggests lead toxicosis.
  - The absence of metal in the GI tract does not exclude a diagnosis of plumbism. Small amounts of lead are often completely absorbed from the GI tract, and therefore no longer visible, prior to the onset of clinical signs.
- Birds with lead toxicosis maybe mildly or severely anemic. Measure packed cell volume (PCV) in birds that appear anemic before collecting blood samples for routine tests. Basophilic stippling of red blood cells is uncommon.

Treatment

- Chelation therapy is indicated in any bird with suspected lead toxicosis. CaEDTA is effective and is the most commonly used chelating agent.
  - Give CaEDTA at a dosage of 35 mg/kg IM q12h for 5 days, off 3 days, then as needed.

- DMSA (25–35 mg/kg PO q12h for 5 days a week for 3–5 weeks) chelates lead in soft tissues more quickly than CaEDTA.
  - D-penicillamine, another chelating drug administered orally can be used for chelation therapy. However, GI side effects (e.g., vomiting) sometimes occur and therapy must be discontinued.
- Magnesium sulfate (Epsom salts) given orally may help bind lead particles in the GI tract and inhibit further absorption. Dosage is empirical (e.g., a pinch dissolved in dextrose or added to food given every 12 hours).
- Supportive therapy includes supplemental fluids, antibiotics, iron supplementation, vitamins, and tube feeding.
- Anticonvulsants are occasionally necessary to control seizures.
- Laxatives or lubricants may help speed passage of metal from the GI tract.
- Persistence of a high blood lead level or clinical signs indicate that a second or third course of therapy is needed.
- Lead stores in bones may be released during calcium mobilization in reproductively active hens.

Prognosis

- Birds with lead toxicosis usually respond quickly to chelation therapy. Clinical signs may diminish significantly after 1 to 2 days of therapy. Birds with leg paralysis from chronic lead toxicosis have a more guarded prognosis.
- Monitor progress by repeating tests for blood lead concentration. If results remain high, repeat chelation treatment for another 5 days and recheck the blood lead concentration.

Other Toxicoses

- Other heavy metals are occasionally associated with neurologic disease in pet birds.
- Exposure to organophosphates and other pesticides may cause incoordination, severe depression, and diarrhea.
- Toxicoses from exposure to marijuana, alcohol, and other drugs have been reported.
- Neurologic abnormalities followed by acute death may be seen in birds exposed to polytetrafluoroethylene (Teflon) (see Chapter 171).

TRAUMATIC INJURY

Head Trauma

- Head trauma can cause mild to severe neurologic signs.
- Treatment depends on the severity of clinical signs.
- Shock or anti-inflammatory doses of short-acting corticosteroids may be indicated in birds with acute trauma.
- Provide general supportive therapy as needed.
- The prognosis depends on the severity of the injury and the response to therapy.

Peripheral Nerve Trauma

- Musculoskeletal injury can result in peripheral nerve damage.
- Treatment and prognosis depend on the extent of tissue damage.

Miscellaneous Disorders

Gout

Gout can cause peripheral gait abnormalities that may appear as neurologic deficits. Gout is most common in old budgerigars but also occurs in other species.

- Ataxia, weakness, and a stiff gait are common signs. Clinical signs usually develop before uric acid deposits (tophi) are visible as subcutaneous deposits in the joints and legs.
- The plasma uric acid concentration may range from normal to significantly high.

Liver Disease

Weakness, ataxia, and abnormal mentation are seen occasionally with severe liver disease (see Chapter 172).

Hypoglycemia

Hypoglycemia can cause weakness, lethargy, and neurologic signs.

▼ ***Key Point*** Measure whole-blood glucose concentration in any bird that is collapsed, weak, having seizures, or comatose. Seizures usually occur at blood glucose levels less than 100 mg/dl. Recently weaned and young birds are most susceptible.

Lipemia

- Signs of central neurologic abnormalities can occur in birds with severe lipemia. Birds with highly lipemic blood may have sludging and resultant anoxic episodes.
  - The cause of the hyperlipidemia is not known, but this syndrome is seen most frequently in reproductive hens and obese birds. In hens, it may be related to high levels of circulating lipoproteins and cholesterol during the egg-laying cycle.
- Treatment with niacin (50 mg/kg q8h) and gemfibrozil (Lopid, Parke-Davis) (30 mg/kg q8h) is sometimes effective in controlling clinical signs in birds with high triglyceride levels. Statins may be effective in birds with high cholesterol levels.

- Atherosclerosis is suspected to cause neurologic clinical signs in birds. These signs can include falls, collapse, and ataxia.

Yolk Emboli

- Yolk emboli to the CNS may result in neurologic abnormalities (see Chapter 173).
- Hens usually remain alert but are ataxic and have a head tilt.
- Treatment is similar to that for birds with lipemia. Hens gradually improve over weeks to several months.

Other Nutritional Factors

- Deficiencies in vitamins A, B_2, B_6, B_{12}, C, and E and in selenium are related to neurologic disorders.
- Because specific vitamin deficiencies are difficult to confirm, give supplemental multivitamins if a deficiency is suspected.

Lorikeet Tetraparesis

- A progressive tetraparetic syndrome has been described in lorikeets.
- The exact etiology is unknown, but a virus or protozoa is suspected.

IDIOPATHIC EPILEPSY

Idiopathic epilepsy has been described as a clinical syndrome in pet birds, most commonly in lovebirds and red-lored Amazon parrots.

- Phenobarbital may be effective in controlling clinical signs.
- The typical dosage range is 4.5 to 6 mg/kg PO q12h, titrated based on blood levels.

Chapter

175 Ferrets

Christine Ellis

Clinical Techniques

RESTRAINT

- Most pet ferrets are gentle, tractable, and are easy to restrain without assistance. Often only minimal restraint is needed when performing a physical examination. Some ferrets may be lightly restrained on the examination table. Others will need to be restrained in a firmer manner.
- Tractable ferrets can be lightly restrained on an examination or treatment table by placing one hand under the chest and lifting slightly.
- Energetic ferrets may be restrained by scruffing (Fig. 175-1). Use one hand to grasp the skin over the back of the neck and lift the ferret up, suspending all the limbs. Stroke the abdomen with a downward motion to relax the ferret. The ferret's back may be supported with the other hand, or the ferret may then be reclined along the forearm of the arm used to scruff the ferret. Most ferrets will become very relaxed, although some young ferrets and some females may resist.
- Firm restraint is often required when administering vaccinations or when performing treatment procedures. Control the head by scruffing, or by cupping the back of the ferret's neck and placing the thumb and fingers along the caudal border of the mandibles. Place the other hand over the pelvis to restrain the hindquarters on the table top with the hind legs underneath the body; do not pull the legs back.
- Aggressive ferrets, such as nursing females, kits, or ferrets raised with little human contact, are uncommon. Restrain these ferrets by the scruff of the neck, using the techniques previously described. Avoid using leather gloves, which are awkward. Use sedation if necessary.

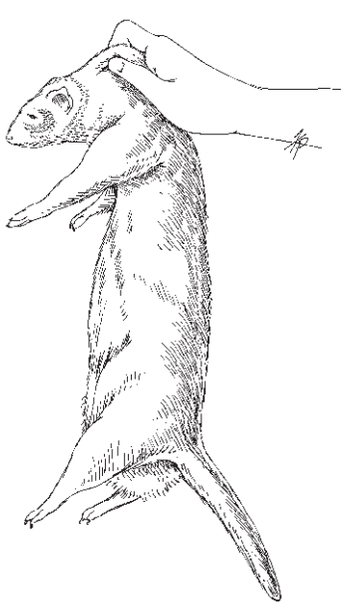

Figure 175–1. "Scruffing" a ferret for restraint.

DIAGNOSTICS

Blood Collection

There are several suitable sites for blood collection in ferrets:

- Cephalic vein
- Lateral saphenous vein
- Jugular vein
- Cranial vena cava
- Ventral tail artery

▼ ***Key Point*** Do not perform cardiac puncture or retro-orbital bleeding.

Indications

- Cephalic or lateral saphenous venipuncture may be used to obtain small amounts of blood (<1.0 ml) for a packed cell volume (PCV), blood glucose, complete blood cell count (CBC), or serum biochemistry analysis.
- The jugular vein, cranial vena cava, cephalic vein, or ventral tail artery may be used to collect larger volumes of blood.
- Use the jugular vein to collect blood for transfusion.

Table 175-1. REFERENCE RANGES FOR HEMATOLOGIC VALUES IN FERRETS

		Fitch Ferrets*		Albino Ferrets†	
Value	Sex	Range	Mean	Range	Mean
Hematocrit (%)	♂	46–57	49.1	44–61	55.4
	♀	47–51	48.4	42–55	49.2
Hemoglobin (g/dl)	♂	15.2–17.7	16.1	16.3–18.2	17.8
	♀	15.2–17.4	15.9	14.8–17.4	16.2
Red blood cells ($\times 10^6$/µl)	♂			7.30–12.18	10.23
	♀			6.77–9.76	8.11
Reticulocytes (%)	♂			1–12	4.0
	♀			2–14	5.3
White blood cells ($\times 10^3$/µl)	♂	5.6–10.8	7.3	4.4–19.1‡	9.7
	♀	2.5–8.6	5.9	4.0–18.2‡	10.5
Neutrophils	♂	616–7020/µl	2659/µl	11–82%	57.0%
	♀	725–2409/µl	1825/µl	43–84%	59.5%
Lymphocytes	♂	1728–4704/µl	3791/µl	12–54%	35.6%
	♀	1475–5590/µ	3426/µl	12–50%	33.4%
Monocytes	♂	0–432/µl	176/µl	0–9%	4.4%
	♀	100–372/µl	263/µl	2–8%	4.4%
Eosinophils	♂	112–768/µl	378/µl	0–7%	2.4%
	♀	50–516/µl	214/µl	0–5%	2.6%
Basophils	♂	0–112/µl	50/µl	0–2%	0.1%
	♀	0–172/µl	48/µl	0–1%	0.2%
Bands	♂	0–972/µl	233/µl		
	♀	0–248/µl	99/µl		
Platelets ($\times 10^3$/µl)	♂			297–730	453
	♀			310–910	545
Mean corpuscular volume (μm^3)	♂				54
	♀				61
Mean corpuscular hemoglobin (pg)	♂				17.6
	♀				19.9
Mean corpuscular hemoglobin concentration (%)	♂				32.2
	♀				32.8

*Males all castrated.
†Males all intact.
‡These white blood cell counts are higher than those currently seen in clinical practice. At our laboratories, the normal white blood cell count is $3–8 \times 10^3$/µl, and most are $4–6 \times 10^3$/µl.

Lab Anim 16:133–137, 1982; and Thornton PC, Wright PA, Sacra PJ, Goodier TEW: The ferret, *Mustela putorius furo,* as a new species in toxicology. Lab Anim 13:119–124, 1979. Copyrights 1979 and 1982, Macmillan Magazines Limited.

Other Considerations

- Sedation: Collection of blood from the jugular veins, cranial vena cava, or ventral tail artery may require sedation and/or the assistance of two people for restraint. Sedation is rarely required for venipuncture of cephalic, lateral saphenous, or jugular veins.
- If necessary, clip the hair over the venipuncture site to see the vein.
- The normal hematocrit of ferrets is high; draw three times as much blood as the volume of plasma or serum required. (See Tables 175-1 and 175-2 for blood values reported in normal ferrets.)
- The PCV, red blood cell count (RBC), hemoglobin, white blood cell count (WBC), and plasma proteins often rapidly decrease after induction of isoflurane anesthesia.

Techniques

Cephalic Vein

- Collect blood from the cephalic vein in ferrets using the same restraint technique described for dogs and cats.
- Use an insulin syringe with a 28-gauge needle or a 1cc tuberculin syringe with a 25-gauge needle to collect volumes of blood up to 1.0 ml. Larger volumes of blood may be collected with a 3cc syringe and a 25-gauge needle.
- Alternatively, place a 25-gauge needle in the vein and collect blood directly from the hub into small blood collection tubes.

Table 175-2. REFERENCE RANGES FOR SERUM BIOCHEMISTRY VALUES IN FERRETS

Value	Albino*	Fitch†
Total protein (g/dl)	5.1–7.4	5.3–7.2
Albumin (g/dl)	2.6–3.8	3.3–4.1
Glucose (mg/dl)	94–207	62.5–134
Fasting glucose (mg/dl)		90–125‡
Blood urea nitrogen (mg/dl)	10–45	12–43
Creatinine (mg/dl)	0.4–0.9	0.2–0.6
Sodium (mmol/L)	137–162	146–160
Potassium (mmol/L)	4.5–7.7	4.3–5.3
Chloride (mmol/L)	106–125	102–121
Calcium (mg/dl)	8.0–11.8	8.6–10.5
Phosphorus (mg/dl)	4.0–9.1	5.6–8.7
Alanine aminotransferase (U/L)		82–289
		78–149§
Aspartate aminotransferases (U/L)	28–120	57–248§
Alkaline phosphatase (U/L)	9–84	30–120
		31–66§
Bilirubin (mg/dl)	<1.0	0–0.1§
Cholesterol (mg/dl)	64–296	119–209§
Carbon dioxide (mmol/L)	16.5–28	16–28§

*Combined values of male (N = 40) and female (N = 24) ferrets from Thornton PC, Wright PA, Sacra PJ, Goodier TEW: The ferret, *Mustela putorius furo,* as a new species in toxicology. Lab Anim 13:119–124, 1979.
†Combined values of intact male, female, and castrated male ferrets (total N = 13, aged 4–8 mo) from Lee EJ, Moore WE, Fryer HC, Minocha HC: Haematological and serum chemistry profiles of ferrets *(Mustela putorius furo).* Lab Anim. 16:133–137, 1982, except where noted.
‡From Brown S: Personal communication, 1995.
§Combined values from cardiac and orbital venipuncture of male ferrets (N = 16) from Fox JG: Normal clinical and biologic parameters. In: Fox JG (ed): Biology and Diseases of the Ferret. Philadelphia: Lea & Febiger, 1988, pp 159–173.

Lateral Saphenous Vein

- The lateral saphenous vein runs diagonally across the lateral surface of the hindleg, just proximal to the hock.
- Use an insulin syringe with a 28-gauge needle or a 1-ml syringe with a 25-gauge needle to collect small blood samples (<1.0 ml).

Jugular Vein

- Several methods are described for jugular venipuncture:
  - The ferret may be placed in sternal recumbency at the edge of the table. Extend the head dorsally with the front legs held down, out of the path of the venipuncturist.
  - Alternatively, wrap the ferret in a towel with the front legs drawn back along the thorax, leaving the head and neck extended from the towel. Position the ferret in dorsal recumbency, and extend the head and neck by scruffing.
  - Restrain the ferret in the same manner described for the cranial vena cava (see below).
  - Ferrets that struggle should be sedated for this procedure.
  - Use a 1-ml or 3-ml syringe with a 25- to 22-gauge needle for sample collection.

Cranial Vena Cava

- This procedure is referred to as cranial vena cava venipuncture, but, in reality, blood is collected from the jugular vein as it passes into the thoracic cavity at the thoracic inlet.

▼ ***Key Point*** Blood collection from the cranial vena cava requires complete immobilization of the ferret; otherwise, do not attempt the procedure. Use sedation or the help of two assistants for restraint.

- Do not use this site if intrathoracic disease (e.g., mediastinal mass, mega-esophagus) or coagulopathy is suspected.

Technique

1. Place the ferret in dorsal recumbency. One assistant restrains the head and neck in extension while holding the forelegs alongside the thorax. A second assistant restrains the hindquarters without pulling the rear legs back. Precise positioning facilitates the procedure.
2. Palpate the manubrium and locate the "notch" on either side where the manubrium and the first rib meet.
3. Insert a 3-ml syringe with a 25-gauge, $^{5}/_{8}$-inch needle at either notch and direct the needle at a shallow angle (<45 degrees) along an imaginary line running from the notch toward the opposite rear leg.
4. Insert the needle to the hub and gently aspirate while withdrawing the needle.
5. If the ferret struggles, abort the procedure, and do not make a second attempt until the ferret is quiet. Ferrets that struggle persistently should be sedated for this procedure.

Ventral Tail Artery

- Venipuncture at this site may be painful.

Technique

1. Scruff the ferret and place it in dorsal recumbency (wrapping it in a towel may help with restraint), or anesthetize the ferret and place it in dorsal recumbency.
2. Prepare the site aseptically.
3. Use a 1- or 3-cc syringe and a 22- to 25-gauge needle for sample collection.
4. Insert the needle on the ventral midline of the tail at 30-degree angle toward the body approximately 2 to 3 cm from the anus.
5. Advance the needle to the bone; withdraw it slowly while applying a slight vacuum to the syringe.

6. Apply direct pressure to the site for several minutes after the needle is withdrawn.

Collection of Blood for Transfusion

A detailed discussion of the techniques used for blood collection for transfusion and blood transfusion is presented in the Hematopoietic System section in this chapter.

Diagnostic Imaging

Radiography

- Use standard radiographic techniques (see Chapter 4), including sedation for correct positioning and to limit exposure of the technician, as well as high detail radiographic film and cassettes.
- When interpreting films, it helps to think of the ferret as an elongated cat.
- The kidneys are relatively short (about two lumbar vertebrae in length).
- Splenomegaly is a common radiographic finding.
- For barium-contrast radiography of the gastrointestinal (GI) tract, give 15 ml/kg of 20% barium solution PO via syringe feeding or lavage tube. Most ferrets will accept syringe feeding of barium. Normal GI transit time is about 3 to 4 hours.

Ultrasound

- Echocardiography may be used to evaluate the heart in ferrets with suspected cardiac disease (see "Cardiovascular Disease").
- Other uses of ultrasound in ferrets include investigation of intra-abdominal or intra-thoracic masses, organomegaly, paraurethral cysts, or prostatic cysts.

Bone Marrow Aspiration

- The indications, guidelines, and techniques for bone marrow sampling are the same as those described for dogs and cats. (see Chapter 22)
- Preferred sites include the proximal femur and humerus. The iliac crest may be used for sample collection as well, but can be a difficult site to access.
- Sedation is required for bone marrow aspiration. Use a 20- or 22-gauge spinal needle with stylet for sample collection.

Splenic Aspiration

Fine-needle aspiration of the spleen has been performed successfully in ferrets and is a rapid means of evaluating splenic cytology. In ferrets, the only contraindication is suspected hemangiosarcoma of the spleen. Sedation is rarely necessary, but is recommended if the ferret persistently struggles.

Technique

1. Two assistants are recommended for restraint. Place the ferret in dorsal recumbency. One assistant should restrain the head and neck by scruffing the ferret with one hand. The other hand is used to restrain the forelimbs. A second assistant restrains the hind limbs by placing one hand around the pelvis.
2. Palpate the spleen and position it against the left lateral or ventral body wall.
3. Clip and prepare the site aseptically.
4. Insert a 25-gauge needle attached to a 3-ml syringe to the hub at a perpendicular angle to the skin and aspirate from the spleen.
5. When a small amount of bloody fluid is visualized in the needle hub, withdraw the needle and prepare slides routinely for cytology.

Cystocentesis

- Urine may be collected by cystocentesis using the same technique described for the cat.
- A 22- or 25-gauge needle on a 1- or 3-cc syringe may be used for sample collection.
- Anesthesia is recommended if the ferret is difficult to restrain.

THERAPEUTIC TECHNIQUES

Intravenous Therapy

▼ ***Key Point*** Sedation is often required for placement of a butterfly or indwelling intravenous (IV) catheter, or for small-volume IV therapy.

- For small-volume IV therapy (0.3–0.4 ml), use an insulin syringe. The cephalic or lateral saphenous veins are the preferred sites for injection. Sedation may not always be required for a single injection.
- A 25-gauge butterfly catheter may be used to administer larger, single-dose volumes into the cephalic vein.
- An indwelling catheter can be placed in the cephalic, lateral saphenous, or jugular vein. Sedation is usually required.
- Flush indwelling catheters with small volumes of heparinized saline solution to maintain catheter patency.
- Peripheral indwelling catheters can be placed rapidly and are useful in emergency situations and for surgery.

Cephalic or Saphenous IV Catheter Placement

Technique

1. Clip and prepare the site aseptically.
2. Tent the skin over the vein and make a small cut-down incision in the skin with a 22-gauge needle, taking care to avoid the vein.
3. Introduce a $^1/_4$–$^1/_2$ inch indwelling catheter (20–24 gauge) through the cut-down incision and into the vein.

4. When catheterizing small or debilitated ferrets it is often helpful to attach a tuberculin syringe containing heparinized saline to the catheter hub after removing the stylet. The heparinized saline may then be flushed through the catheter, dilating the vein while the catheter is advanced. The person holding off the vein must release the vein if this technique is used.
5. Cap the catheter and tape it in place routinely.

Jugular Catheter Placement

Technique

1. Sedation is required for placement.
2. Place the anesthetized ferret in dorsal recumbency. Clip and prepare the site aseptically. Make a small cut-down incision over the jugular vein as described previously.
3. Introduce a 20-gauge or smaller catheter into the vein. Suture in place and place a tape bandage around the neck.
4. Ferrets often do not tolerate jugular catheters. Jugular catheters are not used very often unless venous access is required for treatment purposes.

Intraosseous Catheter Placement

- Sedation is required for placement.
- The femur is the preferred site for IO catheter placement.

Technique

1. Place the anesthetized ferret in lateral recumbency. Clip and prepare the site aseptically.
2. Wearing a sterile surgical glove, palpate the top of the greater trochanter, and locate the trochanteric fossa.
3. Introduce the tip of a 20- or 22-gauge spinal needle with stylet in place into the trochanteric fossa, and advance the needle parallel to the long axis of the femur through the cortical bone and into the medullary cavity. Flush with heparinized saline.
4. Suture into place.

Subcutaneous and Intramuscular Injections

- Restrain the ferret by scruffing. Some ferrets may require two people for restraint.
- SC injections may be given in the loose skin over the shoulders.
- IM injections may be given in the quadriceps, the semimembranosus-semitendonosus muscles of the hind limbs, or in the expaxial muscles of the lower back.
- Limit the volume of the IM injections, due to the small muscle mass of the ferret.

Fluid Therapy

- Fluids may be administered SC, IV, or IO, depending on the needs of the patient.
- The daily fluid requirement for ferrets has not been reported but can be estimated at 70 to 100 ml/kg/day. Adjust for dehydration and fluid loss.
- Administer SC fluids over the dorsal shoulder and thoracic region.
- IV or IO fluid therapy is used for a wide range of medical and surgical situations, and is recommended for ferrets that are >5% dehydrated.
- IV or IO fluids must be administered with an infusion pump. Fluids may be given as a continuous infusion, may be administered by continuous infusion, or may be given in 2 to 3 bolus doses over a 24-hour period.
- Ferrets may require the addition of dextrose to fluids because hypoglycemia is common.

Oral Therapy

- Oral medications are most easily given to ferrets in liquid form.
- If possible, compound medications formulated in tablet or capsule form into liquid suspensions, or crush and mix them with a sweet-tasting substance such as Nutri-Cal (Evsco Pharmaceuticals) feline hairball laxative, or fruit-flavored syrup, and administer by syringe.
- Ferrets suffering from insulinoma should not be given sugar-based treats or medications if at all possible. Hide medications in fatty acid supplements, vegetable oil, whipping cream, or meat baby food.

Nutritional Support

- Supplemental feeding is important in the management of anorectic or critically ill ferrets, and in the treatment and prevention of hypoglycemic episodes associated with insulinoma.
- Most ferrets can be force-fed dietary supplements by syringe. Once they acquire a taste for a given supplement, it may be possible to offer it in a bowl.
- Feed ferrets as much food as they will take comfortably (12–25 ml) 2 to 4 times daily.
- Foods useful for force-feeding include the following: meat baby foods, slurried cat or ferret food, and Science Diet A/Dliquid soy-based formulas (e.g. Deliver 2.0, Mead Johnson Nutritionals) may be added to the mixture to increase the calorie content and improve palatability.

Drug-Dosing Guidelines

- Use of all medications is considered off-label for the ferret; there are no approved drugs available for ferrets in the United States.

- Several exotic animal formularies are commercially available that include drug dosage information on ferrets.
- When dosing information is not available, use feline dosages with the following exceptions:
  - *Chloramphenicol*: (50 mg/kg) bid, IV, SC, IM, or PO.
  - *Aspirin*: (10–25 mg/kg) bid–tid PO (canine dosage).
- Many ferrets become lethargic when placed on enalapril (Enacard, Merck Agvet) for cardiac disease. Start with a very low dose (0.25–0.5 mg/kg) q48h PO. Some ferrets cannot tolerate more than every-other-day therapy.
- *Ivermectin* (0.06 mg/kg) q30d PO for heartworm prevention; (0.05 mg/kg) once 3 to 4 weeks after adulticide treatment as a heartworm microfilaricide; (0.50–1.0 mg/kg) PO, SC, repeat in 14 days for sarcoptic mites; (1mg/kg) instill half the calculated dose into each ear and repeat in 14 days for ear mites.

Blood Transfusions

A detailed discussion of the techniques used for blood collection for transfusion and blood transfusionis presented in the Hematopoietic System section in this chapter.

Urinary Catheterization

- Sedation or isoflurane anesthesia facilitates urinary catheterization. The procedure may be difficult in ferrets with urethral disease or urethral calculi.

Males

1. Position in dorsal recumbency and prolapse the penis from the prepuce.
2. Identify the urethral opening, which lies ventral to the tip of the penis. It is helpful to place a 24-gauge IV catheter (with stylet removed) into the urethral opening as a guide.
3. Use a ferret urinary catheter (Slippery Sam ferret urinary catheter, Cook Veterinary Products) an open-ended tomcat catheter, or a #3.5-Fr. feeding catheter. A wire stylet may be useful.
4. Suture into place.

Females

1. Position in ventral recumbency with the hindquarters elevated and use a tomcat catheter or a 3.5-Fr. feeding tube with or without a stylet.
2. The urethral orifice is located on the ventral floor of the vaginal vault. Catheterize the urethra blindly or after identification using a vaginal speculum.

Ferrets with urethral disease

- The catheter may only pass part way into the urethra (often to the pelvic flexure). This may be sufficient to allow retrograde flushing of urethral calculi into the bladder, or to empty the bladder of a ferret with urethral obstruction secondary to prostatic enlargement.

Sedation

▼ ***Key Point*** Isoflurane administered by face mask is the most convenient method to immobilize a ferret for procedures such as venipuncture and radiography. Induction and recovery are rapid.

Doses for parenteral agents used in ferrets are listed in Table 175-3.

- Acepromazine is useful for sedation.
- Butorphanol tartrate has been used at SC, IM, IV, but can cause very profound sedation in some ferrets.
- Ketamine alone does not produce effective muscle relaxation. Use in combination with acepromazine for minor surgical procedures, or with diazepam for more complicated procedures.
- Medetomidine is not analgesic; animals will respond to painful stimuli. Use with an analgesic agent. This agent is reversible (atapamazol).
- Tiletamine-zolazepam (Telazol, Fort Dodge) gives variable muscle relaxation but is useful for immobilization for procedures such as venipuncture, radiography, and electrocardiography. Recovery may be prolonged.
- Xylazine may cause bradycardia or vomiting, and is not recommended for use.

Anesthesia and Analgesia

- Premedicate with parenteral agents followed by facemask induction. Alternatively ferrets may be given

Table 175-3. DRUGS RECOMMENDED FOR CHEMICAL RESTRAINT AND ANALGESIA OF FERRETS

Drug	Dosage (mg/kg)	Route
Chemical Restraint		
Acepromazine	0.1–0.3	IM, SC
Ketamine	25–35	IM, SC
plus acepromazine*	0.2–0.3	
Ketamine	25–35	IM
plus diazepam	2–3	
Ketamine	10–25	IM
plus xylazine	1–2	
Analgesics		
Buprenorphene	0.01–0.03 mg/kg q8–12h	SC, IM, IV
Butorphanol tartrate	0.05–0.5 mg/kg q8–12h	SC, IM
Carprofen	1 mg/kg q12–24h	PO
Flunixin meglumine	0.5–2.0 mg/kg q12–24h	IM, IV

*Use this combination for minor surgery.
IM, intramuscular; SC, subcutaneous.

inhalant agents without premedication via chamber or face-mask induction.
- Isoflurane is the inhalant anesthetic most commonly used in small mammal practice. Sevoflurane is used in some practices as well. Pharmacokinetic and pharmacologic isoflurane and sevoflurane are very similar; sevoflurane smells better and is better tolerated during face-mask induction.
- Isoflurane does not provide analgesia. Administer an analgesic pre- or intra-anesthesia if a painful procedure is to be performed. Analgesic agents commonly used in ferrets include Buprenorphene (0.01–0.03 mg/kg q8–12h SC, IM, IV), Butorphanol (0.05–0.5 mg/kg q8–12h SC, IM), Carprofen (1 mg/kg q12–24 PO), and Flunixin meglumine (0.5–2.0 mg/kg q12–24h IM, IV).
- Intubate ferrets to facilitate intermittent positive pressure ventilation (IPPV). A 2.5 to 3.5 mm endotracheal tube usually is suitable.
- The same planes of anesthetic depth reported for dogs and cats occur in the ferret.
- Follow basic principles of anesthesia for small animals, (see Chapter 2) and provide supplemental heat during surgery; administer IV fluids (isotonic electrolyte solutions supplemented with 2.5–5% dextrose) during long procedures and for insulinoma surgery.

Infectious Diseases of the Ferret

VIRAL DISEASES

Canine distemper and influenza are the two most common viral diseases of the ferret. Influenza is zoonotic between humans and ferrets, and is typically passed from humans to ferrets. Canine distemper is 100% fatal in the ferret, making distemper vaccination imperative.

Canine Distemper

Etiology

- The canine distemper virus (CDV) is a paramyxovirus. Transmission occurs through direct contact with infected animals of any species, and through contact with fomites such as in shoes or clothing.
- The incubation period for CDV in the ferret is typically 7 to 10 days; however, incubation for some strains of CDV may take up to 21 days. (For discussion of CDV in dogs, see Chapter 13).

Clinical Signs

- Early in the disease the only clinical sign may be a mild unilateral or bilateral conjunctivitis.
- Pyrexia (>40°C), anorexia, and profuse mucopurulent naso-ocular discharge develop as the disease progresses.

▼ ***Key Point*** Ferrets develop a distinct pattern of hyperkeratosis of the integument of the chin, lips, and footpads. Lesions may occur in the rectal and inguinal areas as well.

- Other clinical signs include central nervous system (CNS) abnormalities, diarrhea, and severe depression.

Diagnosis

▼ ***Key Point*** Preliminary diagnosis of CDV may be based primarily on the history, physical examination, and clinical signs, which are unlike those of any other disease in the ferret.

- The history often reveals that the animal is unvaccinated, overdue for booster vaccination, or is improperly vaccinated. There is often no evidence of direct exposure to an infected animal because fomite transmission can occur.
- Differential diagnoses early in the disease include influenza and bacterial conjunctivitis. As the disease progresses, development of the integumentary lesions around the chin, lips, and footpads are pathognomonic.
- A fluorescent antibody test can be performed on blood smears, conjunctival scrapings, or mucous membrane scrapings. This test is only useful in the first days of disease onset; false-negative results are common. Modified live vaccine strains of canine distemper will not affect this test.
- Plasma samples can be submitted to measure antibody titer. A positive result is not always diagnostic of disease because both infected and vaccinated ferrets can have a positive titer. Unvaccinated ferrets with a positive titer are likely infected with CDV.
- Fluorescent antibody staining may be performed on imprints of the lymph nodes, bladder epithelium, and cerebellum postmortem.
- Histopathologic diagnosis may be possible via identification of inclusion bodies in the cytoplasm or nucleus of epithelial cells of the trachea, urinary bladder, skin, gastrointestinal tract, lymph nodes, spleen, and salivary glands.

Treatment

▼ ***Key Point*** Treatment for canine distemper is rarely effective, and is limited to supportive care only. Most affected animals must be euthanized.

- Disinfect the household thoroughly using 0.2% Roccal (Upjohn), 0.75% phenol, or 2% to 5% sodium hydroxide.
- In multiple animal households, remove all clinically affected animals. Vaccinate the remaining animals immediately.

Prevention

▼ ***Key Point*** Preventing infection by vaccination is crucial in pet ferrets, since treatment is not effective.

- Vaccinate all ferrets in the household or facility. Currently only two vaccines are approved for use in ferrets: PureVax (Merial, Athens, GA), and Fervac-D (United Vaccines, Inc., Madison, WI). Give 1 ml SC, using the following schedule:
- If the dam is vaccinated: Vaccinate kits at 8 weeks of age and repeat vaccination every 3 to 4 weeks until the kits are 16 weeks of age.
- If the dam is unvaccinated: Vaccinate the kits at 6 weeks of age and repeat every 3 to 4 weeks until the kits are 16 weeks of age.
- Revaccinate annually. Sources claim that immunity lasts for 3 years; however, outbreaks have been known to occur 18 months after vaccination.
- Use of serum titers as a method to evaluate an animal's current immunological status is unsubstantiated.
- Quarantine new ferrets and canines for 4 weeks before exposure to other resident animals. Vaccinate new animals immediately after acquisition at the beginning of the quarantine period.
- Use of Galaxy D (Schering-Plough Animal Health Co., Omaha, NE) for distemper vaccination has been described. Use of this product in ferrets is extra-label. This product has proved effective in preventing canine distemper in young ferrets; however, duration of immunity is unknown.
- Do not use CDV vaccines that contain canine parvovirus, adenovirus, or other viruses. It is not necessary to vaccinate for leptospirosis unless there is exposure to wild rodents.

Influenza

Etiology

The influenza virus is an orthomyxovirus. Ferrets are susceptible to influenza A and B; this is the only documented zoonotic disease of the ferret. Human-to-ferret transmission is more common than ferret-to-human transmission. Transmission occurs by direct contact with naso-ocular discharges, and via inhalation of aerosolized droplets.

- The incubation period is typically 2 to 10 days post-exposure.
- The clinical course of the disease is typically 7 to 14 days.

Clinical Signs

▼ ***Key Point*** Influenza typically causes only mild illness and discomfort, and is usually self-limiting in an otherwise healthy animal.

- Clinical signs may include any combination of the following:
  - Sneezing with a clear, serous nasal discharge.
  - Mild conjunctivitis with serous ocular discharge. Crusting around the eyes may occur rarely.
  - A nonproductive cough that may be loud and paroxysmal, and often occurs more frequently at night.
  - Diarrhea. Vomiting may occur in rare cases.
  - Partial to total anorexia, listlessness, and fever.
  - Pneumonia, severe illness, or death may occur in neonates, geriatric patients, and in ferrets with concurrent diseases such as lymphosarcoma or insulinoma.
- Ferrets with underlying immunosuppressive disorders, especially lymphosarcoma, may develop repeated or cyclic episodes of influenza. Rule out lymphosarcoma by performing a complete blood cell count (CBC), bone marrow biopsy/cytology, or a peripheral lymph node biopsy (see Lymphoma in this chapter).

Diagnosis

Diagnosis is based primarily on the clinical signs, history, and physical examination.

- The history often indicates recent exposure to a human or another ferret with influenza or signs of upper respiratory tract disease.
- The overall physical condition often remains good, although slight or moderate dehydration may be present if the animal is not eating or drinking normal amounts.
- Differential diagnoses include the very early stages of canine distemper, GI rotavirus infection, and lymphosarcoma. If mucopurulent nasal or ocular discharge is noted, consider early CDV or a secondary bacterial infection.

Treatment

- Supportive care generally is sufficient.
  - Encourage the ferret to eat and drink. Offer 1 to 3 tablespoonfuls of Hill's Science Diet A/D or strained meat baby food bid–qid if the animal refuses the regular diet.
  - If indicated, give an oral electrolyte solution that is palatable to ferrets.
- If sneezing or coughing is excessive and interferes with eating or sleeping, give an antihistamine such as chlorpheniramine (1.0–2.0 mg/kg) bid–tid PO, or diphenhydramine (0.5–2.0 mg/kg) bid–tid PO. Nasal solutions containing phenylephrine may be used to relieve nasal congestion.
- Antibiotics are not necessary unless secondary bacterial infection is present.
- Antiviral medications such as amantadine (6mg/kg) bid PO (Symmetrel, ENDO Pharmaceuticals, Chadds

Ford, PA) may be useful in the treatment of ferrets with influenza. Zanamivir (12.5 mg/kg) once intranasally (Relenza, GlaxoSmithKline, Research Triangle Park, NC) has been shown experimentally to prevent influenza infection.

Prevention

Good hygiene is the key to prevention.

- Discuss the zoonotic potential with the client. Advise clients to wash their hands frequently, and to avoid holding the ferret near the face.
- In the veterinary hospital, do not allow influenza-infected personnel to handle ferrets, especially if the animal is a neonate, a geriatric patient, or a patient debilitated by serious disease.
- Vaccination is not recommended; only short-term immunity results, and the wide variation of the influenza virus makes appropriate vaccination difficult.

Rabies

Etiology

Rabies is caused by a rhabdovirus that results in fatal disease in ferrets. It is transmitted via contact with an infected animal's saliva (see Chapter 15). This is a zoonotic disease; however, there has never been a report of ferret-to-human rabies transmission. Experimentally, the incubation period is 28 to 33 days.

Clinical Signs

▼ ***Key Point*** Very little is known about rabies in naturally infected ferrets.

- It is known that ferrets may become naturally infected; however, there is some question as to how easily they can contract the disease and the length of the incubation period. Information about clinical signs is derived primarily from literature associated with laboratory-infected ferrets. Signs are variable and include:
  - Behavioral abnormalities that range from anxiety and hyperactivity to lethargy.
  - Neurologic signs such as ascending paralysis, ataxia, hyperparesthesia, and posterior paresis.

Diagnosis

Diagnosis is based on clinical signs, and/or a history of known or potential exposure to rabies.

- History may include a recent bite wound or exposure to a rabid animal.
- The ferret may be unvaccinated; however, development of rabies in vaccinated individuals has occurred in other animal species.
- Differential diagnoses include Aleutian disease, botulism, brain hypoxia from severe seizures, CNS neoplasia, insulinoma, intervertebral disc disease, and viral or bacterial encephalitis.
- Postmortem laboratory testing of brain tissue (fluorescent antibody staining [FAS] or virus isolation) confirms the diagnosis (see Chapter 15).

Treatment

- There is no treatment for rabies.
- Euthanize the suspect animal to protect humans and other animals in its environment. Submit animal for postmortem FAS testing of brain tissue.

▼ ***Key Point*** It has not been demonstrated that ferrets are carriers of rabies. Many public health facilities now recognize and accept the 10-day quarantine period for ferrets; however, in some states, unvaccinated ferrets involved in biting incidents will be euthanized and submitted for rabies testing. It is important to be familiar with state and local laws regarding vaccination requirements and the laws following a biting incident.

▼ ***Key Point*** The Compendium of Animal Rabies Prevention and Control recommends that ferrets be confined and observed for 10 days following human exposure. If signs compatible with rabies develop, the animal should be euthanized and protocols for rabies testing should be followed. Vaccinated ferrets exposed to a potentially rabid animal should be revaccinated and quarantined for 45 days. Euthanize any unvaccinated ferret exposed to a rabid animal.

Prevention

- Vaccination is the only prevention, and is mandatory in some states.
- Imrab 3 (Rhone Merieux) is an inactivated rabies vaccine that is currently the only rabies vaccine approved for use in ferrets. Administer at a dose of 1 ml SC.
- Vaccinate initially at 3 months of age. Revaccinate annually.

Aleutian Disease

Etiology

Aleutian disease (ADV) is caused by a parvovirus that affects both mink and ferrets. Transmission occurs by direct contact or via contact with fomites contaminated with any infected body fluid, including blood.

ADV produces a progressive immune-mediated disease accompanied by the deposition of antigen-antibody complexes in multiple organs of the body. The virus is prevalent in the ferret population, but the percentage of ferrets that develop clinical illness is low. In

one survey of 700 ferrets, 10% were serologically positive, but only two animals developed clinically active disease. Some ferrets may be asymptomatic carriers, while others may have natural immunity to the disease.

Clinical Signs

▼ ***Key Point*** The clinical signs of Aleutian disease are extremely variable, and the incubation period can be as short as 1 day or as long as 90 to 200 days.

- Ataxia, mild incoordination, posterior paresis, or tremors may be the initial presenting signs. Initially ferrets often continue to eat, and appear bright and alert. As the disease progresses, paresis progresses to the forelimbs, and wasting develops that may continue for weeks or months.
- Anorexia, lethargy, melena, and urinary incontinence are seen in later stages of the disease.
- A slow wasting disease existing without neurologic signs may also occur.

Diagnosis

- Diagnosis may based on the history, clinical signs, physical examination findings, the presence of high serum total protein and hypergammaglobulinemia, and a positive ADV test. Diagnosis is confirmed with histopathology.
- Differential diagnoses include bacterial or viral encephalitis, CNS neoplasia, canine distemper, lymphosarcoma, gastric foreign body, tuberculosis, intervertebral disc disease, systemic mycoses, and rabies (in cases with behavioral changes and sudden paralysis).
- Exposure history is often not helpful because of the prevalence of asymptomatic carriers.
- High serum total protein may be present. Serum protein electrophoresis may demonstrate hypergammaglobulinemia (>20% of the total serum protein).
- Blood samples may be submitted for counterimmunoelectrophoresis testing (United Vaccines, Inc., Madison, WE) or enzyme-linked immunosorbent assay (ELISA) testing (Avecon Diagnostics, Bath, PA). An in-house saliva sample kit is available as well (Avecon Diagnostics, Bath, PA).
- Histopathology demonstrates lymphocytic plasmacytic infiltration and perivascular cuffing in many organ systems. The kidneys, liver, lymph nodes, and spleen are often affected.

Treatment

▼ ***Key Point*** There is no effective treatment for Aleutian disease. Provide supportive care and do not allow contact between clinically ill animals and healthy ferrets. Euthanasia is usually indicated only for clinically affected animals.

- Asymptomatic ferrets that test FAS-positive for ADV should not be euthanized because they may never become clinically ill. Infected ferrets may remain asymptomatic for life, but can remain persistently infected. Other ferrets may develop nonpersistent, self-limiting disease and fully recover.
- Administration of corticosteroid therapy and supportive care may prolong the life of some ferrets with clinically active disease.

Prevention

Breeding colonies

- Breeding colonies should be closed. New animals should be ADV tested and quarantined prior to introduction.
- Test all resident ferrets and remove serologically positive animals from the population.
- ADV-negative animals should be retested in 6 months, before adding them to the colony, due to the potentially long incubation period.

Pets

- It is not necessary to test a pet ferret unless it has been exposed to a clinically ill animal.
- It is not necessary to euthanize a clinically normal, non-breeding ADV-positive ferret or remove it from contact with other pet ferrets. Advise the client, however, that there is a slight possibility that the pet may develop clinical illness.
- Do not house ferrets in close proximity to mink.
- Retest ADV-positive animals in 6 months since some animals may eventually eliminate the virus and become negative.

Rotavirus

Rotavirus causes gastrointestinal infection and a bright green or yellowish-green diarrhea. Rotavirus is described in the "Gastrointestinal System" section in this chapter.

Lymphosarcoma

Lymphosarcoma is common in the ferret, and is discussed in the "Neoplasia" section in this chapter.

BACTERIAL DISEASES

Common Bacterial Infections

Etiology

Staphylococcus, Streptococcus, Escherichia coli, and other common bacteria from the environment can be introduced through penetrating wounds, punctures, abrasions, contact with mucous membranes, and by inhalation or ingestion.

- Abscessation is an uncommon form of bacterial infection in ferrets.

Clinical Signs

- An abscess may occur in any part of the body, including the anal glands, mammary tissue, mouth, mucous membranes, reproductive tract, respiratory tract, subcutis, and prostatic tissue.
- Body temperature may be ≤40°C if bacterial sepsis is present.
- Bacterial dermatitis causes thickened, irritated areas of skin. Affected ferrets may lick and chew these areas until they become denuded and ulcerated.
- Bacterial conjunctivitis causes a thick mucopurulent ocular discharge and swelling of the conjunctiva; corneal ulcerations may be present.
- Bacterial pneumonia causes lethargy, fever, anorexia, and dyspnea, and is often accompanied by mucopurulent nasal discharge and coughing.
- Bacterial mastitis occurs primarily in the lactating jill, and is accompanied by depression, fever, and anorexia. One or more mammary glands are swollen, discolored, and warm to the touch.
- Bacterial metritis may or may not cause a vaginal discharge; depression, fever, and partial or total anorexia are often present.
- Bacterial vaginitis causes a thick mucopurulent yellow-to-green vaginal discharge with little odor. Fever is usually absent, and the animal does not appear clinically ill.

Diagnosis

- Presumptive diagnosis is based on clinical signs, physical examination, demonstration of bacteria on routine cytology, results of bacterial culture, and sensitivity of the affected sites. The total WBC may demonstrate a marked leukocytosis (>10,000).

Treatment

- Treatment should consist of appropriate antibiotic therapy based on culture and sensitivity results, and surgical drainage or excision of the affected tissue when appropriate.
- Begin treatment with a broad spectrum antibiotic pending the results of culture and sensitivity testing, or when obtaining a culture is not feasible.
- Provide supportive treatment as needed, such as fluid therapy and nutritional support.

Specific Treatment

Cutaneous Abscesses

- Lance and thoroughly flush with an antiseptic solution. Keep the area open and flush twice daily until healing occurs by second intention.
- Administer oral antibiotics until signs of infection are gone and a healthy bed of granulation tissue is present.

Mastitis

See Mastitis in the Reproductive Disease section in this chapter.

Uterine Infection (Metritis, Pyometria)

See Uterine Infection in the Reproductive Disease section in this chapter.

Respiratory Tract (Pneumonia)

- If possible, perform a tracheal wash and submit samples for cytology, bacterial culture, and sensitivity testing.
- If pleural effusion is evident on radiography, perform thoracocentesis. Submit samples for cytology, bacterial culture, and sensitivity testing.
- Start oral broad-spectrum antibiotic therapy immediately, pending culture and sensitivity results. If pleural effusion is present, consider treating with a combination of clindamycin and cephalosporins (use cat dosages).
- Use of bronchodilating agents and/or nebulization therapy may be beneficial treatment modalities as well.

Conjunctivitis

- Treat conjunctivitis with a broad-spectrum ophthalmic ointment.
- Perform a fluorescent corneal staining test to rule out corneal ulcers. (see Chapter 133)

Anal Gland Infection

- Submit samples for bacterial culture and sensitivity testing.
- Begin treatment with broad-spectrum oral antibiotics. Modify treatment based on culture sensitivity results.
- Instruct owners to hot pack the affected area 5 to 10 minutes bid–tid.
- Treat until infection and swelling resolve, then perform anal sacculectomy.
- Continue antibiotic treatment 10 to 14 days postoperatively.

Campylobacteriosis Infection

- *Campylobacter* spp. typically causes GI disease (see "Gastrointestinal System").

Salmonellosis

- *Salmonella* spp. may rarely cause gastroenteritis in ferrets (see "Salmonella" within "Gastrointestinal System").

Botulism

- Botulism is a rarely encountered disease in the domestic ferret caused by the ingestion of food contaminated with the *Clostridium botulinum* toxin. *C. botulinum* is commonly found in the soil.
- Uncooked food or food contaminated with soil can be the source of the infection.

Tuberculosis

- Clinical cases of tuberculosis in the ferret are reported infrequently; however, ferrets are susceptible to bovine, avian, and human *Mycobacterium* spp. infections.
- The disease can be transmitted by ingestion of contaminated meat (poultry or meat), unpasteurized milk, or food contaminated by the droppings of infected wild or pet birds (see Chapter 19 for information about tuberculosis in dogs and cats).
- Clinical signs include chronic weight loss, and diarrhea that is unresponsive to treatment. Vomiting may occur as well in some cases.
- Diagnosis is based on history, clinical signs, and the exclusion of other diseases; it is confirmed by intestinal biopsy. Histopathologically granulomatous inflammation and acid-fast bacteria are identified. Infection may also be confirmed by culturing the organism, and with polymerase chain reaction (PCR) testing.
- Because of the zoonotic potential of this disease, treatment is not recommended. Affected animals should be euthanized.

FUNGAL INFECTIONS

Dermatophytosis

Etiology

Dermatophytosis is rare in the ferret and is typically caused by *Microsporum canis* and *Trichophyton mentagrophytes*. Dermatophytes are transmitted by direct contact with infected animals or contaminated bedding, caging, and fomites.

▼ ***Key Point*** Ferrets are usually not carriers of these organisms. Clinical disease is typically self-limiting. The most common source of infection of the pet ferret is the household cat.

Clinical Signs

- Young, debilitated, or geriatric ferrets are the most commonly affected.
- Lesions are consistent with those described in other species (see Chapter 42). Alopecia with erythema, inflammation, hyperkeratosis, superficial crusting, lichenification, and erythema are present. Pruritis is common and may lead to self-trauma and secondary pyoderma.

Diagnosis

- Diagnosis is based on the identification of the fungal agent on skin scrapings, fungal culture, or a positive Wood's light examination (*M. canis*). (see Chapter 42).

Treatment

- Dermatophytosis is often self-limiting and may resolve without therapy. However, due to the zoonotic potential, treatment is recommended.
- Topical treatment includes the use of keratolytic shampoos, and/or lime sulfur dips. (see Chapter 42).
- Oral therapy consists of the administration of griseofulvin (25 mg/kg) PO sid for 21 to 30 days. Perform a CBC every 14 days while the ferret is receiving treatment.
- Disinfect the home by steam cleaning, the application of dilute (1:10) bleach or chlorhexidine solutions, and vacuuming thoroughly to remove infectious spores. Dispose of the vacuum cleaner bag after vacuuming is complete. A thorough cleaning of the heat ducts and air conditioner/heater filters is also recommended.

Other Fungal Infections

Systemic mycoses are rare in the ferret; however blastomycosis, histoplasmosis, cryptococcosis, coccidioidomycosis, and aspergillosis have been reported.

- Consider these infections in the differential diagnosis of any systemic disease that is refractory to treatment and involves wasting, granulomatous lesions, persistent or recurring draining wound tracts, and respiratory tract disease.
- Diagnosis is based on the histopathological or cytological demonstration of the fungal organism in biopsies or aspirates (see Chapter 20).
- Complement fixation and precipitation tests have been used with variable success.
- Treatment is the same as described for the dog and cat (see Chapter 20).

Hematopoietic System

SPLENOMEGALY

Primary disease of the spleen is uncommon. Splenomegaly is often a common incidental finding in a healthy adult ferret, or it may occur in association with

a wide variety of disease conditions. Perform a complete medical evaluation in all splenomegaly cases.

Etiology

- Splenomegaly may be a normal or incidental finding in some patients.
- Pathological causes of splenomegaly may include chronic immune stimulation, erythroid bone marrow insufficiency, extra-medullary hematopoiesis (EMH), hypersplenism, heart disease, and neoplasia.
- Splenomegaly can occur concurrently with adrenal gland disease and insulinoma, but it is usually an incidental finding.
- *Extramedulllary hematopoiesis (EMH)* may cause enlargement of the spleen. The etiology of EMH is unclear; compensation for myeloid insufficiency and chronic immune stimulation have been suggested as causes. Ferrets with EMH typically do not show evidence of hematological abnormalities. Grossly the spleen has a normal shape and color, but it appears enlarged.
- *Hypersplenism* may cause enlargement of the spleen, but is rare in the ferret.
  - Destruction of one or more blood cell lines by the splenic reticuloendothelial system occurs; affected ferrets will have anemia, leukopenia, thrombocytopenia, or pancytopenia.
  - Bone marrow may be normal or hyperplastic in affected patients.
- *Lymphoma* is the most common neoplasia of the ferret spleen. Hemangioma or hemangiosarcoma may occur as well.
  - When splenic lymphoma is present the spleen typically has irregular borders and a nodular texture. White or tan nodules may be noted grossly on the surface of the spleen and in the parenchyma. Metastasis may be present.
- *Splenic torsion* and *abscessation* are rare in the ferret.

Clinical Signs

- The normal ferret spleen measures approximately 5 cm × 2 cm × 1 cm, and may be palpated in the left cranial abdominal quadrant. The texture of the spleen should be slightly firm, smooth, and the edges should be sharp.
- An enlarged spleen is often noted on abdominal palpation as a firm, elongated smooth mass extending down the left side of the ferret abdomen, or crossing diagonally across the ventral abdomen from the left cranial abdominal quadrant to the caudal right abdominal quadrant.
- Abdominal distention may occur.
- Occasionally the spleen is so large and pendulous that the ferret can barely lift its abdomen off the ground.
- Abdominal discomfort due to splenomegaly appears to be uncommon in ferrets.

Diagnosis

- Perform a CBC, platelet count, serum biochemical analysis, bone marrow cytology, and whole body radiography.
- Diagnosis of hypersplenism is based on the presence of one or more cytopenias, normal to hypercellular bone marrow cytology/biopsy, and the absence of blood loss, infection, or neoplasia.
- Obtain whole body radiographs to delineate the borders of the spleen and to rule out other abnormalities such as cardiomegaly or hepatomegaly that may contribute to splenomegaly.
- Splenic aspiration or biopsy may be performed. Perform fine-needle aspiration of the spleen using a 25-gauge needle (see "Clinical Techniques"). Do not perform splenic aspiration if hemangiosarcoma is suspected.
- Perform an abdominal ultrasound to evaluate the spleen. When the splenic parenchyma appears irregular, an ultrasound-guided biopsy or fine-needle aspiration may be performed.
- Perform a splenic biopsy during abdominal exploratory surgery, particularly if the spleen is irregular or discolored.

Treatment

Treatment depends on the primary disease condition. Usually splenectomy is not necessary.

▼ ***Key Point*** Indications for splenectomy are the same as for other species and include hypersplenism, splenitis, splenic abscess, torsion, rupture, neoplasia, and discomfort caused by excessive splenomegaly.

- To perform a splenectomy, follow the surgical guidelines for splenectomy in dogs and cats (see Chapter 25).
- Anemia may result after splenectomy; the decision to perform splenectomy should be made cautiously, and with consideration to the health of the ferret as a whole.
- Administer antibiotics and fluid therapy pre- and postoperatively.
- Monitor asymptomatic ferrets with splenomegaly with periodic physical examination, CBC evaluation, imaging, and splenic aspiration.

ANEMIA

The clinical approach to anemia in ferrets is the same as for other species. Anemias are classified as regenera-

tive or nonregenerative; treatment is directed at the specific cause.

Etiology

There are many causes of anemia in ferrets; decreased erythropoiesis, destruction of red blood cells, and blood loss contribute to anemia.

- *Nonregenerative anemia* (normocytic, normochromic, nonregenerative anemia) occurs when bone marrow hematopoiesis is disrupted. Bone marrow cytology of affected ferrets may appear normal.
  - Decreased erythropoiesis may be caused by chronic metabolic disease (renal, hepatic), chronic inflammation, hyperestrogenism, bone marrow suppression, and neoplasia.
  - Anemia of chronic disease can occur whenever long-term illness is present and is caused by decreased erythrocyte survival, decreased availability of iron, or a decreased response to the anemia treatment.
  - Anemia associated with chronic inflammation is mediated by sustained inflammatory cytokine release.
  - Hyperestrogenism may cause nonregenerative anemia due to estrogen-induced bone marrow suppression. Unspayed female ferrets, female ferrets with ovarian remnants, or hyperestrogenism associated with chronic adrenal disease may contribute to this syndrome.
  - Myeloid and leukemic neoplasias can cause suppression of bone marrow erythropoiesis due to replacement of normal bone marrow by neoplastic or fibrotic changes.
- *Erythrocyte destruction* may cause anemia; causes include immune-mediated disease, toxins, parasitism, or septicemia.
  - Idiopathic immune-mediated hemolytic anemia, and immune-mediated hemolysis secondary to viral disease or blood parasites have not been reported in the ferret.
  - Drug-induced hemolysis and heavy metal toxicosis (including zinc) are potential causes of hemolytic anemia.
- *Anemia secondary to blood loss* may be secondary to trauma, hemostatic disorders, bleeding lesions, and parasitism.
  - Bleeding lesions may be internal or external.
  - Bleeding ulcers may lead to anemia, and may be associated with *H. mustelae* gastritis, gastrointestinal foreign body, or chronic use of ulcerogenic drugs.
  - Parasitism is uncommon in the ferret. Coccidiosis in the young ferret or severe flea infestation may cause anemia.
  - Hemostatic disorders include thrombocytopenia associated with estrogen toxicity, rodenticide poisoning, and liver disease.

Clinical Signs

- Clinical signs include weakness, pallor, lethargy, and inappetence. Jaundice may be seen if hemolysis is present.
- A soft systolic murmur is common in anemic ferrets.
- A swollen vulva is present in ferrets with persistent estrus, an ovarian remnant, and in some cases of adrenal gland disease. Hair loss may also be present on the shoulders and flanks.
- Ferrets with estrogen toxicity may have signs of thrombocytopenia such as petechiae, ecchymoses, and melena.
- Melena may be noted if GI bleeding is present.
- Palpate the spleen. Splenomegaly may be caused by hypersplenism and subsequent anemia.
- Check carefully for fleas. Perform a fecal examination.

Diagnosis

- Diagnosis is based on the medical history, the physical examination findings, and a complete diagnostic work-up that includes a CBC, reticulocyte count, serum biochemical analysis, whole-body radiographs, and bone marrow cytology if indicated.

History

- Obtain a careful history regarding possible blood loss, toxicity, and foreign body ingestion. Determine the duration of vulvar swelling (if present).

Laboratory Tests

- Characterize the anemia based on RBC parameters and hemoglobin concentration.
  - The normal hematocrit for the ferret is 46% to 61%, higher than that of other animals. The erythrocyte count is higher as well; erythrocyte counts as high as 17.0×10^6 cells/µl have been reported.
  - The normal reticulocyte count may be as high as 10%. Reticulocyte counts greater than 12% are indicative of a regenerative bone marrow response.
  - Regenerative anemia is often the result of blood loss or hemolysis.
- Perform bone marrow aspiration (see Clinical Techniques), particularly if the anemia is nonregenerative, to identify infiltrative processes and assess the morphology of RBC precursors. Bone marrow cytology from animals affected with anemia of chronic disease may be normal. Bone marrow cytology is also indicated in ferrets with nonregenerative anemia that is unresponsive to treatment after 6 to 10 days.
- Obtain blood for blood lead concentration if lead poisoning is suspected.

Diagnostic Imaging

- Whole-body radiographs are indicated to rule out abdominal neoplasia, GI foreign body, and thoracic neoplasia. A GI contrast study may be helpful to rule out the presence of GI ulcers. Ultrasound may be helpful based on the rule outs established.

▼ ***Key Point*** Anemia in an intact female ferret with a swollen vulva for more than 4 weeks most likely is due to estrogen toxicity.

Treatment

The objectives of treatment are to treat both the anemia and the underlying cause.

- General supportive care includes oxygen therapy, subcutaneous fluids, and nutritional supplementation.

Treatment of the Anemia

- Specific supportive care includes whole blood transfusion, iron dextran therapy, and the administration of erythropoietin.
- Oral iron supplements may be administered to replenish whole-body iron stores.
- Erythropoietin may be used to treat ferrets with nonregenerative anemia. Administer 100 U/kg three times per week until the PCV is stable, then administer 1 to 2 times a week. Continue to monitor the PCV, and titrate the dose as needed.

Blood Transfusion

- Indications for blood transfusion include the clinical status of the patient, a low packed-cell volume (PCV) of <12%, the specific cause of the anemia, and the potential for continued blood loss.
- Ferrets lack specific blood types; transfusion reactions are rare in the ferret; up to three transfusions from the same donor and transfusions from multiple donors are considered safe.
- The normal blood volume of an adult ferret may be calculated as 8% of the body weight.
- The ideal value of the PCV post-transfusion would be within the normal reference range; a more likely goal is 5% to 10% higher than the pre-transfusion PCV. For dosage guidelines, see Chapter 22.
- Before transfusion, administer a rapid-acting corticosteroid, such as dexamethasone sodium phosphate (6–8 mg/kg once IV) or prednisolone sodium succinate (22 mg/kg once IV), as a slow bolus infusion, and administer an antihistamine such as diphenhydramine (0.5–1 mg/kg IV, IM, SC) to the recipient ferret.

Collection of Blood for Transfusion

- The normal blood volume of ferrets has not been reported, but is estimated to be 5% to 6% of the total body weight (approximately 60 ml/kg). Twenty percent of the estimated blood volume (approximately 12 ml) may be collected from healthy ferrets.
- The jugular vein is the preferred site for the collection of large volumes of blood for transfusion.
- Sedate the donor ferret and place it in dorsal recumbency.
- Use a butterfly catheter to collect the blood into a syringe containing an anticoagulant such as sodium citrate (0.1 ml citrate per 0.9 ml blood) or acid-citrate-dextran (ACD) (1 ml per 6 ml blood collected).
- Transfer the blood immediately to the recipient. Blood should be filtered as it is transfused to the recipient.
- Administer fresh blood transfusions through an indwelling catheter or via a butterfly catheter into the cephalic or jugular vein. If a vein is inaccessible, administer into the peritoneal cavity or via the intraosseous route into the proximal femur.
- Whole blood is commercially available from Marshall Farms (Marshall Pet Products Inc., Wolcott, NY).
- Hemoglobin substitutes such as Oxyglobin (Bioprure Corporation, Cambridge, MA) (11–15 ml/kg) IV or IO over 4 hours may be used if whole blood is unavailable.
- Administer Oxyglobin slowly in normovolemic patients and in patients with renal disease, heart disease, or when the risk of pulmonary edema is present.

Treatment of the Cause of Anemia

- Stop bleeding (internal or external).
- Correct the underlying cause of GI bleeding, including medical therapy for GI ulceration (see "Gastrointestinal System"), surgery to remove GI foreign body, and antibiotics and supportive care for enteritis/colitis.
- For anemia of chronic disease, treat the underlying primary disease process.
- Address metabolic disease (renal, hepatic) if present.
- To correct estrogen toxicity in the intact female, terminate estrus (see below) and provide supportive care until the bone marrow is functional. Broad-spectrum antibiotic therapy is important for the control of sepsis in leukopenic patients. Estrogen toxicity associated with ovarian remnants is treated by surgical removal of the remnants when the ferret is stable enough for surgery. Estrogen toxicity associated with adrenal gland disease is treated by adrenalectomy. Preoperative care is the same as that described for the intact female (see below). (For diagnosis and treatment of adrenal tumors see "Adrenal Gland Disease.")
- Treat fleas with any product that is safe for use in cats (see Chapter 45).
- Treat lead poisoning following the same protocols recommended for cats (see Chapter 22).

- Anemia secondary to neoplasia is associated with a poor prognosis. Some cases of lymphoma may respond to treatment (see "Neoplasia").

Termination of Estrus

- Administer human chorionic gonadotropin (HCG) in a single injection of 100 IU (or 1000 USP) IM. Repeat this dose in 1 to 2 weeks if vulvar swelling has not diminished.
- Alternatively, give gonadotropin-releasing hormone (GnRH) at a dose of 20 µg IM or SC; repeat in 2 weeks if necessary.
- GnRH and HCG are effective only after the 10th day of estrus. Bone marrow toxicity is not immediately reversible with termination of estrus; the PCV continues to fall for days to weeks.
- Monitor the PCV as a useful guide to therapy and prognosis:
  - PCV > 25%—the prognosis is good and termination of estrus is the only therapy required.
  - PCV 15% to 25%—the prognosis is guarded because the PCV level can decrease further after termination of estrus.
  - PCV < 15%—the prognosis is poor and aggressive supportive care is indicated, including multiple blood transfusions until bone marrow function is restored.

Prevention

- Some causes of anemia in ferrets can be prevented. Educate owners about proper husbandry techniques to avoid flea infestation, foreign body ingestion, and trauma.

▼ ***Key Point*** To prevent estrogen toxicity, spay all female ferrets not used for breeding.

Neoplasia

INSULINOMA

Insulinoma (pancreatic beta-cell tumor) is one of the most common neoplasias of the ferret. Disease is most common in ferrets over 2 years of age, and results in progressive, cyclic, or persistent hypoglycemia.

Etiology

- The incidence of insulinoma is typically higher in ferrets in the United States than in ferrets in other countries. The cause(s) are unknown.
- Possible etiologies include a limited genetic pool and diet. Ferrets in the United States are typically fed processed foods containing large amounts of cereal grains. Ferrets in other countries are typically fed a more natural diet consisting of meats and whole prey items.

Clinical Signs

- Early signs may be subtle and transient. Cyclic or progressive episodes of profuse hypersalivation and pawing at the mouth (which is indicative of nausea), lethargy, depression, "stargazing," and posterior paresis may be seen during periods of hypoglycemia.
- As the disease progresses, or during periods of inadequate food intake, symptoms become more pronounced and may progress to stupor or coma. Seizures may occur.
- Splenomegaly is a common, unassociated finding on physical examination (see "Splenomegaly" under "Hematopoietic System" in this chapter).
- Adrenal disease is often identified concurrently in many ferrets with insulinoma (see "Adrenal Neoplasia" in this chapter).

Diagnosis

▼ ***Key Point*** Base a presumptive diagnosis of insulinoma on the history, clinical signs, and repeated evidence of hypoglycemia in the presence of normal or elevated blood insulin levels. Make a definitive diagnosis via surgical removal and histopathology of a pancreatic tumor or biopsy.

- Differential diagnoses include hepatic disease, sepsis, starvation, and laboratory error.

Fasting Serum Glucose

- A carefully monitored fast of 4 to 6 hours is sufficient.
- If necessary, obtain several samples over a period of several days.
- Normal fasting serum glucose concentration is 90 to 110 mg/dl. Ferrets with insulinoma often have a fasting serum glucose of 20 to 75 mg/dl. Ferrets with fasting serum glucose between 75 to 90 mg/dl are considered suspect and should be monitored.
- Do not fast the animal for more than 6 hours. Discontinue fast if signs of hypoglycemia occur. Prolonged fasting may lead to collapse, coma, or seizures. Feed the ferret a high-protein and high-fat meal as soon as possible after collection of blood.

Blood Insulin Values

- Measurement of blood insulin concentration is not consistently reliable in the ferret.
- False positive results may occur if liver disease, non-islet cell tumors, or sepsis are present.
- Blood insulin concentrations greater than 275 pmol/liter (or 38 µU/ml) are considered elevated in ferrets. However, if the ferret is severely hypoglycemic at the time of sample collection, the blood insulin

value may be normal because insulin and glucose are in a constant dynamic state.

Serum Biochemical Profile and Complete Blood Cell Count

- The serum biochemical profile is typically normal except for the presence of hypoglycemia.
- The CBC is typically normal.
- A slight elevation in alanine aminotransferase (ALT) and aspartate aminotransferase (AST) may be noted. The cause is unknown and may incidental, or may indicate hepatic lipidosis due to chronic hypoglycemia or some hepatic pathology.

Treatment

▼ ***Key Point*** Insulinoma is a progressive disease in ferrets. Educate owners how to recognize the signs of hypoglycemia and how to manage hypoglycemia at home (see "Medical Therapy" and "Hypoglycemia Episodes").

- Treatment options include medial therapy and/or surgical therapy.
- Medical therapy will need to be adjusted as the disease progresses.
- Surgery is used as a management tool and is not curative.

Medical Therapy

Insulinoma is a progressive disease, even after surgical intervention. Medial therapy is often effective in controlling symptoms associated with insulinoma for 6 to 18 months. Frequent feeding is the first step in treatment. Add prednisone and diazoxide as clinical signs and hypoglycemia worsens.

- Feed high-quality protein and high-fat meals frequently, especially after exercise or a long sleep. Avoid foods containing sugar or excessive carbohydrates (except to treat hypoglycemic episodes); these foods cause short term hyperglycemia followed by a period of hypoglycemia 1 to 2 hours later.
- 1 to 3 tablespoons of Hill's Science Diet A/D or meat-based baby foods may be given twice daily and as needed.
- Chromium has been anecdotally reported to stabilize blood glucose and insulin levels in humans. Brewer's yeast, which is a rich source of chromium, has been beneficial in some ferrets with insulinoma. Give $^1/_8$ to $^1/_4$ tsp of Brewer's yeast q12h in the high-quality protein, high-fat meal.
- When frequent feedings no longer control clinical signs, begin corticosteroid therapy. Administer a prednisone or prednisolone suspension at a starting dosage of 0.1 to 0.25 mg/kg bid PO. As clinical signs worsen, increase the dosage gradually as needed to control signs. When the dosage approaches (0.75–1.0 mg/kg) bid PO consider the addition of diazoxide.
- Corticosteroids promote hepatic gluconeogenesis and antagonize the effects of insulin at the cellular level. Ferrets appear to tolerate corticosteroids well; side effects are minimal at lower dosages. Corticosteroids are usually the first treatment of choice because they are inexpensive and cause few side effects in the ferret.
- Add diazoxide (Proglycem, Baker Norton Pharmaceuticals) (10 mg/kg/day) PO divided bid–tid when frequent feedings and corticosteroids no longer control clinical signs. The diazoxide dosage may be gradually increased up to 60 mg/kg/day PO divided bid–tid as needed. Diazoxide is expensive, and is not palatable for some ferrets. Potential side effects at high doses include hypertension, lethargy, depression, anorexia, and nausea.

Treatment of Acute Hypoglycemic Episodes

- Hypoglycemic episodes require specific therapy.
- Mild to moderately severe hypoglycemic episodes often can be treated successfully at home. Instruct the client to give the ferret honey or corn syrup.
  - Owners should be taught how to identify hypoglycemic episodes and how to administer medications with a syringe.
  - If the ferret has collapsed, rub honey or corn syrup on the gingiva (taking care not to be bitten).
  - Once the animal is stabilized, owners should feed a high-protein meal, and make arrangements to bring the ferret in for a blood glucose test.
- Severe hypoglycemic episodes that do not respond to home therapy or that result in seizures require treatment in a veterinary hospital (see Chapter 35).
  - Administer a slow IV bolus of 50% dextrose (0.5–2 ml) until the ferret responds. Give no more than necessary to stop signs of hypoglycemia. If the ferret continues to have seizures or remains comatose, place an IV catheter and administer fluids containing 5% dextrose. Also administer a corticosteroid.
  - Anticonvulsant therapy (diazepam 1–2 mg IV to effect) may be necessary if the ferret is in status epilepticus. Follow anticonvulsant protocols for dogs and cats (see Chapter 127) while correcting the hypoglycemia.
  - Modify the medical treatment as necessary, and consider surgical intervention.

Surgical Therapy

Surgical therapy is the treatment of choice even though surgical removal or debulking of pancreatic tumors or partial pancreatectomy is palliative and provides only temporary remission of signs (6 to 24 months).

- Follow canine preoperative protocols (see Chapter 35). Fast the ferret for only 4 to 6 hours preoperatively to avoid hypoglycemia.
- Administer IV or IO isotonic fluids containing dextrose (2.5–5.0%) 1 to 2 hours preoperatively if possible, during surgery, and continue postoperatively until the ferret is stable and is eating and drinking.
- Evaluate the blood glucose concentration pre-, intra-, and postoperatively if possible.
- See Chapter 35 for information about the surgical removal of insulinoma.

▼ ***Key Point*** Perform a complete abdominal exploratory; insulinomas can metastasize to the regional lymph nodes, liver, and spleen (uncommon). Concurrent adrenal tumors (see Adrenal Gland Disease) are common.

- If the spleen is enlarged and appears irregular or mottled, consider performing a complete or partial splenectomy and submit for histopathology.

Postoperative Care and Complications

- Postoperatively monitor the blood glucose concentration bid–tid until the ferret is discharged from the hospital. Many ferrets become euglycemic immediately after surgery. Some ferrets may remain hypoglycemic. Rarely, ferrets may become transiently hyperglycemic after surgery.
- Most ferrets will require resumption of medical therapy 2 to 6 months after surgery. Some ferrets will need medical therapy immediately postoperatively.
- Monitor blood glucose levels for 10 to 14 days after surgery and at 60 to 90 day intervals.
- *Iatrogenic pancreatitis* is rarely a problem in ferrets; however, as a precaution, withhold food and water for 12 hours postoperatively; give 2.5% to 5.0% dextrose IV during this period. Monitor blood glucose 1 to 4 times daily.
- *Transient diabetes mellitus* may occur postoperatively. Hyperglycemia and glucosuria may be present for 1 to 21 days postoperatively; generally no treatment is required.
- Histopathologic examination of the pancreatic mass may reveal hyperplasia, adenoma, and/or adenocarcinoma of the pancreatic beta cells, even within a single tissue specimen.

Prognosis

- The prognosis is guarded, but with surgery and medical treatment, ferrets have had a good quality of life for more than 1 year after diagnosis of insulinoma. The median survival time was 17 months (range, 0.5–40 months) in one study of 53 ferrets treated with surgery, medical management, or both.

ADRENAL GLAND DISEASE/ADRENAL NEOPLASIA

Adrenal tumors are common in ferrets, and occur with approximately the same frequency as insulinomas. Adrenal neoplasia and insulinomas often appear concurrently. Adrenal tumors have been identified in ferrets as young as 1 year of age, although they typically occur in ferrets >2 years of age.

- Adrenal gland disease in ferrets is not Cushing's disease. Excessive sex steroids, not corticosteroids, are produced by a hyperplastic or neoplastic adrenal gland.

Etiology

- The etiology is unknown. Possible causes of adrenal disease in ferrets include early neutering, genetic factors, and lack of exposure to normal seasonal photoperiods. The incidence of adrenal neoplasia is higher in ferrets in the United States. In the U.S., ferrets are typically neutered at 6 weeks of age, and are housed indoors under artificial light cycles. Ferrets in Europe and Australia are typically housed outside, and are not neutered until 6 months of age.
- Adrenal neoplasia in ferrets causes a variety of clinical signs, and appears to be the result of excessive secretion of estrogens and androgens, not cortisol. Pituitary-dependent hyperadrenocorticism has not been documented in ferrets.
- Adrenal tumors most commonly arise from the adrenocortical tissue. Common histopathological findings include hyperplasia, adenoma, and adenocarcinoma.

Clinical Signs

- Signs include progressive, bilaterally symmetric alopecia, usually starting at the tail base and progressing cranially. Hair loss often starts in the early spring or fall. There may be a history of alopecia and spontaneous hair regrowth as well.
- Pruritis often is reported, along with excessive dryness of the skin and small excoriations. Thinning of the skin is common.
- An enlarged vulva, mimicking estrus, may be the only clinical sign in spayed females. Mucoid or mucopurulent vulvar discharge may be noted. Castrated males may exhibit territorial marking and sexual behaviors, and may develop the strong body odor and oily hair coats of intact males. Mammary hyperplasia can occur in either sex.
- Male ferrets may present with partial to complete urinary obstruction. Persistent elevation of adrenal-derived androgenic hormones may cause development of prostatic hypertrophy, prostatic cysts, or periurethral cysts, which cause narrowing of the

urethra. Affected ferrets may present with stranguria, dysuria, azotemia, and severe metabolic derangement. Male ferrets that are described as straining to urinate should be treated as an emergency (see "Urinary System").

- Atrophy of abdominal musculature and mobilization of fat to the ventral abdomen, leading to a pendulous appearance, may be seen.
- Atrophy of hind limb musculature and rear limb paresis can occur.
- Polyuria/polydipsia is uncommon but has been reported.
- Collapse, anemia, and petechiation resembling estrogen toxicity have been described in male and female ferrets with chronic or advanced adrenal disease (see Hematopoietic System).
- Enlarged adrenal glands may occasionally be noted on the physical examination. The left adrenal gland is easier to palpate than the right.
- Radiographs are not typically helpful in confirming this disease. Ultrasonography may be useful for identification of adrenalmegaly.
- CBC is typically unremarkable unless estrogen toxicity-like anemia is present. The serum chemistry profile is typically within normal limits unless insulinoma is present.

Diagnosis

▼ ***Key Point*** A history of symmetric truncal hair loss suggests the diagnosis. Differential diagnosis includes seasonal alopecia, which typically appears in the spring or fall, affects only the tail, and resolves after several weeks.

- Female ferrets often present with a swollen vulva. Differential diagnoses include an intact female ferret, a female ferret with an ovarian remnant, and seasonal alopecia. Perform a serum steroid panel or administer human chorionic gonadotropin (100 IU) IM to determine if a female ferret is unspayed or has an ovarian remnant.
- A plasma steroid hormone assay may be used to support the diagnosis. Elevated plasma concentration of estradiol, androstenedione, and/or 17-hydroxyprogesterone is a reliable indicator of adrenal gland disease (see Table 174-4). A hormone panel is commercially available through the Clinical Endocrinology Laboratory of the Department of Comparative Medicine at the University of Tennessee.
- The adrenocorticotropic hormone (ACTH) stimulation test and the low-dose dexa-methasone suppression test are not useful in ferrets. Ferrets with adrenal gland disease do not produce abnormal concentrations of cortisol, and adrenal gland disease in the ferret appears to be independent of ACTH. Urine cortisol/creatinine ratio does not appear to be a specific indicator of adrenal gland disease.

Table 175-4. STEROID HORMONE CONCENTRATIONS IN FERRETS

Steroid	Range
Androstenedione (nmol/L)	0–15
Estradiol (pmol/L)	30–180
17-hydroxyprogesterone (nmol/L)	0–0.8

From Clinical Endocrinology Laboratory, University of Tennessee College of Veterinary Medicine.

- Perform exploratory surgery to confirm the diagnosis.

Treatment

- Adrenal tumors can be managed medically or surgically. Surgical management is preferred and recommended.
- Medical treatment may cause clinical signs to regress, but will not stop growth of the adrenal tumor.

Medical Therapy

The goal of medical treatment is to decrease or eliminate the clinical signs of adrenal gland disease. Medical therapy will not stop or prevent the growth of an existing tumor, and should be reserved for ferrets that are poor surgical candidates, ferrets with inoperable bilateral adrenal tumors, or ferrets with recurrent adrenal gland disease.

- Medical treatments described in the literature include mitotane, ketoconazole, androgen receptor blockers, aromatase inhibitors, and gonadotropin-releasing hormone analogs.
- *Gonadotropin-releasing hormone analogs.* There are two general types of GnRH analogs: GnRH agonists and GnRH antagonists. To date only GnRH agonists such as leuprolide acetate (Lupron Depot, TAP Pharmaceuticals Inc., Lake Forest, IL) have been used to control the signs of adrenal disease in the ferret. Of the medical treatments described, anecdotal reports suggest that leuprolide acetate has been most effective in alleviating dermal and urogenital signs of adrenal disease. Administer the 1 month depot formulation of leuprolide acetate at a dose of (250 µg/kg) IM every 30 days.
- *Androgen receptor blockers* theoretically block the actions of androgens at the receptor site, and decrease or reverse the signs of adrenal gland disease. In human medicine these drugs are used to treat men with prostatic carcinoma or prostatic hyperplasia. Flutamide (Eulexin, Schering Corporation, Kenilworth, NJ) and bicalutamide (Casodex, AstraZeneca Pharmaceuticals LP, Wilmington, DE) have been used, primarily in male ferrets. Results are variable.

- *Aromatase inhibitors* such as anastraozole (Arimidex, AstraZeneca Pharmaceuticals LP) inhibit aromatase, an enzyme involved in estrogen production. Some ferrets show decreased evidence of adrenal gland disease symptoms when treated with this drug.
- *Mitotane* (0,p'-DDD) (Lysodren, Bristol-Myers Squibb Oncology, Princeton, NJ) is *rarely effective* in ferrets with adrenal gland disease, presumably because ferrets do not develop pituitary-dependent hyperadrenocorticism. If clinical signs do resolve, they will often recur as soon as the mitotane therapy is withdrawn.

▼ ***Key Point*** Perform a fasting blood glucose test before starting mitotane therapy. Do not use mitotane if blood glucose is low (indicative of concomitant insulinoma). Mitotane causes a decrease in endogenous cortisol production; if insulinoma is present, serum glucose levels also may fall, causing a hypoglycemic crisis.

- Give mitotane (50 mg/kg) PO q24h for 7 days, then q48h until clinical signs start to resolve. At that time decrease to q72h until signs are fully resolved, then maintain the ferret on 50 mg/kg once q7–30d as necessary.
- Mitotane must be compounded in 50-mg aliquots in #1 capsules. Capsules must be administered intact. Have owners coat the capsules with vegetable oil, push into the back of the throat, and follow with a palatable liquid or blenderized cat food to promote swallowing.
- The most common side effect of mitotane is hypoglycemia. Teach owners to recognize the signs of hypoglycemia, and have prednisone available at home. If side effects occur, discontinue mitotane and administer prednisone (1.0–1.25 mg) PO.
- If continuation of mitotane therapy is desired after a hypoglycemic crisis, administer concomitantly with prednisone (see Insulinoma).
- *Ketoconazole* is not effective in the treatment of adrenal disease in the ferret.

Surgical Therapy

Follow the adrenalectomy preoperative protocol described for dogs (see Chapter 33).

- Fast the ferret 4 to 6 hours preoperatively. Place an indwelling IV or IO catheter preoperatively, and administer fluids pre-, intra-, and postoperatively. If insulinoma is present concurrently treat and monitor appropriately.
- Perform a ventral midline laparotomy. Palpate and visualize both adrenal glands carefully. Normal adrenal glands are 5 to 8 mm × 2–3 mm in size, are pale pink in color, and are typically surrounded by fat.
- The left adrenal gland lies in a fat pad cranial to the left kidney. The right adrenal gland is located craniomedial to the right kidney under the caudate liver lobe adjacent to the vena cava. It may be necessary to transect the hepatorenal ligament to fully visualize and palpate this gland.
- Adrenal changes may be subtle, especially in younger ferrets and because the adrenal glands are surrounded by fat. Visual changes, such as dark circular lesions and small raised cysts, may be present instead of gross enlargement.
- One or both adrenal glands may be affected. If only the left adrenal gland is affected, removal is relatively straightforward. If the right adrenal gland is affected, removal can be difficult because of the gland's proximity to the vena cava and liver (see Chapter 33).
- If both adrenal glands are affected, remove the left adrenal gland and debulk the right adrenal gland. Bilateral adrenalectomy has been described in the ferret, but should be done with caution. Monitor postoperatively for development of acute adrenal hypocorticism. If acute AHC develops, treat as described for dogs (see Chapter 33).

▼ ***Key Point*** Always perform a complete abdominal exploratory. Observe and palpate the pancreas at surgery for insulinomas, which often are found concurrently with adrenal neoplasia.

Postoperative Care and Complications

- Monitor fasting serum glucose levels every 60 to 90 days during mitotane therapy and after adrenalectomy, even if no pancreatic nodules were evident during surgery.

Prognosis

- The prognosis following successful surgery is good. A full resolution of clinical signs can be expected in many cases.
- Recurrent or continued symptoms of adrenal gland disease may be associated with development of a tumor on the remaining adrenal gland, or recurrence of an adrenal tumor due to metastasis (which is rare).
- Even without treatment, ferrets may survive up to 2 years or longer after diagnosis, although the hair loss is generally progressive.
- Potential sequelae to chronic adrenal gland disease include prostatic disease, bone marrow suppression, or mechanical interference with the vena cava (right adrenal gland).

Pheochromocytoma

Pheochromocytomas are adrenal tumors that arise from the adrenal medulla and produce excessive amounts of catecholamines. Pheochromocytomas have been reported in ferrets, but are rare. Treatment of choice is surgical removal of the affected gland.

LYMPHOSARCOMA

Lymphosarcoma (lymphoma) is common in ferrets of all ages, and is similar in presentation to the disease in cats and dogs (see Chapter 27). Three presentations may occur in the ferret and include lymphosarcoma, lymphocytic, and lymphoblastic forms.

Etiology

- A viral etiology has been hypothesized.

Clinical Signs

Clinical signs are variable, depending on the form of lymphoma present and the organ system involved.

- *Lymphosarcoma*: Solid tissue tumors are present in the organs or lymph nodes.
- *Lymphocytic lymphoma*: Adult ferrets are most commonly affected. The course and survival time can be long. Peripheral lymphadenopathy is typically present and metastasis to visceral organs may occur. The neoplastic cell identified on cytology or histopathology is a mature, well-differentiated lymphocyte.
- *Lymphoblastic lymphoma*: Young ferrets are most commonly affected. Leukemia and neoplasia in visceral organs occur early in the course of this form of the disease. Large immature lymphocytes are noted on cytology or histopathology.
- *Other forms*: Cutaneous lymphoma may occur in the ferret.
- Clinical signs that may accompany any form of lymphoma include:
  - Inappetence, lethargy, splenomegaly, and weight loss despite a normal appetite
  - Dyspnea, tachypnea, and exercise intolerance
  - Peripheral lymphadenopathy and/or abnormal CBC
  - Acute collapse, often with pyrexia
  - Fever of unknown origin
  - Cutaneous masses
  - Chronic diarrhea and/or rectal prolapse
- Some ferrets are asymptomatic; lymphoma may be an incidental finding during evaluation for another medical problem.
- Lymphoma tends to be a more acute, fulminant disease in younger animals.

Diagnosis

The method of diagnosis depends on the organ system involved.

- Obtain a thorough history and physical examination.
- Perform a CBC, platelet count, and a serum biochemistry profile. If the ferret is anemic, perform a reticulocyte count.
- Often the CBC and differential WBC counts are not diagnostic for lymphoma. The CBC may be normal or may reveal an absolute or relative lymphocytosis. Anemia, leukopenia, and thrombocytopenia may be seen. Abnormal lymphocytes may occasionally appear in the differential count.
- Persistent absolute lymphocyte counts greater than 3500 or a relative lymphocytosis (>60%) are considered suspicious; repeat the CBC in 4 to 6 weeks and perform a bone marrow biopsy and/or lymph node biopsy if the CBC results are repeatable or if lymphadenopathy is present.
- The serum chemistry profile may disclose elevated liver enzymes if the liver is involved; paraneoplastic syndromes are uncommon in the ferret.
- Perform thoracic and abdominal radiography and ultrasonography to evaluate for intra-thoracic and intra-abdominal masses.
- Perform fine-needle aspiration or biopsy of affected tissues for histological and cytological examination. Fine-needle aspiration of the spleen is usually inconclusive.
- Lymph node biopsy is often the most helpful diagnostic tool for diagnosis of lymphoma. If possible, biopsy an enlarged lymph node. When lymphadenopathy is not present, biopsy the popliteal lymphnode. The popliteal lymph node is the most accessible peripheral node for biopsy. Avoid biopsy of intra-abdominal lymph nodes if possible.
- Perform bone marrow aspiration to identify infiltration by neoplastic cells and the disease (see "Clinical Techniques").

Treatment

Splenectomy

- If the spleen is involved, perform a splenectomy (see Chapter 25) to reduce the overall tumor load.

Chemotherapy

Chemotherapy for lymphoma may be successful (approximately 10% remission rate). In general, protocols have been adapted from feline medicine (see Chapters 26 and 27).

- Success of chemotherapy may be affected by the age of the ferret, concurrent disease (e.g., adrenal gland disease, insulinoma), concurrent medication, inappropriate use of and resistance to chemotherapeutic agents (ferrets treated with prednisone prior to chemotherapy), and the type of lymphoma present.
- Ferrets with bone marrow involvement or with solid tumors involving organs typically have a poor prognosis.
- Longer periods of remission tend to occur in individuals with adult onset or lymphocytic lymphoma.
- IV chemotherapeutic agents are given via butterfly catheter or small-gauge needle with the ferret under

Table 175-5. CHEMOTHERAPY PROTOCOL II FOR LYMPHOMA*

Week	Drug	Dose
1	Vincristine	0.07 mg/kg, IV
	Asparaginase	400 IU/kg, IP
	Prednisone	1 mg/kg, PO, q24h and continued throughout therapy
2	Cyclophosphamide	10 mg/kg, SC
3	Doxorubicin	1 mg/kg, IV
4–6	As weeks 1–3 above but discontinue asparaginase	
8	Vincristine	0.07 mg/kg, IV
10	Cyclophosphamide	10 mg/kg, SC
12	Vincristine	0.07 mg/kg, IV
14	Methotrexate	0.5 mg/kg, IV

IV, intravenously; IP, intraperitoneally; PO, per os; SC, subcutaneously.
*Protocol is continued in sequence biweekly after week 14.
From Rosenthal KE: Ferrets. Vet Clin North Am 24:19–20, 1994.

sedation; face-mask administration of isoflurane is the most convenient and rapid method of sedation.
- One chemotherapy protocol is outlined in Table 175-5.

▼ ***Key Point*** Monitor the CBC weekly. If the WBC falls below 2000 WBC/µl, or the RBC falls below 4 × 10^6/µl discontinue vincristine for 1 week or more until the WBC count increases to at least 3000 WBC/µl.

- Palliative therapy may be attempted by administering oral prednisone (2.2 mg/kg) PO q24h.
- Supportive care is important (see "Nutritional Support for Insulinoma").
- Consider referral to an oncologist if experience with chemotherapeutic agents is limited.

OTHER TYPES OF NEOPLASIA

- *Chordoma:* Chordomas are tumors that arise from notochord remnants. Tumors occur most often at the tip of the tail, but may occur in the cervical region as well.
- *GIT:* Gastric adenocarcinoma.
- *Reproductive tract:* Tumors include granulosa cell tumors, luteomas, and leiomyomas in intact females and in remnant tissue in spayed females. Sertoli cell tumors have been reported in intact males.
- *Skin and Subcutis:* See Dermatologic Diseases in this chapter.
- Other tumors reported in ferrets include chondroma, chondrosarcoma, fibroma, fibrosarcoma, hepatic adenocarcinoma, hemangioma, hemangiosarcoma, mast cell tumor, mesothelioma, osteoma, osteosarcoma, schwannoma, squamous cell carcinoma, thymoma, and renal and pancreatic carcinomas.

Dermatologic Diseases

SEASONAL CHANGES IN THE SKIN AND HAIRCOAT

Ferrets may experience dramatic seasonal changes in the haircoat triggered by photoperiod changes. This change is most apparent in the intact animal. If one is unfamiliar with these changes, normal coat changes may be interpreted incorrectly as a medical problem.

▼ ***Key Point*** Individual animals may exhibit different patterns of coat change each successive year.

Haircoat

- A normal, diffuse, gradual thinning of the coat typically occurs in the spring when the photoperiod is increasing and continues through the summer. The coat typically becomes shorter and darker at this time, and the face mask may appear or disappear. Focal alopecia should not be present.
- Some ferrets may experience a dramatic 1-day loss of the undercoat.
- A normal, but dramatic, loss of body weight (up to 40%) may occur at this time as well.
- Hair growth will reverse in the fall and winter. Coats typically become longer, thicker, and lighter. Body weight may change (up to 40%) as well.
- Females in estrus and males "in season" may show an even more marked hair loss but should not have areas of alopecia.
- Males typically lose hair in the inguinal area because of constant rubbing to mark territory; the mid- and caudal abdomen is often wet with urine.
- Neutered ferrets or ferrets kept under artificial lighting conditions often experience no coat changes.
- Neutering or spaying may cause temporary, diffuse alopecia hair thinning postoperatively, particularly if the animal was reproductively active at the time of surgery. The preoperative color pattern may not return.
- At any time of the year, regrowth of hair that has been shaved for medical procedures is slow. This is particularly true in the winter and summer when no active hair growth is occurring.

Skin

- Hair regrowth (regardless of the cause of alopecia) is often preceded by a blue to purple discoloration of the skin that can alarm the owner. This discoloration

is caused by new hairs growing through the dermis, and is most noticeable on the abdomen and face.
- Intact jills may exhibit a bluish discoloration of the skin during estrus. If ovariohysterectomy is performed while a jill is in estrus, this discoloration may occur approximately 10 days postoperatively.
- Pseudonails associated with hyperkeratosis of the footpads may occur in ferrets older than 2 years of age that are housed on carpet or linoleum surfaces. Trim pseudonails as necessary. Rub a small amount of petroleum jelly or vitamin E oil into the pads daily to help prevent lesions.

INFECTIOUS DISEASES

Bacterial Infections

Cutaneous bacterial infections in ferrets are typically manifested as abscesses or as a diffuse, ulcerative pyoderma.

Abscesses

- Abscesses may develop secondary to puncture wounds, bites, or may develop in the inguinal fat after traumatic injury (e.g., being stepped on). For diagnosis and treatment of abscesses, see "Infectious Diseases."

Ulcerative Pyoderma

Ulcerative pyoderma is the second most commonly encountered form of bacterial dermatitis in the ferret.

Etiology

- Various bacteria can cause ulcerative pyoderma. The most common agents are *Staphylococcus* and *Streptococcus* spp.

Clinical Signs

- Focal alopecia with diffusely hyperemic, thickened, ulcerated skin may occur over any area of the body.

Diagnosis

- Perform a cutaneous punch biopsy (see Chapter 37) to rule out diffuse cutaneous mast cell tumor, which may have a similar gross appearance.
- Perform bacterial culture and sensitivity testing.

Treatment

- Administer systemic antibiotics based on culture and sensitivity testing. Antibiotics effective in the treatment of pyoderma in ferrets often include amoxicillin-clavulanate (Clavamox, SmithKline) (13–25 mg/kg) q12h PO and cephalosporins (use feline dosages).
- Topical treatments include twice-weekly cleansing with an antibacterial shampoo containing chlorhexidine or benzoyl peroxide. Daily application of an antibacterial cream may be beneficial if the lesion is small and localized.

Canine Distemper Virus Infection

Dermatologic lesions are quite prominent with CDV infection in ferrets.

- Dermatologic signs typically begin with hyperemia around the lips, chin, eyes, and sometimes the inguinal area. With time, crusts and skin thickening may appear.
- Hyperkeratosis of the foot pads occurs as the disease progresses.
- See Infectious Diseases in this chapter for a detailed discussion of CDV in ferrets; also see Chapter 13 for a discussion of CDV in dogs.

Dermatophytosis

- *Microsporum canis* and *Trichophyton mentagrophytes* are the most common causes of superficial mycotic infections in the ferret.
- See "Infectious Diseases" in this chapter for diagnosis and treatment.

EXTERNAL PARASITES

Fleas

- Flea infestation may be encountered in pet ferrets. Clinical signs are similar to those seen in cats (see Chapter 45).

Treatment

- Flea shampoos, dips, or powders containing pyrethrin may be used. Products containing lindane or organophosphates are not recommended for use in the ferret.
- Imidacloprid (Advantage, Bayer Corporation, Shawnee Mission, KS) (0.4ml) topically every 3 weeks has been reported to be effective. No adverse effects have been noted. This drug may be used in conjunction with lufenuron.
- Lufenuron (Program, Norvartis Animal Health, Greensboro, NC) (45 mg) PO every 4 weeks has been anecdotally reported to be effective. Advise clients that there is a 6- to 8–week period before flea numbers are observed to decline.
- Fipronil (Frontline, Merial LTD., Iselin, NJ). Half the cat dose has been anecdotally reported to be effective. This drug may be used in conjunction with lufenuron.
- Selamectin (Revolution, Pfizer, New York, NY). Administration of the cat dosage has been anecdotally reported to be effective.

- Flea collars are not recommended because they come off easily and small pieces can be ingested.
- Treat the environment for fleas.

Ear Mites

Ear mite infection in ferrets is caused by *Otodectes cyanotis,* the same parasite that infects cats and dogs.

Clinical Signs

- Ferrets rarely exhibit pruritis, even with heavy mite infestation.
- Ferrets normally have large volumes of dark reddish-brown ear wax present in the ear canal, which resembles the debris present with *O. cyanotis* infestation. If ear mite infestation is present, wax production may become excessive and cause occlusion of the external ear canal.
- *O. cyanotis* infestation may be accompanied by secondary bacterial infection, leading to otitis media or otitis interna. Neurological signs such as head tilt and circling may occur (see Chapter 61 for techniques for the management of otitis media in cats).
- When chronic ear mite infestation is present, lichenification and a bluish pigment may appear on the inner surface of the pinnae. These changes are caused by a response to chronic irritation, and usually regress after treatment.
- Rarely, *O. cyanotis* may colonize other parts of the body.

Diagnosis

- Examine all ferrets for ear mites; the incidence of infestation is high in some populations.
- Mites in the ear canal can often be visualized using an otoscope; however, otoscopic examination is often difficult because of the uncooperative nature of the patient and small size of the ear canal.
- Confirm the diagnosis by microscopic examination of ear debris.

Treatment

- Thoroughly clean the ears.
- Administer ivermectin (Ivomec, Merck-Sharp & Dohme Agvet), (1 mg/kg) divided into two doses. Instill one dose into each ear. Repeat in 2 weeks.
- Tresaderm (Merck Agvet, Rahway, NJ) may be used to treat ear mites in ferrets. Administer 2 drops in each ear q24h for 7 days, stop for 7 days, then repeat. This medication has been reported to be effective in treatment of ear mites in the ferret.
- Selamectin may be used for treatment of ear mites in the ferret. Use at the dose described for treatment of fleas.
- Bathe the ferret within 24 to 48 hours after treatment. Wash all bedding and treat all other potential hosts in the household (see Chapter 59).
- Topical treatments may not be effective due to the narrow size of the ear canal, and patient resistance to treatment.
- Persistent infections may be due to the presence of ear mites on the body, or failure to deliver the topical agent effectively. In such cases, parenteral administration of ivermectin (0.5 mg/kg) SC every 7 to 10 days for 2 treatments may be necessary. Do not use topical and parenteral ivermectin together.

Sarcoptic Mange

Etiology

Sarcoptes scabiei mites are transmissible between dogs and ferrets via contact with the infected hosts or their bedding. (See Chapter 44 for discussion about sarcoptic mange in dogs and cats.)

Clinical Signs

- Lesions are typically confined to the feet, which become hyperemic, swollen, and intensely pruritic. Crusting often occurs around the nails, and in severe cases the nails may slough.
- Generalized alopecia, accompanied by intense pruritis, occurs rarely.

Diagnosis

- A positive diagnosis is based on clinical signs, exclusion of differential diagnoses, and positive skin scrapings obtained from several sites (false negative results do occur).
- A common differential diagnosis is contact allergy. Similar lesions have been observed in ferrets housed on plastic-floor cages. These lesions resolve when the cage bottom is changed to wire or wood.

Treatment

- Advise clients of the zoonotic potential of this parasite.
- Treatment may need to be based on differential diagnoses; mites may be difficult to identify on skin scrapings.
- Administer ivermectin (0.5 mg/kg) SC every 2 weeks for three treatments.
- Lime sulfur dips may be used instead of ivermectin. Dip ferrets in 2% lime sulfur every 7 days until signs have resolved for 2 weeks.
- Wash all bedding and treat all potential contact hosts in the household.

Demodectic Mange

Etiology

Demodicosis is rare in the ferret.

Clinical Signs

- Otitis externa has been associated with demodicosis. This may be the only presenting sign.
- Localized alopecia accompanied by pruritis may occur.

Diagnosis

- Mites may be identified on routine skin scrapings and examination of ear canal debris.

Treatment

- Treatment can be difficult. Use ivermectin at the daily dose described for dogs (see Chapter 43).
- Do not use mitotane.

ENDOCRINE ALOPECIA

Tail Alopecia

Etiology

The etiology of tail alopecia in the ferret is unknown but is suspected to be caused by hormonal fluctuations because the disease responds to changes in the photoperiod. Hair loss occurs most commonly at the time of the fall molt, when the photoperiod is becoming shorter, but may be seen any time of year under artificial lighting conditions. Hair regrowth usually occurs in 2–8 weeks. The same pattern of alopecia is not always repeated annually.

Clinical Signs

- Hair loss, ranging from diffuse hair thinning to complete alopecia, occurs from the base of the tail to the tip.

▼ ***Key Point*** Alopecia occurs only on the tail. If alopecia extends to the body, suspect another form of endocrine disease, such as adrenal gland disease.

- Comedones and a brown, waxy scale may accompany the alopecia.

Diagnosis

- Diagnosis is based on clinical signs.
- Differential diagnoses include the early stages of adrenal gland disease; however, hair loss on the body typically occurs as well when this condition is present.

Treatment

- No treatment is necessary. Hair regrowth will occur when the photoperiod changes.
- Artificially lengthening the photoperiod may speed hair regrowth, although not reliably.
- If the tail exhibits excessive amounts of waxy scaling or comedones, clean the tail weekly with a mild shampoo.

Estrus Alopecia

Alopecia may be seen in intact females that have been in estrus for 1 month or longer.

Clinical Signs

- Bilaterally symmetrical hair loss over the shoulders and flanks, which eventually progresses to involve the entire body. Hairs epilate easily, and the underlying skin appears normal.
- A grossly enlarged vulva indicates a state of estrus. Be aware that the ferret also may be anemic and thrombocytopenic (see "Anemia").

Diagnosis

- Diagnosis is based on clinical signs in an intact female.

Treatment

- Perform an ovariohysterectomy (see Chapter 91) if the ferret is stable enough for the procedure, or induce ovulation with HCG (see "Termination of Estrus"; "Anemia").
- Hair regrowth will recur rapidly after surgery or ovulation; however, changes in hair length, color, or thickness are common.

Adrenal Gland Disease

- Bilateral, symmetrical alopecia is a common sign of adrenal disease in the ferret (see "Adrenal Gland Disease").

Hypothyroidism

- Hypothyroidism has not been documented in ferrets.

NEOPLASIA

Neoplasia of the skin is the third most common neoplasia reported in the ferret and commonly occurs in ferrets 1 year of age and older. Complete removal of skin masses using wide surgical excision followed by histopathology is recommended.

Mast Cell Tumors

Mast cell tumors are the most common skin masses encountered and are typically benign in the ferret.

- Individual tumors typically appear as slightly raised, flat, button-like cutaneous masses ranging in size from 2 to 10 mm. The tumors are often tan in color or may be hyperemic with a dark flaky crust. Tumors may also appear as raised, ulcerated areas, or as diffuse areas of erythema and crusting. Pruritis may be present at the site.
- Mast cell tumors have occasionally been associated with diffuse or generalized areas of alopecia that resolve with surgical removal of the tumor.
- Metastasis is rare but has been reported in the lung and gallbladder (see Chapter 28 for information about mast cell tumors in dogs and cats).

Sebaceous Epitheliomas

- These tumors may also be referred to as haral cell tumors or sebaceous adenomas and are common in the ferret.
- Tumors may appear as wart-like, ulcerated, or cystic masses ranging in size from 0.5 to 2 cm.
- Excision is usually curative. Recurrence is rare, and metastasis is not reported.

Other Neoplasms

- Other, less common neoplasms of the skin and subcutaneous tissues include: basal cell carcinoma, basi-squamo-sebaceous carcinoma, hemangioma, histiocytoma, leiomyosarcoma, lymphoma, myxosarcoma, neurofibrosarcoma, perianal gland adenocarcinoma, sebaceous gland adenocarcinoma, and squamous cell carcinoma.
- Adenocarcinomas often metastasize to regional lymph nodes, liver, and lungs.
- Diagnosis, treatment, and prognosis for these tumors in ferrets are the same as for dogs and cats (see Chapter 30).

Cardiovascular Diseases

CHARACTERISTICS OF THE NORMAL FERRET HEART

- Cardiac auscultation is centered more caudally in the thorax than are auscultations in cats.
- The heart extends from the sixth rib to the caudal border of the seventh or eighth rib (compared with cats, where it extends from the second to the sixth rib).
- The heart rate averages 180 to 250 beats per minute.
- A pronounced sinus arrhythmia and pronounced bradycardia are common during auscultation.
- Cardiac disease is relatively common in the ferret. Quality of life and long-term prognosis for ferrets with cardiac disease depends on the type and severity of cardiac disease present, and the initial response to treatment. Many ferrets do well for months on the appropriate medications.

Congestive Heart Failure

Clinical Signs

- Ferrets appear to compensate well for early cardiac insufficiency, perhaps because a slight decrease in activity is not readily apparent to owners.
- Ferrets with congestive heart failure (CHF) may present with clinical signs that resemble symptoms associated with other disease entities, such as anorexia, ascites, coughing, dehydration, dyspnea, exercise intolerance, generalized weakness, hindlimb weakness, hypothermia, lethargy, tachypnea, and weight loss.
- Pale or cyanotic mucus membranes and a prolonged capillary refill time (CRT) may be noted on physical examination.
- Jugular pulses may be present when right-sided CHF is present.
- Femoral pulses may be weak, irregular, or normal.
- Ascites, hepatomegaly, or splenomegaly may be noted on abdominal palpation.
- Murmurs may be noted on auscultation, and are typically associated with valvular insufficiency.

Diagnosis

- History and physical examination findings are important in the diagnosis of heart disease.
- Perform a complete physical examination, including auscultation of the heart, and evaluation of the capillary refill time. Observe for tachypnea or dyspnea and auscult the lungs. Palpate the abdomen and examine for ascites.

▼ ***Key Point*** Proceed with further testing only if the ferret is stable. Otherwise, administer furosemide and oxygen therapy.

- Diagnosis requires information obtained by radiography, ECG, and echocardiography.
- Obtain whole-body radiographs. The cardiac silhouette typically appears enlarged and globoid in shape with rounded right and left ventricles. Ascites, hepatomegaly, pleural effusion, and pulmonary edema may be present as well.
- Evaluate a CBC, serum biochemical profile, and urinalysis to determine if azotemia, electrolyte abnormalities, or other systemic diseases are present. Perform a heartworm test if the history is supportive for potential exposure.
- If thoracic or abdominal effusion is present, perform thoraco- or abdominocentesis and submit fluid for

Table 175-6. ELECTROCARDIOGRAPHIC DATA FOR 52 CLINICALLY NORMAL FERRETS*

Parameter	Mean ± SD (Range)† (n = 25)	Value‡ (n = 27)
Age (mo)	10–20	Average, 5.2
Male:female ratio	All male	1.25
Body weight (kg)	1.4 ± 0.2	NA
Heart rate (beats/min)	196 ± 26.5 (140–240)	233 ± 22
Rhythm		
Normal sinus	NA	67%
Sinus arrhythmia	NA	33%
Frontal plane MEA (degrees)	86.13 ± 2.5 (79.6–90)	77.22 ± 12
Lead II		
P amplitude (mV)	NA	0.122 ± 0.007
P duration(s)	NA	0.024 ± 0.004
PR interval(s)	0.056 ± 0.0086 (0.04–0.08)	0.047 ± 0.003
QRS duration(s)	0.044 ± 0.0079 (0.035–0.06)	0.043 ± 0.003
R amplitude (mV)	2.21 ± 0.42 (1.4–3)	1.46 ± 0.84
QT interval(s)	0.109 ± 0.018 (0.08–0.14)	0.12 ± 0.04

NA, not available; MEA, mean electrical axis.
*All ferrets were sedated with ketamine-xylazine.
†Data from Bone L, Battles AH, Goldfarb RD, et al: Electrocardiographic values from clinically normal, anesthetized ferrets *(Mustela putorius furo)*. Am J Vet Res 49:1884–1887, 1988.
‡Data adapted from Fox JG: Biology and diseases of the ferret. Philadelphia, Lea & Febiger, 1988, p 170; and Edwards J: Unpublished data, 1987.

cytologic examination. Perform centesis as described for cats; take into consideration the relatively caudal position of the heart in ferrets. Sedation is usually necessary. A modified transudate is typically associated with CHF.

- Perform standard six-lead electrocardiography (ECG) if possible (Table 175-6 lists normal ferret ECG parameters). Sedation may be necessary. Electrocardiography may reveal atrial premature contractions, atrial tachycardia, atrial fibrillation, ventricular premature contractions, and ventricular tachycardia.

▼ ***Key Point*** Sedation with isoflurane is recommended when necessary. Sedation with ketamine or a ketamine-diazepam combination raises the heart rate. The heart rate tends to decrease with ketamine-xylazine sedation; therefore, avoid using xylazine in ferrets with suspected cardiac disease.

- Echocardiography is the most useful diagnostic tool in the ferret. The same echocardiographic changes observed in the dog and cat are seen in the ferret. (Table 175-7).

Table 175-7. MEAN ECHOCARDIOGRAPHIC VALUES FOR 34 NORMAL ADULT FERRETS

Parameter	Mean Value
Left ventricle, end-diastolic	11.0 mm
Left ventricle, end-systolic	6.4 mm
Left ventricular posterior or free wall	3.3 mm
Fractional shortening	42%
End-point septal separation	None

From Sitinas N, Beeber N, Skeels M: Unpublished data, 1992.

Treatment

▼ ***Key Point*** Treatment of acute CHF should focus on improving oxygenation and reducing cardiac preload and afterload.

- Place the ferret in an oxygen-rich environment. Administer supportive care such as subcutaneous fluids (e.g. 0.45% saline and 2.5% dextrose), and provide nutritional support for ferrets that are anorexic.
- Administer diuretics such as furosemide (1–4 mg/kg) IM or IV bid–tid.
- Nitroglycerin 2% ointment may be applied to the skin in the axilla, inguinal area, or on a hairless body surface.
- Angiotensin-converting enzyme (ACE) inhibitors may be given to reduce afterload and preload. Give enalapril (Enacard, Merck Agvet Division) (0.5 mg/kg) PO q48h, then titrate up to q24h if possible. ACE inhibitors may cause hypotension in ferrets, titrate to effect.

- When diuretics and ACE inhibitors are used together it is important to monitor for azotemia.
- Perform thoracocentesis or abdominocentesis when indicated.
- Monitor body weight, CRT, heart rate and rhythm, hydration status, mucous membrane color, respiratory rate, respiratory effort, BUN, creatinine, and serum electrolytes.

▼ ***Key Point*** Chronic therapy typically includes the use of ACE inhibitors, and diuretics with the addition of digoxin in ferrets with dilated cardiomyopathy. Whenever possible, try to titrate the diuretic dose to the lowest possible dose without recurrence of pleural effusion or pulmonary edema.

- Administer digoxin elixir (0.01 mg/kg) PO sid–bid to ferrets with dilated cardiomyopathy.
- Side effects associated with digoxin include anorexia, arrhythmias, diarrhea, lethargy, and vomiting.
- Serum digoxin levels should be monitored every 4 to 8 weeks. Normal values have not been published for the ferret; reference values for dogs and cats are used for interpretation.
- Use of antiarrhythmic drugs such as atenolol or diltiazem is not well documented in the ferrets, but may be useful in the treatment of ferrets with hypertrophic cardiomyopathy.
- Salt-free diets may be beneficial; however, they are often unpalatable to ferrets. Instruct the owner to avoid feeding snacks, treats, or food items with a high-salt content.
- Management includes periodic reevaluation of heart rate and rhythm, serum electrolytes, and renal values. Radiographs should be used to monitor for the development of pulmonary edema or changes in the cardiac silhouette. ECG and echocardiography should be repeated periodically as well.

Cardiomyopathy

Cardiomyopathy may occur in ferrets 2 years of age or older. Dilated (congestive) and hypertrophic forms can occur; the dilated form is more common.

Dilated Cardiomyopathy

Etiology

The cause of dilated cardiomyopathy (DCM) in the ferret is unknown.

Clinical Signs

- Abdominal enlargement secondary to ascites, anorexia, dyspnea, lethargy, and weight loss are often noted.
- Ascites, heart murmur, pale mucous membranes, tachycardia, and weakness may be noted on physical examination.
- Moist rales and increased respiratory sounds may be noted when pulmonary edema is present.
- Pleural effusion may be present, and may cause an increased inspiratory effort. The heart may sound muffled on auscultation.
- Coughing generally is not noted.

Diagnosis

- See the CHF section in this chapter.

Treatment

- Treatment is the same as that described for CHF.
- Taurine supplementation does not appear to have any effect on DCM in the ferret.

Follow-Up Care

- See the CHF section in this chapter.

Hypertrophic Cardiomyopathy

Etiology

The cause of hypertrophic cardiomyopathy (HCM) is unknown.

Clinical Signs

- Clinical signs may be compatible with those described for CHF or DCM (see above).
- Other clinical signs are similar to those described for the cat, and include acute onset of congestive heart failure and/or sudden death.

Diagnosis

- Follow the same guidelines described for DCM.
- Include HCM on the rule-out list when evidence of cardiac disease is noted on the physical examination or diagnostic evaluation.
- Radiographs may not be beneficial in the diagnosis of HCM.
- Echocardiography should be used for definitive diagnosis.

Treatment

- Treatment should be aimed toward alleviating signs of CHF and improving the diastolic efficiency of the left ventricle.
- Administer beta-adrenergic blocking drugs such as atenolol (3.125–6.25 mg) PO sid. Titrate to effect.
- Administer calcium channel blockers such as diltiazem (3.75–7.5 mg) PO bid. Titrate to effect.
- Diuretics are indicated if symptoms of CHF are present (see above).

Follow-Up Care

- Follow-up is the same as that described for CHF and DCM.

Heartworm Disease

Natural and experimental heartworm infections have been reported in ferrets (see Chapter 152). The clinical presentation of heartworm disease typically resembles that of cats; however, the life cycle of *Dirofilaria immitis* in ferrets is similar to the life cycle present in the dog. Reported adult worm burdens range from 1 to 10. The presence of only one adult worm in the heart can be lethal.

Etiology

- Heartworm disease is caused by the canine heartworm *Dirofilaria immitis,* a filarial nematode that is transmitted via mosquitoes.
- Ferrets that are housed outdoors in endemic areas are at greatest risk of infection; however, ferrets kept indoors also can become infected.

Clinical Signs

- Clinical signs include coughing, dyspnea, hepatomegaly, inappetence, lethargy, melena, weakness, and symptoms associated with right-sided CHF (pulmonary edema, pleural effusion, ascites). Sudden death due to pulmonary artery obstruction may also occur.
- Microfilaria may be present in the blood of approximately 50% of infected ferrets.

Diagnosis

- Diagnosis is based on the history, clinical signs, heartworm test results, radiographs, and echocardiography.
- If the history is compatible with cardiac failure, inquire about possible mosquito exposure.
- Physical examination findings resemble those of heart failure (see above).

▼ ***Key Point*** Minimize stress in ferrets suspected of heartworm disease. If symptoms of congestive heart failure are present, delay further diagnostic evaluation until the patient is stabilized (see "Treatment of Congestive Heart Failure").

- Obtain whole body radiographs. Thoracic changes may include cardiomegaly with enlargement of the right atrium, caudal vena cava, and right ventricle. Pleural edema and pleural effusion may be present as well. Radiographic changes in the peripheral pulmonary arteries are not typically noted because the worms tend to reside in the right side of the heart and in the main pulmonary artery. Abdominal changes often include hepatomegaly, splenomegaly, and ascites.
- If possible, draw blood for the modified Knott's test for microfilaria. Microfilaria are identified in approximately 50% of infected ferrets.
- Submit blood for an enzyme-linked immunosorbent assay (ELISA) for *Dirofilaria* antigen. Antigen is produced by adult female heartworms; there is a potential for false negative test results in ferrets with low worm burdens. A commercial assay (Snap Heartworm Antigen Test Kit; IDEXX Laboratories Inc., Portland, ME) has been used to detect heartworm infection in the ferret.
- Perform a CBC, serum biochemical profile, and urinalysis to rule out the presence of other systemic diseases.
- If pleural or abdominal effusion is present, submit fluid for cytology. A modified transudate is typically noted when CHF is present.
- Echocardiography may be used to visualize heartworm(s) in the pulmonary artery, right ventricle, and right atrium; dilation of the right ventricle and right atrium may be assessed as well. Doppler echocardiography may be used to evaluate the patient for the presence of pulmonary hypertension.

Treatment

- Treatment of heartworm disease in ferrets is difficult. Success is dependent on early diagnosis, diligent supportive care, and long-term antithrombotic therapy in conjunction with adulticide therapy.
- If signs of CHF are present, treat this first, and stabilize the patient (see the CHF section).
- If the patient is symptomatic and microfilaremia positive:
  - Administer microfilaricidal therapy: Ivermectin (50 µg/kg) SC every 30 days until clinical signs and microfilaremia resolve.
  - Follow with adulticide therapy: melarsomine (Immiticide, Rhone Merieux, Athens, GA) using a two-stage protocol:
    Stage 1: Administer a single dose of melarsomine (2.5 mg/kg) IM.
    Stage 2: 1 month later, administer two injections of melarsomine (2.5 mg/kg) IM given 24 hours apart.
- Transient swelling at the site of injection is common.
- Administer prednisone (0.5 mg/kg) PO sid–tid during adulticide treatment and for as long as clinical signs persist.
- If pleural effusion is present administer diuretics (see the CHF section).
- Cage confinement is important for 4 to 6 weeks after treatment.
- Perform a post-treatment ELISA for heartworm antigen 3 months after adulticide therapy. Repeat every 30 days if results are positive. Most ferrets become seronegative 4 months after treatment.
- Begin heartworm prevention 1 month after adulticide treatment.
- If ferrets are microfilaria negative, administer adulticide therapy as described above.

Prevention

▼ *Key Point* Because of the high mortality associated with heartworm disease, recommend preventive therapy for all ferrets in heartworm-endemic areas.

- Ivermectin may be given as preventive therapy beginning 1 month before and continuing 2 months after mosquito season. Liquid ivermectin 1% may be diluted in propylene glycol (0.3 ml ivermectin in 30 ml propylene glycol) and administered at a dose of (0.2 ml/kg) PO every month. This solution must be stored in an amber glass bottle out of sunlight. Feline Heartguard (Merck Agvet) may be administered using the dose appropriate for a 1- to 5-lb cat.
- If possible, house all ferrets in endemic areas within structures with mosquito-proof screening.
- Follow the same recommended guidelines for heartworm prevention in dogs and cats.

Valvular Heart Disease

Valvular heart disease may occur in ferrets >3 years of age.

Clinical Signs

- Clinical signs depend on the severity of the underlying disease process.
- Mitral regurgitation may be ausculted as a systolic murmur in the left apical region.
- Tricuspid regurgitation is ausculted in the right parasternal region.
- Dyspnea and moist rales may be noted on auscultation of the lungs if CHF is present.

Diagnosis

- Obtain thoracic radiographs to evaluate the size of the heart and to determine if CHF is present. Pulmonary edema typically appears as a mixed alveolar and interstitial pattern in the caudodorsal lung lobes.
- Electrocardiography (ECG) may be normal or may demonstrate evidence of atrial arrhythmias.
- Echocardiography typically demonstrates thickening of affected valves and atrial enlargement.
- Doppler echocardiography may be used to identify and quantify the degree of regurgitation present. Aortic regurgitation is often noted in ferrets and is considered an incidental finding.

Treatment

- Treatment is recommended if CHF is present, or if cardiac enlargement is significant (see the CHF section).

Myocarditis

Myocarditis occurs when the myocardium is infiltrated with inflammatory cells, resulting in the development of reduced myocardial function, arrhythmias, and replacement of the normal myocardial tissue with fibrous tissue.

Etiology

- Causes include sepsis, systemic vasculitis, parasitic, bacterial or viral infection, and autoimmune disorders.
- Aleutian disease can cause fibrinoid necrosis and mononuclear cell infiltration of the arterioles of the heart.

Clinical Signs

- Antemortem diagnosis is difficult.
- Suspect myocarditis if arrhythmia and/or acute myocardial dysfunction is noted in association with multisystemic illness.
- Definitive diagnosis is made by histopathological evaluation of affected myocardial tissue.

Treatment

- Treatment should be directed at identifying and treating the underlying systemic disease.
- Cardiovascular support should be provided and may include the use of diuretics or antiarrhythmic drugs (see the CHF section).

Other Cardiac Diseases

As clinical experience with pet ferrets increases, other types of cardiac disease are likely to be recognized. Third-degree heart block (of unknown etiology) and various forms of valvular disease, including mitral and tricuspid insufficiency and endocarditis, have been seen in ferrets.

- The approach to these conditions in ferrets is the same as for other companion animals; use the drug dosages given previously for cardiac myopathies.

Gastrointestinal System

CHARACTERISTICS OF THE NORMAL FERRET DIGESTIVE TRACT

Teeth

- The permanent teeth erupt between 50 and 74 days of age.
- The dental formula is 2 (I3/3, C1/1, Pm3/3, M1/2).
- The third upper premolar (carnassial tooth) has three roots. The second lower molar has one root. All other premolars and molars have two roots.

Gastrointestinal Tract

- The ferret is an obligate carnivore with a simple stomach, short intestinal tract, no cecum or ileocolic valve, and a short colon.

- The duodenum terminates at the jejunoileum; there is no gross anatomic distinction between the jejunum and the ileum.
- The junction of the jejunoileum and the colon is determined by evaluating the pattern of anastomosis between the jejunal artery and the ileocolic artery.
- GI transit time is approximately 3 to 4 hours.

Anal Sacs

- The anal sacs are located between the external and internal anal sphincter muscles at 4 and 8 o'clock. The ducts are located near the mucocutaneous junction.

Diet

- The exact nutritional requirements of the ferret have not been determined.
- The diet of the ferret must contain predominantly animal protein and fat.
- Due to the short digestive tract and rapid GI transit time, the ferret requires a concentrated maintenance diet high in protein (30–35%) and fat (15–18%), and low in fiber. The protein quality should be 85% to 90% digestible.
- Breeding ferrets and kits may require diets higher in protein and fat.
- Meat, poultry, meat and poultry meals, and other animal-based proteins should appear first, then several more times on the food ingredient list.
- Complex carbohydrates (starch, fiber) are not readily digested by the ferret. High–fiber diets can induce a relative protein-calorie deficiency; the ferret cannot eat enough of a low-density food to meet its high maintenance requirements.
- Premium cat foods and ferret diets typically meet the ferret's nutritional requirements for growth and reproduction.
- Treats and supplements should not exceed more than 10% of the daily diet. Acceptable treats include meat baby foods, and moist cat or ferret diets. High–sugar or carbohydrate treats should be limited, especially if insulinoma is present.
- Fatty acid supplements should be given in measured amounts (a few drops per day). Administration of large quantities of fatty acid supplements may reduce the intake of the balanced diet.
- Canine diets should not be fed to ferrets; the protein, fat, and carbohydrate content is not appropriate, and the diets often contain high percentages of grain and vegetable matter.
- The long–term effect of formulated dry and canned diets on the long–term health of ferrets is controversial among some practitioners.
- Some practitioners feel that feeding commercial diets containing large quantities of plant-based ingredients contributes to the development of eosinophilic gastroenteritis, inflammatory bowel disease, insulinoma, urolithiasis, and general untriftiness. For example, most ferrets in the United States are fed dry kibbled diets, and the incidence of insulinoma is high. Many ferrets in Europe and Australia are fed whole prey items (e.g., a "natural diet), and the incidence of insulinoma is low.
- A correlation between diet and the development of certain diseases in ferrets is hypothetical at this time; however, this controversy demonstrates the need for longer–term diet studies in the ferret.

DENTAL DISEASE

- The canine teeth are often worn or broken at the tips due to biting and gnawing.
- Broken canine teeth typically are not painful unless the dental pulp is exposed.
- Dental tartar and periodontal disease are common in ferrets over 2 years of age.
- Soft, moist diets may predispose ferrets to the development of dental disease.
- Tartar typically accumulates first on the second and third upper premolars.
- Dental abscesses are not common, but may be noted, even in young ferrets.
- Follow the basic medical and surgical treatment principles described for dental diseases in dogs and cats (see Chapter 64).

SALIVARY MUCOCELE

- Ferrets have five major pairs of salivary glands: the parotid, submandibular, sublingual, molar, and zygomatic.
- Salivary mucocele occurs secondary to trauma or infection of a salivary gland.
- Salivary mucocele typically presents as a soft to firm swelling in the region of the orbit, oral commissure, or mandibular lymph node. Aspiration of the swelling often yields a clear to serosanguinous or mucinous fluid; microscopic examination demonstrates amorphous debris and occasional RBCs.
- Treatment of choice is surgical excision of the affected gland (see Chapter 64).
- Advise clients that recurrence is possible.

MEGAESOPHAGUS

Megaesophagus is rare in ferrets.

Etiology

- The etiology of megaesophagus in ferrets is unknown (see list of possible causes in dogs in Chapter 65).

Clinical Signs

- Clinical signs resemble those described for the dog and include: lethargy, anorexia, dysphagia, coughing, choking, dyspnea, weight loss, and regurgitation.
- Clients may indicate that the ferret vomits up large boluses of food.

Diagnosis

- Diagnosis may be based on clinical signs and radiographic evidence of megaesophagus.
- Obtain thoracic radiographs. The esophagus is often dilated and filled with air in the cervical and thoracic regions. Food may be present within the lumen of the esophagus.
- Perform a barium contrast study to delineate the esophageal mucosa and to identify potential mural lesions, strictures, or obstructions.
- Aspiration pneumonia may be visible radiographically.

Treatment

- Follow canine treatment protocols. The prognosis is poor; response to therapy is usually not successful.
- GI promotility agents such as metoclopramide (Reglan, AH Robins Company, Inc., Richmond VA) (0.2–1mg/kg) PO tid–qid may be helpful.
- Administer H2-receptor blocking drugs such as cimetidine, ranitidine (Zantac, Glaxo Pharmaceuticals, Research Triangle Park, NE), or famotidine (Pepcid AC, Johnson and Johnson, Fort Washington, PA).
- Administer antibiotics if indicated for aspiration pneumonia.
- Supportive care includes feeding high-calorie, high-protein slurried diets 3 to 4 times per day, and elevating the ferret for 15 to 30 minutes immediately after feeding.

NAUSEA AND VOMITING

- Ferrets, like other carnivores, are able to vomit.
- Differential diagnoses to consider for vomiting include esophageal and gastroenteric disorders (see below).
- Ferrets often demonstrate symptoms associated with nausea or vomiting when gastroenteritis, GI disease, gastric ulcers, *Helicobacter mustelae* gastritis, or GI foreign bodies are present. Hypoglycemia may cause signs of nausea as well (see discussion of Insulinoma in this chapter).
- Signs of nausea include hypersalivation and pawing at the mouth.
- Ferrets may demonstrate bruxism (grinding of the teeth) when abdominal discomfort is present.

GASTROINTESTINAL PARASITES

- GI parasites are uncommon in the ferret. Coccidiosis and giardiasis are occasionally seen. Nematodiasis is rare.
- Routine fecal testing is still recommended, especially in young animals and ferrets with diarrhea or rectal prolapse.
- Young ferrets with coccidiosis may have diarrhea and may be severely dehydrated.
- Cryptosporidiosis may occur in ferrets, but typically does not result in clinical disease. The zoonotic potential is unknown; however, it may be prudent to warn immunosuppressed owners of the potential for zoonosis.

Treatment

- Treat with appropriate anthelmentics following the protocols and dosages used for cats (see Chapter 69).

GASTRITIS, AND GASTRIC AND DUODENAL ULCERS

Gastric and duodenal ulcers have been documented in laboratory ferrets and reported occasionally in pet ferrets. Clinical signs are often vague, making the diagnosis difficult.

Etiology

- The etiology is unknown but may include stress, GI foreign body, *H. mustelae* gastritis, administration of ulcerogenic drugs, GI neoplasia, and azotemia secondary to renal disease.
- *H. mustelae* is similar to *H. pylori,* the bacteria associated with gastritis and ulceration in humans. *H. mustelae* infection in the ferret can be an incidental finding, or can induce gastritis, duodenitis, and GI ulceration.

Clinical Signs

- Gastritis and ulcers may be acute or chronic.
- Clinical signs include anorexia, lethargy, hypersalivation, bruxism (tooth grinding), weight loss, vomiting, and melena.

Diagnosis

- Presumptive diagnosis may be made based on the history and clinical signs.
- Perform a CBC and serum biochemistry profile to rule out systemic and metabolic disease.
- Obtain fasting whole-body radiographs to help rule out the presence of a GI foreign body or trichobezoar.

- A barium study may be used to demonstrate GI ulceration.
- Exploratory laparotomy/gastrotomy is often required for a definitive diagnosis.
- Diagnosis of *H. mustelae* gastritis is often a diagnosis of exclusion. Definitive diagnosis requires the finding of organisms along typical histological lesions on gastric biopsy specimens.

Treatment

- Debilitated, anorexic ferrets may require hospitalization for supportive care.
- If the patient is vomiting, withhold food for 6 to 12 hours. Administer IV fluids containing dextrose, and monitor for signs of hypoglycemia. When vomiting has resolved begin to offer small, bland meals.
- Feed small meals of a bland, moist diet tid–qid (see diet recommendations in "Insulinoma" section). Avoid feeding high-fiber dry foods.
- Administer broad spectrum antibiotics if the ferret is debilitated.
- Administer a gastric protectant. Options include:
  - Bismuth subsalicylate (Pepto Bismol, Procter & Gamble) (1 ml/kg) PO tid.
  - Sucralfate (Carafate, Marion Merrell Dow, Inc., Kansas City, MO) (100 mg/kg) PO tid–qid.
  - Systemic H_2-receptor antagonists such as cimetidine and famotidine.
  - Omeprazole (Prilosec, Astra Merck, Inc., Wayne PA) (_ the contents of a 10-mg capsule mixed with soft food) PO sid-bid.
- If H. mustelae infection is suspected, administer the following three drugs concurrently for at least 2 weeks ("triple therapy"):
  - Amoxicillin (10 mg/kg) PO, SC bid.
  - Metronidazole (20 mg/kg) PO bid.
  - Bismuth subsalicylate (Pepto-Bismol, Procter & Gamble) (see dosage information above).

GASTROINTESTINAL FOREIGN BODIES

GI obstruction caused by foreign body ingestion or hairballs is one of the most common problems in pet ferrets.

Etiology

- Foreign bodies typically occur in ferrets younger than 1 year of age; trichobezoars (hairballs) are common in ferrets older than 2 years of age.

▼ ***Key Point*** Suspect the presence of a GI foreign body in any young ferret presented for anorexia, even if no vomiting is reported.

- Rubber and foam objects are the most common foreign bodies. Obstruction with a hairball (older ferrets), cloth, or plant material also may occur.

Clinical Signs

- Lethargy, partial or total anorexia, hypersalivation, bruxism, pawing at the mouth, weight loss, and diarrhea are the most common clinical signs of GI foreign body. Hindlimb weakness, dehydration, and melena may be noted as well.
- Vomiting is uncommon; however, if the ferret is vomiting, be suspicious that a GI foreign body may be present.

Diagnosis

- Diagnosis is based on the history, physical examination findings, radiographs, or exploratory laparotomy.
- History: Identify possible types or causes of foreign body ingestion. Ask the owners if hairball preventative is used routinely.
- Physical Examination: Large gastric foreign bodies are often palpable. Small foreign bodies in the small intestine may be associated with localized pain.
- Obtain fasting (4–6 hours) plain whole body radiographs. Radiographs may reveal segmental ileus, and marked gaseous distention of the stomach and/or bowel. Occasionally a foreign body or trichobezoar can be identified.
- Obtain a GI barium contrast study to identify small foreign bodies and to rule out GI ulceration.
- Perform a CBC and serum biochemical panel to rule out hepatic lipidosis and other systemic diseases.

Treatment

Surgical removal is the treatment of choice. If the ferret is debilitated, begin supportive therapy, and perform surgery as soon as possible.

- Surgery: Follow routine preoperative, operative, and postoperative procedures for gastrotomy or enterotomy (see Chapters 68 and 70). Ferret tissues are more delicate than those of a puppy or kitten of equivalent weight. Use 4-0 or 5-0 suture material to close the GI tract.
- Perform gastric biopsy to rule-out underlying *H. mustelae* infection, and other GI diseases. Perform biopsy of the liver.
- Evaluate the entire abdominal cavity prior to closure. Older ferrets often have concurrent diseases such as insulinoma or adrenal gland disease.
- The prognosis following gastrotomy is good with prompt therapy.

Prevention

▼ ***Key Point*** Instruct owners to "ferret proof" the house if ferrets are allowed to roam. In particular, restrict access to rubber toys and rubber objects.

- To prevent trichobezoars, administer a feline hairball laxative product (2–4 cm) PO 2 to 3 times per week.

EPIZOOTIC CATARRHAL ENTERITIS

Epizootic catarrhal enteritis (ECE, "green slime disease") is a highly infectious diarrheal disease that first appeared in 1993.

Etiology

The etiological agent is thought to be a coronavirus. ECE can spread rapidly through a ferret population, often affecting 100% of ferrets within 48 hours. Histological examination of intestinal biopsy samples reveals lymphocytic enteritis with villous atrophy and blunting, and degeneration of the apical epithelium.

Clinical Signs

- The history often includes recent exposure of an older ferret to a new or young ferret that appears healthy. Often within 48 hours the older ferret becomes anorexic and lethargic.
- Four clinical syndromes are typically seen:
  1. ECE may cause relatively mild diarrhea that lasts several days in young ferrets with no underlying disease.
  2. ECE may cause severe diarrhea lasting for several days that may be followed by an acute onset of severe bloody diarrhea in older ferrets or ferrets with concomitant disease. Anemia may develop as a sequelae.
  3. A wasting disease with abnormal stools that have the appearance of bird-seed or of being grainy. These stools may develop in ferrets that initially appear to have recovered from the diarrheal phase.
  4. Voluminous green, watery diarrhea and occasional vomiting followed by chronic wasting may occur in some ferrets.
- The clinical course of disease can be prolonged in some ferrets, and may last weeks to months. Affected ferrets typically appear to recover, but continue to have persistent, intermittent diarrhea.

Treatment

- No one specific treatment is consistently effective.
- Supportive care, including fluid therapy and nutritional support, is very important in the treatment of ECE.
- Treat sick ferrets with aggressive fluid therapy. Administer fluids IV, IO, PO, or SC depending on the ferret's status.
- Administer broad-spectrum parenteral antibiotics.
- Feed a bland, high-calorie diet, such as a mixture of Science Diet A/D (Hills Science Diet, Topeka, KS) mixed with Deliver 2.0 (Mead Johnson Nutritionals).
- Intestinal adsorbents or protectants (e.g., Kaopectate, UpJohn) may help in some ferrets.
- Loperamide (Imodium A-D, McNeil Consumer) (0.2 mg/kg) or (1 ml/kg) PO bid every 1 to 3 days may be helpful.
- Administration of prednisone (1mg/kg) PO bid every 14 days may alleviate the chronic, intermittent diarrhea in ferrets with long-term symptoms.
- The disease may recur in previously affected ferrets; an asymptomatic carrier state appears to be possible.
- Do not house ferrets that have had ECE with ferrets that have not had the disease.

ROTAVIRUS

- Rotavirus has been associated with several outbreaks of diarrhea and high mortality in ferret kits 2 to 6 weeks of age; it is often referred to as "ferret kit disease."
- Rotavirus also causes diarrhea in the young of several other species, including humans, cattle, swine, sheep, and rats.
- In adult ferrets, rotavirus infection is rarely fatal, but may cause bright green mucoid diarrhea that lasts for several days.
- There is no readily available antemortem test for the rotavirus infection; rotavirus particles can be identified in feces by electron microscopy.

Treatment

- Treatment consists of supportive care. Administer fluids, antibiotics, and nutritional support.

SALMONELLA

Salmonellosis is rare in the ferret, and is typically associated with exposure to contaminated raw meat and meat by-products. *Salmonella typhimurium, S. newport,* and *S. choleraesuis* may be associated with clinical disease.

- *Clinical signs* include anorexia, lethargy, fever, and diarrhea (usually bloody). Conjunctivitis and anemia have also been reported.
- *Diagnosis* is based on clinical signs and a positive fecal culture. Multiple fecal samples must be collected, and selective media is used for culture.
- *Treatment* includes aggressive supportive care and antibiotic therapy.
  - Ferrets may be presented in shock. IV fluids and administration of rapidly acting intravenous corticosteroids may be necessary for treatment of these patients.
- Other details of salmonellosis, including its public health significance, are discussed elsewhere in this text.

EOSINOPHILIC GASTROENTERITIS

Eosinophilic gastroenteritis (EGE) is an inflammatory bowel disease that occurs in ferrets and other animals.

Etiology

No specific etiological agent has been identified in the ferret, but food allergy is implicated in humans and other animals.

Clinical signs

- Chronic diarrhea with or without mucus or blood, and weight loss are the most common signs. Inappetence, intermittent vomiting, and skin lesions may be seen as well.
- On physical examination, the mesenteric lymph nodes may be enlarged and the intestines may feel thickened.
- A marked peripheral eosinophilia is often present on the CBC differential.

Diagnosis

- Presumptive diagnosis is based on history, clinical signs, physical examination findings, the presence of a peripheral eosinophilia, and/or the presence of eosinophils on fecal cytology.
- Definitive diagnosis is based on histological examination of intestinal biopsy specimens. Mild to extensive eosinophilic infiltration of the mucosa, submucosa, and muscularis of the stomach and small intestines are noted. Focal eosinophilic granulomas maybe identified in the mesenteric lymph nodes.

Treatment

- Treatment is similar to that described for treatment of dogs and cats.
- Begin corticosteroid therapy with prednisone (1.0–2.5 mg/kg) PO sid every 14 days. Perform a recheck examination and CBC 2 weeks after the last dose. If the ferret has improved clinically and the peripheral eosinophilia is resolving, decrease the prednisone dose by 50% every 14 days, and recheck again. Continue the prednisone taper at 2-week intervals until the ferret is tapered to the lowest possible dose, or withdrawn from the steroids altogether.
- Although food allergy has not been identified as a definitive etiological cause of EGE, changing the ferret to a hypoallergenic diet, such as a feline lamb and rice-based diet may be helpful in resolution of signs.
- There have been reports of ferrets with peripheral eosinophilia (up to 40%), and erythema and crusting of the feet, ears, and face. Histological lesions in biopsy specimens from affected skin were consistent with allergic dermatitis. These ferrets were treated with corticosteroids, and did respond to treatment. One also responded to diet change.

INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) can occur in the ferret.

Etiology

The etiology is unknown; dietary factors, hypersensitivity reactions, or an immune-mediated cause have been considered.

Clinical Signs

- Clinical signs can be subtle and include diarrhea; nausea; occasional vomiting; soft, malformed stools that resemble bird seed; and weight loss. These signs often resemble ECE, EGE, and *Helicobacter* gastroenteritis.
- Affected ferrets are often young or middle-aged adults.
- Elevation of liver enzymes and serum globulins may be noted on serum biochemistry analysis.
- Lymphocytosis may be noted on the CBC.

Diagnosis

- Diagnosis is based on the history, clinical signs, and diagnostic work-up.
- Definitive diagnosis is made by histological examination of gastric and intestinal biopsy samples. Mild to severe lymphoplasmacytic gastritis and enteritis are noted on histopathology.

Treatment

- Administer corticosteroids such as prednisone (1.0–2.5 mg/kg) PO sid every 14 days initially, and taper in a manner similar to that described for EGE. Some ferrets respond poorly to steroid therapy.
- Azathioprine (Imuran, Prometheus Laboratories, San Diego, CA) (0.9 mg/kg) PO q24–72h may be used as an alternative to steroid treatment.
- Hypoallergenic diets may offer some benefit.

PROLIFERATIVE BOWEL DISEASE (PBD)

Proliferative bowel disease (PBD) in ferrets was first reported in 1982, and is similar to the PBD that occurs in swine and hamsters. PBD was a commonly encountered disease in the late 1980s and early 1990s, but is relatively uncommon now.

Etiology

PBD is caused by *Lawsonia intracellularis,* an intracellular bacteria that cannot be propagated by routine culture methods.

Clinical Signs

- This disease affects primarily young ferrets 4 to 14 months of age.
- Acute and chronic forms of the disease can occur.
- Diarrhea is present and often contains mucus and blood. Defecations are frequent and small; ferrets often cry out when they defecate. The rectum may be partially prolapsed.
- Other signs include lethargy, depression, inappetence, weight loss, dehydration, and pyrexia.
- Neurologic signs such as ataxia and muscle tremors may be present.
- The intestines may feel firm or thickened on abdominal palpation.

Diagnosis

- A tentative diagnosis of proliferative bowel disease is based on clinical signs and physical examination. Definitive diagnosis requires intestinal or colonic biopsy, but this rarely is warranted because response to therapy usually is good if initiated early.
- A polymerase chain reaction (PCR) assay specific for the swine isolate, and an indirect fluorescent antibody test (IFA) are available.
- Necropsy lesions include gross thickening and discoloration of the small intestine and/or colon. Ridges of proliferative tissue that are distinct from normal adjacent tissues are present on the mucosal surface.
- Histological examination of biopsy samples or necropsy specimens typically demonstrate epithelial proliferation, hypertrophy of the muscularis, and infiltration of the bowel wall with monocytic or granulocytic inflammatory cells. Silver-stained tissues reveal intracellular, comma-shaped organisms in crypt epithelial cells. Glandular hyperplasia consisting of irregular, branching proliferative glands that lack goblet cells, and necrotic debris may be identified in the crypts. Severe glandular hyperplasia may resemble neoplasia and can metastasize.

Treatment

- Treat mild cases on an outpatient basis.
- Hospitalization for supportive care (fluid therapy, nutritional support) may be necessary when severe disease is present.
- Administer Chloramphenicol (50 mg/kg) q12h, PO, IV, IM, or SC as the drug of choice. Treat for at least 2 weeks; longer therapy often is necessary to prevent relapse.
- Metronidazole (20 mg/kg) q12h, PO may be effective.

Prevention and Prognosis

- The prognosis is good with timely therapy.
- Some ferrets improve temporarily and then relapse at the end of the treatment period. Use a long-term course of antibiotic therapy in these animals.

RECTAL PROLAPSE

- Rectal prolapse is usually a disease of young ferrets, and is often associated with diarrhea.
- Possible causes of rectal prolapse include colitis, diarrhea, GI parasitism (e.g., coccidiosis), PBD, and other diseases that may cause straining or diarrhea.
- Other differentials include GI lymphoma, benign intestinal polyps, and postoperative complications of anal gland removal.
- Perform direct fecal and fecal flotation tests to screen for parasites.
- Medical treatment is similar to that described for other species. Administer anthelmentics and antibiotics when indicated.
- The prolapse may resolve without surgical intervention when the underlying disease process is resolved.
- Surgical correction is usually unnecessary (see below).
- If indicated, perform a biopsy of the prolapsed tissue to rule out lymphoma.

Surgical Therapy

- Flush the prolapsed tissues with sterile saline and replace them into the rectum.
- Place a purse-string suture in the anus with a small opening to allow passage of feces. Keep the purse-string suture in place for 2 to 5 days.
- In ferrets with chronic prolapse, surgery may be necessary to reduce the size of the anal opening. Excise a small triangular wedge of anal mucosa and routinely close the defect by suturing. Alternatively, consider abdominal exploratory surgery and colopexy (see Chapter 75)

ANAL SAC ABSCESS

- Clinical signs and physical examination findings in ferrets with an abscessed anal sac are the same as those described in dogs and cats.
- The recommended treatments include antibiotic therapy, lancing and drainage of the abscess, or surgical removal of both anal sacs (see Chapter 75).

Anal Sacculectomy

Anal sacculectomy is performed as a treatment for anal sac abscesses, or to decrease the musky "ferret" odor. For odor reduction, neutering should be performed simultaneously because the apocrine, perianal, sebaceous, and scent glands in the skin are under hormonal control and contribute to the overall musky odor. Some clinicians believe that neutering is sufficient to decrease odor and that routine anal sacculectomy should be discouraged.

Surgical Technique

1. Grasp the anal sac duct and hold it closed with mosquito forceps. Make a circumferential skin incision around the duct opening.
2. Apply gentle caudal traction to the anal sac, and use a scalpel blade or gauze to tease away the surrounding fascia.
3. Leave the surgical sites open, and allow to heal by second intention.

Alternative Technique

1. Make small, arc-like incisions just lateral to the duct openings.
2. Dissect the subcutaneous tissues bluntly to reveal the neck of the anal sac; grasp the opening and hold it closed with mosquito forceps.
3. Dissect the sac free of surrounding tissues, using gentle traction.
4. Do not suture the incisions.

Urogenital System

REPRODUCTIVE SYSTEM

Characteristics of the Normal Ferret Reproductive System

Ferrets reach sexual maturity during the first breeding season after birth. The breeding season runs from March to August under natural lighting conditions.

Males

- The opening of the prepuce is located just caudal to the umbilical area.
- Males (hobs) have a J-shaped os penis.
- During the breeding season (March–August), testicle size is twice that noted in the fall and winter months.
- Prostatic tissue is located at the base of the urinary bladder and surrounds the urethra. Prostatic disease associated with adrenal gland disease may occur in middle-aged and geriatric male ferrets (see "Adrenal Gland Disease" and "Prostatic Disease").

Females

- Female ferrets (jills) are seasonally polyestrous and are induced ovulators. Ovulation typically occurs 30 to 40 hours after mating.
- The vulva is located in the perineal region ventral to the anus. In non-estrous females the vulva is small, and looks like a slit; during estrus (or when adrenal gland disease is present), the vulva becomes swollen and is easily visualized.
- If mating is unsuccessful, pseudopregnancy results and lasts 41 to 43 days.
- Approximately 50% of females remain in estrus if they are not bred. The resultant prolonged elevation of serum estrogens can cause bone marrow toxicity and pancytopenia (see the discussion of anemia under "Hematopoietic System" in this chapter).
- Submit blood for a CBC and platelet count if the ferret has been in estrus for more than 28 days.
- Termination of estrus is recommended (see "Termination of Estrus in the Hematopoietic".)

Castration

- Most pet male ferrets in the United States have already been neutered prior to 8 weeks of age.
- Castrate intact male ferrets at 6 to 8 months of age in order to reduce aggressive behavior and odor.
- Castration is performed using techniques similar to those used in cats (see Chapter 87).
  - Make an incision in the scrotum over each testicle.
  - Remove the testicles using an open or closed technique.
  - Incisions may be left open to heal by second intention.

Ovariohysterectomy

- Most pet female ferrets in the United States have already been spayed prior to 8 weeks of age.
- Spaying intact female ferrets is recommended to prevent estrogen-induced bone marrow hypoplasia.
- Ovariohysterectomy is similar to the procedure performed in cats (see Chapter 91).
  - The ventral midline incision is made approximately 1 cm caudal to the umbilicus, and may be extended as necessary.
  - The uterus is bicornuate, and is located dorsal to the bladder.
  - Ovarian vasculature may be difficult to locate due to the large amount of body fat typically present in this region.

Pyometria/Metritis

- Pyometra and metritis are uncommon in pet ferrets in the United States because they are usually spayed prior to being sold as pets.

- Clinical signs may include anorexia, lethargy, pyrexia, and vulvar discharge. Polyuria and polydipsia are not usually noted.
- Persistent estrus may predispose ferrets to pyometra.
- Preoperatively perform a CBC and a serum biochemical analysis to rule out estrogen-induced bone marrow hypoplasia (see "Anemia" in "Hematopoietic System").
- Provide appropriate supportive care pre- and postoperatively.
- Perform ovariohysterectomy when the patient is stable (see Chapter 91).
- Start the ferret on broad-spectrum antibiotic therapy preoperatively, and continue postoperatively for 10 to 14 days. Use broad-spectrum antibiotics. Organisms commonly associated with pyometra include *Staphylococcus* spp, *Streptococcus* spp, *Corynebacterium* spp, and *E. coli*.

Vulvar Swelling in Spayed Females

- Vulvar swelling is an external sign of estrus in female ferrets.
- In a spayed female, a swollen vulva indicates a remnant of ovarian tissue, or another source of estrogens and estrogen precursors such as adrenal gland disease (see "Adrenal Gland Disease").
- Ovarian remnants typically induce signs of estrus in ferrets younger than 2 years of age.
- Administer HCG (100 IU) IM. Vulvar swelling should subside if an ovarian remnant is present. If no changes occur, adrenal gland disease is probably the cause of the clinical signs.
- Perform exploratory laparotomy to remove the ovarian remnant (see Chapter 91). Evaluate for uterine remnants and adrenal gland disease as well.
- Preoperatively evaluate a CBC to rule out estrogen-induced bone marrow hypoplasia.

Pregnancy Toxemia

- Pregnancy toxemia is a potentially life-threatening condition that occurs in late pregnancy. Primiparous females are most commonly affected.
- The disease results in high mortality of jills and kits.
- Toxemia can be induced if an accidental fast occurs in the last week of gestation.
- Pregnancy toxemia may also develop in primiparous jills that are carrying large litters due to nutritional compromise induced by the size of the gravid uterus and the resultant reduced capacity of the stomach.
- Advise owners that pregnant jills must have access to food and water *al lib* during pregnancy.
- Suspect pregnancy toxemia if acute lethargy develops in the last week of gestation. Other clinical sings include dehydration, melena, hypoglycemia, ketonuria, and azotemia.
- Affected ferrets usually are presented in an acute state of shock.
- *Treatment* includes aggressive supportive care including IV or IO fluids containing dextrose. Perform an immediate cesarean section (see Chapter 91).
- Postoperative care includes continued supportive care, including frequent feedings of high-calorie critical care diets.
- Jills that survive pregnancy toxemia often do not produce milk. Kits can be difficult to hand rear; if a foster jill is not available, attempts may be made to hand rear the kits using a kitten milk replacer (see below). Kits born before 40 days of gestation often do not survive.
- The prognosis is usually poor, even with aggressive treatment.

Mastitis

- Do not breed females with a history of mastitis.
- Abrasions to the mammary tissue and nipples can cause mastitis. Prevent trauma from occurring by providing a large nest box opening with smooth edges that allows the jill to pass through easily.
- Mastitis may be acute or chronic.
- *Acute mastitis* typically occurs immediately after whelping or during the third week of lactation.
  - Affected glands appear swollen, firm, red to purple in color, and are painful. Gangrene can develop within hours of clinical signs.
  - Treatment must be aggressive. Administer broad-spectrum antibiotics, and apply hot packs to the affected area 2 to 3 times per day for 2 days. Debride necrotic tissue if present. Provide supportive care and analgesic therapy.
  - Submit a sample for bacterial culture and sensitivity testing. Modify antibiotic therapy based on test results.
  - If there is no clinical response to medical therapy in 2 days, or if gangrene rapidly develops, consider surgical removal of the affected mammary tissue. Because of the potential for severe toxicity and life-threatening disease, do not delay surgery if gangrene is already present, or if there is no improvement with medical therapy.
  - If the jill continues to lactate, leave the kits with her. Supplement feed the kits with a kitten milk replacer if necessary. Do not foster the kits with another jill because this may result in mastitis in the foster jill.
  - Ingestion of infected milk may cause gastroenteritis in the kits; kits may need to be treated with antibiotics as well.
- *Chronic mastitis* is often difficult to diagnose. The affected jill often appears normal, while the kits lose weight or fail to thrive.
  - Mammary glands appear firm but are not painful or discolored; often the glands are presumed to be full of milk.

- Affected mammary glands become scarred and are no longer functional. Affected jills should be culled from the breeding program.

Foster Care of Kits

- Hand-rearing kits from birth is difficult. Prognosis is poor for survival.
- It may be necessary to provide supplemental feeding for kits if the jill's milk production is reduced, or if the litter size is large.
- Whenever possible, foster kits with another lactating jill. Most jills will accept kits of any size or age.
- Kits require a milk supplement that contains a high fat content (20%). Kitten milk replacers mixed with cream may be used.
- Feed kits as much as they will eat 4 times per day with a dropper or small pet nurser.
- Begin to mix solid food with the enriched milk replacer when kits are 4 weeks of age. This mixture may be offered in a shallow dish or bowl.
- Kits may be weaned onto a solid diet at 5 to 6 weeks of age. Feline or ferret growth diets are recommended.

URINARY SYSTEM

Characteristics of the Normal Ferret Urinary System

- The right kidney lies cranial to the left kidney. The cranial end of the right kidney often lies under the caudate lobe of the liver.
- The bladder is small, and can hold up to 10 ml of urine.
- Male ferrets have a small prostate gland that surrounds the urethra at the base of the bladder.
- Urinalysis:
  - The normal urine pH is 6.0 for ferrets on a meat-based diet.
  - Normal values for urine-specific gravity have not been reported.
  - There is evidence that proteinuria may be normal in ferrets (7–33 mg/dl in males; 0–32 mg/dl in females) and that bilirubinuria can occur in the absence of liver disease.

Renal Disease

Renal disease in not common in ferrets, but may occur.

Clinical Signs

- Clinical signs are similar to those described in other animals, and include ataxia, bruxism, halitosis, hindlimb weakness, inappetence, melena, mucus membrane ulceration, polyuria/polydipsia, vomiting, and weight loss.
- Physical examination findings may include cachexia, dehydration, irregularity in the shape and size of the kidneys, pale mucous membranes, and oral ulceration.

Diagnosis and Treatment

- Diagnosis is based on clinical signs, physical examination, and CBC, serum biochemical analysis, and urinalysis results.

▼ ***Key Point*** Hyperphosphatemia, hypocalcemia, and high BUN may be noted on serum biochemical analysis. Serum creatinine concentration is often normal or only moderately elevated.

- Treatment should address the underlying cause, if possible.
- Nonspecific treatment includes fluid therapy, nutritional supportive care, and antibiotic therapy based on culture and sensitivity when indicated.
- Prognosis is guarded, depending on laboratory findings and response to treatment.

Renal Cysts

Unilateral or bilateral renal cysts are relatively common in ferrets (see Chapter 77 for a description of this disease in dogs and cats). The condition is usually an incidental finding in middle-aged and older ferrets, although clinical signs associated with this condition can occur at any age.

Etiology

- The cause of renal cysts in the ferret is unknown.
- Heredity does not appear to be a factor. Renal cysts are not associated with hepatic or biliary cysts.
- Renal cysts typically present as one or more smooth masses on the surface of the kidney. On abdominal palpation affected kidneys feel smoothly enlarged or irregular.
- Polycystic disease is unusual in the ferret. When present, affected kidneys appear rough and irregular; multiple cysts are often distributed throughout the renal tissue. Cysts may be present in other organs as well.

Clinical Signs

- Usually there are no clinical signs associated with renal cysts.
- Rarely, there may be enough disruption of normal renal parenchyma to lead to renal failure, and subsequent clinical signs.

Diagnosis

- Palpate the kidneys for irregular shape.
- Perform a CBC, serum biochemical profile, and urinalysis.
- Abdominal radiography usually is not helpful unless the kidneys are very irregular.

- Perform an abdominal ultrasound to detect renal cysts, to evaluate renal architecture, and to rule out other conditions such as renal neoplasia.
- Intravenous pyelography or nuclear scintigraphy may be used to evaluate renal function.
- Renal cysts may be an incidental finding during abdominal surgery.

Treatment

- There is no specific treatment for renal cysts. No treatment is necessary in asymptomatic animals.
- Monitor affected ferrets by periodic abdominal palpation, serum biochemical profile, urinalysis, and ultrasound, if indicated.
- If an affected kidney becomes very large, consider unilateral nephrectomy (if the opposite kidney is functional) (see Chapter 78).
- Symptomatic ferrets may be managed using the same supportive care methods used in dogs and cats with chronic renal failure.
- The prognosis is grave for ferrets in renal failure.

Hydronephrosis

- Hydronephrosis is uncommon in ferrets. Iatrogenic hydronephrosis may occur as the result of inadvertent ligation of a ureter during ovariohysterectomy (see Chapter 77 for information about hydronephrosis in dogs and cats).

Cystitis

- Bacterial cystitis without urinary calculi is rare in pet ferrets. Follow treatment protocols for cystitis in dogs (see Chapter 79).

Urolithiasis

Urinary calculi was a common cause of stranguria in ferrets at one time; improvement in the quality of ferret diets has decreased the incidence of calculi. Calculi are usually composed of calcium oxalate or struvite (magnesium ammonium phosphate hexahydrate). Cysteine calculi also have been reported.

Etiology

- The cause of urinary calculi is unknown; however, diet is believed to be a factor.
- Diets containing plant proteins or poor quality meat-based proteins may be associated with the development of urinary calculi. Urolithiasis is uncommon in ferrets maintained on a high-quality feline or ferret diet containing high-quality animal-based proteins.
- Other factors may include urinary tract infection, metabolic, genetic, and congenital factors.

Clinical Signs

Clinical signs depend on the location of the urolith(s) and may include dysuria, stranguria, hematuria, persistent wetness in the perineal region, and frequent licking of the perineum.

- Urethral calculi may cause obstruction in both male and female ferrets.
  - Ferrets with urethral obstruction often strain and cry as they attempt to urinate.
  - If complete obstruction is present ferrets often appear lethargic and anorexic, and may not demonstrate obvious signs of dysuria.

Diagnosis

- Palpate the bladder to identify cystic calculi. The urinary bladder wall may be thickened; in ferrets with urethral obstruction, the bladder is distended and firm.
- Obtain abdominal radiographs to confirm the presence of radiopaque urinary calculi. Cysteine calculi are not radiopaque and require contrast radiography or ultrasonography for diagnosis.

▼ ***Key Point*** Small stones located at the base of the os penis can be very hard to identify.

- Renal calculi may be an incidental finding on whole body radiographs, or may be associated with renal failure.

Treatment

▼ ***Key Point*** Urethral obstruction is an emergency. Severe metabolic derangement, coma, and death may occur if urethral obstruction is not diagnosed and treated quickly.

- Stabilize non-obstructed ferrets by providing supportive care, fluids, analgesics, and antibiotics (if indicated) prior to performing cystotomy to remove the urolith(s).
- Cystic calculi may be removed surgically via cystotomy; the procedure is similar to that used in cats and dogs (see Chapter 80). Close the bladder wall with 4-0 or 5-0 absorbable sutures.
- Submit a urolith sample for analysis and bacterial culture/sensitivity testing.
- Administer antibiotics for a minimum of 10 to 14 days. Use results of follow-up urinalysis, and urine culture/sensitivity testing to determine when to discontinue antibiotic therapy.
- Begin conversion to a high-quality–animal, protein-based feline or ferret diet. Urinary acidifies are not usually necessary once the ferret is on a high-quality animal, protein-based diet, since this diet alone will cause the urine to be acidic.
- Feline calculi-dissolving diets and preventative diets may be offered to ferrets; however, many ferrets do not find these diets palatable.

- Renal calculi can often be managed medically by administering antibiotic therapy and changing the diet.

Urethral Obstruction

▼ ***Key Point*** The bladder is very fragile in ferrets. Handle ferrets with obstruction gently to avoid bladder rupture.

- Urinary obstruction in the male ferret can be difficult to manage. Catheter placement is challenging due to the small size of the urethra and the J-shaped os penis. (See Urinary Catheterization in the Techniques section of this chapter.)
- To facilitate placement of the urinary catheter, empty the bladder via cystocentesis prior to catheterization. Submit urine samples for urinalysis and bacterial culture/sensitivity testing.
- Use either a ferret urinary catheter (Slippery Sam Ferret Urinary Catheter, Cook Veterinary Products), a standard tom cat catheter, or a 3.5-Fr red rubber catheter for catheterization.
- Inhalant anesthesia with isoflurane or sevoflurane is strongly recommended to facilitate catheter placement.
- If the urinary catheter placement is not successful, consider emergency cystotomy, and attempt to perform anterograde flushing of the urethra via the cystotomy site.
- Perineal urethrostomy may be considered if cystotomy is unsuccessful (see Chapter 82).

Prevention

- Feed a high-quality, animal protein-based feline or ferret diet.

PROSTATIC DISEASE/PROSTATIC CYSTS

Prostatic disease and subsequent urethral obstruction is a potentially life-threatening condition of middle-aged and geriatric male ferrets. This condition typically occurs in association with adrenal gland disease.

Etiology

- Prostatic disease and prostatic cyst formation are presumed to be the effect of excessive androgens on the prostate. Excessive androgen production occurs with adrenal gland disease.
- Squamous metaplasia of prostatic glandular epithelium occurs and may subsequently lead to the development of cysts ranging in size from 1 to 6 cm or larger. Secondary bacterial infection and abscessation may occur.
- Prostatic abscesses associated with transitional cell tumor of the bladder, prostatic seminoma, and prostatic carcinoma have also been reported in the ferret, but are rare.

Diagnosis

History and Clinical Signs

- Clinical signs associated with prostatic disease may include symptoms associated with a urinary tract infection, urethral obstruction, or urinary incontinence.
- Signs of adrenal gland disease are often present (see "Adrenal Gland Disease").

Physical Examination

- On physical examination, a large, firm, often painful caudal abdominal mass is usually palpable. With careful palpation, this mass is found to be bilobed, representing the urinary bladder and a cystic structure. Ferrets with mild to moderate prostatic disease may appear to have a normal-sized prostate on abdominal palpation, yet are still symptomatic.

Diagnostic Tests

It is important to remember that adrenal gland disease is usually the cause of prostatic disease. Perform a complete diagnostic work-up that includes whole-body radiography, CBC, serum biochemistry analysis, and urinalysis. A plasma steroid hormone assay, and abdominal ultrasound may be indicated as well.

- Obtain abdominal radiographs; prostatic enlargement or prostatic cysts appear as mass lesions dorsal to the bladder.
- Perform abdominal exploratory surgery for a definitive diagnosis.

Treatment

- Address urethral obstruction if present (see "Urolithiasis").
- Manage medically until the ferret is stable for adrenalectomy and surgical drainage of the cysts.
- Medical management includes maintenance of urinary catheterization for several days, administration of fluids, antibiotic therapy, anti-inflammatory and analgesic therapy, and nutritional support as needed.
- Consider administration of an androgen receptor blocker (see "Adrenal Gland Disease").
- Consider administration of leuprolide acetate 30-day depot formulation (Lupron Depot, Bristol-Myers-Squibb Oncology, Princeton, NJ) (250 ug/kg) IM; prostatic tissue shrinkage may occur within 48 hours in some individuals. Some ferrets have been maintained successfully on monthly injections of this drug, although results are highly variable.
- Perform adrenalectomy and drainage of the cysts. Large cysts may require debulking.

- Perform bacterial culture and sensitivity testing of the cyst contents.

▼ ***Key Point*** Omental pull-through procedures and marsupialization have been described as means of prostatic abscess management in the ferret. These procedures should be used with some caution. Prostatic abscesses and prostatic cysts can be difficult to differentiate from paraurethral cysts. Paraurethral cysts communicate with the urethra or bladder neck. Consider performing contrast radiography to determine if there is communication between the cyst/abscess and the bladder prior to performing these procedures.

- Administer postoperative antibiotic therapy for a minimum of 10 to 14 days, along with androgen receptor blockers or leuprolide acetate.
- Base the decision to discontinue antibiotic therapy and androgen receptor blocker/leuprolide acetate therapy by monitoring changes on physical examination, follow-up radiography, and follow-up urinalysis.

Prognosis

- The long-term prognosis is good if prostatic changes regress, and if subsequent adrenal gland disease does not occur in the remaining adrenal gland.
- Some ferrets may need to be maintained on androgen receptor blockers or leuprolide acetate indefinitely.

PARAURETHRAL CYSTS

Etiology

Paraurethral cysts are thin-walled single or multiple cysts present on the dorsal aspect of the bladder and proximal urethra. These cysts appear to also be associated with adrenal gland disease and can cause urethral obstruction.

It is important to differentiate between prostatic cysts and paraurethral cysts when planning the surgical protocol.

Clinical signs

- Paraurethral cysts have been reported in male and female ferrets.
- Clinical signs are similar to those described for prostatic disease, and include symptoms associated with a urinary tract infection, urethral obstruction, urinary incontinence.
- Clinical signs of adrenal gland disease are usually present (see "Adrenal Gland Disease").

Diagnosis

Physical Examination

- A large, firm caudal abdominal mass is often palpable dorsal to the bladder, just cranial to the pelvic inlet.

Diagnostic Tests

- Perform a complete diagnostic work-up that includes whole-body radiography, CBC, serum biochemical analysis, and urinalysis.
- Because adrenal gland disease is usually the underlying etiology, consider performing a plasma steroid hormone assay.
- Radiographically, paraurethral cysts appear as mass lesions dorsal to the bladder.
- Ultrasonography may be useful in evaluation of the paraurethral cysts and adrenal glands.

Treatment

- Surgical drainage and debulking of the cysts is the treatment of choice.
- Marsupialization is an alternative, but may lead to a formation of a permanent cystotomy.
- Do not perform an omental pull-through procedure.

Chapter

176 Rabbits

Sue Chen / Katherine E. Quesenberry

Rabbits are popular pets for both children and adults. They are easily litter trained and require minimal maintenance. This chapter stresses diagnosis and management of problems commonly encountered in pet rabbits. Refer to the supplemental readings for more comprehensive information.

BIOLOGIC CHARACTERISTICS

Rabbits, hares, and pikas are members of the order Lagomorpha. Lagomorphs have six incisors, in contrast to the closely related rodents, which have four incisors. The additional incisors (peg teeth) are small, rounded teeth located directly behind the upper incisors. Currently, there are over 100 breeds of rabbits, which vary in size, ear and body conformation, and coat type, recognized by the House Rabbit Breeders Society.

- All domestic rabbits are descendants of European wild rabbits, Oryctolagus cuniculus.
- The two main genera of rabbits are *Oryctolagus,* the European wild rabbits, and *Sylvilagus,* the cottontail rabbits. These genera differ in chromosome number and cannot interbreed.
- Rabbits can range in size weighing from 2.5 lb in the dwarf breeds up to 28 lb in the giant breeds.
- Giant breeds, which average more than 5 kg in body weight, include the American Checkered Giant, the Flemish Giant, and the Giant Chinchilla rabbits.
- Medium breeds, which average from 3.5 to 5 kg in body weight, include the Californian, the Silver Marten, and the Rex rabbits.
- Small breeds, which average less than 3.5 kg in body weight, include the Netherland Dwarf, the Jersey Wooly, and the Polish rabbits.
- Ears vary in size and shape between the different breeds, and most rabbits have upright ears. However, there are breeds that have ears in a downward carriage, which are known as "lops."
- Coats can be divided into normal, Rex, and Satin breeds. Normal fur coats have an undercoat with projecting guard hairs. Rex breeds have short guard hairs that do not project above the undercoat, thus producing a "velvety" fur coat. Satin breeds have a genetic mutation that results in a "shiny" haircoat.
- Specific information concerning breeds can be obtained from the American Rabbit Breeders Association by mail (PO Box 426; Bloomington, IL 61702) or on their Website (www.arba.net).

Anatomic and Physiologic Characteristics

- Females of several breeds of rabbits have a large pendulous dewlap under their chin. This area is a frequent site of moist dermatitis, especially in obese rabbits kept in humid, warm environments that may have difficulty grooming themselves.
- The sense organs of rabbits are well developed. Like other prey species, the eyes are laterally set. This provides a completely circular field of vision with the exception of the small area below the mouth. Thus, long sensory hairs around the snout and the sensitivity of the lips help rabbits discriminate food.
- Teeth are open rooted and grow continuously. The deciduous teeth are shed right around the time of birth and the permanent teeth complete eruption around 3 to 5 weeks of age. The dental formula is 2/1 incisors, 0/0 canines, 3/2 premolars, and 2–3/3 molars. Rabbits are distinguished from rodents by possessing an extra set of upper incisors, which are also known as "peg teeth."
- The gastrointestinal (GI) tract has a simple glandular stomach, a long intestinal tract, and a large cecum.
- The stomach serves as a reservoir for ingesta and is rarely empty. It holds approximately 15% of the GI contents. The cardia and pylorus are well developed, and, due to the anatomic arrangement of the cardia to the stomach, rabbits are unable to vomit.
- The cecum is the largest organ in the abdominal cavity and holds approximately 40% of the GI contents.
- Rabbits exhibit cecotrophy, which means they consume soft cecotrophs, also known as "night feces." Antiperistaltic contractions in the colon retrograde non-fiber particles and fluid back into the cecum for fermentation and the formation of cecotrophs, which are an important source of B-vitamins, electrolytes, and nitrogen.
- The skeletal system is light and delicate compared with most mammals. The skeleton makes up 8% of

the total body weight in rabbits, as opposed to 13% of the total body weight in cats.

▼ ***Key Point*** Red, pink, or orange discoloration of the urine occurs periodically in healthy rabbits. The color may be caused by porphyrin pigments or food-related metabolites excreted in the urine. Cytologic examination of the urine for red blood cells will help distinguish porphyrinuria from hematuria.

- Calcium and phosphorus are excreted primarily through urine in rabbits. Thus, the urine may be thick and creamy due to calcium carbonate precipitate. Calcium is excreted in the bile in most other mammals.
- In rabbits, high total leukocyte counts may not be characteristic of acute inflammation from infectious causes. Instead, the distribution of the white blood cells (WBCs) shifts from a normally high lymphocyte/low neutrophil ratio to neutrophilia and lymphopenia.

Reproductive Characteristics

- Sexual maturity varies in different breeds. As a general rule, females (does) sexually mature at approximately 4 to 8 months of age and males (bucks) sexually mature around 6 to 10 months of age.
- Females have a silent estrus and are induced ovulators.
- Breeding seasons are influenced by day length and temperature, though mating can occur year-round when environmental conditions are controlled. Gestation lasts for an average of 30 to 33 days. Pseudocyesis may last 17 days.
- Depending on the breed, litters range from 4 to 10 kits. Primaparous does usually have smaller litters. Kits are born blind and hairless and remain in the nest for approximately 3 weeks.
- Does have four and five pairs of mammary glands and nipples spread from the axilla down to the inguinal region. Does usually nurse only once daily for 3 to 5 minutes.
- Neonatal rabbits are totally dependent on milk up to day 10. Rabbit milk varies with stage of lactation but is approximately 13% protein, 9% fat, and 1% lactose. Small amounts of solid feed and hay can be digested around day 15 and cecotrophy commences on day 20.

Normal Parameters

Reference ranges for physiologic values are listed in Table 176-1. Reference ranges for hematologic values, serum biochemical values, and urinalysis are listed in Tables 176-2, 176-3, and 176-4.

Table 176-1. REFERENCE RANGES FOR PHYSIOLOGIC VALUES IN RABBITS

Temperature	38–40°C
Heart rate	130–325 beats/min
Respiratory rate	32–60/min
Life span	5–9 yrs
Blood volume	55–65 ml/kg
Food consumption	50 g/kg/day
Water consumption	
General population	50–100 ml/kg/day
Breeding does	<900 ml/kg/day

Table 176-2. REFERENCE RANGES FOR HEMATOLOGIC VALUES IN RABBITS

Erythrocytes	$5.1–7.9 \times 10^6$ m^3
Hematocrit	33%–50%
Hemoglobin	10.0–17.4 g/dl
Mean corpuscular volume	57.8–66.5 µm^3
Mean corpuscular hemoglobin	17.1–23.5 pg
Mean corpuscular hemoglobin concentration	29%–37%
Platelets	$250–650 \times 10^3$/mm^3
Leukocytes	$5.2–12.5 \times 10^3$/mm^3
Neutrophils	20%–75%
Lymphocytes	30%–85%
Monocytes	1%–4%
Eosinophils	1%–4%
Basophils	1%–7%

Table 176-3. REFERENCE RANGES FOR SERUM BIOCHEMICAL VALUES IN RABBITS

Albumin	2.4–4.6 g/dl
Alkaline phosphatase	4–16 U/L
Amylase	166.5–314.5 U/L
Bicarbonate	16–38 mEq/L
Blood urea nitrogen	13–29 mg/dl
Calcium	5.6–12.5 mg/dl
Chloride	92–112 mEq/L
Cholesterol	10–80 mg/dl
Creatinine	0.5–2.5 mg/dl
Globulin	1.5–2.8 g/dl
Glucose	75–155 g/dl
Glutamic-oxaloacetic transaminase	14–113 U/L
Glutamic pyruvate transaminase	48–80 U/L
Lactic dehydrogenase	34–129 U/L
Phosphorus	4.0–6.9 mg/dl
Potassium	3.6–6.9 mEq/L
Serum protein	5.4–8.3 g/dl
Sodium	131–155 mEq/L
Total bilirubin	0.0–0.7 mg/dl
Total lipids	243–390 mg/dl

Table 176-4. REFERENCE RANGES FOR URINALYSIS IN RABBITS

Urine volume	
Large breeds	20–350 ml/kg/day
Average breeds	130 ml/kg/day
Specific gravity	1.003–1.036
Average pH	8.2
Crystals present	Ammonium magnesium phosphate, calcium carbonate monohydrate, anhydrous calcium carbonate
Casts, epithelial cells, or bacteria present	Absent to rare
Leukocytes or erythrocytes present	Occasional
Albumin present	Occasional in young rabbits

PATIENT MANAGEMENT

Caging

- Cages or hutches can be purchased or constructed. Cages should be large enough to allow free movement. Small breeds, which weigh up to 2 kg, require a minimum of 1.5 ft^2 of floor space per animal. Large breeds, which weigh 5 kg or more, require at least 5 ft^2 of floor space per animal. Cages should be at least tall enough to allow the rabbit to stand on its hind limbs and be easy to clean.
- Cages with plastic bottoms and wire tops are easy to clean and are well ventilated. Wire mesh flooring may also be used; however, provide a solid area for the rabbit as wire flooring may predispose rabbits to sore hocks. Use 14-gauge wire with the mesh openings no greater than 1 × 2.5 cm to prevent the rabbit from getting its feet caught.
- Straw or hay bedding should be provided in one area of the cage. Soiled bedding should be cleaned out daily. Because most rabbits are fastidious and prefer to defecate and urinate in one spot, they often can be trained to use a litterbox.
- Rabbits can be housed indoors or outdoors at temperatures ranging from 40°F to 80°F. Rabbits are very susceptible to heat stroke in ambient temperatures above 85°F. If outdoor housing is used, provide ventilation or protection from direct sunlight. In temperatures below 40°F, provide heat or protection from cold.
- Rabbits should be allowed time out of the cage regularly for exercise and socialization. However, they should always be supervised, as they may chew on dangerous objects such as electrical cords and poisonous plants.

Diet

- Free-choice timothy or coastal hay should be provided to maintain the rabbit's dental and GI health. High-fiber diets are required for proper wearing of the continuously growing teeth and have a protective effect against enteritis. Inadequate fiber in the diet results in cecocolic hypomotility and ultimately changes in cecal microflora.
- A variety of vegetables and fresh, leafy greens such as dandelion greens, cilantro, parsley, and romaine lettuce should be offered as a salad one to two times daily.
- Pelleted diets are balanced and convenient; however most of these are alfalfa based and are low in fiber. Most commercial pellets are nutrient dense (high in protein and digestible carbohydrates) and can predispose rabbits to obesity. High-fiber, timothy-based pellets (Oxbow Pet Products, Murdock, NE; www.oxbowhay.com) are preferable over alfalfa-based pellets.
- The high level of calcium in alfalfa diets may result in hypercalciuria or urinary calculi.
- Rabbits like sweet foods. A limited amount (approximately 2 tablespoons per 2 pounds of body weight) of fruits such as papaya, melon, or berries can be provided as a treat or to entice an anorectic animal to eat.
- Foods high in starches or fat such as seeds, nuts, bread, and corn are not advisable as they can predispose rabbits to obesity and GI disease.
- Fresh water should always be available. Rabbits have a higher water intake than many other mammals. Their daily average water intake is approximately 50–150 ml/kg of body weight. Rabbits fed a large amount of leafy greens will have lower water intake.

CLINICAL TECHNIQUES

Restraint

▼ ***Key Point*** Restrain rabbits gently but firmly for most procedures. Inadequate restraint can result in a spinal fracture in the rabbit if it is allowed to kick with its hind legs. Support the hindquarters when carrying or lifting a rabbit to prevent spinal injuries.

- Carry the rabbit with its head tucked under one arm while supporting the body with your forearm; stabilize the back and rump with the other hand.
- Alternatively, while supporting the back of the rabbit against your body, the forelegs can be grasped between the fingers of one hand while the hind limbs are supported firmly between the fingers of your other hand. This method is effective for examining the ventrum of the patient. (Fig. 176-1)
- When examining a patient on a table, keep the rabbit close to your body and always keep a hand on it to prevent it from jumping off the table (Fig. 176-2).
- An especially nervous or aggressive rabbit may need to be wrapped securely in a towel to prevent injury to

Figure 176-1. To examine the ventrum and anal area, cradle the rabbit as shown. Be sure to provide support to the hind limbs.

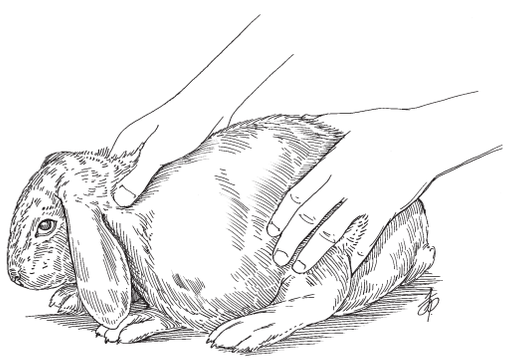

Figure 176-2. Proper method for restraining a rabbit.

itself and to the handler. Some rabbits also calm down if their eyes are covered with a hand or towel.

Diagnostic Techniques

Venipuncture

Blood can be collected from the jugular, lateral saphenous, cephalic, and lateral ear veins. Rabbit veins are thin and fragile, so small-gauge needles (i.e., 25-gauge or smaller) should be used. To prevent hematoma formation, apply direct pressure to the venipuncture site for several minutes. Pluck or wet down the fur from the site for better visibility of the vein.

- Jugular veins lie superficially in the jugular furrow. Hold the rabbit at the edge of a table with the neck held in extension. This technique can be difficult in females with large dewlaps and should not be done for patients in respiratory distress. If anesthetized, the rabbit can be placed in dorsal recumbency with the neck extended down over a table edge for better visibility of the jugular veins.
- The lateral saphenous vein is the preferred site for obtaining blood samples for routine blood tests. A fairly large volume of blood can be collected from this vein, especially in medium and large-sized rabbits. Have the handler place the rabbit in either lateral or sternal recumbency with the hind end directed towards the edge of the table. Have the handler hold off the saphenous vein by hooking one or more fingers around the back of the back leg proximal to the stifle; encircling and squeezing the proximal thigh too tightly will cause the vein to collapse. Wet down or pluck the fur from the mid-thigh region to better visualize the vein. Apply direct pressure after venipuncture to prevent hematoma formation.
- Cephalic veins can be used to collect small volumes of blood. Place the rabbit in sternal recumbency and encircle the foreleg around the elbow to extend the leg. Use either a tuberculin or insulin syringe to minimize the risk of collapsing the vein with too much negative pressure.
- Plucking the hair over the vein is easier than shaving fine fur.
- The lateral ear vein can be used for blood collection in some large rabbits. Use extreme caution however, as thrombosis of the vein can result in sloughing of the pinnae.

Radiography

- Radiographs of the head can provide important information about the sinuses and the dental roots. Sedation is usually required.
- Rabbits have very small thoracic cavities. Thoracic radiographs are useful in differentiating between pneumonia, cardiac disease, and neoplasia.
- The stomach and cecum are often full of ingesta and may obscure abdominal organs. However, moderate to severe gas distention of the stomach, cecum, or intestines suggests GI stasis.

Ultrasonography

- Ultrasound examination can provide useful information about abdominal organs such as the liver, spleen, kidneys, and reproductive tract.
- Urinary calculi and sludge can be seen on ultrasonographic examination of the bladder.
- Guided aspirates of thoracic and abdominal masses can provide representative samples for cytologic examination. However, the patient must be sedated

for the procedure, which should only be performed by experienced practitioners.

Treatment Techniques

- Subcutaneous administration of fluids is acceptable in non-critical cases and may be the only practical route of fluid administration in small rabbits. Estimate daily maintenance fluid needs at 100 to 150 ml/kg/24 hours.
- Use an indwelling catheter in critical cases.
- Small-gauge catheters (i.e., 24-gauge) can be placed in the cephalic or lateral saphenous vein in most rabbits.
- Jugular catheters can be difficult to insert and may require a cutdown procedure.
- Medications can be administered orally into the lateral cheek pouch. Use liquid or paste preparations when possible because rabbits have a long, narrow oropharynx that makes pill administration difficult.
- Anorectic animals can be syringe fed specialized hand-feeding formulas for herbivores (Critical Care for Herbivores, Oxbow Pet Products, Murdock, NE; www.oxbowhay.com). A gruel made of moistened rabbit pellets can also be used. Vegetable baby foods are low in energy content and fiber and should only be used short term.
- Nasogastric tubes can be placed in medium-to-large rabbits that require long-term nutritional support or that have had extensive oral surgery. The technique that follows is similar to that for placing a tube in a cat.
  - With manual restraint, place two to three drops of a topical anesthetic (Ophthaine, Solvay Animal Health, Inc., Princeton, NJ) in the mucosa of one nostril. Wait 5 minutes, and then repeat application.
  - Lubricate the tip of a small infant feeding tube (e.g., 5 Fr., Bard-Parker, Becton-Dickenson and Company, Rutherford, NJ) with topical lidocaine (Xylocaine) jelly. Pass the tube medially along the nasal passage to the level of the last rib. The tip of the tube is located in the distal esophagus.
  - Secure the free end of the tube to the skin above the nose and eye with a butterfly tape and suture. An Elizabethan collar may be necessary to prevent the rabbit from dislodging the tube.
- Dietary supplements containing Lactobacillus spp. may aid in the treatment of enteritis by repopulating the GI tract with healthy bacterial flora, decreasing intestinal or cecal pH, and competing with bacterial pathogens for mucosal attachment sites. Commercial products in paste form are available (e.g., Bene-Bac, Pet-Ag, Inc, Hampshire, IL).
- Commonly used antibiotics are listed in Table 176-5.

Tranquilization and Anesthesia

- Injectable tranquilizers are suitable for short diagnostic or surgical procedures. Ketamine (5–10 mg/kg) and medetomidine (Domitor, Pfizer Animal Health, Exton, PA) (0.15–0.18 mg/kg) in combination given IM or IV provides adequate relaxation and sedation.
- Use inhalant anesthesia for long or painful surgical procedures. Clinically, isoflurane and sevoflurane are commonly used. Anesthetic induction and recovery are usually faster with sevoflurane. Gas anesthesia in rabbits can be induced by face mask or in an induction chamber. Premedicate with a combination of ketamine with medetomidine, diazepam, or midazolam as needed, especially if using isoflurane. Buprenorphine and glycopyrrolate can also be given as needed. Gradually increase the concentration of isoflurane over several minutes until a surgical plane of anesthesia is reached. Anesthesia usually is maintained at 0.25% to 2% isoflurane in oxygen. With sevoflurane, use an induction level of 5% to 8%, reducing to 0.5% to 3% for maintenance.

▼ ***Key Point*** Intubation can be difficult because of the long, narrow oropharynx, large incisors, and large fleshy tongue that can obstruct the view of the pharyngeal cavity. Intubation is most successful in large rabbits; consider intubating medium-sized rabbits for long surgical procedures. However, repeated attempts to intubate can damage the larynx, causing soft tissue trauma or laryngospasm that can be fatal after the rabbit is extubated. If laryngeal trauma occurs during intubation attempts, abandon the procedure and use a face mask, or postpone the procedure to another day. Corticosteroids may or may not be helpful in decreasing inflammation of the larynx and tracheal mucosa.

- The following technique can be used to intubate medium to large rabbits.
  - Administer ketamine (5–10 mg/kg IM) and medetomidine (0.15–0.35 mg/kg IM) in combination. Supplemental isoflurane may be necessary to further relax the rabbit for intubation.
  - Place the rabbit in sternal recumbency. Extend the neck straight up and forward.
  - Place the tip of the short, flat-blade laryngoscope blade (i.e., Miller blade), at the base of the tongue. Hook the base of the blade against the top front incisors, and use the blade as a lever to see the glottis. Pass a small endotracheal tube along the blade into the opening of the glottis. Depending on their size, most rabbits require a 2.5- to 5.0-mm

Table 176-5. DRUGS COMMONLY USED IN RABBITS

Drug	Dose	Comments
Antimicrobials/Antifungals		
Benzathine, penicillin G	42,000–84,000 IU/kg q7d × 3 treatments SC	For treatment of *Treponema cuniculi*
Chloramphenicol	30–50 mg/kg q12h PO	
Ciprofloxacin	10–20 mg/kg q12–24h PO	Have a suspension made by a compounding pharmacist for easy administration
Enrofloxacin	5–15 mg/kg q12h PO, SC, IM	Limit subcutaneous and intramuscular administration due to potential tissue necrosis at injection sites
Gentamicin	4 mg/kg q24h IM, IV, SC	Use with caution or avoid use
Griseofulvin	12.5 mg/kg q12h PO	
Penicillin	40,000–60,000 IU/kg q48 hr SC	Use with caution
Tetracycline	50 mg/kg q8–12h PO	
Trimethoprim/sulfa	30 mg/kg q12h PO, IM, SC	
Antiparasitics/Insecticides		
Fenbendazole	10–20 mg/kg PO, repeat in 14d	
Lime sulfur solution	2.5% dip q7d for 4 weeks	Used in young animals for treatment of mites, fleas, fungal dermatitis
Ivermectin	0.2–0.4 mg/kg q10–14d SC for 2–3 treatments	Effective against ear and fur mites
Piperazine citrate	200 mg/kg; repeat in 2 weeks	
Pyrantel pamoate	5–10 mg/kg; repeat in 2 weeks	
Pyrethrin products	Topically as directed q7d	
Selamectin	6 mg/kg topically	
Sulfadimethoxine	50 mg/kg PO first dose, then 25 mg/kg q24h PO for 10–20 days	For treatment of coccidiosis
Tranquilizers/Premedications		
Acepromazine	0.5–1.0 mg/kg IM/SC	
Atipamazole	Give same volume SC as medetomidine	Reversal for medetomidine
Diazepam	1–3 mg/kg IV, IM	Used in combination with ketamine
Glycopyrrolate	0.01–0.02 SC	
Ketamine	20–50 mg/kg IM	
Ketamine/acepromazine	40 mg/kg (K)/ 0.5–1.0 mg/kg (A) IM	
Ketamine/diazepam	10–15 mg/kg (K)/ 0.3–0.5 mg/kg (D) IM, IV	
Ketamine/medetomidine	0.15–0.35 mg/kg (M) IM/ 5–20 mg/kg (K) IV later	
Ketamine/midazolam	25 mg/kg (K)/ ≤ 2 mg/kg (M) IM	
Medetomidine	0.25 mg/kg IM	
Midazolam	1–2 mg/kg IM or slow IV	
Propofol	2–15 mg/kg IV	
Xylazine	1–5 mg/kg SC, IM	
Analgesics		
Aspirin	10–100 mg/kg q8–24h PO	
Buprenorphine	0.01–0.05 mg/kg q6–12h SC, IM, IV	
Butorphanol	0.1–1.0 mg/kg q4–6h SC, IM, IV	
Carprofen	1.0–2.2 mg/kg q12h PO, SC, IM	
Flunixin meglumine	1.1 mg/kg q12–24h SC, IM	
Ibuprofen	2.0–7.5 mg/kg; PO q12–24h	
Ketoprofen	1 mg/kg q12–24h IM	
Morphine	2–5 mg/kg q2–4h SC, IM	
Oxymorphone	0.05–0.20 mg/kg q8–12h SC, IM	

endotracheal tube. The glottis cannot be seen while trying to pass the tube.

- Alternatively, the glottis can be visualized with an otoendoscope or endoscopic telescope in a sedated rabbit. The endotracheal tube is passed along the endoscope and inserted as above.
- Use a face mask to maintain anesthesia during short procedures or if intubation attempts are unsuccessful.
- Monitor all rabbits closely during any anesthetic episode. A Doppler, EKG monitor, and pulse oximeter can be used to monitor heart rate and oxygen saturation.

DERMATOLOGIC PROBLEMS

Dermatitis/Alopecia

Etiology

- Mange, fur, and ear mites cause localized or diffuse dermatitis, alopecia, or both. The area involved

depends on the type of mite (see "Ear Mites"; "Fur and Mange Mites").
- Dermatophytosis is associated with alopecia and a scaly dermatitis, particularly around the head and ears (see "Superficial Mycosis").
- Fur-barbering is common in rabbits on diets deficient in roughage. A high incidence of barbering in does is seen during breeding season; this is probably related to hormonal influences.
- Ptyalism, alopecia, and dermatitis around the mouth are associated with malocclusion.
- Moist dermatitis of the dewlap is common in does during breeding season, especially in warm or humid environments.
- Moist dermatitis with erythema and ulceration of the ventral abdomen and perineal area results from urine scald. Urine scald is associated with urinary incontinence, cystitis, excessive calcium in the urine, uterine adenocarcinoma, or poor management and unclean caging.
- Treponematosis (rabbit syphilis), caused by Treponema paraluiscuniculi causes a scaly dermatitis in the genital area. The nose, lips, and periorbital area are less commonly involved.

Clinical Signs

- Mite infestations produce clinical signs characteristic of the mite involved (see "Ear Mites"; "Fur and Mange Mites"). Pruritis is common with sarcoptic mite infestations.
- Dermatophytes cause a partial alopecia with slight scaliness and erythema. Rabbits are usually pruritic.
- Fur-barbering is characterized by alopecia of the dewlap, back of the neck, and paws. The underlying skin is normal.
- Moist dermatitis of the dewlap or ventral abdomen is typically erythematous with scaling and ulceration. The fur around the alopecic areas is moist. Rabbits sometimes self-mutilate this area; use a collar to prevent further trauma.

Diagnosis

Determine the primary cause of the alopecia to make a diagnosis.

- Examine skin scrapings of scaly areas for evidence of adult mites or eggs.
- Obtain samples of fur and keratin debris for fungal culture.
- Submit a skin biopsy specimen for histologic examination if the causative agent cannot be determined by other diagnostic tests.
- Examine the teeth in rabbits with excessive ptyalism and alopecia around the mouth (see "Malocclusion").
- Obtain abdominal radiographs of rabbits with urine scald for evidence of cystic calculi. Submit a urine sample for urinalysis and bacterial culture and sensitivity testing.
- Submit a blood sample for serum biochemical analysis to check for high concentrations of calcium, blood urea nitrogen, and creatinine.

Treatment

Treatment is directed toward the primary cause (see "Ear Mites"; "Fur and Mange Mites"; "Hairballs"; "Malocclusion"; "Treponematosis"; "Cystitis"; "Superficial Mycosis").

- Correct the diet to include adequate roughage if fur-barbering is suspected. Perform ovariohysterectomy in females with a suspected hormonal basis for fur-barbering.
- Treat adult rabbits with suspected mite infestations with ivermectin (see Table 176-5).
- Treat treponematosis with penicillin (see "Treponematosis").
- Treat dermatophytosis with antifungal agents, administered topically or orally depending on the extent of lesions.

Ear Mites (Psoroptes cuniculi)

Etiology

- Ear mites are common ectoparasites.
- Psoroptes cuniculi is a large, non-burrowing mite that spends its 3-week life cycle on the host rabbit.
- Mites have biting mouthparts and cause inflammation by biting and chewing the epithelial surface of the skin.

Clinical Signs

- Infestation with psoroptic mites usually is confined to the inner epithelial surface of the ear. Lesions begin in the concha and eventually extend to the inner surface of the pinna. Other areas, such as the dewlap and feet, sometimes are involved.
- Lesions consist of thick, dry, flaky, gray-to-tan crusts on the inner surface of the ear pinna. The underlying epithelial surface is raw, inflamed, and hemorrhagic.
- Psoroptic mites cause intense pruritus. Affected rabbits shake their heads or scratch their ears with the rear feet.

Diagnosis

- Psoroptic mites are large and sometimes visible with the unaided eye.
- Use an otoscope to detect movement of the mites within the ear canal.
- Microscopic examination of crusts and exudate usually reveals mites and eggs.
- Check rabbits with mild cases of otitis for the presence of mites.

Treatment

- Ivermectin is effective against ear mites (see Table 176-5). Repeat treatment in 3 weeks. A combination therapy of ivermectin and topical acaricides can be used for severe infestations.
- Because the lesions are usually very painful, and the aural crusts resolve after ivermectin treatment, avoid pulling off the crusts to clean the ears. Ears can be cleaned 1 to 2 weeks after pain subsides and lesions heal.
- Apply an antibiotic cream topically if a secondary bacterial infection is present. Topical application of anti-inflammatory agents may be beneficial once bacterial infection is under control.

Prevention

- Psoroptic mites are transmitted easily between rabbits. Isolate affected rabbits from healthy rabbits.
- Keep cages and bedding clean to minimize spread through contaminated fomites. The environment should be treated with flea products safe for cats to prevent re-infection.

Fur and Mange Mites

Etiology

- Cheyletiella parasitivorax is the common fur mite of rabbits. Because of its large, white, flake-like appearance, it is often called "walking dandruff." Infestations with other species of Cheyletiella occasionally occur. Listrophorus gibbus is a less common fur mite and is considered nonpathogenic.
- Cheyletid mites are non-burrowing, obligate parasites with an approximate 35-day life cycle.
- Cheyletid mites may cause a self-limiting, transitory dermatitis in humans.
- The cheyletid mite is a known vector of rabbit myxomatosis in Australia.
- Mange mites (e.g., Sarcoptes scabiei, Notedres cati) occur infrequently in rabbits.

Clinical Signs

- Lesions produced by cheyletid mites consist of a scaly dermatitis with a flaky, grayish-white exudate. Mites primarily inhabit the dorsal trunk and scapular region. The underlying skin may appear erythematous and inflamed. Pruritus is not a major clinical sign.
- Other areas of the body can be involved in severe infestations. Rabbits may act as if they are depressed and in pain.
- Mange mites produce a crusty dermatitis with alopecia.
- Intense pruritus results from mites burrowing in the epidermis.

Diagnosis

- Cheyletid mites are easily identified through microscopic examination of cellophane tape preparations of affected skin. Press a strip of cellophane tape to the skin lesions to obtain a sample.
- Deep skin scrapings are necessary to find mange mites. Results are sometimes falsely negative. Differential diagnosis then is based on the typical clinical signs of each type of mite.

Treatment

- Ivermectin (0.4 mg/kg SC q10–14d for three treatments) is effective against most mites that infest rabbits. The treatment period should extend through the life cycle of the mite.
- Topical acaricides, including pyrethrins, carbamates, and lime sulfur solution dips (see Table 176-5), are also effective against fur and mange mites. However, these products should be used cautiously as they have been associated with toxicity in rabbits.
- Cheyletid mites can exist off the host for short periods. Treat the home environment with parasiticides and eliminate potential fomites.
- The mite is highly contagious and all rabbits in contact with the affected rabbit should also be examined and treated. Other pets in the household kept in contact with infested rabbits should be examined.

Myiasis

Etiology

- Myiasis (fly larval infestation) occurs in rabbits kept outdoors in warm weather. Rabbits can become infested with cuterbrid larvae or maggots of the flesh fly. Maggot infestation is also known as "fly strike."
- Obesity, perineal dermatitis, and urine scald predispose rabbits to maggot infestation.

Clinical Signs

- Although some rabbits can be asymptomatic, rabbits may appear to be in pain, reluctant to move, or lame.
- Cuterebrid larvae burrow into subcutaneous tissue and cause one or more firm, fistulated, subcutaneous swellings surrounded by necrotic tissue. Areas commonly involved include the ventral cervical, inguinal, hindquarter, dorsum, and axillary regions.
- Aberrant migrations to the nasal passages, eyes, sinuses, and ear canals have also been described. An infection of the eye is known as ophthalmomyiasis.
- Maggots usually burrow through large, moist necrotic areas at the base of tail and dorsum, as these are difficult areas to groom for overweight rabbits.
- Secondary bacterial infections of the lesion are common.

Diagnosis

Diagnosis is based on a history of outdoor housing, clinical signs, and presence of larvae in wounds.

Treatment

- Sedation and pain medication are usually indicated before clipping soiled fur and removing larvae from the wounds.
- Remove cuterebrid larvae intact with hemostats if possible. Avoid rupture of the larvae.
- Remove maggots from the necrotic wounds.
- Thoroughly debride wounds of necrotic tissue. Perform complete surgical excision of any abscessed skin. Clean the surgical site daily and allow the wound to heal by second intention.
- Ivermectin (0.4 mg/kg SC q14d for two treatments) can be administered to kill larvae, but the larvae still need to be removed from the sites.
- Observe affected rabbits carefully for several weeks for additional lesions.
- Antibiotics with good skin activity such as trimethoprim-sulfa (30 mg/kg PO bid) are recommended for treating secondary bacterial infections.

Prevention

- Keep outdoor rabbits in screened hutches, especially during summer and fall.

Superficial Mycosis

Etiology

- Trichophyton mentagrophytes is the most common dermatophyte that affects rabbits and is usually self-limiting. Infections with Microsporum spp. and other dermatophytes occur much less frequently.
- Infection occurs by direct contact with infected animals, contaminated fomites, or asymptomatic carriers.

Clinical Signs

- Lesions usually appear on the head and ears and can extend to the neck, legs, feet, and nail beds.
- Lesions consist of areas of alopecia with erythema and scaly dermatitis. Rabbits are usually pruritic. Alopecic areas may be circular with slightly raised edges.

Diagnosis

Dermatitis resulting from dermatophytosis must be differentiated from other possible causes, including mites, fur-barbering, and bacterial dermatitis.

- Submit samples of fur from the edge of the lesion for culture on dermatophyte-culture medium.
- T. mentagrophytes does not fluoresce with ultraviolet light.
- The organisms can be demonstrated with either periodic acid schiff (PAS) or silver stains in histologic sections of skin biopsy specimens.

Treatment

Treatment of dermatophytosis is directed toward elimination of the organism while preventing spread of disease. Other animals and humans, especially children, are susceptible to infection.

- Clip affected areas and apply topical antifungal agents daily for 3 to 4 weeks.
- For extensive lesions, lime sulfur solution dips (2%–3%) given every 5 to 7 days are often effective for treating fungal dermatosis. Continue treatment for 4 weeks.
- Griseofulvin is effective if given daily for 4 weeks or until the infection clears (see Table 176-5). Give griseofulvin with fats to enhance absorption. Gris-PEG (Allergen, Inc.), an ultramicronized formulation for improved absorption, is given at one-half the normal dose. Griseofulvin should be administered cautiously, because it can cause bone marrow suppression and panleukopenia at high doses. Do not give it to breeding does, as it may be teratogenic.
- Instruct owners to wear gloves when handling or treating affected animals because of the zoonotic disease potential.
- Check other animals in the household for evidence of dermatophytosis.

Prevention

- Prevent contact with infected animals.
- Disinfection of the environment is important. Vacuum the contaminated area and wipe down all surfaces with a 1:10 dilution of bleach and water. Foggers containing enilconazole or formaldehyde can be used for carpeted areas.

Ulcerative Pododermatitis (Sore Hocks)

Etiology

- Ulcerative pododermatitis (sore hocks) usually develops as a result of management-related problems. Soiled or wet bedding, abrasions from flooring, sedentary behavior caused by obesity, small cages that restrict movement, and abrasions from thumping are predisposing factors.
- Ulcerative granulomatous lesions involve the plantar surface of the hocks and may be unilateral or bilateral. Forepaws are less commonly affected.
- Secondary bacterial infections, usually S. aureus, are common with severely ulcerated lesions.
- Chronic infections can develop into abscesses or may spread to underlying bone, resulting in osteomyelitis.

Clinical Signs

- Early or mild lesions are areas of erythema and thinning fur on the plantar surface of the hock.
- Lesions may progress to raw, ulcerative sores with scabs. Mucoid, purulent, or thick caseous exudate is present with secondary bacterial infections.
- Severe lesions cause lameness and reluctance to move. Rabbits may be anorectic and depressed.

Diagnosis

- Diagnosis is based on clinical signs. If wounds appear infected, submit samples for bacterial culture and sensitivity testing.
- Radiographs of the hocks may be indicated in severe cases to evaluate underlying bone involvement.

Treatment

- Correct the predisposing management and environmental factors.
- Thoroughly clean and debride necrotic wounds. An antibiotic cream such as silver sulfadiazine can be applied topically.
- Topical astringents such as Domeboro solution (Bayer, Inc., West Haven, CT) are beneficial in treating moist wounds. Apply the solution daily until the wound appears dry.
- Protect wounds with sterile, soft, padded bandages.
- Healing is often prolonged. Clean the wound with an antibacterial soak, topical antibiotics, and bandaging, daily or every other day.
- Systemic antibiotics are necessary if infection is present.

Prevention

- Wire flooring should be smooth, nonabrasive, and of sufficient width to prevent abrasions. Place soft, dry bedding, such as hay or several thicknesses of newspaper, in one area of the cage.
- Cages should be clean and of sufficient size to allow free movement.
- Check the feet and hocks periodically for signs of inflammation.
- Overweight rabbits should undergo weight reduction to decrease the risk of developing sore hocks.

RESPIRATORY DISEASE

Respiratory disease is common in pet rabbits and can result from many interrelated factors. Historically, *Pasteurella multocida* has been implicated as the major cause of respiratory disease, though it is probably now less common than in the past. Other bacteria, viruses, and non-infectious causes such as allergens, thoracic/nasal neoplasia, cardiovascular disease, nasal obstruction due to dental disease, and exposure to respiratory irritants should also be considered when working up a patient with respiratory disease.

- Respiratory irritants such as excessive ammonia in dirty, poorly-ventilated cages, aromatic wood shavings (cedar), and cigarette smoke may predispose some rabbits to respiratory infections.

Upper Respiratory Tract Infection (Snuffles)

Etiology

- Bacterial agents that haven been implicated in sinusitis and rhinitis in rabbits include: Pasteurella multocida (see Pasteurellosis), Bordetella bronchiseptica, and Staphylococcus and Pseudomonas species.
- Infections can be transmitted from the doe to offspring or by direct contact with infected rabbits. Infection also may be spread by aerosol (sneezing) or fomites.
- Chronic disease may be subclinical and precipitated by stress.

Clinical Signs

- Intermittent episodes of sneezing and rhinitis with serous or mucopurulent nasal discharge are common findings.
- Exudate can block the nasolacrimal duct resulting in conjunctivitis, serous-to-mucopurulent ocular discharge, and periorbital matting or alopecia. One or both eyes may be affected.
- Auscultation of the nares and trachea often reveal rattles and rales.
- Many rabbits have no other clinical signs. Rabbits with severe disease may be anorexic and lethargic.

Diagnosis

Diagnosis of rhinitis is based on clinical signs and isolation of the causative agent through bacterial culture and sensitivity testing.

- Submit a swab of nasal or conjunctival exudate for bacterial culture and sensitivity testing. Small-tipped culturette swabs are convenient for sample collection (e.g., BBL CultureSwab, Becton, Dickinson & Co., Franklin Lakes, NJ).
- Skull radiographs provide useful information about the nasal passage and sinuses. Increased opacity may indicate accumulation of exudate. Decreased opacity may indicate lysis from advanced infections or neoplasia. Elongated roots of cheek teeth obstructing the nasal passage may be visible. Thoracic radiographs help differentiate upper airway disease from pneumonia, cardiovascular disease, and thoracic neoplasia.
- If available, computed tomography (CT) of the skull will provide detailed information about the nasal passages and sinuses.

Treatment

- Give antibiotics at the first signs of respiratory disease (see Table 176-5). Chloramphenicol, enrofloxacin (Baytril, Bayer Animal Health, Shawnee Mission, KS), trimethoprim-sulfa, or parental penicillin G can be administered until culture results are known. The antibiotic choice may change based on results of bacterial culture and sensitivity testing.
- If conjunctivitis is present, cannulate and flush the nasolacrimal duct of the affected eye or eyes with sterile water or saline. A topical ophthalmic anesthetic is necessary for this procedure. Repeated flushes of the nasolacrimal duct daily for 2 to 3 days or every 3 days for four or five treatments is most effective. Apply an ophthalmic antibiotic solution such as ciprofloxacin (Ciloxan, Alcon Laboratories, Fort Worth, TX) gentocin, or chloramphenicol four to six times daily for 14 to 21 days.
- Long-term therapy may be necessary with chronic disease.

Prevention

General preventive measures are described in the following section on Pasteurellosis.

Pneumonia

Pneumonia can be acute or chronic and may occur alone or accompany upper respiratory disease.

Etiology

- Pasteurellosis is the most common cause of pneumonia in rabbits, though other bacteria such as *B. bronchiseptica* and *S. aureus* may also be involved. The infection spreads to the lungs from the upper respiratory tract through the trachea or, less frequently, through the bloodstream.
- Stress is an important factor in disease. Sudden temperature changes, poor sanitation, or poor ventilation in high-ammonia areas contribute to the development of disease.

Clinical Signs

- Chronic pneumonia is characterized by labored breathing, weight loss, cachexia, and anorexia.
- Clinical signs are often inapparent until disease is advanced.
- Acute death is common in young rabbits.

Diagnosis

Diagnosis of pneumonia is based on clinical signs and supportive diagnostic tests.

- Auscultate the thorax for crackles, expiratory wheezes, or decreased lung sounds over areas of consolidation or abscess.
- Thoracic radiographs help determine the extent of disease and may reveal lung lobe consolidation, air bronchograms, or well-delineated soft-tissue opacities if pulmonary abscesses are present.
- Results of a complete blood count (CBC) may reveal a relative increase in heterophil numbers or a reversal of the lymphocyte/heterophil ratio, indicating an inflammatory response.
- Tracheal washes are very difficult in rabbits because of the anatomy of the oropharynx and are not recommended.
- Postmortem lesions may include acute fibrinopurulent pneumonia, pleuritis, and septicemia.

Treatment

- Parenteral antibiotic therapy is preferred in rabbits with severe pneumonia.
- Supportive therapy includes supplemental fluids, vitamins, and force-feeding of anorectic animals.
- If an indwelling catheter can be placed, give fluids intravenously. Administer subcutaneous fluids if catheter placement is too stressful.
- Force-feed anorectic animals. Hold recumbent animals sternal while feeding and give food slowly to minimize stress and to prevent aspiration.
- Place severely dyspneic rabbits in an oxygen cage.
- Euthanasia often is elected for severely debilitated rabbits with advanced disease.

Pasteurellosis

Etiology

- Pasteurellosis is an endemic bacterial disease of rabbits. It is caused by *Pasteurella multocida,* a small, gram-negative, bipolar coccobacillus.
- Infection is spread by direct contact with infected rabbits or contaminated fomites, aerosolization, or from does to offspring during birth and nursing.
- Bacteria colonize the soft palate and nasal turbinates and may produce a lifelong infection. Infection may be subclinical with intermittent episodes of mucopurulent nasal discharge, which often is precipitated by stress.
- Spread from the nasal cavity can occur by several routes:
  - The eustachian tube to the middle or inner ear, meninges, and brain
  - The nasolacrimal duct to the conjunctiva
  - The trachea to the lungs
  - Hematogenously to the peripheral lymph nodes, reproductive tract, lungs, or other organs.
- Pasteurella infections can also result in abscesses in the subcutaneous tissues, retrobulbar space, and internal organs. Culture of the abscess capsule wall is recommended however, since other bacterial organisms have also been implicated.

Clinical Signs

Clinical signs of disease depend on the site and chronicity of infection.

- Respiratory signs associated with pasteurellosis include rhinitis, conjunctivitis, and pneumonia.
- Neurologic signs, including head tilt, torticollis, nystagmus, and facial nerve deficits, can be seen with infections of the middle or inner ear, meninges, or brain.
- Abscesses can occur in the joints, tooth roots, various organs, and in subcutaneous tissue. Exudate is typically white, thick, and caseous.
- Abscesses in the retrobulbar space often result in exopthalmus and subsequent ocular infections and corneal ulcers.
- Generalized illness, fever, and peracute death may occur from septicemia or pleuropneumonia of more pathogenic strains of *P. multocida*.

Diagnosis

- Submit samples from exudate, blood, or tissue for bacterial culture and sensitivity testing.
- Isolation of *P. multocida* is sometimes difficult. To maximize culture results, the swab should be inoculated onto a blood agar plate or Cary-Blair transport medium. Additionally, when collecting samples from an abscess, the swab should be directed toward the inner wall of the capsule as the necrotic centers are often sterile.
- Enzyme-linked immunosorbent assays (ELISAs) have been developed to detect antibodies to *P. multocida* and may be helpful in detecting subclinical carriers. The test requires whole blood or serum and is reported as high positive, low positive, or negative. Results must be interpreted with discretion, as low positives can occur with antibodies of closely related, but normal bacteria or from maternally acquired antibodies. False negatives may occur early in an infection or in immunocompromised individuals.
- Radiographs of affected areas can help delineate the extent and severity of the disease.

Treatment

▼ ***Key Point*** Successful treatment of pasteurellosis can be difficult, especially in rabbits with advanced disease.

- Antibiotic therapy should be based on culture and sensitivity testing. Enrofloxacin (5–10 mg/kg PO q12h) and chloramphenicol (50 mg/kg PO q12h) administered for several months have been used successfully in the treatment of rabbits with chronic pasteurellosis.
- Injections of penicillin G benzathine/penicillin G procaine (40,000 IU/kg SC q24h for 2 weeks, then q48h for 2 or more weeks) have also had reported success in the treatment of pasteurellosis.
- Perform complete surgical excision of subcutaneous abscesses; the thick-capsule wall and caseous nature of the exudate preclude simple lancing and draining.
- Mandibular or joint abcesses require extensive debridement and wound care (see Mandibular and Joint Abscesses).
- Daily management includes thorough cleaning and flushing until healing is well advanced.
- Debilitated rabbits require supplemental fluids, force-feeding, and general nursing care.

Prevention

- Pasteurellosis is an endemic disease in rabbits, and control is difficult. Colonies are kept Pasteurella-free through serologic testing and strict isolation and sanitation procedures.
- Prevention involves isolation of healthy animals from rabbits with clinical signs of disease. Eliminate rabbits with evidence of disease from breeding colonies.
- Closely examine pet rabbits for signs of respiratory disease before purchase. New rabbits should be quarantined from other rabbits in the household until their disease status is known.
- Minimizing stress, feeding the rabbit a proper diet, and using good husbandry practices are important in preventing the spread of pasteurellosis.

GASTROINTESTINAL DISEASES

Rabbits often are anorectic when a primary GI disease is involved. Anorexia is also common with metabolic abnormalities such as kidney disease and lead toxicoses and with any severe systemic infection. A change in food intake can alter the flora of the GI tract, resulting in the excessive production of volatile fatty acids and subsequent change in cecal pH. This can lead to the overpopulation of pathogenic bacteria resulting in either diarrhea or GI stasis.

Diarrhea/Enteritis/Enterotoxemia

Etiology

▼ ***Key Point*** Lack of roughage in the diet, stress, and antibiotic therapy are all factors that contribute to disruptions in cecal microflora and pH, which can result in diarrhea.

- Diets high in digestible carbohydrates contribute to overgrowth of pathogenic bacteria by supplying a ready source of fermentable products. Toxins produced by these bacteria are primary factors in enterotoxemia.

Bacterial Pathogens

- Clostridium spiroforme, a gram-positive, anaerobic, spore-forming rod, is one of the primary pathogens in bacterial enteritis in rabbits. Although this organism can be present as normal GI flora, with a ready supply of fermentation products (digestible carbohydrates) it produces iota toxin, which causes severe enterotoxemia.
- Escherichia coli causes diarrhea in young rabbits and has a variable morbidity and mortality rate depending on the pathogenicity of the serotype involved. *E. coli* is not part of the normal gut flora but often is found in large numbers in the cecum of rabbits with diarrhea. The bacteria attach to the mucosal epithelium, causing necrosis and disruption of normal intestinal and cecal function. Enterohemorrhagic *E. coli* have also been isolated from rabbits and may pose a zoonotic risk.
- Clostridium piliforme (formerly Bacillus piliformis), which causes Tyzzer's disease, is associated with acute diarrhea and death, primarily in young weanling rabbits. *C. piliforme* may be a subclinical inhabitant of the gut. With stress, the bacteria proliferate and cause severe epithelial necrosis of the cecum, colon, and distal ileum.
- Lawsonia intracellularis, an intracellular, gram-negative, curved to spiral-shaped bacteria has been associated with proliferative enterocecocolitis in weanling rabbits.

Viruses

- A coronavirus has been described as a cause of diarrhea and subsequent death in 3- to 10-week-old rabbits. The virus denudes the intestinal villi; diagnosis is made by identifying the virus in feces or cecal contents.
- Rotavirus may be present as normal flora, but may act as a mild pathogen by destroying cells that produce disaccharidases and by contributing to carbohydrate overload. Severity of the diarrhea is variable and is affected by other contributing microorganisms.

Parasites

- Intestinal coccidiosis is primarily a disease of young rabbits. Twelve species of intestinal Eimeria infect rabbits. Diarrhea secondary to intestinal coccidiosis is usually mild; however, coccidia may predispose rabbits to bacterial enteritis (see "Coccidiosis"). The highly pathogenic Eimeria stieda infects the liver.
- Cryptosporidia parvum may cause a transient diarrhea in young rabbits for 3 to 5 days. No known treatments are available.

Management Related Factors

- Antibiotic therapy can cause suppression of normal gut flora and overgrowth of pathogenic bacteria. Diarrhea is associated with antibiotics that are active against gram-positive aerobes and selective gram-negative anaerobes. Antibiotic-induced diarrhea has been associated with the oral administration of lincomycin, clindamycin, erythromycin, ampicillin, amoxicillin, cephalosporins, and penicillin.
- Stress is a major factor in diarrhea. Stress-related epinephrine release may have a direct effect on intestinal motility and digestion, allowing overgrowth of pathogenic organisms.

Clinical Signs

- Diarrhea may vary from soft, pasty stool to a profuse, malodorous liquid. Mucus and blood may also be present. The perineal region and hindlimbs are often stained with feces.
- Rabbits with mild diarrhea may be otherwise normal. Severe diarrhea may be accompanied by lethargy, weight loss, anorexia, and dehydration.
- Intestinal gas often is detected on abdominal palpation.
- Sudden death may be the only clinical sign in peracute disease. In chronic cases, the rabbit has intermittent bouts of diarrhea and anorexia and may have progressive weight loss.

Diagnosis

Diagnosis of the primary cause is based on clinical signs, history, and specific tests.

- Dietary history is very important. Determine the fiber content of the normal feed and the amount of supplemental roughage.
- Identify bacterial pathogens by submitting fecal samples for aerobic and anaerobic bacterial culture and sensitivity testing.
- Do a direct fecal smear or fecal flotation to check for spore-forming gram-positive bacteria and coccidia.
- Results of serum biochemical analysis often reveal electrolyte and metabolic abnormalities in animals with moderate-to-severe diarrhea.

Treatment

- Correct the diet in animals on marginal or deficient dietary fiber levels.
- Dietary Lactobacillus supplements such as Bene-bac may help repopulate the GI tract with normal flora.
- Metronidazole (20 mg/kg PO, IV q12h) has been effective in treating rabbits with enterotoxemia caused by C. spiroforme.
- Enrofloxacin (10 mg/kg PO q12h) or trimethoprim/sulfa (30 mg/kg PO q12h) is indicated if E. coli bacterial enteritis is suspected.
- Chloramphenicol (30–50 mg/kg PO q12h) can be used to treat proliferative enteritis caused by L. intracellularis.

- Oral administration of antibiotics is effective in rabbits with mild-to-moderate diarrhea. Give antibiotics parenterally in rabbits with severe clinical signs. Avoid antibiotics that may induce enteritis.
- Intravenous fluid therapy is indicated for rabbits with moderate-to-severe diarrhea. Subcutaneous fluids are usually adequate for cases with mild diarrhea.
- Anorectic animals should be force fed replacement diets such as Critical Care for Herbivores (Oxbow Pet Products, Murdock, NE; www.oxbowhay.com).
- If young rabbits test positive for coccidiosis, administer appropriate therapy (see Coccidiosis).

Prevention

- Instruct owners to feed their rabbits proper diets with an adequate content of indigestible fiber, such as timothy hay.
- Minimize stress in young or weanling rabbits. Sudden temperature changes, changes in food, overcrowding, or poor sanitation contribute to disease.
- Isolate diseased animals from healthy rabbits.
- Screen young rabbits for coccidiosis or give prophylactic therapy.

Coccidiosis

Etiology

- Coccidia are host-specific protozoan parasites.
- Twelve different species of intestinal Eimeria infect rabbits, with *E. perforans* being the most common. Pathogenicity varies according to species. *E. magna* is the most pathogenic species affecting the small intestine.
- Hepatic coccidiosis results from infection with the highly pathogenic Eimeria stieda.
- Infection results from the ingestion of sporulated oocysts.
- Coccidiosis is primarily a disease of young and weanling rabbits. Natural immunity develops against each Eimeria species after exposure. No cross protection in immunity exists between different Eimeria species. Adult animals can become ill if exposed to a species against which they have no immunity.
- The severity of disease is determined by the age at time of exposure, the species of Eimeria involved, the number of oocysts ingested, and environmental stress factors.

Clinical Signs

- Intestinal coccidiosis is often subclinical or causes only intermittent mild-to-moderate diarrhea and associated dehydration. However, coccidia may predispose the rabbit to bacterial enteritis (see "Diarrhea/Enteritis"). Clinical signs are usually most apparent in young rabbits.
- Severe diarrhea, intussusception, and death may occur with heavy infections. Blood and mucous may also be associated with the diarrhea.
- Hepatic coccidiosis is associated with anorexia, weight loss, abdominal enlargement, diarrhea, icterus, and acute death.

Diagnosis

- Presumptive diagnosis is based on identifying Eimeria oocysts in a fecal sample or intestinal scrapings. The presence of organisms on histologic examination is required for definitive diagnosis.

Treatment and Prevention

- The age of the host and the severity of clinical signs are factors to consider in treatment. Animals with light parasite burdens usually develop immunity to the organism and recover without therapy.
- Therapy with coccidiostats is more prophylactic than therapeutic. Coccidia are susceptible to treatment only during a specific period in the protozoan life cycle. Clinical signs are usually inapparent during this period.
- Coccidiostats may slow multiplication until host immunity develops.
- Trimethoprim/sulfamethoxazole (30 mg/kg PO q12h for 10 days) has proved effective for the prevention and treatment of coccidiosis.
- Sanitation is of utmost importance for effective therapy and prevention. Routinely disinfect cages, food bowls, and water bottles.
- Screen rabbits for shedding of coccidial oocysts. Separate or cull carriers from colonies.
- Check all young rabbits for coccidia.

Gastrointestinal Stasis

Etiology

- Dietary factors

▼ ***Key Point*** Lack of roughage in the diet is a major predisposing factor in GI stasis.

- Stress is a major factor in GI stasis. Stress-related hormonal release may have a direct effect on intestinal motility and digestion, allowing overgrowth of pathogenic organisms.
- Hairballs slow GI motility, prolonging retention of fermentable food.

Clinical Signs

- No fecal pellet production in over 24 hours. Patients are also often anorectic.
- Some rabbits have painful abdomens and may stay in a hunched position. The stomach or cecum may be

distended with intestinal gas that may be detected on abdominal palpation.

Diagnosis

- Dietary history is very important. Determine the fiber content of the normal feed and the amount of supplemental roughage.
- Results of serum biochemical analysis often reveal electrolyte and metabolic abnormalities.

Treatment

- Fluid therapy is critical in the treatment of rabbits with GI stasis. Stable patients can be administered fluids subcutaneously once to twice a day. Critical patients require IV catheterization.
- Correct the diet in animals on marginal or deficient dietary fiber levels.
- Broad-spectrum antibiotics, such as the fluorinated quinolones, trimethoprim/sulfa, or chloramphenicol are indicated if bacterial enteritis is suspected. Oral administration is effective in animals with mild-to-moderate diarrhea. Give antibiotics parenterally in rabbits with severe clinical signs. Avoid antibiotics that may induce enteritis.
- Force-feed anorectic animals with Critical Care for Herbivores (Oxbow Pet Products) or softened rabbit pellets mixed with vegetable baby food or canned pumpkin.

Prevention

- Instruct owners to feed their rabbits proper diets with an adequate content of indigestible fiber.
- Minimize stress in young or weanling rabbits. Sudden temperature changes, changes in food, overcrowding, or poor sanitation contribute to disease.

Malocclusion

Etiology

▼ ***Key Point*** Malocclusion is one of the most common causes of anorexia in rabbits.

Clinical Signs

- Rabbits with malocclusion often have no other clinical signs. Owners may report that the rabbit shows interest in food, but stops eating after a few bites. Most remain alert and active.
- Excessive salivation is common in rabbits with malocclusion.

Diagnosis

- Perform a thorough oral examination in all anorectic rabbits. Examine the back molars with an otoscope or nasal/vaginal speculum. Sedation may be necessary in some especially nervous or active rabbits.

Treatment

- Incisors can be cut with a diagonal cutter or, preferably, a dental drill. Both pairs of upper incisors should be clipped.

▼ ***Key Point*** Do not use Resco-type nail clippers to cut incisors because excessive trauma can result in split incisors and loosened tooth roots.

- Molar malocclusion requires dentistry with sedation. The procedure is usually short and can be done with an injectable tranquilizer. A combination of medetomidine (0.15–0.35 mg/kg SC, IM) and ketamine (5–10 mg/kg SC, IM) works well and can be reversed when the procedure is finished. Gas anesthesia can be used by holding the anesthetic mask over the rabbit's nostrils, leaving the oral cavity free for working in the mouth.

Technique—Teeth Triming

1. Place the rabbit in sternal recumbency with an assistant extending the neck and head forward.
2. The mouth can be held open by looping strips of gauze around both upper and lower incisors. The assistant holds the gauze around the lower molars in one hand, while the second hand is placed on top of the rabbit's head and holds the gauze looped around the top incisors, forcing the head and neck into extension. Make sure the nostrils are not occluded and the neck is extended or the rabbit will have difficulty breathing. Alternatively, a metal speculum made for rabbit dentistry can be used to hold the mouth open; however, this tool can damage the oral mucosa if used inappropriately.
3. Use a short vaginal or nasal speculum with an attached light source to examine the oral cavity. Check both lateral and medial edges of upper and lower molars.
4. A dental drill rounds and smoothes sharp edges but must be used with care. Use a tongue depressor or the speculum to isolate the arcade and prevent damage to the tongue or buccal mucosa. Burr guards can also be purchased. Long-shank burrs made specifically for use in the long, narrow oral cavity of rabbits are available.
5. A small bone rongeur can be used to clip the sharp edges of the cheek teeth. Use a tongue depressor or speculum to push the tongue to one side while clipping the medial edges of the lower cheek teeth. This method is quick and easy but leaves rough edges and may cause fractures of the teeth.

- Root elongation of the premolars and molars can develop in rabbits with chronic malocclusion. Elongated roots of the mandibular teeth can be palpated as firm bony nodules on the ventral mandible. Roots of the maxillary teeth can invade the nasal passages, sometimes causing obstruction and resulting in inspi-

ratory stridor. The roots often become infected, resulting in mandibular, maxillary, or retrobulbar abscesses (see "Mandibular and Joint Abscesses").

Prevention

- Most rabbits with incisor malocclusion need their incisors clipped every 4 to 8 weeks.
- Check rabbits with molar malocclusion every 2 to 3 months. Dentistry may be needed as often as every month or only once yearly.
- Rabbits with malocclusion should not be bred.
- Instruct owners to feed a high-roughage diet to encourage normal wear of the teeth.

Hairballs (Trichobezoars)

Etiology

▼ ***Key Point*** Inadequate dietary roughage is associated with gastric hairballs in rabbits.

- Other factors may contribute to formation of hairballs. Long-haired breeds may consume large amounts of hair while grooming during shedding. Hormonal influences in breeding season may contribute to aggression and fur-barbering. Mineral deficiencies may cause pica of hair. Boredom also may be a factor in fur-barbering.
- Rabbits are unable to vomit, contributing to accumulation of hair in the stomach.

Clinical Signs

- Anorexia is the primary clinical sign associated with trichobezoars. Often rabbits remain alert and active, with no other signs.
- Weight loss, depression, and palpable intestinal gas may be present in some rabbits. Fecal pellets may appear small, the amount of pellets passed may be less than normal, and hair may be visible in the pellets, causing them to "string" together.
- Diarrhea may develop in some animals because of changes in the cecal microflora from decreased gastric motility (see "Diarrhea/Enteritis").
- Acute pyloric obstruction causes severe depression, lethargy, bloating, dehydration, hypothermia, and shock.

Diagnosis

▼ ***Key Point*** Suspect a trichobezoar in an anorectic but otherwise alert rabbit with a history of inadequate dietary fiber and excessive shedding.

- A soft mass palpable in the stomach area of an anorectic rabbit is evidence of a hairball. The stomach of a healthy rabbit is normally full. However, a rabbit that has been anorectic for several days should have an empty stomach.
- Radiographs are used to confirm a diagnosis. An enlarged stomach may be visible on plain radiographs. Contrast radiography of the upper GI tract may outline the hairball. Give barium at a standard small-animal dose of 10 to 14 ml/kg orally into the cheek pouch.
- Ultrasound examination can be used to detect a mass in the stomach area.
- A CBC and serum biochemical analysis are indicated in dehydrated, severely ill, or debilitated animals.

Treatment

▼ ***Key Point*** Providing adequate dietary roughage and making sure that the rabbit is hydrated are extremely important for successful treatment of rabbits with trichobezoars.

- Medical management is successful in most rabbits. Although a few clinicians advocate routine surgical removal of hairballs, the risk of surgical or anesthetic complications is high considering the debilitated condition of most of these rabbits.
- Give supplemental fluids (approximately 100–150 ml/kg/day) subcutaneously or, preferably, by intravenous catheter in debilitated animals.
- Stimulate GI motility by encouraging the animal to move around. Allow the rabbit out of the cage as much as possible to exercise. Administer GI motility stimulants if no intestinal blockage is suspected and gut motility is poor.
- Give the rabbit petrolatum-based oral lubricants such as Laxatone at 1 to 2 ml/day for 3 to 5 days to aid in fur passage.
- Offer free-choice hay and fresh vegetables at all times. Force-feed anorexic patients with products such as Critical Care for Herbivores (Oxbow Pet Products) several times a day.
- Pain medication such as buprenorphine (0.01–0.05 mg/kg SC, IM q6–12h) or flunixin meglumine (1.1 mg/kg SC, IM q12h for no more than 3 days) may be indicated in patients with abdominal pain and distention.
- Although rare, rabbits with acute pyloric obstruction must be treated surgically. Even with surgery, the mortality rate in rabbits with pyloric obstruction is high.

Prevention

▼ ***Key Point*** Correct the diet to include adequate dietary fiber (see Diet). Provide free-choice timothy hay and fibrous vegetables. Feed rabbit pellets that have a high-fiber content (>20%).

- Routinely brush long-haired rabbits or heavy shedders.
- Some owners administer a petrolatum-based cat laxative to their rabbits every 1 to 2 months.

- Encourage rabbits to exercise. Prevent obesity by restricting the amount of pellets fed and not feeding sweet "treats".

UROGENITAL/REPRODUCTIVE DISEASES

Uterine Adenocarcinoma/Hyperplasia

Etiology

▼ ***Key Point*** Uterine adenocarcinoma is the most common tumor in domestic rabbits.

- Adenocarcinoma rarely occurs in does younger than 4 years of age. The incidence in rabbits older than 4 years of age ranges from 50% to 80% in certain breeds such as the Dutch, French Silver, and Havana, suggesting a genetic component to the disease. Occurrence is independent of breeding status.
- Endometrial changes such as atrophy of the glandular epithelial cells and increased collagen content are associated with development of uterine neoplasia.
- Endometrial changes that may precede neoplastic changes include endometriosis, endometritis, and papillary, cystic, or adenomatous hyperplasia.
- Local metastasis can extend through the uterine myometrium and invade adjacent structures in the peritoneum such as lymph nodes. Hematogenous spread to the liver, lungs, and brain occurs late in the clinical course, after 10 to 12 months.

Clinical Signs

Uterine adenocarcinoma is a slow-growing tumor that can be multicentric and involve both horns of the uterus.

- Clinical signs are usually inapparent during the early hyperplastic stages.
- Hematuria or a serosanguineous vaginal discharge is often the first clinical sign noted.
- Decreased reproductive performance such as small litter size, stillbirths, dystocia, litter desertion, and infertility are seen in breeding does.
- Cystic mastitis is associated with uterine changes in many does.
- Depression, anorexia, dyspnea, and ascites are often noted in late-stage cases, especially if metastasis to the lungs has occurred.

Diagnosis

- An enlarged, thickened uterus or multiple rounded caudal abdominal masses may be palpable on physical examination. A mass may be difficult to differentiate from abdominal fat in small does.
- An enlarged uterus may be visible on abdominal radiographs. Thoracic radiographs should be taken to screen for pulmonary metastasis.
- Abdominal ultrasonography also can be used to identify an enlarged uterus or uterine masses and to detect liver or lymph node metastases.

Treatment

- Ovariohysterectomy is successful if done before metastasis has occurred.
- Surgical resection of early focal abdominal metastasis is the treatment of choice but carries a guarded prognosis because of metastasis that may not be visible at the time of surgery.
- Prognosis is poor after pulmonary metastasis has occurred. Euthanasia is recommended.

Prevention

- Routine ovariohysterectomy of does before 2 years of age is recommended.
- Educate owners with intact does about the early clinical signs of uterine adenocarcinoma and recommend yearly to semi-annual check-ups once the patient is 3 years of age.
- Consider ovariohysterectomy in does older than 3 years of age with evidence of cystic mastitis or increased aggressive behavior.

Mastitis

Etiology

Mastitis in rabbits can be either septic or nonseptic.

- Septic mastitis is most common in lactating does. Trauma from abrasive bedding or caging, heavy lactation, and poor sanitation predispose the mammary gland to infection.
- Staphylococcus aureus and Pasteurella and Streptococcus spp. are the most commonly isolated bacteria. E. coli and Pseudomonas, Pasteurella, and Klebsiella spp. also may cause mastitis.
- Nonseptic, cystic mastitis is seen in both breeding and non-breeding females older than 4 years of age. It may be associated with high estrogen levels, uterine hyperplasia, and uterine adenocarcinoma. In some cases, malignant cellular changes may occur and develop into mammary adenocarcinoma.

Clinical Signs

- With septic mastitis, the affected gland is swollen, firm, erythematous to blue-tinged, and warm to the touch. Infection spreads until all glands are affected.
- Abcesses of the mammary gland can develop independent of lactation status.
- Systemic signs of septic mastitis include pyrexia, depression, anorexia, death of neonates, or death of the doe.
- With cystic mastitis, glands became swollen, firm, and blue-tinged with a clear-to-dark serosanguineous discharge from the teats. Rabbits are not systemically ill.

Diagnosis

- Diagnosis of septic mastitis is based on clinical signs, history of lactation or pseudocyesis, and isolation of bacteria on culture of gland tissue or exudate.
- Cystic mastitis must be differentiated from septic mastitis and mammary neoplasia. Culture and sensitivity testing of the discharge is negative for bacterial growth. Fine-needle aspiration and cytology is indicated to identify any neoplastic tissue.

Treatment

- Administer antibiotics for septic mastitis. Base therapy on results of culture and sensitivity testing.
- Pain medication such as buprenorphine is indicated if the rabbit appears to be in pain. Warm compresses 2 to 3 times daily may be helpful. Consider surgical drainage or excision of mammary abscesses.
- Suckling kits need to be removed from the doe as they may become infected with the bacteria and die from septicemia.
- Cystic mastitis usually resolves within 3 to 4 weeks after ovariohysterectomy. Severely affected glands may require surgical excision.

Prevention

- Keep lactating does in a clean environment. Make sure no sharp surfaces or wire edges are present that can traumatize the teats.
- Routinely examine lactating does for evidence of inflammation or teat injuries.
- Cystic mastitis can be prevented by routine ovariohysterectomy of young, healthy does.

Dysuria/Hematuria

Etiology

- Red, pink, or orange discoloration of the urine occurs periodically in healthy rabbits. The color may be the result of porphyrin pigments or food-related metabolites excreted in the urine.
- Thick, creamy to sandy, white urine indicates the presence of excess calcium in the urine. Unlike most mammals, intestinal absorption of calcium does not depend on vitamin D. Increases in dietary calcium intake results in large amounts of calcium being excreted in the urine.
- Hematuria occurs commonly with cystitis. Frank blood independent of or at the end of urination may indicate uterine adenocarcinoma.
- Cystic calculi occur in both male and female rabbits. Calculi usually are composed of calcium carbonate or calcium oxalate and may be associated with high dietary calcium intake.

Clinical Signs

- Rabbits with urinary pigment changes or excessive calcium in the urine usually have no other clinical signs.
- Dysuria, stranguria, urine scald, lethargy, anorexia, and depression may be seen in rabbits with cystitis or cystic calculi. Rabbits may also exhibit teeth grinding or stay in a hunched position in response to abdominal pain.

Diagnosis

- Differentiate hematuria from pigment changes in the urine by simple dipstick analysis for blood. If urine discoloration is intermittent, dispense dipsticks for owners to check the urine at home.
- Submit a urine sample for urinalysis in rabbits with clinical signs of cystitis, cystic calculi, or hematuria. Calcium oxalate crystals are commonly present, though ammonium phosphate, calcium carbonate, and monohydrate crystals are also often seen. If bacteria are identified, a urine sample collected by cytocentesis should be submitted for culture and sensitivity testing.
- A serum biochemical analysis and a CBC are necessary to assess renal function.
- Distinguish between hematuria and hemorrhagic vaginal discharge occurring secondary to uterine adenocarcinoma by physical examination, history, urinalysis, abdominal radiographs, and abdominal ultrasonography. Uterine adenocarcinoma is likely in a doe older than 3 years of age with a thickened uterus or multiple abdominal masses.
- Obtain abdominal radiographs if cystic calculi are suspected. Calculi are usually radiopaque and therefore visible in the bladder or urethra. Calculi may also be visible in the ureters or kidneys. Large amounts of calcium sediment may be visible in the bladder in rabbits excreting large amounts of calcium.

Treatment

Treatment is not necessary in rabbits with pigment-based changes in urine color.

- Instruct owners to decrease the dietary calcium levels in rabbits with hypercalciuria. Grass hay (e.g., timothy) has a lower calcium content than legume hay (e.g., alfalfa). Feed grass hay, green leafy vegetables, and timothy-based pellets.
- Treat rabbits with simple bacterial cystitis with antibiotics. A 3-week course of chloramphenicol or trimethoprim/sulfa is usually effective. Submit a second urine sample for bacterial culture and sensitivity testing after 4 to 6 weeks.

- Cystic calculi must be removed surgically. Submit calculi for stone analysis. Decrease dietary calcium after surgery to help prevent recurrence.

Prevention

- For prevention, decrease dietary calcium levels, especially in mature or aged rabbits.
- Many pelleted diets are derived from alfalfa and exceed dietary calcium requirements. Change to timothy-based pellets and substitute grass or timothy hay for alfalfa hay in the diet. Discontinue any supplemental vitamins.
- Overweight rabbits are predisposed to hypercalciuria and urolithiasis. Decrease or eliminate pellets from the diet and encourage rabbits to exercise to prevent obesity.

Treponematosis

Etiology

- Treponema paraluiscuniculi is the causative agent of rabbit syphilis.
- T. paraluiscuniculi is a spiral-shaped bacterium transmitted by direct and venereal contact between breeding rabbits or from doe to offspring. It is not a zoonotic disease.

Clinical Signs

- Most lesions develop on the external genitalia and perineum. Infection of the nose, eyelids, lips, and chin may result from autoinfection. Lesions initially consist of erythematous vesicles that progress to papules, ulcerations, scaliness, and dry crusty lesions.
- Nasal lesions in pet rabbits are commonly mistaken for dermatophyte lesions.
- Rabbits remain alert, responsive, and active.
- The incidence of abortions, metritis, and infertility may increase in breeding females.

Diagnosis

- Diagnosis is based on history, clinical signs, distribution of lesions, and response to therapy.
- Submit fur samples for fungal culture and do skin scrapings to rule out dermatophytes and ectoparasites.
- Treponema organisms can be identified by darkfield microscopic examination of skin scrapings. The organisms also can be demonstrated histologically with silver stains of skin biopsy sections.
- Serologic tests such as the rapid serum regain (RPR) are available commercially to determine the presence of antibodies against T. cuniculi. A fluorescent antibody test against treponemal antigen also is used, and an ELISA is available to screen for antibodies. These tests are used for screening in rabbit-breeding colonies.

Treatment

- T. paraluiscuniculi is susceptible to penicillin. Give injections of benzathine penicillin G (a long-acting penicillin) at 42,000 to 84,000 IU/kg IM at weekly intervals for 2 to 3 weeks. Response is rapid; lesions dramatically regress, usually after one injection.
- Tetracyclines and chloramphencol have also been effective against T. cuniculi.

Prevention

- Screen rabbits in breeding colonies for treponematosis.
- The incidence of disease in pet rabbits is low. Preventive serologic screening is not necessary.

NEUROMUSCULAR/SKELETAL DISEASES

Mandibular and Joint Abscesses

Etiology

- Abscesses of the mandible and joints occur frequently in pet rabbits. Bacteria such as Pasteurella multocida, Staphyloccoccus aureus, Pseudomonas aeruginosa, Fusobacterium nucleatum, Peptostreptococcus micros, Strepcococcus milleri group, Actinomyces israelii, Arcanobacterium haemolyticum, Prevotella spp., Proteus spp., and Bacteroides spp. have been isolated. Bacteria can also spread hematogenously from the initial infection.
- Malocclusion and root elongation of the cheek teeth sometimes accompany mandibular abscesses. Infection may spread from the oral cavity along the tooth root.
- Soft-tissue abscesses can also occur in the oral cavity or joints secondary to a penetrating wound from a foreign body.

Clinical Signs

- Joint abscesses are most frequent in the distal limb joints. The swellings are large, firm, and warm to the touch. Rabbits may be lame, depending on which joints are involved.
- Mandibular abscesses occur as firm swellings in the ventral facial area. Abscesses are sometimes quite large before they are apparent to the owner. Excessive ptyalism may be an early symptom.
- Affected rabbits may refuse to eat if mandibular abscesses are accompanied by dental disease.
- Many rabbits remain active and alert with no other clinical signs.

Diagnosis

- Thick, white purulent exudate is present on fine-needle aspirate of the swelling. Cytologic examination of the exudate shows neutrophils and

proteinaceous debris; bacteria may or may not be visible.
- Obtain radiographs to check for and evaluate the extent of any bone involvement.
- Submit tissue samples for bacterial culture and sensitivity testing. Because the necrotic centers are often sterile, collect samples from the inside of the abscess capsule wall.

Treatment

▼ ***Key Point*** Simple lancing of mandibular and joint abscesses is ineffective because of the thick, caseous nature of the exudate.

- Complete enbloc surgical excision of the abscess is the preferred treatment. However, depending on the extent of involvement, this may not be possible and aggressive surgical debridement is the next best option. Remove any molars or premolars that are loose or that have radiographic evidence of extensive infection of the roots. Flush the soft tissue with copious amounts of sterile saline.
- Abscesses often re-occur and multiple surgeries concomitant with antibiotic therapy may be required for resolution.
- Antibiotic-impregnated polymethylmethacrylate (AIP-MMA) beads can improve the success rate of surgical treatment of mandibular abscesses if abscessed tissue cannot by completely excised.
- Amputating the affected limb may be the most effective therapy for abscesses involving the joint and surrounding bone. Rabbits adapt well to amputation of either a fore or rear limb.
- Disease may recur in other joints, even if amputation of the affected limb has been performed. Hematogenous spread of the bacterial infection to other joints may occur at any time during the clinical course.
- Long-term antibiotic therapy is necessary. Some rabbits respond to oral fluoroquinolone or injectable penicillin therapy in combination with surgical debridement or amputation.
- Owners must be able to do extensive nursing care at home. Have the owners flush open wounds with sterile saline once or twice daily.
- The prognosis for successful therapy is guarded. With bony involvement, the prognosis is poor.

Torticollis/Head Tilt/Ataxia

Etiology

- Bacterial infection of the inner ear, middle ear, or meninges is the most common cause of torticollis in pet rabbits. Pasteurella multocida is often implicated as a primary cause, though other bacteria may also be involved.
- Encephalitozoon cuniculi is another common cause of torticollis and incoordination in rabbits.
- Vascular lesions, infection with herpesvirus, cerebral nematodiasis, hypovitaminosis A, and toxicoses (e.g., lead poisoning) are less common causes of head tilt and uncoordination.

Clinical Signs

- Onset may be acute or slowly progressive. The head tilt may be mild or accompanied by torticollis, incoordination, and the inability to stand.
- Some rabbits have no other clinical signs. Other rabbits become depressed, anorexic, and lethargic.
- Rabbits with severe depression, positional nystagmus, and facial nerve deficits may have brain or meningeal lesions.

Diagnosis

Diagnosis is based on clinical signs. Establishing the exact cause may be difficult.

- Carefully examine both ear canals for evidence of infection.
- Rabbits with severe otitis media may have swellings at the base of the ear. White, creamy, caseous debris can often be massaged out of the ear canal. Cultures and sensitivity testing can be helpful in identifying organisms and in directing antibiotic therapy.
- Results of a CBC may reveal an inflammatory response.
- Skull radiographs may aid in diagnosis. Anesthesia is usually necessary for proper positioning. Bony changes in the bulla may indicate osteomyelitis.
- Serologic tests can be used to detect antibodies against E. cuniculi or P. multocida. A positive result is not diagnostic of the specific agent but is helpful in ruling out some possible causes.
- Often, the cause cannot be established, and a tentative diagnosis is based on response to therapy. Rabbits with pasteurellosis often improve with long-term antibiotic therapy and supportive care. Rabbits with parasitic migration may remain unchanged or improve gradually. Rabbits with clinical signs secondary to encephalitozoonosis are usually unresponsive to treatment or they deteriorate clinically.
- The cause sometimes is determined only on postmortem examination.

Treatment

- Give antibiotics long-term, usually a minimum of 4 to 6 weeks. Choose an antibiotic that penetrates the blood-brain barrier and is effective against pasteurellosis (e.g., chloramphenicol and enrofloxacin).
- If exudate is visible in the ear canal, clean and flush the ear thoroughly. Tranquilization or anesthesia may be necessary. Administer a topical antibiotic in the ear canal 3 to 4 times daily. Administer systemic antibiotics based on culture and sensitivity testing.

- Administer an oral Lactobacillus supplement during long-term antibiotic therapy.
- Supportive care is necessary in rabbits that are laterally recumbent or that have severe torticollis. Recumbent rabbits should be turned every 6 to 8 hours or propped up sternally to prevent hypostatic congestion of the lungs. Apply eye lubricants several times daily if the blink reflex is diminished. Hand-feeding may be required. Keep rabbits on clean, dry bedding to prevent urine scalding and contact dermatitis.
- Inform owners about the amount of supportive care needed in recumbent rabbits. Many owners elect euthanasia when faced with the difficulties and the time required for long-term nursing care.
- Euthanasia often is selected in debilitated rabbits if no clinical improvement is seen after several days of therapy.

Encephalitozoonosis *(Encephalitozoan cunuculi)*

Etiology

- *E. cuniculi* is an obligate, intracellular, microsporidian parasite prevalent in domestic and wild rabbits. The organism infects mice, rats, hamsters, and guinea pigs less commonly.
- The major route of transmission is by ingestion of spore-contaminated urine. Inhalation and vertical transmission can also occur. *E. cuniculi* spores are environmentally resistant and can survive for 4 weeks in mild environmental conditions.
- The organism can infect lungs, kidneys, liver, heart, brain, and eye. Many infected rabbits are asymptomatic, or may develop clinical signs after a stressful event or other immunosuppressive conditions.

Clinical Signs

- Depending on the site of infection, clinical signs can vary and include: torticollis, ataxia, nystagmus, rolling, seizures, paresis, and death. Clinical signs of encephalitozoonosis are similar to those of the neurologic form of pasteurellosis.

Diagnosis

- Presumptive diagnosis is based on clinical signs and results of diagnostic testing of rabbits exhibiting neurologic signs.
- Serologic tests are available to detect the presence of antibodies against *E. cuniculi*. These include ELISAs and indirect fluorescent antibody assays.
- Definitive diagnosis requires histopathologic examination of affected tissues. Spores can be seen in the tissue and lesions in the brain usually consist of multifocal areas of necrosis and granulomas with perivascular lymphoplasmacytic cuffing.

Treatment

- Several treatment protocols have been reported; however, results have been variable. Administer fenbendazole (20 mg/kg q24h for 28 days), oxibendazole (30 mg/kg PO q24h for 7–14 days, then reduced to 15 mg/kg q24h for 30–60 days), or albendazole (30 mg/kg PO q24h for 30 days, then 15 mg/kg PO q24h for 30 days or 10–15 mg/kg PO q24h for 3 months).
- Clinical signs may recur in some rabbits when drugs are stopped. These rabbits may require medications indefinitely to control clinical signs.
- For rabbits with suspected concurrent bacterial infection, antibiotic therapy with chloramphenicol (30–50 mg/kg PO q12h for 7 days) can be administered while awaiting the results of serologic testing.
- Patients with severe neurologic signs are often anorectic and will require supportive care such as fluids and force feeding until clinical signs abate.

Prevention

- Identify carriers in rabbit colonies and breeding facilities through serologic testing. Cull animals that test positive.
- Eliminate urine contamination between cages through proper sanitation procedures. Most disinfectants, such as quaternary ammonium compounds, iodophors, phenolic derivatives, alcohols, and hydrogen peroxide, are effective in inactivating spores.
- Prevent possible contact between pet rabbits housed outdoors and wild rabbits or rodents by elevating cages off the ground or housing pets in a rodent-proof enclosure.

Vertebral Fractures/Luxation

Etiology

- The rear leg muscles of rabbits are well developed for strong kicking and thumping.

▼ ***Key Point*** If rabbits are restrained poorly with inadequate control of the rear legs, animals may kick suddenly, resulting in fracture of their spinal vertebrae.

- The lumbosacral region (L7) is the most common site for fracture or luxation.

Clinical Signs

- Clinical signs of a fractured back depend on the degree of spinal cord damage and can include partial or complete paralysis of the rear legs and loss of normal bladder and bowel function.
- Signs are acute in onset and directly related to a traumatic incident.

- Other disease problems may cause clinical signs similar to a vertebral fracture. Multifocal infection of the spinal cord secondary to pasteurellosis, parasite migration, or vascular thrombosis within the cord can cause neurologic deficits. The clinical onset is usually more chronic and slowly progressive than that of a fracture.

Diagnosis

- Diagnosis is based on history and clinical signs.
- Obtain radiographs of the vertebral column to confirm a fracture or luxation.

Treatment

- If a diagnosis is made within 6 to 12 hours of the time of the fracture, administer methylprednisolone sodium succinate, prednisolone sodium succinate, or dexamethasone at shock dosages.
- Conservative medical management such as cage rest and nonsteroidal anti-inflammatory agents can be used to manage mild cases. Anti-inflammatory and pain medication such as Carprofen (Rimadyl, Pfizer Animal Health, Exton, PA) or Meloxican (Metacam, Boehringer, Ingelheim Vetmedica, St. Joseph, MO) are often effective in making the patient more comfortable. Attempts to stabilize the fracture surgically are usually not practical because of the poor prognosis and degree of nursing care necessary.
- Some owners try long-term supportive care to see whether neurologic function returns. They must be instructed on manual expression of the bladder and general nursing care. The rabbit's bedding should be changed multiple times a day to prevent urine scald. The patient will also need to be placed on alternating sides frequently prevent formation of pressure sores.
- Prognosis for recovery is guarded to poor. Euthanasia usually is recommended in rabbits with complete transaction of the cord resulting in complete rear limb paralysis and urinary and fecal incontinence.

Prevention

- See Figs. 176-1, and 176-2 for proper restraint of rabbits.

Bone Fractures/Joint Luxations

Etiology

- The skeleton of the rabbit is light and fragile. The tibia, radius, and ulna fracture easily with traumatic events such as getting a limb caught in wire caging or accidentally being dropped or stepped on.
- Traumatic joint luxations of the elbow or stifle joint occasionally occur.

Clinical Signs

- Rabbits with bone fractures or luxations are acutely lame.
- Rabbits have minimal soft tissue to protect the long bones below the elbow and stifle from penetrating the skin, thus open fractures are common at these sites.
- Fractures are usually palpable on physical examination. Joint luxations are palpable as firm swellings.

Diagnosis

- Diagnosis is based on history, clinical signs, and physical examination.
- Obtain radiographs to evaluate fractures for surgical repair or to confirm joint luxations.

Treatment

- *Splints* used in combination with padded bandages are usually adequate to stabilize metatarsal, metacarpal, and phalangeal fractures. Bandage the foot in a functional position. Contour a moldable splint or casting material such as Orthoplast (Johnson & Johnson, New Brunswick, NJ) or Vet-lite (Runlite SA, Micheroux, Belgium; see www.runlite.com for distributors) along the plantar surface.
- External coaptation can also be effective for closed, simple, long-bone fractures. Maintain the limb in a normal position and incorporate both the joints above and below the fracture into the splint. Ideally, there should be at least 50% cortical contact between the fragment ends.
- *Intramedullary pins* can be used for better axial alignment of long bone fractures and to minimize bending and rotational forces. The pins should occupy at least 60% to 70% of the medullary cavity. Cross-pins can be used for supracondylar humeral or femoral fractures. Bone plates are not usually recommended other than in large rabbits because the thin cortices of rabbit bones makes screw placement difficult.
- *External skeletal fixation* provides rigid stability with minimal soft tissue disruption. Because fixator pin diameter should not exceed 20% of the bone diameter, Kirschner wires are often used in smaller patients. Most metal bars and clamps are too large or heavy for rabbits; therefore, bone cement or acrylics injected into appropriately sized rubber tubing are effective as fixator bars. (see Chapter 111 for examples of external skeletal fixators)
- Severely comminuted or open fractures may be best managed with limb amputation. Rabbits usually adapt well to amputation and can ambulate easily on three limbs. Forelimb amputation is best performed by removing the scapula. Mid-femoral amputation

of the hind limb is preferred over coxofemoral disarticulation.
- With a joint luxation, anesthesia is needed to manipulate the joint into normal position. With the joint reduced and the limb in extension, apply a splint to allow the surrounding soft tissue to develop fibrosis and keep the luxation reduced. Some luxations may additionally require a transarticular pin to stabilize the joint.

See Section 8 for treatment of orthopedic disorders in dogs and cats.

Postoperative Care

- Obtain a radiograph of the leg after repair to assess bone alignment and placement of pins (if used).
- Postoperative management vital for successful healing includes strict cage rest, a clean environment, a good diet, and frequent monitoring any bandages or fixators.
- Antibiotics are indicated in all open and contaminated fractures to prevent subsequent osteomyelitis and abscess formation.

Chapter

177 Pet Rodents

Nancy L. Anderson

Many small rodents are commonly kept for companionship and enjoyment. This chapter provides information needed to diagnose and treat the most frequently encountered problems of mice, rats, gerbils, hamsters, guinea pigs, and chinchillas.

HUSBANDRY

Caging and Sanitation

- Cages should be made of stainless steel, hard plastic, or glass. These materials are cleaned and sanitized easily and are resistant to gnawing or corrosion from urine and fecal matter. Minimum floor space and height requirements are listed for each species in Table 177-1. With the exception of guinea pigs, all cages need secure lids.
- Guinea pigs can be housed in open-topped enclosures with walls higher than 10 inches. Ensure that dogs, cats, wild animals, and small children do not have unsupervised access to these cages.
- Clean cages as needed, usually 1 to 3 times per week for most rodents. A scrub brush, dish soap, and water work well. If cages are not kept clean, ammonia, other irritants, moisture, and bacteria concentrations rise to harmful levels, predisposing animals to disease.
- Disinfect the cage twice a month with 1 part sodium hypochlorite (household bleach) mixed in 30 parts water. Let the bleach solution stand for at least 15 minutes. Rinse the cage well afterward.
- All solid-floored cages need to be covered in bedding. Shredded paper, non-resinous wood shavings, wood wool, and corn cobs are all acceptable. Provide at least 2 inches of bedding. Most rodents enjoy burrowing in deeper bedding when it is provided in one corner of a cage. Do not, however, fill the entire cage with deeper bedding. This usually leads to poor sanitation as a result of owners' failure to recognize buildup of hidden wastes such as moisture from leaking water bottles, cached foods, urine, and feces.
- Wire mesh floors can be used successfully only if the dimension of the mesh is correct. Size the openings to be just large enough for an adult to retract a tarsal joint back through the mesh. Larger holes make it difficult for the animals to walk and cause pressure sores. Smaller openings may cause injuries such as tibial fractures and self-mutilation while struggling to free trapped appendages. Bedding above the wire keeps waste from dropping through the wire and therefore is not recommended. Wire bottom cages do not work well for breeding animals because neonatal rodents must be surrounded by nesting material to maintain moisture in the nest and prevent dehydration. Young rodents often cannot walk correctly on mesh sized for adult feet.
- All pet rodents require visual security. Tubes, jars, or cans made of nontoxic, nonabrasive substances work well for this purpose. Also provide objects for gnawing. Rodents possess open-rooted teeth, and constant wear is necessary to maintain normal dentition. Mice, rats, gerbils, and hamsters enjoy and benefit from exercise wheels.
- A good room temperature range for most pocket pets is 70°F to 75°F. Keep rodents with disease at 85°F to 90°F unless hyperthermia is of concern (some chinchillas).
- Provide 10 to 12 hours of darkness to 12 to 14 hours of light. This light cycle is essential if breeding is desired.
- Hamsters, guinea pigs, and chinchillas that are exposed to temperatures below 65°F may hibernate for a few days or until the ambient temperature rises. Heart rates may be less than 5 bpm during hibernation.

Nutrition

▼ ***Key Point*** Feed pet rodents laboratory animal chow appropriate for their species (Table 177-2). Seed diets are deficient in protein and contain excessive fat.

- Seeds, as well as vegetables and other foods, may be fed as treats but not to provide more than 15% of calories. Intermittent exposure to vegetables and seeds causes mild, transient diarrhea.
- Supplementation of vitamin C is recommended for all guinea pigs.

Table 177-1. CAGING AND ENVIRONMENTAL REQUIREMENTS FOR POCKET PETS

Requirement	Rat	Mouse	Guinea Pig	Chinchilla	Hamster	Gerbil
Air changes/hour	10–15	10–15	10–15	>6	>6	>6
Minimum cage floor space/animal (square inches)	35	15	101	288	20	36
Minimum cage height (inches)	>6	>5	>10	>12	>6	>6
Recommended room temperature (°C)	21.1–26.6	21.1–29.4	18.3–23.8	15.5–21.1	18.3–23.8	21.1
Maximum-minimum room temperature (°C)	18.3–29.4	18.3–31	12.7–32.2	10–23.8	12.7–23.8	18.3–29.4
Room humidity (%)	50–70	30–70	40–70	40–60	30–70	30–50
Cage-cleaning frequency (days)	2–7	2–7	3–4	7	3–7	14
Light cycle-hours light: hours dark	12–14:10–12	12:12	12:12	>12.5:11.5	12:12	12:12

Table 177-2. DIETARY INFORMATION FOR POCKET PETS

	Rat	Mouse	Guinea Pig	Chinchilla	Hamster	Gerbil
Recommended diet	Laboratory rodent chow	Laboratory rodent chow	Guinea pig chow	Chinchilla chow	Hamster chow	Laboratory rodent chow
Supplements	<15% of calories, avoid seeds	<15% of calories, avoid seeds	Vitamin C 200 mg/L, drinking water cabbage/kale	Ad lib grass, hay	<15% of calories, avoid fats and seeds	<15% of calories, avoid fats and seeds
Food consumption (g food/100 g body weight/day)	5–10	15	3–6	3–6	10–12	5–8
Water consumption (ml water/100 g body weight/day)	10–12	15	10–40		8–30	4–7
Recommended protein (%)	12–27	16–20	18–30		15–25	16–22
Recommended fat (%)	5–25	5–25			3–5	2–4
Recommended carbohydrate (%)		45–55	16		8	
Recommended minimum fiber (%)			16–18			

- Adult chinchillas that are not obese should be fed high quality, fresh grass hay ad libitum. Obese animals may need to have the hay rationed. Chinchillas require $^1/_8$ to $^1/_4$-cup of fresh pellets per animal each day. Feeding pellets free choice leads to obesity, and the high protein and calcium levels in these diets may predispose animals to urinary tract disease. Most pellets also do not provide sufficient fiber to maintain normal gastrointestinal (GI) motility.
- Store food in tightly sealed containers at less than 60°F; keep food refrigerated if possible.
- Feed all diets within 90 days of milling to ensure the highest nutritional value. Encourage owners to check dates on packages and ask pet store managers about providing dates on bulk items.
- If possible, feed pet rodents except guinea pigs from overhead racks. These devices reduce wastage and eliminate fecal contamination of food. Covered hoppers, heavy crocks, or stainless steel bowls that are attached to the side of the cage to eliminate spillage are acceptable and recommended for guinea pigs.
- Feed breeding females and their litters from the floor of their cages until the young are large enough to reach overhead feeders or crawl in and out of crocks.
- Cannibalism of neonates commonly occurs as the result of stress associated with cage cleaning. To minimize cannibalism, clean the cage and provide a 10- to 13-day food supply 1 to 2 days before parturition.

Water

▼ ***Key Point*** Provide fresh water in clean containers daily.

- Do not provide water in open crocks. These are contaminated or spilled easily and are a common cause of dehydration and poor sanitation.

Table 177-3. NORMAL PHYSIOLOGIC DATA FOR POCKET PETS

	Rat	Mouse	Guinea Pig	Chinchilla	Hamster	Gerbil
Life span (yrs)	2–4	1–3.5	3–6	8–10	1.5–2.5	3–5
Heart rate (bpm)	250–600	325–780	150–400	40–100	250–600	360
Respiratory rate (breaths/min)	33–127	60–230	42–130	40–80	33–155	70–120
Body weight (g)						
Male	300–520	38–42	900–1200	450–600	85–110	60–110
Female	250–300	30–35	700–900	550–800	95–120	50–80
Birth weight (g)	5–6	0.5–1.5	60–115	30–50	2–3	2.5–3
Body temperature (°C) 35.9–38.2	35.5–38	37.2–40	36.1–37.8	36.2–37.5	38.1–38.4	
Gender determination in neonates	At 7 days, the anogenital distance of males is 5 mm; of females, 2.5 mm. Females show nipples at 8–15 days	Identify testicles through skin in neonates	Anogenital distance in males is 10 mm; in females, 5 mm			

- Sipper tubes and water bottles work well. Clean with dish soap and water daily and disinfect them weekly. Guinea pigs expel food from their mouths into their sipper tubes, so more frequent cleaning is needed.
- Some water bottles have special valves to minimize backflow. Supplement guinea pigs' water daily with 200 mg vitamin C/L. If the water is not dechlorinated, it will inactivate the vitamin C.

Quarantine

Quarantine all newly acquired animals in a different room from current pets for a minimum of 30 days. Feed and handle quarantined animals last. Recommend that caretakers wash their hands and change clothes before handling current pets. Avoid the introduction of adult animals because this frequently results in fighting. Instead, place animals together while young and allow them to mature together. Avoid keeping more than one male per cage because this also usually leads to fighting.

HISTORY AND PHYSICAL EXAMINATION

A systematic history and physical examination are mandatory. Many disease syndromes are caused by poor husbandry. Pets that have been kept isolated from other rodents or acquired from a private breeder are less likely to harbor infectious disease than animals obtained from a pet store, laboratory, or wholesaler. See Table 177-3 for normal physiologic data.

Obtain the following information:

- Species, age, sex (species and sex may not be obvious or the owner may not know this information)
- Origin (e.g., private individual, breeder, pet shop, research laboratory, supply house)
- Length of ownership, owner's previous experience
- Environment, caging (ask owner not to clean cage before coming to hospital), cleaning, temperature, humidity, photoperiod, person responsible for care
- Diet: brand, dating on packages, storage, supplements, type of feeder and waterer and method and frequency of cleaning, feeding schedule, person responsible for feeding
- Cagemates, other pets, quarantine history, presence of aggressive behavior
- Dates of unusual activity: breeding, parturition (Table 177-4), cannibalism, abnormal urination or defecation
- Medical history, previous weights
- Purpose for ownership: pet, breeder, display, education
- Purpose for visit: purchase examination, checkup, problem

Examination of Patient and Environment

- Become familiar with normal behavior, locomotion, haircoat, and stools of each of the pet rodent species.
- Observe the pet in its cage for mentation, activity, locomotion, dyspnea, head posture, haircoat, and any grossly observable abnormalities.
- Note respiratory and heart rates before restraint when possible. Observe the condition of cagemates.

▼ ***Key Point*** If dyspnea or severe depression is detected, warn the owner that the animal is critically ill and could die of stress brought on by an examination.

- Handle such animals as little as possible. Initially, treat severely ill animals symptomatically, then

Table 177-4. REPRODUCTIVE DATA FOR POCKET PETS

	Rat	Mouse	Guinea Pig	Chinchilla	Hamster	Gerbil
Age at puberty						
Males	42–110	35–50	60–120	240–540*	45–98	70–85
Females	42–110	50–60	60–90	240–540*	30–84	65–85
Length of estrous cycle (days)	4–5	4–5	15–17	41	4	4–6
Gestation (days)	21–23	19–21	63–68	105–115	15–18	24–26
Average litter size	6–14	10–12	3–4	2–3	6–8	4–6
Age at weaning (days)	21	18–28	14–28	36–48	20–25	20–30
Litter development	Eyes open 12–17 days	Eyes open 10–14 days	Precocious; eats solid food by 5 days	Precocious	Ears open 4–5 days; eyes open 14–16 days	Eyes open 16–20 days;

*Fall babies breed 1 year later. Normal breeding season is November through May.

perform a complete physical examination after the pet's condition has stabilized.

Evaluate the Cage

- Note the type of diet and bedding as well as the level of sanitation and compare these with what was described in the history.
- Observe quantity and quality of feces and urine. Diarrhea, soft stools, absence of stools, copious urine, and discolored urine all can be signs of illness.
- Coprophagy is a normal behavior in rodents.
- Check the diet and water supply for freshness, quantity, source, and accessibility.
- Evaluate the presence and suitability of cage furniture. Adequate visual security and the ability to exercise and gnaw are extremely important.

Examine the Animal

- An accurate weight in grams is extremely important for evaluating an animal's body condition, calculating drug dosages, and monitoring treatment. The easiest method of weighing a pet rodent is to place it in a box and then subtract the weight of the container.

Restraint

- Restraint of pet rodents is easy with experience. Pets that have been handled frequently and gently by the owners require only minimal restraint. Gentle pressure directs the animal as needed. Grasp less cooperative patients (except chinchillas and guinea pigs) by the scruff over the back of the neck with thumb and forefinger (Fig. 177-1). Take care to pinch enough skin to prevent the animal from turning around, yet leave enough slack for respiration. On smaller specimens, hold the base of the tail, if present, between the fourth and fifth fingers to provide additional restraint.

Figure 177-1. "Scruffing" a mouse.

- Hold docile guinea pigs with the palm of one hand supporting the chest while the other hand supports the hind quarters (Fig. 177-2). Place the thumb and forefinger of the first hand in the axillas for additional control.
- Take care to minimize damage to the fur when handling chinchillas because they lose hair easily. Grasp the animal by the tail and scoop it up into the palm of the same hand (Fig. 177-3). If necessary, grasp the thorax just behind the axillas.
- Calm uncooperative rodents by placing an appropriately sized towel over the head. Complete the physical examination by wrapping the patient in a towel and exposing only needed areas. Even oral, ophthalmic, and aural examinations can be performed with minimal effort if the animal is given the chance to relax in the towel "burrow."
- Remove particularly aggressive patients from their cages by scooping them up in a can or bucket; then slide them out onto a slick surface and pick them up or transfer them to a holding area or scale.

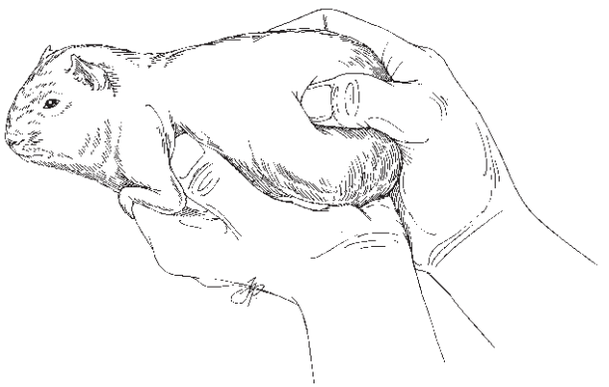

Figure 177-2. Proper method for restraint of guinea pig.

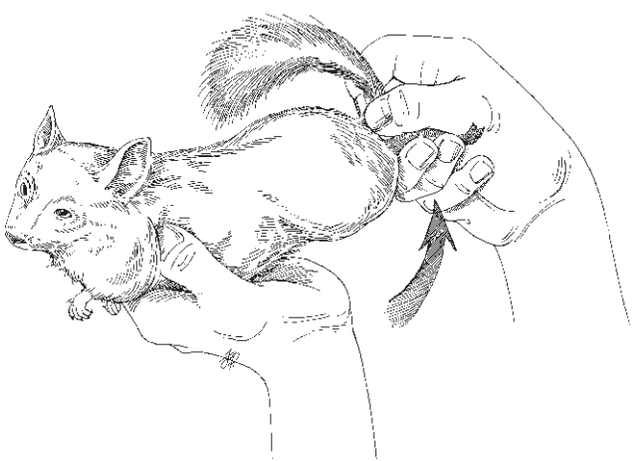

Figure 177-3. Proper method for restraint of chinchilla.

▼ ***Key Point*** Lift the hind quarters of mice and rats by the base of their tails to facilitate scruffing. Never use the tip of the tail for restraint, or the skin of the tail may slough.

Physical Examination

Once the animal is restrained properly, examine the head. Assess the cranial nerves. Check the nose for presence and character of discharge. Examine the mouth for ptyalism, swelling, overgrown incisors, or discharges. To inspect the oral cavity, place an avian speculum across the mouth just caudal to the incisors. Use a light source and a pair of hemostats as retractors to improve access. Alternatively, use an otoscope with a pediatric head to examine the premolars and molars of guinea pigs and chinchillas for overgrowth. Examine the cheek pouches of hamsters for swelling, impaction, or discharge. An ophthalmic examination, including a fundic examination, is important.

- Use a slit lamp to identify superficial pathology, especially corneal ulcers or foreign bodies.
- If indicated, perform fluorescein stain and conjunctival scrapings or cultures.
- Note the presence of conditions such as discharge, asymmetry, and exophthalmos.

▼ ***Key Point*** Gerbils, rats, and mice produce red tears (chromodacryorrhea) with stress or disease. Do not confuse them with hemorrhage.

- Guinea pigs suffering from hypovitaminosis C often produce dry, white tears.
- Check ears for discharge, foreign bodies, and mites. Bluish discoloration of the ears is a sign of cyanosis. Bright red injected coloration is associated with septicemia. Sores behind the ears and on the neck are often a sequela of aural disease.
- Evaluate submandibular, axillary, inguinal, and popliteal lymph nodes for size and consistency. Enlargements usually indicate infectious or neoplastic disease.
- Reevaluate respirations and heart rate after the stress of handling and compare them with the resting rate noted when the animal was in the cage. Note dyspnea or respiratory sounds. Auscultate animals weighing more than 200 g. Counting every third or fourth beat and multiplying by the appropriate factor allows recording of heart rates up to 500 bpm.
- Palpate the abdomen. Pay special attention to differentiating pregnancy from the bladder, kidneys, abdominal masses, enlarged cecum, and fecal balls in the colon. While palpating the abdomen, examine the mammary chain of all female rodents for signs of mastitis, lactation, or neoplasia. Also check male mice and rats for mammary neoplasia. Mammary tissue extends from the base of the neck to the base of the tail. Gerbils typically have an elliptical sebaceous gland on their ventral midline. Do not confuse this with neoplasia or infection. Check the rectum and perineal area for signs of diarrhea, prolapse, irritation, parasites, and bite wounds. Note that coprophagy is normal in rodents.
- Evaluate the urogenital tract for signs of inflammation, foreign bodies, urine scalding, and vaginal discharge. Locate and palpate the testicles in males. The easiest method of determining sex in pet rodents is to compare the anogenital distance, which is twice as long in males as in females. Other characteristics that allow the determination of sex are as follows:
  - Visualization or palpation of testicles or extrusion of the penis from the prepuce indicates a male.
  - The presence of two external openings (i.e., anus and urethra) indicates a male.
  - The presence of three openings (i.e., anus, vagina, and urethra) indicates a female.
- Examine the skin and fur for conditions such as crusts, alopecia, masses, herniations, and wounds.

- Check tail and feet for swellings, coloration, sores, length of toenails, and condition of footpads.
- Evaluate the extremities for trauma or other abnormalities.

DIAGNOSTIC TESTS

Skin and Ear

Apply cellophane tape to crusted areas of the skin and view under a microscope as an aid in diagnosing ectoparasites such as lice, mites, and fleas. Skin scrapings are beneficial in detecting mites and dermatophytes. Dermatophytes are diagnosed best through culture of broken hairs or crust on dermatophyte test medium.

Use small, cotton-tipped swabs to obtain ear swabs from animals weighing more than 25 g. Mix debris with mineral oil and view under low magnification to test for ear mites, or roll onto a glass slide and Gram stain to look for bacterial or yeast infections.

Urine and Fecal Collection

Collect urine by placing the rodent in a clean mesh-bottomed cage with a plastic liner. After enough urine has been produced, collect it off the bottom of the cage with hematocrit tubes or a syringe and a 25-gauge needle. Perform cystocentesis on non-pregnant animals weighing more than 100 g with a 25- to 27-gauge needle.

Collect feces over several hours to provide a volume sufficient for fecal flotation. Flotation allows the detection of nematodes and some trematodes and cestodes. Cellophane tape applied to the perineal area and then viewed under a microscope often reveals oxyurid eggs. Use a fresh saline smear or fecal sedimentation to diagnose protozoal parasites. Fecal cultures are useful in diagnosing bacterial diarrhea.

Radiology

Radiology is an extremely useful tool. Machines capable of exposures as low as 40 kvp and 3 to 10 MAS effectively image mice. Most radiograph machines are capable of generating diagnostic radiographs of guinea pigs, chinchillas, and mature rats at settings used for kittens. Positioning is accomplished with masking tape or Velcro straps. Sedate unruly animals. Techniques used in cats for contrast studies of both urinary and GI systems are modified easily for use in pocket pets.

Blood Samples

- Use lateral or medial saphenous veins to obtain samples in animals heavier than 100 g. Liberally clip the area to allow exposure of the vessel before attempting venipuncture. Place a 25- to 27-gauge needle in the vein and collect blood into microtainers or hematocrit tubes as it drips from the hub of the needle (Fig. 177-4). Take extreme care not to collapse and lacerate the vein with overzealous aspiration if a syringe is attached to the needle.
- It is also possible to use the cephalic vein in guinea pigs.
- Jugular veins are good alternatives in thin individuals under sedation.
- An alternative technique that is useful in smaller animals is to coat the skin over the vein with a thin layer of petroleum jelly and then to puncture the vessel. Blood is collected with a hematocrit tube as it exits the wound. Samples up to 1% of the animal's weight are considered safe, even in stressed animals.

Figure 177-4. Medial saphenous venipuncture; *inset*, lateral tarsal venipuncture.

▼ ***Key Point*** Attempt tail bleeding only as a last resort in mice, rats, gerbils, and hamsters. These techniques often are not acceptable to owners.

To bleed the tail, warm the tail with water or compresses to dilate the tail vessels. In large rats, perform venipuncture with a needle and obtain blood in the usual fashion. In smaller animals, lacerate the tip of the tail. Blood from the wound is collected as described previously. See Tables 177-5 and 177-6 for hematology and chemistry values.

ROUTINE PROCEDURES

Oral Medications: Nutritional Support

Incorporate oral medications into a treat, or administer them in liquid form. If the medication is palatable,

administer it by placing the tip of a dosing syringe into the diastema.

▼ ***Key Point*** Take care not to place the tip into the contralateral cheek pouch, or the patient may store the medication and expel it later.

Administer medication in small amounts. Ensure that the animal swallows the medication in its mouth before more is administered. This technique is useful for force-feeding pellet gruels to anorexic pets if the caregiver is patient. Medication or food that is administered too quickly will be spit out or aspirated.

For rodents that are intractable or for administration of unpalatable substances, pass a stomach tube per os.

- Metal feeding needles, red rubber urinary catheters, or infant feeding tubes work well. Selection is based on the size of the animal and individual preference. Metal feeding needles with ball tips frequently are used in patients weighing less than 100 g (Fig. 177-5). The metal provides the necessary stiffness to pass a tube of small diameter. The ball at the end of the needle makes it difficult (but not impossible) to pass the tube into the trachea. These tubes have the potential to create esophageal tears with improper restraint or when excessive force is applied.
- Measure the length from the tip of the nose to the last rib. Ventroflex the head slightly, and place the tip of the tube through the diastema and over the

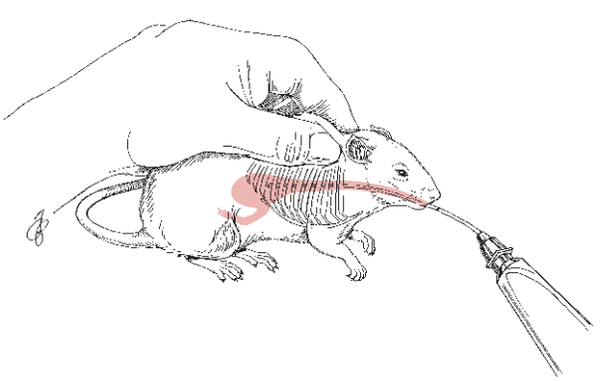

Figure 177-5. Proper placement of a metal feeding tube.

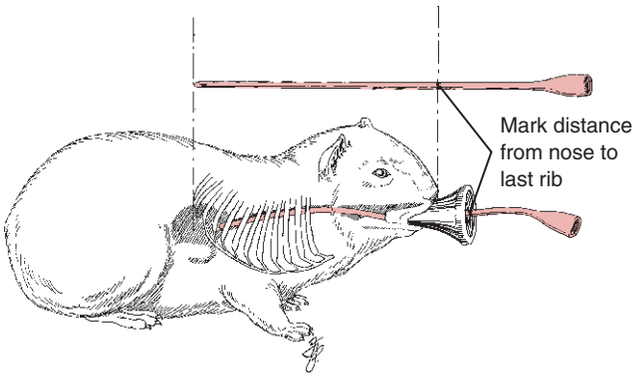

Figure 177-6. Measurement and use of a flexible catheter as a feeding tube.

tongue. If the tube does not pass easily down the esophagus to the premeasured distance, check the tube size and/or reposition the tube before attempting further advancement. The needle is easily palpable percutaneously if it is placed correctly. It is usually safe to administer up to 3 ml/100 g body weight.

- A flexible catheter is ideal for use as a stomach tube in larger rodents (Fig. 177-6). Use a speculum to prevent chewing on the tube. An otoscope head, avian speculum, or piece of wood or plastic with a hole drilled in the center works well. Measure and mark the tube for the distance from the tip of the nose to the last rib. Place the speculum in the mouth and over the tongue. Pass the tube while holding the speculum in place and slightly ventroflexing the head. Resistance is encountered if the tube is malpositioned or is an inappropriate size. The tube must pass over the tongue before it can be advanced down the esophagus. This is difficult in some animals. Palpate the throat to confirm the presence of the feeding tube in the esophagus.

▼ ***Key Point*** Because the placement of a stomach tube is a blind procedure, administer a small volume of sterile saline into the tube before administering the medication to ensure that the tube is not in the trachea. Misplaced medications are fatal.

- This method is also useful for administration of nutrition to anorexic patients. Place a pharyngostomy tube if repeated dosing is necessary, using the technique for cats. Flush pharyngostomy tubes with water at least every 4 to 6 hours. Nasogastric tubes are not recommended because they are difficult to place and maintain patency because of their small size. Securely suture all tubes to the skin. Place a tube collar made of radiographic film or use rear leg hobbles to prevent removal of tubes.
- Nutritional support is critical in rodents because of their high metabolic rate. Provide supplements in animals that are anorexic for longer than 12 hours. If the GI tract is capable of digestion, use a slurry of pellets mixed with a high-calorie supplement. If the tube diameter is too small for this mixture, use avian hand-feeding formula or a mixture of vegetable and cereal baby foods in place of the pellets. If the ability of the GI tract to tolerate enteral feeding is questionable, first try isotonic electrolyte or dextrose solutions. Parenteral nutrition is used successfully in research animals and may be feasible in select pet cases.

Subcutaneous Injections

Administer SC injectable medications or fluids over the shoulder blades or in folds of skin on the flank.

- Avoid irritating substances in rats and mice because their mammary tissue extends into these areas. The resulting inflammatory response is thought to increase the occurrence of mammary neoplasia.

▼ ***Key Point*** In general, avoid streptomycin and the carrier procaine in all pet rodents because of a high incidence of toxicity and hypersensitivity reaction.

Intramuscular Injections

Give IM injections in the semimembranous and semitendinous muscles. Inject only small volumes of nonirritating substances, or tissue damage with resulting self-mutilation may occur. Use the epaxial or triceps muscles if repeated injections are necessary.

Intraperitoneal Injections

▼ ***Key Point*** Use intraperitoneal (IP) injections only as a last resort for large volumes of fluids or for irritating injections that cannot be administered via an IV or IO route.

Express the bladder and aseptically prepare the abdomen.

Restrain the rodent with its head down to move the abdominal organs cranially. Give the injection 0.5 to 2 cm lateral to the midline in the caudal abdomen. Aspirate before injecting to ensure that the injection is not being given into the bladder or bowel. Never use this technique in pregnant animals.

Intravenous Injections

Give IV injections into any of the veins as previously described. In addition, the penile vein may be used in hamsters and guinea pigs. Placement of IV catheters is possible in animals heavier than 100 g.

For small rodents, give a bolus of fluids every 2–4 hours, followed by a diluted heparin flush. A pediatric IV pump is used for continuous infusion of fluids to

larger animals. Maintenance of catheters in active animals is extremely difficult.

Intraosseous Injections

For IO injections, place a spinal needle into the proximal tibia or femur following the technique used for placing an intramedullary pin. Once the needle is seated, remove the stylet. Aspirate and check the hub of the needle for bone marrow. The tip of the needle should be in the bone marrow cavity that directly drains into the central venous system in normal bones (i.e., the cortex must be intact). Administer drugs, blood, or fluids at a rate similar to that used for IV catheters.

ANESTHESIA

Premedication and Patient Preparation

- In chinchillas and guinea pigs, withhold food for 6 hours before anesthesia. Withhold food from smaller, mature rodents for 2 hours. Withhold food from immature animals for up to ½ hour depending on age and condition.
- Use heat lamps and heating pads to prevent hypothermia. Have a prewarmed incubator available for recovery. Preoperative or intra-operative warmed SC or IV fluids are strongly recommended. Place IV or IO catheters whenever possible.
- Administer atropine preoperatively to reduce airway secretions. Acepromazine, diazepam, or midazolam work well as premedications for other anesthetics. Avoid acepromazine in gerbils because it potentiates seizures. See Table 177-7 for anesthetic drugs and dosages.

Monitoring

Surgical anesthesia is reached when toe, tail, and ear pinch fail to generate a withdrawal reaction.

Depth of anesthesia is best monitored by pulse and respiratory rate and character. Pulses drop to within normal ranges after induction. Further reduction, especially to less than 80% of the original stabilized value, is an indication to lighten the plane of anesthesia. Monitor the electrocardiogram (ECG) of small patients by clamping the alligator clips onto the hubs of all-metal 27-gauge needles or steel sutures placed through the skin at the usual sites. Tape cables to the table to maintain placement. Doppler units taped over the chest also provide accurate heart rates. Pulse oximeters are easier to use, more sensitive, and more expensive than the instruments mentioned previously. These instruments are easily taped to the patient's ear, foot, or tail and provide heart rates as well as information regarding oxygenation.

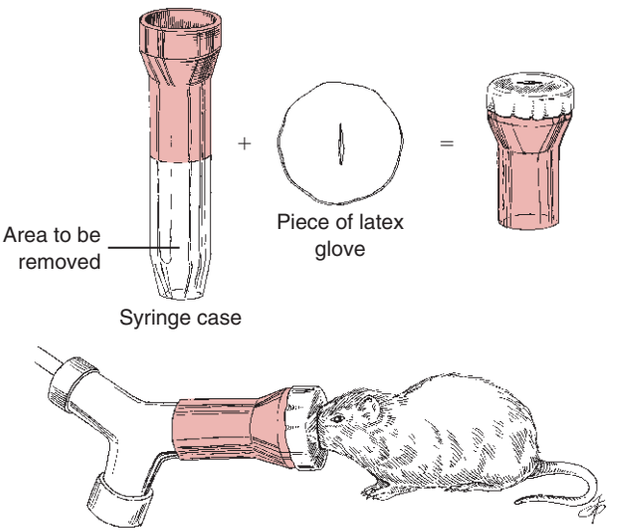

Figure 177-7. A nose cone for anesthesia delivery can be made from a cut-down plastic syringe case and material from a latex glove. Syringe cases from 12 to 60 cc can be used, depending on the size of the patient.

Respirations are often shallow and rapid during induction. They become deep and regular as a surgical plane of anesthesia is reached.

The corneal reflex varies markedly between individuals and anesthetic agents. If the animal has a corneal reflex after induction and then loses it, reduce the anesthetic.

Inhalation Anesthesia

Induction

Induce gas anesthesia using small face masks purchased from laboratory supply houses or make them from syringe cases and latex gloves (Fig. 177-7). Induction in an anesthetic chamber is also possible.

All rodents induced and maintained on gas anesthesia require some form of non-rebreathing system. Usual induction is achieved between 2% and 3% for isoflurane and 2% and 4% for halothane. Maintenance for isoflurane and halothane varies from 0.25% to 2%. There is marked individual variation in the amount of anesthetic required for induction and maintenance. Use of 50% nitrous oxide in oxygen reduces anesthetic concentration requirements for other gases.

▼ ***Key Point*** Some chinchillas and guinea pigs hold their breath while being induced with gas anesthetics and then take deep rapid breaths. If the concentration of anesthetic gases is high enough, this behavior results in death.

The risk of this behavior is reduced by premedication with tranquilizers, initial induction with nitrous oxide with later addition of primary anesthetic gas after

*Wide dosage ranges are due to marked individual variation. Use lower dosages first.
†Dilute concentration to 10 mg/ml before injection.

relaxation, and low induction settings. Changes in respirations, especially erratic or apneustic patterns and decreased respiratory rates, indicate deepening anesthesia.

Endotracheal Intubation

Most pet rodents are not intubated for anesthesia because of their small size. When necessary, as in prolonged oral and other procedures, endotracheal intubation is accomplished with the animal in dorsal or ventral recumbency, depending on the clinician's preference. Small non-cuffed or Cole endotracheal tubes work well. A stylet usually is required to provide enough stiffness for the tube to pass the larynx. Extend the animal's head and neck. Grasp the tongue with forceps and use gentle traction. The tip of the tube then is advanced above the tongue and just past its base. The hard palate is used to deflect the tip of the tube ventrally into the glottis. This is a blind procedure that is difficult to master. Use of a laryngoscope is helpful in larger rodents.

Another technique is to place an over-the-needle catheter in the trachea and move it up retrograde through the larynx to act as a guide. The catheter is removed after the endotracheal tube is in place.

▼ ***Key Point*** If endotracheal intubation is performed, it is extremely important that the tube be checked for patency. Rodents produce copious respiratory secretions, which frequently clog endotracheal tubes.

The small diameter allows these tubes to collapse or kink, resulting in asphyxiation of the patient. Check patency at least every 2 minutes by applying positive pressure ventilation at 10 to 15 cm water and watching for excursion of the chest wall. If extending the head and neck does not result in air flow, suction the tube. If this is either not successful or impossible, remove the tube and continue anesthesia with a mask or reintubate the animal with a new tube. Because of the small diameter of the trachea, endotracheal tube-induced tracheitis and subsequent swelling of the trachea may become a life-threatening situation.

Injectable Anesthesia

Doses and routes for injectable anesthetics are listed in Table 177-7. Needed doses for injectable anesthetics are tremendously variable among species and individuals. Most injectable anesthetics provide safe sedation for minor procedures, but very few induce a safe surgical plane of anesthesia on a consistent basis.

- Ketamine in combination with diazepam is easily obtainable, is given intramuscularly, and has a wide margin of safety, but it does not provide good analgesia.
- Intraperitoneal injections of barbiturates provide surgical anesthesia but have a low margin of safety and a significant mortality rate. Barbiturate anesthesia can result in fatal ileus.

EUTHANASIA

Euthanasia is performed easily by induction of inhalant anesthetic through a mask or chamber followed by an overdose of barbiturates given intraperitoneally, IV, or intracranially. Euthanasia by IP injection of barbiturates alone causes pain in some animals.

SURGERY

Hemostasis

- Surgical techniques for pet rodents are similar to those used in cats and birds.
- Hemostasis is critical because of small blood volumes.
- Electrosurgery for incisions and cautery is highly recommended.
- If necessary, give fresh blood transfusions drawn from a donor of the same species and mixed with sodium heparin (1000 IU/ml) at a rate of 0.005 ml/1 ml of blood directly into an IV or IO line.
- The lack of a filter creates a potential for thrombosis.
- Transfusion reactions are possible.

Pain Management

Administer postoperative analgesics to all rodents undergoing surgical or dental procedures. Common analgesics include buprenorphine, butorphanol, ketoprofen, carprofen and meloxicam. See Table 177-7 for dosages.

Common Procedures

The most common surgeries are laceration repair and removal of dermal or SC masses.

- Most rodents will not gnaw on skin sutures.
- If this occurs, use steel sutures, subcuticular sutures, or tissue glue.
- If an animal still chews at its suture line, physical restraint, such as a tube or an Elizabethan collar, is required.

Castration

Castration is a common procedure in guinea pigs. This usually is performed when owners want to house more than one male together or do not wish to breed their female any longer.

Technique

1. Make a skin incision over each testicle or one incision on the midline just cranial to the prepuce.
2. Remove the testicles via a closed technique (i.e., do not open the vaginal tunics). All rodents possess open inguinal rings and can eviscerate if a closed technique is not used. Ligate the testicular vessels and vas deferens with absorbable suture
3. Close the skin incision with a subcuticular pattern using 4-0 synthetic absorbable suture.

Some surgeons partially suture the inguinal rings for extra security. This technique is also applicable to other rodent species.

Abdominal Surgery

Common abdominal surgeries include cystotomy for urolith removal in guinea pigs and rats, and cesarean section (C-section) in guinea pigs and chinchillas because of dystocia.

Use a technique similar to those described for dogs and cats. Preplaced stay sutures are recommended to define incision edges for closure. Use 4-0 polyglactin 910 or polydioxanone (PDS) on a taper needle and suture in a simple continuous pattern to close the body wall. Close the skin with a subcuticular suture (absorbable) or interrupted skin monofilament, nonabsorbable suture.

Fracture Fixation

Fracture fixation is accomplished best with intramedullary pinning or Kirschner apparatus. Rodents gnaw on bandages until they remove them. If they are unable to remove a splint, self-mutilation often results in self-amputation. If a cast or splint is necessary, physical restraint often is required. Healing usually takes 3 to 6 weeks.

Dental Procedures

Incisors can be trimmed with nail trimmers, but this technique often fractures the tooth, causing abscesses of the root. Instead, use a high-speed dental burr or a flat cutting disk on a Dremel hand tool. Trim molars with a high-speed drill or pediatric rongeurs. A mouth speculum that deflects the tongue and other soft tissues is essential to prevent lacerations and provide working space (Fig. 177-8). Intubate the trachea to prevent aspiration pneumonia when working on molars.

If a tooth is abscessed, extract both it and the occlusal tooth.

- If necessary, approach cheek teeth via an incision through the cheek.
- Use a fine dental elevator to loosen the teeth.
- Patience and firm but gentle pressure are needed, or the root or surrounding bone may fracture.

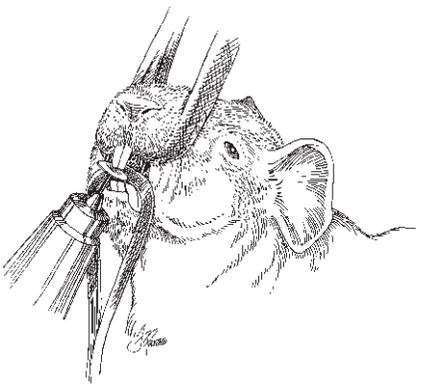

Figure 177-8. Proper technique for dental trimming.

- The roots of the maxillary incisors curve dramatically back into the head. Take care to follow the curve of the tooth.
- Packing an infected tooth socket with a calcium hydroxide paste may decrease the occurrence of persistent infection. Remove the paste in 3 to 4 days.
- Administer meloxicam, carprofen or ketoprofen postoperatively to control pain. See Table 177-7 for dosages.

In chinchillas with dental malocclusion, the roots of the molars can become impacted, causing swelling of the mandible or exophthalmos and epiphora. These teeth are extremely difficult to extract without causing extensive bony and soft-tissue damage. Discourage breeding of animals with malocclusion, unless it was acquired as a result of trauma or infection, because this trait is hereditary.

MOUSE

Most pet and laboratory mice are derived from *Mus musculus*, which is the common house mouse. Mice sold in the pet trade are randomly bred and less likely to suffer from the genetic problems associated with inbred laboratory rodents. Mice possess brown fat tissues between their scapulae that also are known as hibernating glands; these are thought to provide an energy store. The spleen in male mice is 50% larger than that of females.

Dermatology

Ectoparasites

Ectoparasites usually are found in new acquisitions.

- Alopecia and pruritus, especially on the back of the head and dorsal midline, usually are associated with lice (Polyplax serrata), mites, or fleas.

Table 177-8. PARASITICIDE DOSAGES FOR PET RODENTS

Agent	Rat	Mouse	Guinea Pig	Chinchilla	Hamster	Gerbil
Fenbenda zole	20 mg/kg q24h for 5 days	see rat	see rat	see rat	see rat	see rat

PO, by mouth (per os); SC, subcutaneous.

- Mite infestation (e.g., *Mycoptes musculinus, Myobia musculini, Radfordia affinis*) often causes a greasy haircoat and folliculitis.

Transmission of lice and mites occurs via direct contact. Fleas are transmitted by other household pets, such as cats and dogs.

- *Diagnosis* is based on clinical signs, history, visualization of parasite, skin scrape, and cellophane tape test.
- *Treatment* of fleas and lice is with Pyrethrin powder. Ivermectin is recommended for treatment of mites (see Table 177-8).
  - Change the bedding and thoroughly clean the cage between treatments to prevent reinfestation. Occasionally, the surrounding environment needs to be treated with a premises spray used for killing fleas.

Dermatophytosis

- Alopecia also may be the result of dermatophytes (see Chapter 42). Lesions are often hyperkeratotic.
- *Diagnosis* is made by skin scrape or isolation on culture. Most dermatophytes found in pet rodents do not fluoresce under a Wood's lamp.
- *Treatment* is with lime-sulfur dip or griseofulvin (Table 177-9).

Bacterial Disease

- Ulcerative dermatitis is a common syndrome caused by *Staphylococcus aureus* characterized by pododermatitis, mastitis, and abscesses in other areas.
- Administer antibiotics based on culture and sensitivity tests. Chloramphenicol is recommended pending culture results (see Table 177-9). The application of hot packs, local drainage, and topical medications are also beneficial in selected cases.
- Mastitis also may be caused by *Escheria* coli or *Pasteurella,* Klebsiella, Pseudomonas, or *Streptococcus* species. Mastitis usually is caused by poor sanitation, abrasive bedding, or overly aggressive young.
- Preputial gland abscesses are fairly common in males and are usually caused by *E. coli* or *S. aureus.*

Local flushing and topical treatment are usually adequate.
- SC abscesses can be the result of the aforementioned bacteria or *Actinobacillus* spp. or *Corynebacterium kutscheri*. *Corynebacteria* is associated with widespread abscesses, septic arthritis, gangrene, and ulcerated draining tracts. Diagnosis is based on finding gram-positive pleomorphic rods on Gram stain and isolation on culture.
- The bacteria are usually sensitive to ampicillin, chloramphenicol, and tetracycline (see Table 177-9).

Neoplasia

- Lymphoma and mammary neoplasia are common causes of SC masses. Mammary neoplasia is usually malignant in mice, and metastasis to the lungs is common. (Mice have five pairs of mammary glands—three thoracic and two abdominal.)
- Obtain thoracic radiographs before surgery.
- Give a guarded prognosis for long-term survival.
- Other possibilities for SC masses are fungal granulomas, nodules from the *Psorergates* simplex mite, hematoma, hernia, non-neoplastic lymphadenopathy, or emphysema.

Otitis

- Otitis externa usually is caused by ear mites, although bacteria or fungi also may cause primary or secondary otitis.
  - Clinical signs include erythema, pruritus, waxy debris, and excoriations behind the ears.
  - Mites may be diagnosed by identification on otoscopic examination or microscopic examination of ear swabs (see "Techniques").
  - *Treatment* requires cleaning debris from ears with a commercial ear cleanser followed by administration of three doses of ivermectin at 2-week intervals or topical acaricides used daily for 3 to 4 weeks (see Table 177-9).
- Bacterial and fungal otitis is diagnosed by identification of organisms or Gram-stained specimens and isolation on culture.
  - *Treatment* is similar to that used in cats.
- Otitis media/interna usually are caused by hematogenous spread or local invasion of bacteria from a primary abscess.
  - Clinical signs include head tilt, circling, facial nerve paralysis, and otitis externa.
  - Rule out mouse hepatitis virus as the cause of the head tilt (see "Gastroenterology").
  - If treatment of the primary disease is successful, the otitis media usually resolves, although a residual head tilt may persist.
  - If a cluster of *Pseudomonas* infections occurs in a population, evaluate the water source and produce for contamination. Use sodium hypochlorite in the drinking water at 10 ppm to control an outbreak while water quality is being restored.
- Damage to the pinnae can be associated with trauma, dermatitis, pox virus, hypersensitivity reactions, and vasculitis. Dry gangrene is a common sequela and is usually self-limiting.

Miscellaneous

I have observed a steroid-responsive pruritus in pet mice. The pruritus is severe enough to result in significant self-mutilation. This condition has been nonresponsive to treatment with ivermectin, lime-sulfur dips, griseofulvin, multiple antibiotics, oral prednisolone, and antihistamines. Attempts at bacterial and fungal culture have failed to identify a pathogen. An inflammatory response is observed on histologic examination. Mice with this condition respond to repository methylprednisolone injections every 2 to 4 weeks (1.0 mg/kg IM). Most owners have not elected to continue injections for longer than a few months. Once the injections are stopped, the pruritus returns, often requiring euthanasia of the affected mouse.

- Bilateral alopecia found around the muzzle associated with no other abnormalities usually is caused by friction from overhead feeders.
- Alopecia occurring in smaller, weaker individuals is often the result of barbering. Removal of the mice in best condition from the cage results in normal appearance of barbered mice in 2 to 3 weeks.
- Tailhead alopecia and scabbing are usually the result of aggression. Separate affected animals, or additional trauma may occur.
- Other rare causes of alopecia are endocrinopathies, leprosy, and hereditary alopecia in nude mice.

Ophthalmology

Epiphora

- Epiphora is a common condition of pet mice. The most common causes in pets owned for longer than 2 months are ammonia fumes and overgrown incisors.
- Ammonia causing contact irritation is diagnosed by examining an uncleaned cage and checking for odor.
  - *Treatment* is improved sanitation.
- Overgrown incisors are diagnosed easily by oral examination. Treat by trimming the affected teeth and providing opportunities for gnawing.
- Foreign bodies and the resultant corneal ulcers can cause epiphora. An eye examination, including fluorescein stain, is indicated. Treat by removing the foreign body and administering an ophthalmic antibiotic (gentamicin, tetracycline, or chloramphenicol in affected eye, q8h–q6h).
- In newly acquired pets, epiphora is often the first clinical sign of an upper respiratory infection. *Pasteurella*

Table 177-9. ANTIBIOTIC, ANTIFUNGAL, AND ANTIPROTOZOAL DOSAGES FOR PET RODENTS

Agent	Rat	Mouse	Guinea Pig	Chinchilla	Hamster	Gerbil
Amikacin	2–5 mg/kg q8–12h, SC, IM, IV, IO	2–5 mg/kg q8–12h, SC, IM, IV, IO	2–5 mg/kg q8–12h, SC, IM, IV, IO	2–5 mg/kg q8–12h, SC, IM, IV, IO	2–5 mg/kg q8–12h, SC, IM, IV, IO	2–5 mg/kg q8–12h, SC, IM, IV, IO

BID, twice a day; IM, intramuscular; IO, intraosseus; IV, intravenous; PO, by mouth (per os); SC, subcutaneous; SID, once a day; TID, three times a day.

pneumotropica is the most common pathogen, although *Salmonella* spp., mycoplasma, Sendai virus, lymphocytic choriomeningitis, and mouse pox also may cause epiphoria. The ocular discharge later appears mucopurulent (see "Respiratory").

Retinal Degeneration

Retinal degeneration can be either hereditary or (in albino mice) may be caused by exposure to high-intensity lighting. The resulting blindness often goes undetected because patients adapt well and behave normally in their cages.

Miscellaneous

- Cataracts are usually hereditary or post-inflammatory.
- Other hereditary conditions are posterior lens capsule rupture, eyelid malformation, optic nerve hypoplasia, microphthalmos, and retinal dysplasia.

Respiratory

Pneumonia

- *Murine respiratory mycoplasmosis* (MRM) is one of the most common respiratory diseases in pet mice. It is caused by *Mycoplasma pulmonis*. The infection remains dormant for long periods of time and is activated by stress. There are many asymptomatic carriers, and transmission is by aerosol and direct contact. Spread of infection can be hematogenous, causing abscess of the middle ear, uterus, or joints.
- *Clinical signs* include dyspnea (often described as chattering), mucopurulent oculonasal discharge, hunched posture, and anorexia. Animals with a chronic history of this disease are often cachexic.
- Radiology aids in determination of the extent and severity of the pneumonia and the absence or presence of distant foci of infection.
- *Treatment* with tylosin is successful in controlling the disease if it is not too advanced. Tetracycline, enrofloxacin, and chloramphenicol also have been used (see Table 177-8).
- Many patients need nutritional support.
- Mice with pyometra or other abscesses require surgical debridement.
- Recovered animals are carriers and stress elicits clinical signs. Strictly quarantine these animals.

Sendai Virus

A common cause of pneumonia in newly acquired mice is Sendai virus. Acute fatalities are seen in suckling or weanling mice.

- Transmission is by aerosol or direct contact.
- *Clinical signs* in adults are caused by secondary bacterial infections and are similar to those in MRM.
- *Diagnosis* is based on clinical signs and serologic testing.
- *Treat* with antibiotics to control the secondary bacterial infection and provide supportive care as needed.
- Prohibit breeding for 4 to 6 weeks.
- A killed vaccine is available.
- Recovered animals are resistant to new infection.

Bacterial Pneumonia

Common primary or secondary pathogens causing respiratory signs in mice are Streptococcus pneumoniae, Corynebacterium kutscheri, Pasteurella pneumontropica, Pseudomonas aeruginosa, and Klebsiella pneumoniae. Treatment is empiric or based on culture and sensitivity of a tracheal swab sample.

Neoplasia

Dyspnea often is caused by metastasis to the lungs from mammary adenocarcinomas. Primary lung tumors, especially pulmonary adenomas, also occur frequently.

Other

Although not frequently diagnosed, cardiac disease can result in signs of respiratory disease. Diagnosis is based on radiographic evidence of cardiomegaly and pulmonary edema.

Gastroenterology

Parasites

- Tapeworms usually do not cause clinical signs. Occasionally, heavy burdens may cause diarrhea or weight loss. The chief concern is the zoonotic potential of one species, *Hymenolepis nana,* which is directly transmissible to humans.
  - *Diagnosis* is made from visualization of eggs in the feces. Treat with praziquantel or niclosamide (see Table 177-8). Improve sanitation, and remove indirect hosts (e.g., fleas, beetles, roaches).
- Pinworms *(Syphacia obvelata, Aspiculuris tetraptera)* may cause anal pruritus and, in severe cases, rectal prolapse.
  - *Diagnosis* is based on clinical signs and observation of eggs on cellophane tape after application to the perineal region. Treat with piperazine or mebendazole every 7 to 10 days for three treatments or with fenbendazole once daily for 5 days (see Table 177-8) and provide improved sanitation.
- The protozoal parasite *Spironucleus muris* causes diarrhea and slow growth associated with a pot-bellied appearance in young mice.
  - *Diagnosis* is by fecal wet mount, although false-negative findings are common.
  - *Treat* with oxytetracycline (see Table 177-9). Supportive care to combat dehydration and hypothermia is extremely important.
  - Control is achieved with improved sanitation.
- *Giardia* spp. and, rarely, *Eimeria falciformis* show signs similar to *Spironucleus*. Giardiasis is zoonotic. Treat

with metronidazole. Treat *Eimeria* with sulfadiazine/trimethoprim (see Table 177-9). Most other protozoa are considered nonpathogenic.

- *Cysticercus fasciolarus* causes nonpathologic cysts of the liver. These cysts are the infective form of *Taenia taeniaformis* in carnivores.

Diarrhea

Viral Diseases

- Diarrhea in mice 10–20 days old usually is caused by lethal intestinal virus of infant mice (LIVM).
  - This virus may be a variant of mouse hepatitis virus. The mortality rate can reach 80%.
  - *Clinical signs* are yellow diarrhea that mats on the perineal region, causing obstipation and perineal necrosis, anorexia, and stunted growth.
  - Transmission is aerosol or feco-oral from the mother.
  - *Treat* supportively, and quarantine survivors.
- Epizootic diarrhea of infant mice (EDIM) is clinically similar to LIVM. This disease usually affects mice younger than 2 weeks of age but can occur in mice up to 21 days of age.
  - There is low mortality, and nursing continues through the infection.
  - Transmission is feco-oral.
  - *Diagnosis* is based on clinical presentation.
  - *Treat* supportively. Survivors usually are growth-stunted. Quarantine them from other mice.
- Mouse hepatitis virus is a corona virus. Most infections are latent. Outbreaks of yellow diarrhea and encephalitis secondary to viral hepatitis occur in mice 7 to 13 days of age. Older animals show clinical signs of infertility, jaundice, and hemoglobinuria as a result of a slowly progressive hepatitis.
  - *Diagnosis* is based on clinical presentation, serology, and presence of syncytial giant cells in the epithelium of the small intestine.
  - *Treat* supportively, and quarantine affected individuals. The prognosis is grave.
- Although less commonly seen in pet mice, reovirus occurs in older suckling mice. It is characterized by an oily diarrhea, which results in a greasy haircoat. Other signs are conjunctivitis, stunted growth, and tremors. Transmission is by ingestion.
  - *Diagnosis* is based on clinical signs, histology, and serology.
  - *Treat* supportively. The long-term prognosis is grave. Initial survivors are weak and jaundiced, suffer from alopecia, and eventually die.

Bacterial Diseases

- Transmissible murine colonic hyperplasia (MCH) caused by *Citrobacter freundii* is characterized by diarrhea followed by rectal prolapse and stunted growth. Transmission is feco-oral.
  - *Diagnosis* is made by clinical signs and fecal culture.
  - *Treat* with neomycin, tetracycline, or sulfamethazine until sensitivity results are available (see Table 177-9). Severe thickening of the distal half of the colon is observed at necropsy.
- Salmonellosis, also known as mouse typhoid, is transmitted by latent carriers or contaminated feed or bedding. Incubation lasts for 3 to 6 days.
  - *Clinical signs* are lethargy, anorexia, purulent conjunctivitis, arthritis, and diarrhea.
  - *Diagnosis* is based on clinical signs and fecal culture. Treat supportively. Use of antibiotics is controversial.
  - Quarantine survivors.
  - Sanitation is extremely important because *Salmonella* spp. are zoonotic. On gross postmortem examination, erythema of distal ileum and congestion of the spleen and liver are seen. With more chronic infections, necrotic foci are seen in the liver, spleen, and lymph nodes. Prevent infection by feeding a fresh laboratory chow from a reputable source. Thoroughly wash all produce and then dip it in a diluted bleach solution. Rinse completely before feeding.
- Tyzzer disease is caused by *Bacillus piliformis*. Transmission is feco-oral.
  - *Clinical signs* are precipitated by stress and consist of anorexia, diarrhea, and high mortality in weanlings.
  - *Diagnosis* is made by clinical signs or isolation on culture. Enteritis and multiple gray-yellow necrotic foci in the liver are seen on gross postmortem examination.
  - Administer tetracycline for 4 to 5 days (see Table 177-9) and reduce stress to control the disease.

Theriogenology

Breeding systems vary; from one to six females may be placed with one male. All animals are housed together, and the young are removed after weaning. Females in proestrus have swollen vulvas. Vaginal plugs are present post-copulation.

Female mice that have been bred within 4 days abort if a new male is placed in the cage. Inappropriate light cycle, inappropriate age, crowding, and poor nutrition are the most common causes of infertility in pet mice. Pyometra due to *Pasteurella pneumontropica, Mycoplasma* spp., or other bacteria is also common.

Desertion of litters is usually a result of stress, lack of nesting materials, agalactia, or mastitis.

Urology

- Urethral obstruction from proteinaceous plugs of inspissated ejaculum may develop in aged male mice. *Pseudomonas, E. coli,* or *Proteus* are the most frequently cultured pathogens. Before complete obstruction, chronic hematuria may be noticed by the owner.

- Antibiotics, which are chosen based on the results of urine culture, are often curative with early presentation. Complete obstruction requires surgical removal.
- Glomerulonephritis is very common in geriatric mice. It frequently is secondary to chronic viral infection. Clinical signs are anorexia, lethargy, dehydration, and cachexia. Urinalysis demonstrates proteinuria. As the disease progresses, the urine becomes isosthenuric, the blood urea nitrogen (BUN) and creatinine levels rise, and other electrolyte abnormalities typical of chronic renal failure occur. Treat supportively. Prognosis for long-term survival is grave.
- Coccidia (e.g., *Klosseilla muris*) occasionally is found in the urine. The clinical significance of its presence is unknown.
- Mice can be asymptomatic carriers of leptospirosis; however, this is rarely seen in pet mice.
  - *Diagnosis* is based on darkfield microscopy of urine, serology, or histopathology. Euthanasia of carriers is recommended.

Musculoskeletal

- Infectious polyarthritis or mouse rheumatism is caused by *Streptobacillus moniliformis*. In humans, it is known as rat bite or Havernill fever. Transmission is by direct contact. Clinical signs are cachexia, keratitis, edema and ulceration of the appendages, and ankylosing arthritis.
  - *Diagnosis* is based on the bacterial culture findings or the presence of caseous pericarditis and arthritis on necropsy.
  - *Treat* with antibiotics chosen through the results of culture and sensitivity tests. Use penicillin while awaiting results. Supportive care is important. Animals that recover remain arthritic. Control is achieved through quarantine and sanitation.

Neurology

- The most frequently diagnosed neurologic disease in pet mice is head tilt resulting from bacterial otitis media (see "Otitis"). The second most common cause of neurologic signs is trauma.
  - *Diagnosis* is based on history and clinical signs. Consider neoplasia in aged mice with slowly progressive signs.
- Lymphocytic choriomeningitis is a zoonotic arenavirus. Transmission is airborne, transplacental, or by direct contact, fomites, or insect vectors. Acute signs usually occur in mice that are 3 to 6 weeks old. Approximately 20% of infected individuals show acute clinical signs, which include lethargy and photophobia followed by convulsions and paralysis. In animals that are latently infected, glomerulonephritis develops later. Mice infected after weaning and before 1 year in age lose weight, appear arthritic, and show signs of conjunctivitis and photophobia. The virus runs its course in several weeks. Animals that recover show no residual signs.
  - *Diagnosis* is based on clinical signs and the presence of immunofluorescent antibody (IFA). Pleural effusion, splenomegaly, and hepatic lipidosis are found on necropsy. Treat supportively. House survivors separately.
  - Prevent the disease by improving sanitation, providing pest control, and cleaning produce. Consider euthanasia because of the zoonotic potential of the virus.
- Mouse poliomyelitis/encephalomyelitis, also known as Theiler disease, causes clinical signs in 1 in 10,000 infected mice. Two-thirds of healthy mice are carriers. Transmission is by oral or respiratory routes. Mice younger than 4 weeks of age show signs of encephalitis. Animals that are 6 to 10 weeks old are weak in the rear legs and progress to paralysis. The tail may remain mobile. Affected mice continue to eat and be alert. Albino mice are predisposed to show clinical signs.
  - *Diagnosis* is based on clinical signs, serology, or histopathology that shows necrosis of the ganglionic cells of the anterior horn of the spinal cord.
  - *Treat* supportively. Consider euthanasia because of poor prognosis.
- Seizures in mice commonly result from otitis media, trauma, liver or kidney failure, toxin, bacterial meningitis, neoplasia, or viral encephalitis.

Hematology

- Leukemia in mice is usually viral in origin. Transmission is trans-mammary or trans-placental.
  - *Clinical signs* are anemia, dyspnea (with thymic involvement), and those signs that are compatible with chronic disease.
  - *Diagnosis* is based on complete blood count (CBC), bone marrow aspirate, or histopathology. Prognosis is grave.
- *Eperythrozoon coccoides* is a rickettsial red blood cell (RBC) parasite of mice. Affected mice are usually asymptomatic. Occasionally, fever, anemia, and splenomegaly develop in infected animals. Transmission is through the louse *Polyplax serrata*. Control is by extermination of the louse.
  - *Treat* with tetracyclines.

RAT

Pet rats are derived from the Norwegian or brown rat *(Rattus norvegicus),* which did not originate from Norway, but from Asia. Breeds of rats are called strains when they are inbred extensively and stocks when strains are hybridized. Rats have brown fat, as discussed in the section on mice. They do not possess a gallbladder. Their mandibular symphysis is articulated normally.

Rats are neophobic; therefore, make gradual changes in food or environment when possible.

Dermatology

- Fleas, mites (e.g., *Radfordia ensifera, Ornithonyssus bacoti*), lice (i.e., *Polyplax spinulosa*), ear mites (i.e., *Notoedres muris*), and dermatophytes cause similar signs in both mice and rats. Treatment also is similar (see "Mouse").
- SC masses in rats are similar to mice. *Pasteurella pneumotropica* is a very common pathogen in mastitis and SC abscesses.
  - *Treat* with chloramphenicol until culture results are available (see Table 177-9).
- Mammary cancer develops in 50% to 90% of adult female rats and in approximately 15% of male rats. Always submit biopsy specimens for histologic examination. Most, but not all, of these tumors are fibroadenomas, which are benign. Prognosis for long-term survival after surgical removal is good. Other common neoplasms include interstitial cell tumors of the testes, which cause SC swellings in the inguinal region, and squamous cell carcinomas of the Zymbals gland of the external ear canal.
- Ulcerative dermatitis occurs in rats as well as mice. *Staphylococcus aureus* is the causative agent. *C. kutscheri* follows a similar course in rats and mice (see "Mouse").
- Ringtail is the formation of constrictive bands of fibrous tissue around the tail in nestling rats. These bands result in gangrene of the distal tail. This disease occurs when environmental humidity is less than 40%.
  - *Treat* by making a longitudinal incision of the ring to release the stricture and apply topical dimethyl sulfoxide (DMSO), steroid, and antibiotic solution (10 ml DMSO, 6 ml 50 mg/ml amikacin, 4 ml 2 mg/ml dexamethasone) four times daily.
  - To prevent ringtail, keep humidity above 50%, use solid-bottom cages and provide ample nesting material. Prognosis for life is excellent. Prognosis for retention of the distal tail is guarded.

Ophthalmology

- Epiphora and blepharospasm are caused mostly by ammonia fumes, overgrown incisors, or foreign bodies (see "Mouse").
- Sialodacryoadenitis virus is a coronavirus that is endemic in many rat populations.
  - *Clinical signs* vary from mild keratoconjunctivitis to blepharospasm, chromodacryorrhea, severe uveitis, hyphema, buphthalmos, periorbital swelling, and pneumonia. The clinical course of the disease lasts 10 to 14 days. Rats maintain normal activity levels and appetite.
- *Treatment* is not necessary for mild infections. Place rats showing marked ocular disease or discomfort on the appropriate ophthalmic ointments (e.g., atropine, antibiotic, steroid) based on presentation. Administer parenteral antibiotics to animals that show signs of respiratory problems. Recovery is usually complete unless the eye ruptures or self-mutilation occurs.
  - Control is achieved by not introducing new animals for 4 weeks.
- In contrast to mice, Sendai virus rarely causes clinical signs in rats.
- Mucopurulent ocular discharge also may be caused by infection with mycoplasmosis, *Streptococcus pneumoniae, Pseudomonas* spp., and other less common bacterial or viral agents that cause pneumonia.
- Cataracts are primary hereditary defects or occur secondary to severe uveitis or diabetes mellitus. Retinal dystrophy and colobomas are also inheritable traits in rats. Retinal degeneration occurs in rats housed under intense lighting.

Respiratory

- MRM is extremely common in pet rats. Its presentation is similar to the disease in mice (see "Mouse").
- *Streptococcus pneumoniae* is normal flora for rats. However, during stressful situations, bacteremia may occur, resulting in pneumonia. Clinical signs are similar to MRM. Differentiation is based on culture and the presence of extensive fibrinopurulent pleural effusion on necropsy.
  - Ampicillin controls clinical signs if treated early in the course of disease (see Table 177-9). Prevent the condition by minimizing stress.
- *Corynebacterium kutscheri* and *Pasteurella pneumotropica* cause signs similar to MRM (see "Mouse"). There is a serologic test for *C. kutscheri*. See the Mouse section for a discussion of *Pseudomonas aeruginosa*.
- *Pneumocystosis carinii* is an uncommon protozoa that infects the lung. Cysts and trophozoites live in the alveoli. Clinical signs occur only in immunocompromised or geriatric individuals. Signs are cachexia, cyanosis, and dyspnea.
  - *Diagnosis* is based on clinical signs, tracheal wash, response to therapy, or histologic examination.
  - *Treat* with sulfadiazine/pyrinrethamine (see Table 177-9).

Cardiovascular System

- Myocardial degeneration and subsequent congestive heart failure are fairly common in geriatric rats. Diagnosis is based on radiographs of the thorax and clinical signs. Treat supportively, and use furosemide and digitalis at cat dosages to alleviate pulmonary edema.
- Polyarteritis nodosa is an idiopathic condition of geriatric rats that results in thickening and tortuosity of arteries, especially in the mesentery, pancreas, and testicles. Affected areas are predisposed to clot formation and aneurysms.

Gastroenterology

Parasites

- Nematode *(Syphacia muris),* cestode, and intestinal protozoal parasite infestations are similar to those in mice.
- *Capillaria hepatica* has no clinical significance. Yellow streaks on the liver are an incidental finding at necropsy.

Dental

The causes and treatment of malocclusion are similar to those for mice.

Diarrhea

- Epizootic diarrhea of suckling rats is a viral disorder found in rats 7 to 14 days old. The infection causes a mild diarrhea. Most animals recover. Occasionally, stunting occurs. Treat supportively.
- Salmonellosis in rats is similar to that in mice.

Theriogenology

- If breeding is desired, take females showing signs of estrus (e.g., lordosis, hyperactivity, quivering ears, and swollen vulva) to a male rat's cage for 24 hours, or keep one male in a cage with up to six females. Check females for a post-copulatory plug to confirm breeding. Remove females just before parturition, and house females individually while raising the young. A vaginal discharge is seen 1.5 to 4 hours before labor. Parturition is accompanied by stretching and extension of the rear legs. All neonates usually are delivered within 1 to 2 hours.
- Infertility is usually the result of age, malnutrition (e.g., protein, vitamin E), uterine infection, or improper light cycle, temperature, or humidity.
- Litter desertion is usually the result of stress. Inadequate nesting material or agalactia are other significant causes of abandonment and death.

▼ ***Key Point*** To prevent cannibalism, remove male rats from the cage before parturition and do not return them until after weaning is complete.

- Rat virus infection is a parvovirus that is usually inapparent unless individuals are infected in utero. Small litters or jaundiced, stunted neonates are often the only clinical signs. Transmission is both vertical and horizontal.
  - *Diagnosis* is by serologic testing and characteristic histologic findings. Permanently quarantine all in-contact animals.

Urology

- Urolithiasis commonly occurs in older rats. Uroliths usually are composed of ammonium magnesium phosphate or calcium carbonate.
  - *Clinical signs* include anorexia, stranguria, hematuria, and abdominal distention. Urinary obstruction can occur.
  - *Diagnosis* is based on clinical signs, urinalysis, and radiographs.
  - *Treat* by surgically removing uroliths and providing antibiotics based on culture and susceptibility testing.
- Two extremely common conditions in geriatric rats are nephrocalcinosis and chronic progressive nephropathy. Clinical signs are compatible with those of chronic renal failure. Enlarged or small irregular kidneys may be found on physical or radiographic examination. Isosthenuria and marked proteinuria are found in urinalysis.
  - Definitive *diagnosis* is based on renal biopsy.
  - *Treat* supportively. Prognosis for long-term survival is grave.
- *Trichasomoides crassicauda* is an uncommon parasite of the urogenital tract. The adult worms usually reside in the kidney, but they occasionally may wander into the genital tract. The ova are passed in the urine.
  - *Clinical signs* are hematuria and stranguria. Proliferative mucosa of the bladder occasionally may be palpated as an abdominal mass.
  - *Treatment* is somewhat successful with methyridene (see Table 177-8). Sanitation is critical in control of this disease.
- *Klossiella muris* is an incidental coccidia of the urinary tract.

Neurology

- Many geriatric pet rats have chronic progressive radiculoneuropathy.
  - *Clinical signs* are compatible with cauda equina syndrome, including posterior paresis progressing to paralysis, urine retention, and incontinence. Prognosis is grave.
  - *Treat* supportively or euthanize.
- *Streptobacillus moniliformis,* a normal bacteria found in the oral, nasal, and pharyngeal cavities of rodents, is isolated from 43% of middle ear infections and 35% of chronic pneumonias in rats. The bacteria is nonpathogenic for gerbils and guinea pigs.
  - *Clinical signs* vary with the site of infection. Head tilt and circling, septic arthritis, and respiratory disease commonly are seen.
  - *Diagnosis* is based on isolation on culture. The clinical signs mimic many other diseases, especially MRM and *Pseudomonas* infection (see "Mouse").
- Head tilt in rats also may be the result of trauma or neoplasia, especially pituitary adenomas.

Hematology

- *Hemobartonella muris* is an RBC parasite of rats that is nonpathogenic unless the rat is immunocompromised or splenectomized. Transmission is through the louse *Polyplax spinulosa.*

- *Clinical signs* result from hemolytic anemia and hemoglobinuria.
- *Treat* with tetracyclines (see Table 177-9).

HAMSTER

Mesocricetus auratus, better known as the golden or Syrian hamster, is a primarily nocturnal rodent that originated in the Middle East. Almost all hamsters in the United States are the offspring of three siblings imported in the 1930s. Many color variations are available. Long-haired hamsters are called "teddy bear" hamsters. The stomach has two compartments, a non-glandular forestomach, which functions like a rumen, and a glandular stomach. Hamsters are very territorial. They possess flank glands, which are larger in males, that are rubbed against objects to mark their territory. Females are larger than males. Except during estrus, they use this size advantage to attack males. Do not allow groups to estivate together or recently awakened animals may cannibalize sleeping hamsters.

▼ ***Key Point*** Hamsters are extremely sensitive to antibiotics.

Penicillins, clindamycin, lincomycin, streptomycin, tylosin, erythromycin, and cephalosporins eliminate the normal intestinal flora, allowing overgrowth of pathogenic bacteria, particularly *Clostridium difficile*. Diarrhea, which is almost always fatal within 3 to 7 days, subsequently occurs. Even antibiotics considered to be safe can have this effect. Treat by discontinuing antibiotics, providing a *Lactobacillus* supplement, and giving supportive therapy.

Dermatology

- Hamsters are susceptible to *Demodex criceti* and *D. aurati* mites. *D. criceti* is limited to skin folds. *D. aurati* causes hyperpigmentation, alopecia, and seborrhea sicca affecting the dorsal midline. *Demodex* is carried by many normal-appearing hamsters.
  - *Clinical signs* occur in immunosuppressed animals, as would occur with stress, chronic infection, pregnancy, or malnutrition.
  - *Diagnosis* is based on clinical signs and deep-skin scrapings.
  - *Treat* with amitraz every 2 weeks for two treatments past two consecutive negative skin scrapings. Use the manufacturer's recommended dilution for dogs.
- *Sarcoptes* mites infrequently cause facial alopecia. Diagnosis is based on skin scraping. Treat with ivermectin (see Table 177-8). Do not confuse this condition with alopecia caused by contact with feeders or barbering.
- *Notoedres* mites affect only the external ear canal in female hamsters but may affect the ears, feet, genitalia, and tail in males. Diagnosis is made by observation of mites on samples from ear swabs, skin scrapings, or both. Treat with ivermectin (see Table 177-8).
- Other less common causes of alopecia in hamsters are dermatophytosis, endocrinopathies, and genetic defects.
- Dermal SC masses are usually abscesses caused by *Pasteurella pneumotropica, S. aureus,* or *Streptococcus* spp. Treatment is based on results of culture and susceptibility testing. Use chloramphenicol until culture results are available. Other frequent causes of SC swellings are distended cheek pouches and testicles, mastitis, hernias, neoplasia, and lymphadenopathy.

Ophthalmology

- Epiphora and conjunctivitis are caused most frequently by increased environmental ammonia concentrations, incisor overgrowth, foreign body, or lymphocytic choriomeningitis (see "Rat"; "Mouse").
- Mucopurulent discharge is caused by secondary infection by *Pasteurella* or *Streptococcus* spp.
- Hamsters are predisposed to rupture of the eye following trauma or infection. Surgical enucleation is advised. Electrosurgery is extremely helpful in controlling bleeding but do not apply heat to the stump of the optic nerve or vessels, or thermal injury to the brain may result. Place gelfoam in the socket to enhance clot formation.

Respiratory

- Hamsters are susceptible to viral respiratory infections of humans.
  - *Clinical signs* include nasal discharge, sneezing, otitis media, fever, and pneumonia. Uncomplicated cases last 5 to 7 days. Complications are usually the result of secondary bacterial infections.
  - *Treat* supportively. Use of antibiotics is indicated if copious nasal discharge, dyspnea, anorexia, or marked lethargy is observed. Overuse of antibiotics may cause diarrhea-related death in hamsters that might have recovered uneventfully if left untreated.
- Most dyspnea in hamsters is caused by blunt thoracic trauma. Hamsters often bite when startled. Reflex actions on the part of humans, especially children, cause hamsters to be flung against hard objects.
  - *Diagnosis* is by history and presence of fresh epistaxis.
  - *Treat* supportively. Emergency shock therapy, consisting of supplemental heat, oxygen administration, parenteral fluids, and glucocorticoids, frequently is required.
- Sendai virus can cause death in suckling hamsters housed with mice. Adults show no clinical signs (see "Mouse").
- Primary bacterial pneumonia most frequently is caused by *Yersinia pseudotuberculosis, Pasteurella pneumotropica,* or *Streptococcus.* Clinical signs are compati-

ble with those of pneumonia seen in other species, as well as weight loss and conjunctivitis. All three agents have a tendency to form distant abscesses, especially in the uterus.
- *Diagnosis* is based on clinical signs and isolation on culture.
- *Treat* with chloramphenicol until antibiotic susceptibility results are available. Abscesses require surgical debridement; however, anesthesia in affected animals is very risky. Recovered hamsters are carriers and must be quarantined from other rodents. Prognosis is guarded.

Cardiology

- Cardiac thrombosis is seen in 73% of geriatric hamsters. Most thromboses occur in the left atrium and are secondary to degenerative cardiomyopathy, cardiac amyloidosis, sepsis, or calcification of the great vessels. Congenital myocardial necrosis also occurs.
- *Clinical signs* include cyanosis, dyspnea, and acute death. Enlargement of the cardiac silhouette and pulmonary edema sometimes can be seen on thoracic radiographs.
- Furosemide and digitalis (using standard cat doses) may temporarily alleviate clinical signs.

Gastroenterology

Parasites

- Hamsters can carry the zoonotic tapeworm *H. nana* (see "Mouse").
  - *Treat* with niclosamide or praziquantel (see Table 177-8) and provide improved sanitation.
- Pinworms (Aspicularis tetraptera, Syphacia muris, S. obvelata) occur in hamsters as well as in mice.
  - *Treat* with fenbendazole (see Table 177-8).

Dental/Oral

- Hamsters are predisposed to dental caries. A large percentage of affected teeth become abscessed, causing facial swelling, ptyalism, and anorexia.
  - *Diagnosis* is based on clinical signs, oral examination, skull radiographs, and isolation on culture.
  - Extract the tooth and administer antibiotic therapy based on results of susceptibility testing. Prognosis is variable depending on the condition of the animal, tooth affected, and extent of the abscess (see "Mouse").
- Overgrown incisors also occur, as in mice.
- The cheek pouches are very distensible. Impaction of the pouches occurs on occasion.
  - *Clinical signs* vary from ptyalism to swelling from abscess. In simple cases, removal of the material from the pouch with fine forceps is sufficient. Sedation usually is not required.
  - If a fungal or bacterial infection of the pouch is present, remove the exudate, submit samples for Gram staining and bacterial or fungal culture, and flush the pouch with diluted iodine solution. If cellulitis is present, administer systemic antibiotics as well. Fistulas often heal spontaneously.

Diarrhea

- Proliferative ileitis (i.e., wet-tail disease) is thought to be caused by a *Campylobacter*-like organism with or without concurrent bacterial or viral infections. More than 90% of animals with clinical signs die. The highest morbidity and mortality rates occur in hamsters 3 to 8 weeks of age. Teddy bear hamsters may be more susceptible to infection than shorter-haired varieties. Transmission is feco-oral.
- *Clinical signs* include diarrhea, which mats on the ventrum and perineum, and results in anorexia, dehydration, and a hunched posture. The abdomen frequently seems painful on palpation. Bowel loops often are distended on palpation because of ileal obstruction or intussusception. Rectal prolapse usually occurs.
- Administer neomycin, gentamicin, metronidazole, or tetracycline (see Table 177-9). Supportive care is critical. Prognosis is grave, even with treatment. Gross postmortem findings include gas and yellow diarrhea in the distal intestinal tract, mucosal thickening in the ileum and distal jejunum, peritonitis, and liver abscesses.
- Other common causes of bacterial diarrhea include *E. coli,* Tyzzer disease, or *Salmonella* spp. (see "Mouse").

Liver

In hamsters older than 1 year of age, liver cysts that are derived from the biliary duct often develop. Less frequently, similar cysts arise from the pancreas, epididymis, and seminal vesicles. This syndrome is called *polycystic disease.* No clinical signs are associated with cysts in these structures, which are an incidental finding on abdominal palpation. No treatment is recommended.

Theriogenology

- Timing is critical to prevent injury to the male when breeding hamsters. Transfer the female to the male's cage in the early evening 3 days after a creamy, viscous vaginal discharge is noticed. Monitor the pair carefully. Remove the male immediately if the female is aggressive. Remove the male after mating or after 1 to 2 hours even if mating has not occurred. Two days after successful copulation, a gray malodorous vaginal discharge is observed. Pregnancy is highly likely if there is no translucent vaginal discharge 5 to 9 days post-breeding. Pseudopregnancies last 8 to 12 days. Normal gestation is 15 to 16 days. Before par-

turition, a hemorrhagic vaginal discharge appears, and the female may pant. Hamsters rarely suffer from pregnancy toxemia (see "Guinea Pig").
- Infertility may be caused by pyometra (see *P. pneumotropica* and lymphocytic choriomeningitis).
- Cannibalism is most frequently a result of stress or mastitis.

Urology

- In almost 90% of geriatric hamsters, renal amyloidosis develops. The disease tends to develop more rapidly in females.
- *Clinical signs* include edema and ascites due to protein loss in the urine, as well as the typical signs of chronic renal failure.
- *Treat* supportively. Prognosis for long-term survival is grave.

Neurology

- Head tilt is usually secondary to otitis media. Also consider lymphocytic choriomeningitis or neoplasia as differential diagnosis (see "Rat").
- In hamsters fed all-seed diets and deprived of exercise, cage paralysis syndrome often develops. Usually pets are presented for acute posterior paresis which, in reality, was slowly progressive. The distinction is important in ruling out trauma. In mild cases, the hamster is able to move its hind limbs but unable to support weight. Vitamin D and E supplementation, along with nutritional improvement and providing exercise, is curative in 1 to 2 weeks. In severe cases, recovery is negligible or incomplete.

Hematology/Oncology

Lymphoma and lymphosarcoma may be viral in origin. Diagnosis is made by biopsy or fine-needle aspiration of affected lymph nodes. Rule out lymphadenopathy caused by lymphadenitis from infection with *Streptobacillus moniliformis* (see "Rat"). Although many hamsters initially respond well to chemotherapy protocols established for cats and dogs, prognosis for long-term survival is grave.

GERBIL

The Mongolian gerbil *(Meriones unguiculatus)* originates from the deserts of Mongolia and northern China. Gerbils alternate between periods of activity and rest throughout the day. Peak periods of activity are in the late evening. Seed storage and burrowing are important natural behaviors. Most gerbils are brown with cream-colored abdomens (i.e., agouti). Several color variations are available (black, black and white). Gerbils drum their hind legs when alarmed. In general, gerbils are non-aggressive. However, introduction of unfamiliar adults results in fighting.

Dermatology

- Rarely, *Demodex* spp. mites cause alopecia in gerbils.
  - *Diagnosis* is based on skin scraping.
  - *Treat* with rotenone ointment or amitraz dips every 2 weeks for three to six treatments. Use manufacturer's recommended dilution for dogs.
- Acute moist dermatitis usually is caused by *S. aureus* infection. Infection on the face often begins with the harderian glands. The gland secretion is viscous and causes matting, with secondary *staphylococcal* infection occurring under the mats. Attempts at grooming spread the infection to the feet and abdomen.
  - *Diagnosis* is based on clinical signs and isolation on culture.
  - Administer enrofloxacin, tetracycline, or chloramphenicol and apply warm, moist compresses to remove dried debris. Remove possible irritants from cage (e.g., pine or cedar shavings, ammonia). Occasionally, surgical removal of a chronically infected or inflamed gland is needed.
- Alopecia of the facial area, especially when it is symmetric, is usually the result of self-trauma from feeders, cage bars, or overzealous burrowing.
  - *Treat* by changing cage construction or providing better visual security.
- Gerbils that catch their tails in crevices or are restrained inappropriately by their tails often are presented for avulsion of the skin from their tails.
  - *Treat* initially by controlling hemorrhage and hypovolemic shock.
  - Amputate the tail after patient stabilization to prevent ascending infection. In some animals, the infection is localized to the distal tail, which is sloughed in approximately 3 to 4 weeks.
- Generalized alopecia is normal in some weanling gerbils. The hair grows in as the animals mature.
- Melanomas are found most frequently on the ears, feet, or base of the tail.
  - *Diagnosis* is based on biopsy.
  - *Treat* by surgical removal.
- Sebaceous gland disease is usually the result of bacterial infections or neoplasia.
  - *Diagnosis* is based on cytologic examination, culture, histologic examination, and response to antibiotic therapy.
  - *Treat* bacterial infections with parenteral or topical antibiotics based on the severity of signs.
- Sebaceous gland adenomas, basal cell tumors, and squamous cell carcinomas are the most frequently encountered neoplasms.
  - Take a radiograph of the thorax to diagnose metastases. Prognosis for long-term survival is based on tumor type, stage, and character.
  - *Treat* by surgical excision.

Ophthalmology

Chromodacryorrhea and epiphora occur as in mice.

Gastroenterology

Parasites

Tapeworms (i.e., H. nana and H. diminuta) and pinworms (i.e., Syphacia obvelata, Dentostomella translucida, and Aspicularis tetraptera) occur as in mice.

Dental

Incisor overgrowth occurs as in mice.

Diarrhea

- *Salmonella* spp. cause transient diarrheas in gerbils. The source of infection is usually unwashed greens, contaminated feed, or carrier rodents of another species. Most recover. Animals that die have a fibrinosuppurative peritonitis.
  - *Treat* supportively. Use antibiotics in severe cases based on results of culture and susceptibility testing.
- Tyzzer disease, caused by *Bacillus piliformis*, is seen most often in weanlings at 3 to 7 weeks of age and in post-partum females.
  - *Clinical signs* include anorexia, lethargy, rough haircoat, and sometimes diarrhea. Gross postmortem findings include yellow-gray nodules in the liver and hemorrhage at the ileocecal junction.
  - *Diagnosis* is based on postmortem examination or response to therapy.
  - *Treat* with oxytetracycline (see Table 177-9) and supportive care.

Liver

Hepatic lipidosis and gallstones are frequent sequela to lipemia in gerbils fed diets with excessive fat.

Theriogenology

- Breeding is most successful if animals are paired at weaning and kept in these pairs. Male gerbils aid in raising the young. Pairing older animals causes fighting. An average of 20% of neonates fail to survive to weaning. This is usually the result of agalactia and crushing.
- Chronic hemorrhagic discharge from the vulva is usually the result of cystic ovaries or ovarian tumors. Most tumors occur in animals older than 2 years of age and consist of granulosa cell tumors or theca cell tumors. Leiomyomas of the uterus also cause similar clinical signs.
- Rule out urinary tract disease by performing a urinalysis via cystocentesis. Large masses may be visualized on abdominal ultrasound. Definitive diagnosis is based on vaginal cytology followed by exploratory laparotomy.
- Ovariohysterectomy is curative for cystic ovaries and tumors if they have not metastasized.

Urology

- Chronic renal failure develops in most gerbils older than 2.5 years of age.
- *Clinical signs* are polyuria, polydipsia, weight loss, and anorexia. Urinalysis demonstrates proteinuria, hematuria, casts, and an increase in white and red blood cells.
- *Treat* supportively. Prognosis for long-term survival is grave.

Neurology

- Up to 50% of gerbils in certain family lines suffer spontaneous epileptiform seizures. The seizures are induced by stress and are self-limiting. Seizures usually start as the gerbil reaches 2 months of age.
- Treatment is unnecessary.

CHINCHILLA

Chinchilla laniger and *C. brevicaudata* are nocturnal rodents from the Andes mountains in South America. Most animals kept in the United States are the descendants of 11 animals. Aside from pets, chinchillas are raised commercially for their pelts. The most common coat color is gray; the most valuable coat color is black.

▼ ***Key Point*** Chinchillas are sensitive to antibiotics (see "Hamster"); therefore, avoid use of penicillins, lincomycin, erythromycin, and cephalosporins.

House chinchillas in a cool environment because they are prone to overheating. If heat stroke occurs, treat with tepid water baths and supportive therapy.

Dermatology

- Chinchillas require dust baths to keep their skin in condition. Use commercially available chinchilla dust only. Sand substitutions do not condition the coat and occasionally cause conjunctivitis. Offer dust at least once a week.
- Dermatophytosis occurs as in guinea pigs.
- Fur chewing is a serious problem in chinchillas that are farmed for pelts and often is seen in pet chinchillas that are recent culls from a ranch. The etiology of fur chewing is unknown. Some cases seem to be related to chronic disease, malnutrition, poor caging, or stress. Theories for undiagnosed cases include genetic abnormality; undiagnosed dermatophytosis; or adrenal, pituitary, or thyroid gland abnormalities.
- Diagnostics such as skin scraping, fungal culture, fecal, CBC, history profile, and biopsy are recommended. In general, if changes in diet and husbandry do not elicit a response or an underlying treatable disease condition is not discovered, prognosis for cure is grave.

- One source advocates plucking all remaining underfur in chewed areas in an attempt to stimulate new hair growth. Place collars after this procedure until the fur has grown in completely.
- Cystic SC masses may be caused by the intermediate stage of *Multiceps serialis*. Transmission is by ingestion of feed contaminated with canine feces.
- *Diagnosis* is made by histopathologic or cytologic examination of tissue samples. Treat by surgical removal of the masses.
- Otitis caused by *Pseudomonas* spp. occurs as in rats.

Ophthalmology

- Conjunctivitis occurs as in mice.
- Cataracts are congenital or developmental.
- Asteroid hyalosis occurs as a degenerative change.

Respiratory

Pneumonia occurs as in guinea pigs.

Gastroenterology

Parasites

Tapeworms (i.e., *H. nana*) occur as in mice.

Dental

Malocclusion of incisors and cheek teeth occurs as in guinea pigs.

Diarrhea

- Diarrhea is caused most often by *Coccidia* or *Giardia* spp. or a bacterium.
  - *Clinical signs* range from soft stools and weight loss to fluid diarrhea, dehydration, bloating, septicemia, and sudden death.
  - The protozoal parasites are best diagnosed on fresh saline smear or necropsy.
- Bacterial diarrhea is most often caused by contaminated feed and is diagnosed by isolation on culture. *Clostridium* spp., *Pseudomonas aeruginosa, E. coli, Salmonella enteritidis,* and *Pasteurella* spp. are the most common isolates.
  - *Treat* supportively and use appropriate antiprotozoal or antibiotic drugs.
- *Pasteurella pseudotuberculosis* causes acute death from septicemia or a chronic weight loss with intermittent diarrhea. Enlarged mesenteric lymph nodes are a hallmark of this disease.
  - *Diagnosis* is based on clinical signs, histopathologic examination of tissue samples, and isolation on culture.
  - *Treat* with sulfa drugs until sensitivity results are available. Prognosis for recovery is poor. Gross postmortem examination reveals yellow to white necrotic foci in the liver.

Theriogenology

- Check male chinchillas four times per year for penile hair rings. Roll back the prepuce and expose the penis. Roll hair rings off the penis after application of a water-soluble lubricant. Treat ulcerations topically or systemically as needed.
- Dystocia is fairly common in chinchillas (see "Guinea Pig").
- Metritis is suspected when post-partum vaginal discharge, failure to return to a normal estrus cycle, anorexia, weight loss, polydipsia, polyuria, and chewing at flank and abdomen are present.
  - *Diagnosis* is based on history, physical examination, abdominal radiographs, culture, ultrasound, and CBC. It usually is caused by bacteria introduced by the male or spread from an internal abscess. Retained placentas, macerated fetuses, and dystocia are predisposing factors toward metritis.
  - *Treat* with ovariohysterectomy after stabilization. Females used only for breeding purposes may be treated with antibiotics alone, but the prognosis is poor.
- Female chinchillas are aggressive toward male chinchillas when not in estrus. Breeding operations usually have separate cages for females and an interconnecting run for the male. Females are kept out of the male's run by their larger size or collars. The young are precocious and do not need a nest. Chinchillas only produce two litters per year.

Mastitis

- *Clinical signs* include hot, swollen mammary glands. Suspect mastitis if previously healthy neonates become restless, then lethargic.
- Perform bacterial cultures on milk samples, and treat with antibiotics based on susceptibility testing. Administer sulfa drugs until susceptibility results are available. Local hot packing is also beneficial. Occasionally, surgical drainage is required. Foster neonates to another female if possible, or use puppy or kitten milk replacers to hand-raise babies.

Neurology

- Chinchillas seem to be particularly sensitive to *Listeria monocytogenes*. Clinical signs can mimic *P. pseudotuberculosis* and include anorexia, lethargy, abortion, generalized central nervous system (CNS) signs, hepatitis, mild enteritis, and mild emphysematous pneumonia. Necropsy shows yellow foci in the liver.
  - *Diagnosis* is based on isolation on culture.
  - *Treat* with sulfa drugs (see Table 177-9) until sensitivity results are available. The prognosis is poor.
- Other less common causes of neurologic disease in chinchillas include lymphocytic choriomeningitis, *Streptococcus* spp., *Balisascaris procyonis* (i.e., aberrant migration of raccoon roundworm), lead poisoning, and thiamine deficiency.

GUINEA PIG

Guinea pigs *(Caviae porcellus)* are nocturnal rodents that originated in the Andes mountains. They are known for their dietary need for vitamin C. They are used as a food source in their native lands. There are three basic types: English, which have short hair; Abyssinian, which have short, cowlicked hair; and Peruvian, which have long hair. Male guinea pigs are known as boars and the females as sows.

Guinea pigs become neophobic as they mature. Offer a variety of foods early in life and make changes in diet or environment gradually. Guinea pigs stampede when excited. Square cages and strategically placed barriers on external walls prevent the trampling of small or weak animals.

The smooth muscle of the bronchial tree is quite developed in guinea pigs. This places them at high risk for asthmatic-type anaphylactic reactions.

Both male and female guinea pigs have one pair of inguinal mammary glands; however, only the female's are well developed.

▼ ***Key Point*** Antibiotic toxicity (see "Hamster"): guinea pigs also may be sensitive to tetracyclines.

Dermatology

- *Fleas* occur as in mice.
- *Lice* (i.e., *Gliricola porcelli, Gynopus ovalis*) usually cause no clinical signs except occasional alopecia, seborrhea, and trauma secondary to pruritus.
  - *Diagnosis* is made by observation of lice on skin scraping.
  - *Treat* with ivermectin, 5% malathion dust, or pyrethrin shampoo (see Table 177-8).
- The mite *Trixacarus caviae* causes severe pruritus and is zoonotic. It mainly affects the dorsal midline and is difficult to find on skin scraping. It occurs most frequently in recently post-partum females, in which alopecia is the predominant clinical sign. Treat with excellent sanitation and ivermectin (see Table 177-8).
- *Chirodiscoides caviae* lives on the hair shaft of the perineal regions. It does not cause clinical signs.
  - *Treat* with 5% carbaryl or lime-sulfur dip (1:40) (see Table 177-8). Sanitation is critical in preventing reinfestation.
- About 6% to 13% of guinea pigs are carriers of *Trichophyton mentagrophytes.*
  - *Clinical signs* are alopecia and seborrhea sicca, usually starting on the face and spreading along the dorsum.
  - *Treat* with lime-sulfur dips or griseofulvin (see Table 177-9) combined with topical povidone iodine or chlorhexadine shampoos.
- Other causes for alopecia are barbering, alopecia of the flanks in late-gestation females, and generalized alopecia of young at weaning. Subclinical hypovitaminosis C causes a poor hair coat and seborrhea sicca, as well as anorexia and large, malodorous stools.
- "Lumps" is the lay terminology for *cervical lymphadenitis,* which is characterized by lymphadenopathy in the ventral neck region. *Streptococcus zooepidemicus* and *Streptobacillus moniliformis* are the two most frequently cultured pathogens. Transmission is through abrasions of the oral mucosa. The enlarged lymph nodes are filled with purulent exudate.
  - *Treat* with chloramphenicol or sulfa drugs until culture results are available. If surgery is required, attempt to remove encapsulated abscesses intact. If this is not possible, excellent drainage is required. The infection may spread, causing otitis, arthritis, or upper respiratory tract infection. Recovered individuals are carriers. Quarantine both sick and recovered animals.
- *Mammary tumors* occur in the inguinal areas. About 30% are adenocarcinomas; the rest are usually benign fibroadenomas. Other possible causes of masses under the skin include hernias, neoplasias, granulomas, hematomas, or other abscesses.
  - *Diagnosis* is based on cytologic or histopathologic examination of tissue samples. Use thoracic radiographs to determine the presence of metastases.
- *Pododermatitis and sore hocks* are very common in guinea pigs. Predisposing factors are untrimmed toe nails, poor sanitation, and wire flooring. *S. aureus* is the most commonly cultured pathogen.
  - *Clinical signs* range from small ulcers on the soles of the feet to abscesses and gangrene. Radiography is essential in determining whether bony involvement is present. Untreated pododermatitis usually develops into osteomyelitis, which is very difficult to cure.
  - *Treat* mild cases by improving sanitation and grooming. Place affected individuals in solid-floored cages with paper bedding. Use sulfa drugs (see Table 177-9) until results of susceptibility testing are available. Surgically remove or curette abscesses, and apply topical therapy and hot packing. Amputation may be necessary when severe osteomyelitis exists.

Ophthalmology

- Conjunctivitis and epiphora occur as in mice.
  - Inclusion body conjunctivitis is caused by *Chlamydia psittaci* and is self-limiting in 3 to 4 weeks.
  - Perform a conjunctival scraping to differentiate inflammatory conjunctivitis secondary to infection from allergy. I have observed an idiopathic, topical steroid-responsive lymphoplasmacytic conjunctivitis in guinea pigs.
- White, dry ocular discharge is an early sign of hypovitaminosis C.

- "Pea-eyes" is the lay terminology for subscleral fatty deposits or protrusion of the lacrimal gland through the lower conjunctiva. The condition is thought to be hereditary. Treatment is not required.
- Cataracts occur and are either congenital or developmental.
  - Diabetes mellitus in guinea pigs also may cause cataracts. Usually, no other clinical signs are present and urine glucose is greater than 100 mg/dl whereas blood glucose remains within normal limits.
- Corneal or scleral calcification is usually an incidental finding. A thorough workup, including serum chemistry profile and radiographs, is recommended to ensure that generalized metastatic calcification is not present.

Respiratory

- Pneumonia in guinea pigs usually is caused by infection with S. pneumoniae, S. zooepidemicus, or Bordetella bronchiseptica. S. aureus, P. aeruginosa, Klebsiella pneumoniae, and Pasteurella multocida also are cultured frequently. Transmission is by direct contact, fomites, or aerosol. Hypovitaminosis C and stress often predisposes guinea pigs to bacterial respiratory infections. Weanlings are particularly susceptible. Clinical signs and diagnosis are similar to other small mammals (see "Mouse").
  - Take radiographs to rule out abscesses, pleural effusion, or pericardial effusion in refractory cases.
  - *Treat* with chloramphenicol, sulfa drugs, or enrofloxacin (see Table 177-9) and vitamin C (Table 177-10) until results of culture and susceptibility testing are available. Cats, dogs, rabbits, and rats are reservoirs for *Bordetella* spp. As in other rodents, respiratory infections may lead to otitis interna/media. *Bordetella* spp. also cause pyometra and abortions.

Table 177-10. MISCELLANEOUS INJECTABLE MEDICATIONS FOR USE IN PET RODENTS

Rights were not granted to include this table in electronic media. Please refer to the printed publication.

- Nasal discharge is most frequently a sign of upper respiratory tract infection but also may be associated with allergies or volatile irritants.
  - The diagnosis of allergic rhinitis is made by exclusion and through response to antihistamines or environmental changes.
- Bronchogenic papillary adenoma develops in approximately 30% of guinea pigs older than 3 years of age.
  - *Diagnosis* is often an incidental finding when thoracic radiography is performed for another problem.
  - Occasionally, clinical signs are seen as a result of pressure on the heart or great vessels.
- Dyspnea most frequently is caused by heat stress or trauma. Other causes are pregnancy toxemia, gastric bloat, volatile irritants, pleural effusion, pneumonia, or pulmonary edema.

Cardiology

Rhabdomyomatosis is a common necropsy finding. Gross lesions appear as pale foci located on the endomyocardium and valves. Histologic examination reveals myocardial cells that have stored excessive glycogen. Do not confuse these areas with thrombi, abscesses, or neoplasia. Their clinical significance is unknown.

Gastroenterology

Parasites

- *Paraspidodera ucinata* is the cecal pinworm of guinea pigs. They are generally asymptomatic, but heavy infestations can cause diarrhea and weight loss.
  - *Diagnosis* is based on fecal examination or cellophane tape test.
  - *Treat* with piperazine or fenbendazole (see Table 177-8).
- Coccidiosis caused by *Eimeria caviae* is a fairly common cause of diarrhea in guinea pigs recently purchased from pet stores.
  - *Clinical signs* are tenesmus, diarrhea, dehydration, and death.
  - *Diagnosis* is based on fecal examination. On gross postmortem examination, petechiation and thickening of the colon are seen.
  - *Treat* supportively and administer sulfa drugs (see Table 177-9).
- *Cryptosporidium wrairi* and *Giardia* spp. are found rarely. They cause a chronic enteritis. *Balantidium* spp. are thought to be nonpathogenic.

Dental

- Malocclusion in guinea pigs is diagnosed on oral examination.
  - *Clinical signs* are ptyalism and anorexia. The premolars are the most commonly affected teeth.

- Gingivitis secondary to hypovitaminosis C causes similar clinical signs, but the teeth appear normal.
- Long-standing hypovitaminosis C predisposes guinea pigs to malocclusion.
  - *Treat* malocclusion as in other rodents (see "Dental Procedures").

Diarrhea

- Hypovitaminosis C (i.e., scurvy) is associated with soft, malodorous feces. Degeneration of the epithelium of the intestinal tract adversely affects digestion and absorption and allows secondary bacterial infections.
  - *Diagnosis* of scurvy is based on clinical signs, the exclusion of other causes of diarrhea, and response to vitamin C therapy (see Table 177-10).
- Salmonellosis usually is contracted through contaminated feed.
  - *Clinical signs* range from sudden death to diarrhea and anorexia. The diarrhea is frequently light colored. Sepsis is common and may cause conjunctivitis, shock, pneumonia, abortion, and neurologic symptoms.
  - *Diagnosis* is based on isolation on culture of feces or other appropriate tissue samples.
  - *Treatment* is controversial because recovered individuals remain carriers. Use sulfa antibiotics or enrofloxacin (see Table 177-9) until sensitivity testing results are available. Supportive care is essential.
- *E. coli, Arizona,* and *Clostridium* are other commonly cultured diarrhea-causing organisms. *Clostridium* are diagnosed most easily by finding large numbers of spores on a Gram stain fecal specimen. Treat with metronidazole (see Table 177-9).
- *Yersinia pseudotuberculosis* either causes an acutely fatal diarrhea or localizes into regional lymph nodes.
  - *Diagnosis* is based on culture.
  - *Treat* by surgical removal or drainage of abscessed lymph nodes. Mesenteric lymph node involvement necessitates abdominal surgery. Treat with sulfa drugs or enrofloxacin until susceptibility testing results are available (see Table 177-9).

Theriogenology

- One male usually is housed with four to six females for breeding purposes. Signs of estrus are vulvar swelling, lordosis, and opening of the vaginal closure membrane. Fetuses are palpable at 4 to 5 weeks of gestation. Parturition occurs within 48 hours after the pubic symphysis has reached 15 mm. Neonates weighing less than 60 g have a grave prognosis for survival even with intensive care. Neonates normally do not nurse for the first 12 to 24 hours. Litters with five or more fetuses usually result in abortion.
- Dystocia commonly occurs in females bred after the age of 6 to 9 months. After this age, the symphysis fuses and is unable to open the 2 to 3 cm required to allow passage of a fetus. Dystocia in younger guinea pigs may be caused by obesity, large fetal size, fetal malpresentation, subclinical ketosis, or uterine inertia. On presentation, check the pelvic symphysis. If active contractions are present and the symphyseal gap is less than 2 cm, perform a C-section. Normal parturition is very rapid, with a rest of only 3 to 7 minutes between fetuses.
- Perform a C-section if active straining does not produce a fetus within 15 to 20 minutes. Radiograph sows with a history of weak contractions to determine the stage of pregnancy and evaluate the size of the fetuses. If well-developed skeletons of appropriate size are seen and the pubis has not yet fused, give oxytocin and calcium (see Table 177-10). If no fetuses are produced within 15 to 20 minutes, perform a C-section.
  - If poorly developed fetuses are seen radiographically, consider fetal death, ketosis, or a nonreproductive disorder as possible causes of dystocia.

▼ ***Key Point*** Pregnancy toxemia usually is seen in obese sows with large litters in late pregnancy. Other risk factors include systemic disease or diet change causing anorexia, genetics, stress, and first litter.

  - *Clinical signs* are tachypnea, depression, malodorous breath, seizures, and icterus. A urine pH of less than 6 with marked proteinuria is compatible with pregnancy toxemia. A marked hyperkalemia and elevation of liver enzymes often occurs. Thrombocytopenia may be present.
  - *Treat* with IV or IO saline, dextrose, glucocorticoids, and calcium. Surgical abortion of the fetuses may be attempted, but the anesthesia risk is quite high. Prognosis for survival is grave. Do not rebreed affected females. Do not breed sows heavier than 900 g.
- Large litters can cause a hemorrhagic syndrome. Compression of the portal vein and liver causes hepatic dysfunction, which results in vitamin K and clotting factor deficiency.
  - *Treat* with vitamin K supplementation (see Table 177-10). Response is poor in severely compromised patients. Affected individuals are at risk of ketosis developing. Prognosis is guarded.
- Vaginitis in guinea pigs frequently is caused by foreign bodies, usually bedding.
  - *Diagnosis* is made on vaginal examination.
  - *Treat* by flushing the vagina to remove the foreign material.
- Vaginal discharge also can be caused by pyometra, uterine torsion, urinary tract infection, or urogenital neoplasia.
  - *Diagnosis* is based on findings on abdominal palpation, vaginal cytology and culture, urinalysis,

abdominal radiographs, ultrasound, and exploratory.
  - *Treatment* varies with the condition and is similar to that used in cats.
- Ovarian teratomas and uterine tumors occasionally are diagnosed and usually resolve with ovariohysterectomy.
- A symmetric alopecia with concurrent abdominal enlargement may be seen in female guinea pigs with cystic ovaries.
  - *Diagnosis* is based on abdominal palpation, cytology, and ultrasound.
  - *Treat* by performing an ovariohysterectomy. If the guinea pig is not a good candidate for surgery, human chorionic gonadotropin (hCG, 1000 USP units IM, repeat in 1 week) may temporarily resolve clinical signs.
- Male guinea pigs are prone to preputial foreign bodies. A preputial discharge is the usual presenting complaint.
  - *Diagnosis* is based on physical examination.
  - *Treat* by removing foreign bodies and performing local flushing. Chronic problems require a change in bedding.
- Male guinea pigs produce sebaceous secretions in the folds around their perineal area. Clean these areas with soap and water semiannually to prevent localized pyoderma.
  - If pyoderma occurs, treat with topical therapy and oral antibiotics.

Urology

Bacterial cystitis and urolithiasis are relatively common in guinea pigs. Diagnosis is based on a history of stranguria, hematuria, painful abdomen, and anorexia, in addition to abdominal palpation, urinalysis, urine culture, abdominal radiographs, and ultrasonography.

Treatment consists of antibiotics based on results of culture and susceptibility testing and surgical removal of calculi, if present. Prevention of recurrence is difficult if the calculi are not caused by a bacterial infection. Addition of vitamin C to the drinking water as well as changing the brand of diet are sometimes helpful in preventing recurrence of metabolic stones.

Klossiella cobayae is a coccidia that lives in the renal tubules. It has no clinical significance.

Musculoskeletal

The most common orthopedic problem seen in guinea pigs is overgrown toenails. This leads to pododermatitis and sore hocks as well as to degenerative joint disease and a predisposition to tibial fractures.

Tibial fractures are the most common fracture seen in guinea pigs. They most frequently occur after foot entanglement. Internal fixation with an IM pin or application of a Kirschner apparatus is the repair of choice.

▼ ***Key Point*** Signs of hypovitaminosis C or scurvy start to develop in guinea pigs as early as 10–15 days if they are placed on diets 100% deficient in vitamin C.

Early signs are soft, malodorous stools, weight loss, poor hair coat, and anorexia. Later, petechia, gingivitis, cutaneous and oral sores, swollen costochondral junctions, joint pain and hemorrhage resulting in lameness, and conjunctivitis become apparent. Treat supportively and administer parenteral vitamin C (25 mg/day).

Neurology

- Lymphocytic choriomeningitis occurs as in mice.
- Guinea pig paralysis syndrome starts with mild pyrexia and urinary incontinence, followed by weight loss and posterior paresis that progresses to paralysis. Currently, the etiology is unknown, but it does not appear to be contagious.
- *Treat* with supportive care. Prognosis for long-term survival is grave.
- Head tilt is usually the result of otitis or trauma (see "Mouse").

Hematology

Cavian leukemia has a viral etiology. The liver, spleen, and lymph nodes are the primary organs involved. There is no current treatment. Quarantine exposed individuals. Death usually occurs within 5 days after discovery of lymphoblasts in the peripheral blood.

Neutrophils normally have red granules. Kurloff bodies are normally occurring eosinophilic intracytoplasmic inclusion bodies that are found in mononuclear cells. They are seen most frequently in females and appear to correspond positively with estrogen levels.

Metastatic calcification occurs in most guinea pigs older than 1 year of age. It is more severe in females than in males. The stomach is one of the first organs affected. Dysfunction in motility causes obstruction. The tendency appears to be exacerbated by high calcium and low phosphorus diets.

Chapter

178 Basic Husbandry and Medicine of Pet Reptiles

Nancy L. Anderson / Raymund F. Wack

Boas, pythons, king snakes, rat snakes, and milk snakes are the most common snakes kept as pets. Iguanas, geckoes, monitors, and bearded dragons are frequently encountered pet lizards. Amphisbaenians are small, worm-like reptiles not commonly found in the pet trade. Snakes, lizards, and amphisbaenians are all in the order Squamata. The order Chelonia has approximately 235 species and consists of turtles, tortoises, and terrapins. Of the chelonians, box turtles, red-eared sliders, and a variety of tortoises are kept most commonly as pets. The order Crocodilia has only 21 species, including alligators, crocodiles, caimans, and gharials.

PET INDUSTRY

Determine whether an animal is captive bred or wild caught. Captive-born animals have been somewhat genetically selected to tolerate manufactured environments and accept domestic sources of food. In general, they are less likely to be harboring overwhelming numbers of infectious agents (especially parasites) than their wild-caught counterparts. Many wild-caught animals have been collected overseas, then housed in inadequate, overcrowded facilities, and finally shipped to suppliers without having eaten. The ones that survive often are dehydrated, immunosuppressed, and have been exposed to a wide variety of pathogens. Some imported reptiles are injected prophylactically with antibiotics, which, in combination with dehydration, predisposes them to renal failure. Because of the slow metabolic rate of reptiles, many animals survive this abuse for many months before demonstrating obvious clinical signs.

▼ ***Key Point*** Encourage novice potential reptile owners to buy their pets only from reputable breeders.

COMPARATIVE ANATOMY AND PHYSIOLOGY

Body Temperature

Most reptiles need to maintain their core body temperature well above ambient temperatures for at least part of the day and generally achieve this by absorbing radiant heat. Reptiles can minimize body temperature fluctuations by modifying behavior. Reptiles that become too cool seek elevated areas to bask, lay perpendicular to the sun's rays, maximize their surface area by expanding their rib cage, and darken the pigment of their skin to increase heat absorption. If no sunlight is available, some reptiles burrow into warm soil or lay on objects previously warmed by the sun.

- Overheated reptiles place themselves parallel to the sun's rays, seek shade, pant, lighten skin color, and burrow into cool soil to decrease body temperature.
- Overall, reptiles have a limited ability to control their core body temperature. If they are unable to cool themselves, death due to thyroid dysfunction and/or hyperthermia may occur.
- When the body temperature falls below a critical point, enzymes are unable to function. Digestion then ceases or becomes incomplete, immunity is impaired, and reproductive function declines.
- Chilled animals are at high risk of disease, and if they become chilled for a long period, they fall into torpor. Under natural conditions, some reptiles hibernate, but in captivity, reptiles are unable to prepare for hibernation on their own.
- Hibernation is a period of dormancy marked by a decrease in metabolic rate. Before hibernation in the wild, most reptiles have completed metabolically taxing activities (such as reproduction) and have accumulated energy reserves. A period of reduced food sources then begins. The resulting fast empties the gastrointestinal (GI) tract just before hibernation.
- In captivity, this energy loading to provide fat stores and the subsequent fast must be duplicated, in order to prevent putrefaction of undigested food. The most common mistake made by pet owners attempting to hibernate their reptile is to cool the animal into torpor (i.e., it cannot eat) but not enough to truly slow metabolism. In this state, the reptile often slowly starves. Systemic infections are also common while in torpor. Metabolic processes are too slow to allow proper immune function, yet microorganisms still proliferate. Females cannot successfully hibernate if they are in the process of producing eggs or offspring.

Table 178-1. PREFERRED OPTIMUM TEMPERATURE BASED ON HABITAT

Habitat	Temperature Range (°F)
Tropical	85–100
Desert	80–102
Lowland temperate	70–90
Mountain temperate	70–85

Table 178-2. PREFERRED OPTIMUM TEMPERATURE FOR COMMON REPTILES

Common Species	Temperature Range (°F)
Boas and pythons	75–95
Rat/milk/king/garter snakes	68–95
Desert tortoises	65–105
Painted turtles	55–95
Box turtles	65–90
Anoles	70–90
Chameleons	55–75
Green iguanas	75–105

- The ideal temperature range for a reptile is referred to as its *preferred optimum temperature (POT) range*. This range includes all the temperatures that a reptile needs to maintain optimal body function. The cage should contain areas with both the high and low ends of the animal's POT range so that it has an opportunity to self-regulate, much as it would in the wild. Suggested guidelines for temperature ranges based on natural habitats and common pet species are listed in Tables 178-1 and 178-2.

Circadian and Annual Rhythms

Tropical animals in the wild are exposed to very little variation in environmental temperature and therefore are not tolerant of large fluctuations. This is in contrast to desert animals that endure and require high daytime temperatures with an evening cooldown period. Reptiles from temperate climates can be very tolerant of temperature extremes (within reason) if they are free of disease. These species experience seasons in the wild and require seasonal changes in light cycle, temperature, and water or food availability to stimulate behaviors such as hibernation and breeding.

Skin and Sense Organs

Turtle Shells

The upper half of the shell is referred to as the carapace. The bottom half is the plastron. The shell is composed of bone and incorporates the sternum, vertebrae, ribs, and pelvis. Bone is covered by epidermal scales or skin. The shell is metabolically active.

Speculum

The speculum or spectacle is a clear epithelial covering that lies over the cornea of snakes and some lizards, such as Tokay geckoes. Speculums should be shed with the skin at ecdysis. Abnormal retention of these structures is a common problem in snakes. Topical ophthalmic preparations do not penetrate through the speculum.

Oral/Nasal Salt Glands

Salt glands are located in the nares or on the tongue. The glands excrete excess salt and allow conservation of water. Salt is excreted by burrowing or sneezing. Pet green iguanas often are presented for sneezing small amounts of clear fluid that dries to crystals on the walls of the cage. Do not confuse this normal salt elimination with a respiratory infection.

In snakes, the vomeronasal organ is a highly innervated area used in the sense of smell. It is located on the roof of the mouth within the vomer groove and is an extremely sensitive organ.

Parietal Eye

The "third" or parietal eye appears as a grey or clear dot on the forehead of green iguanas. The organ is an evagination of the thalamus and is connected to the pineal gland via the parietal nerve. It aids in regulation of circadian and annual rhythms.

Gastrointestinal Tract

The hyoid apparatus is very well developed in most reptiles. In snakes, it usually extends to the tenth cervical vertebra, allowing the tongue to be extremely mobile. This enables the snake to breathe directly through its glottis even while swallowing prey. In chameleons, the hyoid apparatus extends the full length of the abdomen to the cloaca. This structure allows their long, well-developed tongues the motility and strength necessary to catch flying insects.

▼ ***Key Point*** In reptiles, restrain the head only by its dorsolateral surfaces to avoid damage to the hyoid apparatus and subsequent loss of tongue function. Avoid restraint that places pressure on the ventral cervical region.

Snakes possess an open mandibular symphysis and flexible rami that allow them to swallow large, intact prey. These features also make iatrogenic injury to the mandibles common, especially while performing an oral examination.

▼ ***Key Point*** *Never* force open a reptile's mouth. To open the mouth of a snake or lizard, place a plastic credit card or hard rubber spatula at the corner or front of the mouth and use gentle, prolonged pres-

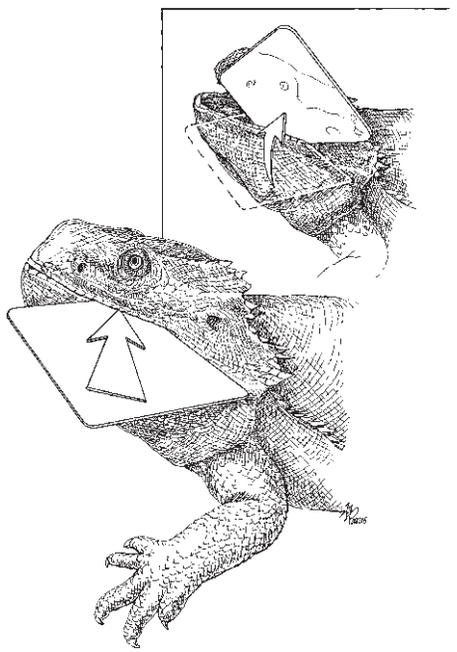

Figure 178-1. To open the mouth, place a plastic credit card or hard rubber spatula at the corner or front of the mouth and use gentle, prolonged pressure combined with a slight wiggling motion.

sure combined with a slight wiggling motion. Once the mouth is opened, slide the card or spatula across the jaws (Fig. 178-1). The beak of larger chelonians can bite through many plastics, so a thin, but sturdy metal spatula may be required to open the mouth. Be careful not to crack the beak. Anesthesia may be required to open the mouths of very large reptiles.

Snakes typically have four rows of teeth in their upper jaw. The teeth of snakes and lizards are fragile and curved caudally to aid in pulling food into the mouth. Be careful not to catch materials on teeth. If items such as swabs or gauze become caught, push caudally to disentangle the fibers before pulling out, or the teeth may break. Broken teeth cause oral pain and anorexia until a new tooth emerges.

Chelonians do not have teeth but rather a horny beak made of keratin similar to that of birds. Treatment of beak problems is similar to beak repair in birds.

The esophagus is lined liberally with mucous glands. Although the musculature surrounding the esophagus is extremely strong in snakes to move whole prey caudally, the esophagus itself is thin and tears easily.

▼ ***Key Point*** When performing stomach intubation in snakes, the esophagus "grabs" the tube. Use liberal amounts of water-soluble lubricating jelly and gentle, constant pressure to pass the tube smoothly. If firm resistance is felt, redirect the tube. Never force a stomach tube because perforation may occur.

In many species of turtles, the esophagus makes a 90 degree turn before entering the stomach. Place medications administered by stomach tube in the distal esophagus. Use small volumes to prevent regurgitation. Also, in chelonians, the pancreatic and bile ducts enter the pylorus instead of the duodenum.

When present, the gallbladder usually is found near the liver in lizards and chelonians but is located caudal to the stomach in snakes. This is an important difference to recognize when performing surgery or diagnostics in this region.

The reptilian pancreas, although sometimes structurally different than in the mammal, is functionally similar. The pancreas usually is located between the ascending and descending portion of the duodenum in chelonians and lizards. In snakes, the pancreas is located caudal to the pylorus in the region of the gallbladder and spleen. In some snakes, the pancreas and spleen are fused.

The cecum is rudimentary in carnivorous reptiles such as snakes, crocodilians, and monitors. The cecum is present in chelonians and herbivorous lizards and functions in post-gastric fermentation in these species.

The cloaca is a common collecting chamber for wastes from the colon and ureters and for the reproductive tract. The cloaca also receives urine from the bladder in species that possess a bladder. It is important to note that unlike mammals, in reptiles, the ureters empty into the cloaca and not the bladder. In males, the hemipenes or phallus everts from the caudal aspect of the cloaca. In some aquatic species, oxygen can be exchanged across the cloaca. Obstruction of the cloaca affects *all* of the aforementioned systems and is therefore much more detrimental than mere constipation affecting the GI system in mammals.

Respiratory System

All reptiles possess a cleft palate (choana) that is necessary for nasal breathing. In contrast to birds, which have a single central cleft, reptiles have paired paramedian clefts. These clefts allow passage of air from the nares into the oral cavity and trachea.

Most reptiles lack a diaphragm, and breathing is accomplished by expansion of the chest wall by intercostal muscles (except turtles), pectoral limb movement (except snakes), and smooth muscle contraction in the lung. Crocodilians also use movement of the liver to create negative pressure. Chelonians use movement of front limbs and visceral organs instead of excursion of the chest wall, which is impossible because of their rigid shell. A minimal amount of oxygen can be extracted from water through the skin in certain species of all reptilian orders. Some aquatic turtles can exchange dissolved oxygen across their pharynx and cloaca while

submerged, although these sources only provide maintenance levels of oxygen.

- In crocodilians, the pharynx has a membrane that can be constricted to allow breathing while the mouth is full of water or food. This membrane must be pushed dorsally to place an endotracheal or stomach tube.
- The glottis in most species is located at the base of the tongue. This makes endotracheal intubation extremely easy. The glottis is very mobile in snakes to allow for respirations while swallowing whole prey.
- The tracheal rings are covered dorsally by smooth muscle in squamates. The rings are complete in chelonians and crocodilians. Therefore, use non-cuffed endotracheal tubes in reptiles. The trachea is lined with many goblet cells that produce thick secretions, which may clog endotracheal tubes. Atropine administration appears to make secretions even more viscous. In some crocodiles, the trachea is bent on itself, making intubation difficult and bronchoscopy impossible. The trachea bifurcates more cranially in chelonians than in other orders, and a short endotracheal tube is needed to ensure aeration of both lung fields.
- The reptilian lung is composed of open-ended sacs lined with alveoli, structurally supported by smooth muscle. Each sac connects directly to a bronchus or to secondary bronchi in more developed species. In many species, the lungs end in thin-walled air sacs. Air sacs aid in respiration and can be inflated for use as a defense mechanism or buoyancy control device. Vipers possess a tracheal lung, which is a collection of alveolar tissue on the dorsal portion of the trachea. This allows for gas exchange even when large swallowed prey compresses the lungs. In most species of snakes, the right lung is larger than the left.

Cardiovascular

Reptiles (except for crocodilians) have a three-chambered heart with two atria and one common ventricle. Deoxygenated blood from the body empties into the right atrium via the sinus venosus. The left atrium receives oxygenated blood from the lungs. In non-crocodilians, both atria open on the left side of the ventricle. Blood from the right atrium tends to stay on the right side of the ventricle and enter the pulmonary artery. Reptiles have two aortic outflow tracts, the right and the left aortas, which combine caudal to the heart into a common aorta. The left aortic arch comes from the right side of the ventricle, carrying less-oxygenated blood. The right aortic arch comes from the left side of the ventricle, which has richly oxygenated blood. The right aortic arch supplies oxygenated blood to the head region before it combines with the left aortic arch.

- Diving causes increased pulmonary resistance, which causes more deoxygenated blood to be shunted into the left aortic arch. This results in increased mixing of oxygenated and deoxygenated blood.
- To shed the skin around the head region, squamates use a vascular phenomenon called the "swell mechanism." Blood pools in the vessels around the head, resulting in swelling of the head area to split the skin.
- The central ventral vein is a large vessel that runs down the ventral midline of lizards and snakes. Avoid this vein during laparotomy. Do not use this vein for venipuncture because life-threatening hematoma formation can occur.
- Paramedian vessels run as pairs parallel to the ventral midline under the shell in chelonians. During celiotomy, after shell removal, use a midline approach to the peritoneum to avoid these vessels. These vessels may be ligated if needed.

Renal System

Most aquatic reptiles excrete ammonia, urea, and uric acid as nitrogenous waste products. Urea and ammonia require more water for their excretion compared with uric acid excretion. Terrestrial animals excrete mostly uric acid. However, sea turtles excrete almost exclusively ammonia or urea; semi-aquatic turtles excrete 0% ammonia, 40%–50% urea, and 50%–60% uric acid; and desert tortoises excrete more than 90% uric acid.

Reptiles can only produce isosthenuric urine. The reptilian nephron contains no loop of Henle and therefore lacks the ability to concentrate urine. Water can be resorbed from the bladder or cloacal wall. If renal blood flow is diminished below a critical level (as in dehydration), urates precipitate in the nephron, causing irreversible obstruction.

Reptiles possess a renal portal system that allows blood from tissues caudal to the kidneys to be shunted directly to kidneys. A valve exists at the junction of the abdominal and femoral veins. When the valve is closed, blood is shunted through the iliac vein into the kidney. When the valve is open, blood enters the systemic circulation through the abdominal vein. Blood entering the kidney through the renal portal system is supplied to the tubules and does not enter the glomerulus. Therefore, drugs such as penicillins, which are cleared via tubular secretion, can be removed by the renal portal system, but drugs cleared by the glomerulus (e.g., gentamicin) are not affected.

▼ ***Key Point*** Do not administer drugs that are cleared by tubular secretion in the caudal half of the body. These drugs may be cleared before achieving therapeutic levels or, if the drug is nephrotoxic, may reach the kidneys in concentrations high enough to cause toxicity.

Not all reptiles have a urinary bladder. The bladder is most highly developed in terrestrial chelonians and some lizards. The bladder acts as a reservoir to store

urine and conserve water. Isosthenuric urine from the kidneys is diverted from the cloaca to the bladder, where water is reabsorbed. The concentrated urine then is routed back to the cloaca for excretion. In reptiles without a bladder, diluted urine is moved from the cloaca into the large colon for water absorption. Salts also may be reabsorbed.

Reproductive System

Male Reproductive System

All reproductive organs, including the phallus in most species, are paired. Chelonians and crocodilians are the exception and have a single phallus. The phallus of adult crocodilians is fibrocartilaginous and is therefore palpable in the cloaca. This is a common sex determination technique used in this order. The male copulatory organs of squamates are paired and are composed of highly vascular fibrocartilaginous and elastic connective tissue called *hemipenes*. Erection occurs secondary to engorgement with blood and contraction of the propulsor muscle, causing eversion of the organ. Hemipenes may be ossified in some monitors and geckoes; sex determination of these individuals can be performed radiographically. Hemipenes frequently have keratin spicules to aid in maintenance of copulation. Only one hemipene is used at a time and it may prolapse if traumatized or following prolonged use.

Seasonal variation in testicular size exists in most species. This is caused by an increase in the number of interstitial androgen-producing Leydig cells during breeding season. Spermatozoa move through the seminiferous tubules and are stored in the epididymis. During breeding, spermatozoa leave via the vas deferens, cloaca, and then hemipene or phallus. The male copulatory organs of reptiles do not contain a urethra and is not involved in the elimination of nitrogenous wastes. Therefore, amputation does not affect urination but does affect breeding ability in animals with nonpaired organs.

Female Reproductive System

The right ovary is located cranial to the left in snakes. Fertilization occurs in the upper portion of the oviduct. Crypt-like pits in the oviduct can store sperm for up to 6 years in some species. Reproduction may be oviparous (egg-layers), ovoviviparous (hold eggs in oviducts until they hatch), or viviparous (live-bearers), depending on the species. The oviduct produces albumin, shell membranes, and the shell. In viviparous species, a placenta-like structure is formed.

Environment for Egg Laying

Many reptiles indefinitely delay oviposition until the right conditions for egg laying occur. These conditions vary with the species. In aquatic turtles, this may be as simple as providing a moist sand pit of sufficient depth for the turtle to dig a nest. In other cases, a female in a multiple-specimen cage may not lay her eggs unless she is housed singly. Certain environmental clues may be required to trigger hormonal cycles necessary to stimulate egg laying. The absence of the proper environmental triggers often leads to dystocia.

Sex Determination in Common Pet Reptiles

Snakes

Females have short, abruptly tapering tails; males have longer, thicker tails necessary to accommodate the hemipenes. In very young snakes, a finger can be rolled from the mid-tail region toward the cloaca in an attempt to evert the hemipenes. This technique is only moderately reliable, and there is a risk of injuring a hemipene.

- Another technique for sexing snakes is commonly referred to as "probing." Commercially available metal probes or small red rubber feeding catheters are used to explore the caudal lateral aspect of the cloaca. In females, the probe falls into a scent gland and advances caudally two to four scales past the vent. In males, the probe enters the inverted hemipene and usually advances at least seven to eight scales caudal to the vent. There have been occasional reports of damage to the hemipene using this technique.
- In boas and pythons, male snakes have more developed paracloacal spurs than females.

Tortoises

In general, female tortoises and box turtles have a flat plastron with a notched caudal region to allow for the passage of eggs. Most females have short, poorly developed tails. The males have a concave plastron to allow for balancing on the female. Males also have long, well-developed tails to allow for copulation and storage of the phallus. Female box turtles have brown to orange irises, whereas male box turtles have bright red irises.

Water Turtles

It is more difficult to differentiate gender in water turtles than in their land counterparts. The females usually have shorter tails than the males. Because the water in the environment bears the male's weight, male water turtles usually do *not* have concave plastrons. In the *Emydoidea* genus, males have very long front claws that they wave in front of females during courtship.

Lizards

In general, males become more brightly colored during the courtship season. Males have more highly developed dorsal spines, dewlaps, and horns. Male iguanas produce keratinaceous plugs along the insides of their thighs from glands called femoral pores. Their function is unknown, but they are thought to be used for

marking territories and to stimulate females by rubbing (scratching) the femoral pores over the female's hind quarters. Females have smaller versions of these pores. Only males of some gecko species have preanal pores that appear as little black pores located near the vent.

Immune System

- Reptiles do not have well-defined lymph nodes but do possess lymphoid aggregates. Lymphatic vessels exist and are well developed. Lymphocytes congregate in a bursa of the cloacal wall, thymus, and spleen. The thymus in chelonians is a distinct lobulated organ in the cervical area adjacent to the parathyroid glands. The spleen may be contiguous with the pancreas in chelonians and snakes.

Endocrine System

- Most reptiles have one to two pairs of parathyroid glands containing a cell type similar to mammalian chief cells. The glands are located at the base of the heart or along the carotid or jugular vessels. They are imbedded in the thymus in chelonians.
- The thyroid, when visible, is found at the base of the heart. The thyroid gland controls both metabolism and ecdysis.

The adrenal glands usually are located just cranial to the kidneys. In the green iguana, the left adrenal gland lies in the mesovarium and must be avoided during ovariectomy. The cortex contains chromaffin cells that produce neuroactive substances. The more centrally located population of cells produce adrenocorticosteroids. The structural architecture of these glands varies tremendously from species to species.

Special Sense Organs

Reptilian ears have no incus, malleus, or cochlea. In snakes and some lizards, the cavity of the middle ear and the tympanic membrane are vestigial. There is no external auditory opening in snakes. In these species, the stapes articulates directly with the quadrate bone. This mechanism picks up low-frequency sound and vibrations. Some snakes can "hear" vibrations transmitted from the body wall overlying the lungs. Crocodilians have a movable ear flap that is located just behind the eye. They are able to open and close this flap to keep water out of their ears.

The eyes of most reptiles (except snakes) are similar to those of mammals with a few exceptions. Bony scleral ossicles support the globe. The iris and ciliary body are composed of striated muscle and do not respond well to mydriatics. The retina contains a darkly pigmented projection called the conus papillarus, similar to the pecten in birds.

- Color vision is present in varying degrees in chelonians and lizards.
- In lidless lizards, a spectacle is present. Lidless lizards have long tongues, which are used to clean their eyes.

Snake eyes are unique among the animal kingdom and are thought to be the result of redevelopment of once rudimentary eyes. The lens accommodates by moving forward and backward. The eyes are covered by a spectacle that is impervious to topical ophthalmic preparations. The retina does not have a conus papillarus but is covered by a thin mat of vessels called the membrana vasculosa.

▼ ***Key Point*** The nasolacrimal ducts drain tears from the subspectacular space of the eye into the oral cavity. Infections in the oral cavity often ascend this duct. Always examine the mouth whenever a snake is presented for ocular disease.

Miscellaneous

Depot fat is stored in fat bodies within the abdominal cavity. These can be quite large and may be detected during abdominal palpation. A lack of fat bodies at surgery or necropsy is a strong indication of starvation.

HUSBANDRY

▼ ***Key Point*** The principal cause of disease and death in reptiles is poor husbandry.

Caging

Terrestrial Animals

Cages should be non-abrasive, escape proof, well insulated, easy to disinfect, and roomy. Aquariums, plastic sweater boxes, and polyurethane-sealed wood and glass cages work well.

Size

Cramped quarters induce stress. Snakes need room to stretch out to at least two-thirds of their length. For lizards, provide a minimum of 6 square inches of cage per inch of body size. Tortoises require a minimum of three times their body area. These are minimum areas for solitary animals. To reduce the chance of cagemate aggression, increase the cage size for more than one animal and for breeding. Clients should be counseled about the size their pet will reach as an adult.

Interior

Cage wall surfaces should be smooth to prevent abrasions, particularly to the nose. A rough branch or stone can be placed in the cage to aid in shedding. Provide cage "furniture," such as plastic containers, clay pots, and plastic plants, to provide visual security. Access to these hiding places allows reptiles to relax and prevents cage pacing. Provide additional furniture that provides a varied terrain, without hazards, to stimulate activity.

Substrates

The ideal cage liner is paper, such as newspaper. It is non-toxic, inexpensive, and disposable. Change cage papers at least once daily or after feeding or defecation for animals that are fed infrequently. Artificial turf is a good alternative to newspaper. Change the turf as soon as it is soiled. It requires 48 hours to completely clean and dry turf, so make plenty of replacement pieces available. Remove loose strings to prevent foreign bodies. Rabbit or guinea pig pellets or recycled paper bedding may be used as cage substrates for herbivorous reptiles if they are replaced at least two times per week, or more often if moist, to prevent fungal and bacterial growth. Large stone gravel and bark chips also can be used but are less desirable because they can be ingested and harbor bacteria, parasites, and moisture. Thoroughly clean and sanitize or replace substrates at least once a month (can be expensive).

▼ ***Key Point*** Do *not* use kitty litter, small gravel, or corncobs as cage liners. These materials often are ingested and cause GI impactions or can be associated with skin infections.

Sand is recommended for desert species only. Other species contaminate sand quickly and are prone to GI sand impactions. Even products commercially marketed as "reptile-safe" such as Calcisand may be ingested and can cause intestinal impactions. Some colors may be more attractive to reptiles to ingest than other colors. Dry sand potentiates low environmental humidity, which is ideal for desert species but causes dehydration in non-desert species. If sand is used for burrowing desert species, it must be changed frequently to prevent buildup of wastes.

Humidity

The environmental humidity should be kept low for most species, because high humidity predisposes animals to disease. Excellent sanitation prevents buildup of wastes, and adequate ventilation allows evaporation of residual moisture, thus keeping the humidity low. Ventilation holes or screening on the top of cages is usually adequate. However, screen lids do not work well for animals that pace in their cage. These animals often rub their noses along the lid, resulting in severe nasal abrasions. Cages used to house animals that produce copious stools, require moisture-laden food, or have high water consumption may need shielded fans to aid in evaporation. On the other hand, some tropical species may require specially designed humidifiers to maintain a supply of fresh, humid air.

Temperature Regulation

Maintain the ambient cage temperature as a gradient incorporating as much of the POT range as possible. One of the easiest methods of accomplishing this is to place a heat source at one end of the enclosure. The heat source should be able to heat the closer end of the cage to the high end of POT and the far end of the cage to the low end of POT. Thermal burns are a common problem. To decrease the possibility of thermal burns if heater malfunctions occur, be certain that the surface temperature at the hottest spot is no hotter than the top range of POT and never higher than 115°F. Heating pads or heating tape *designed for use with reptiles* are the safest to use. It is safest not to place heating elements within a cage. Instead, place the cage on small blocks to create an airspace ($\frac{1}{4}$ inch to $\frac{1}{2}$ inch) between the outside of the cage floor and heat sources. The air space will even out potential hot spots.

Heat lamps also can be used successfully if care is taken to prevent thermal burns. Radiant heat actually is required by many large herbivorous lizards, such as adult green iguanas. To prevent burns, check the temperature by placing a hand directly under the heat lamp (at the site that the reptile would be basking) for 15 minutes after the lamp has been on for 2 to 3 hours. If it is uncomfortable to leave your hand in one spot, the lamp light is too intense. Also, place a thermometer on the surface to ensure that the POT has not been exceeded. Hot rocks are unreliable and only provide enough heat for small species. Any heat sources placed within the cage need to be shielded to prevent animals from coming in direct contact with them.

▼ ***Key Point*** *Any* heating elements that have the potential to attain temperatures greater than 105°F must be shielded. *Routinely* test the thermostats on heating devices. Malfunctioning thermostats cause animal deaths and fires.

Annual and daily temperature fluctuations may be required by some species to maintain health and stimulate breeding.

Arboreal Animals

For arboreal animals, caging is similar to that for terrestrial animals but incorporates more vertical space and objects for climbing. Do not place climbing structures over water or food containers to prevent fecal contamination. Willow, bamboo, oak, birch, beech, and most fruit trees provide safe branches.

Aquatic

▼ ***Key Point*** Strict attention to water quality is essential. A filter system or *frequent* water changing is absolutely necessary.

Never use an under-gravel filter because these may cause anaerobic toxins to accumulate in the gravel. Disturbance of the gravel or an overturn of tank water

allows release of these toxins and may kill tank inhabitants. An out-of-tank biologic filter works best. Flush the sand, gravel, or fibers in these systems frequently to remove gross debris. Even these systems often cannot handle both fecal and discarded food loads. Therefore, offer food for limited periods in a separate tank, then return the reptile to its usual enclosure. The feeding tank does not need a filter because the water is changed completely before and after each feeding session and/or group of animals. Disinfect the tank and allow it to dry after feeding to prevent waste buildup and transmission of disease.

Overpopulation exacerbates water quality problems. A rule of thumb is 1 gallon of water per square inch of turtle carapace.

All aquatic reptiles except sea snakes and sea turtles need adequate basking space. Most "water" turtles drown because of exhaustion if not allowed to rest out of the water. In group tanks, this is often the cause of unexplained deaths of smaller animals. These losses can be eliminated by adding several basking areas, which allows the smaller reptiles to rest even when dominant individuals are defending their territories. Basking also is needed to allow drying of the skin and shell. An increased incidence of skin disease also is seen in reptiles not allowed to bask under ultraviolet (UV) light.

Maintaining appropriate water temperature is very important. A *reliable* waterproof heater is essential. Electric shock from non-waterproof heaters kills not only animals in the tank but also human caretakers. In addition, malfunctions resulting in overheating or failure to heat a tank may kill aquatic animals. In small tanks, an aquarium heater with an *in-water* thermostat works well. Heaters with thermostats above the surface may under- or overheat the water because the thermostat measures the air temperature and not the water temperature.

Take care to ensure tank inhabitants will not burn themselves if they decide to wrap around the heater. This is accomplished most easily by screening the heater. Water temperature in larger enclosures can be maintained by keeping the room temperature at the lower end of the POT range and using infrared lights or heaters at one end to maintain a gradient. Temperature gradients over the basking areas are controlled as in terrestrial cages.

Ultraviolet Light

Many herbivorous and insectivorous reptiles require UV light (280–315 nm) to synthesize vitamin D_3. This spectrum of light is best provided by *unfiltered* sunlight (i.e., *not* passing through glass or plastic). Most plant lights do *not* provide adequate light in the appropriate spectrum. Vita-lite (Durotest, Fairfield, NJ), ReptiSun (Zoomed, San Luis Obispo, CA) are two products that produce the appropriate wavelengths. The intensity of all these lights is much less than that produced by natural sunlight. These lights produce UV radiation in the appropriate spectrum for only 2 to 4 months. Black lights also may be used, but the potential for damage to human as well as reptile vision has not been evaluated. Provide UV light at a rate of 20 watts/3 to 6 cubic feet. Place a basking area 18 to 24 inches from the source. Shield the light from direct animal contact. Provide UV light 8 to 10 hours a day. Constant UV light overstimulates the pineal gland and destroys normal circadian rhythms, which can lead to anorexia and disease.

Light Cycle

Provide 10–14 hours of light *and* dark daily. Base the proportion of light to dark on seasonal variations in the animal's natural habitat. Room light or light from an incandescent bulb used for heating left on at night does not provide adequate darkness. Only use infrared or ceramic bulbs if heating lamps must be used for 24 hours. If room lights must be on into the dark part of the cycle, cover the cage.

Sanitation

Reptiles rarely come in contact with their excrement in the wild. In captivity, the goal is to minimize this contact and the chance of spreading disease when contact occurs. The most important part of sanitation is mechanical removal of fecal material, urates, and leftover food. This can be as simple as removing a soiled sheet of paper, or as time consuming as scrubbing stones. Only after gross debris is removed can disinfectants destroy microbes that cannot be killed by cleaning alone. Disinfection is not a substitute for cleaning.

▼ ***Key Point*** Phenolic cleaners such as Lysol and Pine-Sol can be toxic to reptiles. Bleach (sodium hypochlorite) diluted 1:30 with water is an excellent, safe, and inexpensive disinfectant. It is inactivated by organic matter. Chlorhexidine and Roccal also can be used safely.

Non-sealed and porous surfaces cannot be disinfected thoroughly. Therefore, discard items such as wood, pottery, artificial turf, porous rocks, and bedding if they become too soiled. Do not transfer these items from one group of animals to another. Use great caution in cleaning reptile cages in kitchen sinks or bathtubs as these are likely situations in which salmonella may be transmitted to people.

Cage Density

Plenty of space and visual security is essential when housing more than one animal in an enclosure. Signs of inadequate space are cagemate aggression, disease, high parasite loads, starvation, and cannibalism. Some animals naturally prey on cagemates. These animals should be housed alone or at least with non-prey species.

Mixed-Species Enclosures

Do not mix species. Mixing genuses is often disastrous because organisms that are symbiotic or cause only mild diseases in one species may be fatal to another. An example is amebiasis, which causes a mild disease in turtles but may be fatal in snakes and tortoises.

Quarantine

New animals should be quarantined in a separate building for at least 90 days. Many sources recommend 180 days. If the ideal situation is not possible, quarantine animals in separate rooms. Service new animals last and make sure that clothes are not contaminated. Dispose of wastes and wash hands thoroughly. Clean and disinfect food and water dishes at a separate location from the food preparation area. Animals should be tested for parasites and infectious disease before entering the main collection.

Nutrition

Clean Water

Change water at least every 24 hours. Clean water containers with soap and water daily and disinfect weekly. Large, shallow water dishes that allow reptiles to soak and defecate are preferred. Some lizards (e.g., chameleons, anoles) will not drink from bowls and require a drip watering system or mist sprayed on plants or the side of the cage.

Carnivore

Providing a complete and balanced diet is accomplished more readily in carnivorous reptiles compared with herbivorous or omnivorous ones. Most wild carnivorous reptiles eat whole animals (usually rodents or small birds), which are easily supplied in captivity. When they are fed whole prey, few nutritional deficiencies or excesses occur in this group of reptiles. Severe nutritional disease is seen in animals mistakenly fed only animal parts (e.g., all muscle, liver, etc.).

- Feed carnivores frozen and thawed (to 100°F) or freshly killed prey animals. Live prey may attack and seriously injure reptiles. Domestic animals fed as prey should simulate prey eaten in the wild as much as possible.
- Food animals should be raised on excellent diets because they are the only source of nutrients for the reptile. Do not offer obese prey animals because the excess fat may cause steatitis. Supplements for reptiles eating warm-blooded prey usually are not recommended.

▼ ***Key Point*** Some carnivores such as king snakes only eat other snakes. Be sure that "feeder" snakes used as prey are free from disease and parasites. If the snake eats thawed, frozen prey, it is recommended to freeze all food snakes for at least 30 days before feeding to prevent transmission of parasites. Good-quality feeder snakes can be difficult to obtain. Some snake eaters accept mice stuffed into a shed snake skin.

Some carnivores eat only amphibians or small reptiles of various genera. Freezing to prevent disease transmission is extremely important in these species as well. Some amphibian eaters can be trained to eat mice by placing a mouse inside a fresh frog skin or smearing a mouse with frog slime. Be careful not to attempt to feed amphibians, which produce toxic skin secretions.

Some snakes and monitors eat mostly eggs. Ideally, these eggs should be fertilized and contain embryos at different stages of development. Reptiles fed only unfertilized hen eggs suffer many nutritional deficiencies.

Some reptiles only eat crustaceans, gastropods, worms, or other specialized diets. Special attention needs to be paid to the natural history of reptiles needing specialized diets. If the suitable prey items cannot be obtained year-round, do not keep the animal in captivity.

Crocodilian

Nutritional diseases such as secondary hyperparathyroidism commonly occur when owners feed their crocodiles hamburger or table scraps. Feed only whole-animal diets (e.g., whole fish, rats, chickens, rabbits) to prevent nutritional diseases. Feed crocodilians individually whenever possible to prevent feeding frenzies and subsequent cagemate trauma.

Insectivore

Crickets, mealworms, and inch worms commonly fed to reptiles in captivity are deficient in nutrients. Provide an excellent diet for these insects to replace missing nutrients. To maximize their nutritional worth and provide extra nutrients from the intestinal contents of the insect, raise these insects on a high-calcium medium such as chicken layer mash or commercial cricket diet from a reputable company. Use of dark, leafy greens or orange vegetables as a water source for insects further increases their nutritional value. Before feeding the reptile, dust crickets and mealworms with a vitamin and calcium supplement (daily for reproductively active females and juveniles, 1–3 times per week for others). Large insectivores may accept young, hairless mice (commonly called "pinkies") or captive reared earthworms as an additional source of nutrients. Feed small, chiten-free insects, such as juvenile crickets, mealworms, or wingless fruit flies to small or neonatal insectivores. Some insectivores require highly specialized diets. Do not feed fireflies to reptiles because they are often toxic.

Herbivore/Omnivore

Adult herbivores, such as green iguanas, should receive 90% to 98% of their calories from plants. Ninety percent of the plant diet should consist of a mixture of dark leafy greens, with 10% mixed vegetables and fruits. Many adult herbivorous tortoises require high-fiber diets, such as high-quality grass hay or fresh grass. Omnivores or young herbivores should receive 70% to 95% of their calories from plants. Most herbivores and all omnivores require the addition of some protein to their diets. Good sources of protein are crushed hard-boiled egg (with shell), prepared reptile diets from reputable companies, trout chow, pinkie mice, alfalfa pellets, or tofu. Dog food or monkey chow should not be fed. These foods contain excessive amounts of vitamin D and may cause metastatic calcification of soft tissues and renal failure when fed extensively. Although some experts believe that feeding *any* animal protein to herbivores may cause renal disease, we have found that renal disease is related to the *quantity* rather than the source of protein. To avoid over feeding, be aware that the concentration of nutrients and calories in animal-based food is usually at least an order of magnitude greater than in the same volume of vegetable matter.

- Vitamin and calcium supplements may be used in moderation, but avoid calcium supplements that contain phosphorus and extra vitamin D. These supplements often contribute to metastatic calcification because most reptile diets are already too high in phosphorus from meat and fruit. We recommend Calcium glubionate syrup (Calcionate, Rugby, Norcross, Georgia; 1 tsp = 115 mg Ca glubionate). This syrup is free of phosphorous, is highly palatable, and is readily accepted from a syringe or dropper, allowing individual dosing. Alternatively, crushed *boiled* egg shells, calcium carbonate, or oyster shells are other excellent sources of phosphorus-free calcium. Healthy, adult herbivorous reptiles on excellent diets and provided adequate UV light usually only require vitamin and mineral supplements four to six times per month.

RESTRAINT

Lizards and Crocodilians

Restrain small lizards and crocodilians by using the thumb and forefinger to grasp the caudal mandibular area. Cradle the dorsal body in the palm of the same hand. Control the abdomen, chest, and pelvis with the remaining fingers, thus allowing for respiration (Fig. 178-2).

Grasp medium-sized lizards and crocodilians over the dorsal surface of the head and neck with one hand, and grab the base of the tail and pelvis with the other hand (Fig. 178-3). Wrap the reptile securely in a towel to prevent the back legs from scratching. If necessary, restrain the back legs by taping them to the tail. To capture mildly aggressive animals, use a towel as a blind to hide the restrainer's hand from view. If an aggressive animal is brought in a sack, use the sack as a blind and grasp the head through the sack. Peel the sack away from the body without losing control of the head. A snare or snake hook can be used to pin the head if the animal is extremely aggressive. Care must be taken to use just enough pressure to prevent escape but not enough to cause trauma. Large lizards and crocodilians can inflict serious bites and often use their powerful tails as whips. Tape the snout of aggressive crocodilians shut with duct tape. The masseter muscles are extremely strong; the digastricus muscle, which opens the jaw, is very weak.

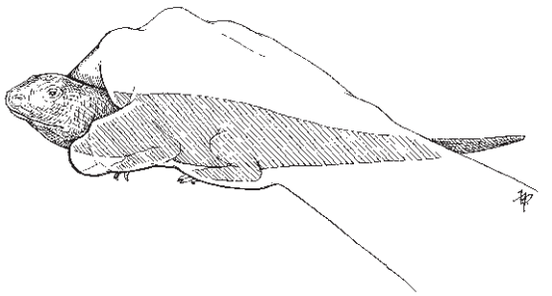

Figure 178-2. One-handed technique for proper restraint of a small lizard.

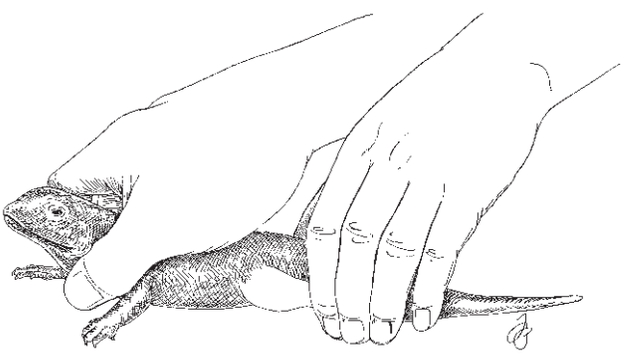

Figure 178-3. Proper restraint of a medium lizard.

Stroking the ventral midline or pushing on the eyes of some lizards induces vasovagal response and a short trance-like state.

▼ ***Key Point*** Large reptiles can inflict serious damage, even death, to the handler. Attempt to handle these animals only if you are experienced and have adequate assistance.

Snakes

Most non-aggressive snakes may be picked up mid-body and allowed to glide from hand to hand. Some snakes

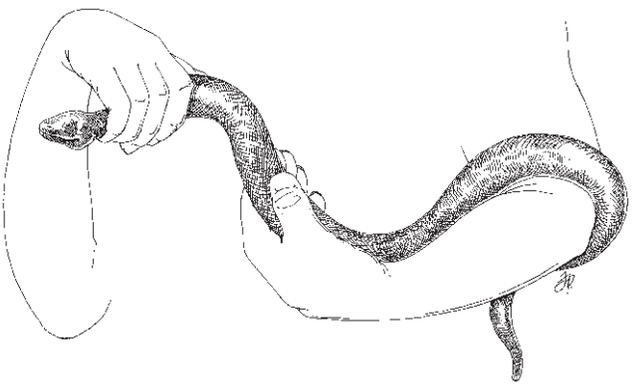

Figure 178-4. Proper restraint of a non-aggressive, non-venomous snake.

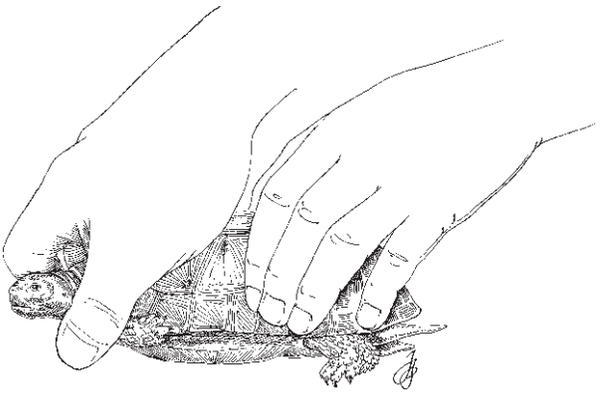

Figure 178-5. Proper restraint of a turtle.

are more secure if allowed to coil around an arm (Fig. 178-4). Most snakes struggle less when handled with minimal restraint. Never let any snake near your face or around your neck!

▼ ***Key Point*** Never pick a snake up only by its head only because serious damage to the spine may occur. Reptiles only have one occipital condyle, making it relatively easy to luxate the spine from the head. Always support the body.

If an aggressive, non-venomous snake arrives in a bag, grasp the head through the bag. If necessary, gently pin the head of free individuals with a snake hook or snare. Be careful not to injure the snake. Alternatively, grab the snake using a towel as a blind.

Large snakes can be very dangerous and may require up to six experienced people to restrain. Squeeze cages and sedation may be required to safely handle extremely large or aggressive individuals.

▼ ***Key Point*** Never handle venomous reptiles without expert assistance and the appropriate antivenin. Any mistake made by the veterinarian, a technician, or the owner may result in human death.

Chelonians

Hold chelonians by the dorsal caudal portion of the shell (Fig. 178-5). This placement makes it difficult for the animal to reach around and bite, or to scratch with its rear feet. Be sure to have a firm grip, especially if the turtle is wet. Always hold a chelonian over a table. Dropping a turtle may cause severe life-threatening shell fractures. Handle soft-shelled turtles with rinsed examination gloves, thus preventing damage to the delicate shell. Snapping turtles and some other long-necked turtles can reach the rear of their shells with their beaks. Grasp these turtles by the base of the tail. Hold them with tail in one hand and the front of the carapace just over the head in the other hand. Large snapping turtles are very dangerous to handle and should be left to experts.

Transportation

Transport non-venomous reptiles of moderate size in a tied cloth sack placed in a styrofoam or dedicated camping cooler containing air holes. Chelonians do not need to be placed in a sack. Coolers can be fitted with space for hot or cold water bottles or chemical packs if extreme temperatures are anticipated. These methods are to be used for transporting animals a short distance only.

History

▼ ***Key Point*** For most reptiles, improper husbandry is the primary predisposing factor for many diseases. Unless the diet and environment are improved, the best treatment plan will fail.

Ask the owner about the following:

- Species, age, sex
- Origin: initially, wild caught or captive bred; recently, pet shop or supply house
- Length of ownership, previous experience
- Environment, caging, cleaning, temperature, humidity, photoperiod, UV light source
- Diet: supplements, appetite, last meal, last stool
- Dates of unusual activity, breeding, egg laying, shedding
- Cagemates, quarantine history, aggressive behavior
- Medical history, previous weights
- Purpose of ownership: pet, breeder, display, education

Physical Examination

Observe the animal's behavior in the cage before handling. If necessary, observe healthy animals to become

familiar with normal behavior, locomotion, weight, skin tone, and color. All terrestrial lizards (legged) and chelonians normally can lift their bodies off the ground when they walk. Fork-tongued reptiles frequently should flick their tongues to sample the air. Prolonged head tilts are abnormal. Legs and/or epaxial muscles should be full and have good tone. The skin should have a healthy color and texture, without moist, discolored, or ulcerated areas. Dyspnea is abnormal, but do not mistake hissing for dyspnea. Examine the stools for abnormal color, consistency, urates, grossly visible parasites, and polyuria.

Develop a routine, systematic technique when performing the physical examination, such as working from head to tail. Check the nose for abrasions or discharge. Perform a thorough oral examination. Look for cyanosis, hyperemia, ulcers, discharge, abscesses, broken teeth, or parasites. Take samples of the choana or tracheal swabs for Gram staining or culture. Clear, viscous saliva is normal. Examine the mandibles for evidence of fibrous osteodystrophy or trauma. Examine the underside of the jaw and the periocular area for parasites. Look for retained spectacles when appropriate, and use a slit lamp and ophthalmoscope to examine the interior of the eyes. Examine the tympanic membrane, when present, which should be pliable with no exudate.

The heart of most herbivorous and insectivorous lizards is located under the pectoral girdle. To auscult the chest, place a moistened gauze sponge between the bell of the stethoscope and the skin, thus minimizing sounds from scales rubbing. The technique can be applied to turtles and crocodiles, but the shell of chelonians and the thick skin of crocodilians make interpretation more difficult. The heart beat of all but the largest snakes can be palpated through the ventral scutes. The heart is located in the first 15% to 25% of the body. Doppler units are helpful for determining heart rates.

Palpate the abdomen to detect masses, eggs, bladder, and feces. In snakes, start cranially and move caudally, letting abdominal organs slip through your hands. A mass is less likely to be overlooked when this method is used.

Check the vent for normal tone. This is an excellent time to obtain cloacal samples for Gram staining or culture and to examine the cloaca for parasites (especially ticks and mites). It is normal for stressed turtles to urinate, providing an opportunity to collect a urine sample. If a turtle does not urinate, this may be a sign of dehydration.

Palpate all extremities and check the skin for lesions. Especially examine the leg cavities in chelonians for external parasites and the ventral surface of all reptiles for signs of cutaneous lesions.

TECHNIQUES

Oral Examination

Snakes and Lizards

Use caution when opening the mouth. The teeth are sensitive and fragile, and broken teeth can cause prolonged anorexia. A snake's mandibles are very flexible and have an open symphysis. The jaws therefore are fractured easily if too much pressure is applied. Support the cranial cervical region to immobilize the head, and use the maxilla as a leverage point. Support the neck to minimize trauma to the cervical spinal cord. Use a thin plastic card or hard rubber spatula as a wedge in the corner of the mouth to gently pry open the mouth. Place pressure only on the gum line and never on the teeth. Once the mouth opens a little, slip the card across the mouth (see Fig. 178-1). A wedge or speculum may be necessary to hold the mouth open if the animal is large. Dewlaps, if present, may be used to provide downward traction.

Chelonians

To capture the head, wait until the turtle extends its head beyond the edge of its shell and quickly grasp the base of the head from over the top of the shell, using the shell as a blind. If a land turtle refuses to open its shell, it can be submerged in water to cover the opening to their shell. The head then can be grasped as it is extended to breathe. Remember this is stressful to the tortoise. Once the turtle is caught, extend the neck and restrain the head from the sides just behind the mandibles. Do not grasp the dorsal or ventral surfaces of the neck because the trachea or hyoid apparatus may be crushed. Gently and with persistent pressure pry the beak open with a thin metal spatula. An avian mouth speculum or hard rubber spatula then may be placed across the mouth. Always use a hard speculum if soft materials such as rubber catheters are going to be placed into the mouth. Use caution when opening the beak of an ill or malnourished turtle because beaks are often friable and easily damaged. Gauze strips may be useful in keeping the beak open and will not damage the beak. Some chelonians, especially tortoises, seal up in their shells, thus requiring sedation to extract their heads.

Venipuncture

Lizards and Snakes

Use the tail vein to draw blood from lizards, large snakes, and chelonians (Fig. 178-6). In snakes and lizards, the vein usually runs just ventral to the spine. In

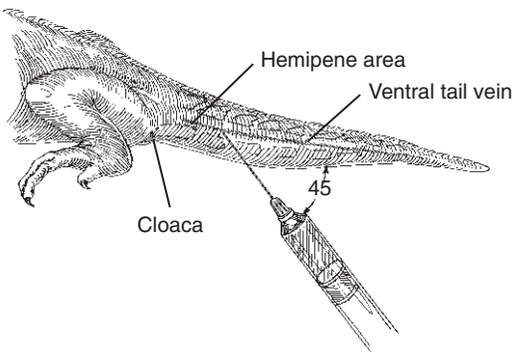

Figure 178-6. Venipuncture of ventral tail vein of a lizard.

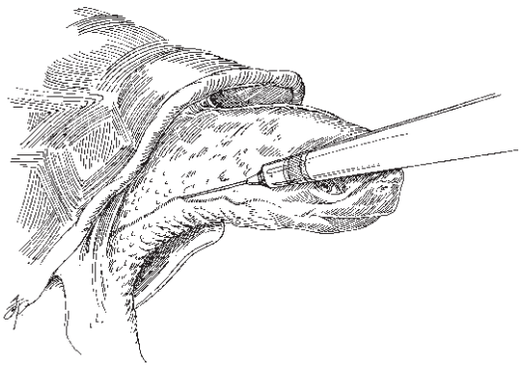

Figure 178-8. Jugular venipuncture site in a turtle.

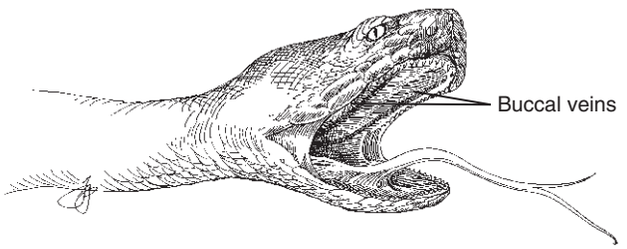

Figure 178-7. Venipuncture sites for the dorsal buccal veins of a snake.

males, be sure to insert the needle caudal to the hemipenes. Insert the needle in a cranial direction at a 45 to 60 degree angle. After the needle contacts the vertebral body, withdraw it 1 to 2 mm while aspirating until blood is seen in the hub of the needle. Aspirate gently to prevent collapse or laceration of the vein. A 1- or 3-ml syringe with a 25- or 27-guage needle works well. In all species, lymphatic vessels run parallel to the tail veins. Mixing of lymph and blood significantly alters hematology and some chemistry results.

Alternatively, open the mouths of boas and pythons with a soft spatula or tongue depressor to collect blood from the buccal veins on the inside of the mouth (Fig. 178-7). We have drawn intracardiac blood samples in hundreds of snakes with no pain response or subsequent ill effects observed.

Chelonians

Collect blood from the jugular vein whenever possible (Fig. 178-8). The vein is very mobile, so position the neck in a straight line. Hold off the vein at the base of the neck and locate the jugular vein visually or by palpation. Holding the turtle in a head-down position helps with filling of the vein. These vessels have a tendency to spasm; use atraumatic technique. Occlude the vessel for at least 2 minutes after venipuncture to prevent hematoma formation. Alternatively, blood may be collected from the tail vein, which is located on the dorsal surface of the spine at the base of the tail. The subcarapacial site is useful as it can be used to draw blood with the chelonian's head withdrawn or extended. A 1- to 1.5-inch needle may be advanced through the skin where it meets the carapace on the dorsal midline. Applying gentle suction, the needle is directed to the base of the eighth cervical vertebrae and into the anastomosis of the common intercostal veins until blood is seen in the hub of the needle. Brachial and femoral veins can also be used in chelonia.

Stomach Intubation

Non-Chelonians

- Warm fluids or formulas to 80°F to 90°F.
- To minimize regurgitation, administer no more than 1 to 6 ml/100g body weight per feeding.
- Measure the distance from the tip of the nose to the last rib in lizards and crocodilians, or from the tip of the nose to the first 10% of the body length past the heart in snakes.
- Open the mouth as described previously.
- Visualize the glottis at the base of the tongue. Avoiding the glottis, pass a flexible tube to the premeasured distance. Be certain the tube is not in the trachea and identify the glottis before administering any medication. If the glottis is not visible, palpate the neck for both the trachea and feeding tube, and administer sterile saline first.
- In animals with jaws strong enough to sever a stomach tube, use an avian speculum, a block speculum with a hole drilled in the center, or a sized-down Frick tube to protect the feeding tube.

▼ ***Key Point*** Medications given inadvertently in the trachea are usually fatal.

Chelonians

- Turtles are more difficult to intubate because their glottis frequently is hidden by the tongue. Some species possess a 90 degree turn in the esophagus just cranial to the stomach.

- Measure the distance from the nose to halfway down the plastron.
- After placing a speculum, aim the tip of the tube toward the dorsocaudal pharynx. Let the tube follow the dorsal wall down into the esophagus. Try to identify the glottis by gently pushing up on the hyoid apparatus. This pushes the tongue forward. If the glottis still is not visible, palpate the neck for both the trachea and feeding tube. Check tube placement with sterile saline before administering medications.

▼ ***Key Point*** Never force a stomach tube because this may create an esophageal tear.

- If regurgitation occurs, cover the end of the tube to prevent dribbling and withdraw the tube. Turn the animal's head down and wipe out the mouth with paper. (Cotton or cloth will entangle on squamate teeth.) Wait until the animal is recovered and less stressed before making a second attempt, and decrease the volume to administer by one half. If no regurgitation occurs, slowly increase the volume over several feedings to the desired amount.

Perform a *stomach wash* on all vomiting reptiles. Intubate the stomach as aforementioned with a red rubber feeding tube, and give warmed 0.9% NaCl (3–6 ml/100 g body weight). Gently massage the stomach and aspirate the fluid. Use the fluid for bacterial or fungal cultures, cytologic examination, Gram staining, immunofluorescent antibody (IFA) tests for *Cryptosporidia*, or direct saline smear for evidence of parasites.

Enema

Administer a mixture of 50% K-Y jelly and 50% 80°F water into the cloaca/colon at a rate of 1 to 3 ml/100 g body weight. Excellent restraint is essential. Select a red rubber urinary catheter that is approximately 0.25 times the size of the vent opening. In very small animals, tomcat catheters may be used to provide rigidity. The catheter is lubricated with a water-soluble lubricating jelly. Start the catheter at a 90-degree angle to the body. After the tip of the catheter passes the opening of the vent, aim it cranially, parallel to the colon, and advance. Never force the catheter or fluid into the cloaca, or cloacal perforations may occur. Never use high pressure to inject fluid into the cloaca. This may cause feces to be forced into the ureters or oviducts, resulting in life-threatening infection.

Injections

Always administer injections cranial to the kidneys to avoid the renal portal system (Fig. 178-9).

Subcutaneous

In non-chelonians, administer fluids or other therapeutic agents over the axillary region as in mammals. In turtles, use the skin folds located around the front and rear legs. If using the inguinal region, be sure not to puncture through the body wall. Fluids should be warmed to 80°F to 95°F.

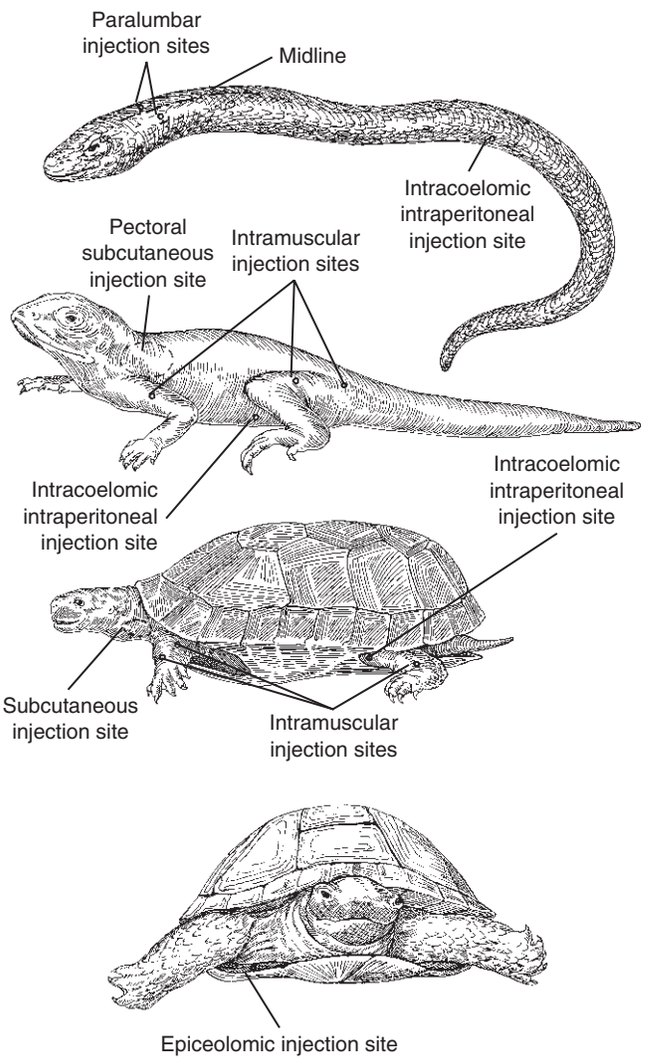

Figure 178-9. Common injection sites in a snake *(top)*, lizard *(center)*, and turtle *(bottom)*.

Epicoelomic

This region is medioventral to the front legs and is used to administer fluids to chelonians. Absorption is excellent in animals with adequate perfusion (see Fig. 178-9).

Intramuscular

In snakes and legless lizards, administer IM injections into the epaxial muscles. In all other reptiles, use the muscles of the front legs. The rear legs and the epaxial muscles of the tail may be used for injection of non-nephrotoxic drugs. Insert the needle between scales to

minimize damage to the skin. With the bevel of the needle pointing up, aim proximally using a 45-degree angle. Always aspirate before injecting.

Intraosseous

Because most reptilian veins are not easily accessible, it may be necessary to use an IO route to administer medications and fluids. In lizards, try the distal femur, proximal tibia, proximal humerus, or distal radius.

- Surgically prepare the entry site.
- Choose a spinal needle that is 33% to 66% the diameter and length of the chosen bone.
- Identify the tibial crest or the dorsal midline of the distal femur just proximal to the condyles. Advance the tip of the needle through the skin at a 45- to 90-degree angle until the tip of the needle is through the cortex of the bone.

▼ ***Key Point*** It is extremely important to keep the needle straight while boring through the cortex to avoid extravasation of fluids.

- A sudden lack of resistance is felt once the tip of the needle enters the marrow cavity. At this point, angle the needle down the length of the bone and advance it until the hub is seated against the skin. The needle should advance easily.
- Once the needle is seated, remove the stylet. Attach a syringe and aspirate. In most cases bone marrow can be seen in the hub of the needle. If no marrow is identified on cytology, obtain radiographs to ensure appropriate placement of the catheter. Flush the intraosseous catheter with heparinized saline. Secure it to the skin with sutures.
- Although it is wise to avoid caustic substances, treat the catheter as if it were an intravenous catheter. Catheters can be maintained for 72 hours.
- In turtles, administer intraosseous fluids into a thickened area of bone (bridge) that underlies the shell where the plastron and carapace meet (Fig. 178-10). Use a spinal needle.

Intracoelomic

▼ ***Key Point*** Intraperitoneal injections have the potential for causing peritonitis or respiratory compromise. Always prepare the area with a surgical scrub.

Use this technique for administration of fluids when other routes are not possible. Warm fluids to 80°F–85°F. Avoid caustic substances because they can cause chemical peritonitis. In chelonians, give injections just cranial to the rear legs. Extend the rear legs and administer the injection with the animal in held in a head-down position. In snakes and lizards, inject fluids slightly off the ventral midline in the caudal third of the abdomen. Hold the head in a downward position while injecting (see Fig. 178-9). Always aspirate to ensure that the injection is not being given into the bladder, oviduct, or bowel.

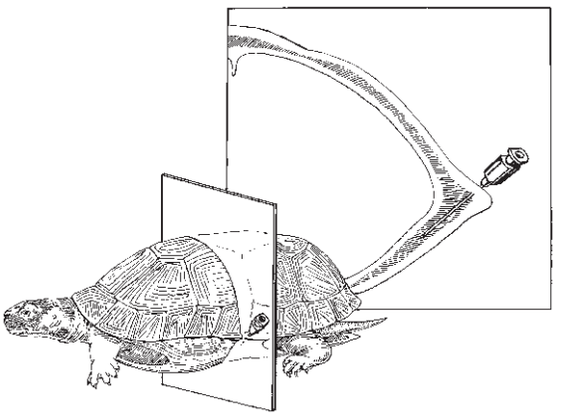

Figure 178-10. Intraosseous injection site of the turtle.

- **Do not use this technique in gravid females. Exceeding 2% to 3% of the body weight in fluids may result in respiratory compromise.**

Radiography

Diagnostic radiographs require a machine capability of at least 100 ma and exposure times of less than 1⁄60 second. Use rare earth screens when possible. Diagnostic radiographs require two views. Dorsal ventral views and standing lateral views are easier to obtain and interpret than ventral dorsal or lateral recumbent films.

To evaluate the lungs of turtles with suspected pneumonia, obtain an anterior/posterior horizontal beam view in addition to those aforementioned.

Contrast Radiography

GI transit times in reptiles are normally prolonged compared with those of mammals. Therefore, contrast studies have limited use. When 20–50 ml/kg of barium is administered to carnivorous lizards, it may take 3–6 days to reach the cloaca. When this dosage is administered to snakes, crocodilians, and herbivorous lizards, it may take up to 30 days. At a dosage of 20 ml/kg, barium requires 40 days to reach the cloaca in tortoises. Always ensure that the animal is well hydrated before the administration of barium, or it may become desiccated in the bowel, often requiring surgical removal. We have had excellent results using a 1:3 dilution of iohexol:saline as a contrast agent.

For evaluation of the coelomic cavity, ultrasound is an extremely useful diagnostic technique. A 5.0, 7.5, or 10 mHz transducer is necessary.

ANESTHESIA

Isoflurane is the anesthetic agent of choice for reptilian patients. Although the recovery period is prolonged, halothane also has been used successfully for anesthe-

sia in reptiles. Methoxyflurane also has been used successfully, but deaths in snakes have been reported. Sevoflurane can be used, but the increased cost compared to isoflurane may not be justified.

A single intravenous or intraosseous bolus of propofol is an excellent induction agent and is also useful for short procedures. Anesthesia from a single injection usually lasts 10 to 15 minutes and reptiles are usually fully recovered in less than 40 minutes. A short-term, self-limiting apnea is common. It is prudent to provide positive pressure ventilation if the apnea persists longer than 2 minutes. All anesthetized reptiles should receive supplemental oxygen.

▼ ***Key Point*** Creating a hypothermic state is never an acceptable method of anesthetizing reptiles. Hypothermia does not provide analgesia, slows healing, and depresses the immune system.

Anesthesia in reptiles is highly temperature dependent. External heat sources are necessary during anesthesia and recovery. Heating pads and forced air warmers work well intra-operatively. Always place the animal in a preheated incubator during recovery. Cold reptiles are immunocompromised, heal slowly, and may take days longer to recover from anesthesia.

Induction

Use mask induction with 2% to 4% isoflurane with the animal restrained in a towel or use propofol. An induction chamber is useful for aggressive animals. The first sign of anesthetic induction is excitement, then voluntary motor control is lost. Loss of the righting reflex is followed by muscle relaxation, indicating a surgical plane of anesthesia. Reptiles with third eyelids retain a slowed third eyelid reflex even when no pain response is elicited. In these animals, a loss of the blink reflex indicates a need to lighten the depth of anesthesia.

Chelonians, aquatic squamates, and crocodilians can hold their breath for long periods of time, so induction with injectable anesthetics is often necessary (see below).

▼ ***Key Point*** Once relaxation occurs, intubate the animal and begin positive pressure ventilation.

If placing an endotracheal tube is difficult in a chelonian, move the front limbs in and out to maintain air flow until a tube is placed.

Intubation

Inflatable cuffs are not recommended for small animals. Inflating the cuff may cause tracheal inflammation severe enough to occlude the trachea. Endotracheal tubes for small individuals can be fashioned from catheters and infant feeding tubes. Because most reptiles become apneic during anesthesia, always have the animal intubated to provide positive pressure ventilation. Ventilate animals at a rate of 3–6 breaths per minute.

Maintenance

Maintain anesthesia at 1% to 2% isoflurane at 1 L of oxygen per 0.3 to 1 kg of body weight. Larger reptiles usually require 1 L per 5 to 10 kg of body weight. Be sure to monitor heart and respiratory rates. A marked reduction in either of these two values is an indication to lighten anesthesia.

Recovery

When isoflurane is used, animals may recover within 20 minutes. Many other anesthetics (and occasionally isoflurane) may cause prolonged recovery periods, lasting hours to days. Assisted ventilation is required until spontaneous respirations occur. Be prepared to offer ventilatory assistance as long as necessary, even if the reptile takes hours to breathe on its own. To speed recovery times, place the animal in a warm environment and continue fluid therapy during recovery. Ventilating with room air or providing small levels of carbon dioxide (such as exhaled air) instead of 100% oxygen will sometimes stimulate the respiratory centers.

Injectable Anesthetics

Isoflurane or propofol should be used for anesthesia whenever possible because recovery times are prolonged and dosage titration can be difficult when using other injectable anesthetics.

Ketamine Hydrochloride

Most reptiles require 20 to 60 mg/kg IM or 5 to 15 mg/kg IV. Crocodilians often require the higher end of the dose range. Ketamine provides marginal relaxation and analgesia. It may be used for as sedation for non-painful procedures or as a preanesthetic for reptiles that cannot be induced with a gas anesthetic.

Tiletamine Hydrochloride

The dose for tiletamine is 10 to 40 mg/kg IM in squamates, 15 mg/kg IM in crocodilians, and 5 to 15 mg/kg IM in chelonians. Induction usually requires less than 30 minutes. At safe levels of anesthesia, the righting reflex is slowed but not eliminated. Expect bouts of paddling and head pressing and expect the palpebral reflex to be unaffected. The recovery period lasts an average of 3 hours. This drug is not recommended for surgical procedures.

Medetomidine

Combinations of medetomidine and ketamine have been used successfully in reptiles. Dose and effect are species dependent. Alligators have been anesthetized with 100 mcg/kg medetomidine and 7 mg/kg ketamine

IM with atipamazole given at 500mcg/kg to reverse the anesthesia. Tortoises typically require less medetomidine with dose ranges of 20 to 60 mcg/kg with 2.5 to 10 mg/kg of ketamine. Consult the literature for specific doses for the species in question.

Propofol

In reptiles with adequate venous access, propofol provides a safe, rapid induction of anesthesia sufficient for short procedures or to facilitate intubation and maintenance with gas anesthetics. Doses range from 2.5 to 15 mg/Kg IV or IO. Supplemental oxygen should always be used, because propofol can cause hypoventilation including apnea.

Analgesia

Reptiles have neurological components similar to those found in birds and mammals and have been shown to experience pain. With careful observation, reptiles can be seen displaying appropriate behavioral responses to nociception stimulation. All procedures that would be considered painful in other classes of animals should include analgesics to alleviate pain. Hypothermia is not considered a effective or humane analgesic. Preemptive analgesia helps to decrease postoperative pain including both neuropathic and inflammatory pain. Butorphanol has been used an analgesic as well as an anesthetic premedication. Meloxicam has been used as a nonsteroidal analgesic for many years in reptiles in Europe prior to its release in the United States. To prevent renal side effects, reptiles should be well hydrated when receiving nonsteroidal anti-inflammatory medications.

SURGERY

Suture Materials and Suture Placement

- Reptiles do not possess the enzymes needed to absorb gut sutures. Polydioxanone is the absorbable suture of choice. Polyglactin 910 or similar materials also may be used. In sea turtles poliglecaprone 25 and polyglyconate caused less tissue reaction than chromic gut or polyglactin 910.
- When closing the coelomic cavity, the peritoneum and muscle layers should be closed, but the skin is the holding layer.
- The skin must be closed in an everting pattern to allow dermis-to-dermis contact. Non-absorbable sutures, such as nylon, should be removed after one to two sheds have occurred.

Approach to the Coelomic Cavity

A perimedian approach is necessary in non-chelonian species to avoid the central ventral vein. In snakes, the location for the approach is usually one to two scale rows dorsal to the belly scute. This site avoids the central ventral vein and the ribs and prevents placement on a surface in constant contact with the ground. Seek assistance before performing a plastronotomy on a chelonian for the first time.

DRUG THERAPY

The use of various drugs in reptiles is similar to that in other genera with application of the following guidelines:

- Maintain reptiles at the high end of POT to enhance normal metabolism of drugs.
- Pay attention to species differences. A snake is less related to a turtle than a cat is to a cow. Drug clearances and toxicities are often species related.
- When available, use published dosages based on pharmacokinetic studies. Be aware that metabolic scaling is not always accurate.
- Weigh all animals before dosing drugs. Accurate dosages based on body mass are extremely important in avoiding side effects.
- When in doubt about renal clearance or hydration status, institute fluid therapy.
- Use bactericidal versus bacteriostatic antibiotics whenever possible.

In general avoid use of injectable gentomycin. Amikacin is much safer. The authors recommend that use of gentomycin be limited to topical preparations.

In general reptiles are exquisitely sensitive to glucocorticoids. Only use when indicated. Use the lowest effective dose for the shortest length of time. Be aware that immunosuppression may persist for months.

▼ ***Key Point*** Never use ivermectin in chelonians. It is toxic and is associated with neurologic dysfunction and possible death.

- See Table 178-3 for dosages of common chemotherapeutic agents used in reptiles.

COMMON DISEASES OF REPTILES

Failure to adapt to captivity is the principal cause of death in captive reptiles. The captive environment is so alien to a wild-caught reptile that stress induces immunosuppression and anorexia. Secondary infections and starvation cause death of the animal.

▼ ***Key Point*** Most diseases of reptiles are secondary to poor husbandry and nutrition.

Bacterial Infections

Both enteric commensal bacteria and pathogenic bacteria are usually gram negative. Large numbers of

Table 178-3. REPTILE CHEMOTHERAPEUTICS

Drug	Species	Dosage	Route	Frequency	Notes
Acyclovir	Tortoises	30–80 mg/kg	PO	sid or tid 10 days	Herpes virus
Allopurinol	Most species	10–20 mg/kg	PO	sid	
	Chelonians	50 mg/kg	PO	sid × 30d, then q72h	
Amikacin sulfate	Sea Turtle	2.5–3.0 mg/kg	IM, SC	q72h × 5 treatments	Loading dose 5 mg/kg, keep hydrated
	Lizards	5 mg/kg	IM, SC	sid	
	Various snakes	2.5–5 mg/kg	IM, SC	q72h	
Aminophylline	Most species	2–4 mg/kg	IM		
Amoxicillin	Most species	10–22 mg/kg	IM	sid, bid	Anaerobic spectrum
Ampicillin	Most species	8–10 mg/kg	IM	bid	Anaerobic spectrum
	Most species	20 mg/kg	IM	sid	
Atropine	Most species	0.01–0.04 mg/kg	IV, IM	q8–24h	
Azithromycin	Ball Python	10 mg/kg	PO	q48–72h	
Barium	Most species	5–20 ml/kg	PO		Contrast studies
Buprenorphine	Most species	0.005–0.02 mg/kg	IM	sid to qid	Analgesic
Butorphanol	Green Iguana	2 mg/kg	IM		Premedicate before administering isoflurane, high dose in literature
Butorphanol	Most species	0.05–1 mg/kg	IM, IV, PO	bid	Analgesic
Calcium glubionate	Most species	1 ml/kg	PO	sid	Rugby Laboratories, Inc., Norcross GA; oral calcium supplement
Calcium glubionate	Most species	10 mg/kg	PO	sid, bid	Hypocalcemia
Calcium gluconate	Most species	10–100 mg/kg	SC, IM, IP	sid	
Calcium lactate/glycerophosphate		5–25 mg/kg	SC, IM	sid	
Carbenicillin	Most species	200–400 mg/kg	IM	sid q48h	Often combine with aminoglycoside
Carprofen	Most species	1–2 mg/kg	IM, SC, PO	q24–72h	Loading dose 2–4 mg/kg, hydration important
Ceftaxidime (Fortaz)	Various turtles	20 mg/kg	IM	q72h	Shell infections
Ceftiofur	Most species	2–4 mg/kg	IM	sid	
Cephalexin	Green Iguana	40 mg/kg	PO	bid	Prophylactic antibiotics during surgery
Clindamycin	Most species	2.5–5.0 mg/kg	PO	sid	Anaerobic spectrum
Colchicine		Dose not established			Treatment of gout
Dexamethasone SP	Most species	0.125–0.75 mg/kg	IM, IV	Once	Use sparingly—prolonged depression of immune system
Diazepam	Most species	2.5 mg/kg	IV, IO		Treatment of seizures
Doxapram	Most species	5 mg/kg	IM, IV		Respiratory stimulant
Enrofloxacin	Leopard Gecko	10 mg/kg	PO	q48h	
Enrofloxacin	Most species	5–10 mg/kg	IM, SC, PO	sid	Irritating IM or SC
Epinephrine 1 : 1000	Most species	0.5–1.0 ml/kg	IV	Once	Cardiac arrest
Fenbendazole	Most species	50–100 mg/kg	PO	Single dose	Repeat in 2 wks
Fluconazole	Sea Turtle	10 mg/kg	PO	q5d	Loading dose, 21 mg/kg
Fluids	Most species	20–25 ml/kg/24hr	IV, PO, IO	Daily	Maintenance dose, shock dose 1–3% BW
Gentocin			TO		Use topically only—renotoxic
Halofusinon		Dose not established			Used in treating cryptosporidium
Iohexol 240mg/ml	Most species	5–20 ml/kg	PO		Contrast studies
Iron Dextran	Crocodilians	12 mg/kg	IM	q2 wks	Anemia
Itraconazole	Sea Turtle	5 mg/kg	PO	sid	
Ivermectin	Most species	0.2 mg/kg	PO, SC		*Never in turtles*
Ketoconazole	Most species	15–25 mg/kg	PO	sid	Antifungal
Ketoprofen	Most species	2 mg/kg	SC, IM	q24–48h	Hydration is important
Levamisole	Various turtles	5 mg/kg	IM	Once	Antiparasitic treatment, can be hepatotoxic

Table continued on following page

Table 178-3. REPTILE CHEMOTHERAPEUTICS—cont'd

Drug	Species	Dosage	Route	Frequency	Notes
Meloxicam	Most species	0.1–0.2 mg/kg	PO	sid	Analgesic
Metoclopromide	Most species	0.06 mg/kg	PO	sid	
Metoclopromide	Tortoises	1–10 mg/kg	PO	sid	
Metronidazole	Corn snake	50 mg/kg	PO	q48h	
Nystatin	Most species	100,000 IU/kg	PO	sid	Antifungal
Oxyglobin	Most species	10 ml/kg	IV		Blood loss, shock, give over 10–15 min, follow with crystalloid fluids
Oxytocin	Turtles	1–10 IU/kg	IM	sid	Induction of oviposition, risk of oviduct rupture
Paromomycin	Green Iguana	100 mg/kg	PO	sid 14 days	Treatment for cryptosporidium—variable results
Pipercillin	Green Iguana	100 mg/kg	IM	q48h	
Praziquantel	Loggerhead Sea Turtles	25 mg/kg	PO	3 doses 3 hours apart	Treatment for spirorchiids, based on plasma levels
Praziquantel	Most species	5–8 mg/kg	IM, PO	Single dose	Repeat in 2 wks
Probenecid		Dose not established			Treatment of gout
Propofol	Marine Iguana	12–15 mg/kg	IV		Anesthesia induction
Propofol	Snakes	2.5–10 mg/kg	IV, IC		Anesthesia induction
Propofol	Various turtles	10 mg/kg	IV		Anesthesia induction
Provent-a-mite	African Spurred Tortoise	Spray on tortoise	TO	q5d	For 6 treatments
Provent-a-mite	Green Iguana, Rosy Boa	Spray in cage	TO	q5d	For 6 treatments

Vitamin E	Most species	1 IU/kg	IM		
Vitamin K_1	Most species	0.25–0.5 mg/kg	IM		

monomorphic gram-negative bacteria or identification of intracellular bacteria on Gram-stained specimens are suggestive of bacterial disease. Perform bacterial cultures on samples collected from suspected infection sites. Anaerobic bacteria are common pathogens found in reptiles with lower respiratory infections.

▼ ***Key Point*** Reptiles are known carriers of leptospirosis and *Salmonella* spp. Inform clients of potential zoonoses. *Salmonella* spp. live in the intestines and are transmitted to people when fecal material is handled.

Many species of reptiles have adapted to some strains of *Salmonella* spp. These bacteria do not cause disease and may be necessary components of the normal intestinal flora. *Salmonella* spp. in this category may or may not cause disease in humans or other species of reptiles. However, certain serotypes of *Salmonella* are highly pathogenic and may cause diarrhea, pneumonia, or septicemia. Fecal cultures do not distinguish pathogenic from nonpathogenic *Salmonella* serotype. Consider *Salmonella* spp. to be a significant pathogen when isolated directly from a grossly visible lesion, the respiratory tract, or intestinal tract of animals demonstrating clinical signs of enteric disease. Prophylactic treatment with antibiotics does not eliminate carrier stages.

It is almost impossible to eradicate *Salmonella* from pet reptiles. The following recommendations are aimed at controlling the spread of *Salmonella* and its ability to cause disease.

1. Minimize stress. Keep reptiles in the best husbandry situation possible. Avoid mixing species.
2. Proper hygiene is essential. Disinfect and clean cages regularly, but do not clean cages in food preparation areas (kitchens) or bathrooms. Wash hands/equipment between animals, after handling, and before eating or smoking.
3. Perform a necropsy on all dead animals.
4. Reptiles are not recommended pets for immunocompromised people, such as infants, toddlers, elderly people, chemotherapy recipients, and people with acquired immunodeficiency syndrome (AIDS).

COMMON DISORDERS IN BOAS, PYTHONS, AND LIZARDS

Anorexia in Boas and Pythons

Etiology

Anorexia may occur with or without obvious weight loss. Obtain a thorough history. Often there are no other signs of disease. Inadequate husbandry, particularly in the areas of temperature gradient, seclusion, selection of prey item (e.g., color, size, temperature if thawed, species, ability to attack), light cycle, crowding, and adequate hydration or access to water, are the most common causes of anorexia.

Diagnosis

If husbandry problems are found and the animal appears otherwise healthy, perform a fecal float and fecal direct smear to rule out intestinal parasitic infections.

If the animal has not eaten for more than 2 months and has lost significant body condition, consider further diagnostics such as hematology, serum chemistry, cultures and radiographs.

Treatment

Treatment is based on improving husbandry and removing any parasites. Common helpful recommendations include:

- Use a thermometer to accurately measure the temperature gradient in the cage.
- Provide a hide box and feed stunned prey in the hide box.
- Monitor the light cycle. Ensure a 12-hour-to-12-hour light-dark cycle.
- Try another species, color, or different size prey. Warm dead prey to 100°F in a plastic bag and ensure that the prey item is not wet when offered to the snake.
- Feed when quiet or dark. Do not handle snakes for 1 week after feeding.
- Provide a water dish large enough for the snake to sit in.
- Feed stunned prey if dead prey are not accepted.

If the reptile appears ill, assume that it also is dehydrated. Rehydrate with intraosseous (non-snakes), subcutaneous, or oral fluids depending on the state of hydration. Pass a stomach tube and administer warmed isotonic fluids to prepare the gut to receive solid food. Later, add glucose or electrolyte powders to increase the osmolality. Once this solution is tolerated, the formula may be changed to an iso-osmolar enteral feeding product such as (Ensure or Critical care). If this is tolerated, add meat baby food to the mixture to begin to introduce solid foods to carnivores. When ready to feed prey to carnivores, offer pinkies or small rodents first, and slowly increase the size of the prey.

In severely ill lizards and chelonians, placement of a pharyngostomy tube will greatly facilitate administration of supplemental nutrition. After herbivores or omnivores accept iso-osmolar diets, use a mixture of vegetable baby food mixed with alfalfa pellets or commercial diet formulated for rabbits mixed with water to increase the fiber load. First feed softer plants and/or insects to herbivores and insectivores to prepare the gut for a regular diet. As these are accepted and digested normally, slowly add in the normal diet.

Respiratory Disorders

Pneumonia

Etiology

Pneumonia is usually secondary to poor husbandry, bacterial septicemia, oral infections (stomatitis) or lung parasites.

Clinical Signs

The clinical signs of pneumonia include nasal discharge, gurgling, bubbling, open-mouthed breathing, and anorexia. Concurrent eye and mouth infections are common.

Diagnosis

Diagnosis usually is based on tracheal cytology and cultures. Other useful diagnostic tests include fecal flotation, hematology, bronchoscopy, and radiography.

Treatment

Administer antibiotics based on culture and sensitivity testing, or anthelmintic or antifungal drugs if indicated. Increase the environmental temperature to the high end of the POT. Parenteral vitamin C, fluid therapy, and nebulization therapy may be necessary.

Nebulize warmed saline to loosen debris in the bronchi. Antibacterial or antifungal medications may be added. A crude but apparently effective form of "nebulization" can be accomplished by the owner at home by using a hot shower to fill a bathroom with steam for 1 hour daily. Severely dyspneic individuals may require oxygen therapy. The long-term prognosis for these animals is grave. Arranging cage furniture to allow postural drainage is particularly helpful in some snakes.

Pentastomids

Etiology

Pentastomids are degenerate arthropod parasites of reptiles that resemble segmented worms. Infection occurs through an indirect life cycle involving insects and mammals. The parasites may live anywhere in the body but prefer the lungs and subcutaneous space.

Clinical Signs

Clinical signs in severely affected animals include dyspnea, hemoptysis, and cachexia. Occasionally a pentastomid may penetrate the body wall. Pentastomids can be acutely fatal in hatchling crocodilians.

Diagnosis

Diagnosis is based on fecal examination, tracheal cytology, or bronchoscopy.

Treatment

There is no routinely effective treatment for pentastomiasis. Ivermectin will kill adults, but debris from dead parasites often still causes clinical signs. A group of Boelen's pythons were successfully treated with a combination of fenbendazole 50 to 100 mg/kg and ivermectin 0.2 mg/kg PO SID for three treatments. Because this parasite may be zoonotic and is not readily treatable, consider euthanizing infected animals. Infection can be avoided in captive-reared animals by feeding only domestically reared prey items.

Infectious Stomatitis (Mouth Rot, Ulcerative Stomatitis)

Etiology

Mouth rot is usually secondary to poor husbandry, trauma from cage rubbing, or trauma from a rodent bite. The most common bacterial agents are *Aeromonas* and *Pseudomonas,* although other bacteria and fungi also are involved frequently. Neoplasia, mycotic infections, parasitic granuloma, or mandibular fractures also may cause stomatitis. Herpes virus in tortoises and vitamin A deficiency in turtles are also often associated with oral ulcers and caseous plaques (See "Chelonians").

Clinical Signs

Early signs of mouth rot include oral petechia, ptyalism, and anorexia. As the infection progresses, caseous exudate, tooth loss, and osteomyelitis may be present. Mouth infections are frequently the nidus for concurrent eye infections and pneumonia.

Diagnosis

Perform a thorough oral examination and collect samples for cytologic examination. Obtain samples for bacterial culture and sensitivity testing, especially if caseous debris is found. The most accurate culture samples are obtained by making a small slit in an affected area of the gum and swabbing the underlying tissues. In advanced cases, perform skull radiographs to determine the extent of osteomyelitis. If animals are anorexic, collect blood samples for hematology and blood chemistries.

Treatment

In mild cases in which petechia and ptyalism are present without anorexia, apply topical iodine, chlorhexidine solution, or hydrogen peroxide twice daily and instruct owners to improve husbandry. Reptiles with stomatitis should be housed at the high end of the POT. In more advanced cases, surgical debridement of the caseous debris, nutritional support, fluid therapy, and systemic antimicrobials may be required. Administer a combination of enrofloxacin and amoxicillin until culture results are available (see Table 178-1).

Prognosis

In mild cases, the prognosis is excellent if husbandry improves. The prognosis is guarded for cases with significant caseous debris and grave for reptiles with significant osteomyelitis.

Gastrointestinal Disorders

Regurgitation in Boas and Pythons

Vomitus often looks like a stool containing no urates. Use pH papers to identify vomitus if necessary. Fresh vomitus has an acid pH, whereas feces are basic. Old vomitus becomes alkaline with bacterial decomposition. The regurgitation of only mucus is a grave sign.

Poor Husbandry

Excessive handling of snakes within 48 hours of ingesting a meal may result in regurgitation. In these animals, regurgitation occurs shortly after handling. Base the diagnosis on history, lack of other clinical signs, and radiographic evidence of calcified remains of a meal in the stomach for more than 50 hours post-prandially.

Diagnosis

A low body temperature inhibits the action of digestive enzymes, resulting in putrefaction of the ingested meal. In these snakes, regurgitation usually occurs 3 to 5 days post-prandially. The diagnosis is based on history and a lack of other clinical signs.

Treatment

Treat by providing an adequate, safe heat source 24 hours a day.

Obstruction

Foreign bodies usually are ingested with prey items and include cage substrates, cage furniture, and foreign bodies inside of prey items. Clinical signs include regurgitation, absence of fecal material, abdominal swelling, and anorexia. Diagnosis is similar to that for mammals and includes plain radiography or endoscopy. Perform hematology and blood chemistries on systemically ill animals.

Treatment

Treatment is similar to mammals. In mild cases in which the obstruction consists of small pieces of granular material, administer saline or mineral oil via stomach intubation. Parenteral fluids are also helpful. If a large foreign body is located in the stomach, endoscopic retrieval is often possible. Gastrotomy or enterotomy may be required to remove large objects or objects distal to the stomach.

Similar clinical signs may be seen in animals with intraluminal or extraluminal GI masses. Causes include neoplasia, abscess, or granuloma of the GI tract or other nearby organs, parasitic blockage, or organomegaly. Diagnosis is based on radiographs, ultrasound, fine-needle aspirate for cytologic examination and culture, or laparotomy and biopsy. Hematology or blood chemistries usually are indicated.

Diarrhea

Etiology

Gastroenteritis may be caused by enteric parasitic infections, gram-negative bacterial or clostridial infection, viral infections, or enteric fungi.

Diagnosis

- To rule out parasitic infections, perform fecal flotation, a fecal wet mount, and stomach wash, especially if diarrhea is accompanied by vomiting. Fecal sedimentation may be required if trematodes are suspected. Most cysts, eggs, and larvae can be identified to taxonomic family to direct anthelmintic treatment.
- Clinical bacterial or mycotic enteritis is often secondary to significant parasite infestations. Perform a fecal Gram stain to diagnose clostridial overgrowth or enteric yeasts. High numbers of monomorphic gram-negative rods are supportive of a diagnosis of bacterial enteritis (see "Bacterial Infections"). Routine culture techniques are not reliable in detecting *Salmonella*.
- Other diagnostic tests that may be useful include hematology, serum biochemistry, peritoneal lavage, and endoscopy.
- Other causes of diarrhea include foreign body, ruptured coelomic abscess, septicemia, and liver or pancreatic disease.

Treatment

- Administer fenbendazole for the prophylactic treatment of intestinal parasites.
- Administer praziquantel if cestodes or trematodes are suspected or found on fecal examination.
- Levamisole or ivermectin may be effective against acanthocephalans. Ivermectin is toxic to chelonians.
- Pending bacterial culture results, administer fluid therapy and parenteral antibiotics. In mild cases of dehydration, subcutaneous lactated Ringer's solution is an excellent choice. Fluid volumes should be calculated as for mammals, incorporating fluid losses from vomiting and diarrhea as well as maintenance needs. In severely dehydrated reptiles, use intraosseous fluids when possible. Administer half-strength lactated Ringer's solution or saline with 2.5% dextrose for the first 4 hours, followed by lactated Ringer's or other balanced electrolyte solution alone. Monitor serum or plasma potassium levels and add potassium to the fluids as needed.
- Parenteral administration of antibiotics is necessary in reptiles with GI disease. A combination of enrofloxacin with amoxicillin or ampicillin is usually effective in the treatment of most gram-negative,

gram-positive, and anaerobic bacterial pathogens. This combination does not appear to have detrimental effects on GI flora when administered parenterally and has low potential for nephrotoxicity in dehydrated reptiles.

Cryptosporidium

Etiology

- *Cryptosporidium serpentis* is a protozoal parasite of snakes and some lizards and tortoises. The parasite infects the stomach and large and small intestines, causing atrophy of intestinal villi and hypertrophy of the stomach wall.

Clinical Signs

- The classic clinical signs include diarrhea, regurgitation 2 to 3 days post-prandially, and marked gastric distention causing a visible fusiform swelling in the stomach region. It has also been associated with biliary disease in corn snakes, otitis in iguanas, and general enteritis in many lizard and snake species. Renal cryptosporidium has been seen in iguanas and chameleons. Chronic disease causes anorexia and weight loss. A subclinical carrier state exists. Cryptosporidium tends to be a gastric disease in snakes and an intestinal disease in lizards.

Diagnosis

- Diagnosis is confirmed by identification of cysts on cytologic examination of fluid obtained from a stomach wash or stomach biopsies. Cysts occasionally are seen in feces. Cysts are 2.6 to 6.0 µm in diameter and stain blue on Giemsa stain. Yeasts can look very similar. If in doubt, stain the slide with iodine. Yeast turns brown and cysts remain colorless. Alternatively, *Cryptosporidium cysts* stain positive with acid fast stains, whereas yeasts do not. Immunofluorescent antibody (IFA, Merifleur) testing is available and is 16 times more sensitive than acid fast stains especially when performed on stomach biopsies. A serological enzyme-linked immunosorbent assay (ELISA) test is available for use in snakes.

Treatment

- There is no effective treatment for cryptosporidiosis. Paromycin, halofuginone, spiramycin reduce shedding of oocysts, but do not eliminate infection. Toltrazuril has been used to relieve clinical signs in one group of tortoises, but is toxic in snakes. Bovine hyperimmune colostrums to *Cryptosporidium parvum* administered via gavage at 1% of body weight once a week for 6 weeks reduced clinical signs and oocyst shedding in several snakes and geckoes, but did not clear the infection. Recommend permanent isolation from uninfected reptiles or euthanasia because animals remain carriers and *Cryptosporidium* oocytes are extremely resistant to environmental degradation.

Amebiasis

Etiology

Amebiasis caused by *Entamoeba invadens* is diagnosed commonly in recently acquired snakes and lizards. The likelihood of infection increases if the animals previously were exposed to chelonians. Amoebiasis can also affect normally resistant groups of reptiles (water turtles, crocodilians, and reptile-eating snakes and lizards). The parasite causes a hemorrhagic gastroenteritis and liver necrosis.

Clinical Signs

Clinical signs include anorexia in early infestations, followed by regurgitation and hematochezia.

Diagnosis

Diagnosis is based on identification of cysts or trophozoites on cytologic examination of fluid obtained from a stomach wash or fecal smear.

Treatment

Administer metronidazole and initiate supportive therapy as needed. Prognosis for early infections is excellent, but for severe infestations is grave.

Constipation

Etiology

Many underlying causes for constipation exist, including exposure to cool temperatures, ingestion of foreign material (especially bedding), and an abrupt dietary change to more fibrous food. There is often a history of recent escape. Constipation also can occur secondary to compression of the colon by extraluminal masses such as eggs, organomegaly, granulomas, or uroliths. In chronic cases, renal failure may occur secondary to compression of the ureters by clocaliths (inspissated feces and urates in the cloaca). Constipation may also occur secondary to spinal osteopathy which impinges on spinal nerves.

Clinical Signs

Clinical signs of constipation vary from decreased stool production alone to signs of GI obstruction such as anorexia and vomiting. The animal may be cachetic if anorexic for long periods of time. Most affected animals are chilled and dehydrated.

Diagnosis

In early cases, abdominal palpation reveals a firm-to-doughy mass in the cloacal region. In chronic cases, the mass is hard and firm, and the animal may be bloated from retained ingesta. Radiographs and, if necessary, ultrasound may delineate the obstruction.

Treatment

If signs of systemic illness are not present, treat simple constipation at home with 1-hour warm water (85°F) body soaks administered two to three times over a 24-hour period. If defecation is not induced, administer an enema consisting of warm water/water soluble lubricating jelly enemas (see "Techniques"). If treatment is effective, some stool should be passed after one to three enemas. If the impaction has been long-standing and large amounts of ingesta are present, consider giving an enema every 2 to 3 days until all the material is expelled. In chronic cases in which stool will not pass and in cases in which the obstruction is secondary to a foreign body or extramural compression of the colon, perform a laparotomy. Because these patients usually are debilitated, surgery is risky. Strict attention to aseptic technique is essential to avoid peritonitis or abdominal abscesses. The surgical approach to the colon is similar to that in mammals.

Cloacal Prolapse

Etiology

- Cloacal prolapse usually is the result of straining due to enteritis, cloacitis, or dystocia.
- Pinworms are the most common cause of cloacal prolapse in lizards.

Diagnosis

Hyperemic, inflamed tissue is observed protruding from the vent on physical examination. Active straining may be present. The prolapse of other organs, such as the hemipene or oviduct, or cloacal neoplasia may appear similar. Use digital manipulation to determine the source of the prolapsed tissue. If in doubt, perform contrast radiography using iohexol (diluted 1:3 with warm water) administered as an enema to delineate the source of the tissue. Determine the primary cause of the straining. Fecal flotation, direct fecal wet mounts, and fecal Gram stains are the minimum diagnostic tests necessary to rule out parasites or clostridial or gram-negative bacterial enteritis.

▼ ***Key Point*** Diagnose and treat the underlying cause of cloacal prolapse to prevent recurrence.

Treatment

Clean the cloaca with warmed sterile saline. Avoid abrading the tissue. Use light sedation with isoflurane, propofol, or ketamine if the animal appears in pain or is difficult to restrain. Once the debris is cleaned from the tissue, determine whether the tissue is in fact the cloaca, and if it is intact. Ensure that the proximal colon is not involved in the prolapse. Until the primary cause for the prolapsed cloaca can be controlled, keep the cloaca in correct anatomic position.

If only the cloaca is involved, lubricate the tissue with water-soluble jelly and replace the cloaca with digital pressure. The application of topical hemorrhoidal medications or 50% dextrose may help reduce edema. If the cloaca is too small for digital pressure, use a well-lubricated cotton swab. Be sure to invert the cloaca entirely into its original position. Place a large horizontal mattress suture at the opening of the cloaca. Pass the needle perpendicular to the cloaca. Leave the ends of the suture long to adjust tension. In general, for reptiles less than 100 g, the opening should allow the passage of one lubricated cotton swab. Reptiles larger than 500 g usually require an opening large enough to accommodate four to six swabs. Adjust the tension so that the animal can defecate through the reduced opening, but the cloaca remains in normal position.

Instruct owners to watch for normal volumes of feces. Sutures are usually left in place 7 to 14 days. Feed a low-residue diet for 2 weeks. If necessary, mix mineral oil with baby food and administer orally to soften the feces.

If the proximal colon is involved in the prolapse, perform surgical correction and cloacopexy. The technique is similar to that used in mammals. If the cloaca is damaged severely, partial amputation can be attempted as long as the ureters and a connection to the GI tract are left intact.

Prognosis

The prognosis for cloacal prolapse detected early with treatable predisposing diseases is good. The prognosis for a long-standing cloacal prolapse or prolapse involving more than the cloaca is guarded. For severely traumatized prolapses in compromised animals, euthanasia may be the most humane alternative.

Reproductive Disorders

Dystocia

Dystocia is the inability to expel term eggs (oviposition) or fetuses. This is in contrast to retained ovarian follicles (see "Green Iguanas").

Etiology

Dystocia usually results from inadequate husbandry, such as inadequate nutrition (especially calcium), temperature, lighting, seclusion, physical activity, or substrate on which to lay. Dystocia also can result from infections of the oviduct or other abdominal disease.

Clinical Signs

Clinical signs include anorexia, partial lay, or straining to lay with no result. The history may suggest that the reptile is overdue for oviposition based on previous laying dates. Some species of reptiles normally harbor eggs internally; therefore determine that dystocia is actually present.

Diagnosis

Diagnosis is based on abdominal palpation and history. Radiographs and/or ultrasound may demonstrate

mature eggs or fetuses in oviducts. Large or misshapen eggs are strong evidence of dystocia. In most gravid reptiles, serum calcium, phosphorus, cholesterol, and total protein levels are higher than concentrations seen in mammals or non-gravid, healthy reptiles. Differential diagnosis for the abdominal masses and clinical signs include granuloma, neoplasia, intestinal obstruction, metastatic calcification, or gout.

Treatment

▼ ***Key Point*** Always determine whether dystocia is present. If the animal is not showing signs of being obstructed or critically ill, try modifying the environment. Provide a warmer temperature, a hide box, and an adequate moistened laying substrate, such as sand or soil.

If eggs are not produced within 2 to 3 days, administer parenteral calcium and either vasotocin or oxytocin. Drugs may be administered every 3 to 4 days as long as a few eggs are passed until all eggs are expelled. Do not give oxytocin or vasotocin daily or if eggs are not produced consistently, or oviductal rupture may occur. If these steps are unsuccessful, gentle manual expression of eggs can be attempted, but oviductal rupture is a common sequela if the veterinarian is not experienced. This technique is usually only effective if only a few (1–3) eggs are left and positioned close to the vent. Use copious lubrication. If a large or misshapen egg is palpated, the contents of the egg may be aspirated percutaneously via an 18-gauge needle and syringe. The resulting reduction in size sometimes allows these eggs to pass on its own. Do not try to manually express over large or misshapen eggs.

- Oviductectomy or oviductotomy frequently is required. If performed before severe systemic illness, the prognosis for life is excellent and for fertility (with oviductotomy) is good. If the animal is systemically ill, stabilize the patient with intraosseous or intravenous fluids and antibiotics before surgery. Correct electrolyte imbalances and perform surgery as quickly as possible.
- If the oviducts have ruptured and yolk is in the abdomen, the prognosis for long-term recovery is grave. Egg-yolk peritonitis not only affects the GI tract but also often induces liver failure. Egg yolk frequently embolizes and can cause infarcts in any tissue including the brain. If infection is present in the oviducts, submit the contents for bacteria culture and remove the oviducts and ovaries.

Prolapsed Hemipenes or Paraphimosis

Etiology

Prolapsed hemipenes usually occur after prolonged breeding. In chelonians, phallus prolapse occurs secondary to trauma by cagemates.

Clinical Signs

A prolapsed male copulatory organ is observed protruding from the cloaca. Bristles may be observed on the surface of the hemipenis in most species of snakes. In all reptilian species, the unique appearance of the hemipenes is sufficient to be differentiated from a prolapsed cloaca, bladder, or oviduct.

Treatment

Clean the exposed tissue with saline and lubricate with water-soluble jelly. If the tissue is swollen, ointments used for the treatment of human hemorrhoids can be used to reduce swelling. Replace the hemipene using gentle digital pressure, inserting the organ through the cloaca in a caudal direction. Place a horizontal mattress suture around the vent to keep the organ in place. In case of recurrent prolapse, a hemipene or phallus can be amputated without affecting urination because the hemipene does not contain a urethra and is only used to transport sperm. Amputation is accomplished under anesthesia by ligating the proximal portion of the organ with horizontal mattress sutures and using sharp dissection to remove the distal portion.

Dermatologic Disorders

Mites

- *Ophionyssus natricus,* or the snake mite, can be seen macroscopically as 0.5-mm black dots on the animal or on paper bedding. Look closely at the spectacle, in the gular fold, and around the vent. Mites can cause anemia and debilitation. They are also vectors for bacteria such as *Aeromonas* as well as viruses and blood parasites.
- Green iguanas have their own species of mite, which is red or gray in color. This mite causes spreading black patches of hyperkeratosis and can be diagnosed with skin scrapings.

Treatment

Treatment with ivermectin is usually effective. Never give ivermectin to turtles. The author has also successfully used products used to remove lice from children to treat many reptile species for mites. The skin of the reptile is rubbed with the product, the animal is restrained for 15 minutes and the product washed off with water.

- Be sure to clean and disinfect the cage. In severe infestations, treat the entire room with a pyrethrin flea product. Treat all animals and the environment every 2 weeks for three treatments. Discard any porous substances such as wood, paper, plants, or non-glazed pottery.

Ticks

Ticks are large enough to be observed macroscopically, with their heads buried under scales. They can be well

camouflaged and tend to congregate under the jaw and around the vent in snakes and in the axilla or groin in tortoises and lizards. As with mites, ticks can carry blood parasites, viruses, and bacteria.

Treatment

Spray a permethrin or pyrethrin flea spray that is labeled safe for use in kittens on a cotton swab and apply it directly to the head region of the tick. Once the tick is stunned, remove it using forceps. Be careful to remove the tick's head to avoid abscessation.

▼ ***Key Point*** Many ticks are imported with the reptile from regions of the world that have serious zoonotic diseases that can be transmitted by ticks. Always use gloves or forceps when removing ticks. Dispose of the remains as biohazardous waste.

Blister Disease

Etiology

Blister disease is a lay term for vesicular dermatitis. It is most frequently caused by a bacterial infection resulting from unsanitary and high-humidity conditions. Occasionally, vasculitis from a viral, fungal or bacterial septicemia causes similar clinical signs.

Clinical Signs

Fluid-filled vesicles or brown desiccated areas may be found on the ventral surface of the abdomen. These lesions may progress to ulcerations.

Diagnosis

Obtain a sample of the fluid within a vesicle for cytologic examination, bacterial and fungal culture.

If the reptile is systemically ill, further diagnostics such as hematology and blood chemistries are recommended.

Treatment

Improve sanitation. Apply topical diluted iodine, and administer parenteral antibiotics. Administer parenteral amoxicillin and enrofloxacin until culture results are available. Nutritional and fluid support is essential in severe cases because these animals may lose large amounts of serum through the vesicles.

Thermal Burns

Etiology

Burns are usually the result of contact with a heat lamp or a "hot rock."

Treatment

Administer parenteral antibiotics to prevent secondary bacterial infections. Apply topical diluted iodine and topical silver sulfadiazine cream daily. Monitor for secondary fungal infections. If large, full-thickness burns are present, fluid and protein losses can be excessive. If the patient becomes dehydrated, administer appropriate fluid therapy. It may be necessary to supplement protein with parenteral amino acids or plasma transfusion. If large areas of skin slough, apply a self-adhesive burn dressing such as Tegaderm (3-M Corporation Minneapolis, MN). This dressing provides the equivalent of a second skin and encourages healing while decreasing pain and fluid losses.

▼ ***Key Point*** Treat thermal burns as soon as possible to decrease the risk of bacterial septicemia and excessive fluid or protein losses. Instruct owners to bring the animal in for treatment as soon as the burn is discovered. The extent of the burn may take several days to become apparent.

Abscesses

Etiology

Abscesses may be secondary to either external trauma or bacterial septicemic emboli. If the abscess is secondary to septicemia, the primary infection must be identified and treated.

Diagnosis

Examine the skin for evidence of a firm swelling in the dermis. Palpate the abdomen to detect firm masses. Aspirate the swelling for cytologic examination and culture to confirm the diagnosis. Cultures taken from the edge of an abscess are the most useful. Blood cultures may be helpful in identifying the causative organism. Most abscesses consist of gram-negative or anaerobic bacteria intermixed with copious fibrous tissue. Other differentials include neoplasia, fungal granuloma, foreign body, parasites, or cyst.

Treatment

Reptilian abscesses contain caseous exudate, which does not drain well. Surgically excise the abscess along with the intact capsule whenever possible. If the entire abscess is not resectable, curette the remaining lesion until only healthy tissue remains. Use local or general anesthetic for this procedure. After surgery, leave the abscesses open to heal by second intention. Flush the lesion with dilute iodine every 6 to 8 hours until completely healed. Enzymatic ointments may be helpful in breaking down caseous debris. In addition to topical treatment, use parenteral amoxicillin and enrofloxacin or amikacin pending culture results.

Nasal Trauma

Reptiles that are kept under inadequate husbandry conditions often pace their cages, resulting in injury to the rostral jaws. Excitable reptiles also may run into walls, which results in trauma to the same area.

Infectious stomatitis is a frequent secondary problem. Treatment is similar to that for abscesses and infectious stomatitis.

▼ ***Key Point*** Providing adequate husbandry is critical. Provide visual security and a smooth cage interior. Padding the cage interior may be necessary.

Gangrene or Abscesses of Extremities

Avascular Necrosis

Etiology

The most common cause of toe loss in lizards is avascular necrosis. Necrosis results from the formation of constricting bands when shedding of the skin on the toes or tail is incomplete. These bands usually form under conditions of low humidity and poor nutrition. Thromboembolism secondary to bacteremia is an additional cause of avascular necrosis.

Diagnosis

Diagnosis is based on clinical signs.

Treatment

Amputation of the affected extremity usually is required. To prevent future lesions, educate the owner about proper husbandry. Recommend warm water soaks to soften and remove dry skin on the extremities. Aggressively treat septicemic reptiles with parental antibiotics.

Trauma Etiology

A second common cause of avascular necrosis is trauma due to tail thrashing or entrapment of a toe in caging. Open or closed contusions, lacerations, or fractures are apparent on physical examination. If the wounds are old, they may be infected or gangrenous.

Treatment

Treat with topical or parenteral antimicrobials. Cultures are indicated if the wound is old. Amputation usually is required. Modify the environment to minimize the chances of trauma's recurring.

Vasculitis

Etiology

Occasionally, gangrene of extremities is seen in reptiles with no known history of trauma. Often, these patients are systemically ill. The lesions are usually caused by vasculitis secondary to septicemia, mycobacteriosis, viral or fungal infection, gout, or ingestion of mycotoxin. In some cases, bites from mites may induce vasculitis resulting in skin necrosis. Diagnosis is based on cytology, including special stains for mycobacteria and fungi, culture and sensitivity, hematology, blood chemistry, histopathology, or feed analysis for mycotoxins.

Treatment

Treat supportively and with appropriate antimicrobials. Surgical amputation of affected extremities almost always is required. Because the disease is usually systemic, prognosis is guarded to grave. Treatment for mycobacteria is difficult, and the zoonotic potential must be considered.

Neoplasia

Most neoplasia in reptiles are either sarcomas or lymphoproliferative disorders and are often associated with retroviruses. In general reptiles are tolerant of most chemotherapy and especially radiation therapy schedules used in mammals. Lympohoblastic leukemia has been successfully treated with radiation therapy. Due to the frequent association with retroviruses the prognosis for remission is guarded. Local tumors can be successfully cured by complete excision. Ovarian teratomas have been found in a significant number of green iguanas. Diagnosis is made by ultrasound examination and biopsy. Early surgical excision may be curative but metastasis is common.

Ocular Disorders

Retained Spectacles

Etiology

Retained spectacles are associated with dysecdysis (abnormal shedding). Poor husbandry, especially low humidity and low temperature, usually is the cause. This condition commonly occurs in pet snakes.

Clinical Signs

Clinical signs include cloudy eyes after a recent shed or a silvery, wrinkled appearance to the eye. If more than a few spectacles are retained, the snake experiences blindness and stops eating. A subspectacular or eye infection may occur below the spectacle.

Treatment

Soak the animal in a warm water bath for 1 to 3 hours. Once softened, the eye cap can be removed by rubbing with a wet cotton ball or with fine forceps. If the spectacle cannot be removed after soaking for a few hours, soak the animal right before next full shed. If the spectacle persists, refer the animal to a hospital equipped to perform microsurgical removal.

▼ ***Key Point*** If the spectacle does not lift easily do *not* force removal, or the primary spectacle may be avulsed, leaving the cornea unprotected. Loss of the eye may ensue.

Subspectacular Infection

Etiology

This is the most common ophthalmic infection in snakes. These infections almost always are associated with stomatitis. The bacteria ascend the nasolacrimal duct, which empties into the space between the spectacle and the cornea.

Clinical Signs

The eye appears to be cloudy. Further inspection reveals that the fluid is under the speculum and there is distention of the subspectacular space. A 27- to 25-gauge needle may be used to aspirate fluid from the space for cytologic examination and culture. In severe cases bulphophthalmia may be present.

Treatment

Treatment with parenteral antibiotics is usually curative. Do not use topical medications because these cannot penetrate the spectacle. In severe cases in which the cornea is in danger of perforation, remove a wedge from the ventral spectacle to allow drainage, flushing, and administration of topical medications. Flush the subspectacular space with saline until all debris is removed, then apply an appropriate topical ophthalmic drop through the wedge. Once this surgery is performed, the cornea is exposed for approximately 2 weeks or until the snake next sheds. Therefore, apply ophthalmic lubricants until the new spectacle forms.

Neuromuscular Disorders

Inclusion Body Disease Virus

Etiology

This disease is believed to be caused by a retrovirus. Transmission may be vertical, by direct contact, from fomites, and through mites. Burmese pythons and boa constrictors seem to be particularly susceptible.

Clinical Signs

Python and boid snakes, especially Burmese pythons, demonstrate neurologic signs such as head tilt, ataxia, opisthotonos, anisocoria, and muscle tremors. Often, the front half of the snake coils in loops. Some snakes, especially boa constrictors, present for chronic regurgitation (not Burmese pythons) with no neurologic component. Burmese pythons often present with neurologic signs only. Stomatitis, lymphoproliferative disorders, and cutaneous sarcomas have been associated with the virus. In general, the virus is slowly progressive.

Diagnosis

Diagnosis currently requires histopathologic observation of inclusion bodies. Submit esophageal lymphoid aggregates, kidney, pancreas, liver, and stomach samples. Snakes with neurologic signs may have lesions limited to the central nervous system, which makes antemortem diagnosis difficult. The main differential diagnosis includes bacterial meningoencephalitis and paramyxovirus. The total white blood cell count in affected snakes is often high (>30,000/uL). In rare cases, occlusion bodies are observed in lymphocytes on blood smears.

Treatment

Although the disease is progressive in most individuals, we have provided supportive care to several boa constrictors that seemed to return to normal after 2 to 3 months of therapy. All affected snakes should be considered carriers that should be kept in strict isolation from unaffected snakes or euthanized. A *minimum* of a 90- to 180-day quarantine is recommended for all snakes entering a new collection. Treatment with nucleoside reverse transcriptase inhibitors (NRTIs; human HIV drug combos) has been attempted but safety and efficacy have not been adequately reported.

Adenovirus of Bearded Dragons

Etiology

Adenovirus in bearded dragons causes acute hepatic coagulation necrosis. Horizontal and vertical transmission is suspected. A case of transmission from juvenile to adult lizards has been documented.

Clinical Signs

Clinical signs occur in neonates and young adults and include seizures, muscle tremors, opisthotonos, lethargy, and icterus. Bearded dragons normally have yellow oral mucous membranes. Lizards with icterus have a deep golden brown colored oral mucous membranes and yellow sclera.

Diagnosis

Diagnosis is based on clinical signs and inclusion bodies in the liver and GI tract. Viral inclusion can sometimes be found in liver biopsies, intestinal biopsies or electron microscopy (EM) of fecal material. The main differential diagnosis for seizures in bearded dragons is hypocalcemia, a common problem in animals fed an all-cricket diet.

Treatment

There is no effective treatment. The morbidity rate appears to be 50%–60%. With supportive care, 30% of animals showing clinical signs survive. Many have residual neurologic deficits. Quarantine survivors and siblings permanently. Do not use these animals for breeding.

Adenovirus in Snakes and Lizards

Adenoviruses have been associated with hepatitis and enteritis in many reptiles. Recently an adenovirus was

recovered from a king snake that had suffered from intermittent head and body tremors for 4 years. Histopathological pathology was limited to the nervous system.

Spondylitis in Snakes

Etiology

Spondylitis is caused most commonly by infection with *Salmonella* spp., although other bacteria have been described. Snakes with spondylitis appear to be stiff or fall off a snake hook.

Diagnosis

Physical examination reveals segmental fused vertebrae and crepitus of the spinal column. In chronic cases, intestinal impaction due to loss of intestinal innervation is palpable. Take a radiograph of the spine to look for lesions suggestive of discospondylitis. Neoplasia should be considered as a differential diagnosis.

Treatment

The prognosis for cure is grave. Progression can be arrested temporarily with parenteral antibiotics based on culture and sensitivity. Surgery can be used to decompress spinal nerves but is not strongly recommended, as lesions are often extensive by the time that clinical signs are noted.

Paramyxovirus Infections in Snakes

Etiology

Clinical signs vary from peracute death to death after a 24- to 48-hour progressive course of paresis. The snake tends to lie stretched out initially, then open-mouthed breathing occurs. Frequently, brown liquid is expelled from the mouth shortly before death. A more chronic form has been diagnosed that is characterized by a proliferative pneumonia, head tremors that can progress to seizures, mydriasis, loss of righting reflex, opisthotonos, and, many times, death.

Diagnosis

Diagnosis is based on clinical signs, necropsy, and a hemaglutination inhibition test offered by the University of Florida Veterinary Medical Teaching Hospital.

Treatment

Snakes with the chronic form may respond temporarily to supportive care and antimicrobial therapy only to relapse weeks to months later. Carriers may be common. Serology should be used to screen for this disease during quarantine of new snakes.

NUTRITIONAL DISORDERS

Secondary Nutritional Hyperparathyroidism

Etiology

The physiology of secondary nutritional hyperparathyroidism (SNHP) in reptiles is similar to that of mammals. Inadequate calcium, vitamin D_3, or UV light source in addition to excess phosphorus (usually from meats and fruits) are the main husbandry problems contributing to SNHP. Primary renal or parathyroid disease also can cause hyperparathyroidism.

Clinical Signs

- Clinical signs include pliable, thickened mandibles, folding fractures of extremities, posterior paresis due to hypocalcemia or fractured spine, kyphosis, ileus from denervation or hypocalcemia leading to impaction and/or incontinence, seizures, dystocia, anorexia, and general malaise.

Diagnosis

- The diagnosis is based on history and physical examination. Serum calcium concentration may be normal even if body stores are low. Ionized calcium may be more helpful than total calcium determination. Radiographic evidence of decreased bone density occurs only in advanced cases. Other causes of seizures include trauma, septicemia, neoplasia, or toxin.

Treatment

- Administer injectable calcium initially, followed by oral supplementation.
- An oral source of vitamin D_3 also is recommended.
- The owner *must* make appropriate environmental changes such as light cycle, UV light, and temperature gradient. Without these changes, medical therapy will fail. Many animals are chronically ill and on the verge of starvation. Tube-feed anorexic animals until their appetite returns, which may take several weeks. Most fractures heal on their own, without internal stabilization. Splinting rear legs against the tail may aid in stabilizing fractures.
- Avoid rough handling, and remove cage furniture to decrease the probability of future fractures. In mild cases, the prognosis is good if owners comply with recommended treatment. If posterior paresis is the result of a spinal fracture, the prognosis for normal ambulation is grave to guarded.

Hypocalcemia

- Reptiles with clinical hypocalcemia present with muscle tremors or seizures. A presumptive diagnosis is based on a history of inadequate diet and hus-

bandry and physical examination findings that support SNHP.

Treatment

- If the animal is having seizures, administer calcium gluconate or calcium chloride IV or IO to effect. Diazepam may be necessary to control seizures.
- If muscle tremors without seizures are present, obtain a blood sample for serum or plasma calcium concentrations, then administer an IM calcium supplement while awaiting laboratory results.
- For long-term care, see the SNHP section.

Hypervitaminosis D_3

- Metastatic calcification of soft tissues frequently is seen in herbivores, omnivores, and insectivores that are over-supplemented with calcium and vitamin D_3. The disease is seen most frequently in 4- to 6-year-old male green iguanas that were fed dog, cat, or monkey chow as a major proportion of the protein in their diet.
- Clinical signs are variable but usually include general malaise followed by anorexia. If the kidneys are mineralized, there are signs consistent with renal failure.
- Diagnosis is based on radiographic evidence of soft tissue mineralization. Diagnosis is difficult if radiographs do not reveal mineralization of soft tissues because serum concentrations of calcium and phosphorus may be within normal limits. Endoscopy or laparatomy may be necessary to make a diagnosis. Provide supportive care and eliminate the vitamin D_3 supplement from the diet.

Thiamine Deficiency

- Thiamine deficiency occurs in carnivores fed a diet high in fatty fishes such as goldfish and smelt. It also occurs in lizards fed muscle meat as a sole food source.
- Clinical signs include paralysis, paresis, pulmonary edema, dyspnea, tremor, cerebral edema, dehydration, enteritis, and blindness.
- Diagnosis is based on history and clinical signs.
- Administer thiamine at 25 mg/kg PO or SC q24h for 3 to 7 days.
- To prevent hypothiaminosis, feed a fresh, varied diet or add 1.1 mg thiamine per kg of fish fed.

Biotin Deficiency

- Biotin deficiency occurs in lizards fed a diet of raw infertile eggs.
- Clinical signs are similar to thiamine deficiency.
- Treat with injectable vitamin B complex that includes biotin.
- Prevent by feeding fertile eggs at different stages of development as well as whole-animal prey. A biotin supplement also can be offered.

URINARY SYSTEM

Gout

Etiology

Gout is the abnormal deposition of uric acid crystals into soft tissue. Gout usually occurs as one of two forms, visceral or articular. In visceral gout, the uric acid precipitates on internal organs, whereas articular gout occurs when uric acid tophi occur within and around joints and tendons. Gout occurs as a result of poor husbandry, dehydration, high-protein diets, and inappropriate use of aminoglycoside antibiotics. In many cases, however, no recognizable risk factor is apparent.

Clinical Signs

- Clinical signs are variable and range from lethargy and anorexia to sudden death. If articular gout is present, affected joints are swollen and painful. In visceral gout, clinical signs are related to failure of the organ affected by the uric acid crystals. Neurologic signs are common if there is uric acid deposition in the brain.

Diagnosis

- Diagnosis is based on physical examination and identification of the uric acid crystals via cytologic or histopathologic examination of tissue samples (do not use formalin as a fixative). Gross lesions may be visible during laparoscopy or laparotomy. Uric acid deposits are sometimes visible on ultrasound or radiographs. Serum uric acid concentrations may be elevated; however, not all reptiles with gout have elevated serum uric acid concentrations. Kidney biopsy may be helpful in cases of renal gout.

Treatment

- Administer supportive care, especially fluid therapy. Improving temperature, humidity, and access to water is critical.
- Avoid high-protein diets (especially those high in purine) and nephrotoxic drugs.
- Avoid use of furosemide because it may inhibit renal excretion of uric acid.
- Antihyperuricemic drugs such as allopurinol, probenecid, sulfinpyrazone, and colchicine can be used to control, but not cure, gout.
- The prognosis for long-term survival is grave.

Urolithiasis

Urolithiasis is seen most frequently in land turtles and lizards fed high-protein diets without adequate access to water.

- Clinical signs include anorexia, straining, or abdominal distension.

- Uroliths are palpable as caudal abdominal masses.
- If necessary, confirm the diagnosis with ultrasound. Radiographs may not be diagnostic because uric acid is often radiolucent.

Treatment

After stabilizing the patient, perform a cystotomy to remove the calculi.

- Culture the calculi, because they can be associated with bacterial cystitis.
- Decrease the protein content of the diet and encourage water consumption.
- Avoid use of nephrotoxic drugs.

DISEASES OF CHELONIANS

Chelonians can acquire most of the disorders described for snakes and lizards. See the previous section for details.

Mycoplasma Pneumonia

Etiology

Mycoplasma and secondary *Pasteurella testudinis* infections are a common cause of upper and lower respiratory tract disease in tortoises.

Clinical Signs

- Clinical signs include nasal and ocular discharge, dyspnea, anorexia, and dehydration.
- Historically, the signs are often unresponsive or only partially responsive to typical antibiotic therapy.

Diagnosis

- Diagnosis is based on clinical signs, culture for *Mycoplasma,* routine bacterial culture and sensitivity, and tracheal cytology. Anemia; elevated sodium, blood urea nitrogen (BUN); aspartate transaminase (AST), and cholesterol; and decreased phosphorus levels often are seen. Serologic testing is available from the University of Florida.
- Differential diagnosis should include bacterial, viral (such as herpes virus), or parasitic infection; aspiration or fungal pneumonia, neoplasia, or foreign body.

Treatment

- Treat with enrofloxacin or tylosin and with fluid and nutritional support.
- Survivors may always be carriers; quarantine them for life.

Herpes Virus of Tortoises

Etiology

Several strains of herpes virus are associated with severe stomatitis and rhinitis in European tortoises. Different strains are thought to have variable pathogenicity and tissue tropism.

Tortoises should be serologically screened with paired samples where possible and quarantined a minimum of 6 months (preferably 12–18 months) before introduction. Do not mix tortoise species.

Clinical Signs

- Clinical signs include nasal and ocular discharge, severe stomatitis, ptyalism, edema of the ventral neck, anorexia, and dehydration. Neurologic signs may develop later in the disease. Lymphoproliferative disease has been reported. The virus has acute, chronic, and inapparent carrier forms. Spur-tailed tortoises *(Testudo hermanni)* seem particularly susceptible, whereas spur-thighed tortoises *(T. graeca)* appear to be more resistant. An iridovirus has been identified that causes similar signs, but is less common.

Diagnosis

- Diagnosis is based on clinical signs, cytology of tongue swabs with Diff-Quik to identify inclusion bodies, paired serologic titers, virus isolation, or histopathologic examination with polymerase chain reaction on submitted tissues. Testing is available through the University of Florida College of Veterinary Medicine.
- Differential diagnosis should include iridovirus, mycoplasma, contact irritant, neoplasia, or bacterial, parasitic, or fungal stomatitis.

Treatment

- Treat with supportive care (fluids, antibiotics, nutritional support). Placement of an esophagostomy tube may be necessary if the tortoise will not eat on its own. Gentle topical cleaning of the mouth and nose with dilute iodine solution. Acyclovir at 30 to 80 mg/kg PO sid to tid may be helpful. Topical acyclovir ointments may be applied to the oral mucous membranes.
- Survivors may always be carriers; quarantine them for life.

Nutritional Disorders

Vitamin A Deficiency

Etiology

Vitamin A deficiency is seen most frequently in juvenile, semi-aquatic turtles older than 6 months of age. Before this age, the remnants of the yolk sac provide adequate levels of vitamin A. Affected animals usually have been fed high-protein, unbalanced diets such as raw hamburger. Vitamin A deficiency results in squamous metaplasia of the glandular structures of the eye, oral cavity, respiratory passages, and genitourinary tract, as well as decreased local immunity. Changes in the kidney predispose animals to gout, particularly if they are on a high-protein diet.

Clinical Signs

- Clinical signs include conjunctivitis, pneumonia, stomatitis, and hyperkeratotic eyelids.

Diagnosis

- Diagnosis is based on history, clinical signs, and biopsy samples, which demonstrate lesions compatible with epithelial squamous metaplasia.

Treatment

- In most cases, oral supplementation of vitamin A is sufficient and safe. Treat with parenteral vitamin A only in severe cases. Long-term improvements of diet and husbandry are essential.

Vitamin A Toxicity

Vitamin A toxicity is seen within 2 weeks of administration of parenteral vitamin A. Toxic levels of vitamin A cause xeroderma initially and necrotizing dermatitis with long-term toxicity.

- Clinical signs include severe sloughing of epidermis, especially in the cervical region.
- Treatment consists of supportive care. Give fluid therapy to replace fluid losses from defects in the dermis and exposed muscle. Apply dressings to open wounds as needed.

▼ ***Key Point*** Never give injectable vitamin A unless there is a history of dietary deficiency and clinical signs of hypovitaminosis A are severe.

Hypothyroidism (Iodine Deficiency)

Hypothyroidism resulting from goiter is recognized in tortoises suffering from iodine deficiency. Iodine is bound by nitrates and compounds found in cabbage, kale, brussels sprouts, and uncooked soybeans.

- Clinical signs include myxedema and goiter.
- Treat with iodine and dietary modification.

Diseases of the Shell

Shell Trauma

The most common causes of shell trauma in turtles are accidental drops, car or lawn mower collisions, and attacks by dogs.

Treatment

- Stabilize the patient and stop all hemorrhage before attempting to repair the shell.
- If possible, draw blood for baseline complete blood count (CBC) and profile.
- Lavage the peritoneum and clean all cracks.
- Bandage full-thickness cracks or openings with nonstick dressings, then wrap the shell in plastic wrap to prevent contamination and loss of peritoneal fluids.
- Administer IV, IO, or SC fluids as needed. If the turtle is in shock, administer one dose of dexamethasone (0.125–0.25 mg/kg). Oxyglobin can be used as a blood substitute if needed.
- Keep the patient warm and administer prophylactic antibiotics.
- Once the patient is stable, treat minor, relatively stable cracks by cleaning with iodine q12h, apply topical antibiotic cream, and stabilize the crack with bandages or steel wires as necessary.
- Most animals heal in 2 to 3 weeks.
- Unstable cracks or large shell defects must be repaired with fiberglass or acrylic resins or UV light-cured polymers.
- Allow ample time for underlying soft tissues to heal before attempting repair.
- Debris or microbes caught under the patch cause granulomas or abscesses.
- Once the wound is clean and has developed a healthy granulation bed, apply silver sulfadiazine cream to the wound.
- Apply Tegaderm (3M Corporation) over exposed soft tissues to provide protection from the polymers to be applied later.
- Clean the scutes adjacent to the defect with ether or acetone.
- Apply a thin layer of epoxy to the shell, then place nylon or fiberglass screening over the defect.

▼ ***Key Point*** Do not let the epoxy come in contact with bone or soft tissue. Also ensure that the epoxy or screening does not create a barrier to prevent granulation tissue from filling in the defect.

- Epoxy can be painted on top of the screen.
- Keep the animal out of water at least 24 hours to allow curing. Use only marine epoxies on aquatic turtles. Ensure adequate hydration for aquatic turtles by providing oral, SC, or IP fluids and a high relative humidity in their enclosure.
- Patches need to be removed in fast-growing animals.
- Complete healing takes 6 to 18 months.

Shell Rot

Healthy shell scutes are periodically shed in rapidly growing chelonians. Normal scute sheds should appear as translucent keratin.

- Most shell infections are secondary to poor husbandry and are caused by bacteria or fungi.
- Occasionally, algae can cause erosions.
- Clinical signs of shell rot include petechia, sloughing of discolored, soft scutes, erosions, hyperemia, and fluffy or granulomatous growths. Dermatitis and septicemia are common.

Diagnosis

- Diagnosis is based on cytologic examination of shell scrapings or biopsy and bacterial or fungal culture and

sensitivity. Differential diagnosis includes infections secondary to trauma, foreign body, or neoplasia.

Treatment

- Administer diluted topical iodine soaks for at least 1 hour daily. Dry the shell by keeping it out of water for at least 1 hour.
- Monitor for dehydration during this period.
- Use a sharp, clean knife to pare away dead sections of shell and expose the infected tissues. Use sterile technique.
- Many early cases of shell rot respond to treatment with iodine, desiccation, and improvement of husbandry.
- Turtles with deep erosions or septicemia need to be treated with systemic antimicrobials based on culture and sensitivity.
- If bone is exposed, the prognosis is guarded to grave.
- Severe erosions must be treated similar to thermal burns.

Pyramiding of Shell

Pyramiding of the scutes of the carapace or doming of the carapace are clinical signs of secondary nutritional hyperparathyroidism. The diet of affected turtles is often high in lettuce, fruit (especially melon), tomatoes, or protein. The shell also may appear to be small for the body in turtles fed too much protein. Concurrent beak deformities are often present. Recent reports indicate that this condition can also be caused by low humidity during early growth.

- Similar lesions can occur in adult chelonians with systemic disease, particularly hepatic or renal disease.
- If caught early, the defects can be minimized with proper nutrition (see above).
- More severely affected animals will be permanently disfigured.

Myiasis

Myiasis may occur in any reptile species but is most common in chelonians. Flies lay eggs into a wound.

- Maggots usually hatch in 12 to 24 hours.
- Remove the maggots and treat similar to mammals. Do not use ivermectin flushes in turtles. Provide supportive care as needed.

▼ ***Key Point*** Ivermectin is toxic to turtles and tortoises.

DISEASES OF CROCODILIANS

Hypoglycemia

Hypoglycemia is seen in stressed alligators, especially when malnutrition, cold temperatures, and high population density are present.

- Clinical signs include tremors, torpor, loss of righting reflex, generalized weakness, mydriasis, and catatonia.
- Diagnosis is based on low glucose levels on blood chemistry. To treat, administer 3 g/kg glucose PO and improve husbandry.

Vitamin K Deficiency

- Vitamin K deficiency can occur in alligators fed marginal diets and placed on long-term antibiotics. Clinical signs are similar to clotting deficiency in mammals.
- Gingival bleeding is an early sign.
- Treat with vitamin K and improve diet. Stop administration of antibiotic if possible.

Caiman Pox

Caiman pox is seen in caimans and Nile crocodiles. It is caused by a pox virus. Clinical signs include gray-white, circular, multifocal "pox-type" lesions that can be widespread on integument. Lesions may coalesce into diffuse necrotizing patches and cause digital necrosis. Proliferative oral lesions also can be seen.

- Diagnosis is made on histopathology in which large intracytoplasmic inclusions bodies are visualized in the epithelial cells.
- No treatment, other than supportive care, is available. Quarantine individuals with active lesions.

West Nile Virus

West Nile Virus was associated with acute die-offs and neurologic signs in American alligators in Florida. Signs included depression, lethargy and neurological signs. Histopathologic lesions included meningoencephalomyelitis, necrotizing hepatitis, splenitis and myocarditis. In contrast, crocodilians in Israel were serologically positive for exposure to West Nile Virus but did not show clinical signs of disease. High sero-reactivity has been noted in alligators at a farm in Idaho.

Coccidia: Eimeria species

- *Coccidia* causes necrotizing enteritis in young crocodiles.
- Diagnosis is made on routine fecal or cloacal swab. Treat with a sulfa antibiotic. Mortality can be high in dense populations.

Appendix

Drug Dosage Guidelines for Dogs and Cats

Acepromazine
0.05–0.2 mg/kg IV, 0.1–0.3 mg/kg, IM, SC (maximum 3 mg)
0.5–2.0 mg/kg q6–8h PO

Acetazolamide
Diamox
5–10 mg/kg q8–12h PO
Glaucoma: 4–8 mg/kg q8–12h PO

Acetylcysteine
Mucomyst
Antidote: 140 mg/kg (loading dose) PO, IV, then 70 mg/kg q4h for 5 doses
Eye: 2% solution topically q2h

Acetylsalicylic acid (aspirin)
Analgesic:
Dog: 10–25 mg/kg q8–12h PO
Anti-inflammatory:
Dog: 20–40 mg/kg q12h PO
Cat: 10–20 mg/kg q48h PO
Antiplatelet:
Dog: 5–10 mg/kg q24–48h PO
Cat: 80 mg q48h PO

ACTH
See Corticotropin gel (ACTH)

Actinomycin D
Cosmegen
0.7 mg/m^2 IV (consult anticancer protocol for intervals)

Activated charcoal
See Charcoal, activated

Albendazole
Valbazen
Dog: 25 mg/kg q12h PO for 2 days for giardia

Allopurinol
Zyloprim
10 mg/kg q8h then reduce to 10 mg/kg q24h

Aluminum carbonate gel
Basaljel
Phosphate binder: 10–30 mg/kg q8h PO (with meals)

Aluminum hydroxide gel
Amphojel
Phosphate binder: 10–30 mg/kg q8h PO (with meals)

Amikacin
Amiglyde-V
5–10 mg/kg q8h IV, IM, SC; or 15–20 mg/kg q24h IV, IM, SC

Aminopentamide
Centrine
Dog: 0.01–0.03 mg/kg q8–12h IM, SC, PO
Cat: 0.02 mg/kg q8–12h IM, SC, PO

Aminophylline
Dog: 10 mg/kg q8h PO, IM, IV
Cat: 6.6 mg/kg q12h PO

5-aminosalicylic Acid
See Mesalamine; Osalazine sodium

Amiodarone
Cordarone
Dog: 10–20 mg/kg q12h PO

Amitraz
Mitaban
Make a 0.025% solution (1 vial of Mitaban/2 gallons of water). Apply every 2 weeks until no viable mites are found (see Chap. 43).

Amitryptyline
Elavil
Dog: 1–2 mg/kg q12h PO
Cat: 5–10 mg/cat q12–24h PO

Amlodipine
Norvasc
Cat: 0.625–1.25 mg/cat q24h PO
Dog: 0.1–0.2 mg/kg q24h or divided q12h PO

Ammonium chloride
Dog: 100 mg/kg q12h PO
Cat: 800 mg/cat (approximately $^1/_4$ tsp) mixed with food daily

Amoxicillin
Amoxi-tabs
Amoxi-drops
11–22 mg/kg q8–12h PO

Amoxicillin plus clavulanate
Clavamox
Dog: 12.5–25 mg/kg q12h PO
Cat: 62.5 mg/cat q12h PO

Amphotericin B deoxycholate
Fungizone
0.25–0.5 mg/kg q48h IV (slow infusion), 3 times per week to a cumulative dose of 8–12 mg/kg in dogs and 4–8 mg/kg in cats

Amphotericin B lipid complex
AmBisome, Amphocil, Abelcet
1.0 mg/kg q48h IV, 3 times per week to a cumulative dose of 12 mg/kg (see Chap. 20)

Ampicillin
Omnipen

10–20 mg/kg q6–8h IV, IM, SC (ampicillin sodium)
Principen
20–40 mg/kg q8h PO

Ampicillin trihydrate
Polyflex
6.5 mg/kg q12h, IM, SC

Amprolium
Amprol
Corid
1.25 g of 20% amprolium powder added to daily feed, or 30 ml of 9.6% amprolium solution to 3.8 L of drinking water for 7 days

Amrinone lactate
Inocor
1–3 mg/kg IV (loading dose) followed by 30–100 µg/kg/min IV infusion

Antacid drugs
See Aluminum hydroxide gel; Calcium carbonate; Magnesium hydroxide

Apomorphine hydrochloride
0.02–0.04 mg/kg IV, IM; 0.1 mg/kg SC; or instill 0.25 mg in conjunctiva of eye (dissolve 6-mg tablet in 1–2 ml of saline)

Ascorbic acid (vitamin C)
Diet supplement or for copper toxicity 100–500 mg/animal qd
Acetaminophen toxicity 30 mg/kg q6h for seven treatments, PO, SC

L-Asparaginase
Elspar
10,000–30,000 IU/m^2 IM, SC, or IP as needed (pretreat with antihistamines, steroids); see Chapter 26.

Aspirin
See Acetylsalicylic acid

Atenolol
Tenormin
Dog: 6.25–25 mg/dog q12h PO or 0.25–1.0 mg/kg q12–24h PO
Cat: 6.25–12.5 mg/cat q24h PO

Atracurium besylate
Tracrium
0.2 mg/kg IV initially, then 0.15 mg/kg q30min (or IV infusion at 3–8 µg/kg/min)

Atropine
0.02–0.04 mg/kg q6–8h IV, IM, SC
Organophosphate and carbamate toxicosis: 0.2–0.5 mg/kg (as needed)

Auranofin (triethylphosphine gold)
Ridaura
0.1–0.2 mg/kg q12h PO

Aurothioglucose
Solganal
Dog <10 kg: 1 mg/dog IM first week, 2 mg/dog IM second week, 1 mg/kg/wk maintenance
Dog >10 kg: 5 mg/dog IM first week, 10 mg/dog IM second week, 1 mg/kg/wk maintenance
Cat: 0.5–1 mg/cat IM every 7 days

Azathioprine
Imuran
Dog: 2 mg/kg q24h PO initially, then 0.5–1.0 mg/kg q48h
Cat: 0.3–0.5 mg/kg PO, q24–48h (q48h is preferred)

Azithromycin
Zithromax
Dog: 10 mg/kg q24h PO × 5 days or 3.3 mg/kg q24h PO × 3 days
Cat: 5 mg/kg q48h PO

AZT (azidothymidine)
See Zidovudine

Baclofern
Lioresal
Dogs: 1–2 mg/kg q8h PO

BAL
See Dimercaprol

Benazepril
Lotensin
Dog: 0.5 mg/kg q12–24h PO

Betamethasone1
Celestone
Betasone
0.1–0.2 mg/kg q12–24h PO

Bethanechol chloride
Urecholine
Dog: 2.5–25.0 mg/dog q8h PO
Cat: 2.5–5.0 mg/cat q8h PO

Bicarbonate
See Sodium bicarbonate

Bisacodyl
Dulcolax
Dog: 5–20 mg qd PO
Cat: 5 mg qd PO

Bismuth subcarbonate
0.5–3.0 g q4h PO

Bismuth subsalicylate
Pepto-Bismol
1–3 ml/kg/d (in divided doses) PO

Bleomycin sulfate
Blenoxane
10 U/m^2 IV or SC for 3 days, then 10 U/m^2 weekly (maximum cumulative dose: 200 U/m^2)

Bromide
See Potassium bromide

Budesonide
Entocort
Dog: 1–3 mg q24h PO
Cat: 1 mg q24h PO

Bunamidine
Scolaban
20–50 mg/kg PO

Bupivacaine hydrochloride
Marcaine
0.5 mg/kg epidural
1 mg/kg total dose for local nerve block

Buprenorphine
Temgesic
0.005 mg/kg q4–8h IV, IM

Buspirone
BuSpar
Cat: 2.5–5 mg/cat q12–24h PO

Butorphanol
Torbutrol
Torbugesic
Dog: Analgesic: 0.1–0.2 mg/kg IV, 0.1–0.4 mg/kg IM or SC Antitussive: 0.55–1.1 mg/kg PO q6–12h, 0.055–0.11 mg/kg SC q6–12h
Cat: Analgesic: 0.05–0.2 mg/kg IV, 0.1–0.3 mg/kg IM, SC

Calcitonin
Calcimar
4–6 IU/kg SC initially q12h, then q8h for hypercalcemia

Calcitriol
Rocaltrol
2–3 ng/kg/d divided q12h for 3–4 days, then 1–2 ng/kg/d maintenance

Calcium carbonate
25–50 mg/kg/d PO
Camalox
60–100 mg/kg/d (in divided doses) as phosphate binder

Calcium chloride (10% solution)
Hypocalcemia: 5–15 mg/kg/h IV

Calcium citrate
Cat: 10–30 mg/kg q8h (with meals) PO

Calcium disodium EDTA
See Edetate calcium disodium ($CaNa_2$, EDTA)

Calcium gluconate (10% solution)
0.5–1.5 ml/kg IV (slowly)
Calcium gluconate tablets
25–50 mg/kg/day PO

Calcium lactate
25–50 mg/kg/d PO

Captan
0.25% solution topically, 2–3 times/wk

Captopril
Capoten
Dog: 0.5–2.0 mg/kg q8–12h PO
Cat: 3.12–6.25 mg/cat q8h PO

Carbenicillin disodium
Geopen
Pyopen
40–50 mg/kg q6–8h IV, IM, SC

Carbenicillin indanyl sodium
Geocillin
Urinary tract infections: 10 mg/kg q8h PO

Carbimazole
Neo-mercazole
Cat: 5 mg/cat q8h PO (induction), followed by 5 mg/cat q12h PO

Carboplatin
Paraplatin
Dog: 250–300 mg/m^2 q3wk IV
Cat: 150–250 mg/m^2 q4wk IV

Carnitine
See Levo-carnitine

Carprofen
Rimadyl
Dog: 2 mg/kg q12h PO

Carvedilol
Coreg
See Chapter 146

Castor oil
Dog: 8–30 ml/dog qd PO
Cat: 4–10 ml/cat qd PO

Cefadroxil
Cefa-Tabs
Cefa-Drops
Dog: 22 mg/kg q12h PO
Cat: 22 mg/kg q24h PO

Cefazolin sodium
Ancef
Kefzol
20–25 mg/kg q6–8h IV, IM

Cefepime
Maxipime
Dog: 40 mg/kg q6h IM, IV

Cefmetazole sodium
Zefazone
15 mg/kg q8h IV, IM, SC

Cefotaxime sodium
Claforan
20–80 mg/kg q6h IV, IM

Cefoxitin sodium
Mefoxin
15–30 mg/kg q6–8h IV

Ceftazidime
Fortaz
30 mg/kg q6h IV, IM

Ceftiofur
Naxcel
Dog: 2.2–4.4 mg/kg q24h SC

Cephalexin
Keflex
10–30 mg/kg q6–12h PO

Cephalothin sodium
Keflin
10–30 mg/kg q4–8h IV, IM

Cephapirin sodium
Cefadyl
10–30 mg/kg q4–8h IV, IM

Cephradine
Velosef
10–25 mg/kg q6–8h PO

Charcoal, activated
Acta-Char
SuperChar Vet/Powder or Vet/Liquid
Toxiban
1–4 g/kg PO (granules)
6–12 ml/kg PO (suspension)

Chlorambucil
Leukeran
2–4 mg/m^2 q48h PO (see Chap. 26)
Cats (FIP): 20 mg/m^2 q2–3 wk PO
Chronic lymphocytic leukemia
20 mg/m^2 q1–2wks PO or 6 mg/m^2/day

Chloramphenicol
Chloromycetin
Dog: 30–50 mg/kg q6–8h IV, IM PO
Cat: 30–50 mg/cat q12h IV, IM PO

Chlorothiazide
Diuril
20–40 mg/kg q12h PO

Chlorpheniramine maleate
Phenetron
Chlor-Trimeton
Dog: 0.4 mg/kg q8–12h PO
Cat: 2 mg/cat q12h PO

Chlorpromazine
Thorazine
0.5 mg/kg q6–8h IM, SC, PO
Prior to cancer chemotherapy: 2 mg/kg q3h SC

Chlortetracycline
25 mg/kg q6–8h PO

Cholecalciferol (vitamin D_3)
500–2000 U/kg/d PO (1 mg = 40,000 U)

Chorionic gonadotropin
See Gonadotropin, chorionic (hCG)

Cimetidine
Tagamet
5–10 mg/kg q6–8h IV, IM, PO
Renal failure: 2.5–5.0 mg/kg q12h IV, PO

Ciprofloxacin
Cipro
5–15 mg/kg q12h PO

Cisapride
Propulsid
Dog: 0.25–0.5 mg/kg q8–12h PO
Cat: 2.5–5 mg q8–12h PO

Cisplatin
Platinol
50–70 mg/m^2 q3wk IV drip (requires aggressive diuresis); do not use in cats

Clarithromycin
Biaxin
5 mg/kg q12h PO

Clavamox
See Amoxicillin plus clavulanate

Clavulanate
See Amoxicillin plus clavulanate

Clemastine
Tavist, Contac 12-Hr Allergy
Dog: 0.05–0.1 mg/kg q12h PO

Clindamycin
Antirobe
Cleocin
Dog: 5–10 mg/kg q8h PO, IV, IM
Cat: 5.5 mg/kg q12h, or 11 mg/kg q24h (staphylococcal infections) PO; 11 mg/kg q12h, or 22 mg/kg q24h PO(anaerobic infections) PO
Toxoplasmosis: 25–50 mg/kg/d PO (in divided treatments) for 2–3 weeks

Clofazimine
Lamprene
10 mg/kg q24h PO

Clomipramine
Anafranil, Clomicalm
1 mg/kg q12–24h PO up to a maximum dose of 3 mg/kg q12–24h PO

Clonazepam
Klonopin
0.5 mg/kg q12h PO

Clorazepate dipotassium
Tranxene
2 mg/kg q12h PO

Clotrimazole (1%)
Lotrimin
Topical intranasal infusion; 50–60 ml per side over 1 hour via indwelling catheter (for aspergillosis, penicilliosis)

Cloxacillin sodium
Cloxapen
Orbenin
Tegopen
20–40 mg/kg q8h PO

Cod liver oil
1 tsp/10 kg once daily PO

Codeine
Dog: Analgesic: 0.5–1.0 mg/kg q6–8h PO
Antitussive: 1–2 mg/kg q6–12h PO

Colchicine
0.025–0.03 mg/kg q24h PO

Corticotropin gel (ACTH)
Acthar
Response test: collect pre-ACTH sample and inject 2.2 IU/kg IM; collect post-ACTH sample at 2 hours in dogs and at 1 and 2 hours in cats

Cosyntropin
Cortrosyn
Response test: collect pre-ACTH sample and inject 5 µg/kg IV in dogs and 125 µg IV in cats; collect post-ACTH sample at 1 hour

Cyanocobalamin (vitamin B_{12})
Dog: 100–200 µg/dog qd PO
Cat: 50–100 µg/cat qd PO

Cyclophosphamide
Cytoxan
Anticancer therapy: 50 mg/m^2 q48h PO, or 50 mg/m^2 once daily 4 days/week PO, or 100–300 mg/m^2 IV and repeat in 21 days (see Chap. 26)
Immunosuppressive therapy: 50 mg/m^2 q48h PO (see Chap. 24)
Cat: 200 mg/m^2 q2–3wk PO (see Chap. 26)

Cyclosporine
Sandimmune, Neoral, Optimmune ointment
Dog: 10 mg/kg q12h PO
Cat: 5 mg/kg q12h PO to 15 mg/kg q24h (adjust dose via monitoring)
Perianal fistulae: 1.75–3.0 mg/kg q12h PO
Topical treatment for keratoconjunctivitis sicca: 1–2% solution in oil: instill 1 drop in eye q12hr

Cyclothiazide
Anhydron
0.5–1.0 mg/kg q24h PO

Cyproheptadine
Periactin
Antihistamine: 0.5–1.0 mg/kg q12h PO
Appetite stimulant in cat: 2 mg/cat q12h PO

Cytosine arabinoside
Cytosar
Dog: 100 mg/m^2 once daily for 4 days IV, SC (lymphoma) q3–4wk (see Chap. 26)
Cat: 100 mg/m^2 IV or SC once daily for 2 days (see Chap. 26)

Dacarbazine
DTIC
Dog: 1000 mg/m^2 IV drip for 6–8 hours, repeat q3wk (see Chap. 30)

Danazol
Danocrine
5–10 mg/kg q12h PO

Dantrolene sodium
Dantrium
Dog: 1–5 mg/kg q8h PO
Cat: 0.5–2.0 mg/kg q12h PO

Dapsone
1.1 mg/kg q8h PO

Deferoxamine mesylate
Desferal
10 mg/kg IV, IM q2h for 2 doses, then 10 mg/kg q8h for 24 hours

Delta-Albaplex (novobiocin plus prednisolone plus tetracycline hydrochloride)
Dog 3–7 kg: 1–2 tablets/d PO
Dog 7–14 kg: 2–4 tablets/d PO
Dog 14–27 kg: 4–6 tablets/d PO
Dog >27 kg: 6–8 tablets/d PO
Cat: 1 tablet q12h PO

Deprenyl (L-deprenyl, selegiline)
Anipryl
Dog: 1 mg/kg q24h PO

Deracoxib
Deramaxx
Dog: 3–4 mg/kg q24h PO for ≤7 days

Derm Caps (omega fatty acid)
1 capsule/9.1 kg daily PO

Desmopressin acetate
DDAVP
Diabetes insipidus: 2–4 drops q12–24h intranasally
von Willebrand's disease: 1.0 µg/kg SC, IV, diluted in 20 ml saline over 10 minutes

Desoxycorticosterone pivalate (DOCP)
Percorten-V
1.5–2.2 mg/kg q25d IM

Dexamethasone
Azium
Anti-inflammatory: 0.1–0.2 mg/kg q12–24h IV, IM, PO
Shock: 2.2–4.4 mg/kg IV

Dexamethasone sodium phosphate
Shock: 1–2 mg/kg IV

Dextran-70
Gentran-70
10–20 ml/kg IV q24h to effect

Dextromethorphan
Benylin DM and others
0.5–2.0 mg/kg q6–8h PO

Dextrose (5% solution)
40–50 ml/kg q24h IV

Diazepam
Valium
Preanesthetic: 0.1–0.25 mg/kg IV, IM, SC
Status epilepticus: 0.25–0.5 mg/kg IV; repeat if necessary; 1 mg/kg rectally
Appetite stimulant in cat: 0.1–0.2 mg/kg IV (q12–24h as needed)
Functional urethral obstruction in dogs: 2–10 mg/dog q8h PO
Urinary disorder in cat: 1.25–2.5 mg/cat q8–12h PO

Diazoxide
Proglycem
10 mg/kg q12h PO, do not exceed 60 mg/kg/d

Diclorophene
See Toluene

Dichlorphenamide
Daranide
2–4 mg/kg q8–12h PO

Dichlorvos
Performer
Dog: 26.4–33 mg/kg PO
Cat: 11 mg/kg PO

Dicloxacillin
Dynapen
11–55 mg/kg q8h

Dicyclomine
Bentyl
0.2 mg/kg q8–12h PO

Diethylcarbamazine
Caricide
Filaribits
Heartworm prophylaxis: 6.6 mg/kg q24h PO

Diethylstilbestrol (DES)
Urinary incontinence (dog): 0.1–1.0 mg/dog q24h PO for 3 days, then 1 mg/wk PO

Digitoxin
Crystodigin
0.02–0.03 mg/kg q8h PO

Digoxin
Lanoxin
Cardoxin
Dog: 0.22 mg/m^2 q12h PO, 0.0055–0.01 mg/kg q12h PO, (reduce dose by 10% for elixir)
Cat: 0.01 mg/kg q48h, 0.007 mg/kg q48h (with Lasix and aspirin)

Dihydrotachysterol (vitamin D)
Hytakerol
DHT
Initial: 0.02–0.03 mg/kg/day PO maintenance: 0.01–0.02 mg/kg q24–48h PO

Diltiazem hydrochloride
Cardizem
Dog: 0.5–1.5 mg/kg q8h PO
Cat: 1.75–2.4 mg/kg q8–12h PO
Dilacor XR
Cat: 30 mg/cat q12–24h PO
Cardizem CD
Cat: 10 mg/kg q24hr PO

Dimenhydrinate
Dramamine (U.S.)

Gravol (Canada)
Dog: 4–8 mg/kg q8h IV, IM, PO
Cat: 12.5 mg q8h IV, IM, PO

Dimercaprol
BAL in oil
4 mg/kg q4h IM

Dinoprost tromethamine
See Prostaglandin $F_2\alpha$

Dioctyl calcium sulfosuccinate
See Docusate calcium

Dioctyl sodium sulfosuccinate
See Docusate sodium

Diphenhydramine hydrochloride
Benadryl
2.2 mg/kg q8–12h IV, IM, PO

Diphenoxylate hydrochloride
Lomotil
Dog: 0.1–0.2 mg/kg q8–12h PO
Cat: 0.05–0.1 mg/kg q12h PO

Diphenylhydantoin
See Phenytoin

Diphosphonate disodium etidronate
See Etidronate disodium

Dipyridamole
Persantine
4–10 mg/kg q24h PO

Disopyramide phosphate
Norpace
Dog: 6–15 mg/kg q8h PO

Dithiazanine iodide
Dizan
6.6–11.0 mg/kg q24h PO for 7–10 days

Divalproex sodium
Depakote
Equivalent to valproic acid (see Valproic acid)

Dobutamine
Dobutrex
Prepare 250 mg in 1 L 5% dextrose
Dog: 2.5–20 µg/kg/min IV infusion
Cat: 2.5–5.0 µg/kg/min IV infusion

Docusate calcium
Surfak
Doxidan
Dog: 50–100 mg/dog q12–24h PO
Cat: 50 mg/cat q12–24h PO

Docusate sodium
Colace
Dog: 50–200 mg/dog q8–12h PO
Cat: 50 mg/cat q12–24h PO

Dopamine hydrochloride
Intropin
2–10 µg/kg/min IV infusion (prepare 40 mg in 500 ml lactated Ringer's solution)

Doxapram hydrochloride
Dopram
5–10 mg/kg IV
Neonate: 1–5 mg SC, sublingually, or via umbilical vein

Doxorubicin
Adriamycin
Dogs ≤ 10 kg and cats: 20–25 mg/m^2 IV q3wk
Dogs > 10 kg: 30 mg/m^2 IV q3wk (maximum cumulative dose 180–240 mg/m^2) (see Chap. 26)

Doxycycline
Vibramycin
3–5 mg/kg q12h PO
Lyme borreliosis:
10 mg/kg q12h PO

Edetate calcium disodium (CaEDTA)
Havidote
25 mg/kg q6h SC for 2–5 days

Edrophonium chloride
Tensilon
Dog: 0.11–0.22 mg/kg IV
Cat: 2.5 mg/cat IV

Enalapril maleate
Enacard
Dog: 0.5 mg/kg q12–24h PO
Cat: 0.25–0.5 mg/kg q12–24h PO

Enflurane
Ethrane
2–3% (induction); 1.5–3% (maintenance)

Enilconazole
Imaverol
Nasal aspergillosis: 10 mg/kg q12h instilled into nasal sinus for 10–14 days (10% solution diluted 50:50 with water)
Dermatophytes: solution diluted to 0.2% and lesion washed with solution 4 times at 3- to 4-day intervals

Enrofloxacin
Baytril
2.5–5.0 mg/kg q12h PO, IM, SC, or 5–10 mg/kg q24h PO, IM

Ephedrine
Urinary incontinence
Dog: 5–15 mg/dog q8h PO
Cat: 2–4 mg/cat q8h PO
Bronchodilator: 1–2 mg/kg q8h PO

Epinephrine
Adrenalin
20 µg/kg, or 0.1–0.5 ml of 1:1000 (1 mg/ml) solution; or 1–5 ml of a 1:10,000 (0.1 mg/ml) solution IV, IM, SC, IC, intratracheally

Epogen
35–100 IU/kg q48h SC until PCV rises, then weekly

Epsiprantel
Cestex
Dog: 5.5 mg/kg PO
Cat: 2.75 mg/kg PO

Epsom salt
See Magnesium sulfate

Ergocalciferol (vitamin D_2)
Calciferol
Initial: 4000–6000 U/kg/d PO
Maintenance: 1000–2000 U/kg q24h–q7d PO (see Chap. 32)

Erythromycin
Antibiotic: 10–20 mg/kg q8–12h PO
Promotility: 0.5–1.0 mg/kg q8h PO

Erythropoietin (r-HuEPO)
Epogen

75–100 U/kg SC 3 times weekly (adjust dose to reach and maintain hematocrit of 30–34%)

Esmolol
Brevibloc
Dog: 50–500 µg/kg IV bolus every 5 minutes (up to 500 µg/kg)

Essential fatty acids
(See also Omega fatty acids)
EFA-Z Plus
<6.7 kg: 3.7 ml/d PO
6.7–22.5 kg: 7 ml/d PO
>22.5 kg: 14 ml/d PO

Estradiol cypionate (ECP)
Depo-Estradiol
Dog: 0.02–0.04 mg/kg IM (total dose not to exceed 1.0 mg) within 3 days of mating
Cat: 0.25 mg/cat IM within 3 days of mating
Use of ECP for mismating is discouraged

Ethanol (20%)
For ethylene glycol toxicity:
Dogs: 5.5 ml/kg IV q4h for 5 treatments, then q6h for 4 treatments
Cats: 5.0 ml/kg IV q6h for 5 treatments, then q8h for 4 treatments

Ethoxzolamide
Cardrase
Glaucoma: 4 mg/kg q8–12h PO

Etidronate disodium
Didronel
5–10 mg/kg q12–24h PO

Etodolac
Dog: 10–15 mg/kg q24h PO

Etomidate
1–4 mg/kg IV

Etretinate
Tegison
Dog: 0.75–1 mg/kg q24h PO
Cat: 2 mg/kg q24h PO

Famotidine
Pepcid
0.5–1.0 mg/kg q12–24h IM, SC, IV, PO

Febantel
Rintal
10 mg/kg q24h for 3 days PO

Febantel plus praziquantel
RM-Parasitacide; Drontal-Plus
15 mg/kg FEB 1.5 mg/kg PRA, PO, for 3 days

Felbamate
Initially 20 mg/kg q8h PO (maximum dose: 3000 mg/d) (see Chap. 127)

Fenbendazole
Panacur
50 mg/kg/d for 3 days PO

Fentanyl
Sublimaze
0.02–0.04 mg/kg IV, IM, SC, or 0.01 mg/kg IV, IM, SC (with acetylpromazine or diazepam)
Analgesia: 0.002–0.005 mg/kg IV; 0.004–0.008 mg/kg IM, SC

Fentanyl transdermal patch
Duragesic
Dog: <10 kg, 25 µg/h, q72h 10–20 kg, 50 µg/h, q72h 20–30 kg, 75 µg/h, q72h >30 kg, 100 µg/h, q72h
Cat: 25 µg/h, q118h

Ferrous sulfate
Dog: 100–300 mg/dog q24h PO
Cat: 50–100 mg/cat q24h PO

Flavoxate
Urispas
100–200 mg q12–24h PO

Florifenicol
Nuflor
Dog: 20 mg/kg q6h PO, IM
Cat: 22 mg/kg q8h PO, IM

Fluconazole
Diflucan
2.5–5.0 mg/kg q12–24h PO or IV (double loading dose on day 1)
(for CNS Cryptococcus: 10–15 mg/kg q12–24h)

Flucytosine
Ancobon
Cryptococcosis: 50 mg/kg q8h or 75 mg/kg q12h, PO combined with Amphotericin B

Fludrocortisone acetate
Florinef Acetate
Dog: 0.2–0.8 mg/dog (0.02 mg/kg) q24h PO
Cat: 0.1 mg/cat q24h PO

Flumethasone
Flucort
Dog: 0.0625–0.25 mg/dog q24h IV, IM, SC, PO
Cat: 0.03–0.125 mg/cat q24h IV, IM, SC, PO
Anti-inflammatory: 0.15–0.3 mg/kg q12–24h IV, IM, SC, PO

Flunixin meglumine
Banamine
1.1 mg/kg once IV, IM, SC, or 1.1 mg/kg/d for 3 days/wk PO
Ophthalmic: 0.5–1.0 mg/kg once IV

Fluorouracil
5-Fluorouracil
Dog: 150–200 mg/m^2 q7d IV
Cat: do not use

Fluoxetin
Prozac
Dog: 0.5–1.0 mg/kg q24h PO
Cat: 0.5–4 mg/cat q24h PO

Folic acid
Folvite
Dog and cat: 0.004–0.01 mg/kg/d (4–10 µg/kg/d)

Follicle-stimulating hormone (FSH)
See Urofollitropin

Furazolidone
Furoxone
4 mg/kg q12h for 7–10 days PO

Furosemide
Lasix
Dog: 2–6 mg/kg q8–12h (or as needed) IV, IM, SC, PO
Cat: 1–4 mg/kg q12h IV, IM, SC, PO

Gabapentin
30–60 mg/kg/d PO (divide bid or tid)

Gentamicin sulfate
Gentocin
Dog: 2–4 mg/kg q6–8h IV, IM, SC, or 6 mg/kg q24h
Cat: 3 mg/kg q8hr IV, IM, SC

Glipizide
Glucotrol
Cat: 2.5–5 mg/cat q8–12h with food

Glucosamine chondroitin sulfate
Cosequin and others
Dog: 1–2 RS (Regular Strength) capsules/d (2–4 capsules of DS (Double Strength) for large dogs)
Cat: 1 RS capsule/d

Glyburide (Glibenclamide)
Diaβeta
Micronase
0.2 mg/kg daily PO

Glycerin
Glyrol
Osmoglyn
Glaucoma: 1–1.5 gm/kg PO initially, then 500 mg/kg q8h; or 1–2 ml of 50% solution q8h

Glycopyrrolate
Robinul-V
0.005–0.01 mg/kg IV, IM, SC q8–12h as needed

Gold sodium thiomalate
Myochrysine
Immune-mediated arthritis: 1 mg/kg once weekly IM

Gonadorelin (GnRH, LHRH)
Factrel
Dog: 50–100 µg/dog q24–48h IM
Cat: 25 µg/cat once IM

Gonadotropin, chorionic (hCG)
Follutein
Dog: 22 U/kg q24–48h IM, or 44 U/kg once IM
Cat: 250 U/cat once IM

Gonadotropin-releasing hormone
See Gonadorelin

Griseofulvin (microsize)
Fulvicin U/F powder or tablets
50 mg/kg q24h PO (maximum dose: 110–132 mg/kg/d in divided treatments)

Griseofulvin (ultramicrosize)
Fulvicin P/G
5–10 mg/kg/d PO (in divided treatments)

Growth hormone
0.1 U/kg 3 times/wk for 4–6 weeks

Halothane
Fluothane
3% (induction); 0.5–1.5% (maintenance) (see Chap. 2)

Heparin sodium
Liquaemin (U.S.)
Hepalean (Canada)
100–200 U/kg IV, loading dose; then 100–300 U/kg q6–8h SC (monitor clotting profiles)
Low-dose therapy (dog and cat): 70 U/kg q8–12h SC

Hetacillin potassium
Hetacin-K
20–40 mg/kg q8h PO

Hetastarch
See Hydroxyethyl starch

Hydralazine
Apresoline
Dog: 0.5 mg/kg (initial dose), titrated to 0.5–2.0 mg/kg q12h PO
Cat: 2.5–5 mg/cat q12–24h PO

Hydrochlorothiazide
Hydrodiuril
2–4 mg/kg q12h PO

Hydrocodone
Hycodan
Dog: 0.22 mg/kg q6–12h PO

Hydrocortisone
Cortef
Replacement therapy: 1 mg/kg q12h PO
Anti-inflammatory: 2.5–5.0 mg/kg q12h PO

Hydrocortisone sodium succinate
Solu-Cortef
Shock: 50–150 mg/kg IV

Hydromorphone
0.1–0.2 mg/kg IV, IM, SC

Hydroxyethyl starch
Hetastarch
Dog: 20 ml/kg/24h (5 ml/kg over 15 min for hypovolemia) (see Chap. 5)
Cat: 10 ml/kg/24h (2.5 ml/kg over 15 min for hypovolemia) (see Chap. 5)

Hydroxyurea
Hydrea
For polycythemia vera: 30 mg/kg/d for 1 week, then 15 mg/kg/d until remission

Hydroxyzine
Atarax
Dog: 2.2 mg/kg q8–12h PO
Cat: 10 mg/cat q12h PO

Hyoscyamine
0.003–0.006 mg/kg q8–12h PO, SC

Imidocarb
5 mg/kg IM SC once and repeated in 14 days

Imipramine
Dog: 1 mg/kg q8h PO
Cat: 2.5–5.0 mg/cat q12h PO

Insulin (NPH isophane)
Dog: 0.5–1.0 U/kg q12–24h SC (to effect)
Cat: 1–5 U/cat q12h SC (to effect) (see Chap. 34)

Insulin (PZI)
Dog: 0.5–1.0 U/kg q12–24h SC (to effect)
Cat: 1–5 units/cat (0.2–1.0 U/kg) q12–24h SC (adjust with monitoring) (see Chap. 34)

Insulin (regular crystalline)
Ketoacidosis:
See Chapter 34 for complete treatment protocol

Insulin, ultralente
Dog: 0.5–1.0 U/kg q12–24h SC (to effect)
Cat: 1–5 U/cat q12–24h SC (to effect) (see Chap. 34)

Interferon-alpha
Roferon A; Intron A (dilute to 30 U/ml)
Cat: 30 U/cat q24h for 7 days on alternating weeks

Interferon-omega (recombinant feline [rFeIFN-omega])
Virbagen
FIP: 1,000,000 u/kg SC (See Chapters 8–10 and 14 for treatment protocols)

Iodide
See Potassium iodide

Ipecac syrup
Dog: 1–2 ml/kg up to 15 ml PO
Cat: 2–6 ml/cat PO

Iron
See Ferrous sulfate

Isoflurane
3.5% (induction); 1.5–2.5% (maintenance)
(see Chap. 2)

Isoproterenol
Isuprel
0.04–0.09 µg/kg/min IV; 0.1–0.2 mg/dog q4–6h IM, SC

Isosorbide dinitrate
Isordil
Sorbitrate
2.5–5 mg/animal q12h PO

Isotretinoin
Accutane
1–3 mg/kg/d (maximum dose: 3–4 mg/kg/d) PO

Itraconazole
Sporanox
Dog: 5 mg/kg q12–24h PO
Cat: 5–10 mg/kg q12h PO, or 20 mg/kg q24h

Ivermectin
Heartgard
Ivomec
Heartworm preventive in dog: 6 µg/kg q30d PO
Cat: 24 µg/kg q30d PO
Microfilaricide in dog: 50 µg/kg PO 3–4 weeks after adulticide therapy
Ectoparasite therapy: 300–600 µg/kg q24h IM, SC, PO (do not use in collie and sheltie dogs)
Respiratory parasites: 200–400 µg/kg weekly SC, PO (do not use in collie and sheltie dogs)

Kanamycin sulfate
Kantrim
10 mg/kg q6–8h IV, IM, SC

Kaolin plus pectin
Kaopectate
1–2 ml/kg q2–6h PO

Ketamine
Ketalar
Ketaset
Cat: 4–10 mg/kg IV, 10–20 mg/kg IM, SC (see Chap 2)
Dog: 1 ml/10 kg IV of ketamine : diazepam mixture (50 : 50)

Ketoconazole
Nizoral
Dog: 10–15 mg/kg q12h PO (*Malassezia canis* infection: 10 mg/kg q24h or 5 mg/kg q12h PO)
Hyperadrenocorticism: 15 mg/kg q12h PO
Cat: 5–10 mg/kg q8–12h PO

Ketoprofen
Ketofen
Dog: 1.1 mg/kg q24h IV, PO for up to 5 days
Cat: 2 mg/kg q24h PO, SC initially, then 0.5–1.0 PO, SC

Lactated Ringer's solution
40–50 ml/kg/d IV for maintenance requirements
Shock therapy:
Dog: 90 ml/kg IV
Cat: 60 ml/kg IV

Lactulose
Cephulac; Duphalac
Constipation: 1 ml/4.5 kg q8h PO (to effect)
Hepatic encephalopathy
Dog: 0.5 ml/kg q8h PO
Cat: 2.5–5.0 ml/cat q8h PO

Leucovorin (folinic acid)
Wellcovorin
With methotrexate administration: 3 mg/m^2 IV, IM, PO
Antidote for pyrimethamine toxicosis: 1 mg/kg q24h PO

Levamisole
Levasole
Tramisol
Dog: 5–8 mg/kg PO once, up to 10 mg/kg PO for 2 days (hookworms); 10 mg/kg q24h PO for 6–10 days (microfilaricide); 0.5–2.0 mg/kg 3 times/wk PO (immunostimulant)
Cat: 4.4 mg/kg PO once

Levetiracetem
500–4000 mg/d PO (divide bid or tid)

Levo-carnitine
Dog: 50 mg/kg q8h PO
Cat: 250–500 mg/cat qd PO

Levodopa (l-dopa)
Larodopa
Hepatic encephalopathy: 6.8 mg/kg initially, then 1.4 mg/kg q6h

Levothyroxine sodium
Soloxine
Thyro-Tabs
Synthroid
Dog: 0.01–0.02 mg/kg q12h, PO
Cat: 0.01–0.02 mg/kg q24h, PO

Lidocaine
Xylocaine
Antiarrhythmia in dog: 2–4 mg/kg IV (maximum dose: 8 mg/kg over 10 min); 25–75 µg/kg/min IV infusion; 6 mg/kg q1.5h IM
Cat: 0.25–0.75 mg/kg IV, slowly

Lime sulfur (2–3% solution)
Topically once/wk for 4–6 weeks

Lincomycin
Lincocin
15–25 mg/kg q12h IV, IM, PO

Liothyronine
Cytobin or Cytomel
4.4 µg/kg q8h PO
Suppression testing: See Chapter 31 for protocol

Lisinopril
Prinivil
Dog: 0.25–0.5 mg/kg q12–24h

Lithium carbonate
Lithotabs
Dog: 10 mg/kg q12h PO
Cat: not recommended

Lomustine
60–90 mg/m^2 q21–28d PO

Loperamide
Imodium
Dog: 0.1–0.2 mg/kg q8–12h PO
Cat: 0.1–0.3 mg/kg q12–24h PO

Lufenuron
Program
Flea control
Dog: 10mg/kg q30d PO
Cat: 30mg/kg q30d PO
Coccidioidomycosis
5 mg/kg PO q24h

Luteinizing hormone
See Gonadorelin

Magnesium citrate
Citroma, Citro-Nesia (U.S.)
Citro-Mag (Canada)
2–4 ml/kg PO

Magnesium hydroxide
Milk of Magnesia
Antacid: 5–10 ml per dog or cat PO
Cathartic:
Dog: 15–50 ml/dog PO
Cat: 2–6 ml/cat q24h PO

Magnesium sulfate
Dog: 8–25 g/dog q24h PO
Cat: 2–5 g/cat q24h PO

Mannitol
Osmitrol
Diuretic: 1 g/kg of 5–25% solution IV
Glaucoma or CNS edema: 0.5–1.0 g/kg of 15–25% solution over 15–60 minutes IV (repeat in 4–6 hours if necessary)

Marbofloxacin
Marbocyl, Zeniquin
Dog: 2.75–5.55 mg/kg q24h PO

Mebendazole
Telmintic
22 mg/kg (with food) q24h for 3 days

Meclizine hydrochloride
Bonine
Dog: 25 mg/dog q24h PO (motion sickness: administer 1 hour before traveling)
Cat: 12.5 mg/cat q24h PO

Meclofenamic acid
Meclomen
Meclofen
Arquel
Dog: 1 mg/kg/d for 5 days, then 0.5 mg/kg q24h PO

Medetomidine
Domitor
Dog: 0.007–0.02 mg/kg IV; 0.01–0.04 mg/kg IM, SC
Cat: 0.01–0.03 mg/kg IV; 0.03–0.08 mg/kg IM, SC

Medium-chain triglycerides (MCTs)
MCT oil
1–2 ml/kg daily in food

Medroxyprogesterone acetate
Depo-Provera
1.1–2.2 mg/kg q7d IM

Megestrol acetate
Ovaban
Dog: Proestrus: 2.2 mg/kg q24h PO for 8 days Anestrus: 0.55 mg/kg q24h PO for 30 days Behavior problems: 2–4 mg/kg q24h for 8 days (reduce dose for maintenance)
Cat: dermatologic therapy or urine spraying: 2.5–5.0 mg/cat q24h PO for 1 week, then reduce to 2.5–5.0 mg once or twice/wk; suppress estrus: 5 mg/cat for 3 days, then 2.5–5 mg once/wk for 10 weeks

Melarsomine
Immiticide
Dog: 2.5 mg/kg, IM, q24h for 2 doses, Alternate: 2.5 mg/kg, IM once; then after 1–2 months give 2.5 mg/kg IM, q24h for 2 additional doses

Meloxicam
Metacam
Dog: 0.2 mg/kg PO, SC initially, then 0.1 mg/kg q24h for 2–3 days
Cat: 0.3 mg/kg SC, one time only

Melphalan
Alkeran
2–4 mg/m^2 q24–48h PO (see Chap. 26)

Meperidine
Demerol
Dog: 0.4–2 mg/kg IV, 1.0–4.0 mg/kg IM, SC

6-Mercaptopurine
Purinethol
50 mg/m^2 q24h PO

Mesalamine
Asacol; Pentasa
Dogs: 20 mg/kg q8–12h PO
(See also Osalazine sodium; Sulfasalazine)

Metaproterenol
Alupent
Metaprel
0.325–0.65 mg/kg q4–6h PO

Metaraminol bitartrate
Aramine
0.1 mg/kg IM, SC

Methazolamide
Neptazane
2–4 mg/kg q8–12h PO

Methenamine hippurate
Hiprex
Dog: 500 mg/dog q12h PO
Cat: 250 mg/cat q12h PO

Methenamine mandelate
Mandelamine
10–20 mg/kg q8–12h PO

Methimazole
Tapazole
Cat: 2.5 mg/cat q8–12h PO (initial), increase to 5–10 mg/cat q8–12h PO by monitoring T4

Methionine (l-methionine, dl-methionine)
Uroeze
Methio-Form
Dog: 150–300 mg/kg/d PO
Cat: 1000–1500 mg/cat PO (added to food each day) (use in adult cats only)

Methocarbamol
Robaxin-V
44 mg/kg q8h PO on the first day, then 22–44 mg/kg q8h PO

Methotrexate (MTX)
2.5 mg/m^2 q24h PO; or 2–3 times per week;
15–20 mg/m^2 IV q3wk (see Chap. 26)

Methoxamine
Vasoxyl
200–250 µg/kg IM, or 40–80 µg/kg IV

Methscopolamine bromide
Pamine
0.3–1.0 mg/kg q8h PO (use cautiously in cats)

Methylene blue (1% solution)
Dog: for pancreatic tumor identification: 3 mg/kg IV slowly, diluted in isotonic saline (can cause hemolytic anemia)
Cat: do not use

Methylprednisolone
Medrol
Dog: 0.22–0.44 mg/kg q12–24h PO

Methylprednisolone acetate
Depo-Medrol
Dog: 1 mg/kg IM q1–3wk
Cat: 10–20 mg/cat IM q1–3wk

Methylprednisolone sodium succinate
Solu-Medrol
For spinal cord trauma: 30 mg/kg IV, repeat at 15 mg/kg IV in 2–6 hours

4-Methylpyrazole (fomepizole)
Antizol-Vet
20 mg/kg initially IV, then 15 mg/kg at 12- and 24-hour intervals, then 5 mg/kg at 36h.

Methyltestosterone
Android
Fluoxymestrone
Dog: 1.0 mg/kg q48h PO
(see also Testosterone cypionate; Testosterone propionate), for sex hormone dematoses in dogs: 1 mg/kg (up to 30 mg total dose)
Cat: 1.0–2.5 mg/cat q48h PO

Metoclopramide
Reglan
Maxolon
0.2–0.5 mg/kg q6–8h IV, IM, SC, PO, or 1–2 mg/kg q24h via continuous IV infusion

Metoprolol tartrate
Lopressor
Dog: 5–50 mg/dog q8h PO
Cat: 2–15 mg/cat q8h PO
or: 0.25–1.0 mg/kg q8h PO (dog and cat)

Metronidazole
Flagyl
Dog: for giardia: 50–65 mg/kg q24h PO for 5–7 days; Antibacterial: 10–15 mg/kg q8–12h PO
Cat: for giardia: 50 mg/kg q24h PO for 5 days; Antibacterial: 10 mg/kg q8h or 15 mg/kg q12h PO

Mexiletine
Mexitil
Dog: 5–8 mg/kg q8–12h PO (use cautiously)

Mibolerone
Cheque
Dog: (2.6–5.0 µg/kg/d PO) 0.45–11.3 kg: 30 µg 11.8–22.7 kg: 60 µg 23–45.3 kg: 120 µg >45.8 kg: 180 µg
Cat: safe dose not established

Midazolam
Versed
0.1–0.25 mg/kg IV, IM, or 0.1–0.3 mg/kg/h IV infusion

Milbemycin oxime
Interceptor
Dog: 0.5 mg/kg q30d PO
For demodex: 1–2 mg/kg q24h PO
For scabies: 2 mg/kg PO twice at 14-day intervals

Milk of magnesia
See Magnesium hydroxide

Milk thistle
Marin
6–100 mg q24h PO

Minocycline
Minocin
5.0–12.5 mg/kg q12h PO

Misoprostol
Cytotec
Dog: 3–5 µg/kg q6–8h PO

Mitotane (*o,p′*-DDD)
Lysodren
For pituitary-dependent hyperadrenocorticism: 50 mg/kg/d PO (may be given in divided doses) for 5–10 days, then 50–70 mg/kg/wk PO
Adrenal tumor: 50–75 mg/kg/d for 10 days PO, then 75–100 mg/kg/wk PO (see Chap. 33)

Mitoxantrone
Novantrone
5–6 mg/m^2 IV q3wk

Morphine
Dog: 0.2–0.6 mg/kg IM, SC (as needed); 0.1 mg/kg epidural
Cat: 0.1 mg/kg IM, SC (as needed)

Nadolol
Corgard
0.25–0.5 mg/kg q12h PO

Nafcillin sodium
Unipen
10 mg/kg q6h IM, PO

Nalbuphine
Dog: 0.5–2.0 mg/kg IV, IM, SC
Cat: 0.5–1.5 mg/kg IV, IM, SC

Nalorphine
Nalline
0.44 mg/kg IV, IM, SC (1 mg for every 10 mg of morphine)

Naloxone
Narcan
0.003–0.01 mg/kg IV, IM, for opiate reversal

Naltrexone hydrochloride
Trexan
Behavior problems: 2.2 mg/kg q12h PO

Nandrolone decanoate
Deca-Durabolin
Dog: 1.0–1.5 mg/kg qwk IM
Cat: 1 mg/cat qwk IM

Neomycin
Biosol
10–20 mg/kg q6–12h PO

Neostigmine bromide
Prostigmin bromide
2 mg/kg/d PO (in divided doses, to effect)

Neostigmine methylsulfate
Prostigmin
Antimyasthenic: 10 µg/kg IM, SC, as needed (atropine may be administered to counteract side effects)
Antidote for curiform block: 40 µg/kg IM, SC (administer with atropine)
Diagnostic aid for myasthenia gravis: 40 µg/kg IM, or 20 µg/kg IV

Nitrofurantoin
Furadantin
Macrodantin
4 mg/kg q8h PO

Nitroglycerin ointment
Nitrol Ointment
Nitro-Bid Ointment
Nitrostat Ointment
(1 inch of ointment is approximately 15 mg)
Dog: 1/4–1 inch topically q12–24h
Cat: 1/4 inch topically q12–24h

Nitroprusside
Nipride
2.5–15 µg/kg/min constant IV infusion

Nizatidine
Axid
2.5–5 mg/kg q24h PO

Norfloxacin
Noroxin
22 mg/kg q12h PO

Novobiocin
See Delta-Albaplex

Olsalazine
Dipentum
Dog: 20–30 mg/kg q8–12h PO

Omega fatty acids
See also Derm Caps
1 capsule q12h PO (see also Essential fatty acids)

Omeprazole
Prilosec
Dog: 20 mg/dog or 0.7–1.0 mg/kg q24h PO
Cat: Not recommended

Ondansetron
Zofran
0.1–0.5 mg/kg q6–12h IV, SC
0.5–1.0 mg/kg q6–12h PO

***o,p'*-DDD**
See Mitotane

Ormetroprim
See Primor

Oxacillin
Prostaphlin
Bactocill
22–40 mg/kg q8h PO

Oxazepam
Serax
Appetite stimulant: 2.5 mg/cat q12h PO

Oxtriphylline
Choledyl SA
Dog: 47 mg/kg (equivalent to 30 mg/kg theophylline) q12h PO

Oxybutynin chloride
Ditropan
5.0 mg/dog q8–12h PO

Oxymetholone
Anadrol
1–5 mg/kg q24h PO

Oxymorphone hydrochloride
Numorphan
Analgesia:
Dog: 0.05–0.1 mg/kg IV 0.1–0.3 mg/kg IM, SC
Cat: 0.01–0.04 mg/kg IV 0.05–0.1 mg/kg IM, SC
For preanesthesia or sedation: see Chapter 2

Oxytetracycline
Terramycin
20 mg/kg q8h PO; 7.5–10.0 mg/kg q8h IV

Oxytocin
Dog: 5–20 units/dog IM, repeat q30min for primary inertia
Cat: 3–5 units/cat IM

2-PAM
See Pralidoxime chloride

Pamidronate
Aredia
1.3–2.0 mg/kg in 150 ml 0.9% saline in 2-hour IV infusion; can repeat in 1–3 weeks

Pancreatic enzyme (pancrelipase)
Viokase
Pancrezyme
2 tsp per 20 kg body weight, or 1–3 tsp/0.45 kg of food, mixed with food 20 minutes prior to feeding

Pancuronium bromide
Pavulon
0.1 mg/kg IV

Pantoprazole
Protonix
0.7–1.0 mg/kg q24h IV, PO

Paregoric
Corrective Mixture
0.05–0.06 mg/kg q12h PO (5 ml of paregoric corresponds to approximately 2 mg of morphine)

D-Penicillamine
Cuprimine
10–15 mg/kg q12h PO

Penicillin G potassium
20,000–40,000 U/kg q6–8h, IV, IM

Penicillin G procaine
20,000–40,000 U/kg q12–24h IM

Penicillin G sodium
20,000–40,000 U/kg q6–8h IV, IM

Penicillin V
10 mg/kg q8h PO

Pentazocine
Talwin
Dog: 1.65–3.3 mg/kg q4h IM
Cat: 2.2–3.3 mg/kg IV, IM, SC

Pentobarbital
Anesthesia: 25–30 mg/kg IV (first ½ of the dose administered rapidly, then remaining administered to effect)

Pentoxifylline
Trental
10–15 mg/kg q8h PO

Petrolatum, white (flavored)
Laxatone
Cat: 1–5 ml/cat q24h PO

Phenobarbital
Luminal
Dog: 2–8 mg/kg q12h PO
Cat: 1–2 mg/kg q12h PO
For seizures: Initially: 2.5 mg/kg q12h PO (see Chap. 127) and adjust by plasma concentration
Status epilepticus (dog or cat): 10–20 mg/kg IV (to effect) or IV loading protocol (preferred; see Chap. 127)

Phenoxybenzamine hydrochloride
Dibenzyline
Dog: 0.25–0.5 mg/kg q8h PO
Cat: 2.5 mg/cat q8–12h PO

Phentolamine mesylate
Regitine (U.S.)
Rogitine (Canada)
0.02–0.1 mg/kg IV (as needed to maintain normal blood pressure)

Phenylbutazone
Butazolidin
Dog: 10–15 mg/kg q8h PO (maximum dose: 800 mg)
Cat: not recommended

Phenylephrine hydrochloride
Neo-Synephrine
0.01 mg/kg q15min IV
0.1 mg/kg q15min IM, SC

Phenylpropanolamine hydrochloride
Propagest
Dexatrim
Dog: 1–2 mg/kg q12h PO
Cat: 1 mg/kg q12h PO

Phenytoin
Dilantin
Antiepileptic in dog: 20–35 mg/kg q8h PO
Antiarrhythmic in dog: 30 mg/kg q8h PO or 10 mg/kg IV over 5 minutes

Phytonadione
See Vitamin K_1

Phytomenadione
See Vitamin K_1

Pimobendan
Vetmedin
Dog: 0.3–0.6 mg/kg/d divided q12h PO

Piperazine
44–66 mg/kg PO once

Piroxicam
Feldene
Dog: 0.3 mg/kg q48h PO (use cautiously)
Cat: dosage not established

Polyethylene glycol electrolyte solution
GoLYTELY
25 ml/kg, then repeat in 2–4 hours PO

Polysulfated glycosaminoglycans
Adequan
1–2 mg/kg IM once every 4 days for 7 injections

Potassium bromide
Dog and cat: 30 mg/kg q24h PO (in food) (see Chap. 127)

Potassium chloride
0.5 mEq/kg/d (do not administer at a rate faster than 0.5 mEq/kg/h)
10–40 mEq/500 ml of fluids, depending on serum potassium (see Chap. 5)

Potassium citrate
Urocit-K
Dog: 50–75 mg/kg q12h PO

Potassium gluconate
Kaon elixir
Tumil-K
2.2 mEq/100 kcal of energy/day PO
Cat: 2–6 mEq/cat daily PO

Potassium iodide
30–100 mg/cat daily (in single or divided doses) for 10–14 days

Potassium (or sodium) phosphate (potassium or sodium)
0.01–0.03 mmol phosphate/kg/hr for 3–6 hours (or, 2.5 mg/kg over 6 hours) (3 mmol/ml or 93 mg/ml phosphate)

Pralidoxime chloride (2-PAM)
Protopam Chloride
Organophosphate toxicosis: 20 mg/kg q8–12h (initial dose slow IV, or IM; subsequent doses IM, SC)

Praziquantel
Droncit
Dog (PO): <6.8 kg: 7.5 mg/kg once >6.8 kg: 5 mg/kg once
Dog (IM, SC): ≤2.3 kg: 7.5 mg/kg once 2.7–4.5 kg: 6.3 mg/kg once ≥5 kg: 5 mg/kg once
Cat (PO): <1.8 kg: 6.3 mg/kg once >1.8 kg: 5 mg/kg once
Cat (IM, SC): 5 mg/kg IM, SC paragonimiasis: 25 mg/kg q8h for 2 days
Liver flukes: 20 mg/kg qd for 3 days; PO, SC

Prazosin
Minipress
0.5–2.0 mg/animal q8–12h PO

Prednisolone
Anti-inflammatory:
Dog: 0.5–1.0 mg/kg q12–24h IV, IM, PO initially then taper to q48h
Cat: 2.2 mg/kg q12–24h IV, IM, PO initially, then taper to q48h
Immunosuppressive (dog and cat): initially 2.2–6.6 mg/kg/d IV, IM, PO, then taper to 2–4 mg/kg q48h

Prednisolone sodium succinate
Solu-Delta-Cortef
Shock: 15–30 mg/kg IV, then repeat in 4–6 h
CNS trauma: 15–30 mg/kg IV, then taper to 1–2 mg/kg q12h

Prednisone
See Prednisolone

Primidone
Mylepsin
Mysoline
Initial dosage: 5–10 mg/kg q8h PO

Primor (ormetroprim plus sulfadimethoxine)
25 mg/kg on first day, followed by 12.5 mg/kg q24h PO

Procainamide
Pronestyl
Dog: 10–20 mg/kg q6h PO (maximum dose: 40 mg/kg); 8–20 mg/kg IV, IM; 25–50 µg/kg/min IV infusion
Cat: 3–8 mg/kg IM, PO q6–8h

Procainamide (extended-release tablets)
Procan-SR
Dog: 20–50 mg/kg q8h PO
Cat: 62.5 mg/cat q8h PO

Prochlorperazine
Compazine
0.25–0.5 mg/kg q6–8h IM, SC

Progesterone, repositol
See Medroxyprogesterone acetate

Promazine
Tranquazine
1–2 mg/kg q6–8h IV, IM, PO

Promethazine hydrochloride
Phenergan
0.2–0.4 mg/kg q6–8h IV, IM, PO (maximum dose: 1 mg/kg)

Propantheline bromide
For detrusor hyperreflexia and urge incontinence:
Dog: 7.5–30.0 mg/dog q8–24h PO (start low)
Cat: 7.5 mg/cat q24–72h PO
For diarrhea: 0.25 mg/kg q8–12h PO

Propofol
2–6 mg/kg IV for anesthesia (see Chap. 2)

Propranolol hydrochloride
Inderal
Dog: 20–60 µg/kg over 5–10 min q8h IV, 0.2–1.0 mg/kg q8h PO
Cat: 2.5–5.0 mg/cat (0.4–1.2 mg/kg) q8–12h PO

Prostaglandin E
See Misoprostol

Prostaglandin $F_2\alpha$
Lutalyse
Pyometra: Dog: 0.1–0.25 mg/kg, once daily for 3–5 days SC (see Chap. 90)
Abortion:
(See Chap. 90 for protocol)

Psyllium
Metamucil
Dog: 1–3 tbsp/d (added to food)
Cat: 1–3 tsp/d (added to food)

Pyrantel pamoate
Nemex, Strongid
Dog: <2.5 kg: 10 mg/kg PO >2.5 kg: 5 mg/kg PO
Cat: 20 mg/kg PO

Pyridostigmine bromide
Mestinon
Regonol
Antimyasthenic: 0.02–0.04 mg/kg q2h IV, or 0.5–3.0 mg/kg q8–12h PO
Antidote (curariform): 0.15–0.3 mg/kg IM, IV

Pyrimethamine
Daraprim
Dog: 1 mg/kg q24h PO for 14–28 days (5 days for *Neosporum caninum*)
Cat: 0.5–1.0 mg/kg q24h PO for 14–28 days

Quinacrine hydrochloride
Atabrine hydrochloride
Dog: 6.6 mg/kg q12h PO for 5 days
Cat: 11 mg/kg q24h PO for 5 days

Quinidine gluconate
Quinaglute
Duraquin
Dog: 6–20 mg/kg q6h IM; 6–20 mg/kg q6–8h PO (of base)
(324 mg quinidine gluconate = 202 mg quinidine base)

Quinidine polygalacturonate
Cardioquin
Dog: 6–20 mg/kg q6h PO (of base)
(275 mg quinidine polygalacturonate = 167 mg quinidine base)

Quinidine sulfate
Clin-Quin
Quinora
Dog: 6–20 mg/kg q6–8h PO (of base)
(300 mg quinidine sulfate = 250 mg quinidine base)

Ranitidine
Zantac
Dog: 2 mg/kg q8–12h IV, PO
Cat: 2.5 mg/kg q12h IV; 3.5 mg/kg q12h PO

Retinoids
See Isotretinoin; Retinol; Etretinate

Retinol
Aquasol-A
625–800 IU/kg q24h PO

Riboflavin (vitamin B_2)
Dog: 10–20 mg/d PO
Cat: 5–10 mg/d PO

Rifampin
Rifadin
10–20 mg/kg q24h PO

Ringer's solution
40–50 ml/kg/d IV, SC, IP for maintenance requirements

Salicylate
See Acetylsalicylic acid (aspirin)

Selegiline
See Deprenyl (Anipryl)

Senna
Senokot
Cat: 5 ml/cat q24h (syrup); $^1/_2$ tsp/cat q24h with food (granules)

SMS 201-995
Octreotide
10–20 µg q8–12h SC

Sodium bicarbonate ($NaHCO_3$)
Acidosis: 0.5–1.0 mEq/kg IV, monitor blood gases (8.5% solution = 1 mEq/ml of $NaHCO_3$)
Renal failure: 10 mg/kg q8–12h PO (adjust as necessary)
Alkalinization of urine: 50 mg/kg q8–12h PO (1 tsp is approximately 2 g)

Sodium chloride (0.9%)
40–50 ml/kg/d IV, SC, IP

Sodium chloride 7% (hypertonic saline)
2–8 ml/kg/ IV for shock therapy

Sodium iodide (20%)
20–40 mg/kg q8–12h PO

Sodium nitroprusside
See Nitroprusside sodium

Sodium thiomalate
See Gold sodium thiomalate

Sotalol
Betapace
Dog: 1–3.5 mg/kg q12h PO
Cat: $^1/_8$ of 80 mg tab q12h PO

Spironolactone
Aldactone
1–2 mg/kg q12h PO

Stanozolol
Winstrol-V
Dog: 1–4 mg/dog q12h PO; 25–50 mg/dog/wk IM
Cat: 1 mg/cat q12h PO; 25 mg/cat/wk IM

Streptozotocin
(See Chapter 35 for administration protocol)

Sucralfate
Carafate
Dog: 0.5–1.0 g/dog q8–12h PO
Cat: 0.25 g/cat q8–12h PO

Sufentanil
Sufenta
2 µg/kg IV, up to a maximum dose of 5 µg/kg (premedicate with acepromazine)

Sulfadiazine
100 mg/kg IV, PO (loading dose), followed by 50 mg/kg q12h IV, PO (see also Trimethoprim)

Sulfadimethoxine
Albon, Bactrovet
55 mg/kg PO (loading dose), followed by 27.5 mg/kg q12h PO (see also Primor)

Sulfaguanidine
100–200 mg/kg q8h PO for 5 days

Sulfamethazine
100 mg/kg PO (loading dose), followed by 50 mg/kg q12h PO

Sulfamethoxazole
Gantanol
100 mg/kg PO (loading dose), followed by 50 mg/kg q12h PO

Sulfamethoxazole plus trimethoprim
Bactrim
Septra
See Trimethoprim plus sulfadiazine

Sulfasalazine (Sulfapyridine plus mesalamine)
Azulfidine (U.S.)
Salazopyrin (Canada)
Dog: 10–30 mg/kg q8–12h PO
Cat: 10–20 mg/kg q12–24h PO
(See also Mesalamine, Olsalazine)

Sulfisoxazole
Gantrisin
50 mg/kg q8h PO (urinary tract infections)

Tacrolimus
Prototopic (ointment)
Apply topically q24h

Taurine
Dog: 250–500 mg/dog q12h PO
Cat: 250 mg/cat q12h PO

Tegaserod
Zelnorm
Dog: 0.05–0.1 mg/kg q12h PO

Telezol
See Tiletamine plus zolazepam

Temaril-P (Trimeprazine plus prednisolone)
0.7–1.1 mg/kg (of trimeprazine) q12–24h PO

Tepoxalin
Zubrin
Dog: 10–20 mg/kg q24h PO then 10 mg/kg q24h PO

Terbinafine
Lamasil
Dog: 30 mg/kg q24h PO for 21–28 days
Cat: 30–40 mg/kg q24h PO for 21–28 days

Terbutaline
Brethine, Bricanyl
Dog: 2.5–5.0 mg/dog q8h SC, PO
Cat: 0.625 mg/cat q12h SC, PO

Testosterone cypionate
Andro-Cyp
1–2 mg/kg q2–4wk IM (see also Methyltestosterone)

Testosterone propionate
Testex
Malogen
0.5–1.0 mg/kg 2–3 times/wk IM (see also Methyltestosterone)

Tetanus toxoid (equine antitoxin)
100–500 U/kg (maximum 20,000 U); IV slowly over 5–10 minutes

Tetracycline
Panmycin
Achromycin
15–22 mg/kg q6–8h PO
4.4–11.0 mg/kg q8–12h IV, IM
(See also Oxytetracycline, Doxycycline, Minocycline)

Theophylline
Dog: 9 mg/kg q6–8h PO
Cat: 4 mg/kg q8–12h PO
(See also Aminophylline)

Theophylline (long-acting)
Theo-Dur
Slo-bid Gyrocaps
Dog: 20 mg/kg q12h PO (Theo-Dur) 30 mg/kg q12h PO (Slo-bid)
Cat: 25 mg/kg q24h PO at night

Thiabendazole
Omnizole

Equizole
Dog: 50 mg/kg q24h for 3 days, repeat 1 month
Cat *(Strongyloides):* 125 mg/kg q24h for 3 days

Thiacetarsamine sodium
Caparsolate
2.2 mg/kg IV twice daily for 2 days

Thiamine (vitamin B_1)
Dog: 10–100 mg/dog/d PO
Cat: 5–30 mg/cat/d PO (up to a maximum dose of 50 mg/cat/d)

Thiomalate sodium
See Gold sodium thiomalate

Thiopental sodium
Pentothal
Dog: 6–10 mg/kg IV (to effect)

Thiotepa
0.2–0.5 mg/m^2 intracavitary or IV

Thyroid hormone
See Levothyroxine, Liothyronine

Thyrotropin (TSH)
Thytropar
Dog: collect baseline sample, followed by 0.1 IU/kg IV (maximum dose is 5 IU); collect post-TSH sample at 6 hours
Cat: collect baseline sample, followed by 2.5 IU/cat IM and collect post-TSH sample at 8–12 hours

Ticarcillin
Ticar
33–50 mg/kg q4–6h IV, IM

Tiletamine plus zolazepam
Telezol
0.5–4.0 mg/kg IV, 4–10 mg/kg IM, SC

Tobramycin
Nebcin
2 mg/kg q8hr IV, IM, SC

Tocainide
Tonocard
Dog: 10–20 mg/kg q8h PO

Toluene
267 mg/kg PO (of Toluene), repeat in 2–4 weeks

Topiramate
2–10 mg/kg q12h PO

Tramadol
Dog: 1 mg/kg q12h PO

Triamcinolone
Vetalog
Aristocort
Anti-inflammatory: 0.5–1.0 mg/kg q12–24h PO, taper dose to 0.5–1.0 mg/kg q48h PO

Triamcinolone acetonide
Vetalog
0.1–0.2 mg/kg IM, SC, repeat in 7–10 days
Intralesional: 1.2–1.8 mg, or 1 mg for every cm diameter of tumor q2wk

Tribrissen: see Trimethoprim sulfadiazine

Trientine hydrochloride
Syprine
10–15 mg/kg q12h, PO (1 hr before meals, do not give concurrently with other medications).

Triflupromazine
Vesprin
0.1–0.3 mg/kg IM, PO q8–12h

Tri-iodothyronine
See Liothyronine

Trimeprazine
Panectyl
0.5 mg/kg q12hr PO (also see Temaril-P)

Trimethobenzamide
Tigan, Trimazide
Dog: 3 mg/kg q8h IM, PO
Cat: not recommended

Trimethoprim plus sulfadiazine
Tribrissen
15 mg/kg q12hr IM, PO, or 30 mg/kg q12–24h SC, PO (for Toxoplasma: 30 mg/kg q12h PO)

Tripelennamine
Pelamine
1 mg/kg q12h PO

TSH (thyroid-stimulating hormone)
See Thyrotropin

Tylosin
Tylocine, Tylan
20–40 mg/kg q12h PO

Urofollitropin
Metrodin
Cat: 2 mg/cat q24h IM

Ursodiol (ursodeoxycholate)
Actigall
10–15 mg/kg q24h PO

Valproic acid
Depakene
Dog: 60–200 mg/kg q8h PO; or 25–105 mg/kg q24h PO when administered with phenobarbital

Vancomycin
Vancocin
Dog: 15 mg/kg q6–8h IV
Cat: 12–15 mg/kg q8h IV

Vasopressin (ADH)
Pitressin
Aqueous (20 U/ml): 10 U IV, IM (see also Desmopressin acetate)

Verapamil
Calan
Isoptin
Dog: 0.05 mg/kg q10–30 min IV (maximum cumulative dose is 0.15 mg/kg); oral dose is not established
Cat: 1.1–2.9 mg/kg q8h PO

Vermiplex
See Toluene

Vinblastine
Velban
2 mg/m^2 q7–14d IV

Vincristine
Oncovin
Antitumor: 0.5–0.75 mg/m^2 q7d IV
Thrombocytopenia: 0.025 mg/kg once/wk IV

Viokase (See Pancreatic enzyme)

Vitamin A (Retinoids)
See Isotretinoin (Accutane), Retinol (Aquasol A), or Etretinate (Tegison)

Vitamin B complex
Dog: 0.5–2.0 ml q24hr IV, IM, SC
Cat: 0.5–1.0 ml q24hr IV, IM, SC

Vitamin B_1
See Thiamine

Vitamin B_2
See Riboflavin

Vitamin B_{12}
See Cyanocobalamin

Vitamin C
See Ascorbic acid

Vitamin D
See Dihydrotachysterol; Ergocalciferol

Vitamin E (Alpha tocopherol)
Aquasol E
100–400 IU q12h PO (or 400–600 IU q12h PO for immune-mediated skin disease, hepatitis, and copper-associated liver disease)

Vitamin K_1
AquaMEPHYTON
Mephyton
Short-acting rodenticide toxicity: 1 mg/kg/d SC, PO for 10–14 days; long-acting rodenticide toxicity: 3–5 mg/kg/d SC, PO for 3–4 weeks; birds: 2.5–5.0 mg/kg q24h
Severe cholestatic liver disease: 1 mg/kg q12hr SC or IM

Warfarin
Dog: 0.1–0.2 mg/kg q24h PO (adjust dose by monitoring clotting time)
Cat: 0.06–0.1 mg/kg (monitor clotting time)

Xylazine
Rompun
Dog: 0.3–0.8 mg/kg IV, 0.5 –1.5 mg/kg IM, SC
Cat: 0.4–1.0 mg/kg IV, 0.8–1.8 mg/kg IM, SC

Yohimbine
Yobine
For xylazine reversal: 0.1–0.4 mg/kg IV

Zinc
Liver copper chelation: 5–10 mg/kg q12hr PO (1–2 hr separate from meals)

Zidovudine (AZT)
Retrovir
Cat: 15 mg q12h to 20 mg/kg q8h PO

Zolazepam
See Tiletamine plus zolazepam

Zonisamide
5–10 mg/kg/d PO (divide bid or tid)
